tension displacement were optimised for maximum failure load. Five-layer laminates were chosen to exclude the possibility of trivial balanced laminates being returned by the optimisation while being within the ± 50 kN load range of the BTA. The material chosen was a unidirectional carbon-Epoxy 150 gsm pre-preg with properties shown in Table 1.

Table 1: CFRP material properties

E_{11}	E_{22}	G_{12}	ν_{12}	ρ
147 GPa	9 GPa	3.3 GPa	0.31	1500 kg m^{-3}
$\hat{\sigma}_{1T}$	$\hat{\sigma}_{1C}$	$\hat{\sigma}_{2T}$	$\hat{\sigma}_{2C}$	$\hat{\tau}_{12}$
2260 MPa	1200 MPa	50 MPa	190 MPa	100MPa
$\hat{\varepsilon}_{1T}$	$\hat{\varepsilon}_{1C}$	$\hat{\varepsilon}_{2T}$	$\hat{\varepsilon}_{2C}$	$\hat{\gamma}_{12}$
0.015	0.008	0.005	0.021	0.030

Each FC was substituted into the objective function (See Equation 1) of the GA-based optimisation approach to determine the failure load (F_F) at SF = 1.

$$F_F = \mathrm{SF} \times F_{1\%} \tag{1}$$

Where, SF is the safety factor determined by the FC and $F_{1\%}$ is the highest load experienced in either the *x*- or *y*-directions of the specimen at a 1% arm displacement. The FE model uses S4R shell elements with a 2D composite laminate applied. Displacements are applied to a point kinematically coupled to the edges of the arms at the extremities of the samples. The model used may be seen in Figure 3.

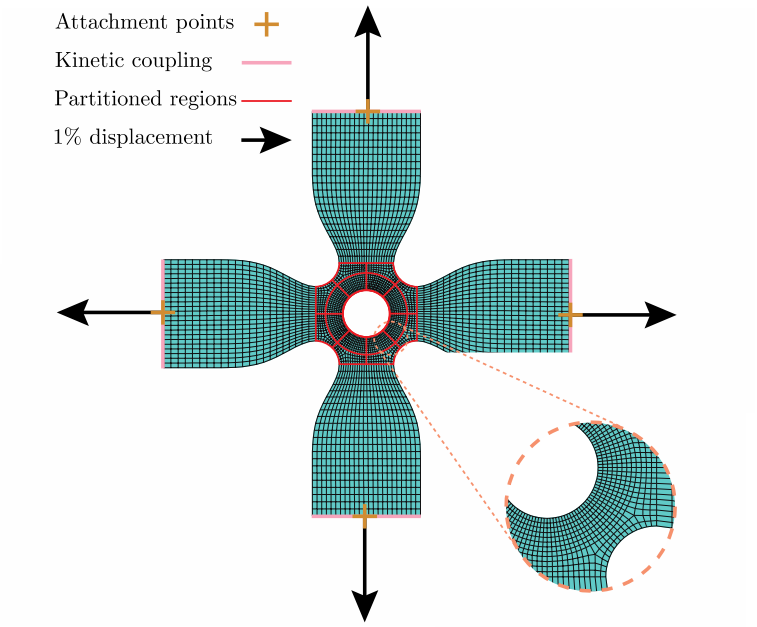

Figure 3: Modelling of the cruciform specimen in Abaqus 2022

3. Results & Discusssion

Seven distinct samples consisting of three specimens were tested to failure using the BTA. The first five samples each used one of the five FC being assessed. The last two sets were four-layer (not five as in the other samples) Cross-Ply (CP) and Dual-Bias (DB) laminates.

Table 2 shows the recorded and predicted failure loads for the CP and DB specimens. *NB:* These specimens are not optimised, but are included to assess the relative accuracy of the FC for standard *quasi-isotropic* laminate configurations.

Table 2: Comparison of recorded and predicted failure loads. CP and DB specimens

	Test mean	TW_P	TH_P	MS_P	P_P	H_P
CP F_F [N]	1849	4294	4532	19902	4142	4590
DB F_F [N]	4076	4344	4462	26258	3878	4462

Subscript P indicates a predicted load according to that FC

Mean error for the CP specimens sits at + 305 %. If MS is excluded as an obvious outlier, this drops to + 137 % error. In the DB case, mean error sits at + 113 % or + 5 % excluding MS. The strain paths generated in the cruciform specimens are aligned at 45° and so the much better accuracy in the DB case is thought to occur because the plies are subject to pure longitudinal (along the fibre) or transverse (across the fibre) stress. The plies would be expected to exhibit higher strength in this configuration and the FC are dealing with less complicated failure mechanisms. In these cases, Puck was found to be the most accurate FC at a still unreliable + 60 % strength prediction.

Figure 4 shows the mean recorded and predicted failure loads for all samples.

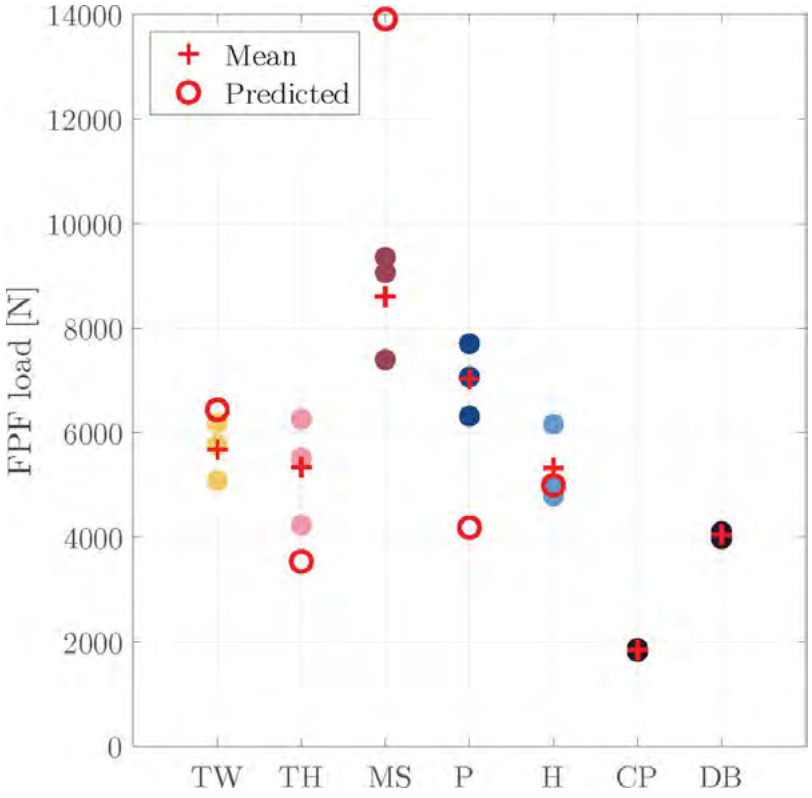

Figure 4: Crucifrom specimen test results

It can be seen that there a range of prediction accuracies associated with each FC. Also notable; the optimised specimens were much more spread out according to their actual failure loads, compared with the CP and DB specimens.

Table 3 shows the mean error of each FC.

Table 3: Mean prediction error by FC

	TW	TH	MS	P	H
Predicted Load [N]	6441	3538	13918	4189	4997
Recorded Load [N]	5681	5340	8607	7032	5326
Error	+ 13 %	- 34 %	+ 62 %	- 40 %	- 6 %

A Bayesian ANOVA was also conducted to assess the significance of choosing one FC relative to another for laminate design. Figure 5 shows how MS- and P-optimised specimens carried significantly higher load than the remaining three.

Here H is taken as the reference FC, It can be seen that MS and P were both significantly different but that using TW, TH, or H did not constitute a significant effect on part performance. This might suggest that MS was the most suitable FC as it produces the strongest laminates, but this is believed to be an isolated case and its poor accuracy means it could not be relied upon to determine structural performance with any confidence.

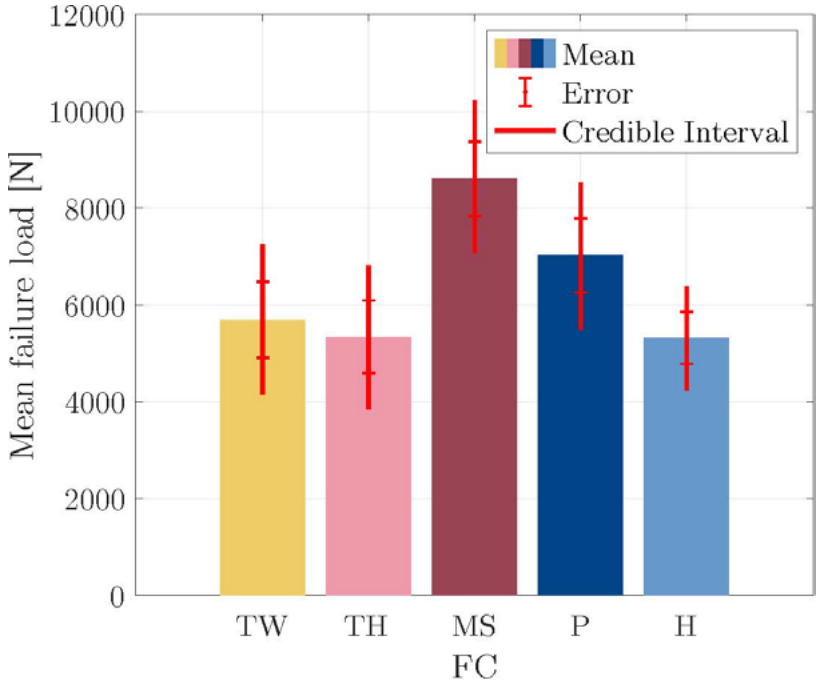

Figure 5: Bayesian ANOVA. FC effect relative to H

After analysing the results of this study and comparing to the results of the WWFE-I [28] and previous work by the author [27], P has been identified as the most favourable FC. It has proven to be the most conservative according to [27], the most accurate according to [28], and P-optimised specimens were the strongest while underpredicting failure load in this work.

4. Conclusions

In the realm of high-performance composite structural design, there must be reliable metrics for strength limit determination. While there are still underlying concerns as to the accuracy of even the most well-established failure criteria, as structures increase in size and complexity make-and-test design procedures become to costly or slow. This work investigated the impact of failure criteria choice within the objective function of an optimisation approach tasked with designing biaxial test specimens. Seven samples of cruciform speimens were tested using a newly implemented biaxial testing procedure and Puck's faiulure criteria was shown to be the most accurate and conservative, and is recommended for optimising the strength of complexly loaded complex geometry FRP laminates.

Abstract
Due to their poor conductivity, carbon fiber reinforced plastics (CFRPs) themselves cannot meet the lightning strike protection (LSP) requirement of modern aircrafts. Metal mesh is always introduced onto the surface of CFRPs for the LSP purpose. Carbon nanotube (CNT) films have been considered as the most promising alternatives for replacing the metal mesh considering that CNT films are lighter and more compatible with CFRPs. However, the conductivity of the CNT films is usually one or two orders of magnitude lower than that of metals like copper (Cu) and aluminum. In this study, CNT/Cu composite films were prepared by electrochemical deposition method, and their microstructure, electrical properties and current-carrying failure behavior were characterized. The results show that CNT/Cu composite films are flexible and have gradient microstructures, where the content of Cu gradually decreases from one side to another. The electrical conductivity of the composite films is 21.6 MS/m, their specific conductivity is 2 times of pure Cu, and the current carrying capacity and specific current carrying capacity are 1.4 times and 7 times of copper mesh, respectively. The simulated lightning tests show compared with copper mesh, CNT/Cu composite films are 61% lighter and possess better protection performance.

1. Introduction

Carbon Fiber Reinforced Plastics (CFRP) is known for its lightweight, high strength and stiffness, as well as strong corrosion resistance, and has long been one of the most important structural materials for aircrafts. For instance, on the Boeing 787, the use of CFRP has exceeded 50%, mainly in the fuselage and wings. Compared to traditional metal fuselages, CFRP has poorer electrical conductivity and cannot meet the lightning protection needs during flight. It is reported that commercial aircraft encounter lightning strikes on average every 3000 flight hours.[1] If the large current generated by a lightning strike is not dissipated in time, the complex electrical, magnetic, and thermal effects can cause the fibers in the composite material structure to break and the resin to decompose, leading to material failure and even serious flight safety accidents.[2] Currently, commercial aircraft primarily use a copper mesh lightning protection scheme,[3] which has disadvantages such as heavy weight and poor integration with CFRP, contradicting the design concept of lightweight aircraft.[4]

Carbon nanotubes (CNTs) have a unique one-dimensional nanostructure and have been proven to have superb mechanical and electrical properties.[5,6] In the last two decades, there has been numerous studies on using CNT films for the lightning protection of CFRP. For example, Dydek et al.[7] covered the CFRP

surface with CNT paper of varying SWCNT content, thickness, and areal density, showing that the electrical performance and lightning protection effect of the CFRP samples improved with the increase of SWCNT content, thickness, and areal density. Zhang et al. [8] interleaved CNT films between CFRP layers to improve their conductivity for lightning protection, obtaining composite materials with lightning protection performance, but the conductivity of the CNT films was lower than that of copper mesh, and their lightning protection was weaker than that of copper mesh. Theoretical studies have shown that the conduction mode of a single CNT exhibits quantum transport characteristics, with a conductivity that can reach 10^9 S/m, but when a large number of CNTs are made into a macroscopic film, the overall conductivity significantly decreases due to the presence of inter-tube contact resistance, with a conductivity of only 10^4 S/m, so the lightning protection effect of pure CNT film materials is still inferior to that of commercial copper mesh.[6] Additionally, based on the characteristics of the instantaneous current generated by lightning strikes, the lightning protection layer needs to quickly dissipate the large current on the surface of the aircraft structure.[4] To minimize damage to the fiber structure layer, the protective layer material needs to have both high conductivity and high current-carrying capacity.

This paper uses a single electrochemical deposition method to prepare CNT/Cu composite films. By optimizing the plating solution formula and electro-deposition process, the CNT/Cu composite structure is controlled, successfully preparing a composite structure with nano-sized Cu grains filled within the CNT network. The conductivity of this composite film is comparable to that of Cu, while its density is much lower than Cu. At the same time, the $CuSO_4$ aqueous plating solution used in the electro-deposition process contains no organic reagents, making the preparation process simple, and a capability for preparing meter-scale CNT/Cu composite films has been formed. Based on the electro-deposition method, CNT/Cu composite films were used to prepare CFRP lightning protection samples. In artificial lightning strike tests, the lightning protection performance of the CNT/Cu composite films was compared with that of commercial copper mesh and CNT/Cu composite films prepared by magnetron sputtering. The internal damage of the CFRP was characterized by CT scanning to evaluate its lightning protection effect, and the lightning protection mechanism of the CNT/Cu composite films was further explored by combining the results of the lightning protection tests and the structural characterization of the protective samples.

2. Materials and Methods

2.1. Preparation of CNT/Cu Composite Films

CNT films used for this study were made by using the Floating Catalyst Chemical Vapor Deposition (FCCVD) method and provided by Suzhou Jiedi Nanotechnology Co., Ltd., as shown in Figure 1(a). The thickness, areal density and electrical conductivity of this CNT film is 35 μm, 17.34 g/m^2 and 2.3 $\times 10^5$ S/m, respectively.

The CNT/Cu composite films were prepared by electrochemical deposition, as shown in Figure 1(b). A phosphor copper plate served as the anode, connected to the positive pole of the power source. CNT film was wetted with ethanol and tightly attached to the surface of a stainless steel plate, connected to the negative pole of the power source. Insulating tape was wrapped around the stainless steel surface surrounding the CNT film to ensure that Cu deposition only occurred on the designated area of the CNT film. An acidic $CuSO_4$ aqueous plating solution was used, with a deposition current density of 0.1 A/dm² and a deposition time of 6.5 hours. To minimize the impact of sample oxidation on electrical conductivity, the sample was quickly washed three times alternately in deionized water and ethanol after being removed from the plating solution, then immersed in a mixed solution of oleic acid and acetone for passivation (volume mixing ratio, oleic acid: acetone = 1:30), dried, and then reduced at 200°C in an H_2 atmosphere for 3 hours.

For comparison, magnetron sputtering was also adopted to metallized CNT films, as illustrated in Fig. 1c. In briefly, a CNT film with a thickness of 35 μm and a size of 350×350 mm was attached to the

roller of a roll-to-roll magnetron sputtering machine. The distance between the target material and the CNT film is adjusted, and the initial roller speed is set to 1 m/min to ensure that copper is uniformly sputtered onto the surface of the CNT film. After the vacuum level of the instrument body is reduced to 3.1×10^{-3} Pa, high-purity argon gas (Ar) with a flow rate of 160 sccm is introduced into the vacuum chamber. To effectively remove impurities from the surface of the copper target, a pre-sputtering of 10 minutes is required. Afterwards, the current is adjusted to 6 A, and the working vacuum level is set to 2.6×10^{-1} Pa.

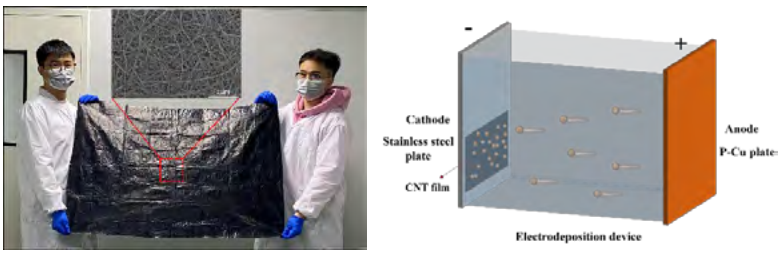

Figure 1. (a) Optical and SEM images of CNT film, and schematic diagrams of (b) electro-chemical deposition processing.

2.2. Preparation of Lightning Protection Layer Laminates

Unidirectional carbon fiber prepreg provided by Guangwei Composites, China was laid in the sequence of $[0,45,90,-45]_{3s}$. The conductive protection layer was directly covered on its surface and co-cured with the prepreg through vacuum bag hot pressing into laminates. The irregular edge areas were cut off, ultimately obtaining a test panel with dimensions of 300×300 mm^2 and a thickness of approximately 4mm. Four different sets of samples with various protection methods were set up: no protection (NP-CFRP), commercial copper mesh protection (Cu mesh-CFRP), CNT film protection (CNT-CFRP), and electro-deposited CNT/Cu composite film protection (CNT/Cu-CFRP). The commercial copper mesh was provided by Hefei Aerospace Electrophysics Technology Co., Ltd., with a specification of Cu-107 g/m², and the copper mesh composite adhesive film with epoxy resin had an areal density of 231 g/m². In addition, the resistance in the long intercept direction and short intercept direction was about 2.10 mΩ and 6.30 mΩ, respectively.

2.3. Characterizations and testing

The electrical conductivity (σ) of the CNT/Cu composite film and the current carrying capacity (J) was calculated by $\sigma=1/(R_{\square}\cdot t)$ and $J=I_{max}/(w\cdot t)$, where $R_{\square}$ is the sheet resistance of the composite film, measured by a multifunctional digital four-point probe, t and w are the thickness and width of the composite film, and I_{max} is the maximum current that can pass through the sample. When testing the current carrying capacity, the CNT/Cu composite film is cut into a size of 30×1 mm, and the two ends of the sample are attached to copper electrodes by using conductive silver paste. The current is increased at a rate of 0.01 A/s until the sample melts, where the current is recorded as I_{max}. Tests were performed within a homemade vacuum box.

Anisotropic electrical conductivity test of the laminated compostites. Laminates were cut into 10×10 mm^2 size using a water jet cutter. Remove the surface resin with 400-grit sandpaper. Based on the direction of the surface carbon fibers, divide into X and Y directions, with the thickness direction being Z. For each group of samples, apply conductive silver paste on both sides of the test surface and affix copper foil, dry it, and then test its resistance by the four-wire method. Calculate the electrical conductivity based on the shape parameters. To reduce errors caused by poor electrode contact, apply pressure to both ends of the sample during testing. After obtaining seven sets of data, remove the highest value and the lowest value, and the average of the remaining values is taken as the final test result.

The direct lightning effect test on CFRP samples refers to the standards SAE ARP 5416A-2013[24] and SAE ARP 5412-2013 [25], conducted by Hefei Aerospace Electrical Technology Co., Ltd. All test areas of the CFRP samples in this paper are chosen from the 2A zone of aircraft lightning effects. The test setup is shown in Figure 2(a), with an arc introduced in the middle of the sample and grounding around it. The current waveform combination is D+B+C*, and the component waveforms of the current are as shown in Figure 2 (b-d).

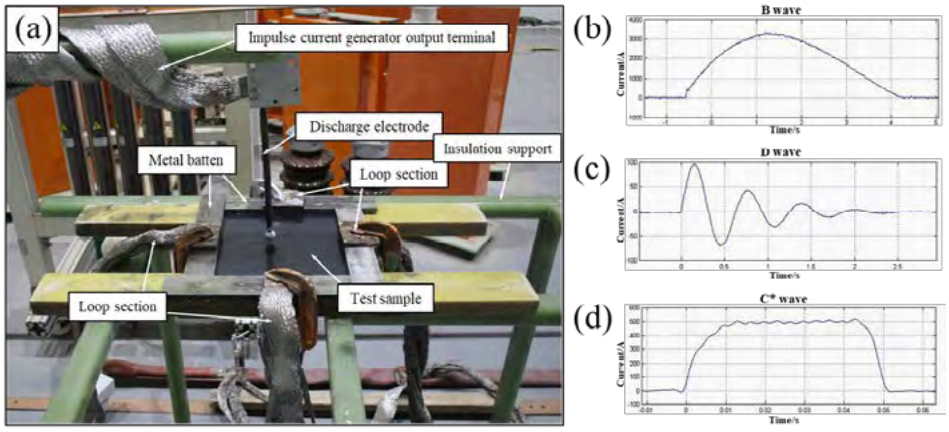

Figure 2. (a) Artificial simulation lightning strike test device, (b-d) Waveform of current components: (b) B wave, (c) D wave, (d) C* wave.

The microstructures and element distribution of the film and plates are analyzed by Scanning Electron Microscope (SEM, Hitachi S4800) and Energy Dispersive X-ray Spectrometer (EDS). The damage of the samples after the lightning strike tests were analized by using 3D confocal microscope (VX-250) and CT (FF35 CT Metrology).

3. Results and discussions

3.1. Structural Characteristics of CNT/Cu Composite Films

During the electrochemical deposition processing, the nano-scale Cu grains reduced in the plating solution deposited onto the CNT film and entered into the internal network of the CNTs under the synergistic effect of a slow deposition rate provided by a small current density. As one side of the CNT film is tightly attached to the stainless steel plate, and the other side is in direct contact with the plating solution, the nano-scale Cu grains are enriched on the side of the film that contacts the plating solution, while the backside retains the porous network structure of the CNT. The prepared CNT/Cu composite film has good flexibility, as shown in Figure 3(a). The thickness of the film was increased from 35 μm to 50 μm. And the volume and areal density of the composite film is 1.8 g/cm^3 and 90 g/m^2, respectively.

Figures 3(b) and 3(c) show the SEM images of the upper and lower surfaces of the CNT/Cu composite film, respectively, where Cu grains with extremely small diameters can be seen attached to the CNT bundles. Figure 3(d) is an SEM image of the cross-section of the CNT/Cu composite film, showing the CNT network distributed throughout the entire thickness of the composite film, with nano-scale Cu grains filling the interior of the CNT network in the film. Figure 3(e) shows the distribution of Cu and C elements in the cross-section of the CNT/Cu composite film, where it can be seen that Cu relatively enriched on the upper side of the film. This indicates that the nano-scale Cu grains fill the network of the CNT film prepared by electrochemical deposition, forming a gradient structure with Cu enrichment on the upper surface and a porous CNT network retained on the lower surface, as shown in Figure 3(f).

3.2. Electrical Properties of CNT/Cu Composite Films

The electrical conductivity and specific electrical conductivity of for the CNT/Cu composite film compared to Cu is shown in Fig. 4(a). The electrical conductivity of the CNT/Cu composite film is 2.16 ×10^7 S/m, which is much higher than that of pure CNT films (2.3×10^5 S/m), while lower than that of pure Cu (5.7×10^7 S/m). However, as the CNT/Cu composite film has a much lower density (1.8 g/cm³) than metal conductors, at only the specific electrical conductivity is 12 S·m²/g, higher than that of pure Cu (6.36 S·m²/g). Fig. 4(b) compares the current carrying capacity and specific current carrying capacity for the CNT/Cu composite film and copper mesh. The current carrying capacity and specific current carrying capacity of the commercial copper mesh are 1.58×10^4 A/cm^2 and 1778 A·cm/g, respectively. The current carrying capacity of CNT/Cu composite film is 2.18×10^4 A/cm^2, and the specific current carrying capacity is 12132 A·cm/g, both higher than that of commercial copper mesh.

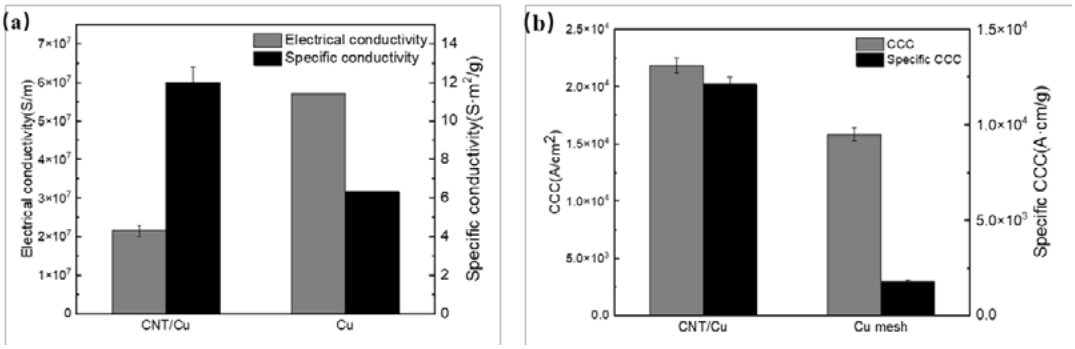

Figure 4. (a) Comparison of electrical conductivity between CNT/Cu composite film and Cu, and (b) comparison of current carrying capability between CNT/Cu composite film and Cu mesh.

To further investigate the failure behavior of CNT/Cu composite films and copper meshes under large current, a current density of 2.18×10^4 A/cm^2 was applied to two sets of samples. The commercial copper mesh failed and broke within 5 seconds, while the CNT/Cu composite film can sustain for much longer time. As shown in Fig. 5(a)-(d), the Cu in CNT/Cu composite film sample migrate from the middle to both ends of the test sample shortly after the large current passed through it. At around 30 seconds, the sample melted and broke at the initial migration location, and completely broke and failed at around 38

seconds. For the commercial copper mesh, the reason for the failure might be that the resistive heating greatly increase the atomic kinetic energy of Cu, promote Cu migration, and result in a local increase in resistance and a sharp rise in temperature, ultimately leading to failure. For the CNT/Cu composite film, Cu migrated first, while the CNT film maintained the conductive path, thereby prolonging the time until complete failure.

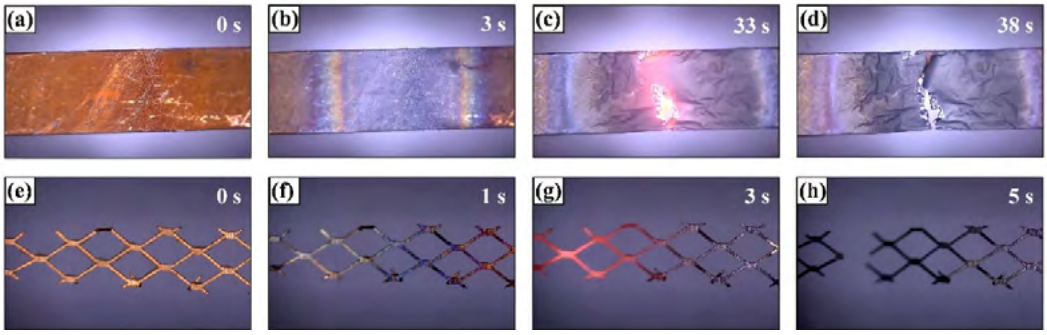

Figure 5. Failure of (a-d) CNT/Cu composite film and (e-h) Cu mesh under larger current.

3.3. LSP Performance of Laminated Composites

Fig. 6 shows the surfaces of different laminates after the lightning strike tests. The non-protected samples (NP-CFRP) had smaller damaged area, but much more carbon fibers were broken (Fig. 6a). The damage area of the CNT-CFRP (Fig. 6b) was slightly larger, and there still exist fiber breakage. The Cu mesh-CFRP (Fig. 6c) and CNT/Cu-CFRP (Fig. 6d) samples have larger damaged area while no obvious fiber breakage were observed, which meas that both the commercial copper mesh and the CNT/Cu composite films are effective in the lightning strike protection.

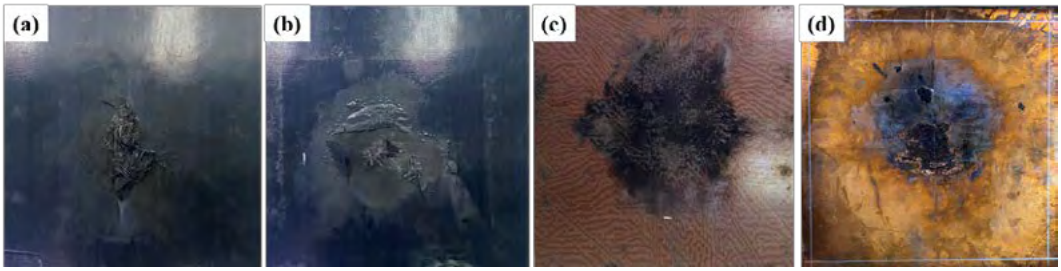

Figure 6. Surface morphology after lightning strike tests: (a) NP-CFRP, (b) CNT-CFRP; (c) Cu mesh-CFRP, (d) CNT/Cu-CFRP.

The damage pattern of CFRP due to lightning strikes is quite complex, including fiber sublimation fracture, resin matrix vaporization melting and carbonization, delamination, and so on. Surface damage analyses alone cannot adequately assess the protective effect. Therefore, CT scanning technology was utilized to characterize the internal damage of samples after the lightning strike test. Fig. 7 shows the CT scan cross-sectional images of four groups of CFRP samples with different protection methods as the depth changes. The damaged area of the four groups of samples decreases with increasing depth, among which the CNT/Cu-CFRP samples have a shallower damage depth and less internal delamination.

To further evaluate the effectiveness of lightning strike protection, cross-sectional CT scans were also performed to characterize the the depth of damage. From Figure 7 (the last column), it can be seen that there is a significant structural absence at the center of the lightning strike in NP-CFRP and CNT-CFRP, indicating a large amount of fiber fracture and resin sublimation. In contrast, Cu mesh-CFRP and CNT/Cu-CFRP samples show no significant damage in the thickness direction. Table 1 compares the damage rate of different laminates, which is defined as the (total damage thickness-protection layer

thickness)/(laminate thickness-protection layer thickness), where we can see that CNT/Cu composite layer has the best protection performance.

The EMI shielding performance of different protection films were also characterized and compared. As shown in Fig. 8, copper mesh film performs poorly due to the presence of macroscopic holes. CNT film shows better EMI shielding performance, and CNT/Cu composite film shows the best.

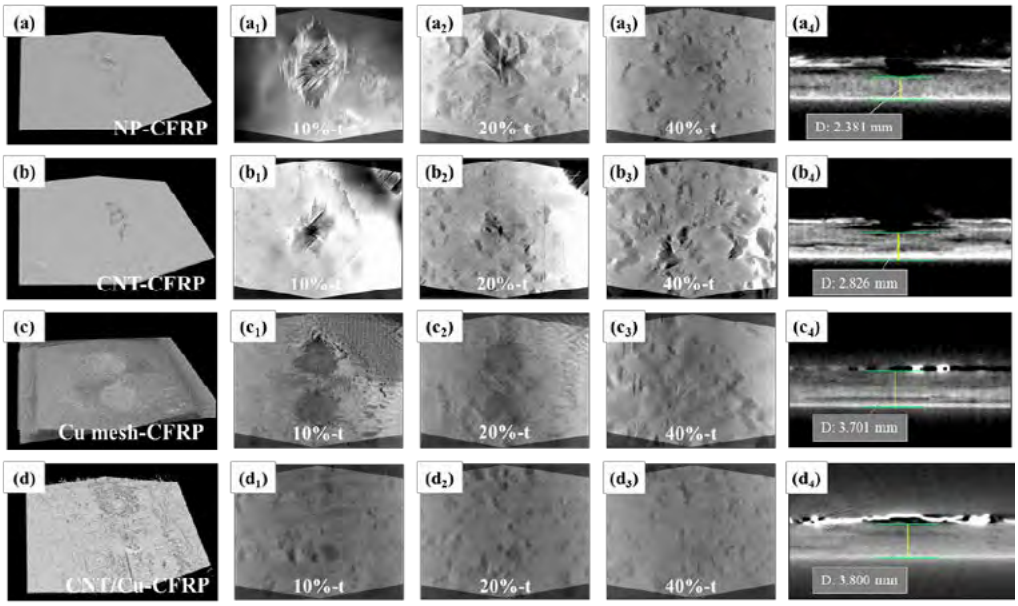

Figure 7. CT scanning of samples after lightning strike test: Overall damage morphology of (a) NP-CFRP ; (b) CNT-CFRP ; (c) Cu mesh -CFRP;(d) CNT/Cu-CFRP; and profile damage morphology varies by 10%, 20% and 40% with depth. (a4)-(d4) the cross-section of different samples.

Table 1. Analysis of damage depth of four groups of CFRP samples after lightning strike test

Samples	Total thickness/mm	Protective layer thickness/mm	Total damage thickness/mm	Damage rate/%
NP-CFRP	3.837	0	1.456	37.95
CNT-CFRP	3.915	0.035	1.089	27.16
Cu mesh-CFRP	4.372	0.218	0.671	10.91
CNT/Cu-CFRP	3.850	0.050	0.050	0

3. Conclusions

In this study, a new method of protecting carbon fiber composite from lighting strike has been proposed. CNT/Cu composite films were prepared by using electrochemical deposition method, and their microstructure, electrical properties and current-carrying failure behavior were characterized. The results show that CNT/Cu composite films are flexible and have gradient microstructures, where the content of Cu gradually decreases from one side to another. The electrical conductivity of the composite films is 21.6 MS/m, their specific conductivity is 2 times of pure Cu, and the current carrying capacity and specific current carrying capacity are 1.4 times and 7 times of copper mesh, respectively. The lightning protection shielding profermance of CNT/Cu composite film were investigated and compared with that of CNT films and commercial copper mesh. It has been found that the CNT/Cu composite film (90 g/m^2) provides better lightning protection for carbon fiber laminates than commercial copper mesh (231 g/m^2). In addition, CNT/Cu film possesses much better EMI shielding performance than Cu-mesh. Although CNT/Cu composite film has demonstrated attractive performance, the underlying protection mechanism and the failure mechanism are still far to be understood. In addition, making continuous, uniform CNT films and CNT/Cu composite films are still challenging now. Further research efforts are needed to address these issues.

Keywords: Long natural fiber, flax and hemp, fiber treatment, Bio-composites

Abstract

The growing usage of natural fiber-reinforced composites for structural purposes is being fueled by their impressive strength-toweight and stiffness-to-weight ratios, as well as their minimal environmental impact. Of all the bast fibers, flax and hemp stand out due to their remarkable tensile strength, making them ideal for situations where toughness and long-lastingness are crucial. Woven long continuous bast fibers are employed in situations demanding structural integrity and load-bearing capacity, facilitating improved load distribution within woven materials. These long continuous fibers also enhance resistance against creep, making them suitable for applications where dimensional stability is crucial. In the manufacturing of polymer matrix composites, the treatment of natural fibers with various chemicals is a pivotal step to enhance their properties. However, commonly used chemicals pose concerns related to health, environmental impact, and potential effects on fiber strength. In this study, we utilized eco-friendly chemicals such as oleic acid, coffee ground extract, citric acid, bee wax, and tartaric acid for flax fiber treatment. Characterization of the treated chemicals involved scanning electron microscopy (SEM) to observe morphological changes, x-ray diffraction (XRD) to assess crystallinity, and atomic force microscopy (AFM) to examine roughness. Composite manufacturing involved the use of a bio-based epoxy resin, "Greenpoxy," and mechanical property characterization. Flax fibers treated with oleic acid exhibited the highest flexural strength, with fiber volume fractions ranging between 35-37%, and calculated pore volume fractions between 5-7%. Additionally, we employed plasma vapor deposition as a physical treatment technique, offering advantages such as producing thin films with high purity, uniform thickness, and improved adhesion. The precursors were deposited onto the woven long fibers through plasma vaporization in a nanoscale, and subsequently, these treated fibers were integrated as reinforcement in the fabrication of bio-composites. Characterization of treated fibers involved SEM and XPS measurements to observe precursor deposition, revealing only marginal improvements in flexural strength within the composites. This investigation demonstrates the high potential of eco-friendly chemical treatments to enhance fiber properties without significantly affecting natural fiber characteristics. Moreover, these treatments contribute to improved mechanical strength and long term water resistance behavior.

1. Introduction

In the last six to seven decades, advancements in polymeric composite materials, predominantly utilizing synthetic fibers such as glass, carbon, and aramid, have enabled the substitution of numerous conventional metallic, polymeric, and ceramic materials. The adoption of advanced composites, particularly in transport sectors, as feasible substitutes for traditional materials primarily stems from

their remarkable mechanical properties and low density. This enables their application in structural roles where lightweight characteristics are essential to the ultimate design[1].

Owing to environmental concerns and the quest for alternatives to fossil-derived resources, a noticeable shift in materials science involves the growing fascination with and utilization of natural fibers sourced from wood or plants like hemp, flax, jute, kenaf, ramie, and sisal[2]. These natural fibers boast biodegradability[3] and suitable mechanical properties stemming from their abundant cellulose content, alongside sustainability[4], rendering them appealing substitutes for synthetic reinforcing fibers employed in polymer composites. Consequently, there has been a notable resurgence in the attention directed towards natural fibers over the last decade, especially for reinforcing polymeric materials. When paired with a degradable polymer matrix, natural fibers present themselves as a cost-effective, renewable, and less harmful option compared to synthetic fibers, all the while providing considerable specific strength and stiffness[5], [6].

The challenge with using natural fibers as reinforcement lies in their inherent hydrophilic nature, which can lead to weaker bonding interfaces within composites. However, various pretreatment methods are employed to address this issue by enhancing the adhesion between the fibers and the matrix. These pretreatments typically involve activating hydroxyl groups or introducing new functional groups that can effectively interlock with the matrix, thereby improving the overall performance of the composite material.

Chemical treatments aim to modify the chemical structure of the fibers, often by introducing functional groups that enhance compatibility with the matrix. This can involve processes such as grafting, acetylation, silane coupling, or alkali treatment[7]. The physical treatment using plasma, corona or chemical etching involves altering the surface characteristics of the fibers to improve adhesion with the matrix material. In our present study, we endeavor to modify the fibers using environmentally friendly chemicals. Additionally, we aim to perform surface modification on the natural fibers using plasma deposition techniques[8], utilizing renewable precursors in the process. The composites were fabricated utilizing a bio-based resin, and subsequently, the mechanical properties of these composites were examined and compared with those of the untreated natural fiber.

2. Experiment

2.1. Materials and Methods

The composites were manufactured using hemp textile fabric sourced from ecological textiles with a grammage of 600 GSM. Modification processes were conducted within a closed vacuum bag, with varying durations for each chemical treatment. The fibers underwent treatment with a range of chemicals including ethanol, citric acid, oleic acid, tartaric acid, bee wax, and coffee ground extract (Figure 1). For treatments involving oleic acid and bee wax, ethanol served as the medium. Treatment durations lasted 16 hours within the vacuum bag, followed by rinsing either with water or ethanol. Subsequently, the treated fibers were sealed in plastic bags for further analysis.

Surface properties of the treated fabrics were characterized using contact angle measurement, atomic force microscopy, scanning electron microscopy, x-ray diffraction studies, and thermogravimetric analysis. Microscopic studies provided insights into surface morphology, while thermal analyses offered insights into changes in thermal stability or fiber degradation post-chemical treatment. To conduct contact angle (CA) measurements, the fiber samples were compacted into uniform pellets, after which the CA was assessed for both untreated and treated fibers.

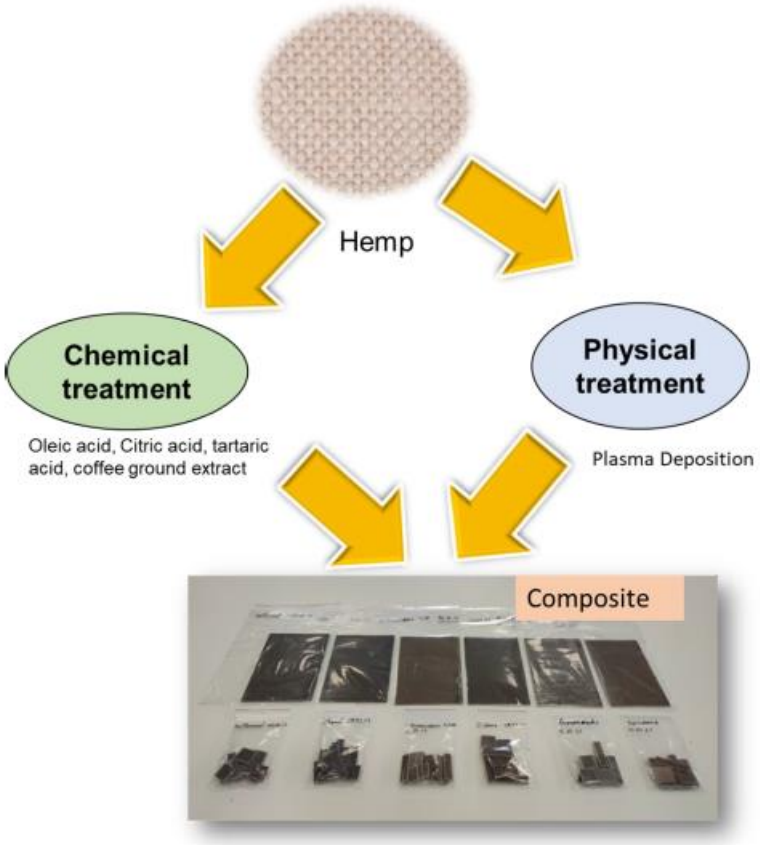

Figure 1: Functionalization of natural fibre and manfacturing composites using surface modified natural fibres

3. Results and Discussion

3.1 Fibre Characterization

Contact angle values for the treated fabrics were determined using various solvents, including water, ethylene glycol, and diiodomethane. The fiber samples were compressed into circular discs, and surface energy was calculated using the OWRK (Owens, Wendt, Rabel, and Kaelble) method based on the measured contact angles. The contact angle data is presented in Table 1.

The untreated fibers exhibited higher contact angles with water, primarily attributable to the water-repellent coating applied during the manufacturing process. Following surface treatment, a noticeable reduction in contact angle was observed, indicating significantly improved wettability. Notably, the fibers treated with oleic acid displayed surface energy values that met acceptable values, coupled with low contact angle values. Similarly, coffee ground extract treatment yielded promising surface energy values, signifying favorable interaction with the fiber matrix.

Table 1: Measured contact angle for the treated fibres and surface energy calculated using OWRK method

Sample	Water		Ethylene glycol		Diiodmethane		OWRK-Method			
	Contact angle [°]	Standard Deviation	Contact Angle[°]	Standard Deviation	Contact angle [°]	Standard Deviation	g_s [mN/m]	R^2	Disp. [mN/m]	Polar [mN/m]
Untreated fibre	121	9.0	68	4.3	63	1.6	32,93	0,45	32,06	0,86
Coffee Ground	111	4.9	74	5.1	57	2.0	30,76	0,82	30,69	0,08
Citric acid	99	12.4	69	5.5	72	5.0	24,26	0,98	22,84	1,43
Ethanol	110	12.5	75	3.2	61	4.0	28,68	0,42	28,66	0,02
Oleic acid	77	7.7	46	5.0	50	6.4	38,60	0,99	32,55	6,05
Tartaric acid	101	9.4	56	4.3	63	3.8	30,86	0,46	30,35	0,50

For Atomic Force Microscope (AFM) measurements, samples were analyzed using tapping mode, capturing both phase and amplitude images (See Figure 2 and 3). The amplitude image provided a visual representation of the contacted surface's shape, while the phase image offered insights into the sample's viscoelastic properties. In the phase image, darker areas indicated harder regions, while brighter areas corresponded to softer regions of the sample.

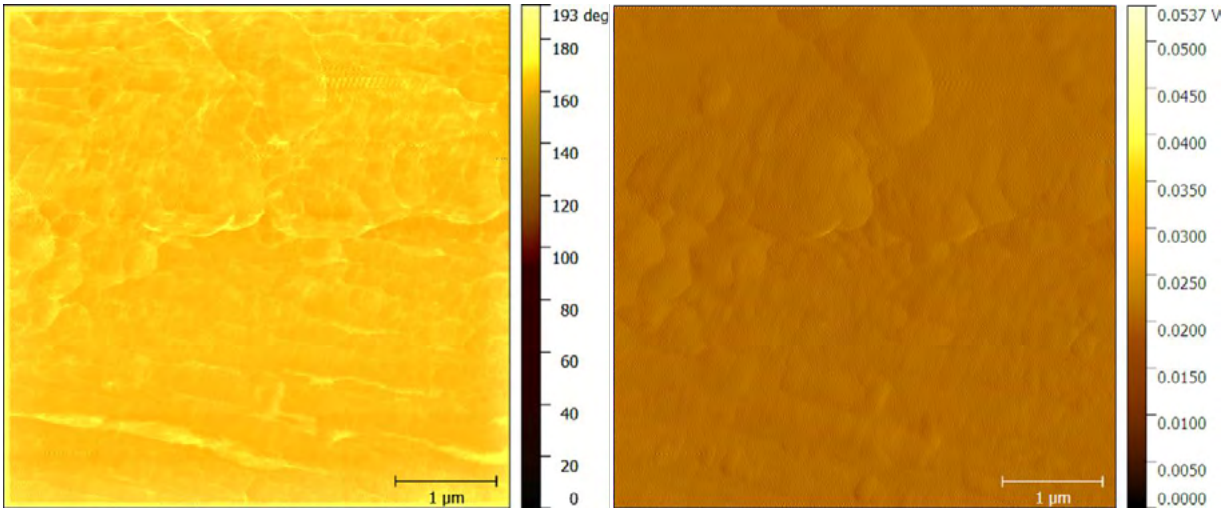

Figure 2. Phase and amplitude images of the untreated fibres in a tapping mode

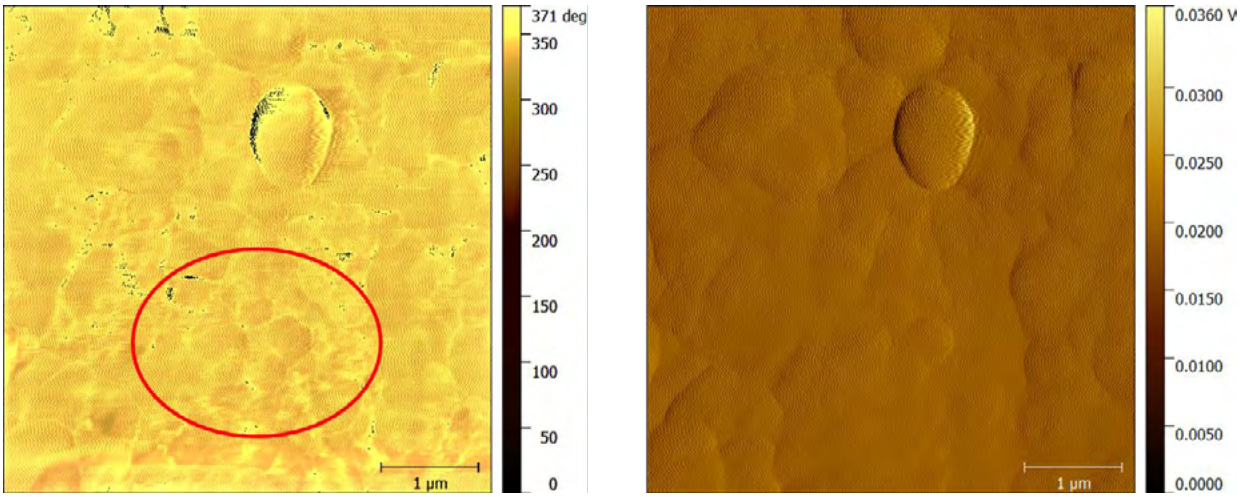

Figure 3. Phase and amplitude images of the oleic acid treated fibers in a tapping mode

The untreated fibers exhibited a finger-like pattern or morphology, which, notably, disappeared upon treatment with the specified techniques. In contrast, the fibers treated with oleic acid displayed a distinct domain-like structure on their surface.

The X-ray Diffraction (XRD) analysis indicates variations in crystallinity resulting from the different chemical treatment techniques (Figure 4). The calculated percentages of crystallinity for the samples are as follows: Untreated: 35.3% , Ethanol-treated: 27.1% , Coffee ground extract: 27.0% , Oleic acid: 32.4% , Tartaric acid: 36.5% , Citric acid: 33.0%. These results suggest that the chemical treatments induced changes in the cellulose structure within the natural fibers, particularly affecting the Cellulose II structure.

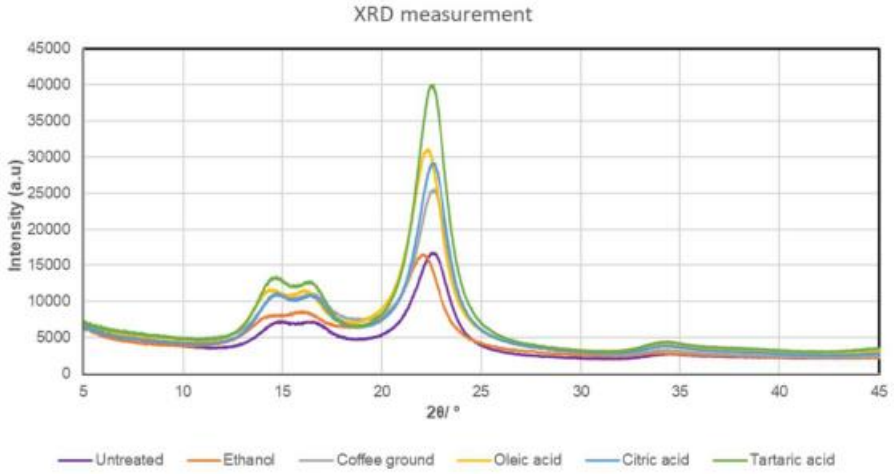

Figure 4. XRD measurement for the treated fabrics

3.2 Composite fabrication

Following the chemical modification, the fiber samples were used for manufacturing reinforced composites by impregnating them with a bio-based epoxy resin inside a vacuum bag. The bio-based resin is a two component resin and the curing agent is an amine derivative. Subsequently, the mechanical properties of the composite materials were evaluated. Additionally, long-term water absorption tests were conducted on the composite samples. This involved measuring changes in weight and thickness swelling of the composites after immersion in water.

Three-point bending tests were performed on the composites to assess how different chemical treatments impacted their mechanical properties. The results for flexural strength and modulus can be found in Figure 5 and Figure 6, respectively.

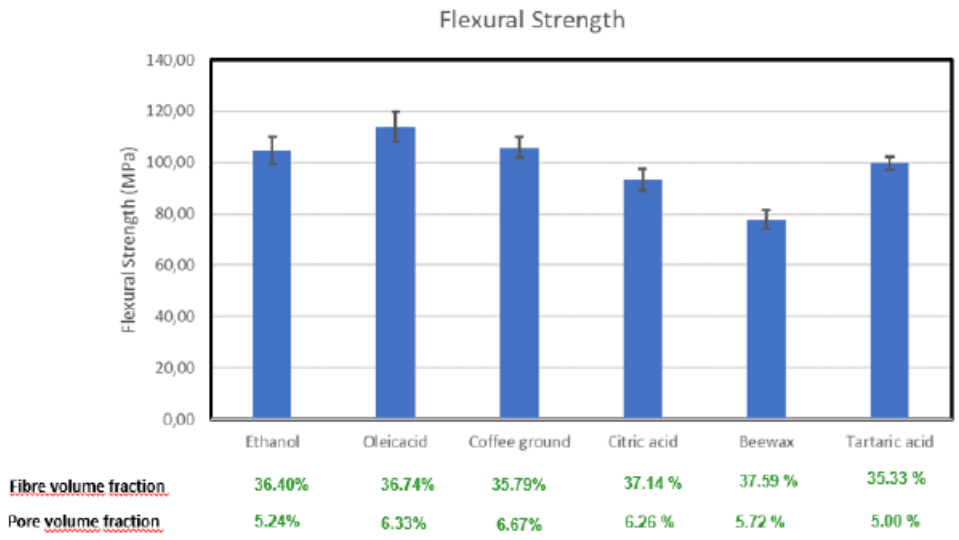

Figure 5: Flexural strengths of the composite made using treated fabrics with bio-based resins

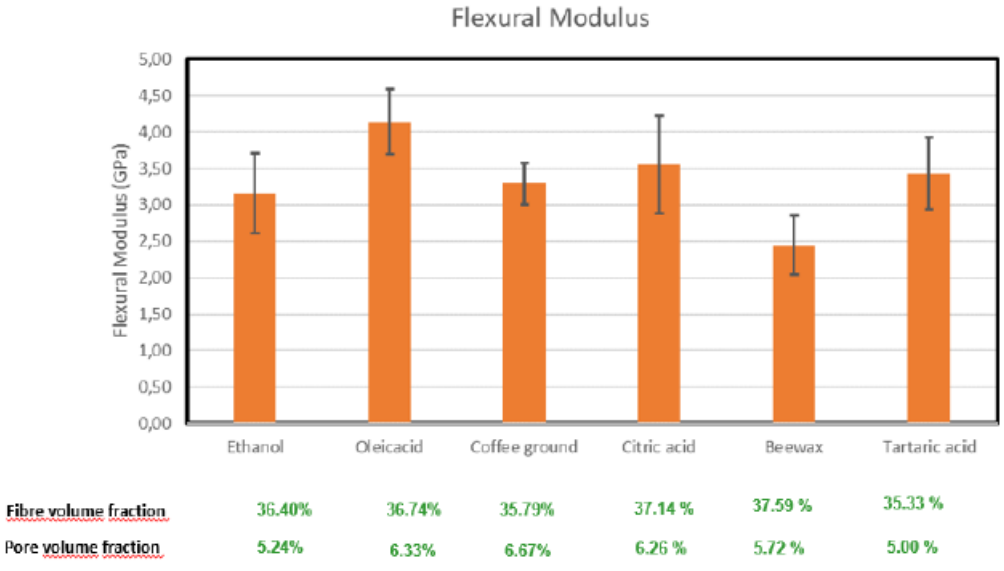

Figure 6: Flexural modulus of the composite made using treated fabrics with bio-based resins

The oleic acid treatment resulted in an increase in both flexural strength and modulus for the treated fabrics. Conversely, the bee wax treatment led to a decrease in flexural strength and modulus, likely due to uneven distribution of wax on the fiber surface. These findings suggest that oleic acid treatment is the optimal choice for treating hemp fibers, as it enhances their mechanical properties.

3. Conclusions

Positive improvements have been observed in the mechanical strength through the use of environmentally friendly chemical treatments.

- The utilization of the vacuum bagging technique demonstrated a viable approach to managing the chemicals.
- The chemical treatment resulted in alterations to the surface morphology of the fibers.
- Following the chemical treatment, there were slight changes observed in the thermal stabilities.
- The eco-friendly chemical treatment caused modifications in the crystallinity of the cellulose structures.
- Further optimization experiments are required for the chosen chemical treatment methods.

Keywords: AFP, carbon fibre reinforced thermoset, gaps / overlaps, damage,

Abstract
This study analyses the impact of singularities caused by the automated fiber placement manufacturing process on the compression behavior of composite coupons. Compression tests are performed on plain and open-hole coupons with standard aeronautical stacking layups, featuring various configurations of gaps and overlaps. A rich multi-instrumentation is used for monitoring and better understanding the effects of singularities on the damage and failure scenario. Micro-computed X-ray tomography (CT-scan) observations performed at different loading steps allow the monitoring of damage within the core of the coupons. The failure scenario is characterized using acoustic emissions sensors and computed tomography observations. The instrumentation helps to understand the effective local loading state at the coupon-scale and highlights the necessity of numerical simulations for better understanding the effect of singularities.

1. Introduction

The aeronautic industry is continuously striving to produce the lightest products while ensuring their robustness. To do so, an increasing diversity of parts and structures are made out of carbon fibre reinforced plastics (CFRP) due to their high specific properties. However, CFRP can be difficult to shape. The complexity of the aforementioned parts and structures keeps increasing. Thus, new industrial processes are required to ensure the production reliability, quality and rate. One of the industrial process that fulfill these constraints is the automated fiber placement (AFP).

Developed from the 1980's, AFP process consists of the deposition of thin tows composed of continuous carbon fibre pre impregnated with matrix (prepreg). This automatic and robotic process allows the manufacturers new parts design opportunities thanks to specific features such as *(i)* the ability to individually stop and restart the deposition of each tow, *(ii)* the ability to control the deposition speed of each tow and *(iii)* the modularity of the process enabling to lay down from 1 up to 32 tows in parallel. (The tows width spans from some millimeters up to tenths of millimeters [1]). This robotized and automatized process ensure to the aerospace industrials a consistent and controlled quality of the produced parts, thus increasing the productivity by reducing the rework time caused by quality control and reducing the material waste. However, AFP induces unavoidable features such as gaps and overlaps. Gaps are created because of an intentional or unintended lack of material while laying down a ply to

build a laminate. Overlaps are created when two prepreg tows, belonging to the same ply, are superimposed. These singularities are induced because of the part design itself or because of non avoidable manufacturing errors. Some composite structures feature non developable surfaces. Therefore, the deposition trajectories that are designed to intersect each others induce gaps or ovelaps. Figure 1 presents two recovering strategies. On the left, the deposition of each tow is stoped as soon as it encounters another tow . That leads to a lack of material in a triangular region thus creates a gap. On the right, with a 100% recovering strategy, the tows are superimposed on each other in order to assure that no areas is let free of prepreg.

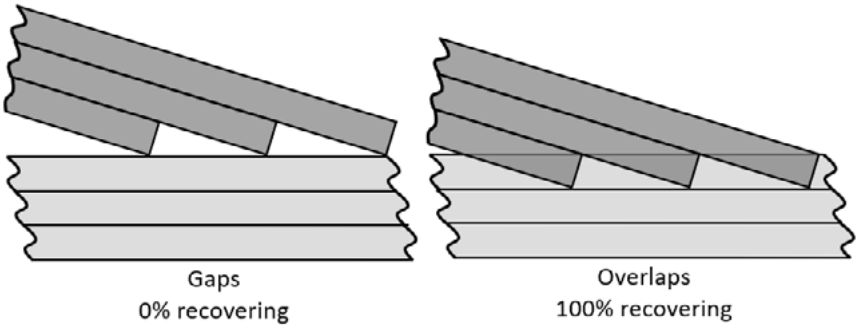

Figure 1. Scheme of the 0% recovering strategy (on the left) and scheme of the 100% recovering strategy (on the right)

Sawicki and Minguet [2] tested plain coupons embodying gaps and overlaps under compression. The presence of gaps or overlaps reduces the compression failure stress. In addition, with a wider singularity the failure stress reduction gets more important until a width limit of 2.54 mm. Turoski *et al*. [3] studied open-hole and plain coupons featuring differents gaps configurations under compression loading. The failure strength decreases for configurations with increasing number of gaps. Croft *et al.* [4] tested open-hole and plain coupons containing gaps and overlaps, as well as half gaps/ half overlaps placed in under compression loading. The effects of singularities is considered neglectable compared to the hole effects. In plain compression, the presence of gaps leads to the reduction of failure properties. The presence of overlaps leads to a slight increase of the failure properties which is in disagreement with the results of Sawicki and Minguet [2]. The authors concluded that the out-of-plane waviness induced by the presence of the singularities is one of the parameters that has the highest influence on the failure properties. Lan *et al*. [5], [6]studied the effect of out-of-plane waviness due to the presence of singularities through optical microscopy observation on the edge of specimens, which included various configurations of singularities in both number and type. Because of gaps, the thickness of the specimen is locally reduced and the empty area is filled by the adjacent plies leading to out-of-plane waviness. At the ply drop, the empty area left by the gap is filled with matrix creating matrix pockets. With the presence of overlaps, the thickness of the coupons is locally increased and the plies adjacent to the overlap are affected by out-of-plane waviness. Under loading, the thickness variation lead to stress concentration regions. The use of a caul plate during curing mitigates this effect. Due to the pressure applied by the caul plate, the matrix pockets are reduced. However, more severe out-of-plane waviness and ply thickness variation are observed within the specimen. In terms of mechanical properties, the caul plate mitigates the effects of singularities in coupons under tensile [5] and compression tests [6]. Del Rossi *et al.* tested configurations with multiple gaps and overlaps oriented along the length or the width of the specimens and located at different places along the length and the thickness of the laminate in [7]. Specimens are cured with a Caul plate and severe out-of-plane waviness is observed through optical microscopy.

It is clear that singularities affects the mechanical properties of AFP manufactured composites. However, it is not clear how the singularities affect the failure scenario. As the total failure of composite specimens under compressive load append abruptly, Woigk *et al.* [8] observed the edge of specimens under compression loading with high speed optical cameras and are able to characterize similarities and differences in the total failure evolution of specimens including gaps and overlaps under compression loading. However, these observation are influenced by the frame rate of the camera that limite the image

definition. This also limits the observable damage types to delamination and to the total failure of the specimen due to fiber breakage. There is a lack of work in the literature studying the damage and failure scenario of coupons under compression loading with gaps and overlaps.

However, in tensile test, many different experimental means were applied to monitor the damage and fialrue scenario of coupons including singularities : acoustic emission in the work of Anay *et al*. [9], DIC in the work of Falco *et al*. [10], optical microscopy in the work of Nguyen *et al.* [11] and CT-scan observation in the work of Falco *et al.* [12]. Overall, the exploration of different experimental means separately seems to be insufficient for properly assessing the effects of singularities on the failure scenario of AFP manufactured coupons.

The objective of the present study is to characterize experimentally the influence of the singularities on the mechanical properties and on the failure scenario of plain and open-hole coupons under compression loading by combining different experimental means. The second section describes the experimental campaign including the design of the coupons embodying singularities and the multi-instrumented set-up used to monitor the failure scenario of the specimens under compression. The third section presents the experimental results and the effects of the singularities.

2. Material and methods

2.1 Specimen design

To test various singulairities configurations, five different plates are manufactured using the AFP process. The plates are built with a 16 plies quasi-isotropic layup of prepreg. During curing, a caul plate is pressed to the plates to ensure a constant thickness of the laminate. 22 coupons are extracted from the plates. The specimens are 115 mm long and 25 mm wide with a nominal thickness of 2.944 mm. The open-holes specimens feature holes with a 4.8 mm in diameter.

Figure 2 presents the design of every specimen. Five designs for plain compression and six designs for open-hole compression. A scheme of singularities' positions within the coupons is indicated with a top view perspective and the layup of each configuration with the position of the singularities in the layup are presented. Plies with gaps are highlighted by stripped lines while overlaps are highlighted with a cross pattern. The rectangular gaps are made by the intentional omission of a tow during the AFP process while overlaps are fulfilled by the superposition of an extra two on top of the initial ply. The colors indicate the orientation of the plies that include singularities. To create design that are representative of industrial part designs, triangular gaps and overlaps are made by shifting tows during the deposition. These triangular gaps are placed at three different positions along the length of the specimens and are staggered along the thickness.

2.2 Test campaign

To achieve a better understanding of the effects of singularities on the failure scenario, observations at the inner core of the tested specimens are performed with a micro-computed X-ray tomograph (CT-scan). An initial CT-scan is performed before any loading to have an overview of the initial state of specimens. Then specimens are loaded until 90% of the failure load and scanned again. This load level is defined from a first batch of test until total failure of specimens and is the best compromise between a sufficient load level to able the observations of damage and a load level that does not lead to the total failure of specimen to ensure the ability to scan it again.

2.3 Experimental set-up

All the tests are carried out up to failure and are performed. The loading frame is a standard Zwick-Roell electromechanical testing machine with a capacitiy of 150 kN. Tests are equipped with a rich multi-instrumentation. The tests' set-up is presented in Figure 3. The multi-instrumentation consists of *(i)* two pairs of optical cameras used to establish two systems of stereo digital image correlation (SDIC) and *(ii)* two acoustic sensors mounted on the clamping jaws to record acoustic emissions. The optical cameras

are positioned following the scheme of Figure 4. The CT-scan were performed at Toulouse, France in IRT Saint-Exupéry facilities in an *EasyTom230* with a spatial resolution of 14 µm voxel.

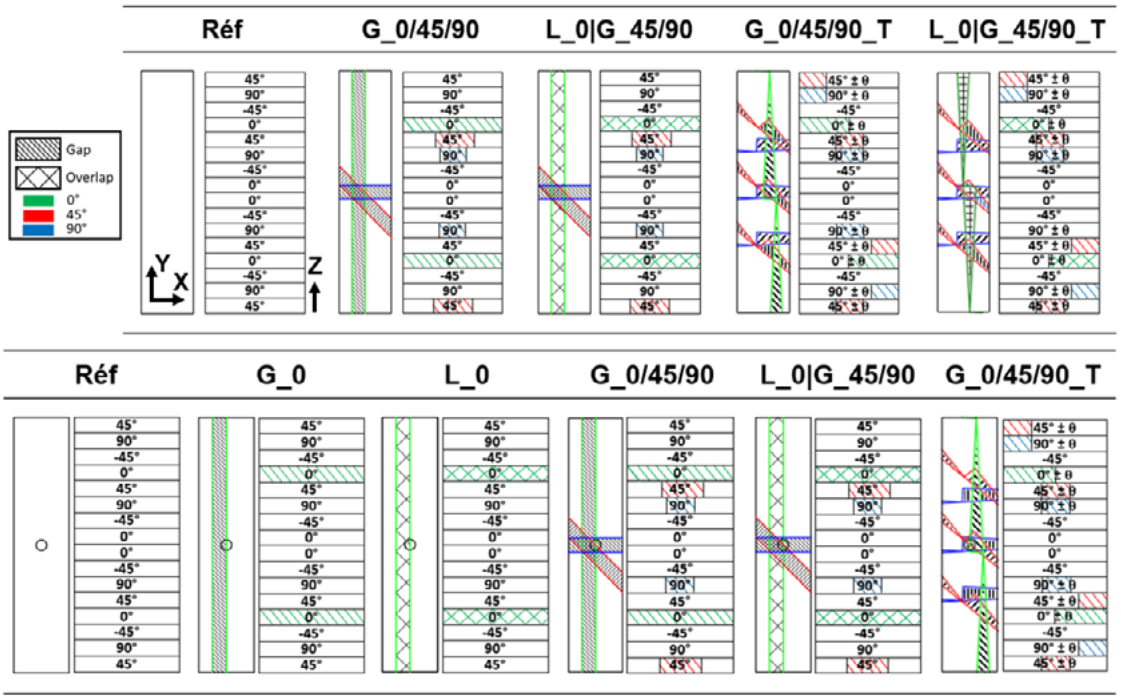

Figure 2. Design and layup of each type of specimen

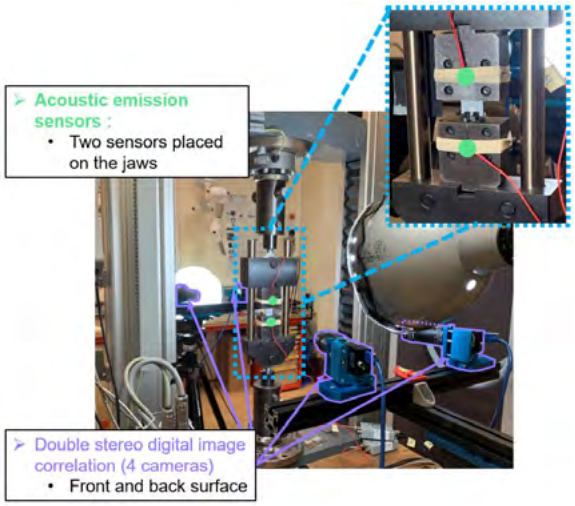

Figure 3. Experimental set-up

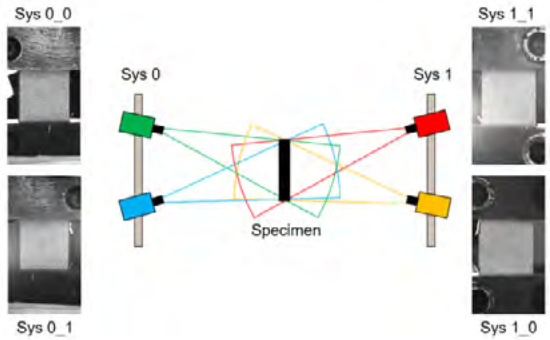

Figure 4. Scheme of the optical camera positions

3. Results

3.1. Mechanical properties under compression

For each configuration, one specimen is tested until failure and another one is tested until 90% of the failure load defined from the first test until failure. Table 1 presents the change in mechanical properties of each configuration and the change in the nominal volume of prepreg material for each configuration with respect to the reference configuration. The change in the volume of prepreg material is calculated from the theoretical layup. The nominal tow dimensions (6.35 mm in width, 0.184 mm in thickness) is considered. The prepreg volume is calculated only for the region of interest, which consists on the area between the jaws. This area is 25 mm wide (width of the specimens) and 27 mm long (distance between the jaws).

In term of compression modulus, the presence of gaps in 0°, 45° and 90° soften the coupons up to 9.4% reduction for G_0/45/90_T. The softening effect of gaps is more important for the configuration with triangular gaps than for the one with rectangular gaps. This might be explained by the misalignement of the fibre that is needed to creat such shape of singularity. The presence of overlaps in 0° (L_0|G_45/90 and L_0|G_45/90) counterbalances the softening effects of gaps. From the table, it is clear that neither the change in compression modulus, the failure strain or the failure stress is correlated with any change in prepreg volume. As an exemple, the OHC design G_0/45/90 present a reduction of 9.97% of the total material volume and a reduction of 12.36% of the material volume in the 0° plies while the reduction of compression modulus is of 3.9% and the reduction of failure strain and failure stress are of 15.1 and 14.6% respectively. In addition, an increase of the material volume in the 0° plies for L_0 does not induce an increase of the compression modulus or of the failure properties.

In open hole compression, the trends obtained in terms of failure properties change depending on the configuration follows those found in literature. The configuration with the greatest amount of gaps presents the lowest failure properites while the presence of overlaps reduces the gap effects. The effects of singularities is less important in plain compression than in open-hole compression. That may be explained by the hole effect that is more important than the effect of singularities. The presence of overlaps limits the softening effects of singulairites or increase the stiffness, as for the coupon L_0|G_45/90. The specimens with the most gaps present the lowest failure properties with a strain reduction of 15.1% and a failure stress reduction of 14.6% for the G_0/45/90 configuration. The reduction effect of triangular singularities on the failure properties is less severe than the rectangular singularities.

Table 1. Results of the compression test campaign and change in volume of material compared to reference coupons

Coupon type	Change in compression modulus [%]	Change in Ɛrupture [%]	Change in σmax [%]	Change in prepreg volume at 0° [%]	Change in prepreg volume at 45° [%]	Change in prepreg volume at 90° [%]	Change in total prepreg volume [%]
(PC) Ref	/	/	/	/	/	/	/

3.2. Failure scenario analysis

The experimental set-up for compression loading tests combines acoustic emission sensors and CT-scans to monitor the damage and failure scenario of specimens. Figure 5 presents two graphs with the curves of the normalized cumulative energy of acoustic emission (CEAE) function of the percentage of applied load normalized with respect of the failure load. The left graph presents the CEAE for all the PC specimens loaded until failure and the right graph present the CEAE for all the OHC specimens . It is worth noting that a steep increase of CEAE occurs after 90%/95% of the failure load. Indeed, these sudden increases are explained by high energy events. These high energy events might be related to damage mechanisms such as fibre breakage or delamination occurring before the total failure of the specimen.

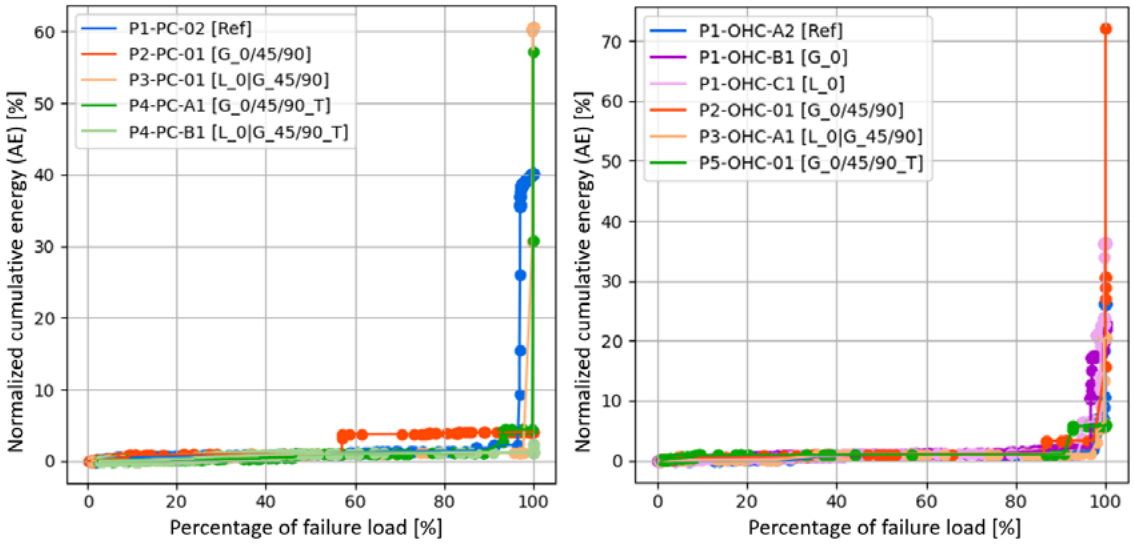

Figure 5. Normalized cumulative energy of acoustic emission function of the percentage of failure load for plain compression coupons (left) and open-hole compression coupons (right)

To confirm that no damage occurs before 90% of the failure load, the CT-scan results are *post* treated in order to obtain a projection along the whole thickness of the specimen of the inner core of the scanned specimen. Figure 6 presents the projection along the thickness of the specimen of P2-PC-03 at its initial state (Figure 6-A) and after a load step at 90% of the failure load (Figure 6-B). The position of the singularities (gaps at 0°, 90° and 45° in this configuration) are highlighted with dotted lines. Voids are clearly visible as black dots in the area where all the gaps intersect each others. Despite the use of a Caul plate during the curing, the matrix and the adjacent plies are not able to completely fill the gaps. No important cracks can be seen and no damage mechanism can be observed. The red arrows point to a tiny crack (0.1 mm) between tow voids that is present at the initial state but no clear extension of the crakc can be observed neither.

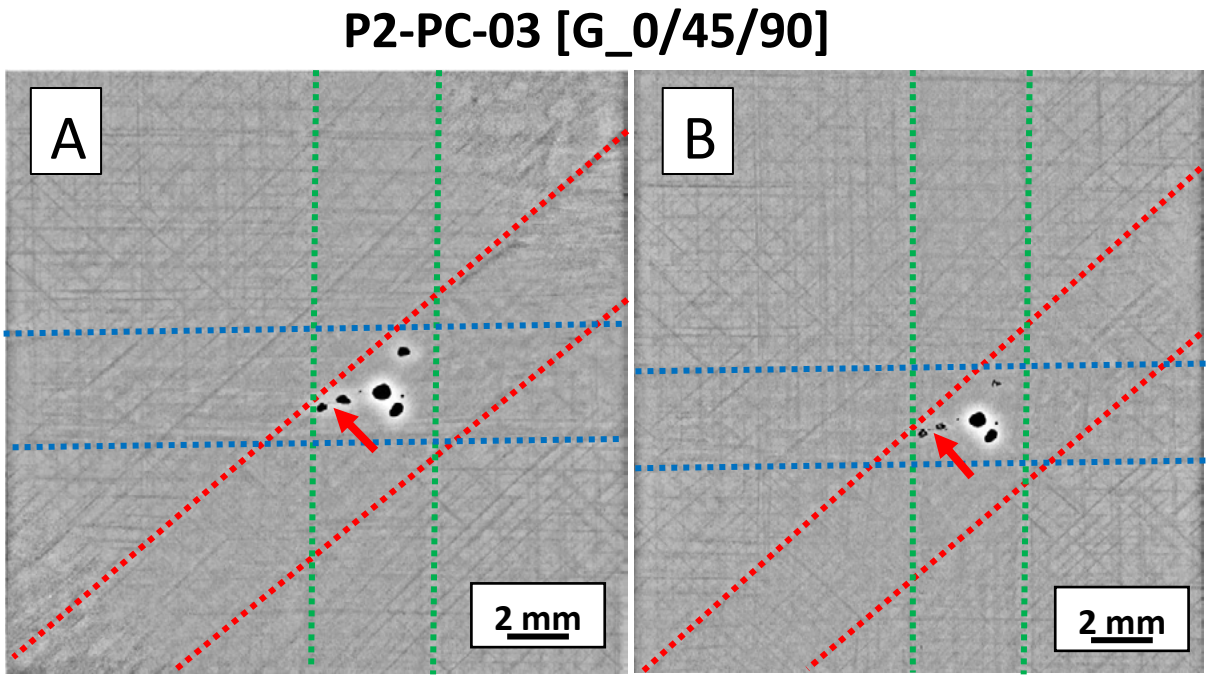

Figure 6. CT-scan image treatment result for a G_0/45/90 specimen at its initial state (A) and after a step loading to 90% of the failure load (B)

In plain compression, the results in failure stress and strain exhibit a certain disagreement with respect of those found in literature. The reference coupons present the lowest failure strain and failure stress while the configuration with the most gaps G_0/45/90 and G_0/45/90_T present the best failure properties with an increase of the failure strain up to 29.3% and 28.3% respectively. These results are not yet completely understood. To better understand the behavior of PC specimens, numerical simulation including boundary conditions measured from experiemental test will be performed. Preliminary analyses of the out-of-plane fields suggest that the loading seen by the speciments is not of pure compression.

5. Conclusions

A total of 5 configurations of plain coupons and 6 configurations of open-hole coupons including gaps and overlaps were tested experimentaly under compression loading up to failure and up to 90% of the failure load. The test were performed with a multi-instrumented set-up in order to monitor the failure scenario and characterize the effects of singularities on the mechanical properties and the failure scenario.

The effects of singularities are stronger on plain coupons than on the open-hole coupons due to the hole effect. However, the results from plain coupons test are unusual and requires deeper analysis. Numerical simulation including experimental boundary conditions computed with digital image correlation are considered in the future to better understand the test that were performed.

Despite the variation of the prepreg volume in the region of interest of the different specimens configurations, any correlation is found between variations in mechanical properties and variations in failure properties.

Regarding the effects of singularities on the mechanical and failure properties of open-hole specimens, the gaps reduce the stiffness and the failure properties of specimens under compression. The presence of overlaps along the loading direction limits the effects of gaps positioned along other directions. In addition, singularities positioned along the loading direction have the most important effect. The triangular singularities have a smaller effect than the rectangular singularities.

Coupling the analysis of acoustic emission data and the post treatment of CT-scan images able to state that no damage can be observed before 90% of the failure load. However, damage may appear after 90% of the failure laod as high energy acoustic events are recorded near 95% of the failure load for most of the specimens. A new CT-scan of the specimens after a new step load at 95% of the failure load could confirm these results and help to characterize the effects of singulairities on the failure scenario of coupons under compression loading.

Abstract
This article outlines a numerical calculation code developed within the framework of finite elements to simulate the thermal aging of epoxy-diamine networks on both sides of the glass transition temperature (T_g). This model couples, in an oxygen (O_2) balance equation, the diffusion of O_2 and its consumption by the chemical reaction with the epoxy matrix. The reliability of the oxidation rate expression has previously been checked for several epoxy-diamine networks. The code gives access to the oxidation gradients through the sample thickness, from which the gradients of properties of interest for the aeronautical field are deduced, *i.e.* T_g and elastic properties. The validity of the oxidation gradients is checked by calculating the corresponding values of the thickness of oxidized layer (TOL). The estimates of TOL are in good agreement with experimental measurements in the glassy state. In contrast, the calculations largely underestimate the experimental measurements in the rubbery state due to the sharp increase of the diffusion coefficient of O_2 above T_g.

1. Introduction

Carbon/epoxy composites are widely used for the design of structural parts in aeronautics because of their high specific properties. However, the long exposure to temperatures close to their glass transition temperature (T_g) can lead to potential risks. Among these risks, those related to the phenomenon of thermo-oxidative aging of the epoxy matrix are particularly critical [1]. Indeed, this aging causes a thin oxidized layer on the surface, leading to local weakening and stress gradients that could result in cracking. Over time, oxidation can reach the core of the parts following a progressive damage scenario and thus lead to their premature failure [2].
In this context, it is crucial to establish a link between the oxidation kinetics of epoxy matrices and the evolution of the thermomechanical properties of the composites. A compilation of thicknesses of oxidized layer (TOL) measured by optical microscopy, IR mapping or (nano or micro)-indentation on epoxy-diamine networks after thermal aging in air, clearly shows a break in the Arrhenius graph at neighbourhood of T_g, as shown in Figure 1. The jump in TOL is approximately of ~50 times when these materials reach their rubbery state.

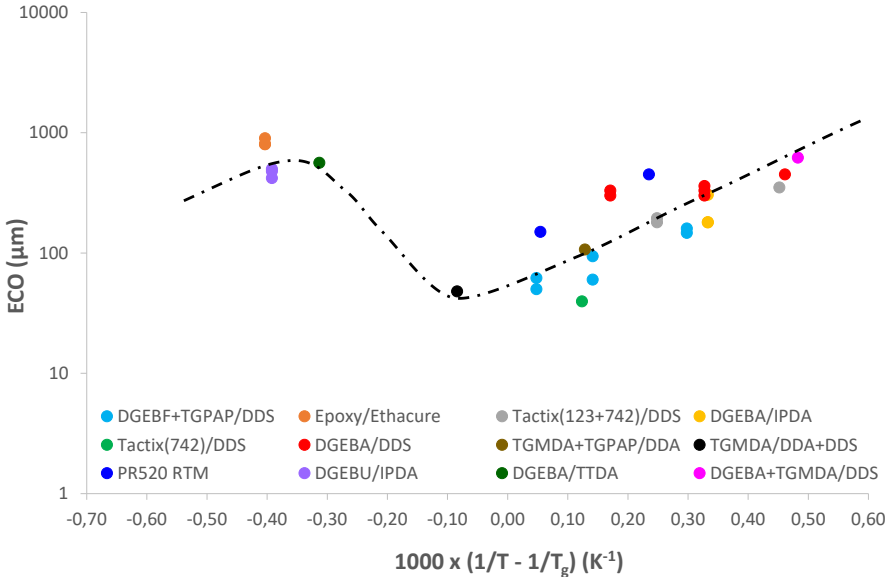

Figure 1. Variation of the thickness of the oxidized layer with the exposure temperature in air for epoxy-diamine networks. Data from 15 bibliographical references.

This jump in TOL above T_g is linked to higher molecular mobility and can have different origins. Any change in the oxidation mechanism with increasing temperature should be excluded because certain epoxy-diamine networks (cf. Figure 1) have very low T_g. Likewise, a slowdown in the rate of oxidation with increasing temperature is inconceivable from a kinetic point of view. Thus, the only realistic cause that could be envisaged would be a sudden acceleration of the diffusion of O_2 above T_g. In order to verify this hypothesis, numerical simulations are necessary. These simulations will not only allow us to better understand the kinetics of thermo-oxidation of the epoxy-diamine networks on either side of T_g, but also to predict the consequences of oxidation on the thermomechanical properties of the composites. Thus, the objective of this article is twofold : *(i)* the proposal of a kinetic model of thermo-oxidation of epoxy-diamine networks faithfully describing the oxidation gradients on either side of T_g, and *(ii)* the relationship between the evolutions of these gradients and the thermomechanical properties of interest for the aeronautical field, *i.e.* the T_g and the elastic properties. To achieve these two objectives, the article is divided into two main parts. First of all, Section 2 deals with the modelling of thermo-oxidation with a numerical calculation code developed by finite elements (FE). Section 3 aims to compare the predicted results using this code to experimental data. For this, TOL measurements will be used for checking the roboustness of the code. Then, the utility of the model for computing the evolutions of T_g and Young modulus (E) during aging will be discussed. Finally, conclusions and perspectives, aimed at predicting the lifetime of neat epoxy and/or epoxy/carbon composites, will be drawn up.

2. Modelling of the oxidation gradient

This section outlines a numerical computer code developed using EF to model the physico-chemical mechanisms involved in the thermo-oxidation of epoxy-diamine networks. It also presents a criterion for estimating the TOL, based on the code's results, to verify the predictive capacity of the kinetic model.

2.1. Description of the model

The propagation of the oxidation front is directly linked to the local concentration of O_2, which is governed by an O_2 balance equation coupling two main mechanisms: *(i)* the diffusion of O_2 and *(ii)* its consumption by the chemical reaction with the epoxy matrix. In the case of unidirectional diffusion (depending on the through-thickness coordinate), this balance equation is written such as:

$$\frac{\partial C(x,t)}{\partial t} = D\frac{\partial^2 C(x,t)}{\partial^2 x} - r(C(x,t)) \quad (1)$$

C(x,t) being the local O_2 concentration, r(C) the local oxidation rate, D the diffusion coefficient of O_2, x the though-thickness coordinate, and t the time.
A recent kinetic analysis of the so-called "*closed-loop*" oxidation reaction has resulted in a comprehensive analytical expression for r(C). Unlike previous versions of r(C), which were much simpler because they were based on simplifying assumptions, Eq. 2 makes it possible to describe all three stages of the oxidation kinetics, namely: the induction period, the sudden self-acceleration of oxidation at the end of this induction period, and the regime established (*i.e.* the steady state). This new equation has been verified for various epoxy-diamine networks on either sides of T_g [3,4].

$$r(C) = 2r_0 \frac{\beta C}{1+\beta C}\left(1 - \frac{\beta C}{2(1+\beta C)}\right)\left(\frac{1}{1+be^{-Kt}}\right)^2 \quad (2)$$

where K is an apparent first-order rate constant, β the inverse of the critical O_2 concentration delimiting the regimes in O_2 deficiency and excess, and r_0 the maximum rate of oxidation in O_2 excess.
To consider the strong coupling between the diffusion of O_2 and its chemical consumption through the thickness of the part and thus, to determine the gradients of C(x,t), we propose a 1D semi-numerical approach under FE to solve Eq. 1 [5]. Figure 2 shows the classical discretization scheme under FE applied to C(x,t). In the x direction, the part is discretized (*i.e.* splitted into thin elementary elements) for each node $x_i \subset [0, x_n = L]$ with $i \subset [0, n]$, L and n being respectively the thickness of the part and the number of elements. Analogically, a temporal discretization is also carried out for each time step $t_j \subset [0, t_m = t_f]$ with $j \subset [0, m]$, t_f and m being respectively the final time and the number of increments.

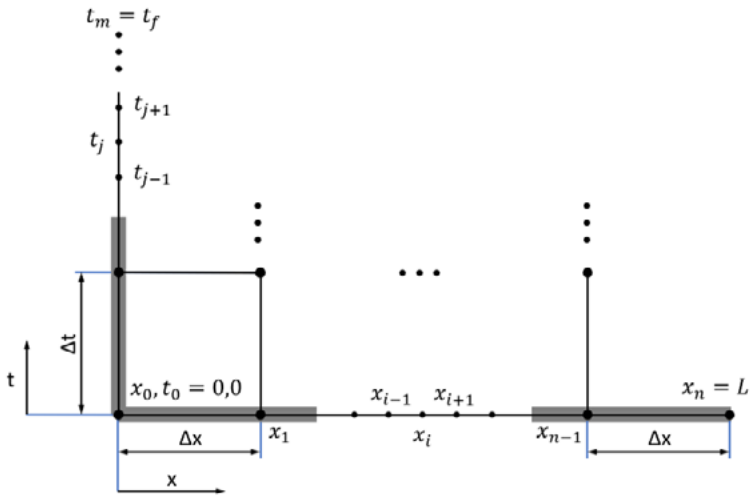

Figure 2. Scheme for discretizing the spatio-temporal problem [5].

Eq. 1 can be written as a variational problem with boundary conditions, whose approximate integral formulation is given by:

$$0 = \int_0^L \psi \left(\frac{\partial C(x,t)}{\partial t} - D\frac{\partial^2 C(x,t)}{\partial^2 x} - f(C(x,t))\right) dx \quad (3)$$

where ψ is a weighting function, and f(C(x,t)) represents the external forces of the problem to be solved. The problem is formulated as a minimization of the residual based on a Garlekin approach. Thus, the concentration $C(x_i,t) = C_i(t)$ in each node i is given by the shape function φ_i such as: $C(x,t) = \sum_i^n \varphi_i(x) C_i(t)$. Because of the EF framework, Eq. 3 can be rewritten in matrix form as follows:

$$M\dot{\boldsymbol{C}} + K\boldsymbol{C} = \boldsymbol{F} \tag{4}$$

with **C**=[C_0(t)…C_n(t)] the vector of O_2 concentrations and **F**=[f_0(t)…f_n(t)] the vector of external forces exerted at the nodes. M and K are the global mass and stiffness matrices of the problem to be computed by assembking the elementary matrices of all the elements of the domain [5]. Concerning the boundary conditions, Dirichlet initial conditions and Neumann spatial boundary conditions were used. Indeed, C(x,0) and f(x,0) are known at the initial time throughout the thickness of the sample, while C(0,t) and C(L,t) are also known at any time at the edges of the sample thanks to Eq. 5.

$$C(x,0) = S_0 p_0 \qquad C(0,t) = S_0 p_0 \qquad C(L,t) = S_0 p_0$$
$$f(x,0) = 2r_0 \frac{\beta C_0}{1+\beta C_0}\left(1 - \frac{\beta C_0}{2(1+\beta C_0)}\right)\left(\frac{1}{1+be^{-K_0 t_0}}\right)^2 \tag{5}$$

To solve the problem, firstly Eq. 4 can be directly solved at the initial time to get $\left.\frac{\partial C(x,t)}{\partial t}\right|_0$. Secondly, Eq. 4 can be iteratively solved by a Crack-Nicolson method to obtain C(x,t) for each time step.

2.2. TOL criterion from oxidation gradient

Solving the 1D problem presented in Paragraph 2.1 gives access to the evolution of the O_2 concentration gradient C(x,t) within the thickness of the sample. Numerical simulations have been carried out in air at 200°C for an epoxy-diamine network; the TACTIX(123+742)-DDS. Figure 3 shows the corresponding oxidation gradients. We see that C(x,t) is symmetrical in the thickness because of imposed boundary conditions. Over time, we clearly see that C(x,t) reaches a limit curve when the steady state is established. The shape of this gradient is strongly dependent on the values of the input parameters, in particular on β, r_0 and D.

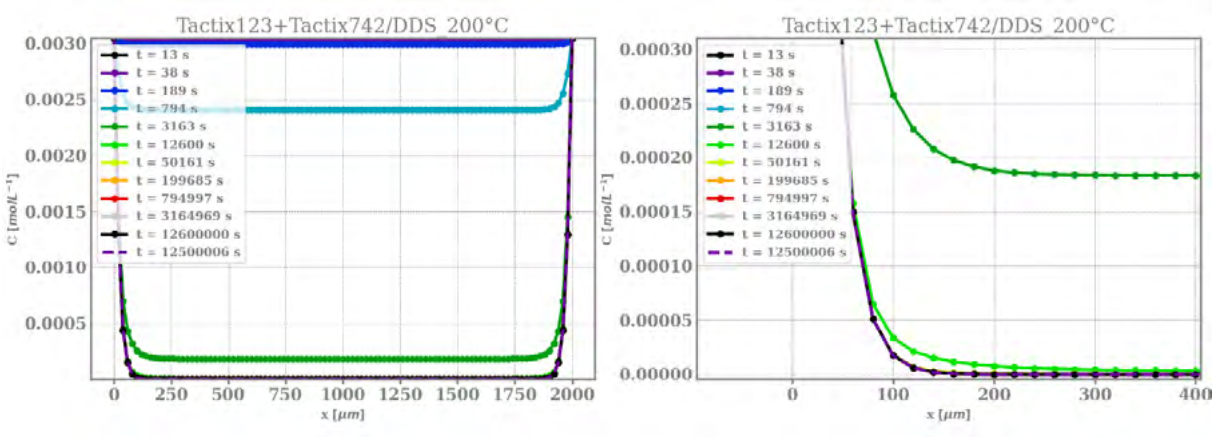

Figure 3. Calculation of the gradient C(x,t) for different exposure times in air at 200°C for the TACTIX(123+742)-DDS network.

Once r(C) calculated with Eq. 2, its temporal integration gives access to the total concentration of oxygen consumed by the chemical reaction, *i.e.* to the oxidation gradients Q(x,t):

$$Q(C) = \int_0^t r(C(x,t))dt = Q(x,t) \tag{6}$$

In order to propose a robust criterion valable to all epoxy-diamine systems for estimating the TOL and for validating the kinetic model, the Q(C) profiles are retained because this gradient can be accessible

experimentally with common laboratory physicochemical techniques, *e.g.* FTIR spectrometry. For it, the difference Q(x,t)-Q(L/2,t) was normalized between its maximum and minimum values in the steady state, as shown in Figure 4. This value has been estimated for each system as the difference between the concentration of oxidation sites PH on the surface when the oxidation reaction is complete and the initial O_2 concentration in the heart of the sample previous to oxidation. Then, an arbitraty criterion of around 0.05% has been considered, leading to the following expression for the estimate of the TOL evolution:

$$TOL(t) = Argmin([\,Q(x,t) - Q(L/2,t)]/[Q_{max} - Q_{min}] - 0.05\%)) \tag{7}$$

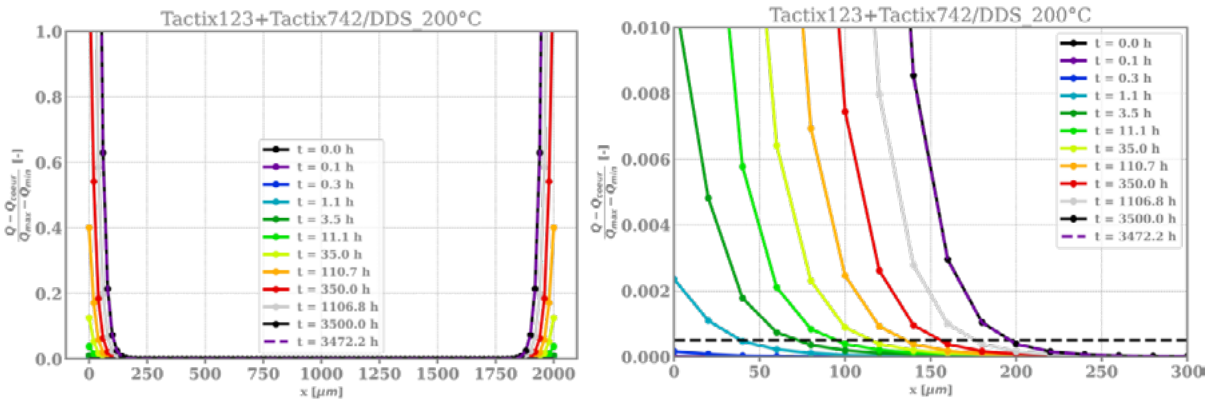

Figure 4. Calculation of the normalized oxidation gradient [Q(x,t)-Q(L/2,t)]/[Q_{max}-Q_{min}] and application of the criterion given in Eq. 7 for the estimate of TOL in air at 200°C for the TACTIX(123+742)-DDS network.

3. Comparison of simulations with experimental results

This section compares results from numerical simulations using the model described in Section 2 with experimental data, specifically TOL measurements. Additionally, the kinetic model is enhanced with structure/property relationships to predict the gradients of thermomechanical properties.

3.1. TOL confrontation

Figure 5 presents the confrontation of numerical simulations with experimental values of TOL (plotted using crosses). For numerical estimates, these TOL values were determined in the steady state using the criterion given in Eq. 7. The maximum TOL values calculated for epoxy-diamine networks with known parameters K, β, r_0, and D are plotted using filled dots. In this case, the diffusion coefficient D is assumed to be known and to follow a standard Arrhenius law in the glassy state, typically:

$$D(T) = 5.0\ 10^{-11} \times Exp\left[-\frac{41600}{R}\left(\frac{1}{T} - \frac{1}{T_g}\right)\right] \quad \text{for aliphatic diamines}$$
$$D(T) = 2.3\ 10^{-12} \times Exp\left[-\frac{9000}{R}\left(\frac{1}{T} - \frac{1}{T_g}\right)\right] \quad \text{for aromatic diamines} \tag{8}$$

In the glassy state (*i.e.* for $T<T_g$), numerical simulations give access to TOL values of the same order of magnitude as the experimental measurements. It can be shown that, as parameters β, r_0 et D follow an Arrhenius law, then the same is true for TOL [3]:

$$TOL = TOL_0\ Exp\left(\frac{E_{TOL}}{8.31 \times T}\right) \tag{9}$$

where TOL_0 et E_{TOL} are respectively the pre-exponential factor and the activation energy. Thus, TOL is a decreasing function of temperature. For epoxy-diamine networks exposed in air, we find that E_{TOL}≈40 kJ/mol. At this point, numerical simulations cannot account for the jump in TOL in the vicinity of T_g. As explained in the introduction, the main hypothesis to explain this jump is a sudden increase in D when the material goes from the glassy to rubbery state ($T>T_g$). To check this hypothesis, new simulations were redone in the rubbery state by increasing D from 10 to 100 times. The O_2 permeation measurements reported in the literature for all polymers confirm this hypothesis [6]. The new estimates of TOL are also plotted in Fig. 5 using filled squares. It is remarked a better agreement with the experimental results because the coupling between the chemical consumption and the diffusion of O_2 in the through-thickness direction of the sample is better respected.

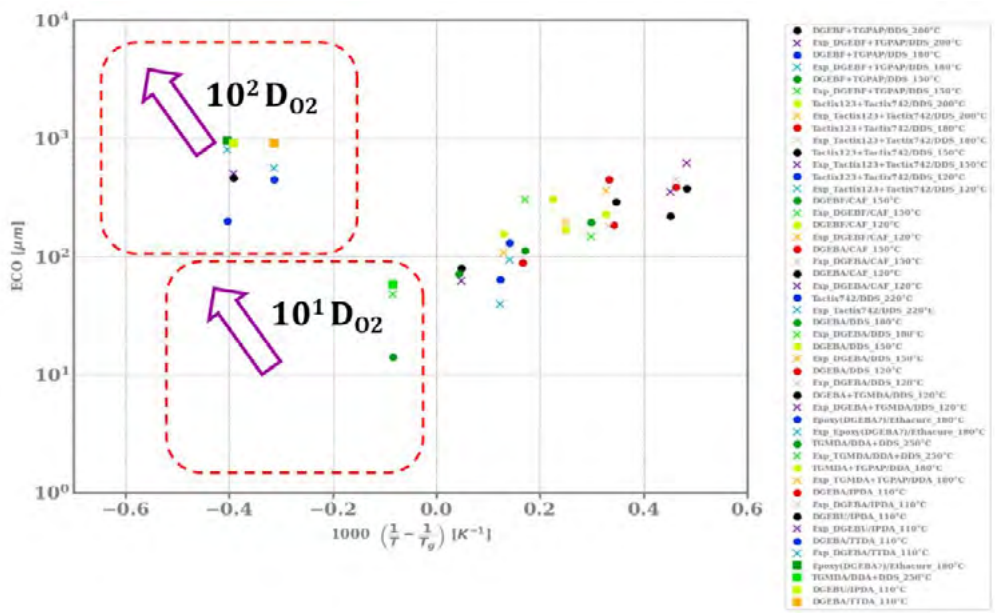

Figure 5. Variation of TOL with the reciprocal temperature for epoxy-diamine networks. Experimental values (crosses) compared to calculated values considering that D obeys an Arrhenius law below T_g (*i.e.* $1/T-1/T_g>0$) (filled circles) and increases suddenly by a factor of 10^1 to 10^2 above T_g (*i.e.* $1/T-1/T_g<0$) (filled squares). The arrows show the effect of the increase in D on the TOL estimates.

3.2. Prediction of degradation of thermomechanical properties

Some authors have shown that thermo-oxidation impacts the thermomechanical properties such as T_g and Young's modulus [7,8,9]. In fact, T_g decreases if chain scissions predominate over cross-linking [7]:

$$\frac{1}{T_g}=\frac{1}{T_{g0}}+\frac{2K_{DM}\,F}{3T_{gl}\,K}(3r_{S\infty}-2r_{X\infty})\left\{Kt+Ln\left[\frac{1+be^{-Kt}}{1+b}\right]-\frac{1}{1+be^{-Kt}}+\frac{1}{1+b}\right\} \quad (10)$$

where $r_{S\infty}$ and $r_{X\infty}$ are respectively the maximum ratess of chain scissions and crosslinking, K_{DM} a universal constant (K_{DM}≈3), F and T_{gl} two parameters linked to the rigidity of the chains of the macromolecular network. Figure 6 (left) shows the evolution of the gradient of T_g at 200°C in air for the TACTIX(123+742)-DDS network. The related thermo-oxidation kinetics were discussed in Paragraph 2.2 (Figures 3 and 4). A significant drop in T_g is observed at the sample edges, which lessens in deeper layers, leading to T_g values which remains almost unchanged in the sample core. Figure 6 (right) illustrates the decreasing evolution of the average value T_g in the whole sample, aligning well with experimental trends from literature.

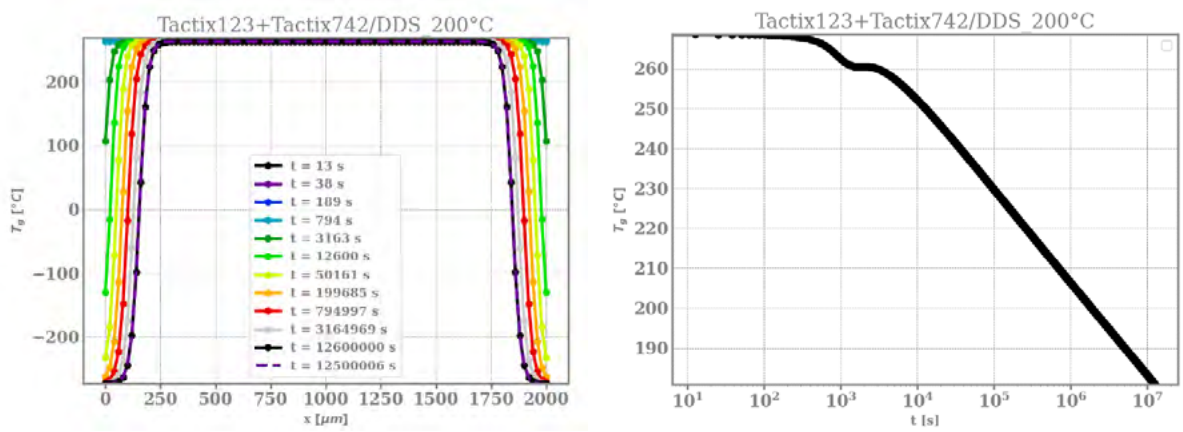

Figure 6. Left: Calculation of the gradient of $T_g(x,t)$ in air at 200°C for the TACTIX(123+742)-DDS network. Right: Evolution of the average value of T_g in the whole sample.

On the other hand, the Young's modulus increases due to an antiplasticization process. Indeed, although T_g decreases, the progressive disappearance of the sub-glass transition β (located around -70°C) ultimately leads to an increase in the Young's modulus between T_β and T_g. The Gilbert equation is generally used to account for this evolution [9]:

$$E(T) = E(0\ K)\left(1 - \alpha\frac{T}{T_g}\right) - \Delta E_\beta \tag{11}$$

where E(0 K) and E(T) are respectively the values of the Young's modulus at -273°C and at the study temperature, and ΔE_β is the drop in Young's modulus at the transition β. To our knowledge, there is still no kinetic law for describing the evolution over time of ΔE_β. However, it is possible to propose an arbitrary antiplastification law based on oxidation gradients. For this, the following relationship is used:

$$\Delta E_\beta = \Delta E_\beta^{max}\,(1 - \phi(x,t)) \tag{12}$$

where ΔE_β^{max} refers to the maximal modulus jump related to the transition β when the oxidation of the sample reaches the steady state. Φ represents the oxidation degree, whose value evolves between 0 and 1 according to normalized values of Q(x,t). Thus, when Q(x,t)-Q(L/2,t) reaches (Q_max-Q_min), it is assumed that Φ is equal to 1. According to Eq. 12, Figure 7 shows the gradienst of E (left) and the evolution of the average value of E in both the TOL and the whole sample, whose evolutions are in good agreement with experimental trends from literature [9].

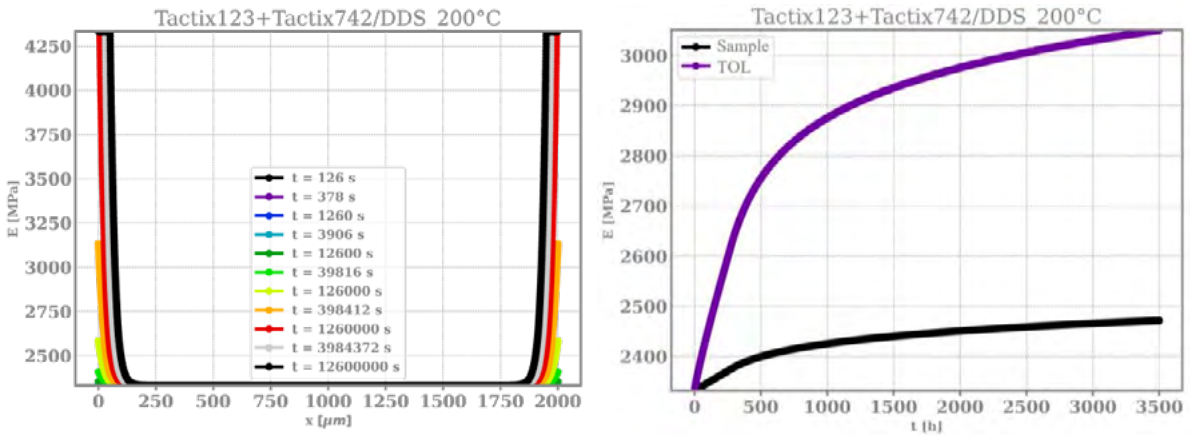

Figure 7. Left: Calculation of the gradient of E(x,t) in air at 200°C for the TACTIX(123+742)-DDS network. Right: Evolution of the average value of E in the TOL and the whole sample.

4. Conclusions and perspectives

A numerical calculation code based on finite elements was developed to solve a diffusion/reaction problem and simulate the oxidation gradients of the epoxy-diamine networks on either side of T_g. A physically-based criterion was chosen to calculate the thickness of oxidized layer (TOL) from the gradients of O_2 consummation. The robustness of this criterion was proven by comparing the estimates of the TOL with experimental measurements on many epoxy-diamine networks. The key role of O_2 diffusion has been highlighted, particularly in the rubbery state, for which the oxidation front evolves deeper in the sample compared to the glassy state. The consequences of oxidation on thermomechanical properties, in particular on T_g and E were then calculated. A significant reduction in T_g was thus shown at the edges, while in the heart of the sample, its value practically did not change. On the other hand, the consequences of oxidation on E has been computed assuming an arbitrary law to describe the effects of antiplasticization. The evolution of the average value E in the TOL and the whole sample have been obtained from the gradients of E, leading to an increase in E as consequence of local stiffness of oxidized layers. As perspectives, the computation of stress/strain states within the material is envisaged. This is, in fact, an important step in the lifetime prediction approach.

Keywords: interface engineering, designed failure, 3D printing, failure mode, interlayer material

Abstract
Without increasing the reliability of composites, their broader use in safety-critical components might be limited by their unfavorable failure process, which is mainly based on the interaction of different damage mechanisms from different sources and often occurs at random locations and without any particular sign. In our research, we developed and investigated a method that can be suitable for controlling and designing the failure process of composites in terms of pre-determined location and mode of failure. For this purpose, we manufactured UD carbon-fiber/epoxy composite plates, which contained a locally weakened adhesion zone formed by polycaprolactone (PCL) thermoplastic interlayer material. The failure mode and location of the composite specimens were evaluated under uniaxial tensile loading. The results show that the application of PCL interlayer material enables the design of the failure process of polymer composites, and it does not influence their mechanical properties significantly.

1. Introduction

Polymer composites, due to their complex microstructure and manufacturing technologies, are fundamentally affected by a wide variety of damage modes from different sources, such as defects in the raw material, manufacturing induced and in-service flaws, which differ significantly in their typical sizes, from nano to macro, and in their effect on the composite structure. The initiation and propagation of damage and the mode of failure that may occur, are essentially determined by the loading conditions and the structure of the composite [1, 2].

Damage in composites, especially delamination, is often difficult to detect and localize. However, its presence usually leads to a reduction in the effective strength and stiffness of the composite, and its propagation can lead to failure. Detecting these damages and investigating the residual mechanical properties of the composite are essential to ensure proper structural health monitoring, which is best achieved by using non-destructive testing methods [3].

Besides other NDT methods such as computed tomography, acoustic emission testing, and ultrasound testing, which are often used for the investigation of composite materials, the digital image correlation (DIC) technique is a cost-effective, relatively simple method - optical analysis of the mechanical

response to mechanical excitation - that can be used to detect damage at the meso- and macro-levels of a composite and to detect the propagation of damage. This information is provided by the high local strain values and the changes in the strain field observed during DIC-based full-field strain measurements [4, 5].

Another problem is that the failure of composites is challenging to predict and often occurs catastrophically. Therefore, to increase the reliability of composites, it is essential to influence their failure processes and make them more controllable. Failure can be partially localized by creating artificial damage, but this usually results in a significant loss of strength and cannot determine the mode of damage [6]. The failure process can be controlled by methods that aim to achieve pseudo-ductile behavior, where one possible method is the modification of interfacial adhesion, e.g., with nanofiber mats [7] or polymer films [8]. Applying polycaprolactone (PCL) thermoplastic interlayer material also seems successful in achieving pseudo-ductile behavior. PCL can be solved in the epoxy matrix. Thus, it does not create a new phase and applying it as interlayer material enables the influence of the failure process by the formation of locally weakened adhesion zones and the local modification of the matrix material [9, 10].

In the present research, we manufactured locally interfacially engineered composite plates containing PCL interlayer material. Our aim was to predefine the failure mode and location. The composite specimens were investigated under uniaxial tensile loading. Based on the measured data, the influence of the local modification of interfacial adhesion and the width of the weakened adhesion zone on the mechanical properties as well as the failure mode and position were evaluated.

2. Materials and methods

2.1. Materials

We applied IPOX MR 3010 (IPOX Chemicals Kft., Budapest, Hungary) DGEBA-based epoxy resin (EP) as matrix material of the composites, which was mixed with IPOX MH 3124 amine type curing agent in a weight ratio of 100:35. The reinforcement material was PX35FBUD0300 (Zoltek Zrt., Nyergesújfalu, Hungary) stitch-bonded unidirectional carbon fabric (309 g/m^2 surface weight), consisting of Panex35 50k rovings. As interlayer material, we used eMorph175N05 (Shenzhen Esun Industrial Co. Ltd., Shenzhen, China) poly (ϵ-caprolactone) (PCL) filament (1.75 mm diameter, 60°C melting temperature, 180°C printing temperature).

2.2. Sample production

Composite plates with [0°$_6$] layup sequence were manufactured by vacuum-assisted resin transfer molding (VARTM). For interfacially engineered composites, the PCL filament was printed directly on the surface of the carbon fabric by fused filament fabrication (FFF) method (Figure 1) using a CraftBot Plus 3D printer (CraftUnique Kft., Budapest, Hungary). Interlayer material was applied perpendicular to the fiber direction and placed only between the two middle plies.

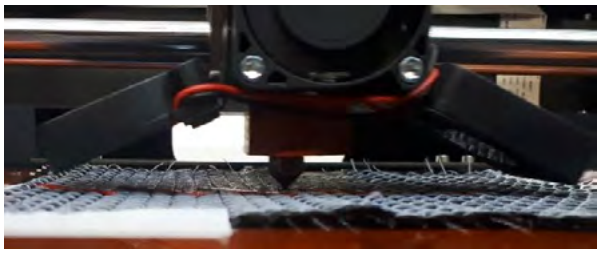

Figure 1. 3D printing of PCL interlayer material on the reinforcement fabric using FFF method

The thickness of the interlayer material, thus the weakened adhesion zone, was constantly 0.4 mm, only width differed in each plate. Plates containing 1, 2 and 3 mm wide interlayer material were produced.

Besides interfacially engineered composites, reference samples containing no interlayer material were also manufactured. Specimens prepared for the material testing were cut from the composite plates with a Mutronic Diadisc (Mutronic, Rieden am Forggensee, Germany) diamond disc cutter.

2.3. Methods

Initially, the fiber volume fractions of the composite plates were determined through density measurements conducted with a Sartorius Quintix 125D weighing scale (Sartorius Lab Instruments GmbH, Göttingen, Germany) following the rule of mixtures principle.

Tensile tests were performed according to ISO 527-4 standard using a Zwick Z250 (Zwick GmbH, Ulm, Germany) universal testing machine with a 250 kN load cell. During the tensile tests, 15 mm wide and 250 mm long specimens were investigated. The specimens were protected with bonded end-tabs, resulting in a free length of 150 mm. The test speed was set at 5 mm/min. Displacements were measured using a Mercury Monet (Sobriety, Kurim, Czech Republic) optical strain measuring system based on digital image correlation (DIC) featuring a 5 MPixel resolution IDS U3-3080CP-P-GL (Imaging Development Systems Inc., Obersulm, Germany) camera and two LED lights. Data acquisition was carried out with a frame rate of 10 Hz. The results were processed with Mercury RT-v2.9 software.

Before testing, the optical strain measurement system was calibrated in order to mitigate lens distortion and establish a correlation between the specimen's actual size and its representation in the recorded images. A gauge length of 75 mm was used for global strain measurement, applying a line probe within the software. Two additional line probes were used: one for further global strain measurement with a length of 50 mm, and another for local strain measurement in the region of the PCL interlayer material, covering 15 mm in length. DIC technique was used to generate a full-field strain map, where the calculated points were spaced at 20-pixel intervals, using a facet window size of 40 pixels × 40 pixels. For the DIC measurements, a high-contrast pattern was painted on the surface of the specimens.

3. Results and discussion

The results of the fiber volume fraction estimation based on density measurement showed that the average fiber volume fraction of the manufactured composite plates was 39.45±1.07 V/V%. The experienced differences do not affect the mechanical properties significantly, which enables the comparison of the different plates.

3.1. Tensile properties

Firstly, the tensile properties – tensile strength and modulus – of the different composite specimens were determined, and the effect of the PCL pattern width on them was evaluated (Figure 2).

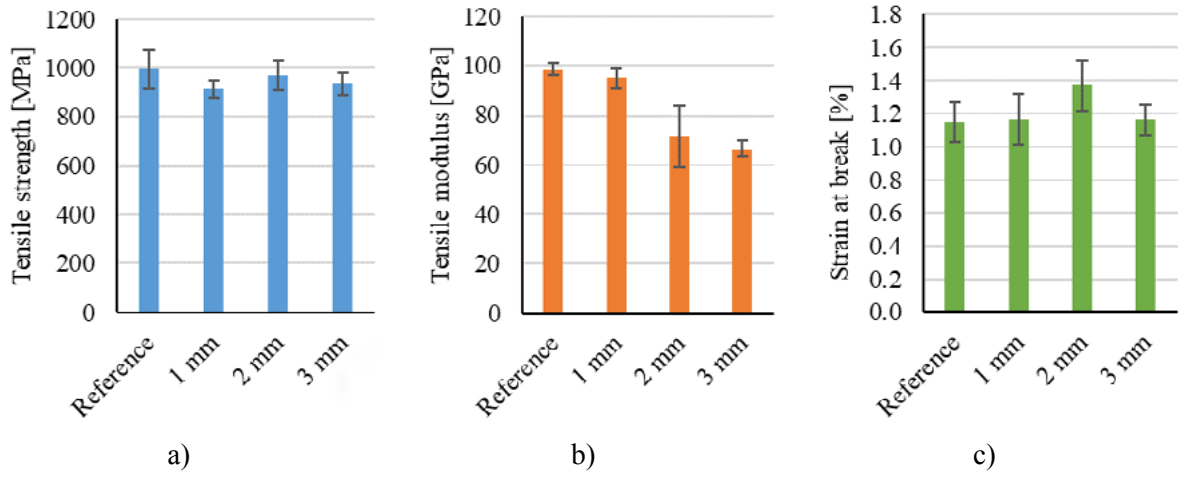

Figure 2. The effect of the width of PCL interlayer material on the tensile properties a) tensile strength, b) tensile modulus, c) strain at break

The results indicate that using PCL interlayer material does not significantly affect the tensile strength and the strain at break. On the other hand, using PCL causes a decrease in the tensile modulus, which is more significant with the increasing width of the interlayer material. This effect might be caused by the locally weakened adhesion, the fiber waviness and the resin-rich areas formed by the PCL interlayer material. During the tensile tests, we experienced that the interfacially engineered composites tend to fail in the region of the PCL interlayer material, and the frequency of the localized failure increases with the width of the PCL pattern.

3.2. Line probe tests

Following that, data obtained from Line Probe (LP) measurements, carried out by DIC during the tensile tests were analyzed to detect potential damage, particularly the formation of delamination. In the line probe test, elongation along three lines of varying lengths was measured. Line probes A2 and A3 provided insights into the global strain, while A1 specifically indicated local strain within the region of the interlayer material (Figure 3). The measured data was evaluated for the reference specimens as well.

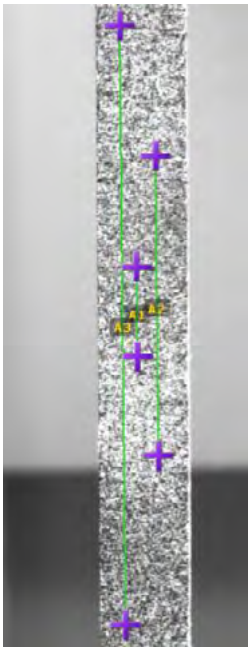

Figure 3. Arrangement of the line probes on the surface of the composite specimen: A1= 15 mm for local strain measurement, A2=50 mm and A3=75 mm for global strain measurement

The measured data indicate that the presence of the PCL interlayer material results in a deviation between the local and global strain values by locally increasing strain in the modified region. Higher strain values in the interfacially engineered region might lead to localized failure by reaching the failure strain earlier. In contrast, in the case of the reference sample, there is no significant difference in the elongations measured by the line probes. The only noticeable difference is that the line probe measuring local strain is affected by higher levels of noise (Figure 4).

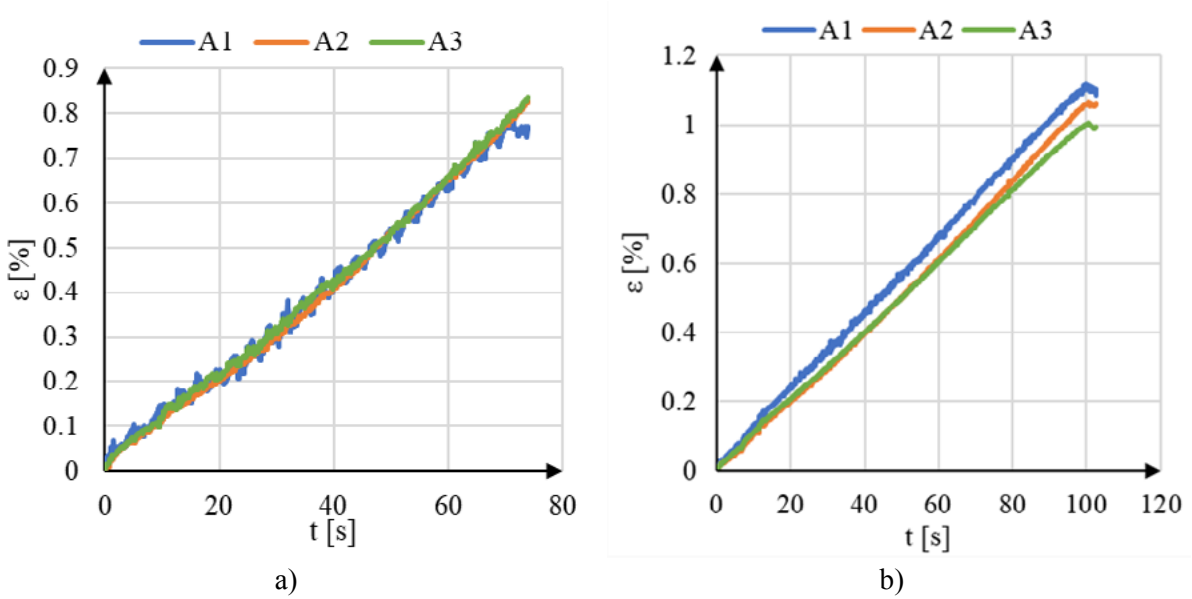

Figure 4. The results of the line probe test for a) a reference specimen, b) a specimen containing 3 mm wide, 0.4 mm thick PCL interlayer material

3.3. Full-field strain measurement

Then, strain fields were determined using the DIC technique, and the strain fields of the different composite specimens were compared at an identical global strain value of 0.7%. The results suggest that, while relatively homogenous strain fields belong to the reference composites, the presence of PCL interlayer material causes local high-strain values. These zones indicate the localization of damage and failure as well as the occurrence of local delamination. This effect was observed to become more significant with the increase in the PCL pattern's width. A characteristic strain field for a reference specimen and a specimen containing 3 mm wide and 0.4 mm thick PCL interlayer material can be seen in Figure 5.

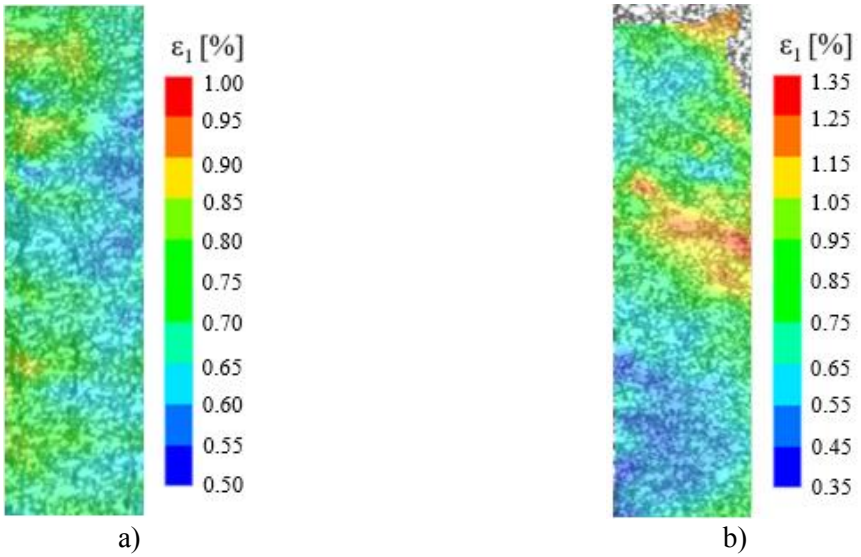

Figure 5. The results of the full-field strain measurement at 0.7% global strain for a) a reference specimen, b) a specimen with 3 mm wide and 0.4 mm thick PCL interlayer material

4. Conclusions

In our research, we manufactured locally interfacially engineered composites by applying 3D-printed PCL interlayer material in order to design their failure. We carried out tensile tests supported by DIC to investigate the effect of the pattern width of PCL on the mechanical properties and the failure process. The results show that the application of PCL interlayer material enables the design of the failure process of polymer composites, and it does not influence their mechanical properties significantly. The mechanism of the method can be explained with several effects of PCL: local modification of interfacial adhesion and the matrix material, as well as the formation of fiber waviness and resin-rich areas.

Keywords: Carbon-reinforced plastic, composite tank, low-velocity impact, Cryogenic temperatures, Progressive damage

Abstract
This research investigates composite overwrapped tank structures produced through filament winding and exposed to cryogenic loads. A 3D-FE Model, including parameters of the mandrel trajectory for designing the dome, junction, and cylindrical shell, is coupled with thermal degradation to replicate physical variations. Intralaminar damages, such as matrix cracking and fiber failures, are predicted using 3D Hashin criteria. The numerical analysis employs a multi-step technique, using Abaqus/Standard for a general static step in thermal simulation and Abaqus/Explicit for impact events on the pre-stressed composite tank. The presented numerical results include contact force, displacement, energy dissipation, and predicted matrix damage in each layer of the tank. The impact of temperature changes on the tank's response to impacts is explored, and a detailed examination of damage zones on the structure reveals that damages increased as the temperature decreased for all test samples

1. Introduction

Hydrogen has gained significant attention in recent years as a promising energy vector, offering a sustainable and environmentally friendly alternative to conventional fossil fuels**[1]** Composite hydrogen tanks are crucial in developing and implementing hydrogen-based energy systems **[2]**. These tanks are designed to store hydrogen under high pressure, enabling its efficient use in various applications, such as transportation, stationary power generation, and portable devices. Composite materials, such as carbon fiber-reinforced polymers (CFRP), are utilized in the construction of hydrogen tanks due to their exceptional strength-to-weight ratio, corrosion resistance, and durability. These properties make composite tanks ideal for safely storing and transporting hydrogen while minimizing the overall system weight **[3,4]**. Hydrogen storage tanks play a crucial role in many applications, particularly in aerospace, where every gram counts. They are designed to safely and efficiently store hydrogen, enabling its use as fuel or as an energy source. Hydrogen can be stored in either gaseous or liquid form, each state having its own advantages and disadvantages. In aerospace, where lightweight design is essential to maximize aircraft range and energy efficiency, storing hydrogen in liquid form is of particular interest. For the certification of hydrogen storage tanks, it is essential that they comply with the relevant standards **[5]**. Therefore, it is crucial to develop a methodology for conducting impact studies before and after thermal degradation **[6]** following the injection and liquefaction of hydrogen in the tanks. This approach is indispensable to support the certification process and reduce the number of required testing campaigns.

2. Type of Hydrogen Tanks

All For hydrogen to serve as a fuel, it must be stored in tanks under considerable pressure. Currently, four main types of tank designs cater to this requirement: Type I, Type II, Type III, and Type IV, as shown in Figure 1. A Type III tank was developed, which is fully composite wrapped, including wrapping at the polar boss, but the liner is still a metallic one [7]. The liner acts as a barrier towards the hydrogen leak or permeation. As compared to Type I and Type II, it is much lighter and hence suitable for vehicle applications. The Type III tanks provide positive results up to a pressure of 450 bars only. Hence, a plastic liner with a complete composite wrap-based tank Type IV is developed [8]. Usually, the plastic liner is made of High high-density polyethylene (HDPE), and the composite used is generally.

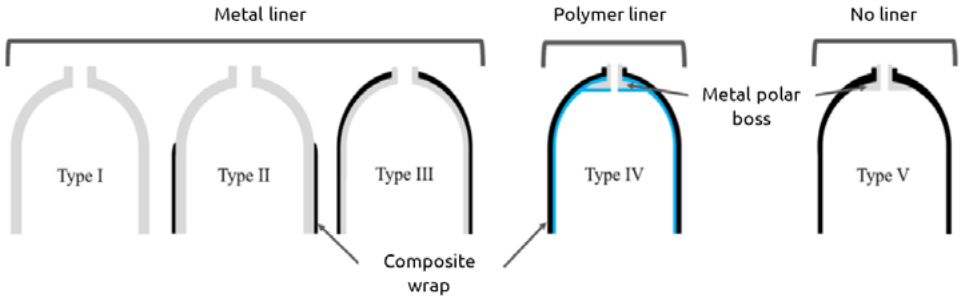

Figure 1. Types of pressure vessels

The transition of hydrogen from the gaseous state to the liquid state involves a significant reduction in volume, allowing for denser energy storage. Liquid hydrogen offers a higher energy density compared to gaseous hydrogen, meaning that a greater quantity of hydrogen can be stored in a smaller space. This is crucial for aerospace applications where weight and space are limiting factors. However, storing hydrogen in liquid form also presents technical challenges. Firstly, it requires extremely low temperatures to maintain hydrogen in a liquid state, typically around -253 degrees Celsius. This necessitates the use of sophisticated cooling systems, adding complexity and weight to the aircraft. Additionally, the process of liquefying hydrogen is energy-intensive, which can reduce the overall system efficiency.

Despite these challenges, liquid hydrogen remains a promising option for aerospace due to its high energy density. Advances in storage technologies and insulation materials could help overcome some of these obstacles in the future, paving the way for more widespread use of hydrogen as a clean and efficient fuel in aviation

3. Conditions for low velocity impact analysis

When dealing with hydrogen (especially for liquid) it is important to incorporate the cryogenic conditions into the simulation for the simple reason that the properties of the composite laminate have different properties at different temperature because of difference in the Glass Transition Temperature (Tg) of the epoxy. Li et al. [9] carried out experimental analysis on composite laminate at various temperatures ranging from 93k to 293k and compared with the RVE model which they developed. Authors presented temperature dependent constitutive damage laws. Since the properties of epoxy resin are dependent on temperature, a temperature dependent elastic-plastic model was developed to take into account this variation and the Young's Modulus is derived as follows:

$$E_m^T = E_m^0(a_{m_0} logT + b_{m_0})$$

where E_m^0 is the Young's modulus at the reference temperature and a_{m_0}, b_{m_0} are the curve fitting constants while T is the ambient temperature. Since the temperature dependence will change the hardening behaviour of the epoxy, the temperature dependent tensile and compressive strengths are provided by

$$\sigma_{m,t}^T = \left(\sigma_{m,t}^0 + H_t^0\left(1 - e^{-n^T \varepsilon^p}\right)\right)(a_{m_t} logT + b_{m_t})$$

$$\sigma_{m,c}^T = \left(\sigma_{m,c}^0 + H_c^0\left(1 - e^{-n^T \varepsilon^p}\right)\right)(a_{m_c} logT + b_{m_c})$$

Here $\sigma_{m,t}^T$ and $\sigma_{m,c}^T$ are the tensile and compressive yield stresses at the reference temperature T0, $H_t^0 and\ H_c^0$ are the hardening moduli in tension and compression at reference temperature.
However, the carbon fiber can be regarded as temperature-independent transversely isotropic material as its mechanical properties remain unchanged below 473K.
Using the RVE homogenization provided the effective properties of the composite laminate at 3 different temperatures , 293K, 193K and 93K have been adopted from the characterization experiments by Li et al [9], which are not shared in the article.

4. NEXTCOPV - Design of Tank

NEXTCOPV, the cutting-edge software for the design, simulation, and optimization of filament winding pressure vessels (COPVs), represents a significant leap forward in the field. Drawing on over a decade of experience in composite pressure vessels, the developers and mechanical engineers at Capgemini have successfully tackled the numerous challenges and complexities inherent in the design and simulation of COPVs. The outcome is a tool that revolutionizes the user experience, making the design process for COPVs simpler, faster, and more efficient. NEXTCOPV seamlessly integrates with Dassault Systems SIMULIA Abaqus Unified FEA, offering a robust and enduring solution. CAPGEMINI provide steadfast commitment for support, maintenance, and continuous development.

Several mathematical models have been implemented to achieve a realistic design, considering manufacturing parameters. The variation in thickness in the dome and the boss has been addressed, including a junction between the cylindrical part and the dome. To facilitate the ease of designing the COPVs with minimal knowledge in ABAQUS software, an user- interface (UI) is developed as an ABAQUS Plugin which directly takes input from the user. Due to this UI, it will help in fast optimization of the designs as presented in the process flow diagram below (Figure 2).

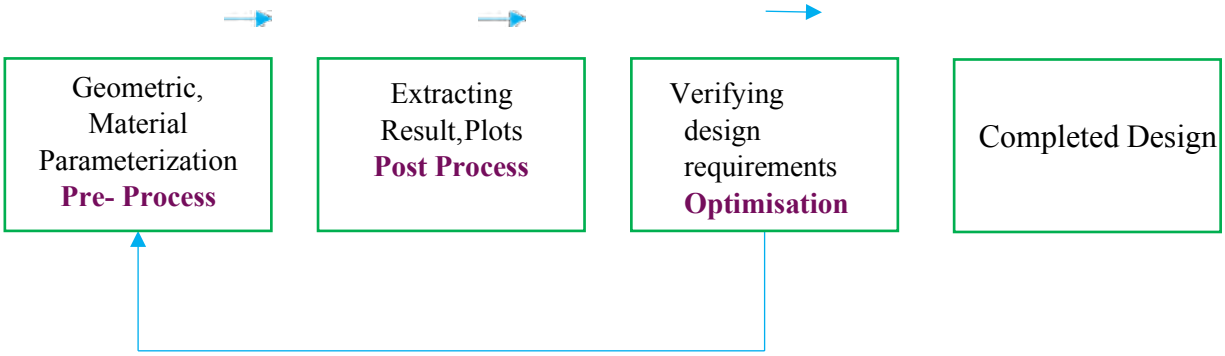

Figure 2. Process flow for the design using UI.

In the interface, there are 3 modules namely: Model setup, Geometry and Property. The 1st module is shown below (Figure 3). This allows user to select the type of theory amongst Constant Thickness and Variable Thickness. The user then can select the type of tank for the analysis. Type 3 is with a metal liner; Type 4 iswith a polymer liner while Type 5 has no liner. The user can also give the Part name and the internal pressure value which will be loaded as a ramp.

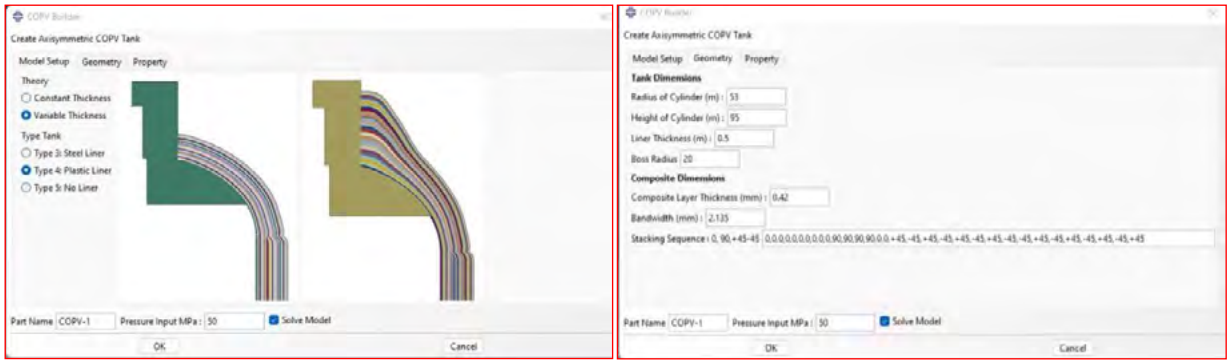

Figure 3. Model Setup and Geometry Modules.

Next, the geometry module allows the user to input all the geometrical parameters of the COPV (Figure 4). Lastly, the property module allows the user to input all the property parameters related to the composite/epoxy,liner and the plasticity related to the boss (see Figure 4). Once the user validates its options, the model is generatedalong with the mesh. An additional option is also given if the user wants to solve the model.

Figure 4. Property Module

5. FEM Modeling of Low Velocity Impact analysis

Curved composite laminates are brittle in nature and hence are prone to failure due to impact [10]. The impact caused on these structures can be due to low velocity Impact (LVI) or High Velocity Impact. The sensitivity towards the impact leads to over-dimensioning of the structure that further reduces the potential gain in ensure residual strength after the impact. In this study, LVI is of our interest. LVI occurs if the impact velocity is less than 10m/s and this can lead to Barely Visible Impact Damage (BVID) or directly failure of the structure. During the impact, the kinetic energy is converted into internal energy and an amount of this energy is stored as an elastic energy while the other part is dissipated by the damage. The damage in the structure can occur in terms of matrix crack, fiber fracture and delamination [11]. The first damage to appear is matrix cracking that occurs just below the impact zone. When these matrix crack grow during the fiber tension phase a disjointed strip between the plies is created that gives rise to interlaminar zone of tension stress between the two plies[11]. This further induces the phenomenon of delamination. In COPVs the resistance to LVI can depend on number of parameters like stacking sequence,thickness of each layer, properties of impactor, impact energy etc. For this analysis, progressive damage model is used to predict the damage onset and propagation of COPV before and after cryogenic load (see Figure 5).

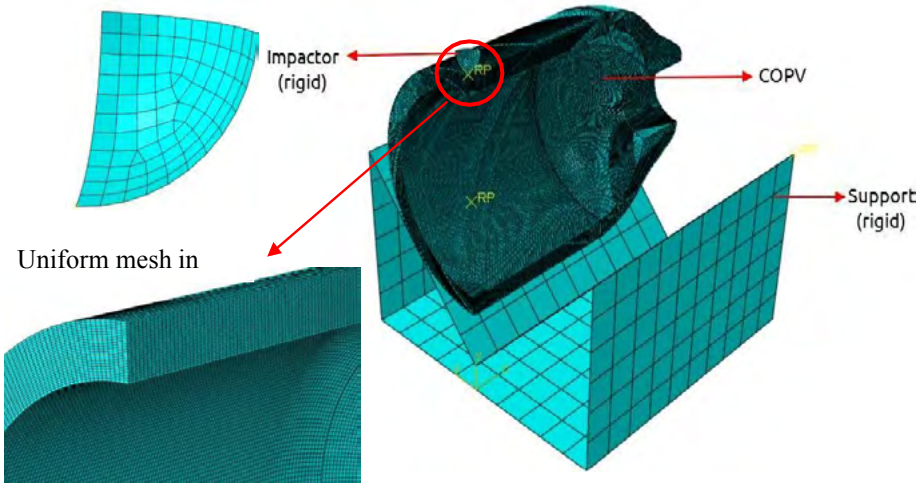

Figure 5. Low velocity impact model setup (1/4th model).

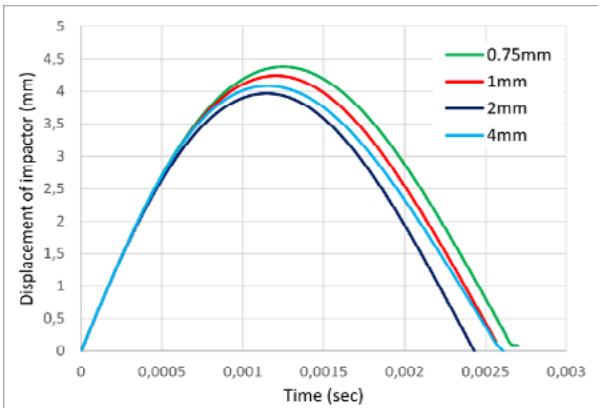
The impact is carried out at the middle of the cylindrical section and 1/4th model is used as shown in Fig.5 According to experimental setup [12] ASTM D7136/D7136M-05.

To save the computing time, a hemispherical impactor of diameter 16mm is selected which is impacted at various velocities (2m/s, 4m/s and 6m/s). These velocities account for the impact energies of 4J, 16J and 36 J respectively for the complete model.

Two models are developed with different stacking sequences. The 1st model has a stacking sequence of [0]10/ [+-45]2/ [0]2/ [+-45]3/ [45] while the 2nd model has a stacking sequence of [0]3/ [20]3/ [22]3/ [28]3/ 40/ [56]3/ [62]3/ [75]3/ [82] keeping all the remaining parameters same.



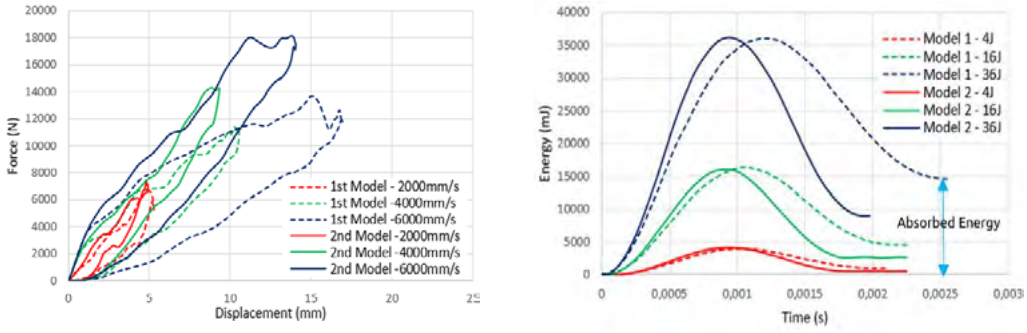


Figure 6. Mesh convergence

But before carrying out full analyses, mesh convergence studies are performed with element size 0.75mm, 1mm, 2mm and 4mm. The displacement of the impactor vs time is plotted in the Fig.6. Keeping in mind the complexity of the model and the computational time, mesh size of 1mm for the COPV is chosen for all the LVI analysis. but due to the complexity ofthe model, usage of continuum shells, and inability to reduce the mesh size less than 1mm, the percentage obtained is approximately 12%. Continuum shell elements SC8R are used in the tank accounting to a totalof 587,504 number of elements while rigid elements are used in the impactor and the support.

a) b)

Figure 7. Comparison of the results from two models: a) Force versus displacement b) Variations in energy.

As can be seen in Figure 7.a, the 2nd model resists more force due to the presence of the helical layers which also shows that instead of completely failing, the tank tries to resist the force over a period before rebound takes place. Figure 7.a provides the force vs displacement curves for both models at 3 different impact velocities. It can be observed that at low velocities or lower impact

energy there is no permanent displacement. But with increase in the energy a permanent displacement is observed. The ascending and descending part of the force displacement curve depict the loading and unloading. The ascending part relates to the stiffness and higher the peak force, stiffer the COPV is, and hence higher energy is needed to damage the COPV. Another information is about the energy absorbed which is area under the curve. Looking at the above figures it can be noticed that at lower energy of 4J, both models exhibit similar behaviour, but as the impact energy increases, the Model 2 shows a stiffer behaviour with higher peak force as compared to Model 1. However, the area of force-displacement for the 1st model at 36J is higher than that of 2nd model indicating that 1st model has absorbed higher energy which is validated by the energy-time graph. Clearly, Model 2 COPV which has helical layers is much stiffer than the model which has only 0° and 45° plies.

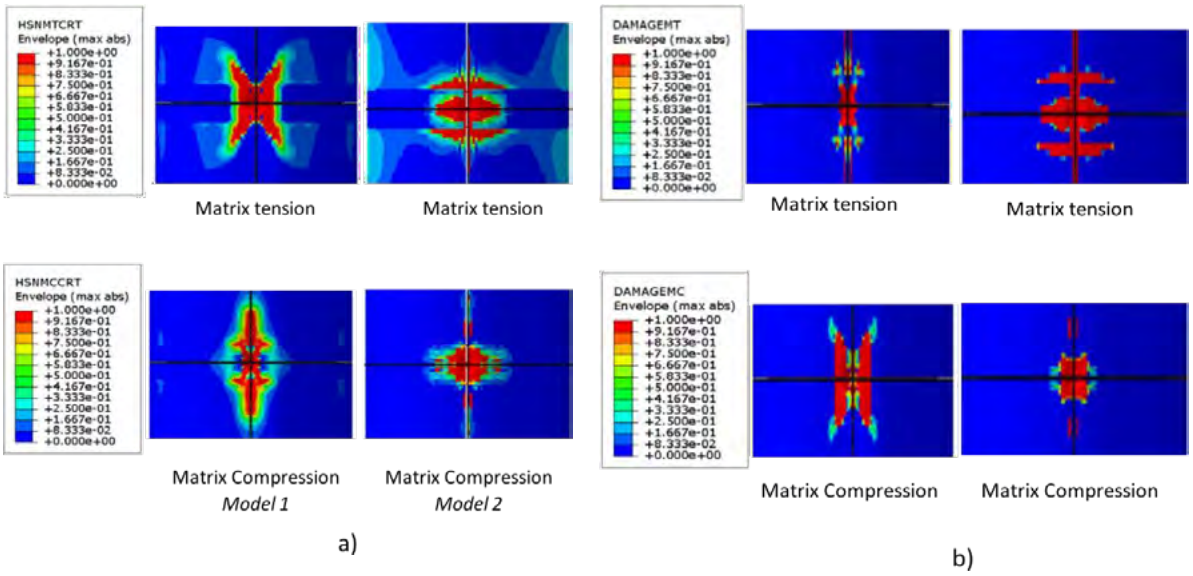

Figure 8. a) Hashin damage initiation; b) Damage evolution at 6m/s impact velocity at maximum displacement of the impactor

Fig.8(a) shows Hashin damage initiation for matrix under tension and compression and compares both the models subjected to impact velocity of 6m/s. This behaviour is captured as a complete model, and it is seen from the impacted side. As expected for the winding sequence that for the *Model 1*, damage initiates at 45° while for *2nd Model* it is more in the hoop direction. For the *2nd Model*, there is considerabledamage initiation on the non-impacted side under matrix tension when compared to the *1st Model*. This suggests that the 45° plies prevent the damage to initiate from the non-impacted side. The damage initiation due to matrix compression is small. Fig.8 (b) shows damage evolution of the matrix under tension and under compression for the *1st Model* at impact velocity of 6m/s. As the outer most layer in this model is at 45°, the damage of the matrix is along the direction of the fiber and hence the typical damage is observed under matrix compression [13]. In the stacking sequence of the *2nd Model*, since the outermost layer is oriented at 82°, we can observe the change in the damage for matrix under compression. It is, as expected, aligned more on the hoop or circumferential direction. Even thought the damage initiation under matrix compression is larger for both the models, the actual damage is relatively small. We also observe that there is damage in the axial direction as well in *Model 2*.

6. Cryo-impact analysis

After carrying out cryogenic and LVI studies, a multi-step analysis was carried out. From the Fig.9, it can be observed that after carrying out cryogenic analysis, the results from the last static step are

used as an input for the LVI. It can be observed that before the beginning of the LVI, at time step 0, there is already stress in the 1st stacking layer due to thermal loadings.

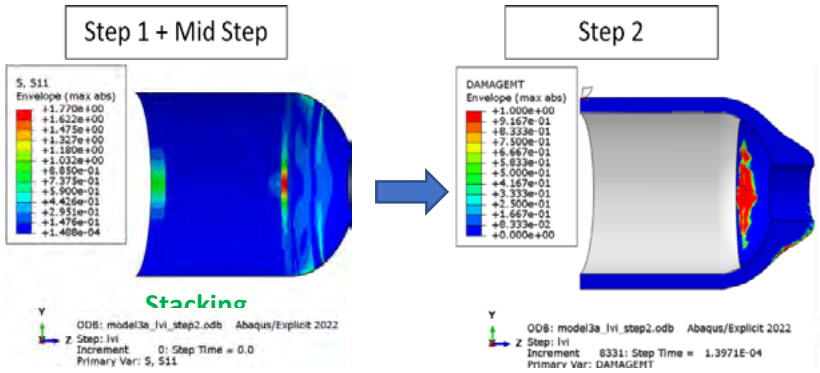

Figure 9. Behaviour under multi-step loading of cryo-impact damage.

After this, the LVI is performed which shows the damage in the impact region and as well as in the 1st layer of the dome. This is due to the lack of information on toughness and energy release rate of composite layers of the tank, which can affect the results. This is likely due to the stacking sequence, which can affect the composites under thermal conditions. The thermally induced effects are particularly severe on matrix damage, where the orientation of the carbon fibers varies in each layer. In these materials, low temperatures generate interlaminar residual thermal stresses that are significant enough to accelerate matrix cracking during LVI.

In future work, it is essential to thoroughly characterize the material to gain more detailed information on the behavior of carbon epoxy in a cryogenic environment. Additionally, several parameters related to fluid-structure interaction need to be implemented to predict the accuracy behaviour.

7. Conclusions

A study on the low-velocity impact of composite tanks, both with and without liquefied storage in a cryogenic environment, was conducted. It is well established that damage induced in COPV by low-velocity impact loads increases with impact energy. Results from this study showed that cooling the tank before impact has not similar effect on damage as increasing the impact energy, resulting in larger matrix cracking, while the energy absorbed by the composite is roughly proportional to the impact energy, the increased damage extent caused by low temperatures does not correspond to greater energy dissipation. This is due to the lower specific fracture energy of the epoxy matrix at cryogenic conditions. The embrittlement of the polymeric matrix, along with the interlaminar thermal stresses generated in the curved laminate at low temperatures, contributes to onset the damage.

8. Acknowledgments

The authors would like to express their sincere gratitude to the entire team of NEXTRUCTURES R&I Project for their valuable contributions and insightful discussions, the Research and Innovation department at the Technology Engineering Center (R&I TEC) and the Physical and Mechanical Engineering Unit for their sponsorship and support. The authors would also like to acknowledge Professor Frederic Lachaud from ISAE-SUPAERO, providing additional insights that enriched the discussion.

Keywords: Thermoplastic filament winding, composite rings, embedded sensors, Structural Health Monitoring, finite element modeling, split-disk test

Abstract
Filament winding enables the integration of sensors within the core of composite structures during manufacturing for Structural Health Monitoring (SHM). This study proposes a split-disk test using fiber-reinforced polymer composite rings as an alternative to traditional filament wound pressure vessel testing methods. The research aims to evaluate the mechanical effects of embedding fiber optic sensors in various orientations within the rings through experimental analysis. Additionally, it seeks to predict the damage initiation and progression in composite rings using a finite element model of 3D Puck failure criteria and Element Weakening Method (EWM). Validation of this computational method was conducted via 3D Digital Image Correlation (3D DIC) and experimental tensile tests. Results reveal the numerical approach's capability to predict the low hoop strain field near the split area as indicated by the 3D DIC due to the local bending. The experimental data show that embedding fiber optic sensors has a minor influence on the apparent modulus and a negligible effect on the apparent strength of thermoplastic composite rings. However, parallel fiber optic installation aligned with the reinforced fibers is recommended over perpendicular orientations, given the former's less pronounced effects.

1. Introduction

Filament wound composite pressure products (such as vessels and pipes) are employed largely for high-pressure gaseous or liquid storage applications in aerospace, automotive and naval industries [1], [2], [3]. Given that composite tanks are subjected to harsh threats such as critical loadings, temperatures and bursting, a permanent in-situ and online monitoring approach of the structural integrity of storage tanks is of interest. This requires the development of a diagnostic and inspection technique for monitoring the state of health of the composite tank from the damage onset. SHM approach employed for filament wound products is established by the use of a complex strategy based on sensors. Before the employment of SHM technique, a fundamental step is required to understand the mechanical behavior of instrumented composite rings and study the potential influences of embedded sensors on the material degradation of fiber reinforced composite products.

For certification, filament wound pressure vessels must fulfill several mechanical tests, including the hydrostatic burst test for evaluating their circumferential tensile properties. However, the implementation of the burst test is very complicated due to several constraints such as the need for special facilities, trained personnel, and associated costs. To overcome these limitations, an alternative cost-effective testing method involving testing lab-scale specimens of filament wound composite rings cut from composite tubes, is proposed instead of testing the whole pressure vessel. This last test is known

as split-disk test. The split-disk test focuses on measuring the mechanical properties of a filament wound composite, mainly hoop tensile modulus, strength and strain [4], [5], [6].

The most common sensors used for the composite pressure tanks monitoring are fiber optic (FO) sensors [7], [8], [9], [10]. The fundamental reason to integrate a fiber optic sensor is that the sensor itself is a fiber which can easily fit with other fibers of the composite shell. Thanks to its small dimensions, it can be smoothly embedded into composite materials without causing any risk to the structure.

In recent studies, efforts are directed towards damage predictions of filament wound composites using classical failure criterias such as maximum stress, Tsai-Hill [11] and Tsai-Wu [12]. These criterias have the inconvenience of not taking into consideration the identification of failure mode such as matrix crack, fiber failure nor interlaminar failure. Therefore, a more advanced criteria based on the physical prediction mode of the damage onset is needed. The Puck failure criteria [13], based on Hashin criteria [14], is founded to overcome the aforementioned limitations.

In this paper, Puck criteria is coupled with EWM to predict damage initiation and growth in composite rings. Moreover, the mechanical impact of fiber optic sensors embedded in the core of thermoplastic composite rings is studied experimentally to assess their influence on the integrity of the structure.

2. Materials and methods

2.1. Materials and manufacturing of composite tubes

Composite tubes are manufactured using a filament winding technique with impregnated tape of glass fibers and polypropylene resin supplied by AVIENT (see Figure 1), ref Polystrand™ IE 7034B.

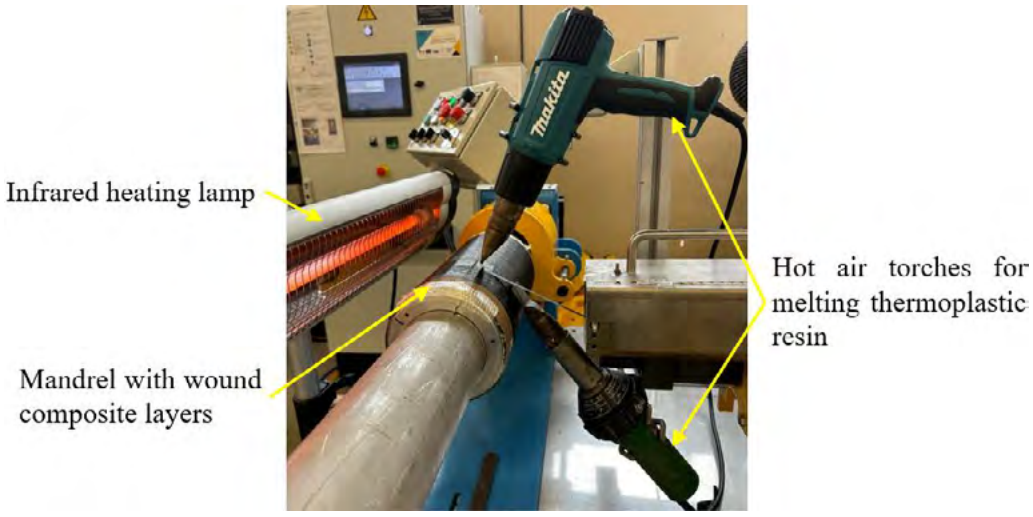

Figure 1. Filament winding process of thermoplastic composite tubes.

The main process-controlled parameters during the manufacturing are reported in Table 1 and include: filament winding angle, tape tension, number of layers, process temperature and the mandrel rotational speed. The tubes have a length of 275 mm and an internal diameter of 150 mm. Each layer has a theoretical thickness of 0.23 mm (initial tape thickness). For this study, only hoop winding is considered. The filament winding process requires to heat the incoming tape and the already deposited substrate up to the resin melting temperature. The tape is preheated to 100 °C, then hot air torches are used to heat locally the deposited tape on the mandrel until reaching the melting point at 200 °C. During winding, an infrared heating lamp is added behind the mandrel to maintain a high temperature of the composite layers, reduce the temperature difference and prepare the deposited layer to re-melt and to bond with the new layer. Once the tube is cooled down, it is put in the freezer for three hours to facilitate its unmolding. The process time for one tube manufacturing is in an average of 70 minutes.

Table 1. Manufacturing parameters of composite tubes.

Winding angle (°)	Winding tension (N)	Number of layers	Resin melting temperature (°C)	Rotation speed of mandrel (rpm)
88.8	40	6	200	5

2.2. Fiber optic sensors integration in composite tubes

Fiber optic cables are supplied by RS Components, France, with a core diameter of 125 μm. In total, seven fiber optic cables are embedded between the third and the fourth layer. Four tubes (T) are manufactured (see Figure 2 (a)). Two tubes (T1) and (T2) are instrumented with a total of six optical fiber sensors embedded circumferentially, thus in parallel to the reinforced glass fibers. Three rings from each tube are equipped with fiber optic sensors, while the remaining three rings within the same tube are sensor free. The goal of this division is to maintain the same manufacturing conditions with and without sensors. The third tube (T3) is instrumented with one fiber optic sensor embedded axially along the cylinder axis, thus perpendicular to the reinforced fibers. In tubes T1, T2 and T3, notches were introduced in ring specimens as recommended by the standards ISO 8521:2020 [15] to initiate damage in one localized zone that represents the Region of Interest (ROI) for the 3D DIC measurements. The tube (T4) is sensor free and three full ring specimens are extracted for testing and comparison with the numerical simulation. Four types of rings are tested: notched rings without sensors, notched rings with parallel FO sensors, notched rings with perpendicular FO sensors and full rings without sensors (see Figure 2 (b)). Three samples from each tube are used for fiber volume fraction (FVF) determination via burn-out tests. The location of FOs in the case of circumferential installation are positioned in the middle of the ring. In the case of axial installation, FOs are positioned in the middle of the notched area (in the most reduced section). The dimensions of notched rings are in accordance with the ISO 8521:2020 [15] standards, and are presented in Figure 2 (c) . Full rings are presented in Figure 2 (d). Tests are conducted on 15 or 35 mm wide cut-out rings from the manufactured cylinders.

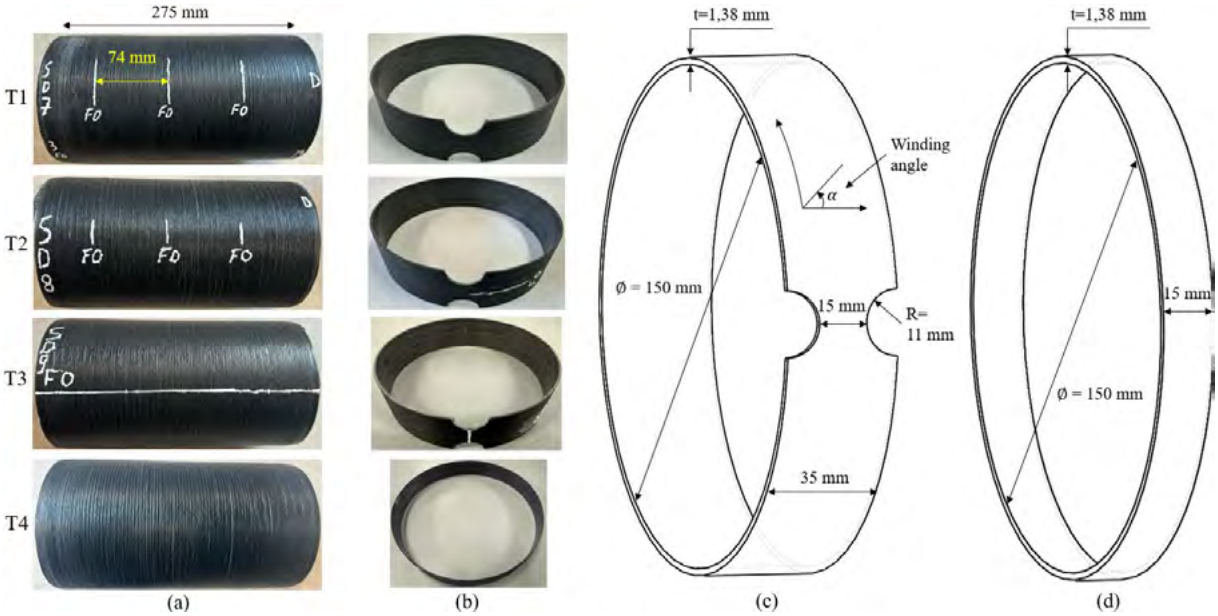

Figure 2. (a) Four manufactured thermoplastic composite tubes (white lines represent the location and direction of FO sensors); (b) four tested types of composite rings without and with FO sensors; (c) dimensions of notched composite rings; (d) dimensions of full composite rings.

2.3. Preparation of test composite rings

Rosette strain gauges are bonded using Loctite adhesive on the outer surface at an angular position of 10° with respect to the disks split line. The position of strain gauges for stiffness calculation is chosen as recommended by Zhao et al. [4] due to the absence of the influence of local bending. Apparent hoop modulus is measured by the real longitudinal strain gauges and virtual DIC longitudinal extensometer.

Three-dimensional DIC system equipped with two cameras is used to measure local hoop strain on the outer surface of the rings to accurately characterizing the complex three-dimensional deformations exhibited by non-planar structures. A black and white speckle pattern is applied to the tested ring specimens by covering only a 45° of the ring circumference around the notched zone for stereo images acquisitions. The covering area of speckles is defined as the ROI. A prepared notched and full ring specimens for testing are presented in Figure 3 (a) and (b), respectively, with added strain gauges and speckle pattern for DIC.

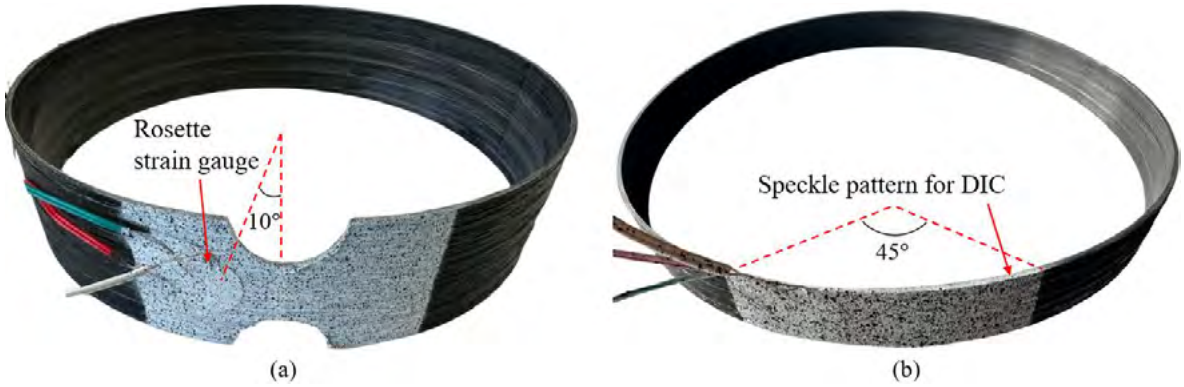

Figure 3. Ring specimens preparation before testing: (a) notched ring; (b) full ring.

2.4. Setup of split-disk test

The 3D DIC system with the split-disk setup mounted on the tensile test unit is presented on Figure 4 (a). The experiment is conducted on an Instron 1185 universal mechanical testing machine in accordance with ISO 8521:2020 standards [15]. The schematization of the 3D DIC system is shown in Figure 4 (b). Each specimen is loaded to the final failure by using a load cell of 100 kN. All tests are conducted under displacement control at a loading rate of 10 mm/min and at a room temperature of 23 °C. Due to the bending generated at the split line of separation of the two half-disks during testing, an apparent tensile strength and modulus are obtained.

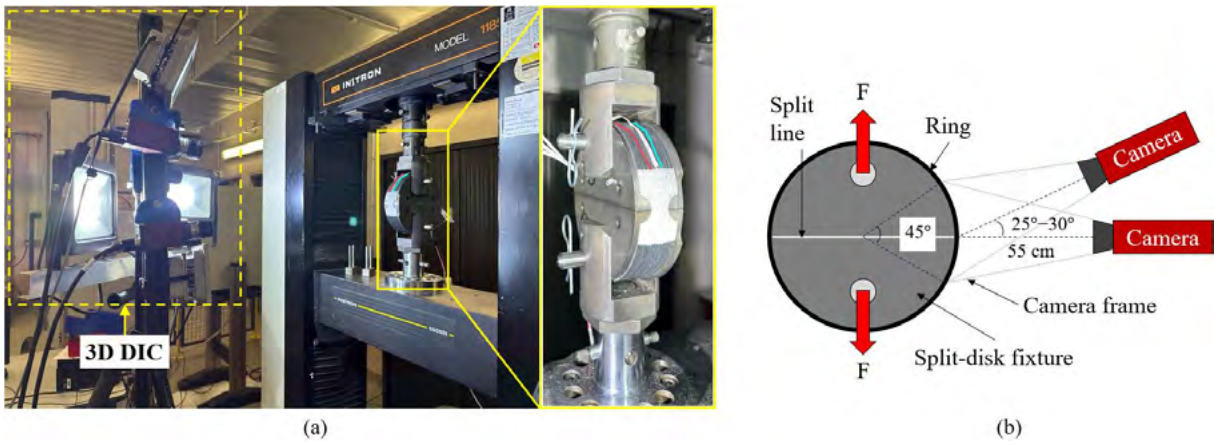

Figure 4. (a) Setup for split-disk testing in the tensile machine with 3D DIC system; (b) schematization of the 3D DIC system.

3. Results and discussion

3.1. Finite element analysis of full ring specimen

Finite element (FE) numerical simulation aims to: 1) analyze the hoop strain distribution along the circumference and compare it with full field strain obtained by 3D DIC, and investigate the bending effect; 2) evaluate the ultimate force predicted by the numerical model and compare it with the experimental results. Damage modeling is performed using a developed UMAT subroutine (User defined MATerial behavior) code on Fortran coupled with Abaqus FE commercial software. Damage modeling includes two parts: a damage initiation prediction using 3D Puck failure criteria and Progressive Failure Analysis (PFA) using Element Weakening Method (EWM).

3.1.1. Finite element model

A symmetrical FE model is developed to represent half of a ring, with a thickness of 1.38 mm, a width of 15 mm, and an internal diameter of 150 mm. The disk is treated as a discrete rigid part with a diameter of 150 mm. Contact properties are defined with tangential behavior and a low friction coefficient of 0.01, along with hard contact normal behavior between the disk and composite ring. Calibration of the assigned mechanical properties in the numerical model is achieved by comparing its force-displacement response with the experimental data from the tested full ring specimens. Considering the actual composition of the ring constituents, material heterogeneity through the thickness, and the presence of a resin layer on the outermost surface of rings as depicted by microscopic images due to manufacturing; the composite ring model is segmented into two equal parts through the thickness to take into account various areas dense in fibers and others in resin. The lower segment presents a FVF of 50 %, and the upper segment a FVF of 33 %, with material properties defined using the rule of mixture. The segments are composed of pure hoop layers with a 88.8° winding angle with respect to the ring main axis. The numerical model employs C3D8R elements for the composite ring, with a total of 56880 elements. The numerical model is able to render the complex mechanical behavior of the composite rings under an applied tension of an 8 mm displacement. The numerical predictions are compared to experimental results in terms of force-displacement response in Figure 5 (a). Tensile tests indicated an average failure load of 32096 N. In the numerical model, fiber failure, often considered the ultimate failure in fiber-reinforced polymers, is assumed to occur when fiber fracture extended across the specimen width in all plies, accompanied by a sudden drop of the displacement. Based on these assumptions, as shown in Table 2, the numerical model predicts failure at a maximum force of 30032.4 N, representing 6.4 % error compared to the average experimental results. Similarly, regarding displacement at failure, the simulations closely matched experimental values, with an average difference of less than 15 %. The numerical model predictions closely correspond to the observed mechanical response, providing validation of its accuracy and reliability in predicting the structural behavior of the composite rings.

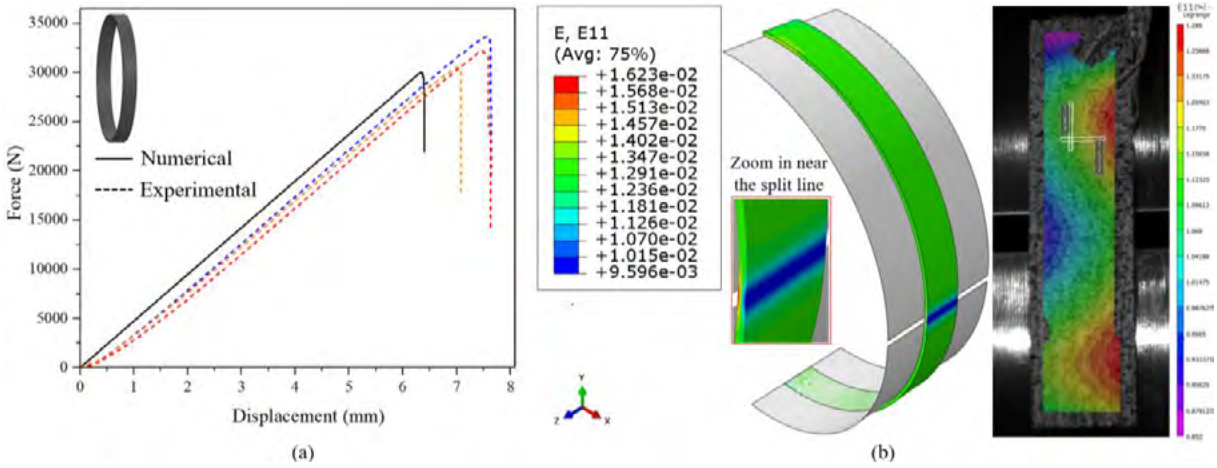

Figure 5. (a) Numerical and experimental force-displacement response of full ring specimen; (b) comparison between the first local strain E11 (in fiber direction) fields obtained numerically (left) and experimentally (right) for an applied load of 14.95 kN.

Table 2. Comparison between experimental and numerical simulation results.

Analysis method	Maximum load (N)	Maximum displacement (mm)
Experimental tests (mean values)	32096 ± 1563	7.44 ± 0.317
Finite element analysis	30032.4	6.403
Relative deviation (%)	6.4	13.9

Figure 5 (b) presents a comparison among the strain field predicted by the numerical simulation and 3D DIC measurements. This analysis involves evaluating the first local material coordinate strain E11 field at the outermost full ring specimen's surface. In general, there is a strong alignment between the predicted strain fields and the 3D DIC measurements. Particularly, at a load of 14.95 kN, the predicted and measured strain by 3D DIC at the location of strain gauge agree well with values of 1.32 % and 1.25 %, respectively. When focusing on the region surrounding the split line in the numerical simulation, the coupling of Puck criteria with the EWM demonstrates its ability to predict the high strain area at the inner surface and the low strain area at the outer surface, attributed to local bending. These findings are supported by the 3D DIC strain maps. Experimental results indicate localized bending near the split line, which can be characterized by the low strain area observed on the outermost surface at the same location.

Figure 6 illustrates a comparison between the typical failure observed numerically and experimentally. At maximum load, Figure 6 (a) depicts the final failure stage of the full ring close to the split line region, introduced by the fiber failure. During testing, the final failure occurs abruptly. Figure 6 (b) exhibits the final failure of the full ring, revealing a significant fiber breakage accompanied by delamination and matrix splitting. The predicted failure from FE simulation aligns well with experimental testing.

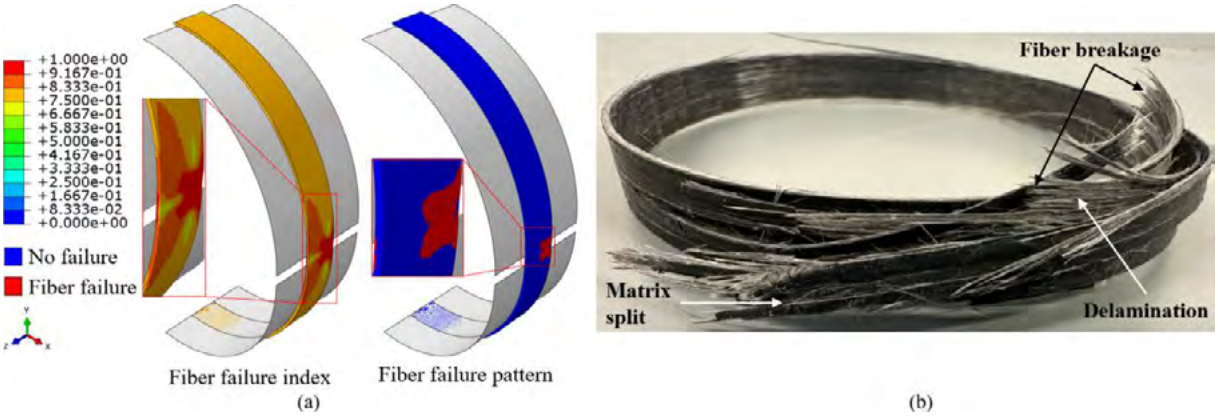

Figure 6. Comparison of damage: (a) fiber failure predicted by FE simulation; (b) failed ring.

3.2. Apparent hoop tensile properties for notched ring specimens

3.2.1. Apparent modulus

Longitudinal hoop strains measured by strain gauges and 3D DIC at an angular position of 10° serve for calculating the apparent hoop tensile modulus for the three different types of notched ring specimens. The theoretical modulus for each ring is determined using the rule of mixtures, considering the corresponding FVF for T1 (38.7 %), T2 (41.52 %), and T3 (42.61 %). The calculated apparent hoop modulus and theoretical modulus are shown in Figure 7 (a). Comparison of results shows that apparent hoop tensile modulus based on strain gauges and 3D DIC measurements are the highest for ring specimens without sensor. Apparent modulus decreases by 2.8% and 3% when a parallel FO is embedded among layers based on strain gauges and 3D DIC measurements, respectively. When FO sensor is embedded perpendicular to the orientation of reinforced fibers, the apparent hoop modulus is decreased by 7.52% and 7.67% based on strain gauges and 3D DIC, respectively. Based on these findings, 3D DIC exhibits strong agreement with strain gauges measurements, indicating its suitability for strain measurements in composite rings. Embedding FO sensors perpendicular to reinforced fibers degrades more the stiffness of the thermoplastic composite rings than the parallel FO embedment. In

other words, embedding FO sensors aligned with the reinforced fibers is the most effective way to minimize degradation of the composite's stiffness. Theoretical modulus cannot be compared since they are based only on the physical properties of the materials and do not depend on the existence of FO sensors within the composite rings.

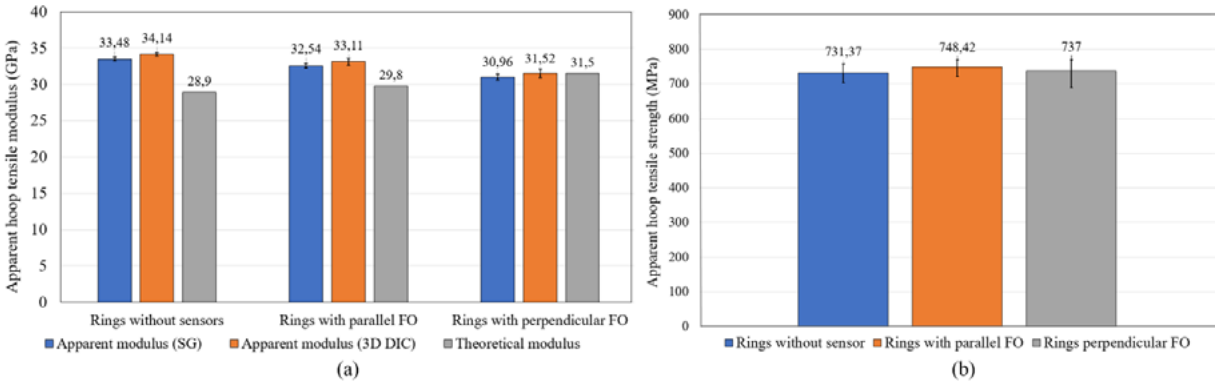

Figure 7. Comparison of the hoop tensile apparent properties for the three types of notched rings (a) calculated modulus based on hoop strains from strain gauges and 3D DIC, and the theoretical modulus; (b) calculated ultimate longitudinal strength.

3.2.2. Apparent strength

Apparent hoop tensile strength is calculated based on the average of the ratio between the half of the maximum load and the cross-sectional area of the notched zone at the split line. The theoretical tensile strength given by the material supplier is 765 MPa with a FVF of 45 %. Due to the existing bending moment in the notched zone during tension, the obtained apparent tensile strength is slightly underestimated for ring specimens without sensors with an average value of 731.37 MPa as can be seen in Figure 7 (b). The slight difference between the obtained tensile strength and that given by the supplier can also be influenced by other factors, including the discrepancy in FVF, as well as the presence of the notch, which initiate cracks earlier due to the emergence of matrix splitting in hoop direction near the notches at earlier load stages. The standard deviations of the three ring specimens types overlap with each other, indicating that the embedment of FO sensors does not influence the hoop tensile strength. Therefore, the embedment of FO sensors has no impact on the mechanical strength of the material.

4. Conclusions and perspectives

This paper presents a FE numerical simulation and an experimental analysis of filament wound thermoplastic composite rings. The numerical study investigates the implementation of 3D Puck failure criteria for damage initiation and EWM for damage progression prediction in full composite rings. The FE approach effectively predicts the low strain field at the outer surface near the split region when compared with 3D DIC, as well as the ultimate failure load with less than 7 % error with respect to tensile tests results. Experimental tests explore the mechanical impacts of embedding FO sensors within composite rings, examining two extreme cases: parallel and perpendicular orientations relative to the reinforced glass fibers. Results revealed that embedding FO sensor parallel to the reinforced fibers slightly reduces the apparent hoop tensile modulus by approximately 3 %, while the perpendicular orientation showed a reduction of about 7.5 %. However, the apparent hoop tensile strength remained unaffected by sensor embedding, as the standard deviation among each case overlapped. Overall, embedding FO sensors in the core of thermoplastic rings had a negligible impact on the filament wounded composite's mechanical performance, but parallel embedding is recommended for minimal disruption. The subsequent phase of this analysis involves conducting a finite element numerical study based on 3D Puck failure criteria and EWM to investigate the mechanical effects of FO sensors within composite rings using the embedded element method for modeling the presence of FO sensors.

Abstract
This study presents a modeling investigation into the initiation and propagation of transverse cracking in unidirectional fiber-reinforced composites, focusing on factors like fiber arrangement and matrix properties. Microscale computational models are created to address those challenges. Since existing fiber distribution generators are criticized for not representing features like resin-rich pockets, a deep learning approach is utilized to produce realistic microstructures for finite element modeling. A constitutive material model, incorporating epoxy plasticity and damage, successfully predicts the transverse crack formation and propagation under periodic boundary conditions. The study evaluates the impact of fiber arrangement on cracking behavior using microstructures generated by different methods, revealing similarities and differences in predicted outcomes. This research offers insights into enhancing the accuracy of computational models for simulating transverse cracking in composites.

1. Introduction

The initiation and propagation of transverse cracking in composites are governed by factors such as defects, arrangement of fibers, and properties of the matrix and fiber-matrix interface. Microscale computational models have been developed to simulate transverse cracking. The key challenges for such models lie in the 1) development of physics-based material models for the fiber, matrix, and interface and 2) generation of a representative volume element (RVE) that reflects the microstructure. In the existing models, fibers are often simplified to linear isotropic materials, while for the matrix, a few different plasticity and damage models have been proposed, such as those in [1, 2]. A vital challenge for these material models is the correct identification of the input parameters since those measured via macroscale testing do not always represent the behavior of the material at the microscale [3].

It is well established that the spacing between neighboring fibers determines the level of stress concentration between them. Therefore, predicting the transverse properties of composites depends heavily on the arrangement of fibers. Early models assumed regular distributions, i.e. square or hexagonal packings [7, 8], which led to poor estimation of transverse properties since in reality fibers are distributed in a random pattern [9, 10]. Usually, to achieve a random fiber distribution, a real microstructure is mimicked, like in [11], or random distribution generators are used. For the latter, a few methods have been proposed [12, 13], among which the one by Melro et al. [14] is commonly used.

Despite their high efficiency, these types of generators are criticized because they do not represent features like resin-rich pockets [15].

In the current study, micromechanical Finite Element (FE) models are developed to predict the transverse cracking and failure (transverse strength) of unidirectional fiber-reinforced composites, focusing on enhancing the two abovementioned issues. We have exploited deep learning to generate realistic images of transverse microstructures of unidirectional composites, yielding representative fiber distributions. Using these realistic GAN-generated microstructures, FE models for the simulation of transverse cracking are created. A constitutive material model, based on that developed by Morelle et al. [2], accounting for epoxy plasticity and damage, is implemented for the matrix. Applying periodic boundary conditions [6] to the RVEs, the implemented model can successfully predict the formation and propagation of transverse cracks. To evaluate the quality of our GAN-generated RVEs, experimental RVEs (from the real computed tomography images) as well as RMG-generated RVEs (based on the Melro's random generator [14]) are created for comparison. Analysis of different RVE generation methods demonstrates that the predicted transverse cracking behavior is similar in the deep-learning and real-image-based models, and slightly distinct from that in the random-generated one. A quantitative approach to compare the crack propagation path between these three microstructures is being developed.

2. Model development

2.1. RVE generation approaches

We employed three distinct methods to generate four periodic RVEs with a fiber volume fraction of approximately 51%: experimental, GAN-generated [16], and RMG-generated [15]. Each RVE measures 83.2 μm * 83.2 μm and contains over 100 fibers. As the validation outlined in [17-20], utilizing such large RVEs can effectively mitigate the influence of RVE size effects. The details of the generation algorithm are provided below.

- These microstructures are non-periodic for the experimental and GAN-generated microstructures; we use a Python script to convert them into periodic structures while preserving the original fiber distribution and minimizing variations in fiber volume fraction. According to our previous work [16], the calculated fiber diameter needs correction with an appropriate correction factor. However, this adjustment can lead to touching fibers, necessitating control measures to optimize finite element model generation. Moreover, in the process of creating periodic microstructures, it is necessary to iteratively adjust fiber positions to ensure the fibers on the model edges satisfy equation (1):

$$d_{i,j} \geq \left(1 + l_{ifd}\right) \cdot \left(r_i + r_j\right), \; for \; i \neq j \tag{1}$$

  where $d_{i,j}$ represent the distance between the i and j fibers, $r_{i,j}$ is their radius, and l_{ifd} corresponds to the ratio defining the minimal inter-fibre distance which is set to [0.05, 0.15] for the generation of high-quality elements. When we generate the periodic microstructures, the inter-fiber distance might not satisfy this requirement.

- For RMG-generated microstructures: these generated microstructures are periodic, but the fiber radius is constant. The inter-fiber distance is limited to the range of 0.1R and 0.3R, maintaining a constant fiber diameter (2R) of 6.5μm.

2.2. Constitutive material models

Fiber. Under the transverse tension, the fibers will not break and thus were considered linear elastic. Table 1 provides the properties of the fiber, matrix, and interface.

Table 1. The elastic material properties for carbon fiber, matrix, and interface.

Fiber properties [4]

Longitudinal Young's modulus (E_{11}^f)	238 GPa
Transverse Young's modulus ($E_{22}^f = E_{33}^f$)	28 GPa
Longitudinal Poisson's ratio (v_{12}^f/v_{31}^f)	0.28/0.02
Transverse Poisson's ratio (v_{23}^f)	0.33
Longitudinal shear modulus ($G_{12}^f = G_{31}^f$)	24 GPa
Transverse shear modulus (G_{23}^f)	7.2 GPa
Density (ρ^f)	1.8 g/cm^3
Matrix properties (RTM-6) [4, 21]	
Young's modulus (E^m)	3 GPa
Poisson's ratio (v^m)	0.34
Density (ρ^m)	1.14 g/cm^3
Drucker–Prager – Friction angle (β)	7.86 °
Drucker–Prager – Flow stress ratio (K)	1
Drucker–Prager – Dilatation angle (ψ)	0 °
Fiber-matrix interface properties [4]	
Elastic stiffness (K^i)	10^8 N/mm^3
Density (ρ^i)	1.14 g/cm^3
Mode I maximum traction [22]	50 MPa
Mode II & III maximum traction [22]	75 MPa

Matrix. A constitutive material model, based on that developed by Morelle et al. [2] and Chevalier et al. [4], accounting for epoxy's elasticity, plasticity and damage, is implemented for the RTM-6 matrix. This model accounts for yielding based on the linear Drucker-Prager criterion and isotropic strain hardening, which includes pre-peak hardening, softening, and rehardening. Moreover, failure is included based on critical equivalent plastic strain. Input parameters for the pre-failure phase are taken from compression tests, accounting for the compression-tension stress ratio. Macro-scale experimental results indicate that epoxy exhibits brittle fracture behavior at very low strains under uniaxial tension and can withstand larger strains in uniaxial compression and pure shear [4]. Consequently, a stress triaxiality-dependency is often assumed to predict its damage initiation. At the same time, epoxy demonstrates a strong size dependency [3, 5]. Sui et al. [5] showed that microscale epoxy fibers can reach 80% of strain before failure, suggesting that the stress triaxiality-dependency assumption may be invalid for microscale simulation. Therefore, in the definition of the epoxy material model, we assumed the same failure strain value for tension and compression. The elastic properties are given in Table 1. The governing equation for the linear Drucker-Prager model (available in Abaqus) is:

$$F = t + p\tan\beta - d = 0 \tag{1}$$

where t is the yield stress, p denotes the pressure, β corresponds to the friction angle, and d stands for the cohesion term. The friction angle β defines the slope of the yield surface in the t-p plane. The expression for t is:

$$t = \frac{\sigma_{eq}}{2}\left[1 + \frac{1}{K} - \left(1 - \frac{1}{K}\right)\left(\frac{I_3}{\sigma_{eq}}\right)^3\right] \tag{2}$$

where σ_{eq} is the von Mises equivalent stress, K is the stress ratio between yield stress under triaxial tension and triaxial compression, and I_3 is the third invariant of the deviatoric stress tensor. According to equation (2), with the fact $K = 1$ [4], we can obtain $t = \sigma_{eq}$.

The isotropic hardening law for the tension case is defined from the compression stress-strain curve. Consequently, the cohesion term d in equation (2) can be expressed as:

$$d = (1 - \frac{1}{3}tan\beta)\sigma_c \tag{43}$$

σ_c represents the compression yield stress and the data for σ_c is collected from the literature [4] at a strain rate of 10^{-4} s^{-1}. The associated flow rule is given by:

$$G = \sigma_{eq} + ptan\phi \tag{54}$$

Here, G represents the flow potential, and ϕ corresponds to the dilation angle. The value of ϕ is set as zero as plastic incompressibility was assumed. Along with the increase in plastic strain, it is essential to account for the damage initiation. To consider the matrix scale sensitivity, we assume that the failure strain for epoxy under tension is the same as in compression, specifically 0.572 [2, 4].

After failure initiation, the damage evolution follows a progressive procedure controlled by the damage variable (D). This variable increases as damage accumulates, according to the following expression:

$$\dot{D} = \frac{\dot{\bar{u}}^{pl}}{\bar{u}_f^{pl}} = \frac{L\dot{\bar{\varepsilon}}^{pl}}{\bar{u}_f^{pl}} \tag{6}$$

where L is the characteristic length, $\bar{\varepsilon}^{pl}$ and $\bar{u}^{pl}$, respectively, are the equivalent plastic strain and plastic displacement. Before the onset of the damage, $\dot{\bar{u}}^{pl}$=0, which means D is equal to 0. After the damage initiation, the damage variable $\dot{\bar{u}}^{pl}$ is equal to $L\dot{\bar{\varepsilon}}^{pl}$. When $\dot{\bar{u}}^{pl}$ reaches $\bar{u}_f^{pl}$, it indicates that the elements have reached the equivalent plastic displacement at failure and will be deleted. To determine the plastic displacement at failure, $\bar{u}_f^{pl}$, we can relate it to the yield stress and the fracture energy per unit area G_f:

$$G_f = \int_0^{\bar{u}_f^{pl}} \sigma_y \, d\bar{u}^{pl} \tag{75}$$

The value we set for G_f is 100 J/m^2.

Interface: To account for debonding at the interface between fibers and the matrix, zero-thickness cohesive elements (COH2D4) are inserted. These elements follow a bi-linear traction-separation law to describe their mechanical behavior. The initial response is linear, with a large stiffness value (K) equal to 10^8 MPa/mm. This choice ensures displacement continuity at the interface.
In our study, the quadratic nominal stress damage initiation criterion is used to determine the damage initiation as:

$$\left\{\frac{\langle t_n \rangle}{t_n^0}\right\}^2 + \left\{\frac{t_s}{t_s^0}\right\}^2 + \left\{\frac{t_t}{t_t^0}\right\}^2 = 1 \tag{86}$$

where $\langle t_n \rangle$ indicates the Macaulay brackets for the normal stress (they return zero if the term inside the brackets is negative). t_n^0, t_s^0, t_t^0 are the normal and shear strengths of the interface.
Once the damage initiation criteria are met, the cohesive element's elastic stiffness is degraded with a scalar damage variable D with the below equation [23].

$$D = \frac{\delta_m^f(\delta_m^{max} - \delta_m^0)}{\delta_m^{max}(\delta_m^f - \delta_m^0)} \tag{97}$$

δ_m represents the mixed mode effective separation: $\delta_m = \sqrt{(\delta_n)^2 + (\delta_s)^2 + (\delta_t)^2}$ and δ_m^{max} is the maximum effective displacement attained during the loading history. δ_m^0 and δ_m^f correspond to the effective displacement at the initiation of damage and complete failure, respectively.
δ_m^f can be defined by effective traction at the damage initiation T_{eff}^0 and critical energy G^c:

$$\delta_m^f = 2G^c/T_{eff}^0 \tag{108}$$

Here, the Benzeggagh-Kenane fracture criterion [24] is used, which assumes the critical fraction energies along the mode II (G_s^c) and mode III (G_t^c) are the same.

$$G^c = G_n^c + (G_s^c - G_n^c)(\frac{G_S}{G_T})^\eta \tag{11}$$

where G_S represents the sum of the two shear energies in two directions and G_T represents the sum of all fracture energies. For mode I fracture toughness (G_n^c), we set it as 10 J/m^2, while for Mode II & III fracture toughness (G_s^c), it is set as 50 J/m^2. η is a material parameter and is taken as 1.45 [24, 25].

2.3. Periodic boundary conditions

Periodic boundary conditions are employed with linear equations constrained in Abaqus. 4-node plane strain, reduced integration elements (CPE4R), and a few 3-node triangle elements (CPE3) are used to mesh the fiber and matrix. Using more than 2 elements in an area with possible stress concentration between the fibers is reasonable to capture the localized effects. The simulation was performed in Abaqus/Explicit to overcome the convergence issues as the damage considered in the matrix and interface.

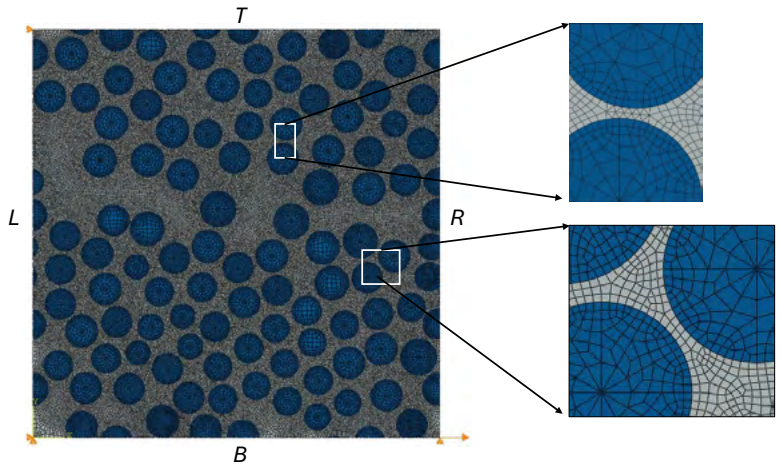

Figure 1. Periodic boundary condition for the RVE and their finite element discretization.

3. Results and discussions

Transverse tension loading simulations were conducted on three distinct types of microstructures: experimental, GAN-generated, and RMG-generated. Each type of microstructure was analyzed using four different RVEs. These RVEs demonstrated minor differences in their fiber volume fraction: 51.1%±1.0% for experimental, 50.5%±0.2% for GAN-generated, and 51.3%±0.3% for RMG-generated microstructures.

Figure. 2 illustrates the strain-stress curves for the different types of microstructures. We define failure of the RVEs as the point when the curve exhibits a notable drop, with the corresponding strain value referred to as the failure strain. From Figure 2a, it is evident that the strength and failure strain exhibit some variability across different RVEs. The mean strength is 60.2 MPa, with a standard deviation of 0.7

MPa. The mean failure strain is around 1.82%, with a standard deviation of 0.09%. For the GAN-generated RVEs (in Figure 2b), the mean strength and mean failure strain are 59.50 MPa and 1.73%, respectively. Their standard deviations are 0.13 MPa and 0.07%. For the RMG-generated RVEs, the mean strength is 59.5 MPa with a standard deviation of 0.4 MPa, and the mean failure strain is 1.75% with a standard deviation of 0.03%. We can observe that their mean strength values and failure strain are similar for all of these cases, as also concluded in [7]. However, their standard deviation values show differences, which can be attributed to the variation in their fiber volume fraction. Specifically, the trend of the standard deviation of strength follows the variation of fiber volume fraction. Interestingly, while the RMG-generated RVEs exhibit a relatively large variation in strength, their failure strain displays a relatively small variation and does not follow the fiber volume fraction variation trend. This suggests that the presence of resin-rich pockets might contribute to delaying failure, as similarly observed in [26].

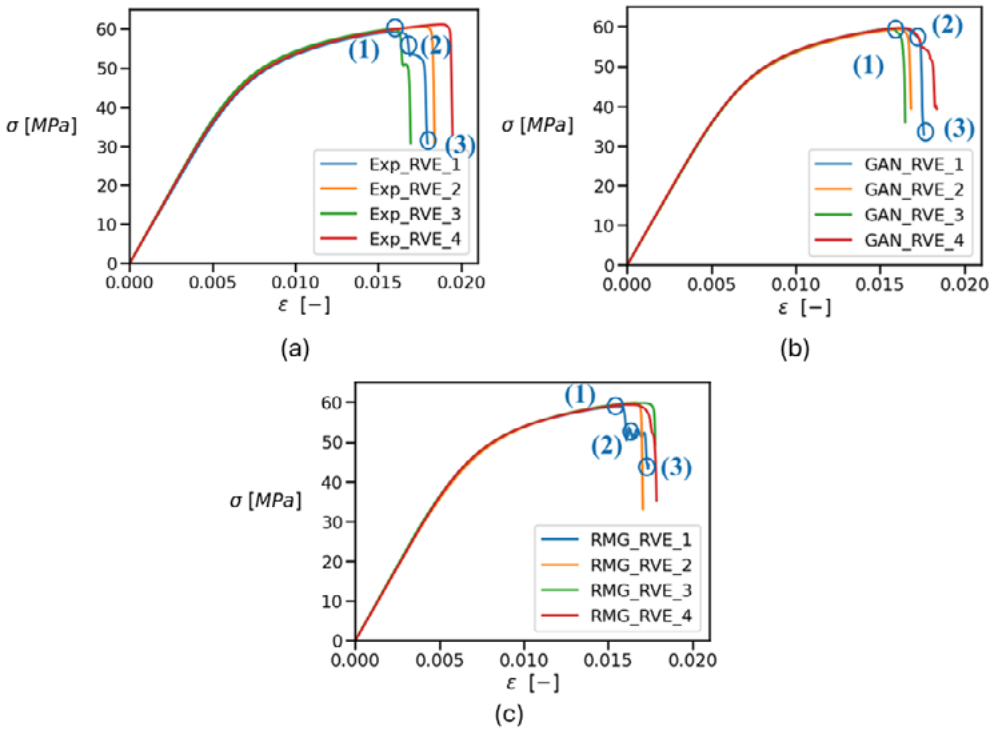

Figure 1. Comparison of stress-strain curves under transverse tension for (a) experimental microstructures, (b) GAN-generated microstructures, and (c) RMG-generated microstructures.

In Figure 3, we depict the damage evolution for the three different types of RVEs. Each case corresponds to the first RVE and is labeled Exp_RVE_1, GAN_RVE_1, and RMG_RVE_1. The results at points (1), (2), and (3) within each case correspond to the strength, matrix damage initiation, and RVE failure (), respectively (as highlighted in Figure 2). Across all three types of microstructures, stress values start to decrease during debonding initiation. These debonding areas primarily occur within the region of fiber clusters (as seen in the evolution process labeled (1) in Figure 3a-c). In the subsequent evolution process labeled (2) in Figure 3a-c, multiple debonding events occur near closely spaced fibers. During this phase, stress values rapidly decline, and the matrix undergoes deformation, reaching the matrix initial failure strain. As the loading continues, more matrix elements start to incur damage due to the accumulated effects of debonding and localized stress concentrations, eventually resulting in macroscopic transverse cracks.

Notably, the crack path does not traverse areas with large resin-rich pockets and initially occurs at the closely spaced fibers, consistent with observations in [27]. While some studies [28, 29] argue that resin-rich pockets significantly initiate damage evolution, an important consideration is that these pockets can exist only when the inter-fiber distance is decreased elsewhere, provided that the fiber volume fraction remains constant.

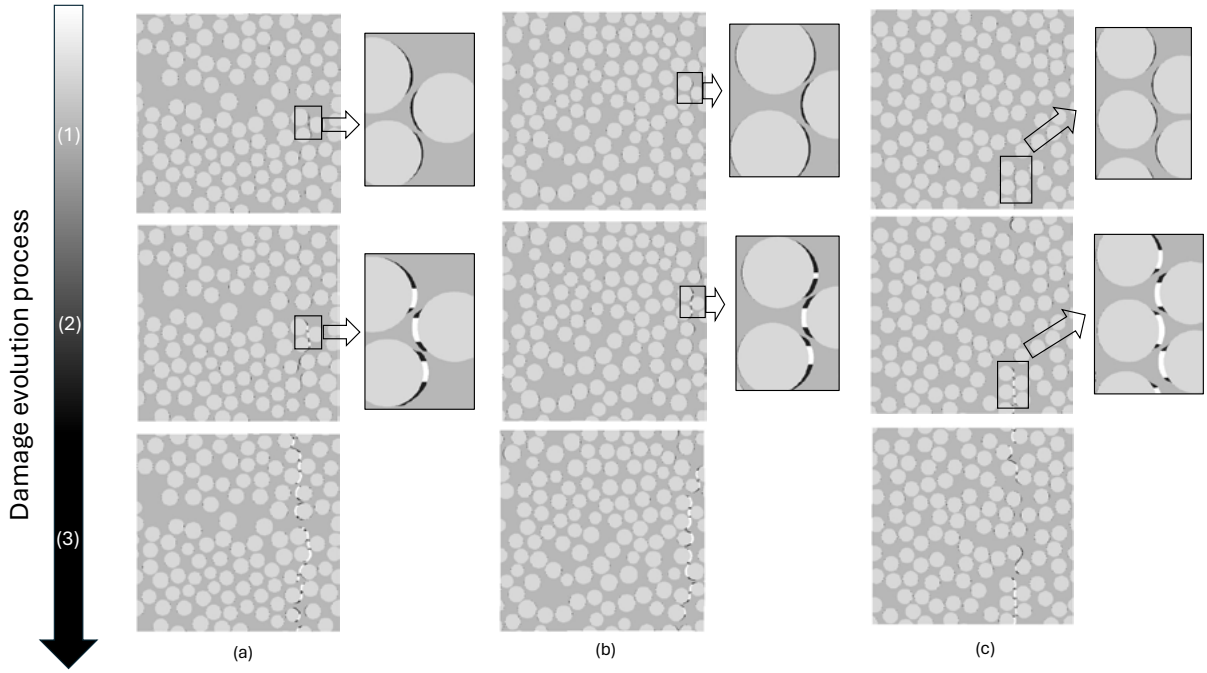

Figure 2. Comparison of damage evolution process under transverse tension for (a) experimental data, (b) GAN-generated microstructures, and (c) RMG-generated microstructures. (1), (2), and (3) correspond to the points indicated in the stress-strain curve in Figure 2.

4. Conclusions

The study compared the damage evolution process in three different unidirectional fiber-reinforced composite microstructures: realistic experimental data, deep learning-generated data, and RMG-generated microstructures. In our models, we first convert the non-periodic CT data into periodic data for real experimental and deep learning-generated cases. And then, for all three cases, four models are prepared, each containing more than 100 fibers to eliminate RVE size effects. Matrix scale effects are also considered, where the matrix exhibits strong nonlinear deformation at the micro-scale. We have found that the interface debonding predominantly occurs around the fiber cluster region. Stress values decrease when multiple debonding events happen at adjacent fibers. As loading continues, matrix damage initiates and more debonding happens, leading to the formation of unstable damage and eventual failure strain. Interestingly, debonding does not initially occur in the resin-rich pockets under transverse tension, so their existence might be able to inhibit damage propagation.

Abstract

Here we investigate the adhesive properties of Selective Laser Melted (SLM) titanium surfaces in metal-composite co-bonded joints without any prior surface treatment, to explore the inherent surface roughness of SLM parts to potentially create strong adhesive bonds.

Double Cantilever Beam (DCB) tests were carried out to assess the joints mode I fracture toughness involving untreated SLM titanium and woven Carbon Fibre Reinforced Polymer (CFRP) adherends, co-bonded with an epoxy film adhesive. The same type of DCB joints, but now with sandblasted SLM titanium adherends, were tested to compare the adhesion strength of the untreated SLM surface versus the sandblasted surface.

The findings reveal that joints with untreated SLM titanium adherends exhibit similar toughness to those with sandblasted SLM titanium adherends, indicating that the surface morphology of as-printed SLM titanium is suitable for manufacturing robust adhesive joints. The elimination of the surface treatment in the manufacturing of adhesive joints with SLM adherends could increase the interest of many industrial fields towards the use of adhesive bonding over other joining techniques.

Keywords

Fracture toughness, Ti6Al4V, Carbon Fibre Reinforced Polymer (CFRP), Selective Laser Melting (SLM), Co-bonding

1 Introduction

The rising adoption of Fibre Reinforced Polymers (FRPs) in manufacturing lightweight structures is evidence of their high strength and stiffness-to-weight ratios and consequent advantages over conventional materials. Indeed, FRP laminates are often joined with metals in large components to reduce costs and increase thermal resistance and crashworthiness [1], [2]. Adhesive bonding offers numerous advantages for joining FRPs, particularly in lightweight structures, by eliminating the need for drilling it minimizes the risk of introducing defects like delamination, which can compromise structural integrity, and becomes especially relevant for joining dissimilar materials. Additionally, it helps save weight, especially in scenarios where long bondlines would necessitate numerous rivets or bolts [3], [4].

One significant challenge of adhesive bonding compared to other joining methods is the necessity of surface treatments to ensure optimal adhesion, which are usually expensive, time-consuming and present difficult repeatability.

In this context, Selective Laser Melting (SLM) represents a strategic technology due to its inherently rough surface morphology [5], [6], [7], [8], which is often associated with good adhesion strength [3]. Nevertheless, the literature on adhesive bonding of as-printed SLM with FRP laminates is still quite limited and with a higher focus on metal-metal joints. Few works can be highlighted from literature:

- the work of Nguyen et al. [9], in which untreated SLM Ti6Al4V was either co-cured with CFRP or bonded using a film epoxy adhesive with another untreated SLM titanium adherend to form Double Cantilever Beam (DCB) joints. For the titanium-titanium joints, the fracture toughness was similar to the one indicated in the adhesive's datasheet. Also, they compared the results with the fracture toughness of grit-blasted titanium-titanium joints

©2024 | 3_MICHELE_Gulino_ABKO3.pdf

from the work of Brack and Rider [10], showing minor differences. For metal-composite joints, the innate surface morphology of the SLM process, together with sub-millimetric outward and inward features printed on the titanium adherend, promoted crack deflection in the composite adherend.

- another investigation on the topic was carried out by Fielden-Stewart [11], revealing that in SLM aluminum-CFRP secondary bonded joints printed with several build angles, the mixed-mode fracture toughness was higher for untreated joints compared to mechanically abraded joints, regardless of the build angle.

However, to the knowledge of the authors, a direct comparison of the mode I fracture toughness of co-bonded metal-composite joints with and without surface treatments has never been investigated.

Considering that the elimination of surface treatment in the manufacturing of adhesive joints could significantly increase the interest of many industrial fields in employing adhesive bonding over other techniques, such as mechanical fastening or welding, the use of as-printed SLM substrates can be a promising solution to promote their wider use.

Therefore, this research is part of a larger project aiming to 1) expand the literature in the field of SLM metal-composite joints and 2) develop a toughening technique for metal-composite joints, employing SLM to produce metal adherends with structured interfaces, enabling the composite to be co-bonded without the need for surface treatments.

For that, DCB joints with as-printed SLM Ti6Al4V adherends were compared to control joints where the titanium substrate is sandblasted after printing, given the fact that sandblasting is a well-known and often employed surface treatment for adhesive bonding [12].

2 Materials and method

The SLM Ti6Al4V substrates, measuring 130x25x6 mm³, were provided by 3T-Additive Manufacturing Ltd (Newbury, United Kingdom). They were manufactured using an M290 printer (EOS Gmbh, Krailling, Germany), with a 90° build angle and a layer thickness of 60 µm (**Figure 1**).

The CFRP adherend was made from woven GG630T (T700 carbon fibres) - DT120 prepregs supplied by Bercella Srl (Varano de' Melegari, Italy), with a stacking sequence of $[0\text{-}90]_{13}$. The number of plies (i.e., the thickness of the laminate) to obtain pure mode I, the bending and out-of-plane shear moduli of the composite, and Young's modulus of the Ti6Al4V adherends were determined with the same procedure used in the previous work by the authors [12], [13], [14].

To guarantee pure mode I on the crack tip of the dissimilar DCB joints, the resulting target thickness of the laminate is 8.23 mm, which rounds down to 8.11 mm with 13 plies, considering the estimated cured ply thickness of 0.624 mm MPa (**Table 1**).

Table 1 *- Mechanical properties of the CFRP: t_{ply} is the ply thickness expected after curing, E_{cfrp} and G_{cfrp} are the laminate's flexural and out of plane shear moduli considering a stacking sequence of $[0\text{-}90]_{13}$ and E_{ti} is the Young's modulus of the titanium.*

t_{ply} (1)	E_{ti} (2)	E_{cfrp} (2)	G_{cfrp} (2)
mm	MPa	MPa	MPa
0.624	118030	60079	2555

(1) CFRP datasheet values
(2) Experimental values [12]

Optical profilometries using Keyence VR-5000 wide-area 3D non-contact measurement system and contact angle measurements using KSV Instruments CAM 200 optical angle meter were performed on 2 spare titanium adherends, with 3 repetitions each.

2.1. Manufacturing of the DCB specimens

Half of the adherends were sandblasted with alumina particles at 0.5 MPa, with the nozzle at approximately 10 centimetres from the samples' surfaces. All the titanium adherends (sandblasted included) were cleaned with an ultrasonic acetone bath for 10 minutes before bonding to remove dirt and contaminants from the surface.

After that, a Teflon strip was inserted at the joints' tip, positioned 15 mm away from the load application point to simulate an artificial crack.

The joints were co-bonded using HexBond ST 1035 (Hexcel, Stamford, USA) epoxy adhesive film with a polyester carrier mat supplied by Bercella Srl. This bonding process occurred in an autoclave and vacuum bag setup, undergoing a curing cycle at 130°C for 2 hours under 6 bar of pressure.

©2024 | 3_MICHELE_Gulino_ABKO3.pdf:2

Following curing, the bonded joints were machined to the required dimensions, and a loading block was bonded to the CFRP adherend with EA Loctite 3425 (Henkel AG&CO. KGaA, Düsseldorf, Germany) bi-component paste epoxy (**Figure 1**). The thickness of the adhesive was not controlled with a spacer and it is assumed to be equal to the thickness of the adhesive carrier mat of 0.1 mm, measured with a micrometre after dissolving the epoxy matrix of the film adhesive in acetone.

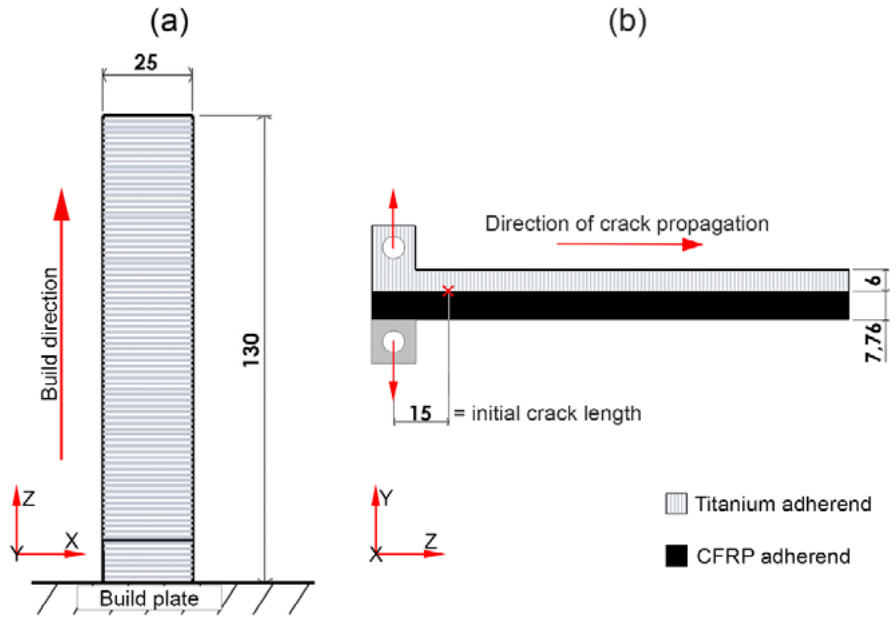

Figure 1 *– a) Titanium adherends, top view. b) Side view of the co-bonded joints. The titanium adherends were printed with an integrated loading block, which was then drilled to allow the positioning in the testing machine, whereas a separate loading block was glued onto the CFRP adherend. Grey lines representing the layers. Dimensions in millimetres.*

2.2 Testing setup

A speckle pattern was spray painted on one side of the DCB samples to evaluate the Crack Mouth Opening Displacement (CMOD), using a virtual extensometer via 3D Digital Image Correlation (3D DIC) with Vic3D software from Correlated Solutions Inc. The DIC cameras (5 megapixels sensor and lens with 23 mm of focal length) were positioned at 57.4 centimetres from the speckled surface and the pictures were taken with a 2 Hz frequency. The region of interest was defined around the load application line, and it was discretized using a 33 pixels subset size and 11 pixels step size.

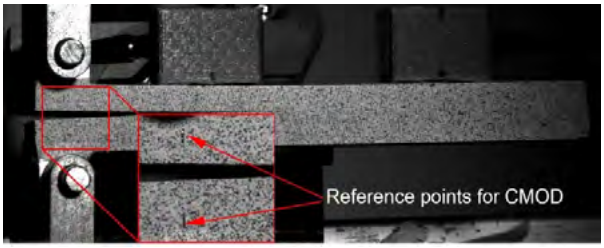

Figure 2 *– DIC evaluation of the CMOD, with region of interest highlighted in red. The relative displacement was evaluated in the 2 reference points aligned with the load line, as indicated in the figure.*

The joints underwent testing under displacement control at a rate of 2.5 mm/min using a Zwick-Roell electric testing machine, equipped with a 10kN load cell. The displacement rate was taken from the ASTM D3433 standard [15] for metal-DCB joints, since there is no standard available for metal-composite DCB testing. The DIC picture acquisition was

©2024 | 3_MICHELE_Gulino_ABKO3.pdf:3

synchronized with the load and displacement data from the testing machine. Testing concluded upon reaching a crosshead displacement of 6 mm.

2.3. Data reduction method

For the data reduction of the DCB tests, the Compliance Beam Based Method (CBBM) [16], [17] was employed, enabling the measurement of crack length a based on the DCB's compliance during testing.

In this study, the joint compliance was assessed through the linear regression analysis of the CMOD-load curve, evaluated during 14 unloading phases.

Knowing the crack length, the mode I fracture toughness G_{Ic} can be calculated as

$$G_{Ic} = \frac{F^2}{2B}\left[a^2\left(\frac{1}{E_{ti}I_{ti}} + \frac{1}{E_{cfrp}I_{cfrp}}\right) + \frac{6a}{5BG_{cfrp}}\left(\frac{1}{h_{ti}} + \frac{1}{h_{cfrp}}\right)\right] \qquad \text{Eq. (1)}$$

F is the test load, E are the elastic moduli of the adherends, I are the second moment of area of the cross-section of the adherends, and B is their width. The subscripts ti and $cfrp$ indicate the properties of the titanium and CFRP adherends, respectively.

3 Results and discussion

3.1 Titanium surface profilometries and water contact angle measurements

The surface profilometries of both as-printed and sandblasted samples are shown in **Figure 2**. The surface parameters and the contact angles of both types of samples are shown in **Table 2**.

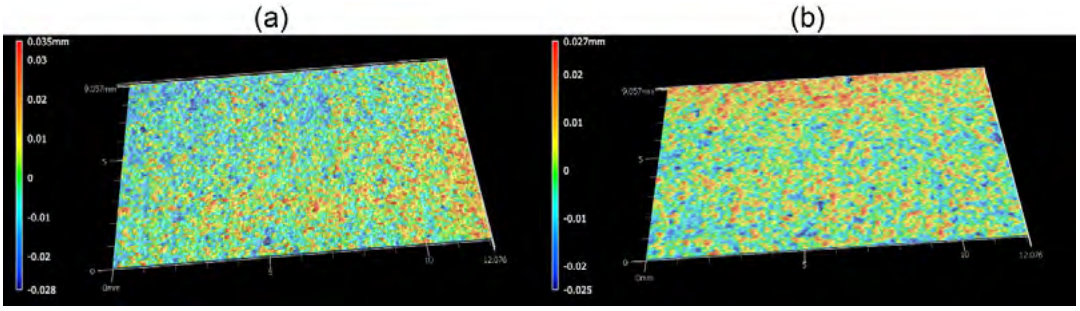

Figure 3 *– Surface profilometries of a) as-printed samples and b) sandblasted samples.*

Table 2 *– As-printed and sandblasted samples' surface parameters and distilled water contact angles.*

	Sa [µm]	Ssk [-]	Sku [-]	θ [°]
as-printed	9.26 ± 0.18	0.23 ± 0.08	3.63 ± 0.18	89.44 ± 3.86
sandblasted	7.13 ± 0.32	-0.1 ± 0.13	3.71 ± 0.43	77 ± 2.95

The optical profilometries shown in **Figure 2** reveal a noticeable contrast between the surfaces before and after sandblasting, with the latter exhibiting a smoother texture, indicated by the lower arithmetical mean height S_a. However, the sandblasting process does not alter the shape of the surface asperities significantly; these remain relatively sharp, as evidenced by S_{ku} values exceeding 3. The S_{sk} values, which indicate the skewness of the surface profile, generally hover around 0, meaning that the waviness is distributed symmetrically around the mid-plane for both surface types.

Regarding the water contact angle, **Table 2** shows a substantial improvement in surface wettability following sandblasting treatment. This enhancement could be attributed to the roughness of the SLM-printed substrates, where acetone cleaning alone may not effectively remove all contaminants from the deep valleys of the as-printed surface. Conversely, the lower contact angle observed on sandblasted surfaces suggests that an acetone bath adequately cleans this type of sample.

3.3 Fracture toughness of the titanium-CFRP joints

©2024 | 3_MICHELE_Gulino_ABKO3.pdf:4

The R-curves and the load-CMOD curves of the DCB samples are shown in **Figure 4**. When referring to the fracture toughness, the subscript T in place of I in G_{Tc} is used hereafter because a small percentage of mode II loading is expected since the actual thickness of the composite after curing was 7.76 mm (**Figure 1**) i.e., 5.7% lower than the target thickness of 8.23 mm.

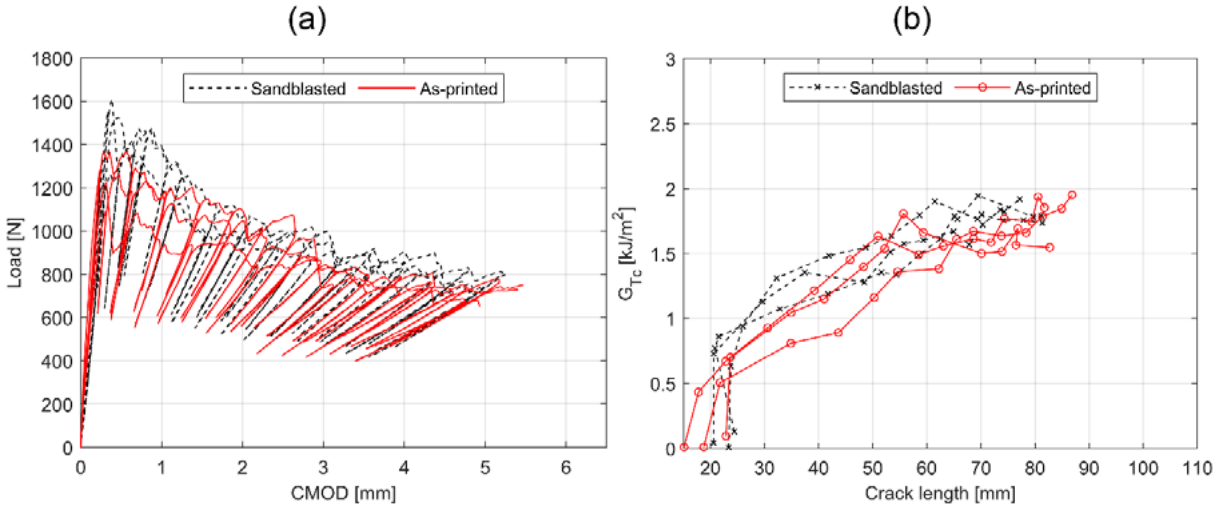

***Figure 4** – a) Load-CMOD curves with 14 unloading phases each. b) R-curves of the titanium-CFRP DCB samples, where the markers indicate the fracture toughness evaluated for a specific unloading. Three samples per batch were tested.*

A remarkable rising R-curve effect characterized the tests, which made the evaluation of a steady-state value of fracture toughness unfeasible. Hence, the values of initial and average fracture toughness (**Table 3**) are chosen to describe the behaviour of each batch of joints. The first unloading was not included in the calculation since it occurred in most of the samples' linear elastic phase of the test, with no visible crack propagation.

***Table 3** – Initial fracture toughness, average fracture toughness and maximum load of the titanium-CFRP DCB joints.*

	As-printed	**Sandblasted**
Initial G_{Tc} [kJ/m^2]	0.55 ± 0.14	0.71 ± 0.07
Average G_{Tc} [kJ/m^2]	1.42 ± 0.4	1.5 ± 0.36
Maximum load [N]	1317 ± 82	1536 ± 69

Figure 5 shows the fracture surfaces of the tested samples. The sandblasted samples consistently showed cohesive failure in the early stages of crack propagation, whereas in the as-printed samples the failure mode was mostly mixed cohesive-adhesive, probably due to less consistent adhesion. **Figure 6** makes a direct comparison of the R-curve of the sample AP2 with the correspondent fracture surfaces. AP2 was the one with the lowest values of fracture toughness (**Table 3**) associated with mostly adhesive failure in the first part of the test. Nevertheless, all 6 samples showed cohesive failure and small areas of CFRP first ply failure (region 2 in **Figure 6**) with an increase in fracture toughness. A final increase in the fracture toughness was observed when the crack deflection and further propagation within the composite layer occurred (region 3 in **Figure 6**). This failure mechanism is likely the reason behind the rising R-curve effect that characterized all the samples and led to comparable values of fracture toughness between the as-printed (1.42 kJ/m^2) and sandblasted (1.50 kJ/m^2) joints.

©2024 | 3_MICHELE_Gulino_ABKO3.pdf:5

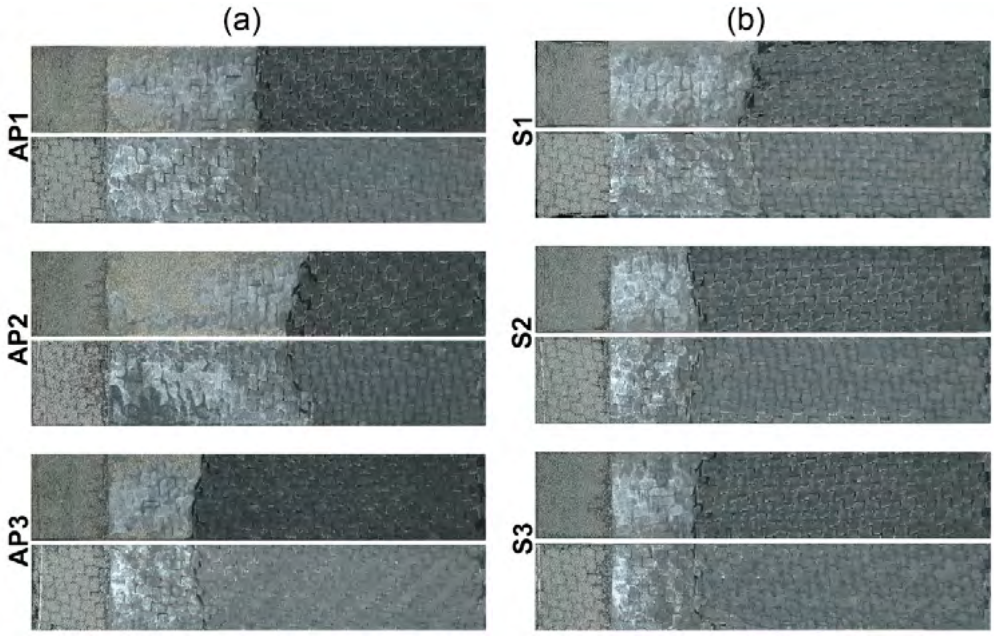

Figure 5 *– Fracture surfaces of the titanium-CFRP samples. "S" are the sandblasted joints and "AP" are the as-printed joints. For each joint, the titanium adherend is displayed above the CFRP adherend.*

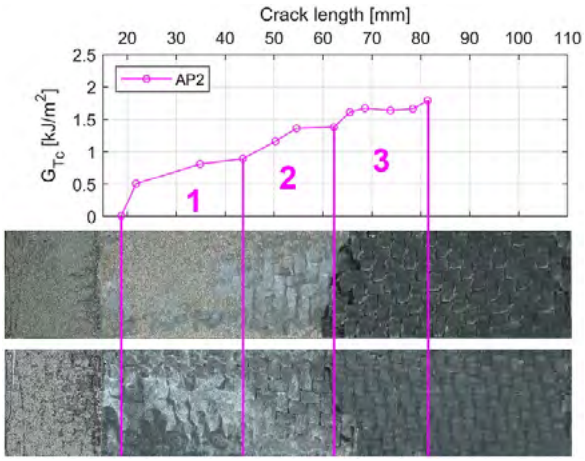

Figure 6 *- R-curve of sample AP2. The rising trend of the toughness is correlated to the transition from adhesive to cohesive failure (region "1"), then to cohesive and CFRP first ply failure (region "2"), eventually leading to crack deflection in the composite (region "3").*

4 Conclusions

The aim of this work was to evaluate the mode I fracture toughness of co-bonded joints involving untreated SLM Ti6Al4V and CFRP substrates using DCB tests. The untreated joints were compared with the same type co-bonded DCB specimens in which the SLM substrate was sandblasted. Both types of surfaces were characterized with optical profilometries and distilled water contact angle measurements. The following conclusions can be drawn:

- The as-printed surface has on average a 30 % higher roughness compared to the sandblasted surface, but the latter has a higher wettability (14% lower water contact angle), likely because the removal of contaminants on the titanium surface due to the mechanical treatment.
- In the first part of the crack propagation, the good wettability of the sandblasted surface is reflected in consistent cohesive failure, as opposed to mixed cohesive-adhesive failure of the as-printed samples. As the crack

©2024 | 3_MICHELE_Gulino_ABKO3.pdf:6

propagates, both sandblasted and as-printed joints show cohesive and CFRP first ply failure and eventually crack deflection in the composite adherend.

- Sandblasting leads to only a minor improvement of 6% in fracture toughness. It is believed by the author that the unstable crack propagation of the as-printed joints promoted dissipation phenomena, increasing the apparent fracture toughness of the as-printed joints. Nevertheless, the as-printed samples have worse wettability and higher percentage of adhesive failure compared to the sandblasted joints. This could be a concern for the long-term durability of the untreated samples since humidity can diffuse through the cracks at the adhesive-adherend interface, degrading the mechanical properties of the adhesive [18].

As a general conclusion, it was shown how the as-printed surface of SLM Ti6Al4V has great potential for the adhesive bonding of metal-composite joints, given its inherently rough surface morphology that can be exploited to avoid time-consuming treatments.

Abstract
The development of bio-based fibre-reinforced polymer composites (FPRs) has accelerated in recent years aiming at replacing synthetic FRPs in primary structures. Comparative case studies on biobased fibres (such as flax and hemp) indicate their potential to replace synthetic glass and carbon fibres in certain FRP structures as more sustainable and environmentally friendly alternatives. In those studies, the effects of in-situ hygrothermal conditions on the physical and mechanical performance of the natural fibre composites were generally overlooked, however, due to hygroscopicity of lignocellulosic natural fibres, flax fibre composites mechanical response is sensitive to its environmental temperature and relative humidity. To quantify and understand the effects of in-situ hygrothermal conditions on flax FRP composite, a quasi-static tensile testing campaign was conducted at various temperatures and relative humidities. Glass and flax FRP laminates were tested in cross-ply and angle-ply configurations. It was observed that the strength and stiffness of cross-ply and angle-ply FFRP laminates were significantly affected by relative humidity contrary to GFRP counterparts. All laminates exhibited strength and/or stiffness variation with temperature that can be attributed to the sensitivity of the common epoxy matrix. However, a distinct difference was observed between the flax and glass cross-ply laminates with the modulus of the flax FRP being highly affected by temperature and relative humidity while the glass FRP modulus was unaffected.

1. Introduction

In the quest for optimal performance in structural engineering, synthetic fibre-reinforced polymer composites (FRPs) have emerged as promising materials for light weight design of structures thanks to their high specific stiffness and strength. Regarding durability, synthetic FRPs do not rust or corrode or biologically decay unlike traditional materials such as steel or wood. Degradation in FRPs due to harsh environmental conditions can be mitigated by selecting a matrix system or coating designed to not degrade in the in-situ environmental conditions by preventing water diffusion through the matrix. Furthermore, the mechanical response of synthetic FRPs remains stable in most in-situ hygrothermal conditions because synthetic fibres such as glass are insensitive to moisture and have little stiffness variations with temperatures ranging from -20 to 50°C [1].

Due to recent sustainability and environmental concerns with synthetic FRPs, biobased FRPs have emerged as an alternative with the replacement of synthetic fibres such as glass by plant fibres such as flax. In addition to sustainability benefits, flax fibres have the structural advantages of being comparatively light [2] and effective at damping vibrations [3]. However in terms of durability, the cellulosic microstructure of flax fibres is hygroscopic resulting in a high moisture sorption in flax FRPs (FFRPs) [4] compared to the sorption in glass FRPs (GFRPs) [5]. This high moisture absorption and desorption induces swelling and shrinkage of the fibres, respectively, an order of magnitude larger than the swelling/shrinkage of the matrix [4]. Consequently, internal stresses are created, the fibre-matrix interface might get damaged, and the presence of water at the interface might reduce the fibre-matrix interface strength [6]. Furthermore, the stiffness and strength of single flax fibres are dependent on the moisture level in the fibres, with an increase in moisture reducing the modulus, and increasing the strength [7]. Regarding temperature (T), the mechanical properties of single flax fibres are affected with a significant reduction of modulus and strength between 20°C and 60°C [8].

Since the properties of flax fibres significantly vary at different in-situ temperatures and relative humidities due to their viscoelastic and hygroscopic nature it is pivotal to assess the mechanical response of biocomposites at different environmental conditions. As example, biobased FRP bridges and wind turbine are structural applications subjected to diurnal and seasonal variation of in-situ hygrothermal conditions.

In this study, we aim to evaluate how in-situ hygrothermal conditions impact the quasi-static tensile performance of composite laminates made from flax and glass fibres. Four FRP laminates were characterized at in-situ conditions ranging from -20 to 50C and 50% to 90% relative humidity. Cross-ply [0/90/0] and angle-ply $[+45/-45]_S$ laminates were manufactured and tested to highlight hygrothermal effects on fibres and the combination of matrix/interface, respectively. This experimental investigation helps to assess how the in-situ hygrothermal conditions affect the mechanical response of flax and glass FRP laminates.

2. MATERIALS AND METHODS

2.1 Composite laminates architecture/manufacturing

In this study, four types of composite laminates were manufactured by vacuum infusion. These include GFRP [0/90/0], GFRP $[(+45/-45)]_S$, FFRP $[0/90/0]_S$, FFRP $[(+45/-45)_2]_S$. The glass fibres employed are non-crimp high stiffness glass fabric with an aerial weight of 1260 g/m^2 manufactured by Kush Synthetics PVT.LTD. The flax fibres employed are quasi-unidirectional flax mat Amplitex, weighing 280 g/m^2 and manufactured by Bcomp (Switzerland). The epoxy resin system, SWANCOR 2511-1AL/BL, was used as matrix for manufacturing both GFRP and FFRP laminates. The method employed for manufacturing was vacuum assisted resin infusion (VARI) followed by autoclave post-cure at 70°C for 18 hours. The specimens were then cut into rectangular coupons of dimensions 250 × 15 mm using a waterjet cutter. Optical microscopy was utilized to qualitatively evaluate the consistency of the manufacturing quality. Differential scanning calorimetry (DSC) analysis was used to verify the completion of the epoxy curing. The fibre volume fraction was determined through density calculations at 42% and 53% for FFRP and GFRP laminates respectively.

2.2 Pre-conditioning protocol

Pre-conditioning was performed to ensure that the specimens are at equilibrium with the selected in-situ hygrothermal conditions during testing. To that end, the specimens were placed in a WK11-340/40 climate chamber at 50°C and at the desired relative humidity (RH) for at least two weeks to equilibrate the moisture content. To ensure that the specimens reach at least 90% of saturation, the moisture content was tracked by weight measurements initially at daily intervals and then 3 days intervals. Once the desired moisture content was reached the specimens were transferred to the climate chamber enclosing

the tensile testing setup set to the in-situ hygrothermal testing conditions. Specimens stayed at least 30 minutes in the climate chamber to equilibrate to the testing temperature.

2.3 Quasi-static tensile testing

Tensile testing was performed on an Instron 1251 with a 100 kN loadcell and equipped with hydraulic grips and a Klimaatkast Weisstechnik climate chamber enclosing the grip area. An extensometer is attached to the specimen with rubber bands to measure the strain. A thermocouple is attached with tape to the surface of the specimen to ensure the specimen is at the desired temperature during testing. Loading is performed at a rate of 2 mm/min up to failure. The in-situ hygrothermal conditions range from -20°C to +50°C and 50% to 90% RH to simulate common and extreme outdoor conditions.

3. Results

3.1. Effects of temperature and relative humidity on the tensile response of GFRP laminates

3.1.1. Cross-ply laminate

The stiffness of GFRP cross-ply laminate was observed to be negligibly affected by the temperature and the relative humidity with an overlap of all the stress-strain curves (figure 1). The highest ultimate tensile strength (UTS) was observed at -20°C and the lowest at 50°C showing an effect of temperature on UTS despite no remarkable effect on the modulus.

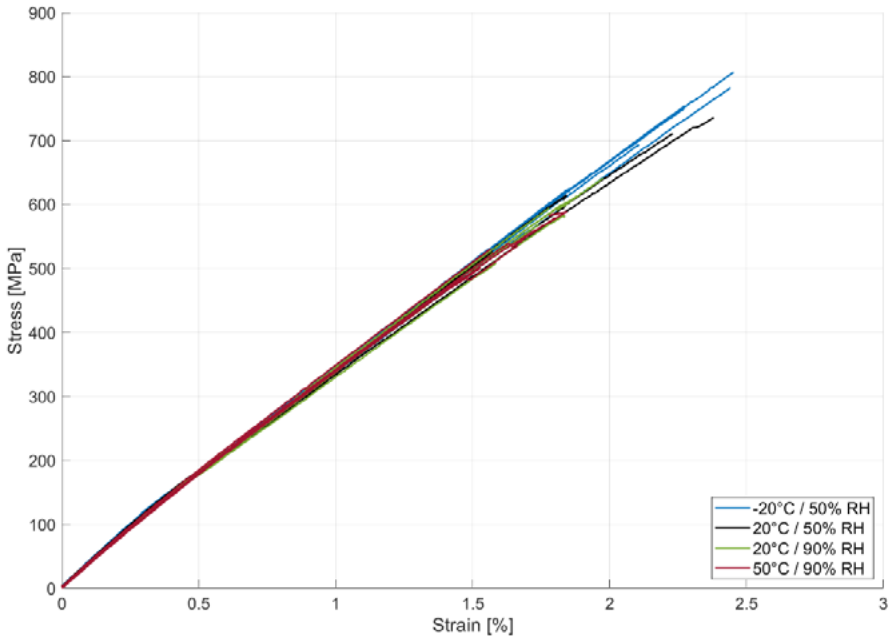

Figure 1. Stress-strain curves of the GFRP [0/90/0] laminate for 4 different in-situ hygrothermal conditions.

3.1.2. Angle-ply laminate

The stress-strain curves of the angle-ply GFRP laminate show three distinct responses governed by the in-situ temperature with a temperature increase resulting in lower modulus, lower UTS, and higher strain to failure (figure 2). The in-situ relative humidity had a negligible effect both at 20°C and 50°C.

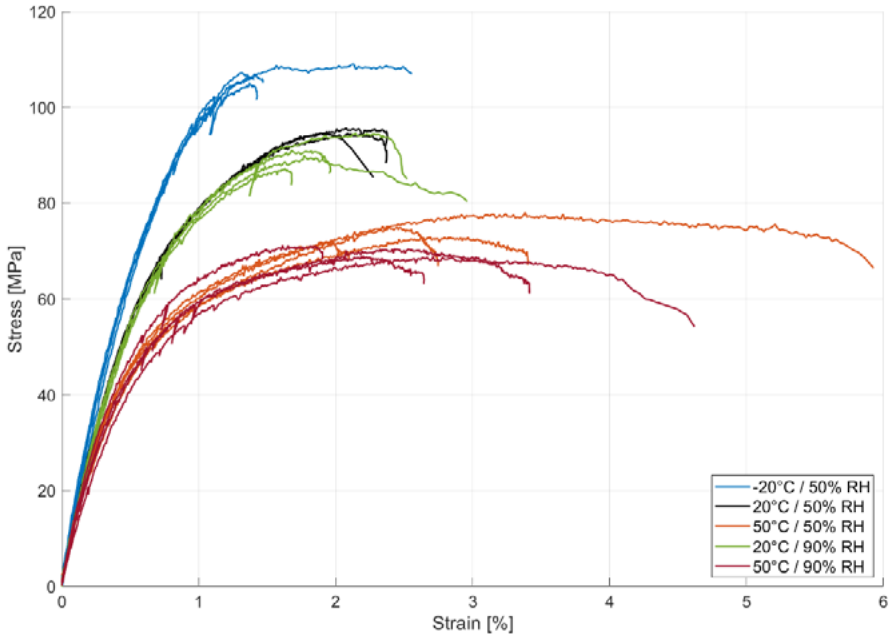

Figure 2. Stress-strain curves of the GFRP $[+45/-45]_S$ laminate for 5 different in-situ hygrothermal conditions.

3.2. Effects of temperature and relative humidity on the tensile response of FFRP laminates

3.2.1. Cross-ply laminate

The mechanical response of the cross-ply FFRP laminate was observed to be significantly dependant on the in-situ temperature and relative humidity (figure 3). The increase in temperature was observed to decrease the modulus and UTS of the laminate manifested by knock down effect on the entire stress-strain curve, observation valid at 50% and 90% RH. Interestingly, the high in-situ relative humidity of 90% caused the shape of the stress-strain curve to change compared to that at 50% relative humidity. The high relative humidity increased the UTS of the laminate.

3.2.2. Angle ply laminate

The angle-ply FFRP laminate exhibit three distinct yield plateau for the three in-situ temperatures (figure 4). The modulus was reduced by the increase in temperature and the increase in relative humidity. Remarkably high strains to failure were reached by the FFRP angle-ply laminate in particular at 50°C where the displacement limit of the tensile testing machine of 16% strain was reached by some specimens without failure. The flax fibre angle was measured on the post-mortem specimens of the angle-ply FFRP laminate (figure 5). At -20°C an angle of 45° was measured, corresponding to the flax fibre angle on the pristine specimens. At 20°C and 50°C the fibres show a permanent rotation of the fibres towards the loading direction.

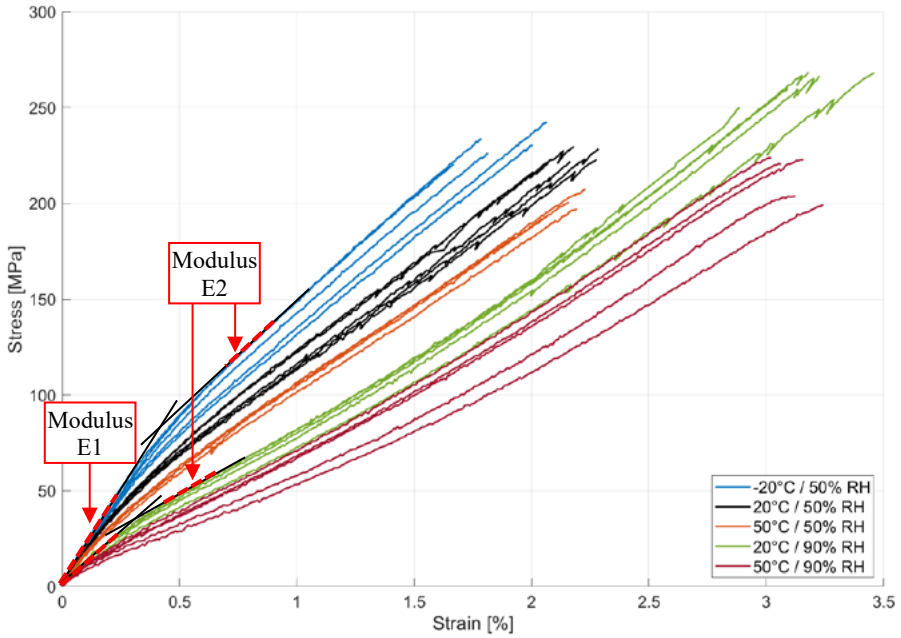

Figure 3. Stress-strain curves of the FFRP $[0/90/0]_S$ laminate for 5 different in-situ hygrothermal conditions.

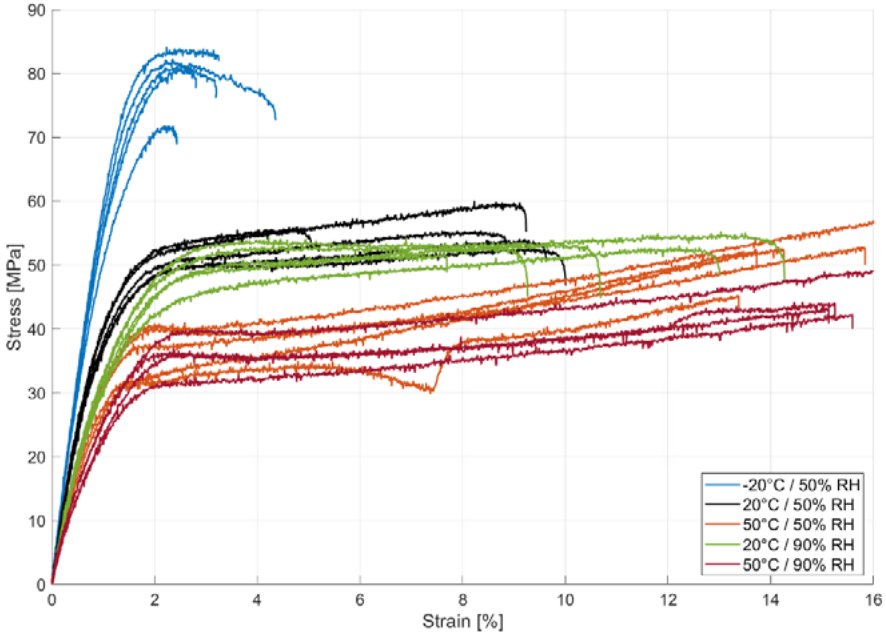

Figure 4. Stress-strain curves of the FFRP $[(+45/-45)_2]_S$ laminate for 5 different in-situ hygrothermal conditions. Beyond 6% strain the deformation was calculated based on the actuator displacement.

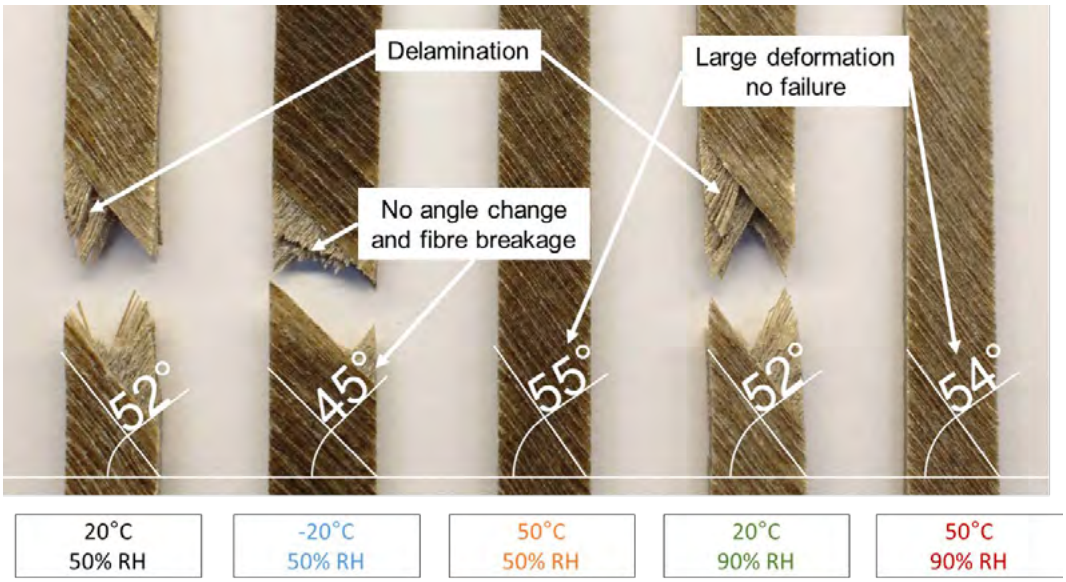

Figure 5. Pictures of post-mortem specimens and visual measure of fibre angle. Observation of different failure mechanisms (or no failure) for different in-situ temperatures.

4. Discussion

The characterisation of the four laminates at -20, 20, and 50°C showed a general trend of lower mechanical performance at higher temperatures (figure 6). While the GFRP and FFRP angle-ply laminates have a similar temperature effect on their modulus, likely due to the common temperature sensitive epoxy matrix system, the GFRP and FFRP cross-ply laminates have a distinct modulus sensitivity to temperature visible by comparing figure 2 with overlapping stress-strain curves and figure 4 with 3 distinct stress-strain curves. This observation suggests that the glass reinforcement is not sensitive to the in-situ temperature but the flax reinforcement is.

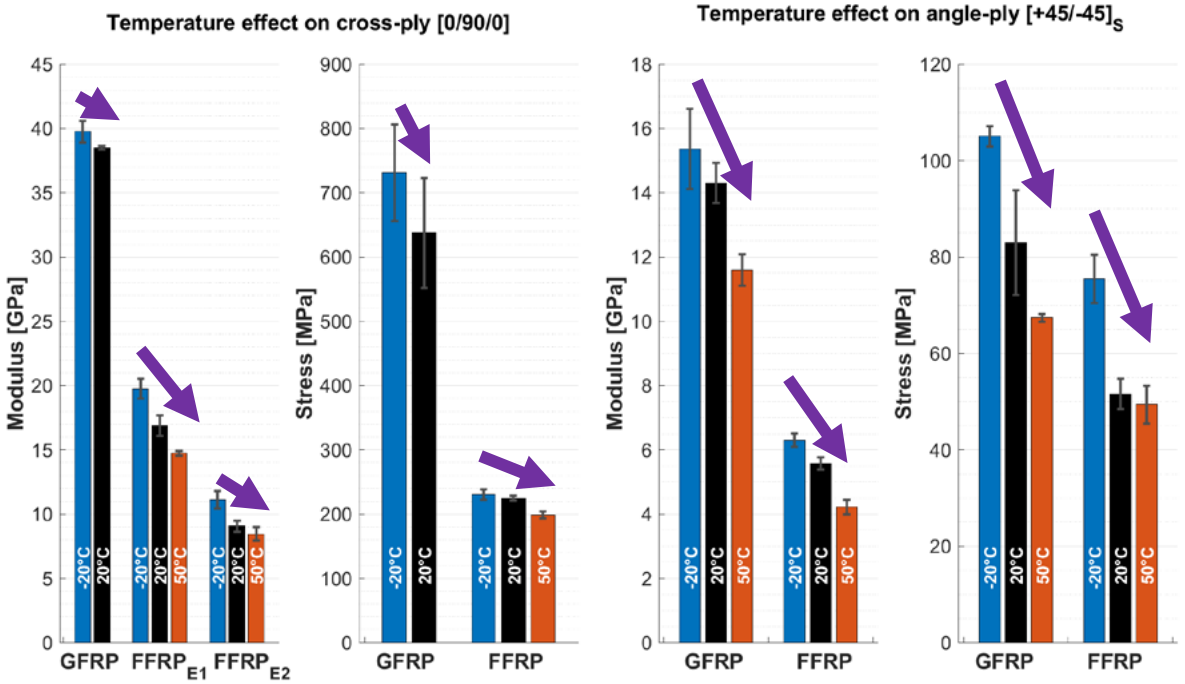

Figure 6. Tests at 50% RH. Decrease of stiffness and strength with increase of temperature. For cross-ply FFRP the E1 modulus is measured from 0 to 0.2% strain (before the knee) and the E2 modulus from 0.7 to 0.9% strain (after the knee) as indicated in figure 3. For the other laminates, the modulus is measured from 0 to 0.2% strain. The stress is measured at tensile failure.

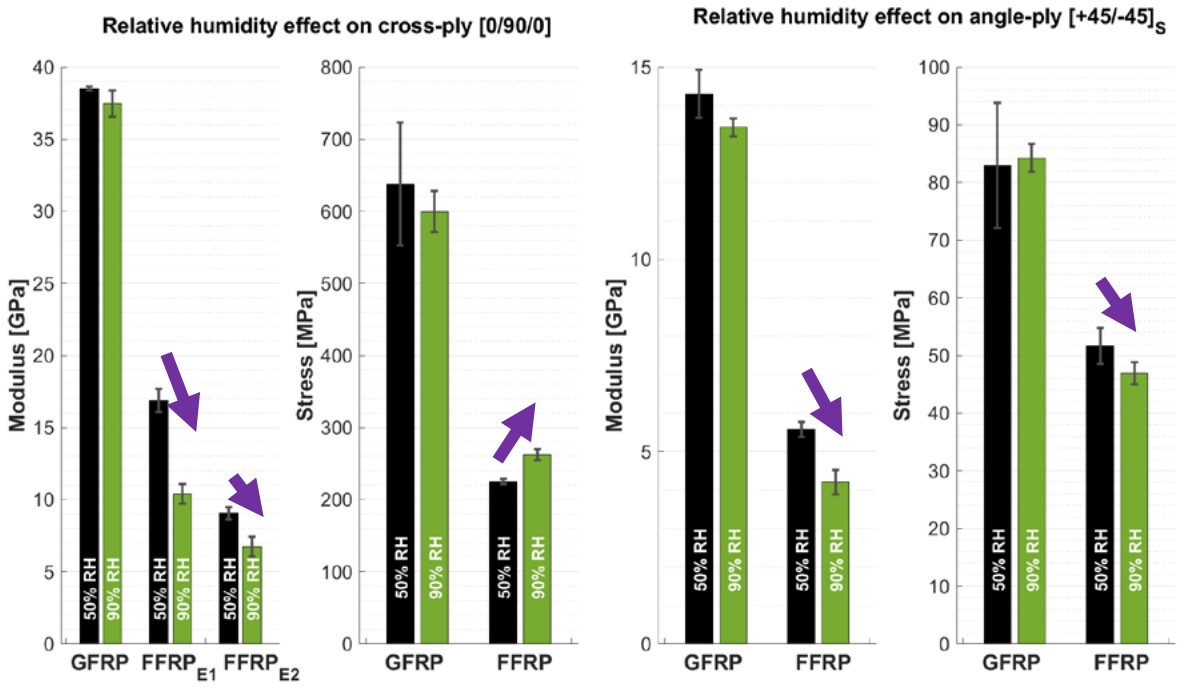

Figure 7. Tests at 20°C. Sensitivity of FFRPs stiffness and strength to relative humidity and insensitivity of GFRPs. For cross-ply FFRP the E1 modulus is measured from 0 to 0.2% strain (before the knee) and the E2 modulus from 0.45 to 0.65% strain (after the knee) as indicated in figure 3. For the other laminates, the modulus is measured from 0 to 0.2% strain. The stress is measured at tensile failure.

The characterisation of the four laminates at 50% and 90% RH showed that the effect of in-situ relative humidity is not significant on GFRP laminates (within standard deviation) but significant on FFRP laminates highlighting flax sensitivity to moisture and its consequences on the mechanical response of the composite (figure 7). Surprisingly, the shape of the cross-ply FFRP laminate stress-strain curve at 90% RH matches that of single flax fibres found in literature [9].

With the combination of in-situ temperature and relative humidity effects (50°C and 90% RH) the results of the FFRP laminates suggest a possible superposition of effects allowing modelling of hygrothermal effects by independent temperature and humidity knock-down factors. For example in figure 3, a factor could be applied on the 20°C/50% RH curve to obtain the same slope as the 50°C/50% RH curve. Then, the same factor could be applied on the 20°C/90% RH curve to obtain the slope of the 50°C/90% RH curve.

.

On the plastic region of the angle-ply FFRP laminate, a surprisingly high strain to failure was reached especially at 50°C with some specimens reaching more than 16% strain (figure 4). This large deformation cannot be solely explained by the fibre deformation as single flax fibre reach failure before 4% strain, even at 50°C [8]. However, a rotation of the flax fibres from the initial 45° to 55° (scissoring) was measured on the surface of the post-mortem specimens (figure 5). By trigonometry, this fibre rotation results in a longitudinal strain of 15.8% explaining the 16% strain reached. How such a large deformation can occur is not clear yet as the maximum strain reached by the equivalent GFRP angle-ply laminate is below 6%. The large rotation in the FFRP angle-ply laminate may be allowed by a weak flax fibre-matrix allowing for a relative displacement without failure which is exacerbated by elevated temperatures increasing matrix plasticity. The microstructure of the FFRP laminate may also contribute to allowing large fibre rotation because of larger spacing between fibres tows in FFRP than in GFRP, resulting in matrix rich areas susceptible to scissoring (figure 8). Also, low spacing between glass fibre tows in the fabric can also limit the scissoring effect.

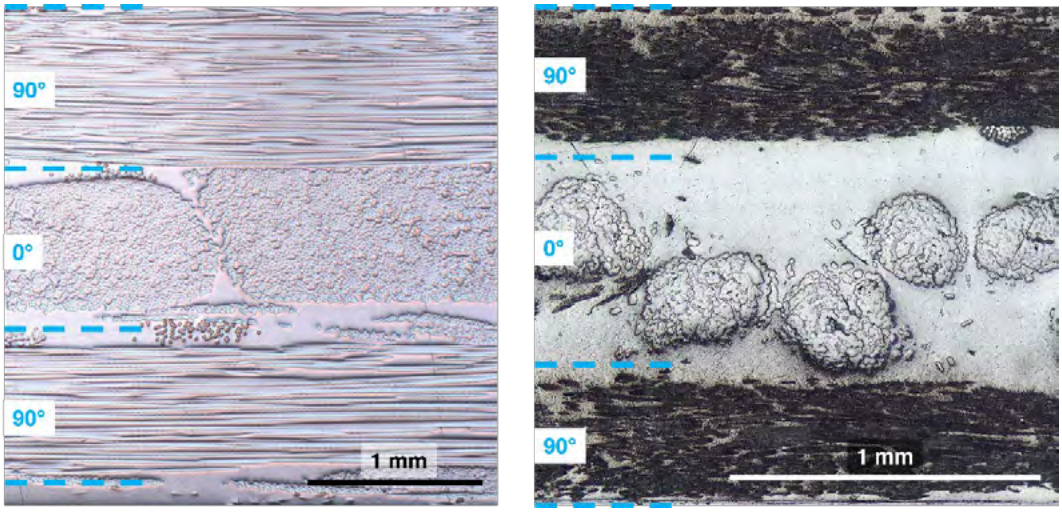

Figure 8. SEM images depicting microstructure of GFRP laminate (left) and FFRP laminate (right) demonstrating smaller spacing between glass tows compared to flax yarns. The delimitations of the plies and fibre angle relative to the observer are indicated.

4. Conclusions

In this study, we investigated the effects of in-situ temperature and relative humidity variations on the quasi-static tensile response of flax and glass FRP composites. Cross-ply and angle-ply laminates were manufactured, equilibrated to five different hygrothermal conditions with temperature and relative humidity ranging from -20 to 50°C and 50% to 90% RH, respectively and subsequently tested under controlled hygrothermal conditions. Below are the key findings:

- At higher in-situ temperatures, a general decrease in mechanical performance is noted across all laminates, with FFRP laminates displaying a more pronounced sensitivity, likely attributed to the cellulosic nature of the flax reinforcement.
- While the in-situ relative humidity had limited effects on the GFRP laminates, a significant effect of in-situ condition was observed on stiffness, strength, and strain to failure of FFRP laminates. Additionally, a change of the stress-strain curve shape was noted for the FFRP cross-ply laminate
- The in-situ temperature and relative humidity have distinct effects on the FFRP laminates. The results suggest that those effects can be modelled separately and superposed.
- For angle-ply laminates, the matrix sensitivity to in-situ environment has a large influence on the mechanical response of the composite while the hygrothermal sensitivity of the cross-ply laminates is predominantly dependant on fibre properties.
- Exceptionally large strains to failure, exacerbated at high temperatures, were measured with the FFRP angle-ply laminate and were accompanied by a fibre rotation. This large deformation is possibly attributed to scissoring in matrix rich region of the FFRP microstructure.

As a general conclusion, the results presented in this study show that the mechanical performance of FFRP laminates is sensitive to in-situ temperature and moisture conditions, and this to a significantly larger extent than in GFRP laminates. It is therefore pivotal for the safe and reliable use of biocomposites in structural applications to understand and account for in-situ hygrothermal effects.

Acknowledgments

The authors wish to thank the Suzlon company for the delivery of the epoxy resin used in the manufacturing of the specimens. Authors wish to sincerely thank the continuous support of all the technicians within the Macrolab/Stevinlaboratory of the faculty of Civil Engineering and Geosciences, and the ASM laboratory of the faculty of Aerospace Engineering at TU Delft.

Keywords: interlaminar fracture, mixed mode I/II, mode decomposition

Abstract
The double cantilever beam (DCB) test was designed to characterize interlaminar fracture in pure mode I and the end notched flexure test (ENF) was designed to analyse interlaminar fracture in pure mode II. Nevertheless, in the case of geometric, material or combined asymmetry of the cracked arms of the specimen, combination of modes appear in both test configurations. In the present study, some aspects of a new analytical model to decompose the energy release rate in mode I and mode II are presented. The model is based on the assumption of concentrated loads at the crack tip zone. The J integral is determined in the case of a small fracture process zone. Thus, J_I and J_{II} are obtained as a function of the loads and derivatives of the displacements at the crack tip. The calculation process is based on the derivatives of the complementary strain energy or coenergy in both, ADCB and AENF test configurations.

1. Introduction

Double Cantilever Beam and End Notched Flexure tests were designed for the determination of interlaminar fracture behavior in mode I and mode II of composite materials. The same configurations were used in the characterization of adhesive joints in modes I and II. When geometric or material symmetry does not exist, mixed mode fracture could appear. Recently, pure mode conditions have been related to the J-integral [1]. The same relation between thicknesses and flexural moduli was obtained for pure mode I and pure mode II of bimaterial specimen joints. The energy release rates (ERRs) that correspond to each specimen were obtained and the results were compared with numerical models, obtaining good agreement [2]. It is worth noting that numerical approaches were developed with cohesive elements. Thus, the results correspond to the J-integral determined by the cohesive law at the crack tip, while the results of the analytical approach correspond to the ERR (G) determined by the coenergy derivatives. The equivalence between J and G was established in cases of small and great fracture process zones (FPZs), provided that the global behaviour of the specimen was elastic. This equivalence is due to the equivalent crack length, which incorporates all sources of compliance changes in the specimen, was used for the determination of G.

The problem of the decomposition of fracture modes has been analyzed by several authors [3-7], following different approaches. In the present study, the decomposition in fracture modes I and II is analyzed in the case of the Asymmetric Double Cantilever Beam (ADCB) and the Asymmetric End Notched Flexure tests (AENF). The analytical model is based on the assumption that the crack tip effects are replaced by the resultant forces of stresses at that zone. The ERR that correspond to each mode, is determined analytically in a similar way as the virtual crack closure technique (VCCT) is applied in the

finite element method (FEM). Besides the forces at the crack tips, the displacement fields are also necessary for that calculation.

2. *J*-integral and VCCT

In the present section, it is shown that in the case of small fracture process zones (FPZ), the *J*-integral is equivalent to the virtual crack closure technique. Figure 1 shows the fracture process zone, the beginning of the FPZ, that is named *lagging crack tip*, and the end of the FPZ, that is named *leading crack tip*, according to the nomenclature used by Turón [8].

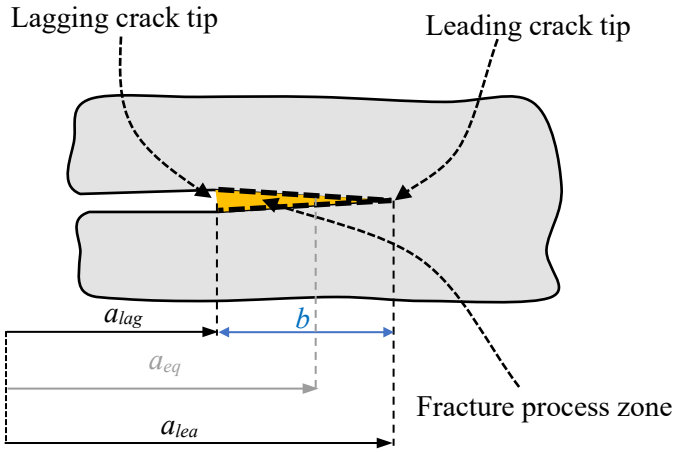

Figure 1. Fracture process zone and definition of crack lengths.

Being b the length of the fracture process zone, the *J*-integral can be expressed as [1]:

$$J = \int_0^{-b} \sigma \delta_{n,x} dx + \int_0^{-b} \tau \delta_{t,x} dx \tag{1}$$

where σ and τ are normal and shear stresses and δ_n and δ_t are the normal and tangential relative displacements of homologous points of the cohesive zone. Homologous points are defined as those that were the same point before fracture. In this way, the *J*-integral corresponds to the FPZ, and stresses and displacements refer to different points. As the relative displacements of the cohesive zone or FPZ are a function of the coordinate x:

$$d\delta_n(x) = \delta_{n,x} dx \text{ and } d\delta_t(x) = \delta_{t,x} dx \tag{2}$$

Furthermore, the integral limits in Eq. (1) change as follows:

$$\begin{cases} x = -b \Rightarrow \delta_n = \delta_n^*, \delta_t = \delta_t^* \\ x = 0 \Rightarrow \delta_n = 0, \ \delta_t = 0 \end{cases} \tag{3}$$

where δ_n^* and δ_t^* are the values at the lagging crack tip, i.e. at the beginning of the cohesive zone. Replacing Eqs . (2) and (3) in Eq. (1) the integral variables are the relative displacements:

$$J = \int_0^{\delta_n^*} \sigma d\delta_n + \int_0^{\delta_t^*} \tau d\delta_t \tag{4}$$

The derivation of Eq. (4) does not depend on the length of the cohesive zone. σ, τ, δ_n and δ_t correspond to the beginning of the FPZ. Therefore, Eq. (1) can be seen as a spatial interpretation of the *J*-integral,

evaluated in a given process configuration, taking into account all points of the FPZ. Alternatively, Eq. (4) can be seen as an evolutionary integral, taking into account the change of stresses and displacements at a fixed position as fracture process develops. This interpretation is applied to define the cohesive laws.

Figure 2 shows a fracture process zone of lengthe Δa, where stresses and relative displacements are linearly distributed, according to:

$$\sigma = \sigma_0\left(1+\frac{x}{\Delta a}\right) \quad \tau = \tau_0\left(1+\frac{x}{\Delta a}\right)$$
$$\delta_n = -\frac{\delta_n^*}{\Delta a}x \qquad \delta_n = -\frac{\delta_t^*}{\Delta a}x \tag{5}$$

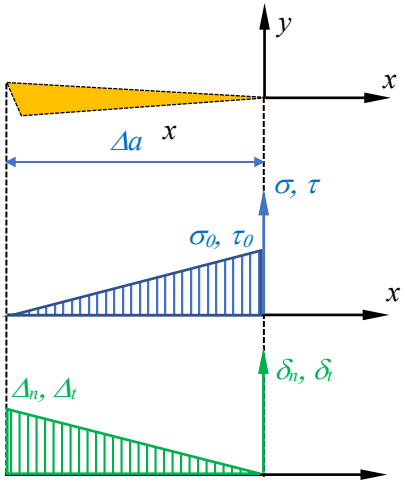

Figure 2. Linear stresses and displacements along the FPZ.

Replacing Eq. (5) in Eq.(1) and taking into account that $b = \Delta a$:

$$J = \tfrac{1}{2}\sigma_0\delta_n^* + \tfrac{1}{2}\tau_0\delta_t^*$$
$$\sigma_0 = \left[\frac{dF_n(x)}{wdx}\right]_{x=0} \qquad \tau_0 = \left[\frac{dF_t(x)}{wdx}\right]_{x=0} \tag{6}$$

where F_n and F_t are the normal and tangential forces, respectively. When $\Delta a \to 0$:

$$\left(dF_n\right)_{x=0} = F_n(0) - F_n(-\Delta a) = F_n(0) = F_n^*$$
$$\delta_n^* = \delta_n(-\Delta a) = \delta_n(-\Delta a) - \delta_n(0) = -\left(d\delta_n\right)_{x=0} \tag{7}$$

Eq. (7) can be extended to tangential components. Assuming crack closure, $dx = -da$. Replacing Eq. (7) in Eq. (6), the J-integral is:

$$J = \frac{1}{2w}F_n^*\left(\frac{d\delta_n}{da}\right)_{x=0} + \frac{1}{2w}F_t^*\left(\frac{d\delta_t}{da}\right)_{x=0} \tag{8}$$

Eq. (8) is the same as that of the virtual crack closure technique (VCCT). As the models of the present study are based on concentrated loads, Eq. (8) can be applied in the analytical approach. The relative normal displacement and its derivative are:

$$\begin{aligned}\delta_n &= v_1 - v_2 = (v_1 - v_2)_b + (v_1 - v_2)_s \\ \frac{d\delta_n}{da} &= (\theta_1 - \theta_2)_b + \left(\frac{dv_1}{da} - \frac{dv_2}{da}\right)_s\end{aligned} \tag{9}$$

where v_1 and v_2 are vertical displacements at the upper and lower sub-beams, respectively. The subscripts b and s refer to bending and shear, respectively. Grouping terms of each sub-beam, Eq. (9) can be expressed as:

$$\frac{d\delta_n}{da} = \left(\theta_{1b} + \frac{dv_{1s}}{da}\right) - \left(\theta_{2b} + \frac{dv_{2s}}{da}\right) = \phi_1 - \phi_2 \tag{10}$$

Moreover, the relative tangential displacement and its derivative are:

$$\begin{aligned}\delta_t &= u_1 - u_2 \\ \frac{d\delta_t}{da} &= \varepsilon_1 - \varepsilon_2\end{aligned} \tag{11}$$

In Eq. (11), ε_1 is the normal strain on the lower face of the upper arm and ε_2 is the normal strain at the upper face of the lower arm. Replacing Eqs. (9) and (11) in Eq. (8) it results:

$$J = \tfrac{1}{2} F_n^* (\phi_1 - \phi_2)_{x=0} + \tfrac{1}{2} F_t^* (\varepsilon_1 - \varepsilon_2)_{x=0} \tag{12}$$

According to Eq. (12) pure mode contributions are:

$$\begin{aligned}J_I &= \tfrac{1}{2} F_n^* (\phi_1 - \phi_2)_{x=0} \\ J_{II} &= \tfrac{1}{2} F_t^* (\varepsilon_1 - \varepsilon_2)_{x=0}\end{aligned} \tag{13}$$

Moreover, pure mode conditions can be formulated in the following manner:

1. Pure mode I occurs when $F_t^* = 0$ and $\varepsilon_1 = \varepsilon_2$ at the crack tip.
2. Pure mode II occurs when $F_n^* = 0$ and $\phi_1 = \phi_2$ at the crack tip.

It is worth noting that the force and deformation condition are both simultaneously satisfied in each case. The physical meaning is that if the force is zero, there is no cause to generate an associated deformation. Conversely, if the deformation is zero, there is no need of an associated force to prevent it.

3. Strain coenergy and partial derivatives

The complementary strain energy or coenergy of a laminated beam constituted by orthotropic layers, when normal forces are zero, axial-bending coupling and hygrothermal effects are zero, is given by [2]:

$$C = \tfrac{1}{2} d \int_{L_x} M^2 dx + \tfrac{1}{2} s \int_{L_x} V^2 dx \tag{14}$$

Where; M is bending moment; V is the shear force; d is the flexural flexibility, being: $d = (EI)^{-1}$; E is the bending modulus; I is the moment of inertia; s is the shear flexibility [2]; L_x is the length of the beam. We assume that the coenergy is a function of generalized applied forces F_j, the crack length a, and some unknown parameters λ_k, i.e. $C = C(F_j, a, \lambda_k)$. Then, a generalized displacement δ_j in the direction of the

generalized force F_j, the ERR G and the unknown parameters λ_k can be determined by the derivatives of the coenergy [2]:

$$\delta_j = \frac{\partial C}{\partial F_j} \qquad G = \frac{1}{w}\frac{\partial C}{\partial a} \qquad \frac{\partial C}{\partial \lambda_k} = 0 \tag{15}$$

4. Asymmetric Double Cantilever Beam Test: ADCB

Figure 2 shows the configuration of an Asymmetric Double Cantilever test. The asymmetry could be due to different thicknesses of the same material or due to the joint of two different materials. The rotation of the non-cracked part of the specimen indicates mode II.

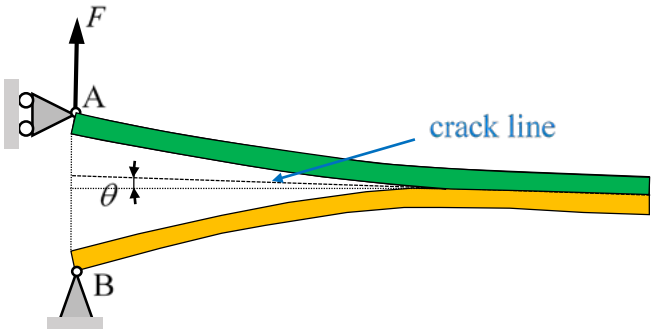

Figure 3. ADCB test configuration.

The rotation angle of the crack line can be determined by the Engesser-Castigliano's theorem given in Eq. $(15)_1$, being:

$$\theta = \frac{Fa^2}{4h}\left(h_1 d_1 - h_2 d_2\right) \tag{16}$$

Where h is the total thickness; h_i are the thicknesses of each arm, being i = 1, 2 the upper and lower cracked arms, respectively. In pure mode I, the cross section of the whole specimen at the crack tip is not plane due to crack tip effects. Then, the two sub-beams that constitute the specimen are assumed to be connected with normal concentrated forces [2] at a distance λ. In the case mode combination, horizontal forces are also added to the model, as shown in Figure 4.

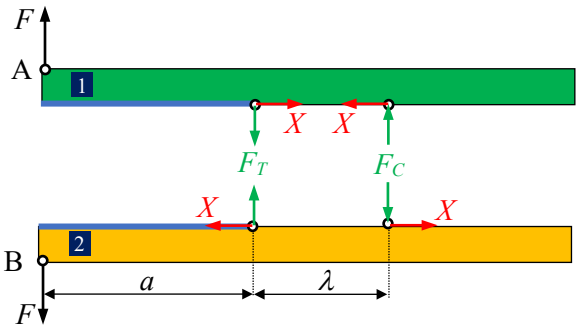

Figure 4. Forces in the ADCB configuration.

The distance λ and the force X are determined by stationary values of the coenergy C:

$$C_{,X} = 0 \rightarrow X$$
$$C_{,\lambda} = 0 \rightarrow \lambda \tag{17}$$

The relative angles and strains can be calculated by the Engesser-Castigliano's theorem, applying unit loads in the statically determined system to obtain the derivatives of the section forces and moments.

5. Asymmetric End Notched Flexure Test: AENF

Figure shows the AENF configuration. It is assumed that the contact in the cracked part exist only above the support A. In the case of pure mode, the hypothesis is correct. In the case of combined modes, it depend on the relative position of both sub-beams: when the most flexible sub-beam is in the lower part, the hypothesis is correct, as there is separation between both of them, as shown in Figure 5. In the opposite case, in a first approach, it can be assumed full contact between both sub-beams.

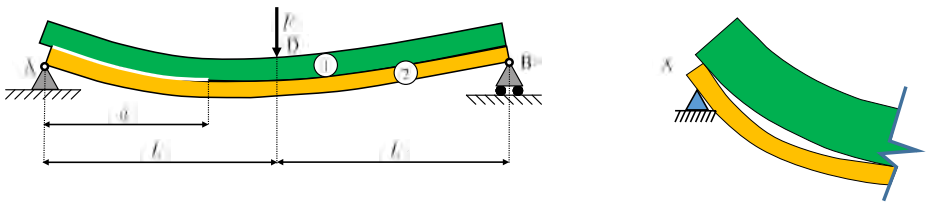

Figure 5. AENF configuration and separation between cracked arms.

In the case of pure mode II, we assume that the non-cracked part is a beam that satisfies the Euler-Bernoulli hypothesis, as the section at the crack tip remains plane. In the case of mode combination, it is assumed that mode II is related to the shear stress distribution that corresponds to the plane section hypothesis and mode I is related to normal vertical forces F_T and F_C that lead to the difference between bending angles at the crack end, as in the case of the ADCB test.

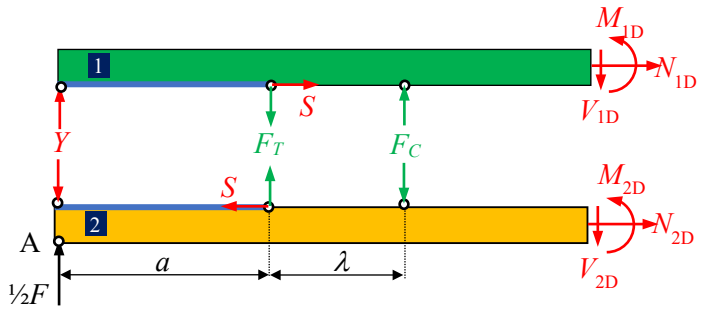

Figure 6. Forces and moments on the two sub-beams in the AENF configuration.

Figure 6 shows the force configuration assumed in the left half of the specimen, where N_{iD}, V_{iD} and M_{iD} correspond to the middle cross section D. Shear stresses that correspond to the complete beam are not included. These section forces and moments and shear stresses between both sub-beams, are determined by the classical beam theory [1,2]. The concentrated shear force S in this case is due to the equilibrium of the whole upper part: in the right half there is a uniform shear stress distribution over the length L, while in the left half, the shear stress distribution with the same value acts on the length (L-a). Then, S force equilibrates this difference, as occurs in an ENF test. The unknowns Y, F_T and F_C can be determined by the following equations:

$$\sum F_y = 0 \Rightarrow Y + F_C - F_T - V_{1D} = 0$$
$$\sum M_T = 0 \Rightarrow M_{1D} - V_{1D}(L-a) - \tfrac{1}{2}N_{1D}h_1 + F_C\lambda - Ya = 0 \tag{18}$$
$$C_{,Y} = 0$$

It is worth noting that N_{1D}, V_{1D} and M_{1D}, S and shear stresses do not depend on Y, as they are determined by equations that correspond to the whole specimen. Otherwise, bending moments and shear forces related to F_C and F_T, generate independent normal and shear stresses in each sub-beam.

6. Conclusions

Assuming a small fracture process zone, the J-integral can be used to determine the contribution of mode I or mode II as a function of concentrated forces and deformations at the crack tip. In mode I, the relative normal force and the relative angle between the elastic curves of each sub-beam at the crack tip are the main parameters. In mode II, J_{II} depend on the relative tangential force and the relative strains at the contact surfaces at the crack tip.

The models of ADCB and AENF where crack tip effects are incorporated as concentrated forces and the steps for their calculation have been described. When analytical approach is developed, the results can be compared with numerical results obtained applying the VCCT.

Abstract

A higher-order zigzag theory is developed, which is independent of the number of laminae. This theory contains only five unknowns (three translations and two average cross-sections shearing strains). In various plate theories, the cross-sectional rotations are considered as the independent field, while in the present plate model, it is the average cross-section shearing strains. This higher-order zigzag theory formulation is motivated by elasticity solutions, revealing that the transverse shearing stresses are continuous at the interface of two different laminae. Therefore, the transverse shearing strain capture jumps at the interfaces and varies quadratically along the thickness of the plate. Numerical problems are solved analytically to assess the accuracy of the present theory, for thick laminated composites and sandwich plates of thickness ratio ($a/h = 4$). Results obtained for a cross-ply plate having all four sides simply supported and cylindrical bending case of angle-ply sandwich plates respectively, and are compared with exact three-dimensional elasticity (Exact-3D) solutions and various equivalent single-layer theories (ESL) such as First Order Shear Deformation Theory (FSDT), Murakami Zigzag Theory (MZT), and Sorrenti Enhanced-Refined Zigzag Theory (En-RZT). The numerical results show that the present theory captures very close to exact three-dimensional elasticity solutions for Laminated Composites and sandwich plates.

Keywords: Laminate, Sandwich, Zigzag, Enhanced-RZT

1. Introduction

Laminated composite plates are extensively used in engineering applications due to their high strength-to-weight ratio and customizable mechanical properties. These plates consist of layers of various materials, like fibers and resins, stacked together to achieve specific structural characteristics. Analyzing laminated composite plates involves examining their behavior under different loading conditions, including mechanical, thermal, and environmental factors. The main goals of this analysis are to understand the deformation patterns, stress distributions, failure modes, and overall performance of the plates. This is crucial for designing lightweight and efficient structures in industries such as aerospace, automotive, marine, and civil engineering. Laminated composite plates are manufactured using techniques that involve layering multiple plies of materials like glass, carbon, or aramid fibers, which are then bonded with polymer-based adhesives. These adhesives, typically low-strength polymers, contribute to the inherent weakness at the laminae interfaces, leading to reduced interlaminar strength and the occurrence of delamination and transverse cracking. Therefore, accurately predicting the interlaminar strains and stresses is essential for structural analysis and failure prediction in multi-layer thick composite and sandwich plates [15]. Significant shear deformation and discontinuities in material properties at inter-layer interfaces in multilayered laminated plates cause rapid changes in slope, a phenomenon known as the zigzag effect [1]. Various plate theories within ESL, such as CLPT, FSDT, and TSDT, have been developed, but none adequately capture the warping of in-plane displacements in thick laminated composites

and sandwich plates. The Zigzag theory represents a significant advancement in ESL theory by accurately capturing the warping of in-plane displacements in thick laminated plates. It also incorporates continuity functions to manage abrupt changes in transverse shear strains, ensuring the continuity of transverse shear stresses at the interfaces between layers [3]. The effectiveness of this model lies in its ability to provide accurate results while maintaining a fixed number of unknown variables, making it economical for analyzing general laminates with diverse material layers [6, 10, 2]. The Refined Zigzag Theory (RZT), developed by Tessler et al. [16] offers a crucial improvement by accurately simulating clamped boundary conditions. In RZT, in-plane strains exhibit a piecewise linear distribution across the laminate thickness, while transverse shear strains display discontinuities at layer interfaces but remain piecewise constant within each material layer. For thick plates, linear piecewise models are insufficient due to the nonlinear behavior observed in in-plane displacements. Di Sciuva [10] pioneered the development of a third-order zigzag plate model that captures nonlinear behavior in in-plane displacements throughout the thickness while satisfying stress continuity conditions at layer interfaces. Nemeth [7] further enhanced RZT by incorporating continuous piecewise-cubic zigzag functions, surpassing the limitations of piecewise-linear functions. Tessler et al. [14], and Iurlaro et al. [4] expanded the linear RZT model by including stretching effects, using cubic zigzag functions. Kreja [5] examined FSDT and zigzag theory. In his study of FSDT, he considered one classical and three different global shear coefficients, whereas, for Zigzag theory, he focused on MZT and RZT which share the same kinematics but different zigzag functions. Computational models for analyzing laminates with a larger number of layers, enhanced by the application of zigzag functions, tend to be very stiff while FSDT models with global shear correction coefficients performed better. Sorrenti et al. introduced Enhanced-RZT [12], which incorporates linear zigzag functions with improved coupling effects where RZT fails to provide the desired results for angle ply laminates. In recent developments, Sorrenti et al. introduced another version of Enhanced-RZT [13], featuring cubic zigzag functions. Additionally, Si et.al., [11] proposed a higher-order zigzag theory using $nine$ kinematic fields, although this approach comes with higher computational costs.

In this study, a higher-order zigzag theory that is independent of the number of laminae is developed, featuring just $five$ unknowns. This formulation is inspired by elasticity solutions, which reveal that transverse shearing stresses are continuous at the interfaces of dissimilar laminae. Consequently, the transverse shearing strain varies quadratically along the thickness of the plate, capturing jumps at the interfaces. The analytical solution of multilayered laminated composites and sandwich plate problems using this zigzag model is compared with various structural theories available in the literature, including FSDT, Murakami's Zigzag theory, the Enhanced-Refined Zigzag Theory by Sorrenti et al., and exact three-dimensional elasticity theory. These comparisons consider various stacking sequences, such as symmetric cross-ply and symmetric angle-ply.

2. Mathematical Formulation for Higher Order Zigzag Theory

Take into account that the laminated plate is made up of a finite number of linear-elastic anisotropic layers, each of which has distinct mechanical and physical characteristics. To prevent delamination or slide at any lamina interface, it is expected that the layers are perfectly bonded. The thickness of the k^{th} constituent layer and of the entire plate is denoted by $h_k (k = 1, 2, ..., N)$ and $h = \bigcup_{k=1}^{N} h_k$, respectively, where N denotes the total number of constituent layers

2.1. Kinematics

The elasticity solutions show that the transverse shearing stresses are continuous at the interface of two dissimilar laminae and assume zero values at the bounding surfaces of the plate in the absence of surface shear traction. Therefore, the transverse shearing strains encounter the jumps (i.e., discontinuity) at the interfaces. The simplest form of kinematics that accounts for these requirements can be achieved by superposing a piece-wise constant shearing strain field (i.e., different values in different laminae) on an overall quadratic varying field. We start with the following piece-wise quadratic distribution of the

transverse shearing strain fields in the thickness direction of the plate.

$$\begin{Bmatrix}\gamma_{xz}\\ \gamma_{yz}\end{Bmatrix} = \left(\begin{bmatrix}Q_{44}^{(m)} & Q_{45}^{(m)}\\ Q_{54}^{(m)} & Q_{55}^{(m)}\end{bmatrix}^{-1}\begin{bmatrix}(Q_s^{av})_{11} & (Q_s^{av})_{12}\\ (Q_s^{av})_{21} & (Q_s^{av})_{22}\end{bmatrix}\right)\begin{Bmatrix}\overset{0}{\gamma}_x\\ \overset{0}{\gamma}_y\end{Bmatrix} + 2z\begin{Bmatrix}\overset{1}{\gamma}_x\\ \overset{1}{\gamma}_y\end{Bmatrix} + 3z^2\begin{Bmatrix}\overset{2}{\gamma}_x\\ \overset{2}{\gamma}_y\end{Bmatrix} + \sum_{k=1}^{m-1}\begin{Bmatrix}\overset{0}{\gamma}_x^k\\ \overset{0}{\gamma}_y^k\end{Bmatrix}Y^-(z,k) + \sum_{k=m}^{N-1}\begin{Bmatrix}\overset{0}{\gamma}_x^k\\ \overset{0}{\gamma}_y^k\end{Bmatrix}Y^+(z,k) \tag{1a}$$

or in compact form written as :

$$\gamma(x,y,z) = \left(\mathbb{Q}_s^{(m)^{-1}}\mathbb{Q}_s^{av}\right)\overset{0}{\gamma}(x,y) + 2z\overset{1}{\gamma}(x,y) + 3z^2\overset{2}{\gamma}(x,y) + \sum_{k=1}^{m-1}\overset{0}{\gamma}^k(x,y)Y^-(z,k) + \sum_{k=m}^{N-1}\overset{0}{\gamma}^k(x,y)Y^+(z,k) \tag{1b}$$

with the various shear-constitutive coefficients defined as:

$$\mathbb{Q}_s^{av} := \begin{bmatrix}(Q_s^{av})_{11} & (Q_s^{av})_{12}\\ (Q_s^{av})_{21} & (Q_s^{av})_{22}\end{bmatrix} = \frac{1}{h}\sum_{k=1}^{N}\int_{z_k}^{z_{k+1}}\begin{bmatrix}Q_{44}^{(k)} & Q_{45}^{(k)}\\ Q_{54}^{(k)} & Q_{55}^{(k)}\end{bmatrix}dz;\ \ \mathbb{Q}_s^{m} := \begin{bmatrix}Q_{44}^{(m)} & Q_{45}^{(m)}\\ Q_{54}^{(m)} & Q_{55}^{(m)}\end{bmatrix} \tag{2}$$

In Eq. (1), m bears the affliation of the middle layer number. $\overset{1}{\gamma}_x(x,y)$, $\overset{1}{\gamma}_y(x,y)$, $\overset{2}{\gamma}_x(x,y)$, $\overset{2}{\gamma}_y(x,y)$ denote the independent shearing strain fields associated to the linear and quadratic through the thickness distribution, respectively. $\overset{0}{\gamma}_x^k$, $\overset{0}{\gamma}_y^k$ for $k = 1, N-1$ represent the independent interfacial shearing strain jump fields and $Y^+(z,k) = H(z - z_{k+1})$, $Y^-(z,k) = H(-z + z_{k+1})$ are the Heaviside-Unit-Step functions with $H(x) = 1$ for $x \geq 0$ and $H(x) = 0$ for $x < 0$.The independent averaged shearing-strain like variables $\overset{0}{\gamma}_x(x,y)$, $\overset{0}{\gamma}_y(x,y)$ are introduced in order to keep a balance between the piece-wise constant strain part in Eq. (1) for a general laminated situation. Using the static continuity conditions (i.e., $\tau_{xz}|_{z_{k+}} = \tau_{xz}|_{z_{k-}}$, $\tau_{yz}|_{z_{k+}} = \tau_{yz}|_{z_{k-}}$ for $k = 1, N-1$), one calculates the interfacial shearing strain jumps and then applying strain displacement relations we get the in-plane displacements and transverse displacements which involve only $nine$ fields (independent of a total number of layers). Now applying shear traction free conditions at the bounding surfaces(i.e.,$\tau_{xz}|_{z_1} = \tau_{xz}|_{z_{N+1}} = \tau_{yz}|_{z_1} = \tau_{yz}|_{z_{N+1}} = 0$) led the total number of independent fields (i.e., 9) may be reduced further to $five$. The geometric insight of different terms in Eq. (1) are illustrated in Fig. 1 for a five-layer symmetric angle-ply (30/-30/30/-30/30) laminate. Now, finally, we have the following five parametric displacement fields that are obtained:

$$\begin{aligned} U(x,y,z) &= u(x,y) - z\frac{\partial w}{\partial x} + g_{11}(z)\overset{0}{\gamma}_x + g_{12}(z)\overset{0}{\gamma}_y\\ V(x,y,z) &= v(x,y) - z\frac{\partial w}{\partial y} + g_{21}(z)\overset{0}{\gamma}_x + g_{22}(z)\overset{0}{\gamma}_y\\ W(x,y,z) &= w(x,y)\end{aligned} \tag{3a}$$

with $g_{11}(z)$, $g_{12}(z)$, $g_{21}(z)$, and $g_{22}(z)$ are the zigzag functions which depends upon the geometric properties (thickness of laminae) as well as material properties of each laminae and it yields continuous shear stresses at the interfaces of dissimilar lamiane when calculated using constitutive equations.

3. Numerical Results

Numerical studies have been carried out in order to assess the existing model's accuracy and reliability. The calculations were carried out in accordance with the methods Pagano [8],[9] devised for an exact three-dimensional elasticity solution. Pagano acquires the plot in the figure referred to as Exact-3D. Additionally, numerical outcomes from the En-RZT developed by Sorrenti et al. [12] and MZT developed by Murakami [6] are also shown. There are no in-plane prescribed tractions on the top and bottom surfaces, only sinusoidal distributed transverse load has been applied at the top and bottom surface of the plates. The total transverse load is equally divided into two parts. One half is applied on top and the other half on the bottom external surfaces in a three-dimensional solution.

Field Variables for Symmetric Cross-Ply Laminate having simply supported boundary conditions on all four sides. By using Navier's method to obtain the solutions for symmetric cross-ply orthotropic rectangular plates having simply supported boundary conditions (SS-1) under transverse bi-sinusoidal distributed load $q(x,y) = q_0 \sin\left(\frac{\pi x}{a}\right) \sin\left(\frac{\pi y}{b}\right)$, the equilibrium equations, and the boundary conditions can be satisfied by using the following sets of trigonometric functions:

$$\begin{aligned} u &= U_{mn} \cos\left(\frac{\pi x}{a}\right) \sin\left(\frac{\pi y}{b}\right), \quad v = V_{mn} \sin\left(\frac{\pi x}{a}\right) \cos\left(\frac{\pi y}{b}\right), \quad w = W_{mn} \sin\left(\frac{\pi x}{a}\right) \sin\left(\frac{\pi y}{b}\right), \\ \overset{0}{\gamma}_x &= \overset{x}{\gamma}_{mn} \cos\left(\frac{\pi x}{a}\right) \sin\left(\frac{\pi y}{b}\right), \quad \overset{0}{\gamma}_y = \overset{y}{\gamma}_{mn} \sin\left(\frac{\pi x}{a}\right) \cos\left(\frac{\pi y}{b}\right), \end{aligned} \tag{4}$$

Field Variables for Symmetric Angle-Ply Laminate having an infinite length in the y-directions and simply supported along the two opposite edges . Under transverse sinusoidal distributed load $q(x,y) = q_0 \sin\left(\frac{\pi x}{a}\right)$, the equilibrium equations and the boundary conditions can be satisfied by using the following sets of trigonometric functions.

$$[u, v, \overset{0}{\gamma}_x, \overset{0}{\gamma}_y] = [U_{mn}, V_{mn}, \overset{x}{\gamma}_{mn}, \overset{y}{\gamma}_{mn}] \cos\left(\frac{\pi x}{a}\right), \quad w = W_{mn} \sin\left(\frac{\pi x}{a}\right) \tag{5}$$

Normalized Values for Laminated Plates and Sandwich Plates. The displacements and stresses for Laminated Plates and Sandwich Plates are normalized throughout the problem unless stated otherwise, as given below:

Normalized Values for Laminated Plates

$$(u^N, v^N) = (100 \cdot E3)\frac{h^2}{q_0 a^3},\ w^N = (100 \cdot E3)\frac{h^3}{q_0 a^4},\ (\sigma^N_{xx}, \sigma^N_{yy}, \sigma^N_{xy}) = h^2\frac{q_0}{a^2},\ (\sigma^N_{xz}, \sigma^N_{yz}) = h\frac{q_0}{a} \quad (6)$$

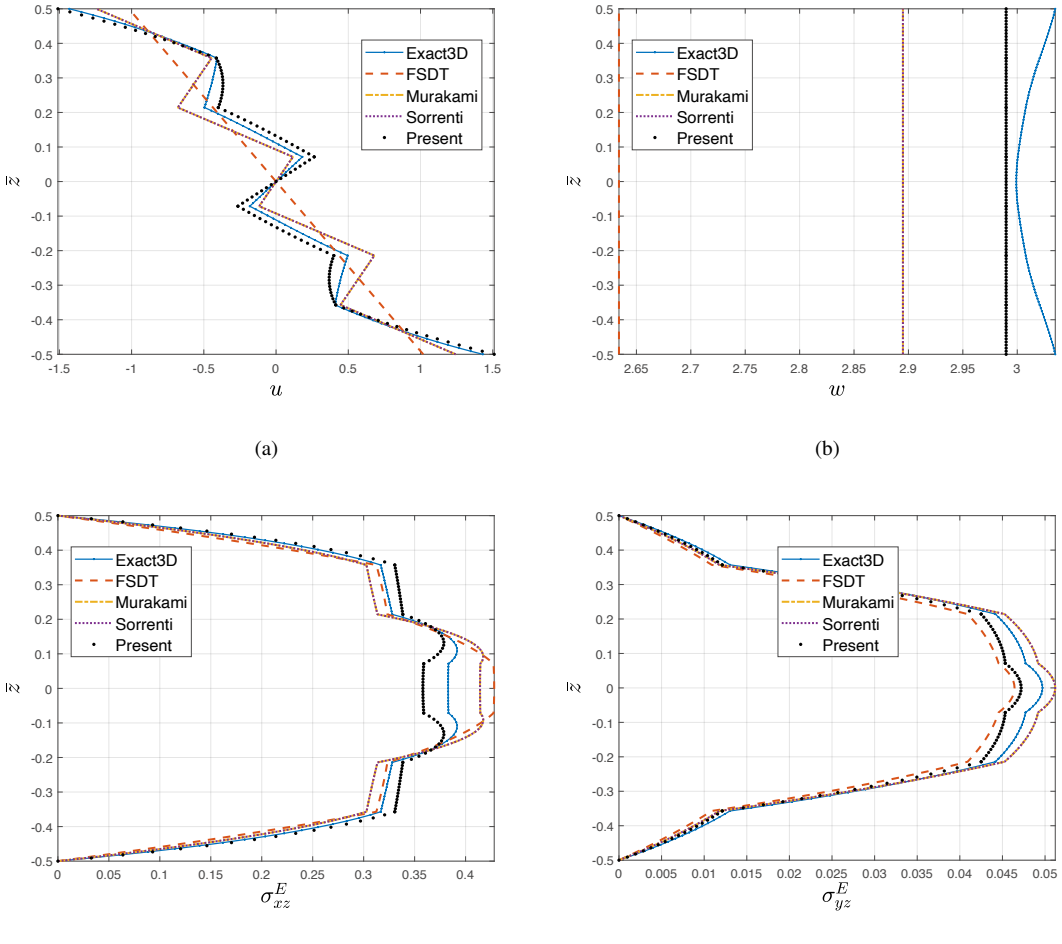
Normalized Values for Sandwich Plates

$$(u^N, v^N) = E3\frac{h^2}{q_0 a^3},\quad w_N = E3\frac{h^3}{q_0 a^4},\quad (\sigma^N_{xx}, \sigma^N_{yy}, \sigma^N_{xy}) = h^2\frac{q_0}{a^2},\quad (\sigma^N_{xz}, \sigma^N_{yz}) = h\frac{q_0}{a} \quad (7)$$

3.1. Problem.1: Numerical examples on Cross-ply laminated plates

A simply supported laminated cross-ply rectangle plate (0°/90°/0°/90°/0°/90°/0°) are adopted. The thickness and the material properties of each layer are uniform. The size of the plate model: length along x-axes is $a = 1m$ while length along y-axes is $b = 3m$, thickness is $h = 0.25m$. The plate is subjected to bi-sinusoidal distributed load $q(x, y) = q_0 sin(\pi x/a) sin(\pi y/b)$. bending load is $q_0 = 1kN/m^2$. The material constants are, $E_1 = 172.4Gpa$; $E_2 = 6.89Gpa$; $E_3 = 6.89Gpa$; $G_{12} = 3.45Gpa$; $G_{13} = 3.45Gpa$; $G_{23} = 1.378Gpa$; $\nu_{12} = 0.25$; $\nu_{13} = 0.25$; $\nu_{23} = 0.25$;

3.1.1. Results for seven-layer laminated composite plate with the symmetric cross-ply stacking sequence having $a/h = 4$ and $b = 3a$



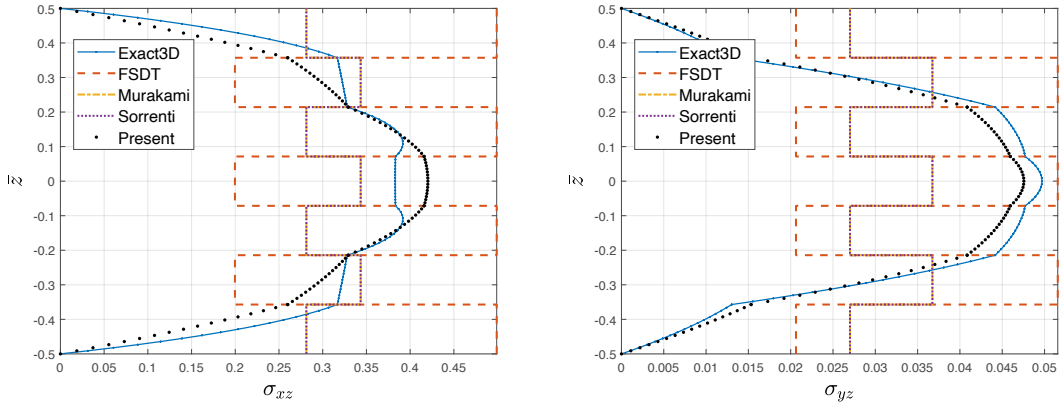


Figure 2: Dispacements $(2a, 2b)$, and transverse Shear stress as obtained from integration of equilibrium equations $(2c, 2d)$ for symmetric cross-ply seven-layer laminated plate for $a/h = 4$

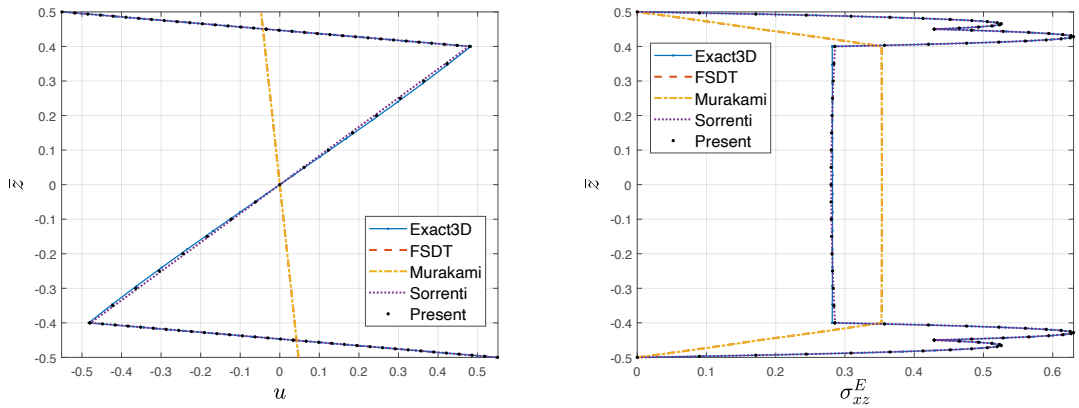

(e) (f)

Figure 2: Transverse Shear stress as obtained from Constitutive relations $(2e, 2f)$ for symmetric cross-ply seven-layer laminated plate for $a/h = 4$

3.2. *Problem. 2: Numerical examples on five-layer sandwich plates with the symmetric angle-ply configuration*

A five-layer sandwich plate with the symmetric angle-ply configuration (30°/-30°/$Core$/$-$30°/30°) simply supported on two opposite edges while infinitely long along y-directions are adopted. The thickness of skin is $h_{skin} = 0.05h$ and the thickness of core is $h_{core} = 0.8h$. The size of the plate model: length along x-axis is $a = 1m$, thickness is $h = 0.25m$. The plate is subjected to sinusoidal distributed load $q(x, y) = q_0 sin(\pi x/a)$, where $q_0 = 1kN/m^2$. The material constants for the face-sheets (transversely orthotropic) and core (isotropic) are given below. The superscript f and c are used for face-sheets and core respectively. $E_1^f = 110000Gpa$; $E_2^f = 7857Gpa$; $E_3^f = 7857Gpa$; $G_{12}^f = 3292Gpa$; $G_{13}^f = 3292Gpa$; $G_{23}^f = 1292Gpa$; $\nu_{12}^f = 0.33$; $\nu_{13}^f = 0.33$; $\nu_{23}^f = 0.49$; $E^c = 40.3Gpa$; $G^c = 12Gpa$; $\nu^c = 0.30$;

3.2.1. *Results for five-layer Sandwich plates with the symmetric angle-ply stacking sequence having* $a/h = 4$

(a) (b)

Figure 3: Displacement $(3a)$, and transverse Shear stress $(3b)$ as obtained from integration of equilibrium equations for the symmetric angle-ply five-layer sandwich plate for $a/h = 4$

Each of these numerical problems as shown above will provide valuable insights into the mechanical behavior and performance of the laminate under different layer-stacking configurations. σ_{xz}^{E}, and σ_{yz}^{E} represents the stresses obtained by integrating of equilibrium equations while σ_{xz}, and σ_{yz} are obtained from the constitutive equations.

4. Results and Discussions

For seven-layer symmetric cross-ply laminated composite plates, the results are shown in Fig. 2. The present model captures the in-plane displacements as shown in Fig. $2a$ very close to Exact-3D solutions. The FSDT fails to capture warping (zigzag effect). Murakami zigzag model and Sorrenti zigzag model get stiffened at the top and bottom of the laminate while the present model captures throughout the plate thickness. Fig. $2b$ shows the transverse displacements where the present model is very close to Exact-3D solutions. Fig. $2c$ and Fig. $2d$ results of transverse shear stresses obtained from the integration of equilibrium equations and the present model captures very close to Exact-3D solutions. Fig. $2e$ and Fig. $2f$ show the results of transverse shear stresses obtained from the constitutive equations and the present model captures very close to Exact-3D solutions and is continuous at the interfaces of the laminae and satisfies the shear stress-free conditions at the top and bottom surface, while other theories are piecewise constant in each lamina and fail to satisfy the continuity conditions at the interfaces and also fails to satisfy shear stress-free conditions at top and bottom surface of the laminate. For five-layer symmetric angle-ply sandwich plates, the results are shown in Fig. 3. The results in Fig. $3a$, and Fig. $3b$ show that the present model and Sorrenti model accurately captures the Exact-3D solutions while FSDT and Murakami Zigzag model fails to do so.

5. Conclusions

In this study, we propose a higher-order Zigzag Function-based formulation for thick and highly anisotropic multilayered laminated composite and sandwich plates. This advanced formulation effectively captures the warping of the plates, manifesting as zigzag effects in the in-plane displacements, and ensures continuity of transverse shear stresses at the interfaces of the laminated plates. Additionally, it satisfies the condition of zero shear stresses at the top and bottom surfaces of the plate. Unlike traditional linear zigzag theories, our approach is devoid of the stiffening effect that typically arises with an increased number of layers and does not require any shear correction factors. To validate the proposed formulation, we solved two problems with different stacking sequences: a symmetric cross-ply laminated composite plate and a symmetric angle-ply sandwich plate. The first case involves a seven-layer symmetric cross-ply laminated plate, which yields results closely matching the exact three-dimensional elasticity solutions. The second case analyzes a five-layer sandwich plate, with outcomes also aligning closely with exact three-dimensional elasticity solutions. These results underscore the robustness of the higher-order zigzag model, showcasing its exceptional performance even with highly anisotropic material properties and its immunity to the stiffening effect observed in other zigzag theories such as Sorrenti-En-RZT and Murakami Zigzag theory. This makes the proposed formulation a reliable and effective tool for analyzing complex laminated composite and sandwich plates.

Keywords: composite, polymer, environment, effect, recommended practice

Abstract
Composites provide an appealing substitute for metals, with excellent environmental resistance and stiffness-to-weight ratio. These distinctive qualities yield significant advantages in subsea structures, pipelines, and energy applications. However, resistance to challenging environments, high testing costs, and long-term efforts have hindered industry adoption. The DNV Recommended Practice (RP) addresses the critical challenge faced by several industries: The environmental exposure and degradation of composite materials. Models and assessment methodologies, supported by experiments, have been developed to enhance understanding and address the effects of fluid exposure and temperature in composites. Various methods have been developed to evaluate the chemical interactions with liquids and gas and to obtain Arrhenius-based Time-Temperature-Saturation-Superposition-dependent polymer and composite properties. The RP provides testing procedures for assessing the occurrence of chemical degradation. Other reversible interactions associated with swelling are addressed separately. Methods are given for polymers to obtain stiffness and strength over the design life. Cyclic fatigue and creep rupture are included, also covering applications both below and above the glass transition temperature. This RP establishes a reliable framework to quickly assess the mechanical properties of polymers and composites under various conditions, facilitating the qualification of new materials and technologies essential for high-risk transport, storage assets, and the energy transition.

1. Introduction

Reinforced and non-reinforced polymers have been offering an alternative to conventional material systems used by humankind from wood to stone and metals. It can be claimed that synthetic polymers made out of oil and gas since the early 20th century have been the foundation of our modern economy, enabling the emergence of consumerist societies. They have been used in consumer goods, electronics, construction, pharmaceuticals, pipelines, pressure equipment and many other applications.

One key feature of these materials compared to metals is their low reactivity to the environments they are exposed to. While corrosion has been a major challenge for metals, polymers and their products, such as composites, have been offering a way out of this challenge in industries such as water, oil and gas, and maritime.

With the age of fossil fuels approaching its end and with a dire need to decarbonize our economies, polymers and their products are key to the development of new green technologies, such as batteries, renewables, hydrogen, and carbon capture and storage.

Even though polymers do not corrode and have a low reactivity compared to metals, environmental exposures do impact them. Exposure to sunlight, water, oil and various chemicals can change their properties and their degradation. While we have extensive knowledge of the corrosion of metals, the environmental degradation of polymers and composites is still not very well understood and explored. Quantitative knowledge of the change in mechanical properties is essential for the acceptance of high-performance safety-critical applications.

Standards and recommended practices concerning the exposure and degradation of composite materials are essential for qualifying materials and determining design values in challenging environments. In addition, the industry's adoption of composites has been hindered by high testing costs, lengthy testing campaigns, and the inherent complexity of assessing composites' long-term durability under exposure. This challenge is particularly pronounced for high-risk assets such as deep-sea risers, subsea pressurized tanks, and large offshore floating fish-farming structures, where extensive test programs are necessary and where safety and reliability are paramount. There is today a pressing need for new standardized practices to ensure the efficient and reliable implementation of test programs tailored to any specific applications.

This conference paper gives a brief introduction to some of the main concepts used in the RP.

2. Core methodologies in the new RP

2.1. Organization of the RP

The RP is organized in eight main sections, as shown in Figure 1. Section 1 describes the objective and scope, as found in most standards and RPs. Section 2 describes methods to determine whether chemical interactions occur between polymers and fluid, as will be described further below. Section 3 addresses the changes of mechanical properties of polymers in the presence of temperature and a fluid. Sections 4 and 5 extend the content of Sections 2 and 3 for polymers to the case of more complicated composites.

Section 6 describes the procedure for confirmation testing, which is important from an RP point of view. Sections 2 to 4 describe theoretical procedures for predicting material performance under challenging environments. Some of the procedures are well-established, while others are relatively new. In addition, all procedures have some limits to their validity. The confirmation testing is used to show that the chosen approaches are valid for the particular polymer and fluid investigated.

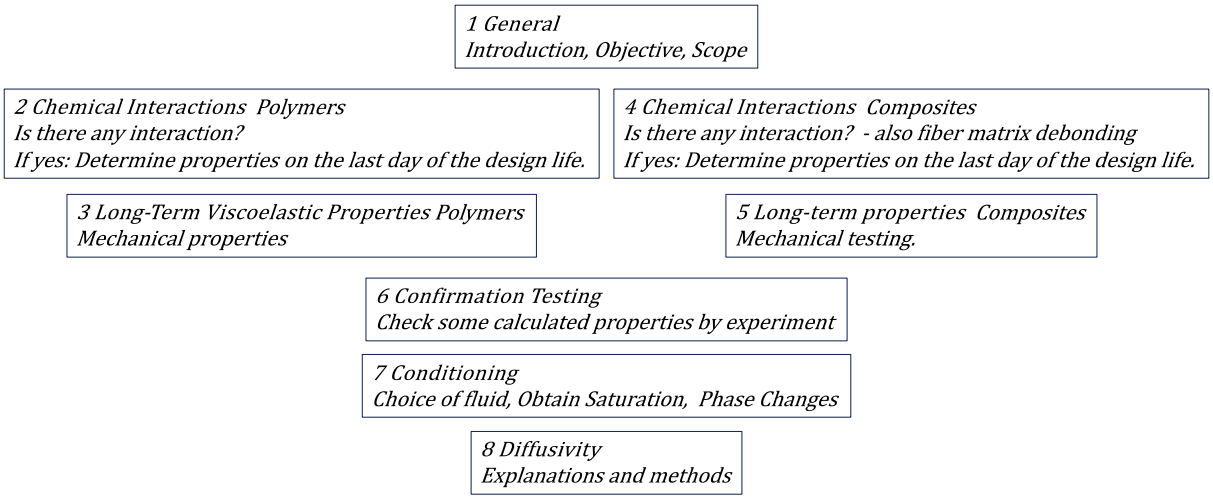

Figure 1. Organization of the recommended practice.

Section 7 describes how the test samples should be conditioned before mechanical testing is done. It describes mainly experimental details. One challenge with the conditioning is the time to reach saturation. It is important that the samples are fully saturated when being tested so that no concentration gradients of the fluid exist inside the sample. Section 8 gives some information on diffusivity, especially anisotropic diffusivity, and how saturation times can be calculated.

2.2. Chemical degradation

When a fluid diffuses into a polymer or composite, it causes swelling. The diffusion continues until the polymer is saturated, as shown in Figure 2 (blue line). This swelling changes the mechanical properties, as shown by the green line. Strength and modulus usually drop, while strain to failure would typically increase.

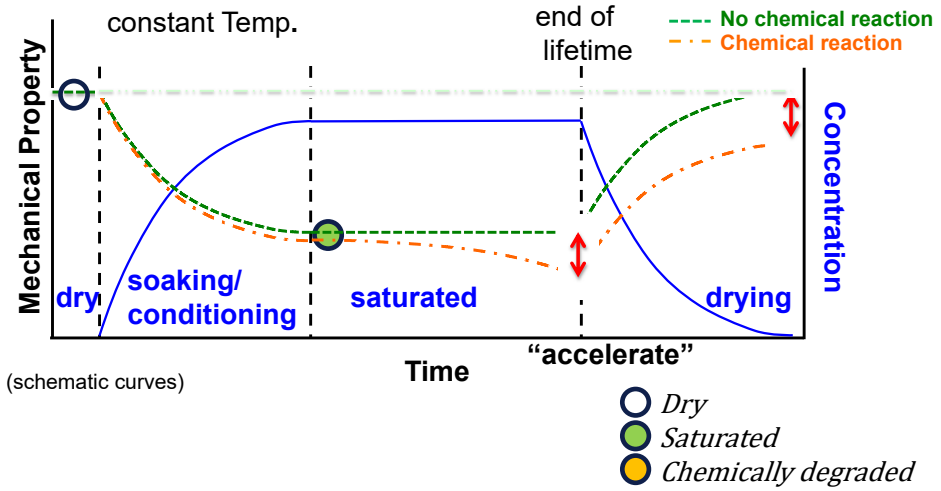

Figure 2. Schematic showing the change of a mechanical property with time due to saturating of the material with a fluid and chemical reaction with the material, from [1].

When saturation is reached, the properties no longer change if there is no chemical interaction between polymer and fluid. It is sufficient to test the material after saturation is reached, at the green point in Figure 2. Also note that if the fluid is removed, the mechanical properties change (almost) back to the original properties; the property changes are reversible.

A very different situation happens when chemical interaction happens between the polymer and the fluid. In that case, chemical bonds get broken or created. The change of properties is irreversible. The polymer continues to degrade after saturation is reached. If chemical degradation happens, the properties of the yellow dot at the end of the design lifetime need to be determined.

In most applications materials would be chosen that do not show chemical interactions with the polymer to avoid the extra degradation. It is, however, not trivial to proof that there is no chemical degradation. The RP provides procedures on how no chemical degradation can be demonstrated based on showing no change in fracture toughness characteristics within a test period of typically 1,000 to 10,000 hours, depending on the design lifetime and scatter of the test results.

If chemical degradation takes place the properties at the yellow point in Figure 2 have to be obtained in an accelerated way. The RP gives procedures on how this can be done by conditioning the sample in the fluid at higher temperatures using a modified Arrhenius approach. Mechanical properties can subsequently be measured on the conditioned/degraded samples.

The same approach described for polymers can also be used for composites. However, the RP also considers matrix fiber debonding as "chemical degradation", even though it may be caused by swelling stresses alone.

2.3. Master curves

Once the materials are conditioned for the case of chemical degradation or no degradation, the mechanical properties can be measured. The main approach in the RP is based on creating master curves according to the Arrhenius [2,3] or WLF method [4]. This method is well known. It was found that dry and saturated curves can also be superimposed on each other [5], as shown for compliance measurements in Figure 3.

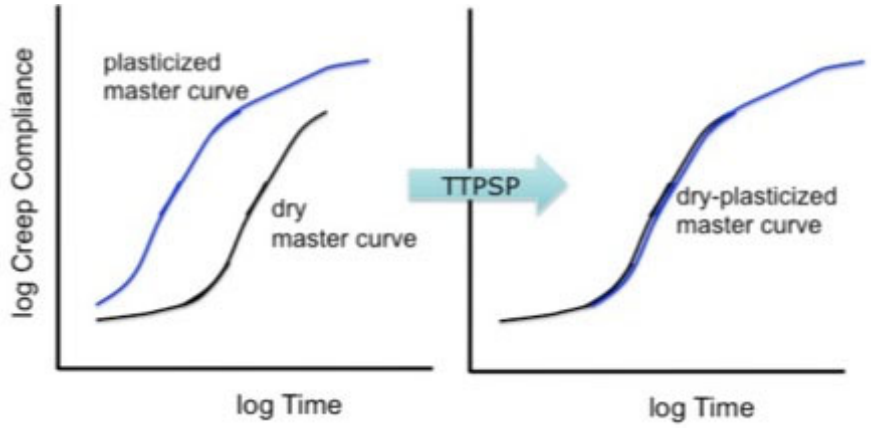

Figure 3. Schematic illustration of the Time – Temperature – Plasticization Superposition Principle (TTPSP) for the relaxation modulus from [1].

In most applications, obtaining strength over elastic properties is more important. This RP provides procedures for this, too, based on modified Arrhenius calculations or Prony series methods. Figure 4 shows cyclic fatigue SN curves of dry, wet, and re-dried epoxy. These data can easily be superimposed on a master curve [6]. Similar results were found for the interlaminar shear strength of glass fiber-reinforced epoxy [7].

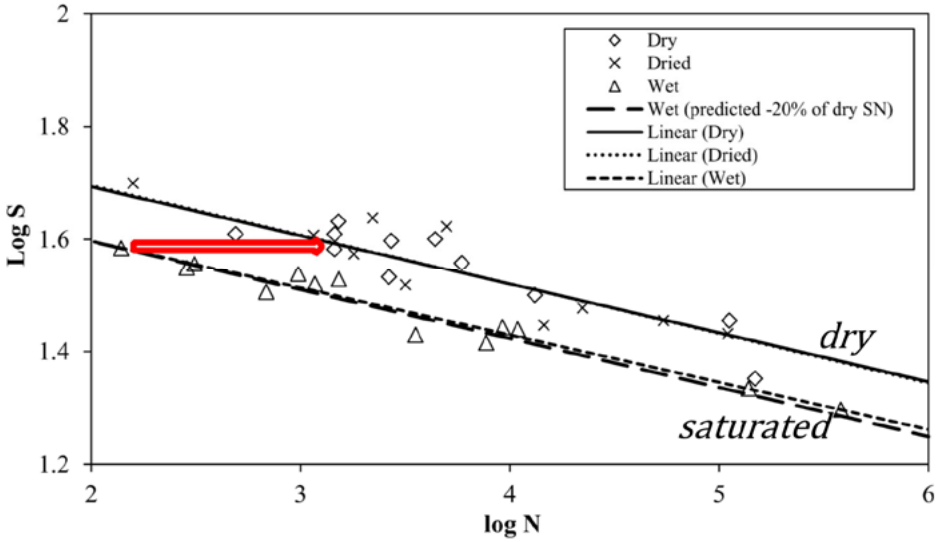

Figure 4. S-N curves of initial (dry), saturated and dried epoxy specimens. The curves can be superimposed to a master curve along the red arrow, modified from [5].

The approaches shown here are just a few examples. Other approaches could be added to the RP in the future and used for materials, provided the confirmation tests show that the approach is valid.

3. Industry examples

3.1 TCP

Thermoplastic composite pipes (TCPs) are increasingly used in subsea applications such as flowlines, jumpers, risers, and intervention lines due to their easy installation, resistance to corrosion, and versatility. However, their exposure to environmental factors presents significant challenges. The external cover of TCPs is predominantly subjected to seawater due to diffusion, while the internal laminates face various internal fluids, including both liquids and gases. These fluids can range from water and hydrocarbons to service fluids like methanol, as well as CO2 and H2, with temperatures fluctuating from a few degrees up to 120°C. The materials used in TCPs, such as HDPE, PA12, PEEK, and PVDF, along with reinforcing fibres like glass and carbon fibres, must withstand these harsh conditions. Understanding the environmental effects of seawater and internal fluids on these materials is crucial for ensuring the reliability and longevity of TCPs in demanding subsea environments.

3.2 Wind turbine roots

With the wind turbine blades increasing in size to improve efficiency and reduce the cost of wind energy, the root connections of the blades are increasingly exposed to large static and cyclic loads. These increasing loads, as well as the difficulty in sealing the root connections, leading to exposure to water and hydraulic oil, have led to a series of failures and design challenges. This has been especially the case for the leak of hydraulic oil to the root connections, leading to the softening of the thermoset resin used in the connections and a reduction in its load-carrying capacity.

3.3 Aquaculture

Aquaculture structures situated inshore or nearshore, with dimensions ranging from 40 to 60 meters, present significant economic and environmental risks due to their large sizes and high fish capacities. These structures are continuously exposed to seawater at temperatures between 0 and 30°C. They are typically constructed from conventional, low-cost thermoset composites, such as glass fibre combined with polyester or vinylester resins. While the evolution of properties of these materials is generally well understood in marine environments, and the reduction in fibre-dominated and resin-dominated properties is well documented, it is crucial to establish design allowable for these high-risk assets precisely. This involves accurate, reliable, time- and cost-efficient material properties determination, including those at the end-of-life, to be used in the design and for specific material systems to be used later in production. Moreover, the large structures are assembled using bonded or overlaminated joints, whose properties and capacities must be thoroughly evaluated to ensure reliability throughout their service life.

3.4 Deepwater H2 storage

With the emergence of green hydrogen and the need for storage of large amounts of it, concepts for storage of hydrogen offshore are gaining traction. Composite pressure vessels are popular for high-pressure hydrogen storage onshore for cars and refuelling stations and are naturally considered for offshore hydrogen storage underwater. However, the challenge of the impact of seawater on highly stressed composite materials remains to be solved. It is expected that over time, seawater will permeate through the material, impacting both the resin and fibres. However, there is limited knowledge of such interactions with the environment of subsea pressure vessels for hydrogen.

4. Conclusions

A Recommended Practice is about to be published that describes methods for analyzing polymers and composites to determine long-term properties in the presence of absorbed fluids in the material. A key issue is distinguishing reversible property changes due to fluid absorption when no chemical interaction is happening from irreversible changes when the fluid changes the chemical bonds of the polymer. Properties can be predicted based on Arrhenius and WLF methods, extended to account for fluid

interaction. The relevance and need for such an RP have been demonstrated by some industrial examples.

Keywords: magnetostrictive composite, finite element analysis, effective properties, RVE, periodic boundary condition (PBC)

Abstract
In the current research, the response of magnetostrictive composites to external magnetic fields has been investigated. The composite is comprised of magnetic particles embedded polymers, and is distinguished by their ability to undergo dimensional, elastic, and electromagnetic changes in the presence of a magnetic field. Contrasting with bulk magnetostrictive metals, such composites possess superior qualities, including high resistivity, lightweight composition, effective formability, and enhanced mechanical properties. The present study introduces a computational methodology aimed at extracting homogenised effective properties of the magnetostrictive composites, comprising of an elastic polymer reinforced by magnetostrictive particles. To achieve this, a representative volume element (RVE) is developed to model the random and repetitive heterogeneous magnetic microparticles within the polymer. Employing the finite element analysis in Abaqus, the RVE is analysed numerically, and its effective elastic and magnetic properties are extracted through the application of periodic boundary conditions (PBC). It is imperative to highlight the implementation of MATLAB and Python coding for generating randomly distributing particles within the RVE and for applying PBC. The emphasis is also made on the formulation of the PBC that allows the simulation of all modes pertaining to the spatial mechanical deformation arising from any arbitrary combination of mechanical and magnetic loading. Furthermore, investigations are carried out to study the influence of various parameters such as the volume fraction, morphology and distribution of the particles on the effective properties. To validate the numerical RVE model, its solution is compared with those derived from the analytical homogenisation method and the experimental data obtained from quasi-static uniaxial tensile testing of dogbone specimens (made of iron particles embedded polylactic acid polymers) subjected to magnetic fields. In conclusion, the comprehensive magneto-mechanical exploration offers a robust and nuanced understanding of the behaviour of magnetostrictive polymer composites for magnetic field assisted shaping (e.g. structural tailoring, novel morphing or draping during composite manufacturing) paving ways for innovative advancements, offering new avenues for exploration and technological breakthroughs in the realm of advanced magnetic composites.

1. Introduction

Magnetostrictive materials have gained significant attention due to their unique ability to alter dimensions, elasticity, and electromagnetic properties when exposed to magnetic fields. Traditionally, bulk magnetostrictive metals such as Terfenol-D have been widely studied and utilized in various applications, ranging from sensors to actuators. However, these materials often come with limitations related to flexibility and formability. To overcome these challenges, recent advancements have explored the development of magnetostrictive composites, which integrate magnetic particles within a polymer

©2024 | 3_PANTEA AFSHARI_Pantea_8WY9W .pdf

matrix. These composites present several advantages, including reduced weight, enhanced formability, and superior mechanical properties [1].
Understanding the equivalent properties of magnetostrictive composites is crucial for predicting their performance, optimizing design, and ensuring reliability in various applications. Magnetostrictive composites are heterogeneous materials composed of randomly distributed magnetic particles within a polymeric matrix. To predict the effective properties of these composites, numerical homogenization techniques based on finite element modeling (FEM) of a representative volume element (RVE) was utilized in the present work. The RVE represents the smallest region of the composite that can be considered homogeneous, effectively mirroring the overall properties of the original material. One of the major advantages of using numerical methods is the complete control they offer over the model. This allows for the application of various loads and boundary conditions, the use of different materials with different shape, size and distributions.

2. Finite element model of the magnetocomposite

In modeling the behavior of magnetostrictive composites, it is essential to understand the governing equations that describe the material's response to magnetic fields and mechanical stress. Magnetostrictive materials exhibit a nonlinear coupling between magnetic and elastic behavior. This nonlinear magnetostriction arises due to the dependence of the strain in the material on both the applied magnetic field and mechanical stress. However, under certain conditions, this complex nonlinear behavior can be approximated by linear relations.When the response of the magnetostrictive material involves only small deviations around an operating point, also known as a bias point, the nonlinear interactions can be effectively represented using linear coupled constitutive equations. This simplification is particularly useful for practical engineering applications, where it is often sufficient to consider the material's behavior near a specific working condition rather than over its entire operational range.
In this linear approximation, the magnetostrictive effect can be described by piezomagnetic relations. These relations are the linear counterparts to the nonlinear magnetostrictive effects and provide a manageable framework for finite element modeling. The piezomagnetic equations couple the mechanical and magnetic fields in a way that is analogous to the piezoelectric effect in electro-mechanical systems [2]. They can be expressed as:

$$\begin{aligned} \mathbf{S} &= c_{\mathrm{H}}\varepsilon - e_{\mathrm{HS}}^{T}\mathbf{H} \\ \mathbf{B} &= e_{\mathrm{HS}}\varepsilon_{\mathrm{el}} + \mu_0\mu_{\mathrm{rS}}\mathbf{H} \end{aligned} \tag{1}$$

where $\mu 0$ is the magnetic permeability of free space; c_H is the stiffness matrix; and μr_S is the relative magnetic permeability measured at constant strain and constant stress, respectively. The matrix e_{HS} is called piezomagnetic coupling matrix.

2.1. Distribution of Particles within an RVE

In the present study, a MATLAB code is employed to generate the Representative Volume Element (RVE). The random sequential adsorption (RSA) algorithm is utilized to position the inclusions within the RVE [3]. This algorithm introduces particles randomly into the RVE and adsorbs them into the system if they do not overlap with previously adsorbed particles.
The RSA algorithm operates iteratively, beginning with the creation of an inclusion particle within the unit cell. This process is repeated until the desired volume fraction is achieved. Each particle is randomly assigned a position within the unit cell. The algorithm then checks whether the new particle's location overlaps with any previously placed particles. If there is no overlap, the particle is accepted and incorporated into the RVE; if overlap occurs, the particle is discarded, and the search for a new particle position begins again.
Furthermore, to ensure that the RVE exhibits periodicity, the algorithm accounts for particles that may overlap with the boundaries of the unit cell. If a particle overlaps with one or more boundaries, it is replicated on the opposite faces of the unit cell to maintain periodicity. This approach ensures that the microstructure of the RVE accurately represents the infinite material and allows for the correct application of periodic boundary conditions during finite element analysis.

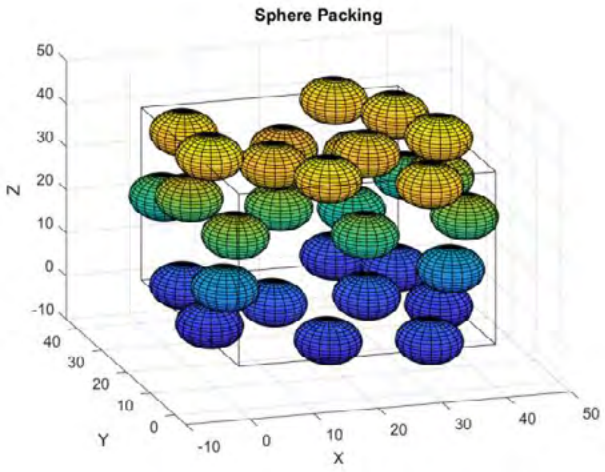

Figure 1. Representative Volume Element congaing randomly distributed spherical inclusions ($v_f = 0.25$)

2.2. Boundary Conditions

Composites can often be represented as a periodic array of RVEs or unit cells. To accurately simulate the responses of these composites, periodic boundary conditions (PBC) are applied [4]. The application of PBC ensures that the deformation mode remains consistent across the RVE and prevents interpenetration and separation between neighboring RVEs.

To implement periodic boundary conditions in ABAQUS, specific equations must be defined for each pair of nodes on opposite surfaces of the RVE. This process involves two key steps:

1. **Equal Meshing Pattern**: The meshing pattern on opposite surfaces of the RVE must be identical. This ensures that corresponding nodes on opposing faces can be correctly paired and constrained.
2. **Constrain Nodes by Periodicity Equations**: Once the meshing pattern is established, periodic boundary equations are applied to constrain all nodes on opposite surfaces. These equations ensure that the displacement and traction at each node on one surface are matched by the corresponding node on the opposite surface, maintaining periodicity.

The periodic boundary equation can be expressed as follows

$$u_i^{K^+} - u_i^{K^-} = \bar{S}_{ij}(x_j^{K^+} - x_j^{K^-}). \tag{2}$$

Where u is displacement and S is average strain tensor.

Since applying these constraints manually to each pair of nodes is impractical, they are implemented using Python scripting in ABAQUS. The next step is finding the averaged properties .

2.3. Calculation of Effective Properties

This section explains the calculation of the effective properties. We assume that the average mechanical and magnetic properties of our RVE are equivalent to those of a magnetic composite, as illustrated in Equation 3.

$$\langle T_{ij} \rangle = \overline{T_{ij}}, \quad \langle D_k \rangle = \overline{D_k}, \quad \langle \mathrm{H}_k \rangle = \overline{\mathrm{H}_k}, \quad \langle \mathrm{B}_k \rangle = \overline{\mathrm{B}_k}, \tag{3}$$

These average values can be defined as in Equation 4.

$$\overline{T_{ij}} = \frac{1}{|V|}\left(\int_V T_{ij}\, dV\right), \quad \overline{S_{ij}} = \frac{1}{|V|}\left(\int_V S_{ij}\, dV\right)$$
$$\overline{\mathrm{B}_i} = \frac{1}{|V|}\left(\int_V \mathrm{B}_i\, dV\right), \quad \overline{\mathrm{H}_i} = \frac{1}{|V|}\left(\int_V \mathrm{H}_i\, dV\right) \tag{4}$$

These calculations are repeated for every element or integration point in the FE model. In ABAQUS, the volume of the integration points can be requested. By multiplying the field values at each integration point by the corresponding integration point volume and summing these products, the total value is obtained. This total value is then divided by the total volume of the RVE, resulting in the average value of the property for the RVE.

3. Results and Discussion

In this research, Terfenol-D particles were chosen as inclusions within the polymer matrix to study the magnetostrictive behavior of the composite. Terfenol-D, known for its high magnetostrictive properties, was selected to enhance the composite's performance. The particles used in the study had a size of 10 micrometers.

The effective properties of the composite were determined for various volume fractions of Terfenol-D particles. To achieve this, different load cases were defined, and periodic boundary conditions were applied to the RVE in ABAQUS to simulate the material's response accurately. The periodic boundary conditions ensured that the deformation and stress distribution within the RVE correctly represented the behavior of an infinite composite material.

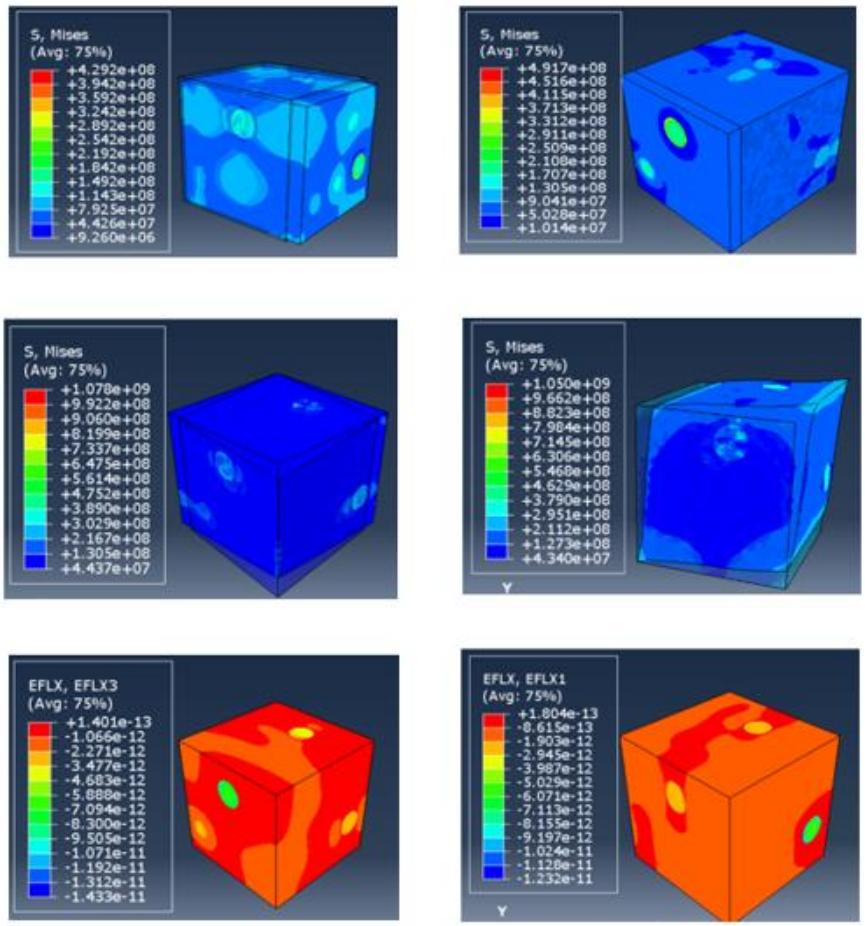

Figure 2. Different load cases defined for finding effective properties (v_f =0.1)

4. Conclusions

This research focused on determining the effective properties of magnetostrictive composites with Terfenol-D particles as inclusions. Through numerical homogenization techniques using finite element modeling, we analyzed the composite's behavior for different volume fractions of the particles. As expected, increasing the volume fraction of Terfenol-D significantly enhanced the magnetic properties of the composite. However, it was also observed that excessively high volume fractions led to increased stiffness, thereby reducing the composite's flexibility. These findings highlight the importance of

balancing magnetic performance with mechanical flexibility in the design of magnetostrictive composites. This research is currently undergoing further investigation to optimize the material properties for specific applications and to explore additional aspects of the composite's behavior under varied conditions.

Keywords: Structural biocomposite, Flax fibre reinforced polymer composite, Creep, Fatigue, pre-straining

Abstract
Synthetic fibre-reinforced polymer composites (FRPs) have long been favored in structural engineering for their exceptional mechanical properties. However, their environmental impact due to energy intensive manufacturing, and disposal has prompted exploration into sustainable biobased alternatives such as flax FRP composites (FFRPs). While using flax fibres as composite reinforcement has lightness and damping benefits from a structural point of view, it also introduces design challenges as the complex microstructure of flax fibres and flax FRPs induces a more viscoelastic fatigue response. Therefore, pre-straining and pre-creeping are proposed in this study as simple methods to improve fatigue performance by taking advantage of alignment mechanisms intrinsic to flax fibre and yarn microstructure. An experimental campaign was conducted on $[0/90/0]_S$ flax FRP laminates (hence, predominantly UD) to compare the tension-tension fatigue performance of reference specimens to pre-strained and pre-creeped specimens. It was observed that pre-straining and especially pre-creeping are effective at improving FFRPs fatigue performance with significant increase in fatigue life, increase in dynamic modulus, and decrease in accumulation of deformation (ratcheting).

1. Introduction

In the pursuit of peak performance in structural engineering, synthetic fibre-reinforced polymer composites (FRPs) have emerged as promising materials in multiple contexts, offering simultaneously high specific stiffness, and high specific strength along with design freedom. Currently, glass and carbon fibres dominate reinforcement of FRP composites for structural applications. While offering attractive mechanical properties, using synthetic fibres in large quantities is harmful to the environment as the production of those fibres consumes a large amount of energy and deplete non-renewable resources. Additionally, disposing of or incinerating synthetic FRP materials at the end of their lifespan causes environmental harm, and recycling them poses challenges. Consequently, numerous researchers and industries are exploring biobased FRPs as an alternative to synthetic FRPs where strong natural fibres such as flax are used as reinforcement instead of synthetic fibres, particularly glass fibres.

Elementary flax fibres have a complex microstructure mainly composed of cellulosic microfibrils [1] and those microfibrils are not naturally aligned with the axis of the flax fibres [2]. Coincidentally, cyclic

mechanical testing on single elementary fibres reveals a non-linear and viscoelastic behaviour with a peculiar increase of modulus [3], [4] suggesting that an alignment of the microfibrils occurs during loading. Direct observations of microfibrils angles during mechanical loading revealed that an alignment indeed occurs, however, the change of microfibrils angle is small and therefore unlikely to have a significant impact on the composite properties. Adding to the complexity of understanding the mechanics of flax FRP composites (FFRPs), flax fibres preforms utilized for manufacturing are often made of yarns in which a degree of twist is applied on the elementary flax fibres. This twist angle of the elementary fibre with respect to the yarn axis and the loading axis of the composite may again lead to alignment mechanisms upon loading but at a different scale due to unravelling of the twist [5].

Regardless of the exact mechanisms behind the viscoelasticity of flax fibres and its composites, this material must meet safety and serviceability requirements to be utilized in structural applications. In particular for fatigue applications, the fatigue life, stiffness (modulus) degradation, and accumulation of permanent deformation (ratcheting) must be within limits for structural design. Currently available results of FFRPs fatigue tests show that in predominantly UD laminates ratcheting is significantly larger than in glass FRP composites and that the modulus increases during fatigue while it decreases in glass FRPs [6].

In this paper we present two novel and yet simple methods aiming at improving the fatigue performance of FFRP composites by taking advantage of their intrinsic viscoelasticity and related alignment mechanisms within their intricate multi-scale microstructure. To demonstrate the effects of those two methods, namely pre-straining and pre-creeping, a fatigue experimental campaign was performed on $[0/90/0]_S$ FFRP laminates. Pre-strained and pre-creeped specimens were subjected to the same force-controlled tension-tension fatigue as reference specimens to measure the effects of the proposed methods. Results show that both methods are beneficial for fatigue performance, pre-creeping in particular.

2. MATERIALS AND METHODS

2.1 Composite laminates

In this study, the FFRP laminate employed is a 2.8 mm thick coupon with a narrow central cross-section and a wider cross-section towards the grips, as illustrated in figure 1, to prevent failure at the clamps' edges during fatigue testing which was observed in preliminary testing with rectangular coupons. Strain measurements are obtained using an extensometer in the narrow cross-section. The FFRP laminate comprises six layers of Bcomp quasi-unidirectional flax mat Amplitex, with an aerial weight of 280 g/m^2, stacked in a $[0/90/0]_S$ lay-up configuration. The choice of this lay-up configuration was driven by the aim to examine the mechanical behavior of flax fibers under loading along their primary axis, necessitating the inclusion of 0° layers. Although a strictly unidirectional lay-up was initially considered, preliminary testing showed susceptibility to fatigue-induced splitting in such specimens. Consequently, 90° layers were introduced to mitigate the occurrence of splitting phenomena.

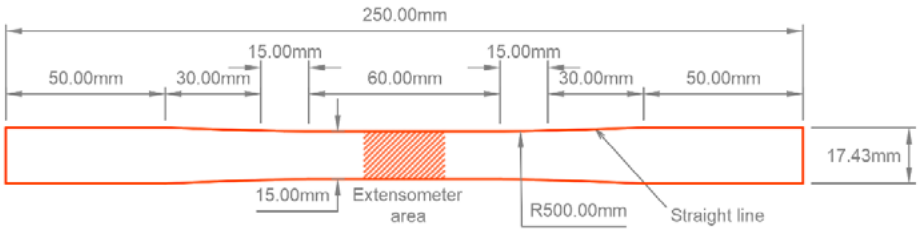

Figure 1. Specimen geometry.

FFRP plates were manufactured using a vacuum-assisted resin infusion process using the Swancor 2511-1 resin epoxy system. The infusion was followed by an 18-hour post-cure in an autoclave set at 70°C and 7 bars of pressure. Subsequently, the plates underwent cutting into test coupons utilizing a waterjet cutter. To ensure the completion of resin curing, a differential scanning calorimetry (DSC) analysis was conducted after the manufacturing process. This involved subjecting the specimens to three heating/cooling cycles between 0°C and 150°C, The midpoint of the stepwise change in the heat flow versus temperature curve in the first and third thermograms were measured to ascertain that the glass transition temperature (Tg) did not deviate by more than 3°C. Optical microscopy was employed to qualitatively assess the microstructure of pristine specimens, ensuring the absence of cracks or manufacturing defects/voids significant enough to impact fatigue damage. The fibre volume fraction was estimated at 42% based on calculations considering the density of the fiber mats, epoxy resin, and composites.

2.2 Pre-straining and pre-creeping protocols

For the experimental campaign, specimens were placed in an MTS 60 kN fatigue machine equipped with hydraulic grips (figure 2). An extensometer was attached to the specimens with rubber bands to measure the strain. As testing was not performed in an environmentally controlled environment, a thermocouple was installed to capture air temperature at proximity of the specimen and another thermocouple was installed on the specimen to measure its surface temperature.

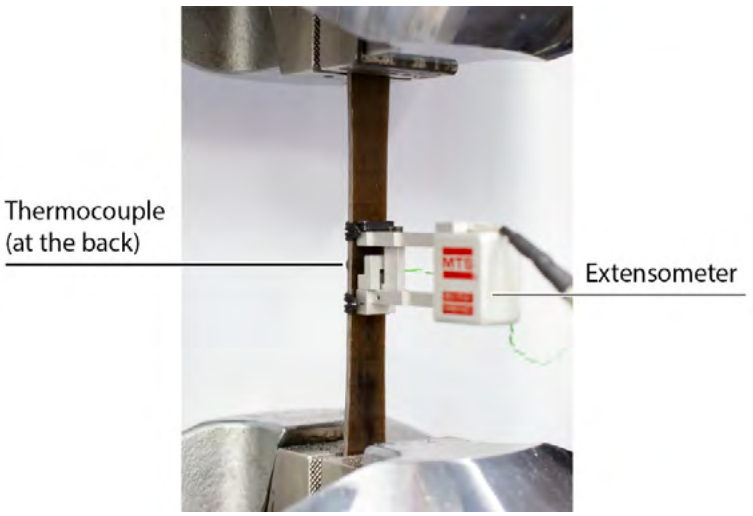

Figure 2. Tensile testing setup.

Loading prior to fatigue for the reference, pre-strained, and pre-creeped specimens are described in figure 3. All the loading and unloading were performed at a rate of 2 mm/min except for the pre-creeping plateau during which a constant force corresponding to the maximum fatigue load was maintained until a strain of 1.6% was reached.

The maximum stress reached during pre-straining corresponds to 80% of the material ultimate tensile strength (UTS). The start of fatigue testing, at the mean fatigue stress, is indicated by a star for each case in figure 3.

2.3 Fatigue testing protocol

Tension-tension fatigue tests were carried out under force control mode, employing a loading ratio (R) of 0.1 and a frequency of 5 Hz. The maximum fatigue load was set at 133 MPa corresponding to 60% of the UTS determined by quasi-static tensile testing at a loading rate of 2 mm/min. In the fatigue testing,

the data pulling was set such that 50 data points were recorded every cycle for the first 500 cycles and then 1 cycle was recorded every 1'000 cycles.

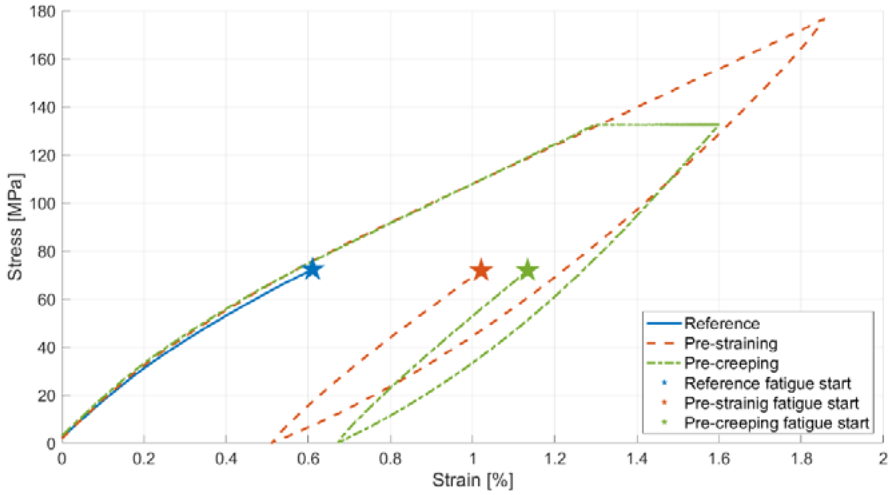

Figure 3. Depiction of pre-straining, pre-creeping and quasi-static ramp protocols before fatigue.

3. Results and discussion

Tests results were obtained with 3 repetitions for each fatigue case studied; reference, pre-straining, and pre-creeping symbolized by different colors. As the machine did not instantly reach the targeted fatigue force, all the analysis take the 10^{th} cycle as reference from which the minimum and maximum force remained constant.

3.1. Effect of pre-straining and pre-creep on the evolution of the dynamic modulus during fatigue

The dynamic modulus is defined here as the slope of the line connecting the top and bottom points of the hysteresis loop in a stress-strain graph. Figure 4 shows that the dynamic modulus as a general tendency to increase during fatigue but pre-straining and especially pre-creeping mitigate this increase in dynamic modulus. Furthermore, the dynamic modulus of pre-creeped specimens is significantly higher than the dynamic modulus of reference specimens and this throughout the entire fatigue life.

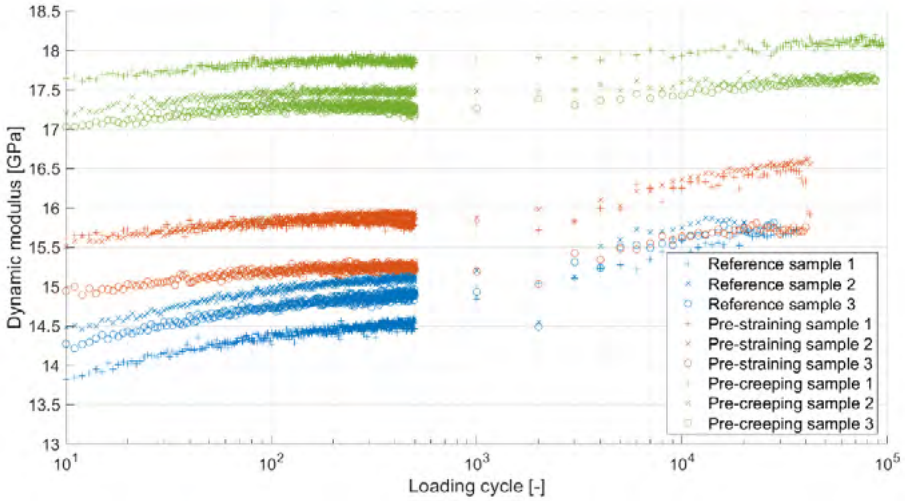

Figure 4. Effect of pre-straining and pre-creeping on dynamic modulus.

3.2. Effect of pre-straining and pre-creep on ratcheting

Ratcheting refers to an the incremental plastic strain accumulation during fatigue. Therefore, ratcheting is generally undesirable for structural applications as it creates significant deformation over the long-term. Here ratcheting is computed by measuring the shift in strain at the bottom of each hysteresis loop relative to the strain at loading cycle 10. Figure 5 shows that the ratcheting in the reference fatigue testing can be mitigated by the application of pre-straining. Furthermore, pre-creeping almost completely eliminates ratcheting and tends to a perfectly elastic behaviour with ratcheting values remaining below 0.05% strain for the entirety of the fatigue life.

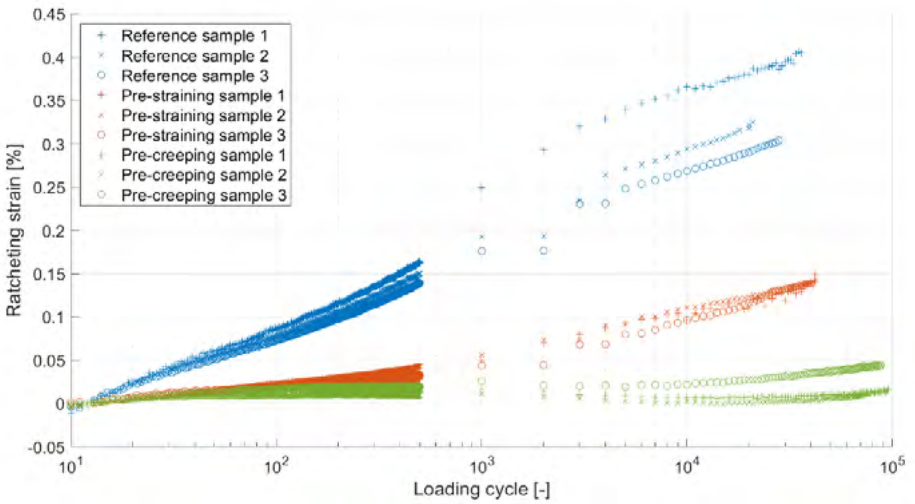

Figure 5. Mitigation of ratcheting with pre-straining and pre-creeping.

3.3. Ratio of inelastic work over total work

The ratio of inelastic work over total work is computed for individual loading cycles by dividing the area inside of the hysteresis loop by the area inside of the hysteresis loop plus the area below the hysteresis loop [7]. Figure 6 shows that this work ratio is decreasing during the entirety of the fatigue life indicating that most of the fatigue damage accumulation occurs towards the beginning of the fatigue life. The ratio is reduced by applying pre-straining or pre-creeping suggesting that less damage is accumulated at each loading cycle.

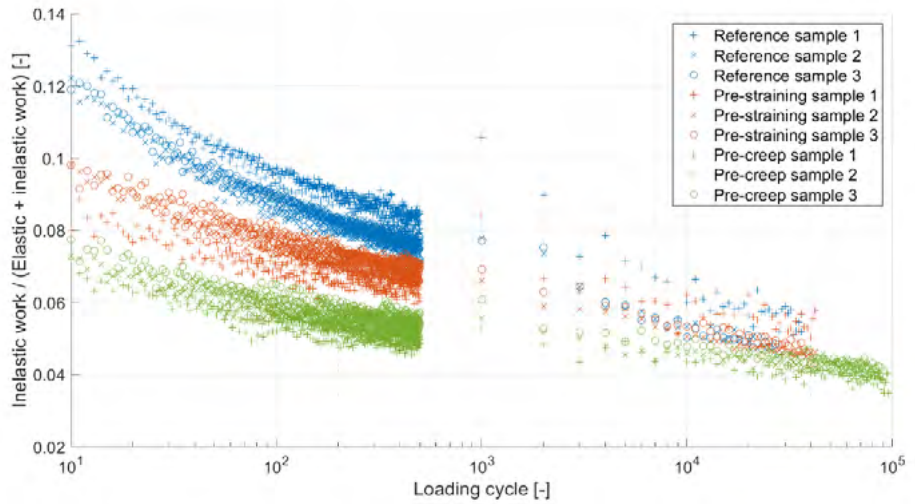

Figure 6. Effect of pre-straining and pre-creeping on the ratio of inelastic work over total work. The ratio is computed for individual loading cycles.

3.4 Effect of pre-straining and pre-creeping on fatigue life

Fatigue life results in figure 7 show that the pre-straining and pre-creeping methods have a significant impact on fatigue life. Pre-straining increases fatigue life by a factor of 1.3 compared to the reference specimens and remarkably pre-creeping increases the average fatigue life by a factor of 3. The comparatively large effect of pre-creeping compared to pre-straining highlights the importance of loading rate and viscous effects in FFRP composites. Given an alignment hypothesis, pre-creeping has a surprisingly significant impact, especially considering that the maximum strain achieved during pre-creeping is less than that reached during pre-straining.

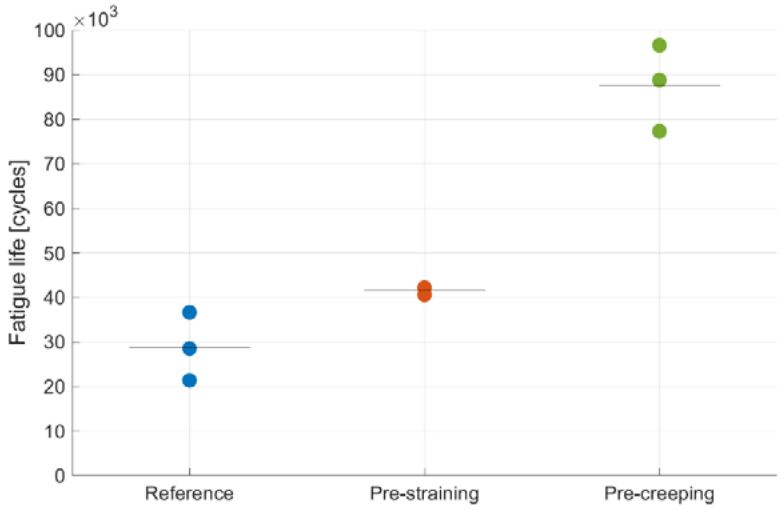

Figure 7. Effect of pre-straining and pre-creeping on the fatigue life .

3.5. Effects of temperature

Analysis of the recorded temperature during fatigue reveals that the air temperature in proximity to the specimen remained relatively constant at 22°C ± 2. However, the surface temperature of the specimen increased by up to 10°C between the first and the 2'000th loading cycle (figure 8) likely due to the 5 Hz testing frequency and associated dissipation of energy. Then, temperature slowly decreased during fatigue until final failure at which point the surface temperature was about 3°C lower than at cycle 2'000.

Assuming that the stiffness of FFRPs is sensitive to temperature [8], the temperature profile in figure 8 can be used to explain the different dynamic modulus trends at the beginning and end of life in figure 4. Furthermore, at cycle 2'000 the temperature peaks indicating the equilibrium between the heat generated by the specimen deformation and the heat of the specimen dissipated to its environment due to the temperature gradient. Since the temperature decreases after 2'000 cycles, it suggests that either less heat is generated by the specimen deformation or more heat is dissipated to the environment. The decrease of the inelastic work/total work ratio observed in figure 6 is in agreement with the hypothesis that less heat is generated by the specimen deformation of every next cycle.

Additionally, the uncontrolled air temperature affected the repeatability of pre-creeping even with a ±2°C variation. Since the end of pre-creeping was defined with a strain limit, the ambient temperature variation from run to run affected the repeatability of the pre-creeping duration by affecting the stiffness of the FFRP composite [8]. Combined with sample to sample variation it resulted in the shortest pre-creeping lasting 5 hours and the longest 15 hours.

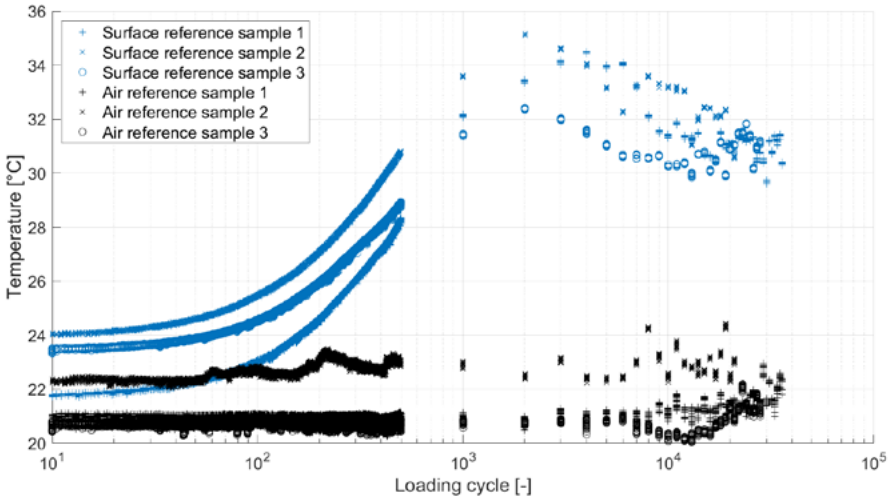

Figure 8. Comparison of the air temperature and the specimen surface temperature during fatigue

4. Conclusions

In this study, we presented a novel way of improving fatigue performance of structural flax fibre reinforced polymer composites. To this aim, we delved into the effectiveness of pre-straining and pre-creeping as methods for improving the fatigue performance of predominantly UD biobased FRP by taking advantage of the alignment mechanisms intrinsic to flax FRP composites. The main conclusion is that both methods, pre-straining and pre-creeping, have beneficial effects on the tension-tension fatigue performance of flax FRP composites with pre-creeping being the most effective.

The comparison of results of pre-strained and pre-creeped specimens highlighted the FFRPs mechanical response time dependency or viscoelasticity. Indeed, across all measured metrics - fatigue life, dynamic modulus, ratcheting - pre-creeping exerted a larger effect than pre-straining despite pre-straining inducing a higher maximum strain prior to fatigue. This implies that the loading rate plays a crucial role in any alignment mechanism occurring within flax FRP composites. By extension, the choice of the testing frequency is also susceptible to affects the fatigue response due to viscoelasticity. Additionally, flax FRPs were found to be sensitive to the temperature elevation generated by the 5 Hz testing frequency.

Keywords"As-built" Simulation, Process simulation, Mapping, FEA, Structural simulation, Diaphragm forming process

Abstract
This paper presents a structural "as-built" simulation of carbon fiber reinforced plastics (CFRP) manufactured in the diaphragm forming process, emphasizing the importance of accounting of process-induced effects for a more accurate prediction of the mechanical behavior. The study expands an existing draping simulation with a curing simulation and links it to an "as-built" structural analysis of a 3-point bending test. By transferring residual stresses, fiber orientations, and deformations from the process simulation to the structural simulation, a more precise depiction of manufacturing conditions were achieved. The results of the "as-built" simulation are validated against physical 3-point bending tests and compared to an "as-designed" simulation to highlight the impact of "as-built" characteristics. The methodology introduces an approach for transferring field quantities between simulation steps, utilizing a material point ID system and a mapping module developed in Python. The findings emphasize the need to consider process-induced effects such as folds and deviations, which influence damage initiation and progression in CFRP structures. The study concludes that "as-built" simulations align more closely with experimental observations compared to "as-designed" simulations, but further research is required to refine material parameters for damage behavior and improve simulation accuracy.

1. Introduction

To fully harness the potential of carbon fiber reinforced plastics (CFRP), it is crucial to find optimized, yet reliable designs. However, designing with CFRP poses challenges due to the inherent inhomogeneity, anisotropy, and process-induced effects and defects. Iterative product and process optimization, with loops of prototyping and testing, results in expensive and time-consuming part development [1]. Accounting for unknown inhomogeneities with generous safety factors further diminishes the lightweight potential. Process simulation is a common tool to overcome these challenges. By linking process simulations with structural simulations, an 'as-built'-simulation, accounting for process-induced effects, can be realized. Depending on the required level of detail, various process-induced effects can be used to model the 'as-built' characteristics. Residual stresses, local fiber orientations and macroscopic deformations are, among other effects, the most critical aspects for the structural performance of the part. By accurately modeling these effects, the presented approach aims to represent the manufacturing conditions. Furthermore, it can reduce development time and cost in processes, such as the depicted diaphragm forming process [2], [3], [4]

The diaphragm forming process is a cost-effective manufacturing process for CFRP that utilizes a single tool to create complex shapes. This makes it highly suitable for automated manufacturing, offering great potential for efficient and streamlined production processes[5], [6]. However, the complex interactions

between tools, materials, and process parameters can lead to significant deviations between the designed and the manufactured part [7].

In this study, an existing draping simulation of the diaphragm forming process, was extended with a curing simulation and further linked with a structural 'as-built' analysis of the 3-point bending test. This was done by transferring process-induced residual stresses, local fiber orientation and global deformations from the process simulation to the structural simulation. The results from this "as-built"-structural simulation were compared to the results of a 3-point-bending test of manufactured specimens and an "as-designed" simulation of the test. The simulation platform Abaqus 2019 with the Compro plug-in was used for the simulations.

2. Methods

2.1. Experimental Set-up

The "as-built "-simulation is a virtual model of the 3-point-bending test of a c-section part manufactured in the single diaphragm forming process. The part is stacked from three layers (90°, 0°, 90°) of unidirectional carbon fiber prepregs with a low temperature curing epoxy resin (*HexPly® M79/34%/UD300/CHS*). This stack is then positioned beneath the membrane of the diaphragm forming machine and draped over an aluminum tool geometry using vacuum pressure. After draping, the part is cured at 120°C for 19 minutes and cooled down for 25 minutes without vacuum pressure. The temperature and pressure curve during the process and the final part and tool geometry are shown in Figure 1.

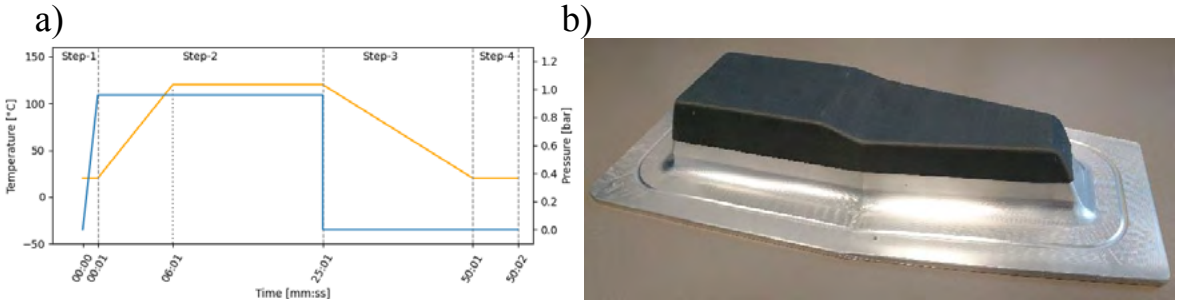

Figure 1: a) Temperature (orange) and vacuum pressure (blue) during process cycle where Step-1 represents draping process, Step-2 to Step3 curing and Step-4 demolding and b) final part and tool geometry

To validate the mechanical behavior and "as-built" (AB) characteristics the final part was tested in a 3-point bending test. Digital image correlation (DIC) was used to measure the strain distribution during the test. The setup of the 3-point-bending test and the corresponding dimensions are shown in Figure 2 a) and b) respectively.

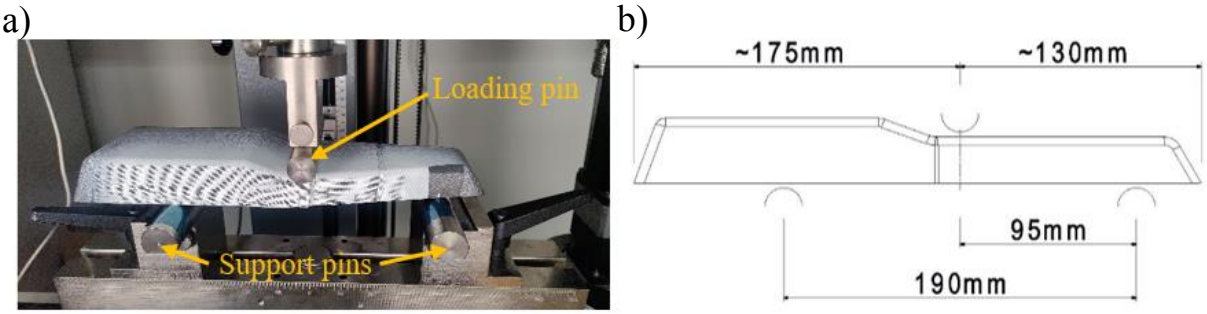

Figure 2: 3-point-bending test of a structural c-section part with DIC pattern and corresponding dimensions of the part, load and support pins.

2.2. Transfer of Field Quantities

In this work we transferred the deformed geometry, residual stresses, and local fiber orientations to link the simulation steps. Because continuum and shell elements were used in the simulation chain a method to transfer field quantities from conventional shell to continuum solid elements and vice versa was developed.

To account for process-induced deformations, the deformed mesh from the previous stage was used as a starting point for the next process stage. To change between element types the source mesh was thickened to generate solid elements or generating an off-set surface from solid elements to create a mesh with shell elements [8]. This operation can be done in *Abaqus CAE* and is shown in Figure 3.

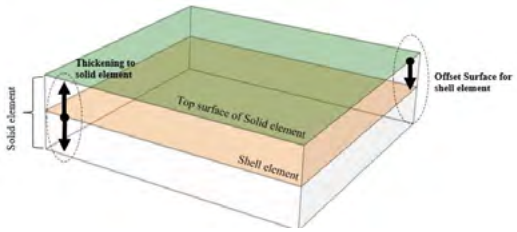

Figure 3: Visualization of thickening shell surface to solid element and offset surface from top surface of solid element to create shell element

Beside interpolation methods [9] we used a material point ID to transfer the field quantities. In Abaqus the material points of solid and shell elements with composite sections have identical coordinates (see Figure 4). Therefore, a material point identification numbering was introduced, which is composed of the element-, integration point-, layer- and section point-number. This is a fast and accurate method but can only be applied if the element basis does not change between simulation stages.

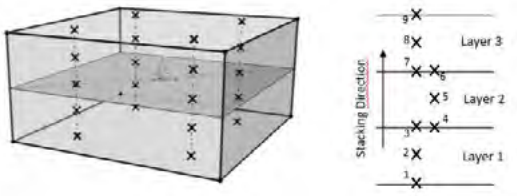

Figure 4: Material points of shell and solid elements with composite sections (left) and layer and material point numbering (right).

A 5-dimensional array is created to transfer stresses:

$$Array[E, IP, L, SP, 1{:}6] = [S_{11}, S_{22}, S_{33}, S_{12}, S_{13}, S_{23}]$$

and local fiber orientations:

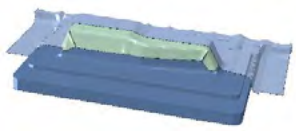
$$Array[E, IP, L, SP, 7{:}12] = [e_{1x}, e_{1y}, e_{1z}, e_{2x}, e_{2y}, e_{2z}]$$

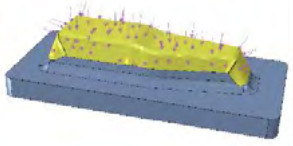
, where *E, IP, L, SP* refer to the element-, integration point-, layer- and section point-number, S_{xx} to the stress component in corresponding direction and *e1* and *e2* to the longitudinal and transversal fiber direction.

To automate the mapping process the mapping routine was implemented in a python module. By providing the file and instance name of the source data and the model and instance name of the target

model the routine automatically reads the data from the *Abaqus* output-file and writes them to a csv-file. The data can then be read from the user subroutine UEXTENALDB and will be provided for SIGINI and ORIENT user subroutine to transfer stresses and local fiber orientation, respectively.

2.3. "As-built" Simulation





To capture the AB characteristics of the proposed c-section part (c.f. 2.1) and to provide practical computation time, the process simulation was divided into a macroscopic draping and curing simulation.

To model the uncured draping behavior of the prepregs the Abaqus FABRIC* material model can be used. This approach was proposed by [10], where they characterized the rate dependent in-plane tension, compression, bending and shear behavior of the M79 prepreg and demonstrated the applicability of this model.

The CHILE material model, implemented in the Compro Plug-In was used to model the curing behavior. This model requires solid elements to model the thermal and chemical shrinkage of the resin[11]. The cure kinetics and material parameters of the M79 prepreg were determined in a previous work [12] and were used for this model.

Finally, the results from the process simulation were used as a starting point for the structural simulation of the 3-point-bending test. A linear-elastic material model with the Hashin damage criteria and energy-based damage evolution law was used. The parameter for strength and fracture toughness were used from [13] where similar elastic properties to the M79 prepreg where used. In Table 1 the simulation stages of the process and AB simulation are summarized.

Table 1: Simulation stages of the process and "as-built" simulation

	Draping	Curing	3-point-bending
Material Model	*FABRIC	CHILE from Compro Plug-In	Linear-elastic, Hashin damage criteria, linear damage evolution
Element type	S4	C3D8	S4
Element size	3mm	3mm	3mm
Model	Dynamic, explicit	Standard & Explicit	Standard & Explicit
			

3. Results and Discussion

In Figure 5 left the reaction forces of the loading pin from the bending tests are shown. Almost linear-elastic behavior can be observed until 1.5-2mm displacement of the loading pin. After reaching 2mm displacement the slope begins to decrease indicating degradation. At 7mm displacement the maximum load capacity is reached, and the structure fails. At this point a crack at the bottom of the part underneath the loading pin appears, which can be seen in Figure 5 right from the DIC evaluation of the strain field.

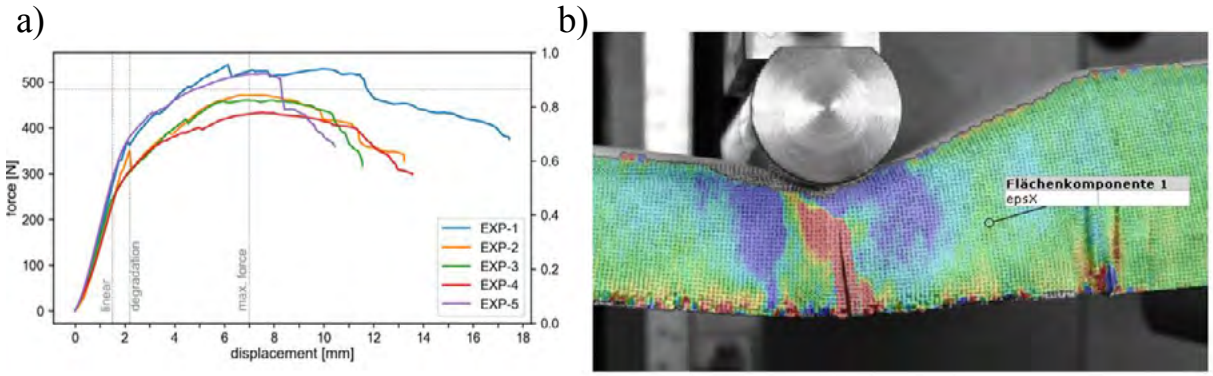


Figure 5: a) Force-displacement curves of bending test and b) DIC evaluation of strain distribution in transvers direction

By using the proposed method from section 2.2 for transferring field quantities, stresses and local fiber orientations can be transferred without errors. In ***Figure 6*** the results from a mapping procedure are visualized by a heat map of the part (left) and the stress distribution through thickness of an element at integration points from an source and target element (right). These results show that flawless transfer of the stresses from source to target has been achieved.

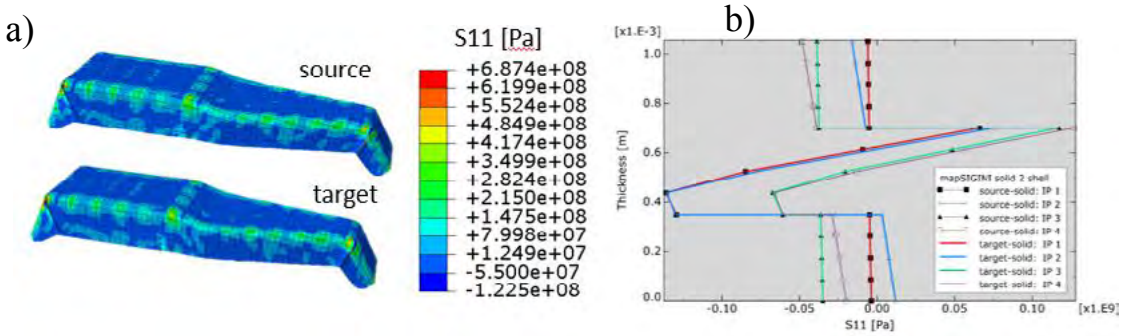

Figure 6: a) Heat map of S11 of source and target mesh from mapping procedure and b) stress distribution over thickness at integration points from source element (points) and target element (lines).

In Figure 7 the Hashin matrix tension criteria (MT) is plotted for an “as-designed” (AD)-simulation a), where no process-induced effects where included and three AB models b) - d). The “as-built”- models differ in mesh size and the presence of darts in the corners. By comparing the region where MT occurs in the models it can be observed that in the AD model the MT criteria initializes under the loading pin (Region 2 in Figure 7). Whereas in the “as-bulit” models the criteria initialize under the profile tapering of the c-section (Region 1 in Figure 7). This is because a fold developed during the process simulation and therefore shifts the area of damage. Furthermore, their is apparent that the fold is more pronounced with the 3mm mesh size, resulting in higher stress concentration.

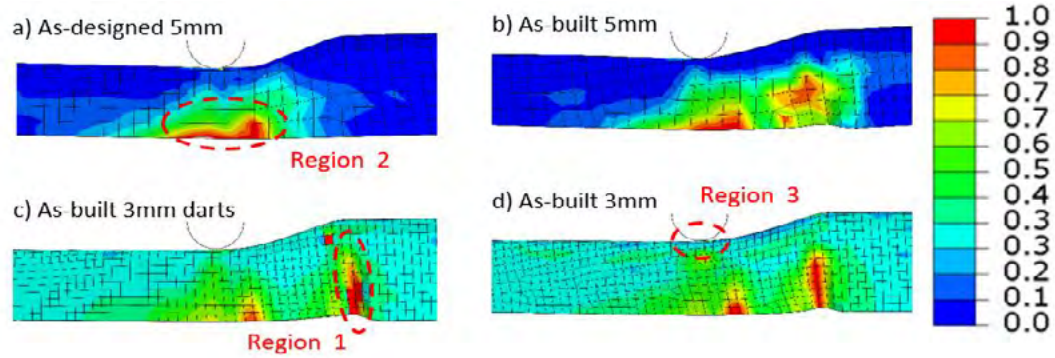

Figure 7: Initial Hashin criteria in fiber tension for "as-designed" and "as-built" simulations.

This fold could also be observed in the experiments but occurs as a smaller double waved fold (***Figure 8*** top). A much smaller mesh size would be required to reproduce this fold. However, comparing the areas of the strain distribution, good results can be observed.

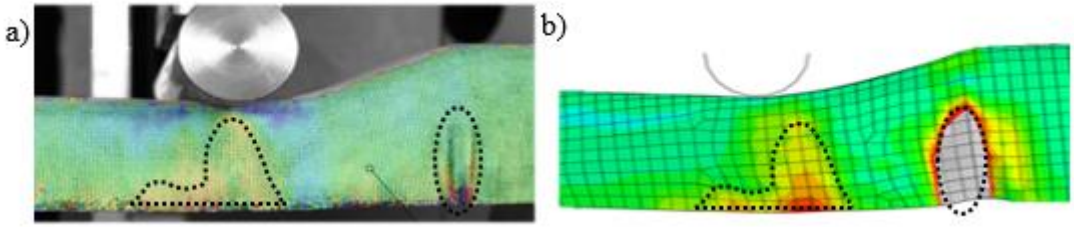

Figure 8: Transversal strain distribution of a) DIC evaluation and b) AB-simulation with identical marked areas (dotted lines)

Fehler! Verweisquelle konnte nicht gefunden werden. shows that in presence of AB characteristics, the maximum load is reduced significantly. Since crack propagation was neither modeled in the AB nor the AD simulation, the maximum load is compared before the crack initialization, observed in the experiment, at a displacement of 6.22 mm. At this position, the load capacity of the experiment is overestimated by 181% for the AD. The AB simulation provides more accurate results, overestimating the load capacity by 17%. This suggests that the material parameters do not fully represent the actual behavior of the structure. To further improve the results additional process-induced effects, like fiber waviness or voids, could be considered in the model.

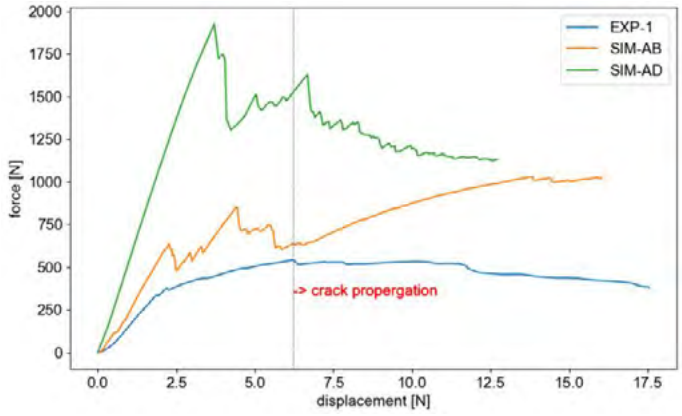

Figure 9: Load-displacement curves of experiment (EXP-1), "as-built"-simulation (SIM-AB) and "as-designed"-simulation

The initiation points of the Hashin criteria in region 1-3 (Figure 7) are are shown in Figure 10. If the damage characteristics, apparent as sudden drops in the force curve, are compared to the AB simulation, they appear at approximately the same displacement as in the experiment. However, the exsessive magnitude of the drops indicates improper material parameters.

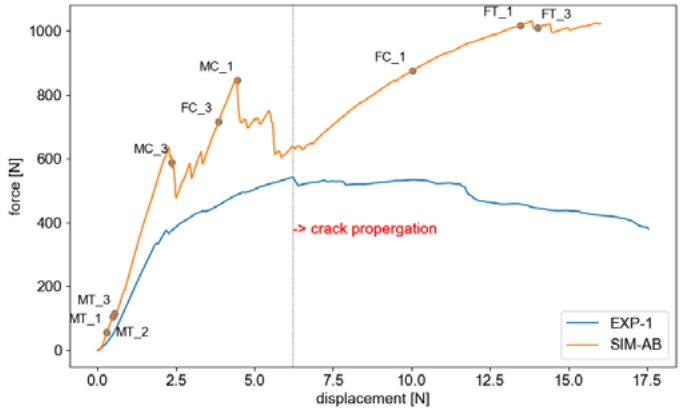

Figure 10: Load-displacement curves of experiment (EXP-1) and "as-built"-simulation (SIM-AB) with initiation points of Hashin criteria at region 1-3

4. Conclusion

In this study, a process simulation chain and "as-built" simulation for unidirectional epoxy prepregs manufactured with the diaphragm forming process were presented. The deformed shell mesh and local fiber orientations from the draping simulation were transferred to the curing simulation to model the thermal and chemical shrinkage. The results of the curing simulation were further used as initial conditions for a structural simulation of a 3-point-bending test to simulate the as-built characteristics of the part.

A material point ID of solid and shell elements was introduced to transfer field quantities with user subroutines in *Abaqus*.

We could show that a fold, which occurred during the process simulation, changed the location of damage initiation and progression of the structure. The as-built simulation was able to capture the damage events that could be observed in the experiments.

Compared to the as-designed simulation, the as-built simulations showed the correct damage initiation location and showed much more agreement in the force displacement curves of the loading pin.
Overall, the presented approach demonstrates the importance of including process-induced effects in the structural analysis for an accurate prediction of the part performance. But further research has to be made to determine material parameters for the damage behavior.

Abstract
In the present study a novel induction heating system for curing of carbon/epoxy composites has been developed and tested. Direct induction heating approach with carbon fibers acting as susceptors for heat generation was used. The novelty of the approach lies in the application of electromagnetic induction which is performed using a moving coil able to perform translation movement in x, y, z directions with respect to the plane of the manufactured plate. Intention of such design is to increase uniformity of induced temperature, which is known to be highly non-uniform as a result of material anisotropy which is in turn strongly related to laminate lay-up.
Carbon/epoxy cross-ply laminates made from unidirectional prepreg layers were manufactured using induction heating and with a pre-defined path of coil movement set up using Linux CNC software. Temperature distribution was monitored using a high resolution thermal imaging camera A6752sc from FLIR. Specimens from the induction cured laminates were cut and tested in uniaxial tensile loading to measure their elastic and micro-cracking properties. In addition DSC tests were performed to estimate the degree of cure of the specimens. The results were also compared with reference specimens, which were manufactured using conventional oven curing at a constant temperature.

1. Introduction

High performance lightweight composites, such as carbon fiber reinforced polymers are increasingly used in various engineering applications. Nevertheless, conventional manufacturing methods for production of lightweight composites are highly energy-consuming. For example, oven curing has been estimated to consume approximately 20 MJ/kg largely due to excess heating of chamber volumes and molds [1]. To reduce the high energy consumption in the composites manufacturing process alternative curing methods that can deliver heat directly to the composite part must be exploited. A highly promising direct curing method which stands out with low power consumption, ability to provide high heating rates, flexibility to deliver contactless energy to a targeted location in complex components and low health and safety requirements is electromagnetic induction heating [1-3].
Induction curing of thermoset composites holds a strong promise for fast, controlled and highly adjustable internal curing of high performance carbon fiber composite parts. Although carbon fibers have favourable electric conductivity and electromagnetic properties, the anisotropic nature of composite layer properties in fiber and transverse directions leads to significant difficulties to obtain uniform heating and a uniform degree of cure [4].
As part of a larger scale research project the non-uniformity of temperature distribution is solved by designing and applying in manufacturing a frame of a prototype with movable induction coil in 3 dimensions that uses feedback from thermal imaging camera to ensure even volumetric temperature distribution during the curing.

In the present study, the focus is on elastic and micro-cracking properties of carbon/epoxy UD, cross-ply composites manufactured with the above described induction heating rig with movable coil. Cross-ply composite plates of 300 x 300 mm were manufactured from UD carbon/epoxy prepregs. Tensile tests were performed on specimens from the manufactured plates to determine elastic properties. Loading-unloading tensile tests with increasing maximum strain levels were performed to study initiation and evolution of transverse matrix cracks. Additional characterization of the glass transition temperature and degree of cure were performed using DSC analysis.
Results were compared with corresponding reference materials manufactured from the same raw materials but instead using conventional oven curing.

2. Manufacturing

2.1. Material system

Composite laminates were made from UD carbon/epoxy prepregs XC130 from Xpreg. Carbon fibers were from Pyrofil high strength carbon fiber grade and the recommended pre-preg curing cycles range from minimum of 80°C to maximum of 120°C. The curing times accordingly correspond to a range between 1 to 16h depending on the temperature. In the present work, taking into consideration the capabilities and limitations of the manufacturing rig a curing cycle of 4 hours at 100°C temperature was selected and applied. A higher temperature would be preferable, however, it was not achievable with the present set-up consisting of a power supply, a coil and an electronic controler unit. One of the challenges was also the thickness of a non-inductive glass/epoxy base plate on which carbon pre-preg layers were placed and which acts as a spacer between the coil and carbon/epoxy laminate. It was found that 2 mm thickness suits well for effective application of heat to the carbon/epoxy laminate plate via induction.
Laminates with lay-up [0/90]s were manufactured. Each laminate consists of 4 UD layers each with approximate weight of 150 g/m^2. The plate size was 300 x 300 mm.

2.2. Induction heating system

In the present work, a custom made induction heating rig was built. The frame design is shown in Figure 1. The system consists of the main frame, thermal imaging camera and a control/inspection unit as shown in the figure. The frame was built in similarity to 3D printers and CNC machines capable of performing independent translation movements in x, y and z axis directions controled by Linux CNC software.

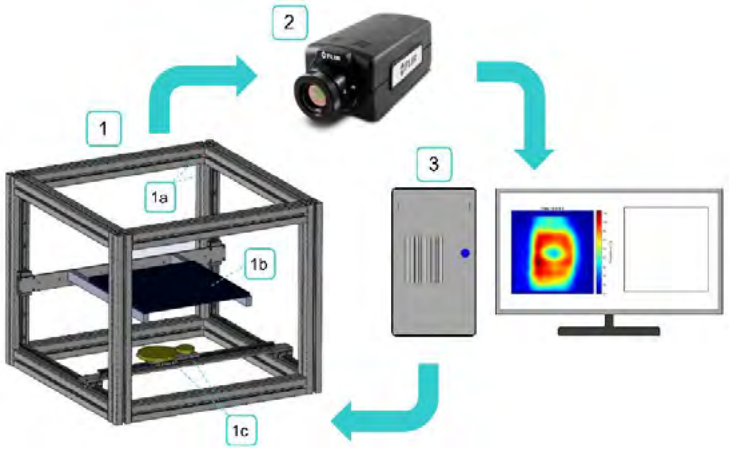

Figure 1. Drawing of an induction heating manufacturing rig: 1) main frame; 2) high resolution thermal imaging camera; 3) control and inspection unit

The size of the frame was 160 x 90 cm, and the height is approximately 60 cm. The diameter of induction coil was 150 mm. A control unit was built providing a constant frequency of electromagnetic field. The coil was connected to an adjustable power supply to control the output current of the induction coil.

2.3. Manufacturing process

As found in previous trials and in the literature [4,5], high non-uniformity of temperature is expected when the induction coil is static (no movement). The novelty of the present approach and test set-up is movable coil which can be pre-programmed to perform various heating paths in order to mitigate the non-uniformity. A trial circular heating path approximately following the inscribed circle inside the square plate of 300x300 mm was first applied leading to conclude that large cold spots near the plate corners are present irrespective of the coil output and speed of the movement. For better results of heating and curing uniformity, the heating path was applied in two consecutive rectangular paths each covering approximately one half of the composite plate, i.e., 150 x 300 mm. This approach according to observations on FLIR A6752sc thermal imaging camera during the induction heating led to the most uniform temperature distribution, however, with a drawback of increased time consumption to complete the curing of the whole 300 x 300 mm plate. The carbon/epoxy composite plate was placed on a non-conductive glass fiber base plate. Vacuum bag was applied for compacting the plate, however, only the vacuum film was put on top without any plate typically used to apply mechanical pressure as typically done in conventional hot-press manufacturing. This was done to enable a clear temperature distribution inspection with the FLIR A6752sc thermal imaging camera as shown in Figure 2.

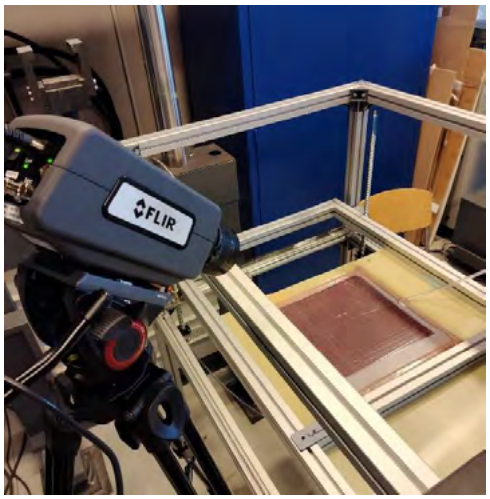

Figure 2. Overview of induction heating process: carbon/epoxy plate placed on a base plate and sealed in vacuum bag with thermal imaging camera placed to record temperature distribution from top view.

A constant output from the induction coil was applied to generate heat. Maximum temperature of 100°C was reached in a region approximately corresponding to the size of the coil. When the coil moved away from the heated part, a slight decrease of temperature was observed. An example temperature distribution is demonstrated in Figure 3.

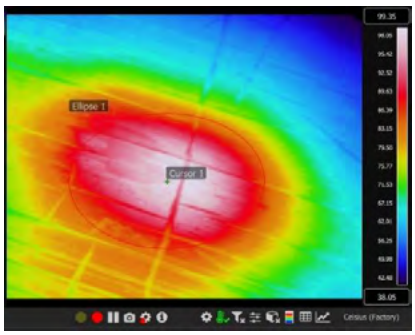

Figure 3. An instant temperature distribution during induction heating. Diameter of the highlighted region approximately corresponds to 150 mm.

As mentioned above, induction coil was following a programmed path of a rectangle corresponding to a half of the plate. In total, induction heating was applied for 4 hours on each half of the plate following the manufacturer's recommended curing cycle. It was clearly observed that the corners of the plate have significantly lower temperature, which was expected as it is typically difficult to induce the Eddy currents in the corners. For manufacturing of reference plates, a cross-ply plate with size of 150 x 300 mm was placed on a glass fiber/epoxy base plate and packed in a vacuum bag with no additional mechanical pressure applied to match conditions used in induction curing. Reference plates were cured in an oven at 100°C for 4 hours.

3. Experimental testing

3.1. Specimen preparation

After curing, plates were removed from the vacuum bag and specimens cut according to Figure 4. As shown in the figure, specimens were cut from regions which were in the central part of the plate where temperature distribution was the most uniform during the induction heating. In total 9 specimens from induction heated plate were obtained with size of 20 x 100 mm. Specimens were cut and their ends reinforced with tabs prior to testing. From the reference plate specimens with dimensions 20 x 150 mm were cut.

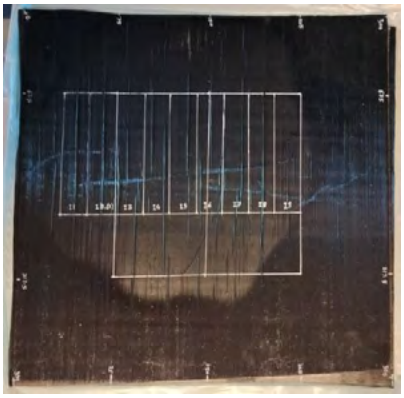

Figure 4. Specimens cut from the induction heated cross-ply laminate.

3.2. Testing procedure

Tensile tests were performed on tensile testing machine Zwick/Roell Z150 using 1% per minute tensile strain rate. At first, elastic modulus was measured, followed by cyclic loading/unloading cycles with increasing maximum strain level. Specimens were removed for optical microscopy inspection and reloaded in the testing machine to apply higher strain levels in the next step. The initiation of transverse cracking was monitored in optical microscopy by quantifying the amount of transverse (intralaminar) cracks in the 90° layers of the cross-ply laminate specimens. Additionaly DSC scans were performed on both induction heated and reference plate specimens to analyze the degree of cure in both composites. DSC tests were performed on specimens cut from area in vicinity to the ends of the tensile test specimens.

3.3. Results and discussion

The elastic modulus results are summarized in Figure 5. Specimen numbering corresponds to induction cured (I1 to I4) and oven cured (O1 to O4). In general, approximately 10% higher tensile elastic modulus was found for the oven cured (reference) materials as shown in Figure 5. These results also correlate well with the nominal glass transition temperature (Tg) obtained from DSC tests which are also plotted in the results summary in Figure 5. For the oven cured specimens, the nominal glass transition temperature Tg is slightly above 120°C while for the induction cured specimens the nominal Tg is approximately equal to 100°C.

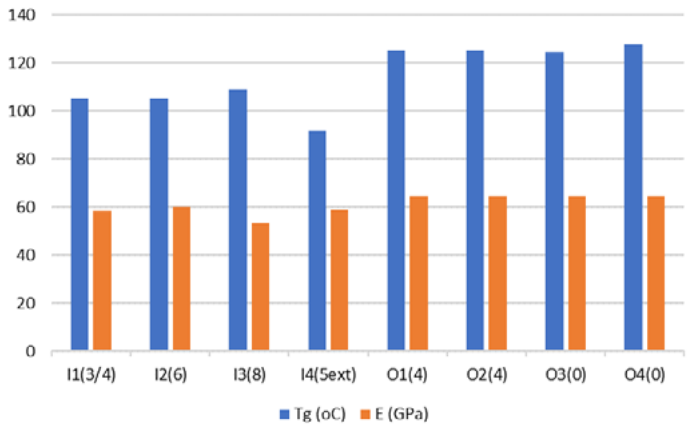

Figure 5. Summary of tensile elastic modulus and glass transition temperature from DSC tests.

Initiation and evolution of micro-damage was studied with optical microscopy and the results are summarized below in Table 1. Notation of specimens follows induction curing (I1, I2, I3, I4, I8) and oven curing (O1). According to the data summary in Table 1, micro-cracks (in form of transverse matrix cracks in the 90° layers) initiate at around 0.75% tensile strain for the oven cured (reference) specimens. For induction cured specimens, on the other hand, crack initiation takes place at significantly lower strain of 0.50% for several specimens. A significant increase of the amount of transverse cracks was observed for induction cured specimens at 0.8% strain. Such significant differences in micro-cracking were found to be related to significantly higher amount of voids in the induction cured specimens as shown in Figure 6, despite using the same vacuum pressure and curing temperature and time. Although at present only two plates have been tested, this observation deserves a more thorough study in the future work.

Table 1. Write your table caption here.

ε [%]	O1	I1	I2	I4	I3	I8
0.50	0	-	0	0	3	1
0.55	0	-	0	1	-	2
0.60	0	-	-	-	-	2
0.70	0	-	-	-	-	3
0.75	4	-	-	-	-	3
0.80	4	17	-	-	-	-

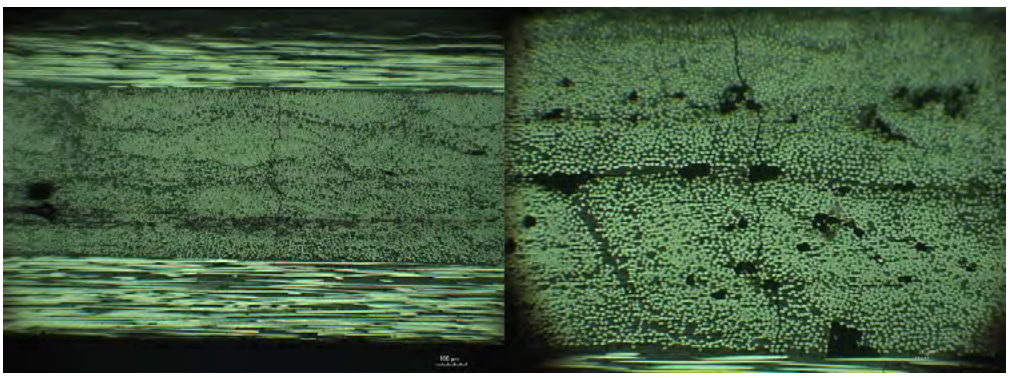

Figure 6. Comparison of micro-structure between oven cured (left) and induction cured (right) laminates showing significantly more voids in the latter.

4. Conclusions

The present study investigates elastic and micro-damage properties of induction heated cross-ply laminates and the results are compared with reference material manufactured using oven curing. In general, a higher elastic modulus was found for the oven cured material than for induction cured material. The found differences were also confirmed by DSC tests, which showed a higher nominal Tg, and thus presumably a higher degree of cure for the oven cured specimens than for induction cured specimens. Significant differences were also found in the microstructure in both materials. While oven cured specimens appeared to be in typical pre-pleg quality with a few voids, the induction cured specimens had a significant amount of voids which contribute to an earlier micro-crack formation. The future work will address improvement of the induction curing process to obtain a fully-cured condition and better uniformity of the temperature during induction heating. In addition, the observed high amount of voids in induction heated specimens needs a futher research.

Abstract
Fiber-reinforced composites are susceptible to failure by delamination. Hence, transverse reinforcements have been thoroughly researched, including the technology of z-pinning, with the insertion of pins in the thickness direction of laminate layups before curing. Such reinforcements act as strong crack bridging elements and enhance the interlaminar fracture behavior. To predict and design resulting delamination behavior, detailed models are needed. In this study a new enhanced model describing the delamination of pinned laminates for the example case of double cantilever beam tests is proposed. The new approach takes into account the cantilever beams' transverse compliance near the crack tip through an incorporation of a Winkler elastic foundation. Also first order shear deformation is introduced in the beam kinematic in order to also allow for accurate analyses for configurations with non-negligible shear compliance. To be able to investigate inter-laminar crack propagation in different composites featuring through-thickness reinforcements, an effective parametric iterative solving is implemented. The bridging zone is modeled by a linearly idealized bridging law. The models beam behavior at characteristic states of the crack propagation shows very good agreement with finite element reference simulations. The refined analytical model offers valuable insights for the design of composite laminates with enhanced resistance to delamination.

1. Introduction

Composite laminates are used in a wide range of applications, including aerospace, military, automotive and sports equipment due to their high ratio of mechanical performance to weight. With great in-plane properties they are however vulnerable to delamination damage, as they are usually not reinforced in through-thickness direction. There is a range of measures than can be utilized to add translaminar reinforcement to a composite laminate, including stitching, weaving and z-pinning. While the model proposed in this paper can be potentially applied to different kinds of translaminar reinforcement methods as well as crack bridging phenomenon in general, it's using the z-pin reinforcement as an example. This is a technique, in which pin shaped elements, made of either fiber-reinforced plastics or metal, are brought into usually uncured thermoset laminates in the through-thickness-direction (z) [1]. The pins are usually placed in the composite in a rectangular pattern, where the pins cross-sectional area per laminate area defines a z-pinning density. This measure has been shown to enhance the damage behavior through an increase in the apparent fracture toughness, while deteriorating the in-plane properties [2]. Song et al. [3] have proposed analytical model for the crack propagation in z-pinned double cantilever beams (DCB) under mode I loading and found good agreement with a finite element analysis and an experimental study. However, the model did not take into account shear deformations in the beams. Also the cantilevers are considered clamped at the crack tip, impeding rotation and elastic deformations at and in front of the crack tip due to the beams transversal compliance, as described by Kanninen et al. [4]. To account for these an enhanced model is proposed including first-order shear deformation theory (FSDT) [5] as well as adding a Winkler elastic foundation (WEF) to the uncracked zone of the cantilevers.

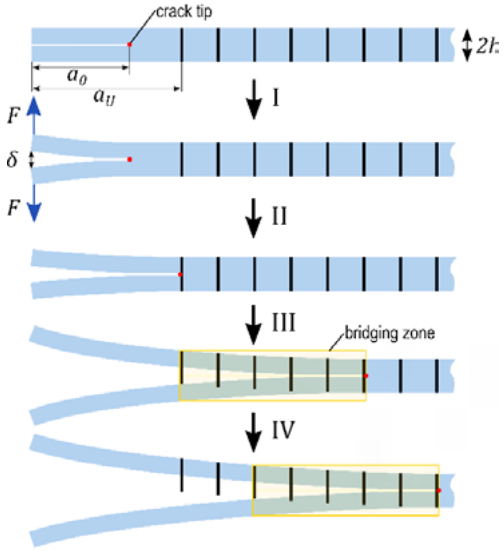

Figure 1. Characteristic phases testing a bridged DCB

2. Derivation of mechanical model for double cantilever beam

We study the case of a DCB that consists of two cantilever beams, each with a rectangular cross section described by height h and width b as depicted in Figure 1. In the initial (uncracked) state, the beams are connected along the interface, except for an initial crack with length a_0. The DCB features a transverse reinforcement starting from a_U on. During loading of the DCB crack opening deflection δ is applied at the cantilever ends, resulting in a transverse force F. The symmetry of the DCB is exploited.

2.1. Phases of bridged DCB testing

The bridged DCB test consists of different phases (see Figure 1.). Phase I starts in the unloaded state and is characterized by the linear-elastic deflection of the precracked end of the beam with the initial crack length a_0, when δ is increased. The DCB behavior in phase I is characterized by the beam compliance, given for Timoshenko beams on a Winkler elastic foundation by Kondo et al. [6]. Phase I ends when the fracture of the unbridged zone starts. There phase II concludes and the apparent crack length a_p increases with increasing δ. The critical force and corresponding deflection at the transition between phase I and II as well as all states in the unbridged crack propagation in phase II can be calculated from [6]

$$F_c = \sqrt{\frac{\mathcal{G}_{Ic} E_{fx} b^2 h}{12}} \left(\left(\frac{a}{h}\right) + \sqrt{\left(\frac{E_{fx}}{6E_z}\right)^{\frac{1}{2}} + \frac{1}{12}\frac{E_{fx}}{\kappa G_{xz}}} \right)^{-1} \tag{1}$$

At the end of phase II, the crack tip reaches the first row of the z-pin reinforcement at $a_p = a_U$. Then phase III starts, describing the crack propagation in the reinforced section of the DCB developing a bridging zone with a length of c_B. The total crack length then is $a = a_p + c_B$. Phase III proceeds up to the point when the first reinforcing elements are no longer exerting a bridging force, in this case, when the first row of pins is fully pulled out. Then phase IV, the migration of the bridging zone through the length of the DCB, succeeds, characterized by an increase in a_p.

2.2. Governing equations

To describe the behavior of crack propagation in the bridged zone, a model coupling the deflections of the three different zones, the unbridged (U), the bridged (B) and the foundation (F) is required (see Figure 2.). With constant material properties and beam cross section along the beam, the Timoshenko beam equations can be formulated as [7]:

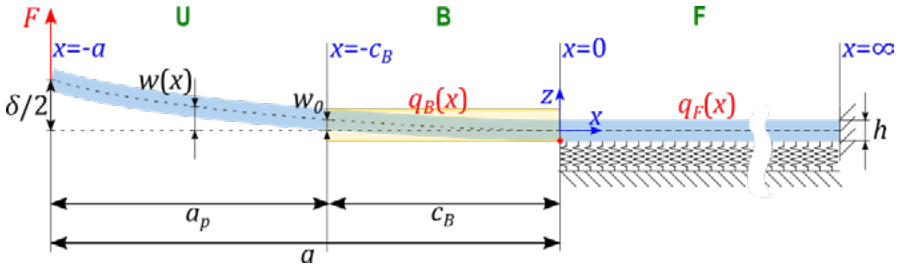

Figure 2. Schematic representation of a single bridged cantilever

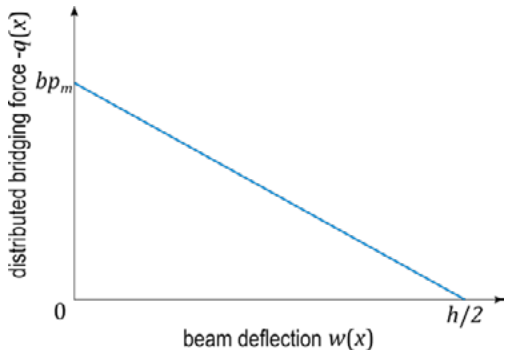

Figure 3. Linearly idealized pin-bridging law

$$E_{fx}\frac{\mathrm{d}^4 w}{\mathrm{d}x^4} = q(x) - \frac{E_{fx}}{\kappa A G_{xz}}\frac{\mathrm{d}^2 q}{\mathrm{d}x^2} \tag{2}$$

As in the unbridged zone (U) the cantilever doesn't feature a distributed load, the right hand side of this ODE vanishes. Taking into account the bending moment in the unbridged zone ($M_U(x) = F(x+a)$) the deflection is

$$w_U(x) = \frac{F}{E_{fx}I}\left(\frac{1}{6}x^3 + \frac{1}{2}ax^2\right) - \frac{Fx}{kAG_{xz}} + \frac{1}{E_{fx}I}C_1 x + C_2. \tag{3}$$

In the bridged zone (B) the bridging forces are characterized by the z-pins' pull-out behavior which can be idealized to a linear bridging law (see Figure 3.): [3]

$$q_B(x) = -bp_m\left(1 - \frac{2}{h}w_B(x)\right). \tag{4}$$

Here, $p_m = Nf_m$ is the maximum pin force per area, calculated from the number of pins per area N and the pin's maximum frictional pull-out-force f_m. In case not directly given, N can be calculated from the pin diameter d_{pin} (for circular pins) and the areal pinning density $\rho_{A,\mathrm{pin}}$ as $N = \frac{\pi d_{\mathrm{pin}}^2}{4\rho_{A,\mathrm{pin}}}$. Inserting this distributed bridging force into the governing ODE the bending deformation is obtained as

$$w_B(x) = C_3\cos(\gamma_1 x) + C_4\sin(\gamma_1 x) + C_5\cosh(\gamma_2 x) + C_6\sinh(\gamma_2 x) + h/2, \tag{5}$$

with

$$\gamma_1 = \sqrt{\frac{\alpha\beta_B}{2} + \sqrt{\left(\frac{\alpha\beta_B}{2}\right)^2 + \frac{\beta_B}{E_{fx}I}}}\,,\quad \gamma_2 = \sqrt{-\frac{\alpha\beta_B}{2} + \sqrt{\left(\frac{\alpha\beta_B}{2}\right)^2 + \frac{\beta_B}{E_{fx}I}}}$$
$$\alpha = \frac{1}{\kappa A G_{xz}},\quad \beta_B = \frac{2bp_m}{h}. \tag{6}$$

In the foundation zone (F) the transversal compliance of the beam can be accounted for by a distributed load

$$q_F(x) = -k_e w_F(x) \tag{7}$$

using a foundation stiffness obtained from the transversal stiffness of the beam and its thickness [4]

$$k_e = \frac{2E_z b}{h}\,. \tag{8}$$

The solution of the governing ODE requires to distinguish two cases in order to avoid complex solutions:

$$w_{F,A}(x) = \begin{cases} C_7 e^{-\psi_1 x} + C_8 e^{-\psi_2 x} + C_9 e^{\psi_1 x} + C_{10} e^{\psi_2 x} \\ \text{for } \dfrac{E_z E_{fx}}{24\kappa^2 G_{xz}^2} \geq 1\,, \\ C_7 e^{-\psi_3 x}\cos(\psi_4 x) + C_8 e^{-\psi_3 x}\sin(\psi_4 x) + C_9 e^{\psi_3 x}\cos(\psi_4 x) + C_{10} e^{\psi_3 x}\sin(\psi_4 x) \\ \text{for } \dfrac{E_z E_{fx}}{24\kappa^2 G_{xz}^2} < 1, \end{cases} \tag{9}$$

with

$$\psi_1 = \sqrt{\frac{\alpha\beta_F}{2} + \sqrt{\left(\frac{\alpha\beta_F}{2}\right)^2 + \frac{\beta_F}{E_{fx}I}}}\,,\quad \psi_2 = \sqrt{\frac{\alpha\beta_F}{2} - \sqrt{\left(\frac{\alpha\beta_F}{2}\right)^2 + \frac{\beta_F}{E_{fx}I}}}$$

$$\psi_3 = \frac{1}{\sqrt{2}}\sqrt{\sqrt{\frac{\beta_F}{E_{fx}I} + \frac{\alpha\beta_F}{2}}}\,,\psi_4 = \frac{1}{\sqrt{2}}\sqrt{\sqrt{\frac{\beta_F}{E_{fx}I} - \frac{\alpha\beta_F}{2}}}\,,$$

$$\beta_F = \frac{2E_z b}{h}. \tag{10}$$

2.3. Boundary conditions

To determine the deflections of the three beam zones, constants need to be calculated by boundary - , equilibrium - and continuity conditions. In both cases of the foundation zone solution for the far end boundary condition of

$$w_F(\infty) = 0\,,\quad \theta_F(\infty) = 0 \tag{11}$$

the ascending terms need to be eliminated leading to the simplification

$$C_9 = C_{10} = 0. \tag{12}$$

The eight remaining constants can then be determined through

$$\begin{gathered} w_U(-c_B) = w_B(-c_B), \\ \theta_U(-c_B) = \theta_B(-c_B), \\ M_B(-c_B) = a_p F(-c_B), \\ w_B(0) = w_F(0), \\ \theta_B(0) = \theta_F(0), \\ Q_B(0) = Q_F(0), \\ M_B(0) = M_F(0). \end{gathered} \tag{13}$$

One additional boundary condition is defined by the parameter controlling the DCB. Generally the test is controlled by the deflection at the loaded end

$$w_U(-a) = \delta/2. \tag{14}$$

2.4. Iteration solution of the crack propagation

The iterative solution of the crack propagation follows the phases described in 2.1. starting with the critical force and deflection for the end of phase I, the linear elastic deformation. Then for a range of

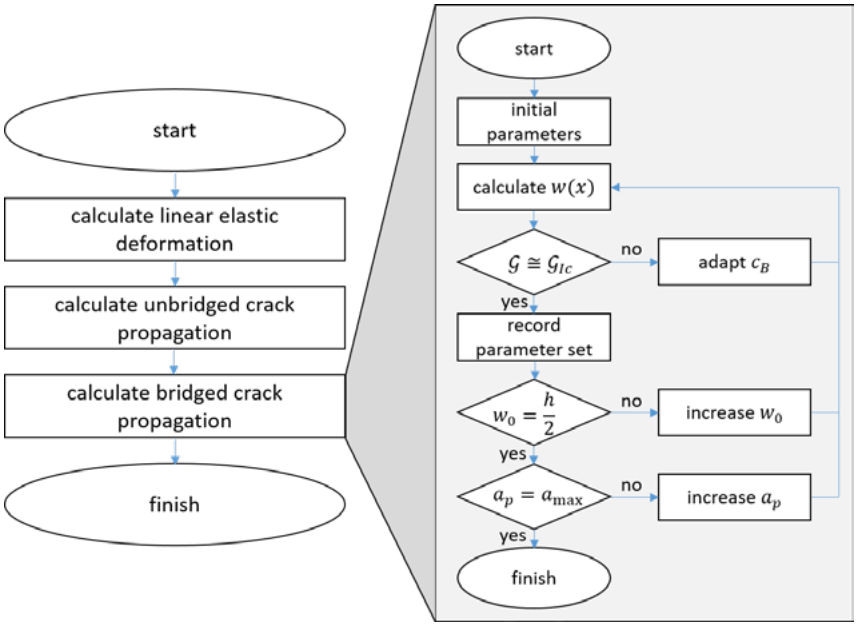

Figure 4. Flowchart of the schematic structure of the DCB crack propagation model

$a_0 < a_p < a_U$ forces and δ are calculated for phase II, the unbridged crack propagation. For phase III and IV, the crack propagation in the bridged zone, the steps shown in Figure 4. are performed. Starting from a w_0 slightly bigger than the $w(0)$ at state c) a corresponding c_B is determined, using a numerical root search method on the function

$$\frac{\mathcal{G}(c_B)}{\mathcal{G}_{Ic}} - 1 = 0. \tag{15}$$

This means, for that set of w_0 and c_B the Griffith criterion is fulfilled and the crack propagates. The energy release rate is calculated in displacement-controlled compliance approach [8]

$$\mathcal{G} = \frac{F^2}{2b}\frac{\mathrm{d}C}{\mathrm{d}a} = \frac{\delta}{2b}\frac{\mathrm{d}F}{\mathrm{d}a} \tag{16}$$

where the force is numerically differentiated with the symmetric difference quotient

$$\frac{\mathrm{d}F}{\mathrm{d}a} = \frac{F(c_B+\Delta) - F(c_B-\Delta)}{2\Delta}. \tag{17}$$

Subsequently w_0 is incrementally increased and the procedure repeated until $w_0 = h/2$, when the first pin row is fully pulled out and the bridging zone starts to migrate. There in phase IV a_p is incrementally increased and the calculation repeated until a defined $a_{\max}$ has been reached. It needs to be noted that in order to keep the assumptions for the far end (equation 11.) applicable, the crack is not allowed to run to the very end of the DCB. The solution is efficiently implemented in a Python routine.

3. Results and discussion

As a sample configuration the DCB definition used by Song et al. [3] based on experimental studies of Cartié [9] and a pin-bridging law by Dai et al. [10] was applied to the analytical model and investigated. The dimensions of the DCB and the material properties can be found in Table 1. The modelled DCB bridging behavior can be seen in Figure 5., where both the shear force and the zone lengths have been plotted over the increasing δ. The different phases described in section 2.1. can be observed. The linear increase of F over δ in phase I, the decline of the required force for crack growth with increasing a in phase II, followed by increase in force again as the bridging zone develops, exerting increasing bridging forces counteracting the crack propagation.

To validate the beam deflections determined by the solving of differential equations throughout the model run, an FE model was set up. It was built in Abaqus with a parametric Python script using beam

ν_{xy}	0.34
$\mathcal{G}_{Ic}$	258 N/m

elements of the type B31, also featuring Timoshenko kinematics with shear deformation. The different zones were sectioned and both the pins as bridging elements and the foundation's springs were modelled as distinct axial connector elements, which were assigned the pin bridging law and the foundation spring stiffness, respectively. With the FE model characteristic states in the DCBs loading were statically simulated and compared to the results of the analytical model. The state directly before the crack starts to propagate into the bridged zone in the transition of phase II and III as well as the state, when the

bridging zone is fully built out and starts to migrate between phase III and IV where chosen. The first featuring only the unbridged and foundation zone, the later one utilizing all three zones defined. The resulting deflection curves can be observed in Figure 6. Both states show a very good agreement of the analytically and numerically determined deflections. The discretization of the elastic foundation in the FE model leads to minor offsets visible in the detail of the foundation zone. In the foundation a traction zone near the crack tip followed by a compression zone, characteristic for beams on WEFs, can be observed. The visible deflection of the beam's mid-plane at the crack tip $w(0) > 0$ as well as its slope result in an overall more compliant beam behavior compared to a model with a clamped boundary at the crack tip.

To investigate the importance of the implementation of the FSDT in the model, the configuration has also been processed in an ideally shear-stiff variant representing Euler-Bernoulli- instead of Timoshenko beam theory. In effect the DCB is stiffer, which was especially visible in phase I, where an increase in the critical force before unbridged crack growth could be observed. While $F_{c,\mathrm{TB}} = 42.06\,\mathrm{N}$ without FSDT it was $F_{c,\mathrm{EBB}} = 43.30\,\mathrm{N}$, an overestimation of about 2.95 %. A test with both shear deformation and elastic foundation taken out of consideration, so with a clamped crack tip, yielded a critical force of $F_{c,\mathrm{EBB,clamp}} = 44.99\,\mathrm{N}$, even 7 % higher than with the FSDT and WEF implementation.

4. Conclusions

An enhanced analytical model for the analysis of z-pin-bridged DCBs has been developed, taking into account shear deformations and compliance at and in front of the crack tip modelled with a WEF. The three-zone model has shown good agreement with reference FE simulations. Additionally the influence and importance of the model features are shown at hand of an exemplary case study. With this setup, the model can be applied to a wide range of DCB configurations, including non-isotropic and shear-compliant materials. Also the implemented z-pin bridging law can easily adapted to other transverse reinforcements or bridging phenomena's laws, opening a wide range of possibilities of application.

Keywords: Carbon/Carbon, Oxidation, Damage, Modeling

Abstract
The study focuses on developing a model for the specific lifetime of Carbon/Carbon (C/C) ceramic matrix composites in aeronautics braking systems, considering the effect of carbon oxidation on the thermo-mechanical properties. During the landing and taxi-out phases, brake temperatures range from 400°C to 800°C, leading to significant oxidation reactions with atmospheric oxygen. The literature review and the tests carried out in this study show that the duration but also the temperature of oxidation affect the mechanical properties. An in-depth understanding and advanced modeling approach are required to explain the results obtained. The modeling involves two main steps. First, the oxidation state of the material is estimated considering the environmental conditions. Then, the effects of oxidation on the mechanical properties are considered. A thermodynamically consistent behavior law based on the continuum damage framework has been developed, considering both the effects of mechanical loading and oxidation. The predictions of the model have been compared with the available test results and is able to reproduce the observed trends.

1. Introduction

Carbon-Carbon (C/C) composites are Ceramic Matrix Composites (CMCs), but with some specifities compared to classical C/SiC or SiC/SiC material [1]. C/C composites have found many applications in the aerospace industry. For instance, in nose cones for reentry vehicles and ballistic missiles, as well as in the leading edge of the Space Shuttle and in aircraft breaking systems which represent the largest consumption of this material. The latter is the practical application of the material in this study which constitutes the heat sink of the brake, as shown in Figure 1 [2], which captures the heat generated by braking, thus protecting other parts sensitive to high temperatures. However, C/C composite is susceptible to oxidation phenomena. Above 400°C, oxygen reacts strongly with carbon, which consumes the composite and degrades its mechanical properties. The C/C composite studied is a needle-punched 2.5D preform stacked in [0/±60] orientations, then densified by a CVI (Chemical Vapor Infiltration) process. The microstructure of the material under study is similar to that shown in Figure 2.

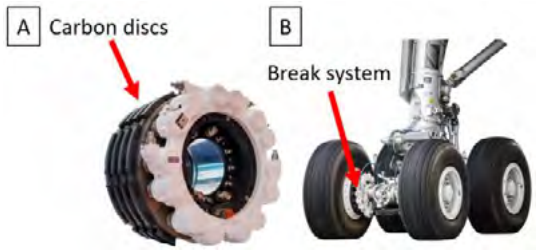

Figure 1. A- A330 break system. B- Wheel-integrated braking system [2].

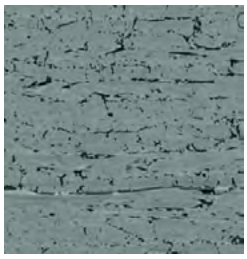

Figure 2. Material microstructure [3].

Figure 3. Pores due to CVI process [4].

The CVI densification process generates pores, as shown in Figure 3 [4], which facilitate oxidation ansd this promote the degradation of the mechanical properties. Therefore, the aim of this study is to propose a constitutive law able to describe the evolution of the mechanical properties (rigidity and damage) as a function of the oxidation. Firstly, the definition and the modelling of the oxidation state in /C composites is provided. Then, the influence of the oxidation on elastic properties and on the damage process are described. Finally, the model predictions are compared with experimental data.

2. Modeling the influence of oxidation on the mechanical behavior

2.1. Formalism for describing the oxidation state

The rate of oxidation is usually estimated by measuring the loss of mass, noted as Δm, compared to the mass of the material after manufacture. In standard application of brakes, the oxidation rate, also known as burn-off, does not normally exceed 5%. For C/C materials, three oxidation domains can be distinguished. Below 400°C, the oxidation reaction is not activated or takes a very long time. Between 400°C and 800°C, it can be reasonably assumed that oxidation is mainly uniform throughout the volume, due to the considerable pore rates. Above 800°C, surface oxidation phenomena predominate over volume mechanisms. In this study, the temperature range for describing oxidation corresponds to the second domain. The overall oxidation kinetics of C/C materials, denoted by the variable Δm, is assumed to follow an Arrhenius law [5], as reported in Eq 1., where E_a is the activation energy, the R perfect gaz constant, T the temperature, and A a material parameter to be defined :

$$\dot{\Delta m} = A \exp\left(-\frac{E_a}{RT(t)}\right) \tag{1}$$

Nevertheless, for the same mass loss obtained at different oxidation temperatures, the effect of oxidation on the mechanical properties are different, as shown in Figures 4 and 5. This means that the global variable Δm is not sufficient to describe the oxidation rate.

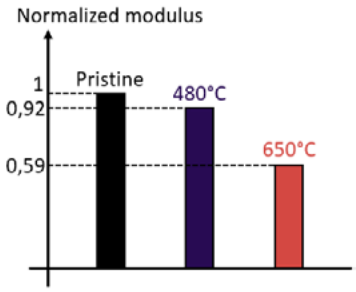

Figure 4. Effect of oxidation ($\Delta m = 5\%$) on the Young's modulus of the material under study.

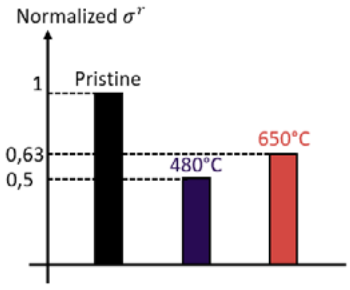

Figure 5. Effect of oxidation ($\Delta m = 5\%$) on the material's tensile strength σ^r.

To take account of this specifity, the idea is to create as many oxidation state variables as there are oxidation mechanisms to be described. In a first time, only two variables, homogeneous as mass loss, are considered : one to describe mechanisms occuring at low oxidation temperature (400°C), denoted Δm_1, and a second, Δm_2, for those occuring at higher temperature (800°C). Eq. 2 defines the evolution of these variables, and their relation to the measured global mass loss :

$$\Delta\dot{m} = \Delta\dot{m}_1 + \Delta\dot{m}_2 \quad \text{and} \quad \begin{cases} \Delta\dot{m}_1 = \zeta(T)\Delta\dot{m} \\ \Delta\dot{m}_2 = \big(1-\zeta(T)\big)\Delta\dot{m} \end{cases} \tag{2}$$

The term ζ corresponds to a logistic function, that allows the transition from one oxidation mechanism to another as a function of the oxidation temperature, as given in Eq. 3.

$$\zeta(T) = \frac{1}{2}\big(1-\tanh\big(\gamma(T-T_c)\big)\big) \tag{3}$$

Two coefficients control the transition between oxidation mechanisms: γ to calibrate the transition rate and T_c to define the transition temperature, as shown in Figure 6.

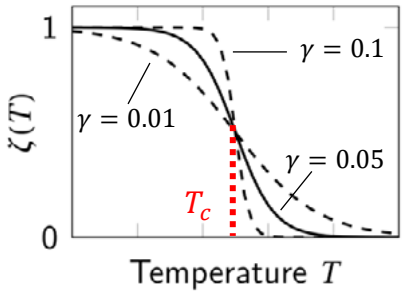

Figure 6. Representation of the logistic function ζ

Thanks to the introduction of the two variables Δm_1 and Δm_2, it is now possible to attribute different effects of oxidation on mechanical properties at low and high temperatures. Indeed, it is clear that the oxidation mechanisms associated with Δm_1 will predomine at temperatures lower than T_c, and vice versa the oxidation mechanisms associated with Δm_2 will predomine for temperatures higher than T_c.

2.2. Evolution law of the elastic compliance tensor due to oxidation without damage

In this part, we consider only the linear elastic part of the behavior (Eq. 4). The tensor $\mathbb{S}^0$ is the elastic compliance tensor at the initial state. The tensor $\mathbb{S}^{\mathrm{Ox}}$ corresponds to the one after oxydation. So, without oxydation $\Delta m = 0$, the two tensors are equal, meaning $\mathbb{S}^{\mathrm{Ox}} = \mathbb{S}^0$.

$$\boldsymbol{\varepsilon} = \mathbb{S}^{\mathrm{Ox}}(T, \Delta m_k) : \boldsymbol{\sigma} \tag{4}$$

The objective is to establish a law describing the evolution of the oxidized tensor $\mathbb{S}^{\mathrm{Ox}}$ as a function of temperature and the two mass losses associated to the different mechanisms. Considering the evolution of the compliance tensor as a function of time is a convient framework, as reported in Eq 5.

$$\frac{\mathrm{d}\mathbb{S}^{\mathrm{Ox}}(T, \Delta m_k)}{\mathrm{d}t} = \frac{\partial \mathbb{S}^{\mathrm{Ox}}}{\partial T}\dot{T} + \sum \frac{\partial \mathbb{S}^{\mathrm{Ox}}}{\partial \Delta m_k}\Delta\dot{m}_k \tag{5}$$

As described in Eq. 5, the evolution of the oxidized tensor due to the temperature is distinguished from the evolution due to the oxidation mechanisms. Firstly, the definition of the temperature-induced

variation of the compliance tensor is considered. Temperature has a particular effect on the C/C elastic stiffness. Research studies in the literature [4,6] indicate that the apparent stiffness increases with temperature up to about 1500°C, after which it decreases sharply, as shown in Figures 7 and 8.

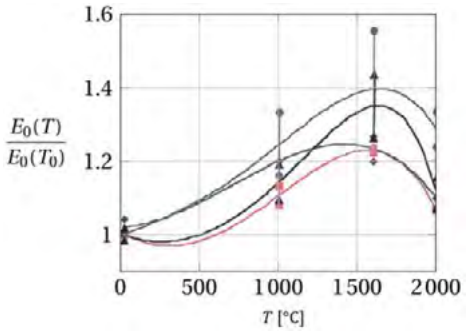

Figure 7. Effect of temperature on the stiffness of a C/C material [4]

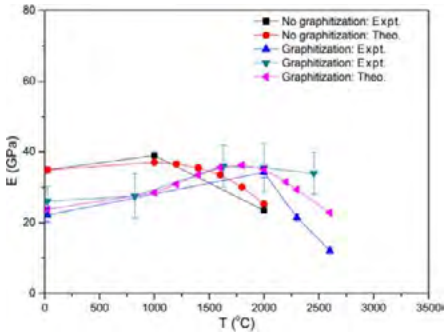

Figure 8. Effect of temperature and graphitization on the stiffness of a C/C material [6]

For now, the Young's modulus E_i and the shear modulus G_{ij} are assumed to be affected in the same way. The Poisson's ratios ν_{ij} are assumed to be constant due to measurement issues during experimental tests. Its means that all coefficients of $\mathbb{S}^{\mathrm{Ox}}$ are affected in the same manner. The chosen analytical expression for the Young's modulus is given by Eq. 6.

$$E^{\mathrm{Ox}}(T,\Delta m_k) = E^{\mathrm{Ox}}(T_0,\Delta m_k)\left(\frac{1}{1+\exp\left(\frac{T-T_s}{\alpha}\right)} + (T-T_0)\beta\right) \tag{6}$$

The coefficient T_s corresponds to the temperature at the maximum stiffness, α controls the shape of the peak, β controls the stiffness increase before the peak and T_0 is the ambient temperature.

Secondly, a definition of the oxidation-induced variation of the compliance tensor is considered. An expression for the evolution of the tensor $\mathbb{S}^{\mathrm{Ox}}$ due to oxidation is given by Eq. 7.

$$\sum \frac{\partial \mathbb{S}^{\mathrm{Ox}}}{\partial \Delta m_k}\Delta\dot{m}_k = \mathbb{S}^0(T)\,g\left(\Delta\dot{m}_k\right) \tag{7}$$

The effect of the oxidation on the evolution of the tensor $\mathbb{S}^{\mathrm{Ox}}$ is governed by the scalar function g expressed in Eq. 8. Two coefficients have been introduced : ξ_1 to calibrate the effect of the oxidation mechanism $\Delta\dot{m}_1$ on $\dot{\mathbb{S}}^{\mathrm{Ox}}$ and ξ_2 to calibrate the effect of $\Delta\dot{m}_2$.

$$g\left(\Delta\dot{m}_k\right) = \xi_1\,\Delta\dot{m}_1 + \xi_2\,\Delta\dot{m}_2 \tag{8}$$

To illustrate the oxidation process, let us consider an oxidation that takes place in an isothermal environment, *i.e.* $\dot{T} = 0$, and the temperature rise is instantaneous, as shown in Figure 9. The temperature T_{Ox} is the oxidation temperature. The time t_0 corresponds to the initial state and t_1 to the start of oxidation. The time $t_{\Delta m}$ corresponds to the time required to reach an oxidation rate of Δm and t is the current time after oxidation. Eq. 5 can be integrated with respect to the time through the oxidation path, between t_0 and $t > t_{\Delta m}$. At ambient temperature T_0, the material is not oxidized, or according to the Arrhenius law, over an extremely long time. So, the variation of $\mathbb{S}^{\mathrm{Ox}}$ between t_0 and t_1 as well as between $t_{\Delta m}$ and t can be neglected.

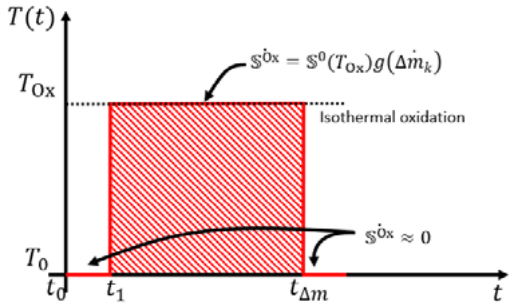

Figure 9. Thermal loading of the example

The calculations lead to Eq. 9, which describes the evolution of the normalized elastic modulus as a function of the oxidation rate, depending on the oxidation temperature T_{Ox}.

$$\begin{cases} \Delta m_1 = \zeta(T_{Ox})\Delta m \\ \Delta m_2 = \big(1 - \zeta(T_{Ox})\big)\Delta m \\ g(\Delta m_k) = \xi_1\,\Delta m_1 + \xi_2\,\Delta m_2 \\ \dfrac{E^{Ox}(T_{Ox}, \Delta m_k)}{E^0(T_{Ox})} = \dfrac{1}{1 + g(\Delta m_k)} \Leftrightarrow \dfrac{E^{Ox}(T_0, \Delta m_k)}{E^0(T_0)} = \dfrac{1}{1 + \dfrac{E^0(T_0)}{E^0(T_{Ox})} g(\Delta m_k)} \end{cases} \tag{9}$$

The expression for the shear modulus evolution is similarly assumed. Figure 10 shows the effect of the oxidation temperature T_{Ox} on the Young's modulus for several values of global mass loss. The purple crosses represent experimental measurements made at $\Delta m = 5\%$ for oxidation temperatures equal to 480°C and 650°C. The shape of the curves depends on the material coefficients γ, T_c, ξ_1 and ξ_2. For now, the lack of experimental data makes the identification of these coefficients difficult. Nevertheless, this model effectively describes the effects of oxidation on the elastic properties at low and high oxidation temperatures for a given mass loss. The decrease in the apparent modulus, shown in Figure 11, is similar to test results found in the literature for another C/C material [7].

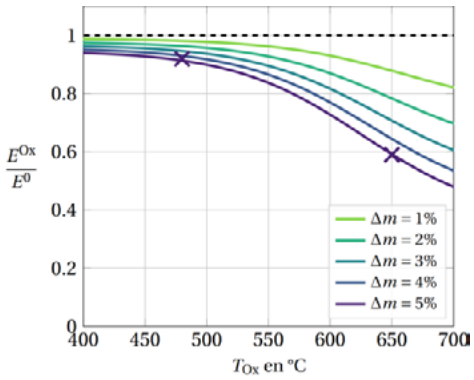

Figure 10. Evolution of the elastic modulus relative to the initial modulus as a function of T_{Ox} for several Δm.

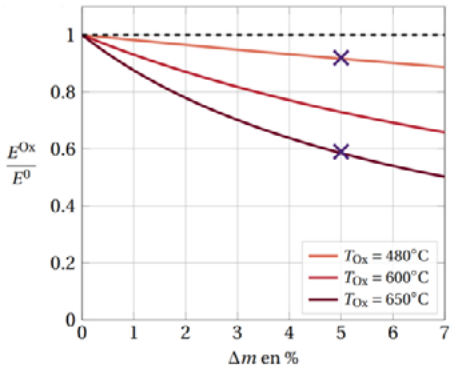

Figure 11. Evolution of the elastic modulus relative to the initial modulus as a function of Δm for several T_{Ox}.

2.3. Effect of oxidation on damage

The model considered to take into account the effect of damage on the material behaviour is OḊM for Onera Damage Model. This model was developed for static loading [9], and more recently for fatigue [10]. In this paper, only the static one part is considered for simulations. Some details about the

behaviour law, provided in Eq. 10, are given below. More details are provided in the literature [8,9,10].

$$\begin{gathered}\boldsymbol{\sigma} = \mathbb{C}^{\text{eff}} : (\boldsymbol{\varepsilon} - \boldsymbol{\varepsilon_0}) + \mathbb{C}^{\text{Ox}} : \boldsymbol{\varepsilon_0} \\ \mathbb{C}^{\text{eff}} = \left(\mathbb{S}^{\text{eff}}\right)^{-1} = \left(\mathbb{S}^{\text{Ox}} + \sum d_i \mathbb{H}_i\right)^{-1} \\ \dot{d}_i = (d_i^{\infty} - d_i) \left\langle \frac{\varepsilon_{\text{eq}_i}^{\max} - \varepsilon_{\text{eq}_i}^{0s}}{S_i^s} \right\rangle_+^{p_i^s} \left\langle \dot{\varepsilon}_{\text{eq}_i}^{\max} \right\rangle_+ \text{ and } \varepsilon_{\text{eq}_i} = \sqrt{y_i}\end{gathered} \tag{10}$$

Where $\boldsymbol{\sigma}$ is the stress, $\boldsymbol{\varepsilon}$ the total strain, $\boldsymbol{\varepsilon_0}$ the closure strain and $\mathbb{C}^{\text{Ox}}$ the non-oxidized elastic stiffness tensor. The effective tensor $\mathbb{C}^{\text{eff}}$ is degraded during the mechanical loading above a certain damage threshold. The scalar variables d_i are the damage variables representing the matrix meso-damages oriented at 0°, ±45° and 90° and an additional variable is considered through the out-of-plane direction of the material. The evolution of these variables is defined by non-linear differential equations, reported in Eq. 10. The different material parameters to be identified with the mechanical tests are: a threshold (occurence of the first crack) y_{0_i}, the kinetics of the damage evolution y_{c_i}, and the damage saturation d_i^{∞}. $\mathbb{H}_i$ are the effect tensors identified by homogenisation [8], using the elastic properties of the material. They are defined in such a way that the damage variables affect the elastic properties only when the cracks are opened, i.e. the unilateral aspect of the damage is guaranteed.

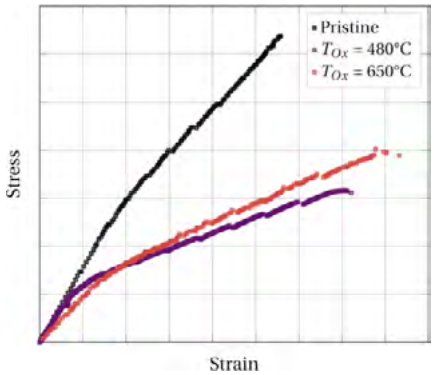

Figure 12. Envelope of the behaviour curves of the pristine and oxidized material ($\Delta m = 5\%$) for two different oxidation temperatures.

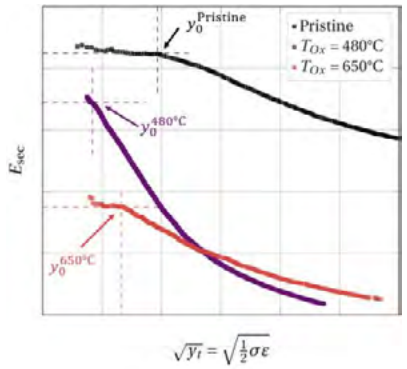

Figure 13. Evolution of the secant modulus during loading after oxidation as a function of the total energy.

Figure 12 shows the envelope of the behaviour curves. Linear elastic behaviour is at the beginning of the curves, followed by damaged behaviour. The damage threshold y_{0_i} can be measured graphically using Figure 13 from the point where the secant modulus drops.

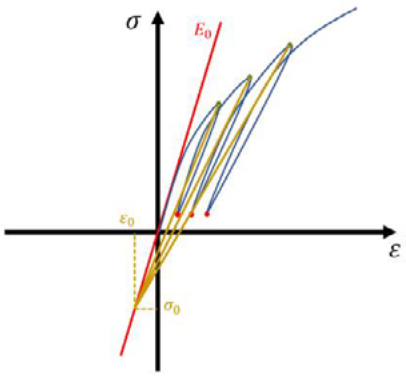

Figure 14. Definition of the closure strain.

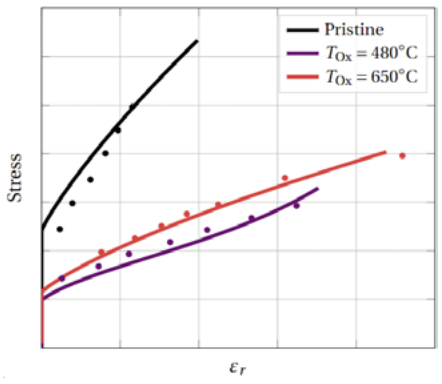

Figure 15. Identification of the closure strain using the measured permanent strains.

The damage threshold decreases as a function of oxidation, and appears to be lower at higher oxidation temperatures. This result needs to be confirmed by further measurements. An analysis of the effects of oxidation on the coefficients associated with the damage kinetics led to the conclusion that the damage saturation may not depend on the level of oxidation. The closure strain ε_0, defined in Figure 14, allows a precise description of the permanent strain after unloading. To identify the value of ε_0, the difference between the measured permanent strains, points reported in Figure 15, and those obtained numerically, lines in Figure 15, is minimized. Higher weights are affected to the measured large permanent strains in the minimization as their measurements are more reliable. Oxidation has therefore an important effect on the permanent strains. In addition, the closure strain allows residual strains to be accurately described in a simple manner.

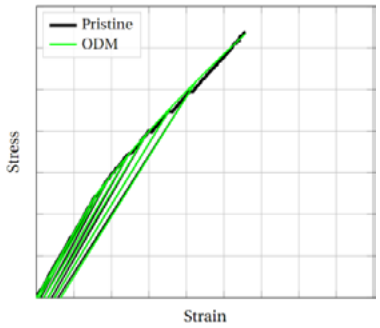

Figure 16. Stress-strain curve of the pristine material and the identified model.

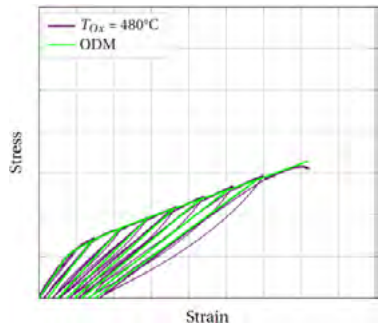

Figure 17. Stress-strain curve of the oxidized material ($T_{\mathrm{Ox}} = 480°C$, $\Delta m = 5\%$) and the identified model.

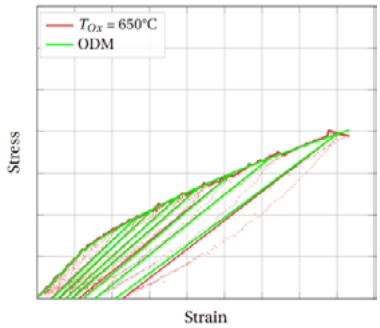

Figure 18. Stress-strain curve of the oxidized material ($T_{\mathrm{Ox}} = 650°C$, $\Delta m = 5\%$) and the identified model.

Once the damage threshold and closure strain have been identified graphically, the damage kinetics coefficient y_{c_i} can be determined. At this stage, all the coefficients are identified. The comparison between test and simulation for different oxidations can be seen in Figures 16 (pristine state with $\Delta m = 0\%$), 17 (oxidized at 480°C with $\Delta m = 5\%$), and 18 (oxidized at 650°C with $\Delta m = 5\%$) and the predictions are quite promising.

3. Conclusions

A formalism has been proposed to describe the oxidation state of C/C materials. For C/C materials, it has been established that for the same global mass loss, which is the commonly measured quantity to describe the oxidation state, is not fully relevant. Indeed, a high oxidation temperature degrades the elasticity tensor more than a low oxidation temperature for the same global mass loss. The main modeling idea is to assume that two oxidation mechanisms are in competition: at low temperatures, the mechanism noted $\Delta\dot{m}_1$ is larger than the mechanism $\Delta\dot{m}_2$, and vice versa at high temperatures. A Arrhenius-based model was proposed to predict the oxidation rate of each basic mechanism as a function of the oxidation time and the duration. Then, the effects of the oxidation states on the elastic properties but also on the damage indicators (onset of damage, permanent strain,) have been introduced in a continuum damage model. The predictions are in good agreement with the available experimental data, but additional tests are needed for validation.

In perspective, the effect of oxidation on the material parameters related to the damageable part of the model will be further investigated. This model is being implemented in a commercial finite element code. The effect of oxidation on fatigue behaviour will then be investigated.

Abstract

During the service life of high-performance engines, essential components in the high-temperature parts undergo simultaneous exposure to high temperatures and aerodynamic vibrations. Elevated vibrations in high-temperature conditions not only influence engine performance, but also expedite structural fatigue, resulting in premature failure. Selected SiC/SiC composite materials, renowned for their superior high-temperature performance, present considerable advantages and application potential. However, under such multi-field coupling hush service conditions, ceramic matrix composites (CMCs) demonstrate complex dynamic nonlinear and hysteresis behavior, which limits the ability to predict material failure. Thus, establishing a dynamic failure model and efficient computational methods for high-temperature CMCs are crucial. These advancements will accelerate structural material design and validation, enabling real-time monitoring and prediction of failure behavior in high-temperature composites, with significant engineering application potential.

To address the aforementioned challenges, this study developed mechanical loading and vibration experiment systems to obtain constitutive and dynamic data, respectively, at 1100℃. Tension and loading-unloading mechanical tests were conducted to obtain the tensile curves and skeleton curves for 2.5D CMCs at 1100℃. These data were used to establish arbitrary cyclic tensile and compressive constitutive model. A numerical model was stablished to simulate the stress-strain curves. This model integrated matrix cracking, interface friction and fiber fracture, and is applicable to 3D stress states. The calibrated parameter values in the constitutive model were applied to calculate the response of CMCs to dynamic loading at 1100℃. Combining the constitutive model and an explicit dynamic numerical method, a nonlinear dynamic simulation model was established for CMCs structures, to predict the first-order natural frequency and amplitude of 2.5D CMCs at 1100℃. This work contributes a better understanding of the CMCs' behavior under high-temperature dynamic loads.

1. Introduction

Ceramic-matrix composites (CMCs) have become indispensable in replacing high-temperature alloys in aero-engines due to their high strength, temperature resistance, excellent toughness, crack resistance,

and low density. Exposed to prolonged high temperatures and vibrations, aero-engines exhibit significant behavioral changes, necessitating a nonlinear dynamic calculation methodology to accurately assess CMCs' responses in such environments.

The theoretical framework for analyzing composite materials has evolved considerably. Love [1] introduced the classical laminate-plate theory, simplifying calculations significantly. This theory was further developed by Mindlin [2] and Naghdi [3], who included considerations for transverse shear and extrusion, thus enhancing dynamic response accuracy. Advances by Nagesh and Hanagud [4] using finite element methods revealed natural frequency reductions due to delamination. Librescu and Nosier [5] further refined dynamic equations with transverse shear deformation and higher-order effects, surpassing classical theory accuracy.

Recent studies have further examined the vibrational behaviors of composites under varied conditions. Lee et al. [6] analyzed carbon-fiber epoxy composite plates in supersonic airflow at different temperatures, while Xia et al. [7] developed models for wall plate vibrations under constant temperatures, linking decreased vibration frequency to thermal stresses. Fu et al. [8] created a dynamic model for composite beams across different temperatures.

Experimental validations by Spivey et al. [9] on aircraft structures under thermal loads confirmed the effectiveness of finite element methods, clarifying modal characteristics in high-temperature environments. Jeyaraj et al. [10] observed natural frequency variations in composite plates across temperatures. Birman et al. [11] studied the impact of matrix cracking on woven CMCs, finding minimal effects on stiffness and natural frequency. Gao et al. [12] introduced a three-dimensional shear lag model to analyze the vibration response of unidirectional CMCs, integrating multiscale simulation with finite-element methods.

While much research has focused on laminate-plate composites, the dynamic responses of CMCs with complex woven structures in high-temperature environments have received less attention.

This study conducts tensile, loading and unloading, and vibration tests on 2.5D woven SiC/SiC composites under high-temperature conditions to establish a macroscopic intrinsic model, assess high temperature's impact on natural frequency, and predict the first-order natural frequency and amplitude.

2. Methods Experiment

2.1. Specimen and Material

The material investigated in this study comprised a 2.5D woven shallow-bend SiC/SiC ceramic matrix composite (CMCs). In order to enhance the material's mass density, we utilized Chemical Vapor Infiltration (CVI). Through multiple cycles of vapor deposition applied to the preform surface using CVI, the preform was filled with SiC matrix, effectively compacting the CMCs. Consequently, CMCs composite plates were produced, boasting a density of approximately 1.8 g/cm³ as determined by displacement method.

The 2.5D woven SiC/SiC composites were prepared with a thickness of 3 mm, and for processing the CMCs test pieces, waterjet cutting [13], selected for its superior processing efficiency and cutting precision, was employed.

The specimens obtained through water cutting were utilized for mechanical property tests, and their dimensions and physical conFigureurations are depicted in Figure 1. The overall length of the specimen measured 200 mm, with a clamping end length of 25 mm, width of 12 mm, test section length of 100 mm, and width of 6 mm.

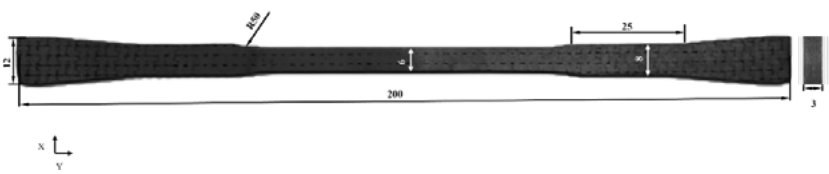

Figure 1. Dimensional drawing and picture of the dog bone specimen of 2.5D woven CMCs(mm)

Additionally, water jet cutting was utilized to procure rectangular specimens for dynamic response testing. These specimens measured 143 mm in length, 10 mm in width, and 3 mm in thickness. The clamping end was positioned on one side of the rectangle, featuring a clamping length of 20 mm, as depicted in Figure 2.

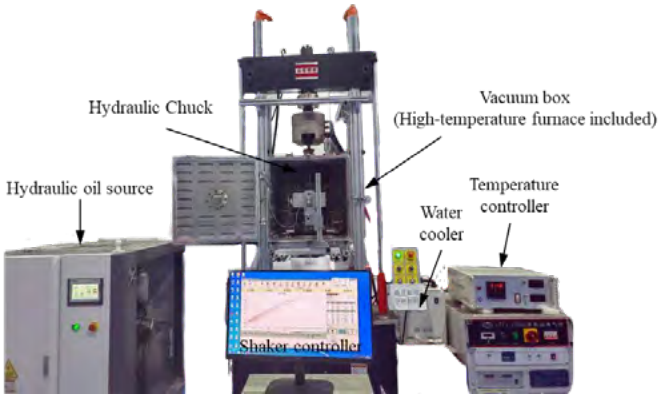
Figure 2. Dimensional drawing and picture of the rectangular specimen of 2.5D woven CMCs (mm)

2.2. Experimental Method

2.2.1. Intrinsic structure response test

Tension and loading-unloading mechanical tests were performed to obtain the tensile curves and skeleton curves for 2.5D CMCs at 1100℃. These data were utilized to establish an arbitrary cyclic tensile and compressive constitutive model.

To conduct static tensile, loading, and unloading tests on 2.5D woven SiC/SiC composites at 1100℃, a test system illustrated in Figure 3 was devised in this study. The test system primarily comprised a fatigue testing machine, high-temperature furnace and temperature control device, vacuum apparatus, water circulation cooling system, and strain measurement device.



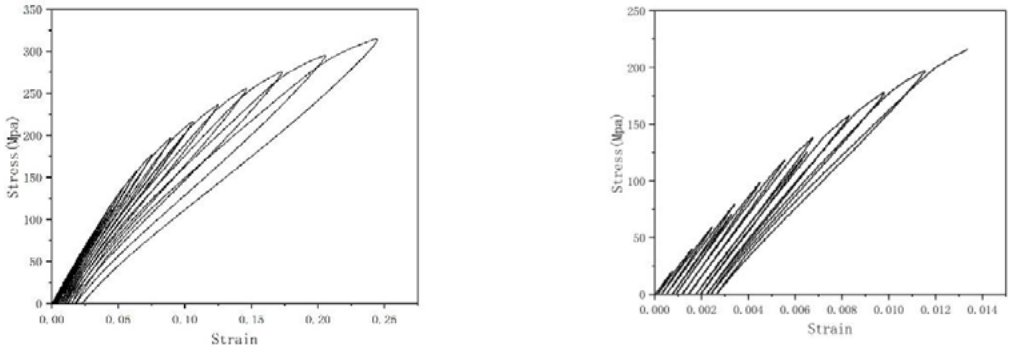


Figure 3. High temperature tensile, loading and unloading test system

The tensile test was executed under force loading at a loading rate of 0.05 kN/s until fracture occurred in the test specimen. For loading-unloading tests, force-controlled loading was employed at a loading rate of 0.05 kN/s, and loading paths were governed by a programmed sequence. Initially, tensile loads were applied until reaching the specified load, followed by unloading and reloading according to the program's parameters. Multiple loading-unloading cycles with decreasing maximum loads were included to validate the arbitrary nature of loading-unloading and the randomness of vibrational loads, thereby mitigating potential anomalies, as depicted in Figure 4.

(a) 25℃ (b) 1100℃

Figure. 4 Loading and unloading curves and skeleton curves of SiC/SiC composite.

The skeleton curves depicting cyclic loading and unloading stress–strain behaviors of the 2.5D woven CMCs at various temperatures closely mirrored the overall shape and trend observed in the monotonic tensile curve. These curves exhibited three distinct segments: initial linear, nonlinear, and secondary linear sections. The specimens' strength under cyclic loading and unloading conditions notably lagged behind that of monotonic tensile test specimens. This disparity stemmed from frictional forces between internal fibers, the matrix, and the interfacial layer, encompassing warp and weft yarns along with different transverse and longitudinal layers. Such frictional forces dissipated energy, consequently diminishing material strength [14-16].

At room temperature, the stress–strain curves of the 2.5D woven CMCs in the low-load range of the skeleton curves displayed almost linear profiles with minimal hysteresis, suggesting negligible frictional damage and energy dissipation. Conversely, in the high-load range, hysteresis loops formed in the cyclic loading and unloading stress–strain curves, with the loop area expanding alongside increasing loads. This occurrence arose from heightened interfacial frictional damage as load intensified, leading to gradual reduction in interfacial shear stress and increased interfacial debonding length. Consequently, residual strain and energy dissipation during loading and unloading augmented, contributing to a decline in material elastic modulus. Notably, the history of maximum load influenced the hysteresis loop's configuration [17].

In scenarios where tensile stress persisted at the maximum load point of the hysteresis loop, the stress–strain curve followed a monotonic tensile trajectory. This was attributed to the Ceramic-matrix's low fracture toughness, rendering it resistant to damage under cyclic loading, thereby exhibiting a "memory effect" within the hysteresis loop [18].

Comparatively, the high-temperature cyclic loading and unloading stress–strain curve largely retained its characteristics observed at room temperature. However, it no longer precisely mirrored the hysteresis loop of room-temperature loading and unloading, particularly in traversing through the historical maximum load point. This deviation became more pronounced with escalating temperatures. The weakening of initial interfacial bonding, expansion of interfacial slip zones, and exacerbation of interfacial wear at higher temperatures led to additional material damage during unloading and reloading processes. This observation underscores that elevated temperatures exacerbate material degradation [19].

2.2.2. Dynamic tests

Experimental setups suitable for high-temperature vibration tests were developed for 2.5D woven SiC/SiC composite flat-plate structures at 1100℃, as shown in Figure 5. This apparatus, designed to facilitate vibration performance testing, incorporated a vibrator, a high-temperature furnace, and precision measurement equipment, among other components. The system enabled vibration tests and dynamic response analyses under elevated temperatures.

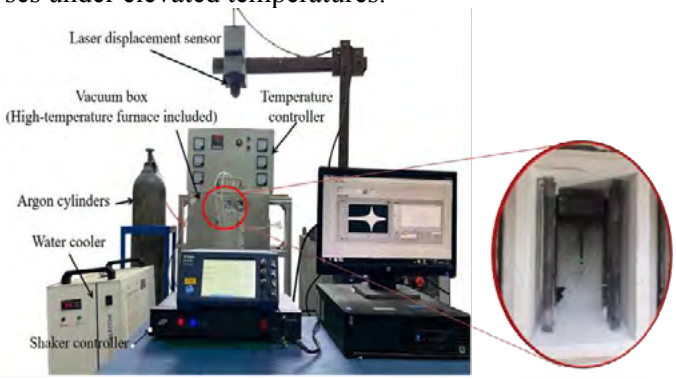

Figure. 5. High-temperature vibration experiment system

The high-temperature furnace, equipped with water cooling and gas filling functionalities, maintained a controlled environment. It featured quartz glass windows and a high-temperature resistant glass cover plate to minimize heat loss while ensuring a sealed environment. The vibration table, connected to the furnace through a vacuum-sealed interface, supported fixtures made of 310S stainless steel.

During the experiments, the vibrator's sampling frequency was set to 8192 Hz with an accuracy of 0.1μm. Initial tests involved a rapid sinusoidal sweep across a broad frequency range to estimate the first-order resonance frequencies of the undamaged CMCs. Subsequent tests increased the vibration load to

examine the material's nonlinear stress-strain characteristics. The acceleration excitation of the vibration table was set to 5 m/s², scanning frequencies near the first-order resonance frequency at a rate of 0.5 Hz/s. This method successfully captured the first-order natural frequency of the material at 1100℃. Fourier transform analysis converted time-domain data to frequency-domain signals for precise vibration analysis.

Figure 6 illustrates the vibration sweep tests on the 2.5D woven CMCs plates, demonstrating how frequency sweeping through the first natural frequency induced resonance and a significant displacement increase at 25 ℃ and 1100 ℃. This result confirmed the test data's integrity and showed a gradual increase in the first-order natural frequency with rising temperature, which, however, decreased at 1100 ℃. This behavior reflects changes in material stiffness due to temperature variations, influencing the natural frequency. Below 1100 ℃, as temperature increases, the difference in thermal expansion coefficients between the fibers and matrix decreases, enhancing material stiffness and increasing natural frequency. Above 1100 ℃, however, high temperatures cause SiC matrix degradation, fiber damage, and matrix cracks, reducing the composite's structural stiffness and lowering its natural frequency.

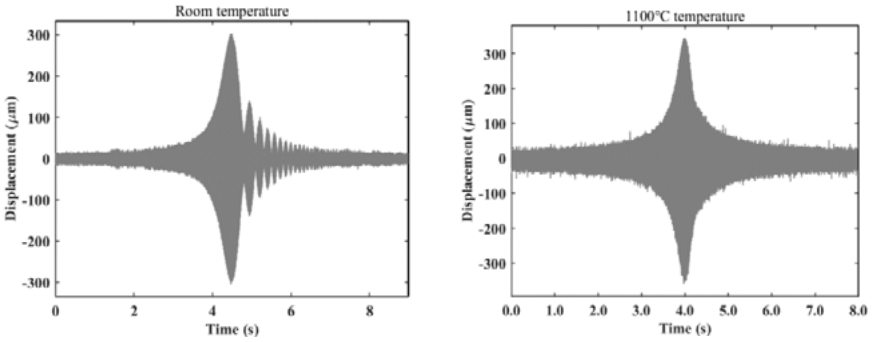

Figure. 6 Vibration time domain plot

2.3. Numerical modeling

The vibrations of CMCs beams involve individual units undergoing arbitrary cyclic tensile and compressive loads. Accurate simulation of these vibrations necessitates an intrinsic model that captures the repetitive stress behaviors under vibrational conditions. Establishing this model requires high-temperature tensile tests on 2.5D woven CMCs.

We utilized the cyclic loading and unloading stress-strain curves from these tests to model the behavior of 2.5D woven CMCs at high temperatures. This model, derived from the skeleton curves' trends, establishes a relationship between the historical maximum strain and the stress-strain response during each cycle.In the low-load range, linear fitting addressed the loading and unloading behaviors, where the modulus decreased in line with the skeleton curve. At high loads, direct fitting of the hysteresis loop was impractical due to the lack of a memory effect and material damage from high temperatures. However, the sub-loop displayed nearly linear behavior with minimal hysteresis, suggesting that friction damage had largely stabilized after the initial cycle. This finding highlighted the role of historical maximum stress in assessing material damage.

In conclusion, the completion of fitting arbitrary cyclic tensile and compressive stress–strain curves for 2.5D woven CMCs in 1100℃ environments provides a comprehensive understanding. Based on this macroscopic intrinsic model, stress at a given time can be calculated when the stress and strain at that time, the strain at a previous time, and the historical maximum stress and its corresponding strain are known., as shown in Eqs. 1:

$$^{t+\Delta t}\sigma = f(^{t}\sigma, ^{t}\varepsilon, ^{t+\Delta t}\varepsilon, \varepsilon_{\max}, \sigma_{\max}) \tag{1}$$

A finite-element model of the CMCs beam, matching the dimensions of the test specimens, was developed to simulate the effects of sinusoidal gravity fields at varying frequencies. This model helps to mimic the conditions of vibration tests effectively.

The structure of the cantilever beam is simple, and during its bending vibration, normal stress acts along the axial direction. Thus, each small element on the beam can be considered to undergo arbitrary tensile

and compressive behavior. Therefore, it is reasonable to use a CMCs arbitrary loading and unloading constitutive model considering temperature effects for dynamic response calculations, which can reduce computational complexity.
The vibration of the fixture base has been reflected in the equation through the global inertial load , and the displacement of the vibrator is very small and can be ignored in the simulation. Hence, this boundary condition is set:

$$u(x = 0) = v(x = 0) = w(x = 0) = 0 \tag{2}$$

$$\boldsymbol{f} = (0, 0, f)^T = (0, 0, \bar{f} \sin \omega t)^T \tag{3}$$

Based on the principle of virtual displacement, the dynamic control equation for CMCs is established as follows:

$$\int_\Omega \sigma_{ij} \delta \varepsilon_{ij} dV - \int_\Omega \rho \ddot{u}_i \delta u_i dV - \int_\Omega c \dot{u}_i \delta u_i dV - \int_{\Gamma 2} q_i \delta u_i ds - \int_\Omega \rho \bar{f} \sin(\omega t) \delta u_i dV = 0 (i, j = 1, 2, 3) \tag{4}$$

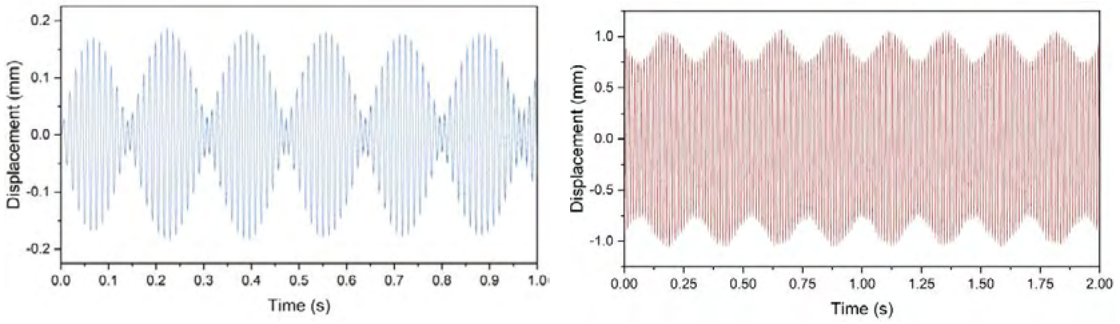
Where u, v, and w represent displacements in the x, y, and z directions, respectively.

By balancing (stress) differential equations and geometric differential equations, the control equation is simplified to:

$$\boldsymbol{K}^T \delta \boldsymbol{a} - \ddot{a}^T \boldsymbol{M}^T \boldsymbol{a} - \dot{\boldsymbol{a}}^T \boldsymbol{C}^T \delta \boldsymbol{a} = \boldsymbol{Q}^T \delta \boldsymbol{a} \tag{5}$$

Where:

$$\begin{cases} \boldsymbol{M} = \sum_e \int_{\Omega^e} \rho \boldsymbol{G}^{eT} \boldsymbol{N}^{eT} \boldsymbol{N}^e \boldsymbol{G}^e \mathrm{d}V \\ \boldsymbol{C} = \sum_e \int_{\Omega^e} c \boldsymbol{G}^{eT} \boldsymbol{N}^{eT} \boldsymbol{N}^e \boldsymbol{G}^e \mathrm{d}V \\ \boldsymbol{K} = \sum_e \int_{\Omega^e} \boldsymbol{G}^{eT} \boldsymbol{B}^{eT} \boldsymbol{\sigma}^e \mathrm{d}V \\ \boldsymbol{Q} = \sum_e \int_{\Gamma^e} \boldsymbol{G}^{eT} \boldsymbol{N}^{eT} \boldsymbol{q} \mathrm{d}S \end{cases} \tag{6}$$



It should be noted that K here is not the stiffness matrix, but a vector with the same dimensions as the degrees of freedom of the structure. Writing the dynamic equation in this form facilitates the subsequent solution of the dynamic equation. Although not a stiffness matrix, it effectively reflects the stiffness of CMCs, and material nonlinearity is manifested in K.
This study employs the center difference method to solve the dynamic equations. This method is based on the finite difference method rather than the derivative of displacement with respect to time. The velocity and acceleration are obtained using the first-order and second-order derivatives of displacement, respectively. Utilizing the center difference method not only avoids matrix inversion but also accelerates the calculation speed and does not produce mathematical discontinuity points in the calculation process of the intrinsic model, effectively avoiding iterative operations and saving space in the calculation. This method is very suitable for calculating the nonlinear vibration response of CMCs.
Based on the established macroscopic arbitrary tensile and compressive intrinsic model of 2.5D woven CMCs in different temperature environments, a self-developed solver was programmed to import the material properties. Subsequently, leveraging the theory of the central difference method, self-developed solver was developed to calculate the vibration response.

3. Conclusions

The nonlinear constitutive behavior of CMCs is calculated using the shear-lag model, and the parameters involved in the calculation are shown in Table 1.

Table 1. Parameters of constitutive model.

Item	Value	Item	Value
E_m / GPa	369.75	τ_i /MPa	50
E_f / GPa	223.80	r_f / μm	6
α_m /$\times 10^{-6}$ / ℃	4.53	L_{sat} / mm	0.54
$\alpha_f \times 10^{-6}$ / ℃	0.1252	ΔT / ℃	-1000
ν_f	0.2	σ_{mR} /MPa	140
ν_m	0.8	m	2

In this study, progressive intralaminar and interlaminar damage models suitable for simulation of impact phenomena in woven fibre reinforced plastic (FRP) composites are introduced. In order to reduce costs of development and production of structural components in aeronautical, space, military and automotive industry, development of high-fidelity numerical models suitable for capturing the mechanical behaviour of FRP composites in all loading regimes is inevitable. Moreover, in order to accurately predict the load bearing capabilities and to be able to design the structural elements correctly, taking the strain rate effects in consideration is also imperative, as concluded in a large number of researches. Thus, by implementation of this comprehensive mesoscale numerical model in the commercial finite element method (FEM) software package Abaqus/Explicit as a VUMAT user-defined material model subroutine, an effort is made in advancing the current state of available woven FRP material models.
Intralaminar failure initiation and damage evolution is based on the Continuum Damage Mechanics (CDM) approach, whereas the interlaminar damage is modelled based on the Fracture Mechanics (FM), i.e., the Cohesive Zone Model (CZM) in the form of the decoupled bilinear traction-separation law. Both failure initiation and damage propagation are considered to be strain rate dependent. Hence, empirical logarithmic functions are utilized to scale both intralaminar material strengths and fracture toughness values based on the reference strain rate value and experimentally obtained data in quasi-static loading conditions. The fitting parameters of the empirical strain rate effect curves were then fitted according to dynamic experimental results. Material degradation is captured by a total of seven intralaminar damage variables, and a single interlaminar damage variable. Removal of both cohesive (representing interfaces) and solid (representing FRP plies) finite elements is utilized in order to simulate the complete failure of the material point. Characteristic finite element length is used in the CDM approach in order to overcome the mesh dependency of the solution. Inherent oscillations of numerically obtained values in explicit integration procedures are treated by a low-pass filter-like algorithm.
In order to verify and validate the developed model, impact simulations at various impact energies, i.e., initial velocities, were performed according to experimental and numerical investigations found in the available literature. The results obtained by utilization of developed material model demonstrate a good agreement with the referent ones.

Keywords: resistance welding, heating element, single lap shear, wind turbine blades, glass/epoxy composites

Abstract
Commercial wind turbine (WT) blades that are now being operational globally, are primarily made of glass-reinforced composites using epoxy or polyester matrix systems, mainly epoxy. The industry is rapidly growing (2100 TWh currently; 17% growth annually) with a forecast of 7400 TWh by 2030. The average lifespan of a WT is 20-25 years, which signifies the importance of repairing the damaged blades. Amongst the methods that have been exploited so far, resistance welding shows eminent potential, due to its ease of operation, promptness of the repair process, and cost effectiveness. Resistance welding was exploited previously for repairing thermoplastic composites. But in this project, repair of thermoset composites was evaluated using thermoplastic welding medium. The project focused on parametric optimisation of resistance welding, evaluation of welding via single lap shear strength, and COMSOL multiphysics modelling to examine the homogeneity of heat-distribution across the welding region. Stainless steel mesh and carbon nonwoven sheet were used as heating elements, while polymethyl methacrylate and thermoplastic polyurethane were used as welding medium. The highest single lap shear strength was shown as 6.4 MPa when nonwoven carbon sheet was used along with thermoplastic polyurethane. COMSOL modelling with a custom-designed heating element showed improvement in thermal homogeneity; however, further modifications will be required to better optimisation of welding.

1. Introduction

Wind turbines (WTs) are pioneering now globally in terms of renewable energy and this industry shares 7.33% of the global electricity generation, which is double of what was in 2015 before Paris Agreement [1]. For the EU including the UK, this figure is 17% [2]. Solar and wind energy are two of the major sources for renewable energy globally, which combinely share 23% of global energy market. The new target to meet by 2030 is to capture 42.5% of the energy market by renewable sources to meet the climate and energy goals [3]. While these stats implies a substantial growth of the WT industry, it can be envisaged that the necessity of operations, repair and maintenance of wind turbine blades (WTBs) will significantly rise [2]. Operations and maintenance may account for 25% to 40% of the levelised cost of energy [4].

As the necessity of the operations relating to repair and maintenance can be substantiated from the above discussion, it can also be noteworthy that the average lifespan of a wind-turbine blade is around 20 to 25 years [4]. In 2022, 19 gigawatt (GW) of WT plants were installed in the EU, and the figure will be 129 (GW) by the period of 2027 [2]. Understandably, the industry now heavily focuses on repair and maintenance of WT plants.

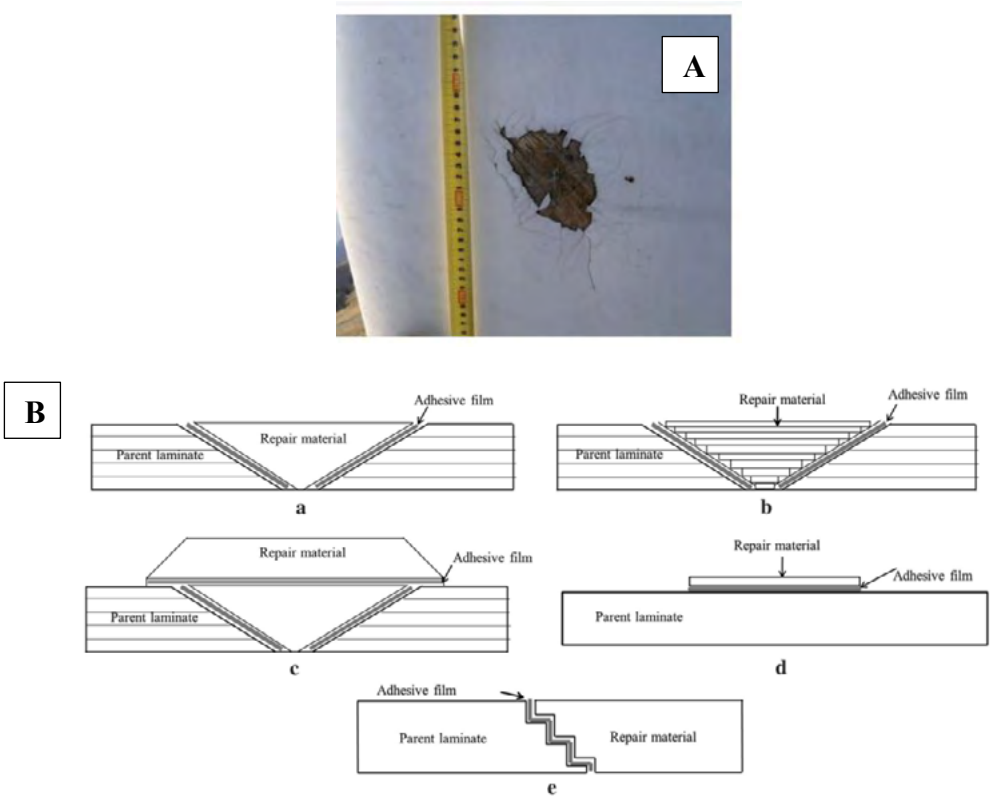

Figure 1 (A) A damaged WTB [15]; (B) Types of bonded joints [16]

This research work focuses on repairing wind turbine blades (WTBs) by bonded joints. As the blades are continuously operational and exposed to the environment, different types of damages including delamination, failure at joints, and leading-edge erosion occur frequently [5]. A typical example can be seen in **Figure 1**A. In terms of common damages and the corresponding repairs, Xiao et al. (2020) have conducted an intensive review, wherein, attaching repair patch to the damaged area has been shown as a frequently occurring repair method [6]. The most commonly used materials for WTBs are thermoset glass fibre/epoxy composites (GFC). Some of the common types of repair patches are shown in **Figure 1**B. RW is a technique, wherein, the damaged interface is subject to localised heating, with precision time, temperature, and an effective welding media, which joins the repair patch to the damaged surface. In this method, electrical energy is transmitted through an heating element (HE), which are commonly comprised of stainless-steel mesh (SSM), carbon nonwoven sheet (CNWS), or printed HE. The transmitted electrical current eventually generates heat energy within the HE, which is then dissipated to the welding medium, mainly polymeric materials, located on the top and/or at the bottom of the HE. A schematic diagram of a welding stack is shown in **Figure 2**. When the current passes through for a certain amount of time, the temperature rises up to the melting point of the polymers. When the molten polymers get cooled, it joins the repair patch to the damaged substrate. Normally, the heat generation and the melting of the polymers happen in less than 40 seconds of current flow, and the cooling down of the materials through convection (of heat to the surrounding air) also happens within a few minutes.

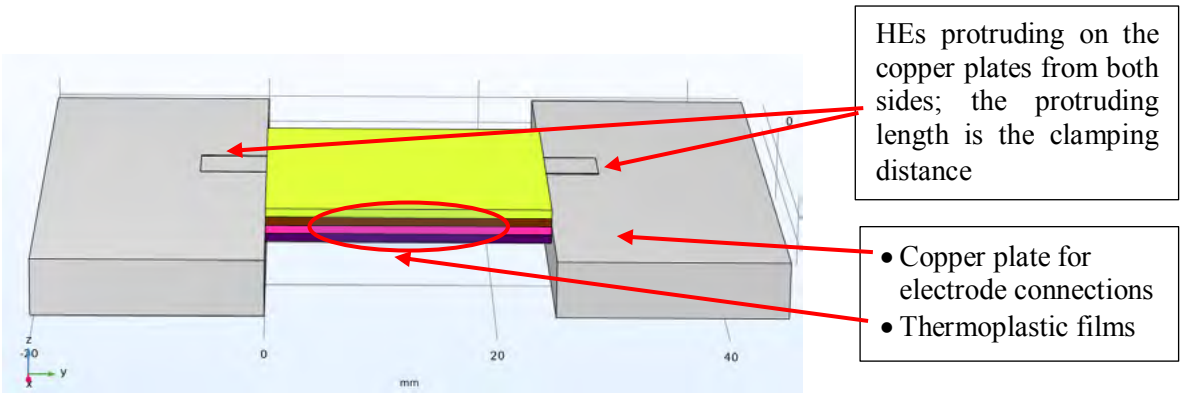

Figure 2 A schematic diagram of a single lap shear test coupon (Z-axis is magnified 5 times)

So far, a number of research works have been found to have critically evaluated resistance welding of thermoplastic composites with differet polymers as welding mediums and different HEs such as: CNWS, SSM and printed HE with conductive ink [7-13]. However, one research can be found from Yunhao and Shi (2023), wherein, two GFC composites were bonded via RW using SSM as a HE, and polymethyl methacrylate (PMMA) as a welding medium [14]. However, the homogeneity of heat distribution, evaluated via COMSOL multiphysics was found as an area of development. Due to the lack of homogeneity, the single lap shear strength was found as 3.6±0.3 MPa, which was less than the benchmark sample made by them: 5.1±0.4 MPa. The less strength was attributed to the 'edge-heating' phenomena as shown in **Figure 3**.

In this current study, resistance welding was evaluated via single lap shear strength, using SSM and CNWS as HEs. As welding medium, TPU film was used. Besides, a custom-designed HE was evaluated via COMSOL multiphysics modelling to improve the heat-distribution homogeneity.

2. Materials

2.1 Heating element

Plain woven SSM with 30 µm diameter and 110 µm opening width, 66 µm thickness with resistivity as shown in **Figure 4** A. Also, we have procured a range of nonwoven mesh with different areal densities (20 to 80 g/m2) and surface resistivity (27 to 0.4 ohm/square); an example is shown in **Figure 4**B. Secondly, carbon nonwoven sheet with 35 g/m2 areal density and 0.38 ohm/square and 0.48 ohm/square.

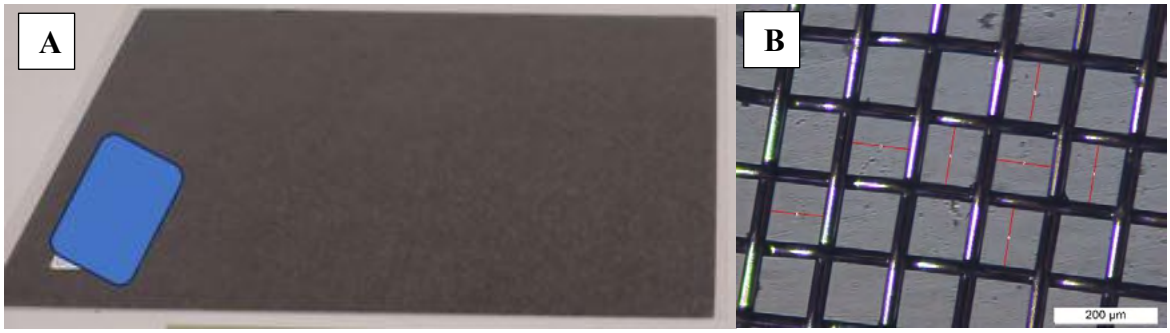

Figure 4 (A) SSM; and (B) Nonwoven Carbon mesh (A4 size)

2.2 Welding medium:

DUPONTTM TE-11C TPU films has been procured from DUPONT, as shown in **Figure 5**, with 133 g/m^2 areal density, 110 µm thickness, 160 ºC melting point, 270 ºC degradation temperature, and 1500 J/kg-K heat capacity.

Figure 5 TPU film

3. Experimentals

3.1 Composite panels:

Glass/epoxy preforms were purchased from SHD composites under the commercial brand name VTC 401, with 290 gsm (gram per square metre). The panels were made using vacuum bagging at the following curing cycle: 80 ºC for 4 hours and 120 ºC for 1 hour; the glass transition temperature, T_g, was 130 ºC. **Figure 6** shows the laminates. 8 layers of prepregs were used and the cured laminate thicknesses were measured as 1.77 ± 0.04 mm, with around 52% fibre volume fraction.

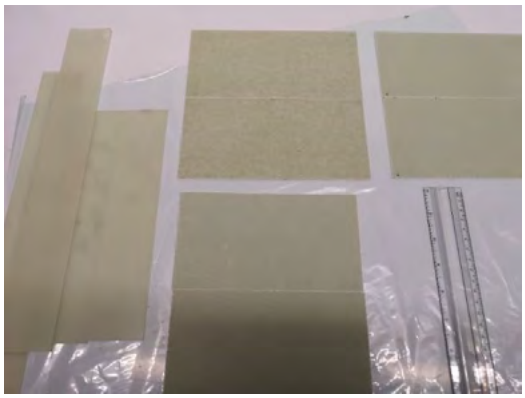

Figure 6 Glass/epoxy composite panels

3.2 Resistance welding

A welding rig has been constructed to produce test coupons for single lap shear (SLS) strength as shown in **Figure 7** A. The welding region of a test coupon was 25.4 mm^2. Firstly, the TPU films and the HEs were cut according to the appropriate sizes, as shown in **Figure 7** B to construct the welding stack. In this project, the typical welding stack was constructed with: 2 TPU films at the top, 2 SSMs or 1 CNWS in the middle, and 2 TPU films at the bottom. The stack was then placed between two laminates,

wherein, the HE protrudes at a certain length from the edges. Those two protruding HEs are then gets in contact with the copper plates from both sides by two side clamps, as shown in **Figure *8*** B. Finally, the copper plates were connected to the power supply unit (Elektro-Automatik 9080; 60A – 80V – 1500 W).

Figure 7 (A) RW setup, and (B) cut pieces of films and SSM

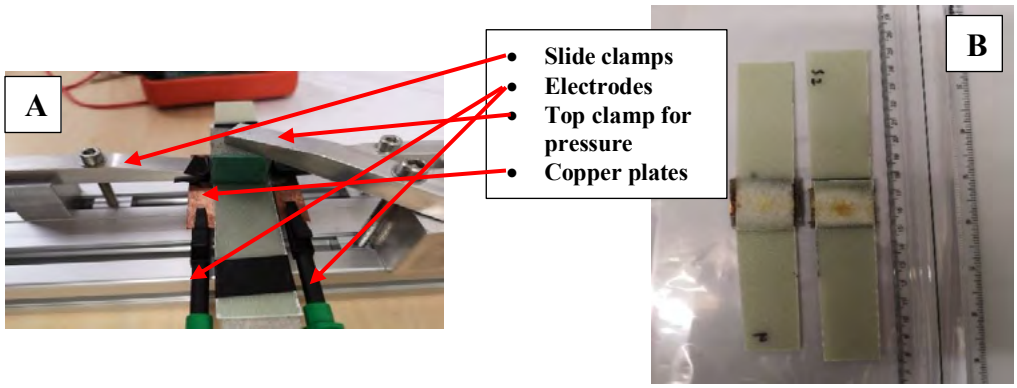

Figure 8 (A) The welding setup; and (B) Welded samples.

An important controlling point of this RW is to minimise heat dissipation via convection as much as possible. To do this, we have put a cement block on the top of the welding region, as shown in **Figure 9**.

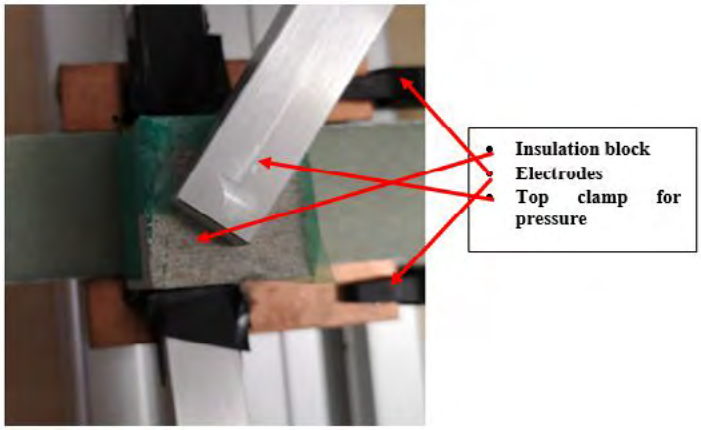

Figure 9 Top view of the RW rig

3.2 Single lap shear (SLS)

Single lap shear tests were carried out using an Instron 3369 machine, as shown in **Figure 10**.

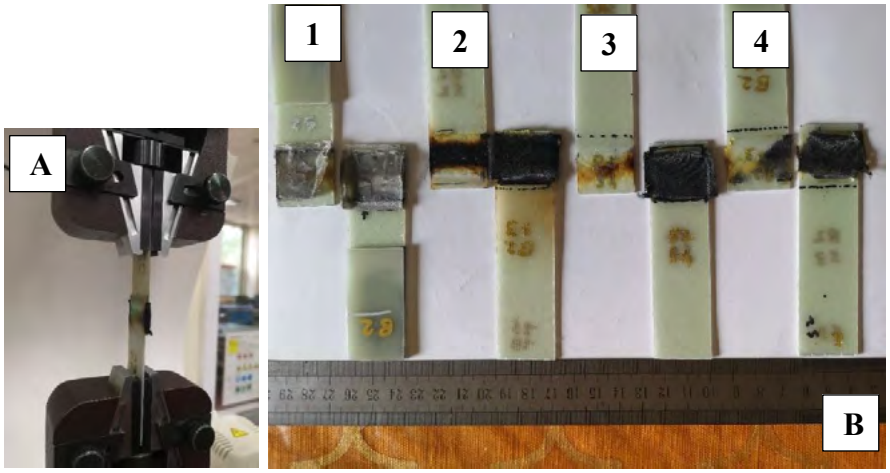

Figure 10 (A) Instron 3369 machine; and (B) SLS tested coupons

Figure 11 Damaged test coupons from SSM as HE; 50W, 1mm, 50s; 5.9 ± 0.3 MPa

4. Optimisation of welding parameters

$$Weight\ of\ the\ TPU\ films, m\ (in\ kg) = areal\ density\ \times area\ of\ film \times no.of\ layers$$

$$Heat\ required\ to\ melt\ the\ films, E = m \times c\ \times \Delta\theta \ldots\ldots\ldots\ldots \textbf{\textit{Equation 1}}$$

$$c = heat\ capacity\ in\ Jkg^{-1}K^{-1}$$

$$\Delta\theta = difference\ between\ room\ temp.\ and\ melting\ temp.$$

For each SLS test coupon, with a welding stack consists of 4 layers of TPU film, around 83 Joule heat will be required. To generate that heat, the following equation can exhibit the required power density:

$$E = P \times t \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \textbf{Equation 2}$$

$$or, R = \frac{V^2}{E}.t$$

$$Wherein, E = energy$$

$$P = power\ in\ watt, W$$

$$V = voltage\ in\ V$$

$$R = resistance\ in\ ohm, \Omega$$

$$t = time\ in\ seconds\ for\ the\ electricity\ to\ pass\ through$$

If electricity runs for 30 seconds and apply 5 volts, a resistance of 9Ω will generate the required amount of heat to melt the TPU films fully, for a typical SLS coupon made in this project. And with this setup, 2.8 Joule of heat will be produced in each second, and 1.9 Joule heat energy will be required to increase the overall temperature by each degree. Provided that some of the heat energy, for example, 15% will be dissipated via conduction and convection, the welding time can be increased by 5 sec to match that. Based on the above equations, two welded samples are shown in
Figure *8* B. The sample on the right has a brown patch visible in the mid region. This was due to running the current for a longer period (more than 50 seconds).

5. Discussion of single lap shear tests and COMSOL modelling

Table **1** summarises the results for SLS. It can be seen that the TPU and CNWS combination showed the best result among the lots. Compared to SSM and PMAA combination, TPU and CNWS showed better result due the presence of carbon fibres. The mechanical interlocking between carbon and thermoplastic polymers was better compared to that between SSM and polymers, due to lesser frictional coefficient of stainless-steel. Although, the tensile strength of PMAA is higher than that of TPU [17], PMAA was not used due to its unavailability for commercial grade films. **Figure 10B.1** shows a SLS

Table 1 Single lap shear strength results

Heating element	Welding medium	Single lap shear strength (MPa)	Welding thickness (mm)	Power density (watt)	Welding time (seconds)	Composite type	Fibre volume fraction
CNWS	TPU	6.4±0.8	1.2±0.15	50	50	GFC	53%
SSM	TPU	4.2±0.9	0.9±0.14	50	50	GFC	51%
SSM	PMAA	5.9±0.3	1.3±0.21	50	50	GFC	54%

coupon with SSM. The other three coupons (B.2, B.3, and B.4) are comprised of CNWS. It can be observed that the failure mode was cohesive. In terms of parametric optimisation, the calculations based on **Equation 1** and **Equation 2** did not take into account the heat dissipation from HE and welding regions to the air. Therefore, it was observed that when the welding time was 30s, the welding was not fully completed, but running for around 50 sec created some burning marks, as shown in **Figure 10B.2.** This probably had occurred from polymeric films being risen above their degradation temperature. **Figure 11** shows the damaged test coupons from SSM as HEs; the brown marks at the edges indicates heat-concentration during welding. Therefore, further optimisation will be required to obtain a better welded region, which may result in higher SLS strength. In order to further evaluate the welding parameters and to minimise 'edge-heating', a COMSOL multiphysics modelling is shown in **Figure 12**. The model still shows 'edge-heating' phenomena to some extent, but further modification of the custom-designed HE can potentially solve this problem.

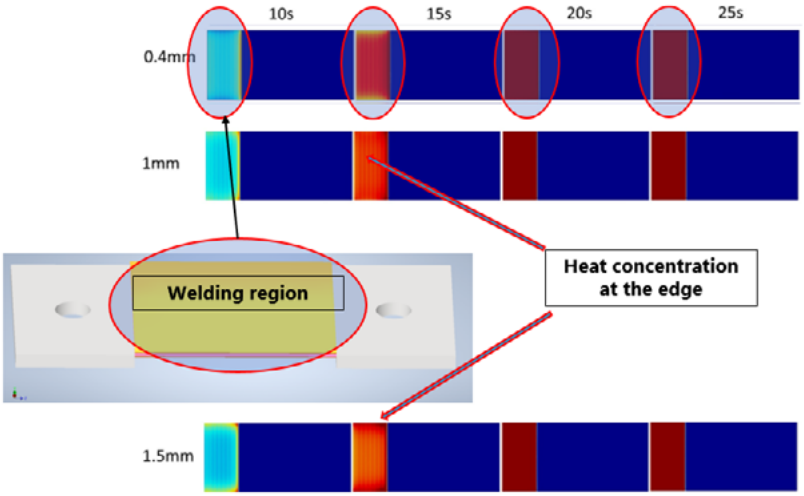

Figure 12 COMSOL modeling; custom-designed HE with PMAA film; the surface is in between the PMAA film and top GFC

6. Conclusion

A novel resistance welding solution has been investigated to provide repair services for thermoset glass/epoxy wind turbine blades, using thermoplastic welding medium. When stainless-steel mesh was used as a heating element along with polymethyl methacrylate (PMAA) film as a welding medium, the single lap shear strength was found to be 5.9 MPa. However, when carbon nonwoven sheet was used as a heating element with thermoplastic polyurethane (TPU) as a welding medium, the lap shear strength was found to be slightly higher, 6.4 MPa. Although the tensile strength of PMAA is higher than that of TPU, the higher lap shear strength from TPU and nonwoven sheet can be plausibly attributed to the better mechanical interlocking of the nonwoven carbon with the thermoplastic polymers. Fractography revealed some burning marks across the welded regions, which might be stemmed from lack of homogeneity towards heat-distribution. Hence, a custom-designed heating element was generated and

COMSOL multiphysics modelling was conducted, which still exhibited heat-concentration at the edges; however, in a lesser extent. Further modification of the heating element, thus, will be required to ensure a better homogeneity in heat distribution, which will eventually lead to obtaining an improved mechanical strength for the welded regions. Furthermore, thermoplastic films with higher load bearing properties, along with carbon nonwoven sheet as a heating element will potentially improve the welding strength. Further research of this project thus aims to produce a novel-designed heating element for resistance welding to repair offshore wind-turbine blades that will have superior bonding strength.

Keywords: composites, fire, thermophysical properties, numerical-experimental, inverse analysis

Abstract
During a fire, the composite material is exposed to an external heat flux and a rising pressure, undergoing chemical and physical change that affects its thermal, mechanical and physical properties as temperature rises. To anticipate fire safety concerns, CFD simulations can be used at the structural scale in the design phase. The models developed for this goal require an identification of the thermophysical properties of the material, which can be obtained from experimental testing. This identification can be difficult, given their temperature-dependent change with the phases of thermal decomposition.

This paper proposes a simple methodology for this task. A thermophysical model combines mass-loss kinetics and heat transfer to simulate temperature change in the material. A modified cone calorimeter test provides the necessary experimental data for the calibration of the thermophysical properties using inverse analysis.

1. Introduction

High-pressure filament-wound composite cylinders have become the most common option for hydrogen fuel transport due to the lightweight nature and mechanical performance of the material. The alignment of carbon fiber-reinforced resin tapes in the direction of maximum stress provides a strong load-bearing element for the vessel. However, safety concerns dictate that the vessel should withstand its load-bearing capacity in the case of a fire. It is then of primordial importance that the material demonstrates high fire resistance, controlled by its thermophysical properties.
The identification of the thermophysical parameters can be difficult [1-3]. This is due to the fact that the properties of the material vary with the temperature as the mass undergoes thermochemical change under fire. Moreover, the coupling between the kinetics of decomposition that happen at the low scale and the global thermal behaviour at the larger scales must be taken into account. In the uncoupled analysis done by Hidalgo et al. [3], the heat equation is first solved with the assumption of an inert material and using effective thermophysical properties, then the remaining mass is estimated in the pyrolysis model. This of course assumes a decoupling between the two phenomena, which explains the further assumptions taken as the imposed heat flux changes. Tranchard et al. [2] used a two-step decomposition model as a basis for the thermal model, where temperature-dependent thermophysical properties of both virgin and fully degraded materials were measured. In this study, discrepancies between the experimental profiles

of temperature and those predicted by the model were found, highlighting the difficulty of accurately identifying the heat flux at the exposed surface.
In the proposed study, a multi-step kinetic model is also introduced and coupled with the thermal model where the thermophysical properties are expected to depend on the temperature and the mass loss kinetic aspect of decomposition. This comprehensive model is used to simulate a cone calorimeter test, where the temperature profiles are also experimentally measured at specific depths. This establishes a basis for the inverse analysis to identify the thermophysical properties at different steps of decomposition.

2. Model and boundary conditions

2.1. Thermal decomposition equations

In this model, the overall density of the material evolves as a function of the constituents of each reaction i, considering a unit volume, as shown in the following:

$$\frac{\partial \rho}{\partial t} = \rho_0 \sum_{i=1}^{N} \left(- \sum_{\gamma \in R_i} r_\gamma + \sum_{\delta \in P_i} \nu_\delta r_\delta \right) \tag{1}$$

where ρ_0 denotes the overall density of the virgin material, r_δ the production rate of products P_i and r_γ the consumption rate of the reactants R_i. ν_δ is a stoichiometric coefficient which takes into account the reduction of mass due to the decomposition and the evaporation of reaction gases. In a single-step kinetic model, it is assumed that a single reaction converts a homogeneous mass $\rho_{\gamma,0}$ into a product, with a remaining reactant mass $\rho_{\gamma,e}$. The mass loss rate follows an Arrhenius function [2]:

$$r_\gamma(t) = \frac{\partial \rho_\gamma}{\partial t} = -\rho_{\gamma,0} \left(\frac{\rho_{\gamma,0} - \rho_{\gamma,e}}{\rho_{\gamma,0}} \right)^{n_\gamma} A_\gamma \cdot e^{-\frac{E_{a,\gamma}}{RT}} \tag{2}$$

where R is the universal gas constant, A and E_a are the pre-exponential factor and the activation energy of the Arrhenius model, respectively. n is the reaction order. For a multi-step model, it is assumed that density ρ_0 undergoes consecutive steps of the same equation (Eq. 2), with the product of each step being the reactant of the next. It is therefore convenient to consider mass m as a vector for simple calculations. In the case where a reaction converts one reactant into a single product, the consumption and production rates are equal (with the stoichiometric coefficient dictating the conversion rate).

2.2. Heat transfer equations

From energy conservation principles, the heat equation governing temperature T evolution (including transient heat transfer) for a 1D system can be written as:

$$\rho_s C_{p,s} \frac{\partial T}{\partial t} = \frac{\partial}{\partial x} \left(\lambda_s \frac{\partial T}{\partial x} \right) + \dot{q} \tag{3}$$

The 3 thermal properties are the density ρ_s, heat capacity $C_{p,s}$ and conductivity λ_s. $\dot{q}$ is the heat source. To account for the enthalpy of reaction ΔH_r during pyrolysis, the heat source includes:

$$\dot{q}_{pyr} = \sum_{i=1}^{N} r_i \Delta H_{r,i} \tag{4}$$

Since the previous equation is applied to a homogenised material, the thermal properties are dependent on the evolution of the reaction steps as well as temperature. Due to the difficulty of measuring the said properties as the material undergoes decomposition, the mixture laws proposed by Tranchard et al. [2] are used, using only the apparent properties at the beginning and end of the reaction step. For instance, the heat capacity will be calculated using the following mixture law:

$$C_{p,s} = \frac{1}{\rho_s} \sum_{\delta=1}^{N} \rho_i C_{p,i} \tag{5}$$

where the densities are calculated from the reaction rates using Eq. (1).

2.3. Boundary conditions

The heat transfer thermal problem posed above is applied to a modified cone calorimeter test where the top surface of the sample is exposed to a uniform heat flux from the cone source, with conditions that allow for the exchange of heat through radiation and convection. The bottom surface, on the other hand, is isolated. In order to capture the evolution of temperature inside the material, a special mould was used whereby thermocouples can be inserted at specific distances inside the sample, as illustrated in Figure 1. The presence of the thermocouples is assumed not to disturb the heat transfer along the thickness.

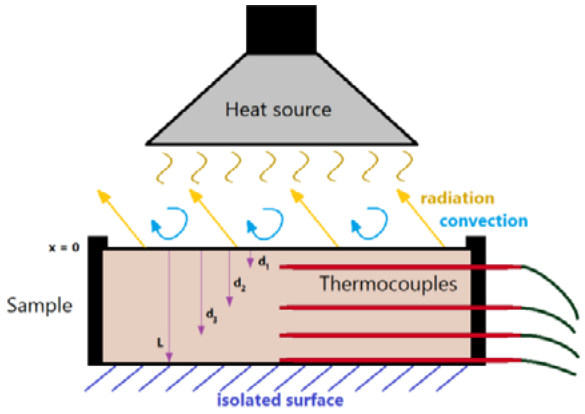

Figure 1. Modified cone calorimeter test with thermal boundary conditions shown.

The net heat flux on the surface exposed to the continuous heat source from the cone is the sum of both contributions from the convective and radiative heat transfer with the surrounding ambient air:

$$-\lambda_s \frac{\partial T}{\partial x}(x=0,t) = \dot{q}_{conv} + \dot{q}_{rad} \tag{6}$$

The convective part is expressed as a function of the temperature-dependent convective heat transfer coefficient $h(T)$:

$$\dot{q}_{conv} = h(T)(T - T_\infty) \tag{7}$$

while the radiative part includes both the flux from the energy source and the thermal radiation emitted by the surface following the Stefan-Boltzmann law:

$$\dot{q}_{rad} = \epsilon\sigma(T^4 - T_\infty^4) \tag{8}$$

where T_∞ is the ambient temperature of the gas flame, ϵ is the emissivity of the material, σ is the Stefan-Boltzmann constant. On the isolated back surface, the heat flux is null:

$$-\lambda_s \frac{\partial T}{\partial x}(x=L,t) = 0 \tag{9}$$

The kinetic parameters A_γ, $E_{a,\gamma}$, n_γ and ν_γ are first to be determined from a TGA decomposition curve, then the rest of the model's thermophysical properties must be identified by inverse analysis from the cone calorimeter test.

3. Materials and experimental data

The material used is a carbon fiber-reinforced thermoplastic resin (PA11) composite. Small scraps of the composite material were extracted for TGA under air atmosphere, with the temperature rising from 40°C to 900°C at a heating rate of 10°C/min. As shown in Figure 2, the decomposition shows 3 peaks. In the first step, oxidation of the resin in the range 300-380°C reduces the mass by about 3-4%. The higher peak in the second step represents the pyrolysis of the resin which accompanies a rapid decrease in mass, reaching a value of 0.08g.s^{-1} around 440°C. The third peak of resin decomposition is associated

with the oxidation of the residue between 480°C and 600°C. As the experimental curve from Figure 3 demonstrates, the final mass represents 69.37%, which is the mass of the non-decomposed carbon fibers. In the cone calorimeter test [5], samples of the same material of total surface 100mm² (with an exposed surface of 88.36mm², as required in ISO 5660 [6]) is used. Since the insertion of thermocouples leads to incorrect mass measurements, 2 sets of samples are used: the first is the standard test where the mass loss is measured accurately without interference from the thermocouples, and the second set where mass measurements are ignored, as thermocouples measure the evolution of temperature at 4 specific heights: 1mm, 3.3mm, 5.6mm and 6.6mm (using the middle of the top surface as a reference point). The cone calorimeter apparatus is conducted under air with a heat flux of 50kW.m^{-2}.
As shown in Figure 4 (below), a reduction in mass begins after about 30s, and the total mass gradually decreases until about 600s, reaching a value close to 68% of the initial mass. Figure 5 demonstrates that the mass loss kinetics in the cone calorimeter test undergoes 2 peaks, the first peak around 100s shows the decomposition of the top surface which then acts as an isolating barrier for the bottom surface, that is until enough heat is transferred to accelerate their decomposition as the peak is reached after 400s.

4. Simulation results: identification of the model parameters

4.1. Kinetic parameters

As shown in Figure 2, the TGA curve of the composite presents 3 different peaks. Therefore, the kinetic model includes 3 steps, each pertaining to a specific reaction that converts a part of a single reactant (the resin mass) into a single product with a stoichiometric coefficient to be identified.
Based on the work of Batiot et al. [9], the influence of each of the kinetic parameters can be analysed. Both A_γ and $E_{a,\gamma}$ have an impact on the peak temperature of the reaction step, while n_γ and ν_γ influence the shape and the height of the peak. Table 1 presents the parameters of the kinetic model found for the 3 steps through an inverse analysis using a Particle Swarm Optimization algorithm [10-11]. The reaction enthalpy for the pyrolysis step is taken from Dao et al. [12]. Figures 2 and 3 show a good agreement between the experimental and numerical curves of MLR and mass loss, respectively. Both peaks of the 1st and 3rd steps are accurately represented. The maximum mass loss rate of 0.08%/s in the 2nd peak was not reached. A decrease in ν_2 would lead to an increase in the peak value, but would reduce the amount of mass produced for the next step, thereby reducing the size of the last peak. Therefore, a compromise has been reached. Regardless, the mass loss is accurately represented in Figure 3, with a final mass of 68.6%, close to the experimental value of 68.2%.

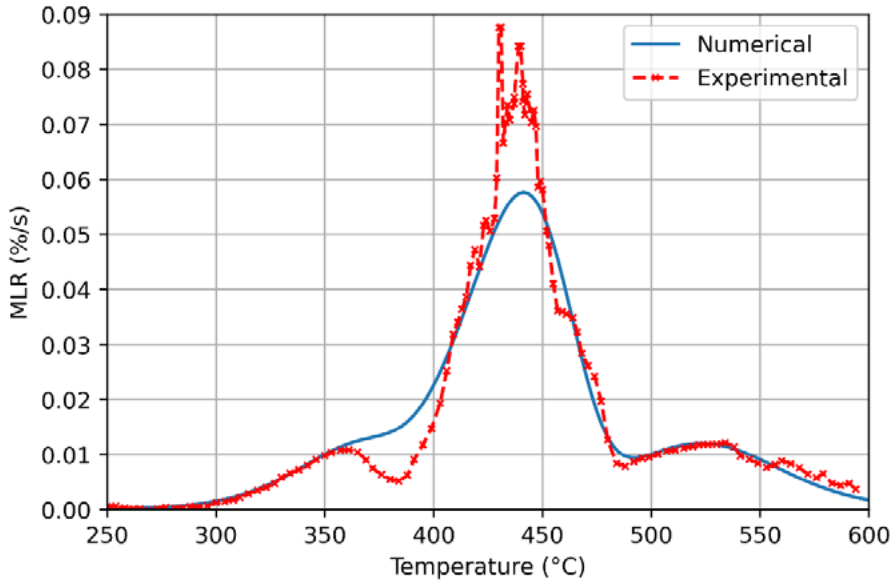

Figure 2. Thermal decomposition of the composite (TGA curve): normalized mass loss rate (MLR) as a function of temperature.

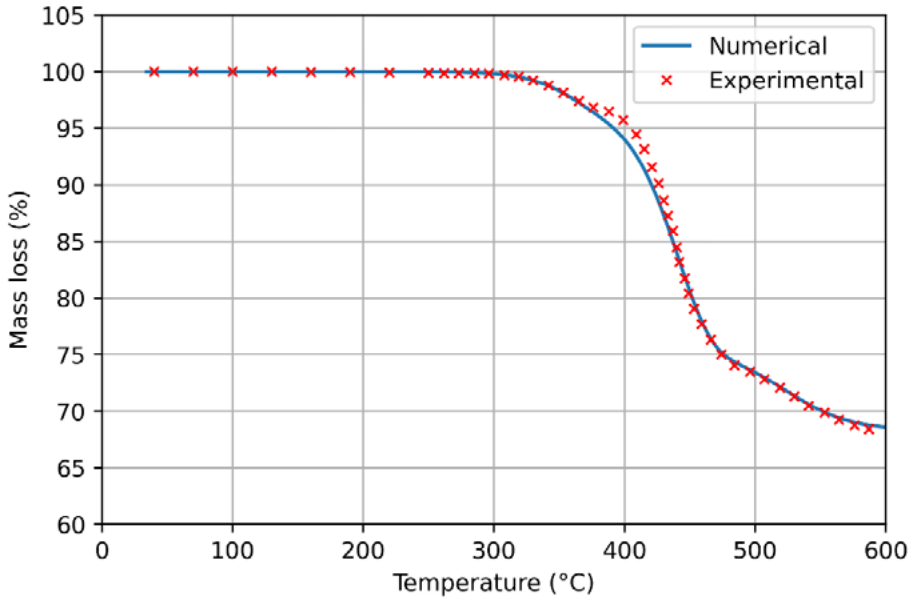

Figure 3. Thermal decomposition of the composite (TGA curve): normalized mass loss (ML) as a function of temperature.

Table 1. Kinetic parameters identified for the multi-step model.

Kinetic parameters	*Step 1*	*Step 2*	*Step 3*
A (s^{-1})	10^{10}	10^{11}	3.10^{10}
E_a ($kJ.mol^{-1}$)	139	171	174
n (-)	1	1	1.6
ν (-)	0.89	0.25	0.02

4.2. Thermophysical properties

The kinetic model is integrated in the thermal transfer equations of Section 2 where the decomposition reactions' rates help determine the evolution of the thermophysical properties. By using Eq. (5), these properties vary from the properties of an unaffected virgin material to those of a completely degraded material. Since decomposition is triggered at different times throughout the thickness of the sample, the same set of thermophysical properties will affect each of the temperature profile curves differently. Due to the coupling between the kinetic and thermal transfer models, thermophysical properties also have an effect on the mass loss measured by the cone calorimeter balance. For example, it is found that increasing λ_s or decreasing $C_{p,s}$ for the virgin material accelerate the mass loss rate without affecting the final value of the degraded material mass, and this has an incidence on the entire temperature profiles, particularly the lower temperatures. On the other hand, increasing λ_s or decreasing $C_{p,s}$ attributed to the degraded material has little incidence on the mass loss kinetics of the cone calorimeter, since by the time that these properties reach their degraded value, the mass at the end of the kinetic step had already been converted. The temperature curves are, however, greatly affected, particularly near thermal equilibrium. Evidently, the change in the material properties as previously stated leads to higher temperatures than necessarily found on the experimental curves. These facts help establish a strategy to identify appropriate intervals for the thermophysical properties in optimization by inverse analysis, first by determining the properties assigned to the virgin material leading to the correct mass loss kinetics, then identifying the properties of the degraded material that provide an accurate prediction of the temperature profiles. The optimized thermophysical properties found for the sample studied above are summed up in Table 2.

Table 2. Thermophysical properties identified through inverse analysis.

Thermal properties	*Virgin material*	*Degraded material*
ρ_s (kg.m^{-3})	1575	1100
$C_{p,s}$ (J.kg^{-1}.K^{-1})	2000	1350
λ_s (W.m^{-1}.K^{-1})	0.17	0.033
ϵ (-)	0.95	0.9

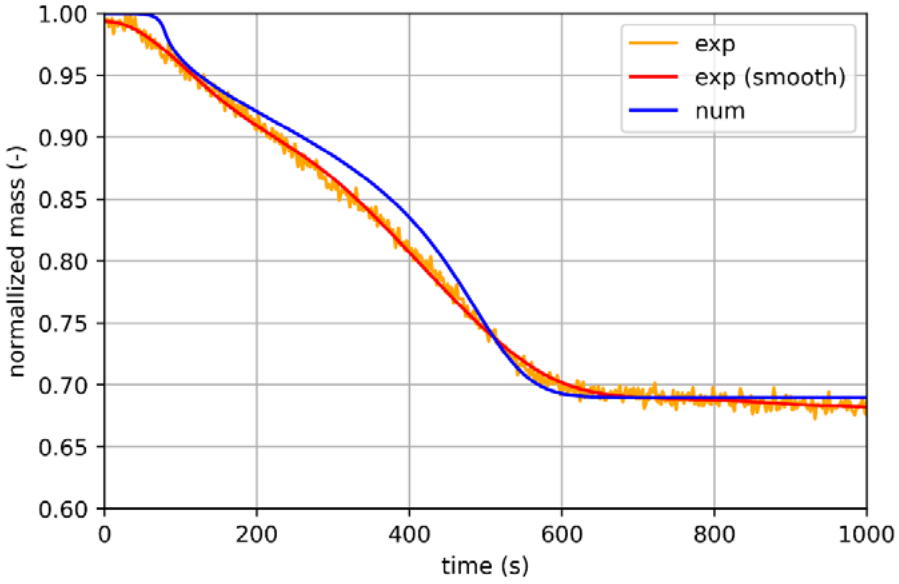

Figure 4. Normalized mass loss due to thermal degradation under the cone calorimeter test: comparison between experimental mass measurements and model simulation results.

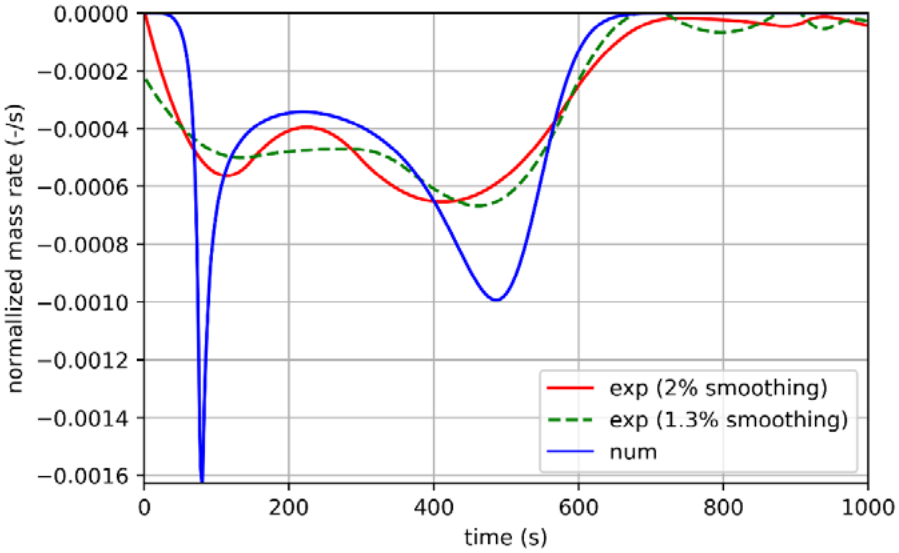

Figure 5. Normalized mass loss rate (MLR) due to thermal degradation under the cone calorimeter test: the experimental curve is derived using a de Boor-Cox algorithm with 2 smoothing ratios.

Figures 4 and 5 show respectively the mass loss and mass loss rate curves, measured experimentally by the cone calorimeter balance (the mass loss curve is first smoothed before derivation of MLR using a de Boor-Cox algorithm [7-8]).The comparison shows a fairly good reproduction of the curves by the model. The model also captures the two peaks shown in the MLR curve. The first peak is sharper in the model. As the first few layers degrade rapidly after ignition, their properties drop rapidly and isolate the rest of the material. This explains the delay in mass loss until after the first minute. The sharp peak leads to an intense increase in the temperature of the first layer, as shown in the temperature curve for a 1mm depth in Figure 6. While the model overestimate of the peak values in the MLR curve, the mass loss identified by the model neatly follows the experimental curve.
Figure 6 presents the temperature evolution curves within the 4 predefined depths of the material. For the lower depths (3.3, 5.6 and 6.6mm), the simulation curves are well-fitted to the experimental trends, demonstrating the ability of the algorithm to fairly represent the temperature profile within the material using a few parameters. Particularly notable are the temperatures reached near the end of the test, which match the temperatures measured within the material. At 1mm depth, the temperature is reached quicker than expected. This gap can be attributed to the sensitivity of measuring the temperature at a depth very close to the inflammable surface. If a heat barrier is formed, then the temperature would evolve slower than expected. Regardless, the simulation curve follows the trend of the experimental data after 600s.

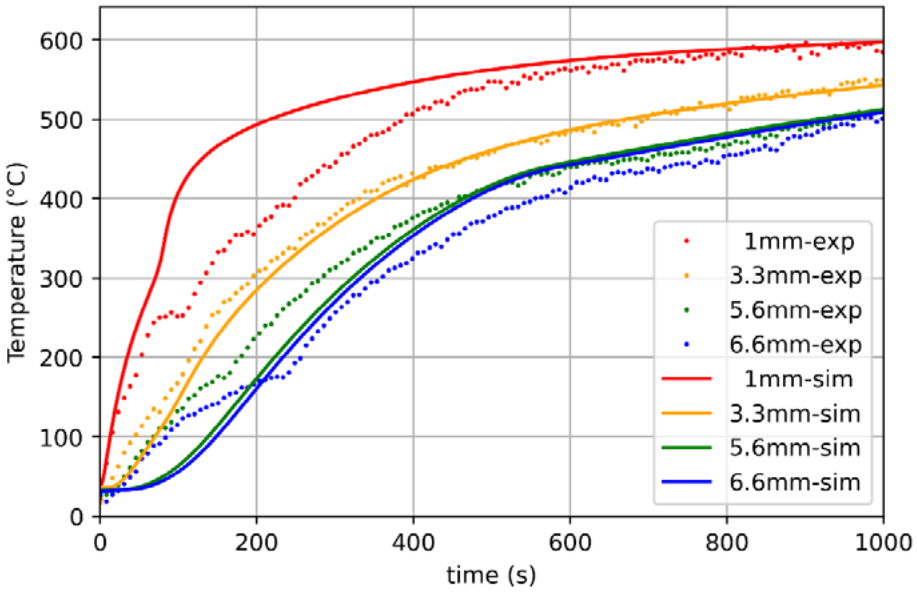

Figure 6. Evolution of temperature within the thickness of the material: comparison between measurements by thermocouples and model simulation results.

In the model presented above, a link is established between the thermal decomposition kinetics at the low scale and the thermal transfer phenomena at the upscale. For this reason, this homogenization nature provides a simple yet effective thermophysical model for predesign simulations at the structural scale.

5. Conclusions

A thermophysical model is described, combining multi-step kinetics that describe the decomposition of the material undergoing multiple chain reactions, coupled with thermal transfer modelling equations to determine the temperature mapping inside the bulk of the material. Simulations of the said model are run against experimental data obtained from TGA and a cone calorimeter test help identify the various parameters of the kinetic model, as well as the temperature-dependent thermophysical properties of the material. An example of an application on fiber-reinforced thermoplastic resin composite shows a good comparison between simulation results and experimental data.

Using the current model in an upscaling approach requires a reduction in the complexity of the model while keeping an accurate representation of small-scale phenomena as much as possible. In this regard, a sensitivity analysis can be applied to the model parameters to trace the most influential parameters to be kept in the simplified model.

Keywords: experimental-numerical validation, event-driven process chains, model-based systems engineering, product lifecycle/data management, hybrid fiber-reinforced composite structures

Abstract
The management and digitalization of experimental-numerical validation and verification processes within product development (PD) for innovative, lightweight, high-performance composite materials is a major challenge due to increasing process chain complexity, highly heterogeneous data and the need to consider product-related data and processes over their entire life cycle. Methods for modeling the experimental and numerical validation process using Product Lifecycle Management (PLM) concepts to manage and integrate data and Model-Based Systems Engineering (MBSE) approaches to track data links and process steps are elaborated. A process roadmap is created including key processes, subprocesses and metadata for procedures in PD which are subsequently illustrated by an event-driven process chain showing linked processes, inputs/outputs, software needs and iteration points. This is used as a base to model key processes and their properties by creating customizable, connectable blocks in MBSE, where digital data is accessible through an interface linked by respective metadata in a PLM-tool. Excerpts of linked processes and respective metadata are exemplarily shown for a hybrid composite structure to illustrate the potential of the elaborated approaches for improved PD efficiency through data reuse, workflow execution, consistent data management and traceability.

1. Introduction

Within the product development processes for composite structures, the growing need for enhanced energy efficiency and reduced emissions increasingly gains attention. To achieve this, an optimized process chain, computer-aided methods, predictive modeling as well as sustainable digitalization and data management are considered vital, especially for the design phase with its multifaceted tasks: requirement analysis, product planning, specification and design on system level and subsequent, mechanical analysis, design, modeling and detailing of subsystems and components. Based on this, the process steps like manufacturing, experimental-numerical validation and verification are detailed. This information are being used back on system level, as described by the V-model approach [1]. Furthermore, processes and data related to the product lifetime and recycling also have to be managed. PLM offers new possibilities for such optimized PD processes but also affects the engineering workflows, regarding required skills, competencies, interdisciplinary, the design processes themselves and the tools for data analytics supporting data-driven processes [2]. To improve process efficiency, the data and metadata generated within a digitalized process chain have to be comprehensively structured by data and version management, following the FAIR principle [3].

1.1 Experimental and numerical validation in product development for composite materials

A key aspect within the product development process of composite materials is the experimental-numerical validation and verification, which is iteratively connected to the design of lightweight structures. The principle of this approach is based on the test/validation pyramid, which was introduced in [4] and is used to describe the building block approach [5]. On coupon level, the materials base properties are experimentally determined and transferred into the numerical processes to build up models and calibrate material cards. These processes continue on the structural element level where more application-oriented test setups and specimen geometries are used for advanced material and structure characterization [6]. Especially composite materials usually require considerable calibration and validation efforts for numerical models [7]. Furthermore statistical deviations in material properties and manufacturing influences often play a non-negligible role. On higher levels the focus shifts towards verification and certification using more complex components and tests [5].

The described experimental-numerical processes are very resource-intensive in terms of the physical testing requirements, costs and energy. To reduce these efforts, a shifting of the physical procedures towards a predictive virtual testing and certification is pursued [6, 8]. For this, a comprehensive data and revision or version management for highly heterogeneous linked data types like models, lists, tables, diagrams, images, scripts and other software specific data is required. The advantages of the processes according to the building block approach are their similarities and comparability, regarding testing type, specimen geometry, material model selection, modeling approach or numerical methods [6, 9, 10]. This emphasizes the potential for standardization with respect to process naming, categorization, definition of required input, output and metadata and structuring or management concepts within PLM and MBSE tools. Here, the metadata is assigned a special role: to create and save knowledge that is not directly included in the used data files and to ensure the FAIR principle.

1.2 Efficient product development with product lifecycle management and model-based systems engineering

The basis of efficient modern product development is PLM. PLM is understood as a strategic approach or a comprehensive management concept that relates specifically to technical products and the value-added processes associated with their manufacture and operation, as well as the information generated in the process [11]. The aim of PLM is to manage all information about a product and the associated production systems (and resources) consistently over the entire life cycle and to provide this information for all future tasks in the product development process [11]. This objective is realized by various IT systems that perform specific tasks and work together in a system landscape. Typical tasks are, for example, product data management (PDM), the management of customer relationships using customer relationship management (CRM) or systems that are used for the management of products in their utilization phase (maintenance, repair and overhaul (MRO)).

Within the PLM strategy, PDM is responsible for the consistent storage of the product model and the mapping of defined processes such as release and change management. Company-wide product information from all phases is processed in the value creation process [12]. This is the basis on which it is possible to keep product models consistent throughout their entire life cycle. The PDM forms the data backbone within the PLM strategy and enables the availability of information at the required time, in the required quality and in the right place. However, access to granularly related information across domain boundaries is difficult and not mapped in the data models of the PDM systems. The philosophy of systems engineering offers an approach to overcome this situation. In combination with the MBSE methodology, it is possible to model complex systems and map the relationship between properties at parameter level in the system model. The resulting system model can also be used to map the sources of the necessary information; while the documents continue to be stored in their domain-specific systems and are managed within the PLM strategy. If the resulting MBSE models are also integrated into the product data management, the system model can be understood as a special view of the product information that is implemented in a formalized manner (using SysML). The use of standardized, digitally linked models and workflows enables efficient and sustainable handling of process information and data.

2. Methods

2.1 Process roadmap and metadata categorization

The PD process consists of linked processes and subprocesses that either have to be run through linearly one after another, in parallel or iteratively through process loops and include a high amount of different input and output data. These among others include requirement analysis, decomposition of the overall system into substructures and individual components, loading and boundary definition, concept development and design, manufacturing, experimental characterization and all processes regarding modeling and simulation. A comprehensive process roadmap for the product development processes with focus on experimental-numerical validation processes has been elaborated. The main categories are defined based on the mid-level ontology Platform MaterialDigital Core Ontology (PMDco) [13] to standardize and link the semantic terminology. In order to subdivide the processes more specifically, the terminology has been extended. In the context of simulation, processes like simulation geometry modeling (meshing), sensitivity analysis, material card calibration, stability analysis, modal analysis, sub-modeling, virtual validation, mesh study, parameter optimization or stress prediction have been added. All of these processes contain descriptive property templates with features like characteristic name, process category, linked requirements, description (aims, methods, models), processing nodes (tools, equipment), revision/version, changes and other information like responsible person, confidentiality, organization, project assignment, priority, status, and remarks.
Additionally, the processes are connected with certain input and output objects regarding data such as requirement documents, literature, standards and legal documents, testing plans, CAD models, FE meshes, simulation files, evaluation data or other process related documents. A major focus for the description of this data lies on the definition of metadata. This gives information similarily to the process properties mentioned above in addition to the group classification and data type specification. The aim is to give the opportunity of including more specific information than usual, like material type, manufacturing parameters, types of element formulations, material models in FE simulation files, occurred errors or most important parameters from a data set, without the need to look into individual files or folders. The terminology of metadata descriptions is, like for the processes and their properties, again oriented and extended from the ontological classifications mentioned above [13] to structure and support digital system modeling and standardization.

2.2 Event-driven process chain

An event-driven process chain (EPC) is used as a method to capture and analyze existing processes. EPCs are a process modeling language that offer function elements (rounded box) which represent activities in the process and event elements (hexagonal box) which describe pre- or post-conditions of the function elements [14]. The elements are used alternately and are connected via control flow elements (arrow), which can be extended by connector elements (circle) that contain logical functions like AND, OR and XOR. The EPC is expanded to include swimlanes in which the data processing activities of various software tools that are involved in the process are compiled. The goal of this analysis is to capture the process and the included manual and automated data processing activities, as well as software tools and the produced documents and files that are inputs and outputs of the functions.
The analysis of the captured process leads to a complete overview of the involved stakeholders and domains, the system landscape, as well as generated data and information. The analysis of the EPC reveals a high degree of manual data processing activities together with unstructured and distributed data. In addition several process steps and data processing activities occur multiple times throughout the whole EPC, showing potential for a simplification of the representation of the process and the integration of the produced data in PLM/PDM systems. **Figure 1** shows a small excerpt of the EPC, namely the preparation of CAD-models and the following meshing for simulation on the left and the associated manual data processing activites for the model preparation in CAD-systems on the right.

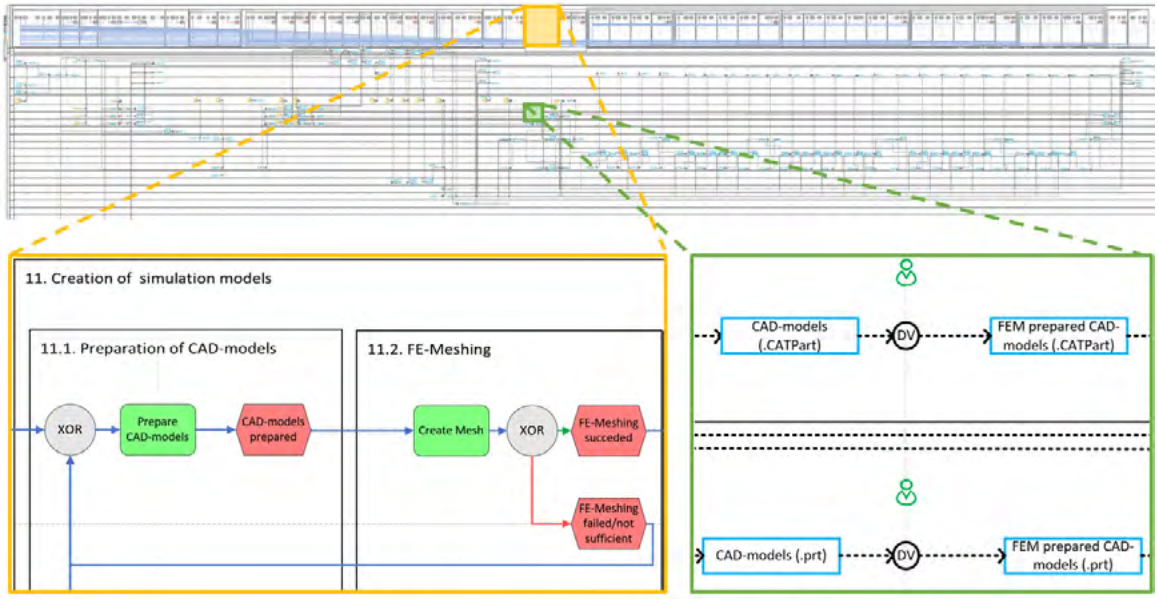

Figure 1. Exemplary EPC, left: excerpt of the EPC, right: excerpt of the data processing activites

2.3 Development of process chains with model-based systems engineering

New research focuses arise in the transfer of the MBSE methodology to the modeling of processes (not just product systems). Processes also access information from different sources, which are not always managed consistently and require network structures instead of hierarchichal structures as modeling basis. This is evident in the described EPC analysis. To reduce the complexity of the captured process, generalized process steps with a focus on the domain of experimental-numerical validation within the PD are defined and templates are developed (**Table 1**).

The process steps are modeled in the Software Enterprise Architect as SysML blocks and contain metadata as properties/values as well as proxy ports that can be utilized to model the information flow. In addition to the process steps, the input and output of the steps need to be captured for a consistent documentation of the development process – enabling future analysis and well-founded decision-making. These in-/outputs are categorized by the objects component and document (**Table 1**) which are modeled as blocks. A component describes a physical constituent of a product e.g. a part, assembly, system or material. Documents describe the data that is used and produced in the virtual product development (see chapter 2.1) and are further grouped into generalized categories, such as information documentation, scope statement, design geometry, testing plan, simulation model, simulation output data or process documentation. A document can contain a single file or also a group of files as data set. The documents can be linked to the components. Both component and document contain metadata (modeled as properties/values) and can be differentiated by definition of a group or type (before mentioned examples). It is important to note, that document blocks do not contain the actual documents, but only provide a link to e.g. PLM/PDM systems which handle the actual data, see chapter 2.4. Creation, manipluation and version control of data is still handled by the domain specific authoring systems.

Table 1. Overview of developed process steps and input/output objects

Process Steps	Input/Output Objects
Information research and analysis process Requirements management process Manufacturing process Mechanical testing process CAD modeling process Simulation geometry modeling process Simulation setup process Numerical simulation process Evaluating process	Component (part, assembly, system, material) Document (e. g. information documentation, scope statement, design geometry, testing plan, simulation model, simulation output, process documentation)

Through the application of the described approach it is possible to model the development process and the used input/output data for each process step including the defined properties/values (**Figure 2**). In addition the decisions and the development path can be captured and managed consistently. The MBSE model is completely machine-readable and provides a promising basis for assisted (e.g. through machine learning) analysis and process optimization or adaption to new challenges.

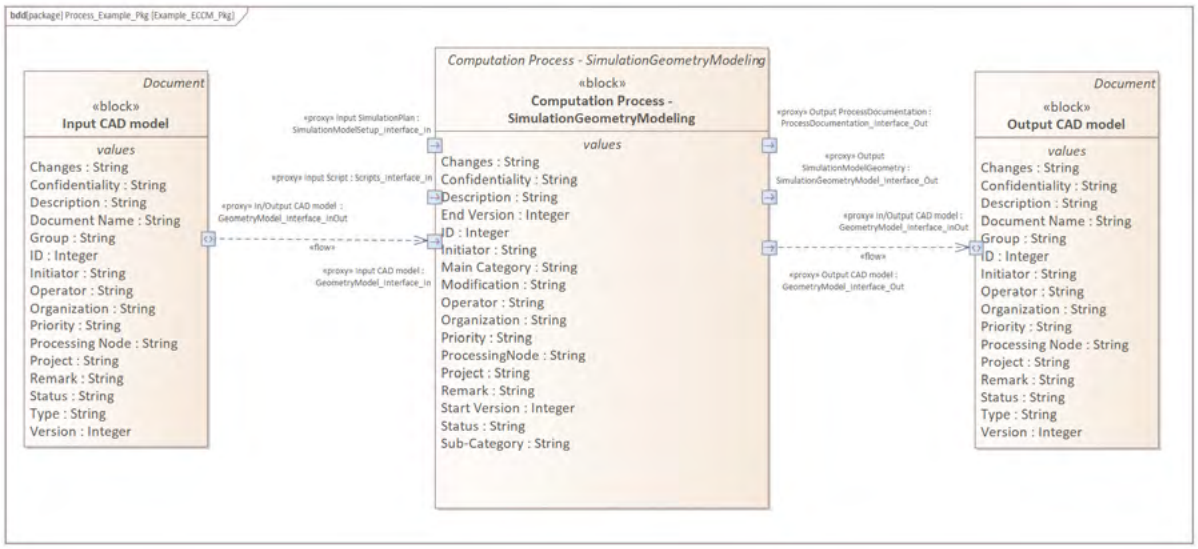

Figure 2. Exemplary blocks (document and process step) to model information flow in the process chain

2.4 Coupling of process information and digital data management

To enable access to the digital data used and generated as input or output documents respectively, a data model is used to implement a data management solution using Aras Innovator as a PLM/PDM system, which has been accordingly customized. With regard to relevant simulation data the model is structured by simulation studies and simulation tasks. Each task contains the document group classifications of design geometry (e. g. CAD model), simulation model geometry (e. g. FE-mesh), simulation model (e. g. an FE mesh with all defined loads, boundary condition and material cards), simulation output and task documents referencing other document types that are not models (**Figure 3**). These documents represent essential data necessary for the execution of typical simulation tasks. The coupling between the MBSE model in Enterprise Architect where only information about processes, documents and their links are modeled, and the PLM/PDM system with the actual data, is realized by a software interface provided by XPLM. The metadata for the documents between both is synchronized as the same entries to ensure consistency. Additionally, in each document block in the MBSE model a reference to the location of the stored related data is assigned which enables direct data access when modeling processes. The data can either be selected from files previously uploaded into Aras Innovator or uploaded directly when creating the document block in Enterprise Architect. A simulation task in context of the MBSE model is considered as a container consisting of the four process steps design, simulation geometry modeling, simulation model setup and numerical simulation. Whenever a new simulation task is defined in a typical workflow the respective template blocks are created as a base that can be individually extended, e. g. if further numerical processes are required to fulfil the task. The different simulation outputs can then be uploaded into the respective category within Aras Innovator. Additionally, the task has to be assigned to an existing or new simulation study. Documents that do not belong to a simulation process are structured in a general category that can be browsed according to the metadata information like group classification or data types.

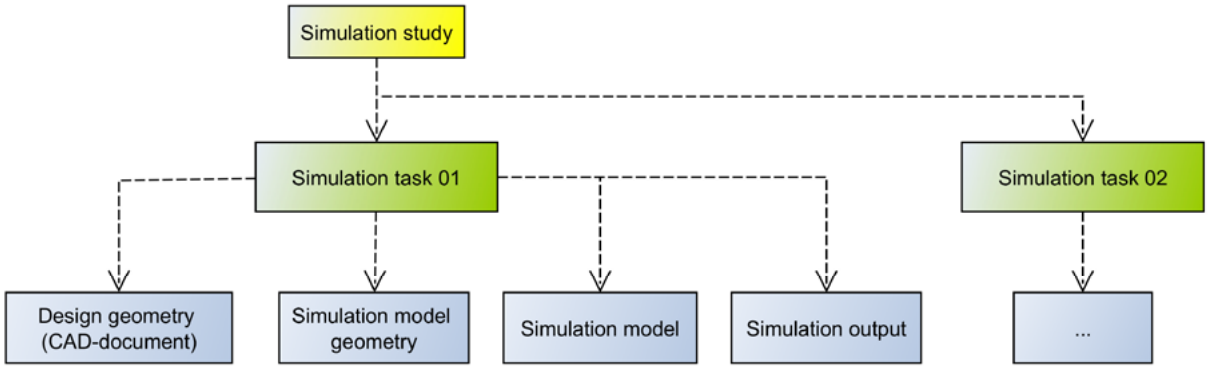

Figure 3. Customized structure for simulation data management in Aras Innovator

3. Results - Exemplary concept implementation and discussion

The elaborated concepts for process, object and metadata classifications, templates and links between MBSE and PLM/PDM tool have been investigated using the data from the design and experimental-numerical validation of an exemplary hybrid composite structure (**Figure 4**).

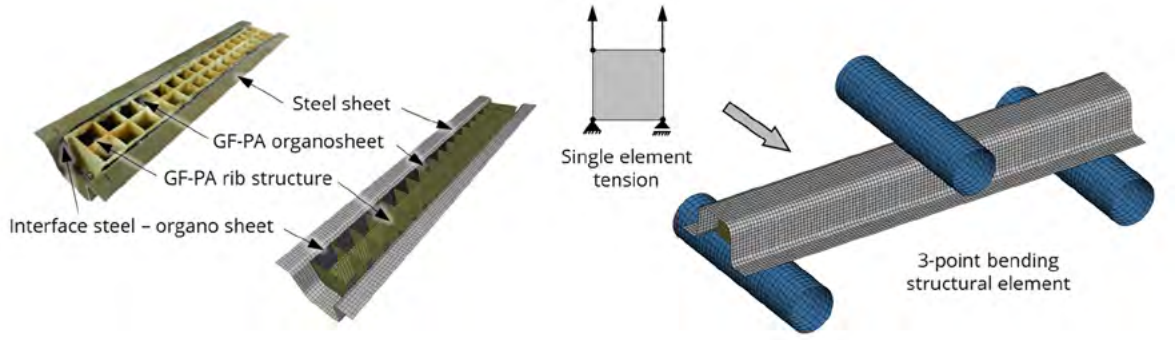

Figure 4. Exemplary simplified hybrid composite structure as an element of an A-pillar with data used for evaluation of the MBSE and PLM/PDM concepts

Starting with the requirements e. g. regarding maximum mass and energy absorption capability the component is designed and a comprehensive testing and simulation plan is derived to validate design variants. The processes conducted include e. g. specimen manufacturing and material characterization on coupon level with tensile, compression and shear tests to determine the required data for the components steel, organosheet, rib structure and interface. This data is used in the numerical material card calibrations where processes like single element tests for material model understanding, meshing, simulation model setup, parameter studies and optimizations take place. On structural element level the design is extended with more details and a prototype is manufactured and tested under low-velocity 3-point-bending conditions. On the numerical side the model setup process gets more complex and further processes like numerical contact investigation, error analysis in case of instability issues, model validation and stress prediction for other load cases are conducted. Here not only component- but also process-relevant requirements like demanded mesh size and percentage of allowed mass scaling effect can be necessary. Several iterations between design variants and numerical stress predictions take place and therefore a version management is crucial. In summary and based on the concepts described in chapter 2 the whole process chain for the development of the structure is captured and can be traced including all data used for a certain process step as well as information stored as metadata.

Figure 5 shows a simplified excerpt of the processes for the calibration of the material card regarding tensile properties on coupon level which are required to validate the product to be developed and functionalities on higher level within the building block approach. Additionally, exemplary documents that are used within the processes are connected as input and output. Both are modeled in MBSE as instances of the blocks defined in chapter 2.3. In this example, the documents “Coupon specimen CAD

model" or "Coupon specimen meshing script" are required for the simulation geometry modeling process "Coupon specimen mesh creation" for manual meshing or automated meshing using a parametric Python script. Here, an exemplary remark for the mesh size of 3 mm is added. In the simulation model setup process "Coupon specimen model setup" the boundary conditions are defined (e. g. load introduction and constraints) and a base material card is created by using the datasheet document "Organosheet properties" for the respective material (organosheet). In the subsequent numerical simulation process with the name "Parameter optimization", the software LS-OPT and LS-DYNA are used to calibrate the material card parameters by iteratively mathematically comparing the "Tensile test simulation optimization output" with the experimental "Tensile test results" (input document) which were generated in an earlier process. Another document "Optimization procedure documentation" is created as output that contains information about settings or changes that were made in the process step, e. g. as a tabular file. Finally the most relevant output is the "Calibrated organosheet material card", that can be either defined as new version of the document "Base organosheet material card" or as completely new object in case both have to be stored separately. The processes themselves can also have different versions, e. g. in a case where modeling issues are noticed within a numerical simulation process that have to be fixed within the simulation model setup process before the former process is repeated with the fixed model. This procedure is used to consider iterations and versioning in the MBSE model.

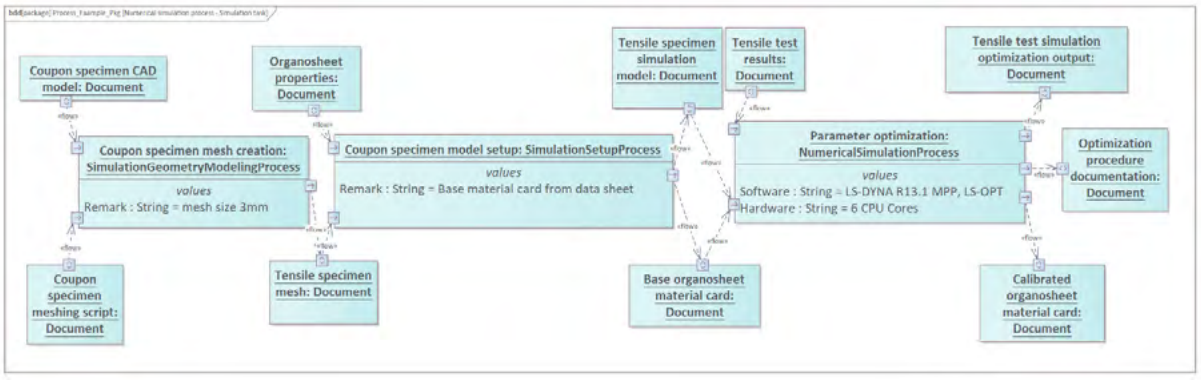

Figure 5. Simplified example of the process chain for a typical simulation task

4. Conclusion and outlook

A digital solution for modeling process steps and linked data generated within the PD with focus on experimental-numerical validation is proposed using MBSE and PLM/PDM approaches. The relevant processes, data and metadata are identified and classified to elaborate methods for improved data reuse according to the FAIR principle while using uniform vocabulary based on ontologies. The processes are visualized in an EPC together with the input/output and required software tools, giving an overview of involved stakeholders, domains, data and information in the system landscape and enable identification and analysis of dependencies and interactions of linked processes and data. The processes and their inputs/outputs, defined as objects, are further generalized and transferred into MBSE by modeling as SysML blocks with respective properties/metadata and proxy ports to model information flow. These customizable templates can be used for a consistent documentation of the development process to support consistent workflows, subsequent analysis, evaluation and decision-making improving data and information reusability when conducting similar processes. The MBSE model is flexible with regards to adaptation when executing and tracking process steps to suit individual needs. Since it is completely machine-readable, it is suitable for automated analysis (e. g. by machine learning) to optimize processes and derive or propose new process chains adapted to respective future use cases. The data used as input or output object for processes in MBSE can be manually linked and stored in a PLM/PDM tool which enables direct access during process modeling. Additionally, metadata is recorded containing important information about the object properties as well as links to connected processes or other objects, e. g. the links between a component and a CAE model or material model. This transforms data into information and subsequent knowledge improving its reusability.

An exemplary use case is introduced by means of the experimental and numerical processes required for the development of a hybrid composite structure and an excerpt of a process chain is shown. In this way, process steps are structured and executed in a consistent manner and the workflows including used data and information are managed, traceable and reusable to support future development processes. The open interfaces of the MBSE concept in combination with the linked data management allows to extent and specify the process modeling into further domains like manufacturing, design processes or other types of simulations (e. g. process simulation or computational fluid dynamics), taking into account the whole PD. Furthermore, the customizability of both used systems regarding user interface and script integrability enables the potential of creating automated workflows regarding simulations and data integration as well as coupling to other software tools.

Abstract
Recent advancements in additive manufacturing (AM) have facilitated the production of foamed biodegradable materials like Lightweight Polylactic Acid (LW-PLA). This study investigates the influence of density and infill angle on the elasticity modulus, shear modulus, and Poisson's ratio of foamed LW-PLA, aiming to establish the printing parameters to obtain the desired material properties. A screening of the manufacturing variables including flow rate, temperature, printing velocity, and raster width was conducted to obtain three part densities. Tensile tests, following ASTM D638-02a standards, were performed to determine elasticity modulus and Poisson's ratio, supplemented by Digital Image Correlation for Poisson's ratio assessment. Sandwich panels comprising aluminum skins and LW-PLA core were fabricated and subjected to bending tests, following ASTM D7250M-20 standards for three-point bending tests.

Results reveal significant variations in elasticity modulus and Poisson's ratio with respect to part density and infill angle, with higher density parts exhibiting elevated properties. Bending tests show the anisotropic nature of 3D printed LW-PLA.

1. Introduction

Fused deposition modelling (FDM) is a well-known additive manufacturing (AM) technology to print thermoplastic polymers. In this process, the material, typically in filament form, is fed through a heated nozzle, where it melts and is extruded onto a build platform. Once deposited, the material rapidly solidifies, gradually forming the desired object layer by layer [1].

Polylactic acid or Polylactide (PLA) is a biodegradable and bioactive thermoplastic derived from renewable resources, typically through the fermentation of corn starch or sugarcane into lactic acid. PLA is renowned for its eco-friendly characteristics, as it is compostable under industrial conditions, making it a sustainable alternative to traditional petroleum-based plastics. This versatile material is utilized in various applications, including packaging, food containers, disposable tableware, biomedical implants. The thermoplastic nature of PLA makes it suitable for AM, generating interest among researchers in a wide range of fields [2].

In an interesting review, Suteja and Soesanti [3] found 19 research works analyzing the influence of several printing parameters on the mechanical properties of PLA, and found that nozzle diameter, nozzle temperature, printing speed, filament feed rate, layer thickness and raster width are the most influential ones. Additionally, they observed that alternative printing strategies such as infill pattern, infill angle,

infill density, number of shells and build orientation also play a substantial role in influencing the mechanical properties.
In 2019 the company ColorFabb released the so-called lightweight PLA (LW-PLA) filament to manufacture foamed PLA by FDM [4]. The input filament material is saturated by a blowing agent which is activated when passed through the hot nozzle, obtaining a stochastic porosity distribution in the final part which is dependent on the printing conditions, mainly flow rate and temperature [5,6,7,8,9]. In all the referenced works, the printed maximum and minimum densities are around the one stated in the official technical datasheet of the material, which states that the maximum density achievable of the LW-PLA is 1240 kg/m^3 and the minimum 400 kg/m^3. However, there is a considerable difference between the measured densities by each author due to the difference in the printing strategy used by each researcher.

The special properties of having high stiffness-to-weight ratio and high bending strength-to-weight ratio make sandwich composite structures very suitable for many applications, reducing weight without compromising the mechanical performance. Therefore, they are widely used in all mechanical industrial sectors such as automotive, aerospace and construction [10]. The potential of LW-PLA material as a core of sandwich structures is considered in this study.

As mentioned above, the influence of the infill angle and part density on the mechanical properties was not studied in deep. In addition, due to the infill angle, the behaviour of the part might not be isotropic, and thus, the elasticity modulus, Poisson's ratio and the shear modulus will be independent. In order to analyze this behaviour, this study investigates the process-structure-property relationship of 3D Printed LW-PLA to manufacture desired material densities. Tensile and flexure samples were printed and tested to find static elastic modulus, shear modulus and Poisson's ratio.

2. Methodology

2.1. 3D Printing of Specimens

Printing parameters in FDM technology are abundant, so the first task was to define the variable parameters that allow to manufacture several densities using 3D printed LW-PLA and to establish the parameters that need to be kept constant, see Table 1. Printing temperature, flow rate, raster width and printing velocity were adjusted to manufacture three densities, see Table 2.

Literature states that the influence of the infill angle is significant in AM components [11], so it was taken as a variable to see the influence of it on the mechanical properties.

Determining the part density was straightforward, volume measurements were done with a digital caliper and weight measurements with a high precision scale. The achieved densities were: 450 kg/m^3, 610 kg/m^3 and 1115 kg/m^3. Three specimens for each configuration were manufactured to determine the mean density and the measured standard deviation was below 1%.

Table 1. Fixed parameters for 3D printing LW-PLA.

Parameters	Value
Fixed parameters	
Nozzle diameter	0.4 mm
Layer height	0.4 mm
Bed temperature	60°C
Overlap	30%
Build orientation	Flat
Number of shells	1
Infill density	100%
Infill pattern	Straight lines

Table 2. Variable parameters for 3D printing LW-PLA.

Parameters	Value
450 kg/m^3 part density	
Flow rate	50%
Printing temperature	230 °C
Raster width	1.15 mm
Printing speed	20 mm/s
610 kg/m^3 part density	
Flow rate	65%
Printing temperature	230 °C
Raster width	0.65 mm
Printing speed	60 mm/s
1115 kg/m^3 part density	
Flow rate	100%
Printing temperature	205 °C
Raster width	0.46 mm
Printing speed	20 mm/s

2.2. Tensile Test

The test methodology was established following the standard ASTM D638-02a [12] recommendations, type I specimen dimensions were used, with a nominal width and thickness of 19 mm and 3.2 mm, respectively. Three part densities and three infill angles were analyzed. Nine cases with three repetitions for each case, so 27 specimens were tested in total. The chosen infill angles are: ± 45º, 0º/90º and 0º. The three densities mentioned before were analyzed.

Tensile tests were performed on a Instron universal testing machine equipped with a 50 kN load cell and at a load-rate of 2 mm/min. Longitudinal and transverse strains were measured with a GOM-Aramis DIC system in order to obtain the Poisson's ratio. Only the linear elastic deformation region of the strain-stress curves was considered to obtain the elastic modulus and Poisson's ratio, disregarding the initial offsets or discontinuities.

2.3. Three Point Bending Test

The ASTM D7250M-20 [13] recommendations were followed to design the specimens. Sandwich beams were manufactured using aluminum face sheets and LW-PLA cores with variable density and infill angles, with thicknesses of 1 mm and 10 mm, respectively. All specimens have a width of 25 mm and length of 220 mm. The span length was defined at 75 mm. Only two densities were tested: 450 kg/m^3 and 1115 kg/m^3. The analyzed infill angles are the same as in the tensile tests, but they are only studied in cores with the highest density. Three specimens were used for each configuration, so a total of 12 specimens were tested. Figure 1 shows the experimental set-up.

The adhesion between the core and face sheet was done by applying Epoxy EA 9466 to the face sheet surfaces and after assembling the parts, pressure was applied during 24 hours using a glass with weight on top of it.

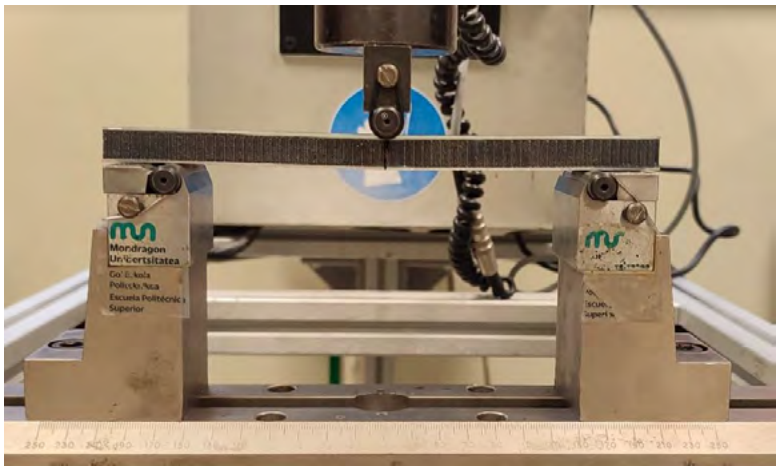

Figure 1: Three point bending test.

Bending tests were performed on a Instron universal testing machine at a load-rate of 0.5 mm/min. It is assumed that all the pure bending efforts are supported by the face sheets, so the bending stiffness is calculated by (Eq. 1),

$$D = \frac{E_{\text{face}}\,(h_{\text{tot}}^3 - h_{\text{core}}^3)\,b}{12} \tag{1}$$

where E_{face} is the elastic modulus of the aluminium, h_{tot} is the total thickness of the sandwich beam, h_{core} is the thickness of the core and b is the width of the beam. It is also assumed that all the shear efforts are assumed by the core, so the transverse shear stiffness is calculated by equation (Eq. 2),

$$U = \frac{S}{4\left(\frac{\Delta}{P} - \frac{2\,S^3}{96\,D}\right)} \tag{2}$$

where S is the span length, Δ is the measured displacement and P the applied load. Finally, the shear modulus of the core is calculated by equation (Eq. 3).

$$G = \frac{U\,(h_{\text{tot}} - 2\,h_{\text{face}})}{(h_{\text{tot}} - h_{\text{face}})^2\,b} \tag{3}$$

3. Results and Discussion

3.1. Tensile Test

The measured strain-stress curves for each configuration are illustrated in Figure 2.

It is observed that the highest yield strength is achieved in the highest density parts and infill angle of 0º, obtaining almost 10 times higher values than in the ±45º configuration. All the configurations showed a elongation strain of around 3% with a considerable plastified region before failure, and the lowest strains were measured in the infill angle of 0º. In Figure 3 the results for the elastic modulus and Poisson's ratio are displayed.

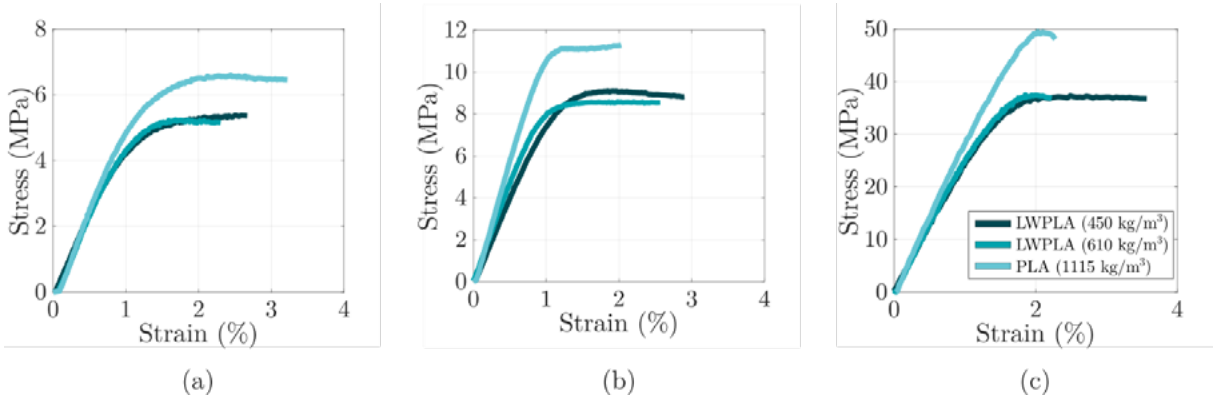

Figure 2. Strain-stress curves of tensile tests for several infill angles and part densities: (a) infill angle of ±45º, (b) infill angle of 0º/90º, and (c) infill angle of 0º.

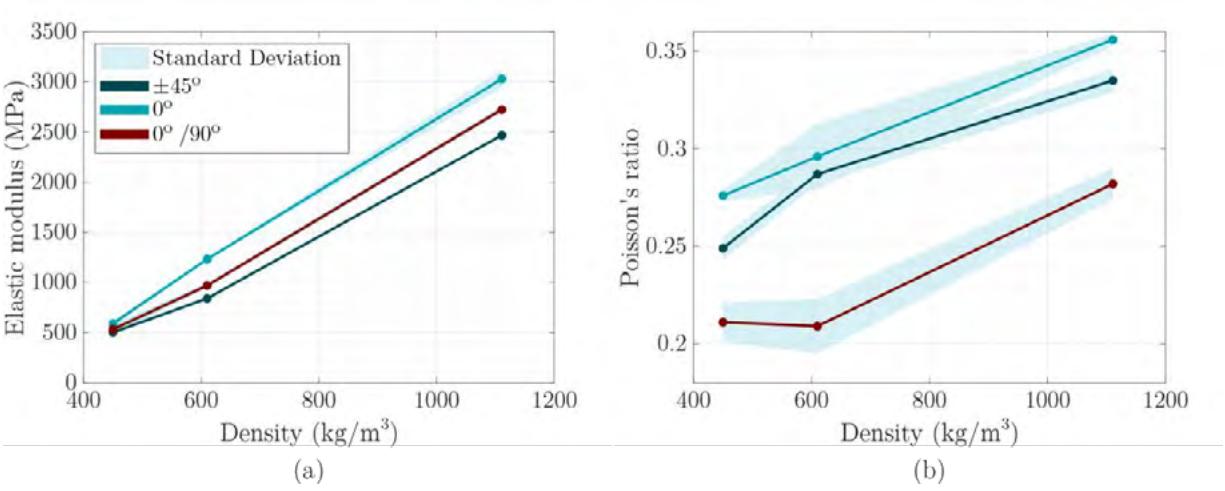

Figure 3. Tensile test results: (a) Elastic modulus and (b) Poisson's ratio.

The influence of the density is as expected, higher density parts are stiffer. However, the reason why the influence of the infill angle in low density parts is smaller is not straightforward. A hypothesis is that in fully foamed parts the infill cavities tend to homogenize. In foamed parts, the infill has numerous cavities minimizing the impact of the orientation of the interlayer gaps. In non-foamed parts interlayer gaps are the primary cavities and their orientation significantly affects the elasticity modulus of the part.

The Poisson's ratio results, ranging from 0.21 to 0.35, indicate the potential to attain a significantly broader range of values compared to those reported by Kanani and Kennedy [7], who measured values of 0.36 for foamed parts and 0.34 for non-foamed parts. Interestingly, in our tests, we observed an opposite trend, being the highest Poisson values obtained for the highest density parts.

3.2. Three Point Bending Test

In conventional foams, the isotropic relationship of equation (Eq. 4) is often considered to calculate the shear modulus [14],

$$G_{\text{iso}} = \frac{E}{2\,(1+\nu)} \tag{4}$$

where E is the elastic modulus and ν is the Poisson's ratio, both obtained in the tensile tests. In Figure 4 the measured shear moduli calculated using equation (Eq. 3) are compared with the shear modulus estimated using equation (Eq. 4).

The big differences between the measured shear moduli and isotropic values suggest that these parts posses anisotropic properties, but also that the assumption that all the bending stiffness is supported by the face sheets and that the core works in pure shear is incorrect. The bending stiffness of the face sheets is only 15 times bigger than the bending stiffness of the core. In the lowest density core case, the bending stiffness ratio goes up to 90, making the assumptions made by the standard more realistic, and thus, the differences in the measured and isotropic shear modulus are smaller.

It is also appreciated that the influence of the infill angle is small compared to tensile tests. When working on shear, the influence of the angle decreases.

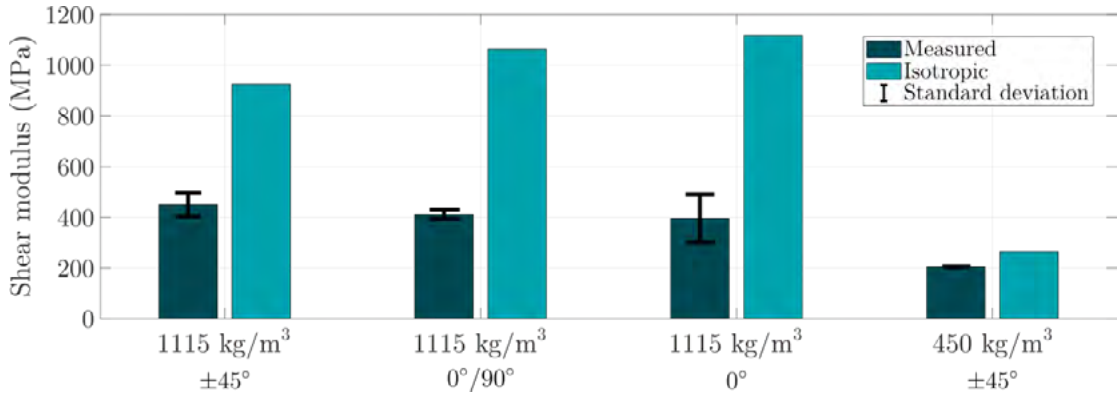

Figure 4. Three point bending results.

4. Conclusions

In this study, printing temperature, flow rate, raster width and printing velocity were adjusted to manufacture three densities and the influence of the infill angle and part density on the elastic modulus, Poisson's ratio and shear modulus of 3D printed LW-PLA was analysed. The tensile test and digital image correlation technique were employed to obtain the elastic modulus and Poisson's ratio and the three point bending test to get the shear modulus.

Non-isotropic properties were observed in the shear moduli of the high density parts in Figure 4, where almost two times bigger shear modulus was estimated in the isotropic material assumption respect to the one calculated using the equation (Eq. 3) of the standard ASTM D7250M-20. In low density parts, due to the bigger difference in the bending stiffness of the face sheets and the core, the shear modulus estimations using both assumptions are similar.

Moreover, the influence of the infill angle was only observed in the elasticity modulus of high density parts and in the Poisson's ratio of all density parts. However, the influence of the infill angle was minimum in the elastic modulus and in the shear modulus of fully foamed parts.

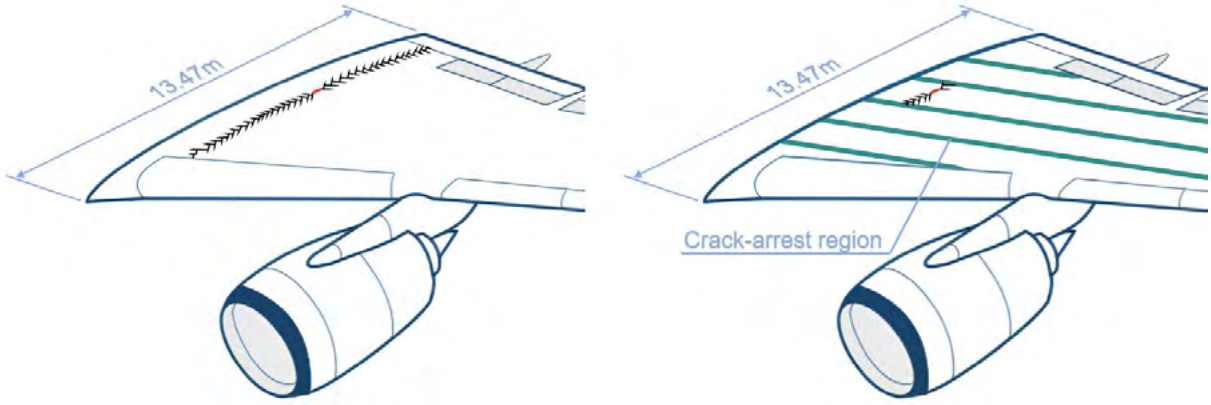
Keywords: Composite materials, Compression, Unstable failure, Crack arrest, Kink-band



Abstract
The compressive properties of fibre-reinforced composites are significantly inferior to their tensile equivalent. This factor, allied to the 'no-damage growth' design philosophy currently used in aerospace, results in significantly oversized structures. The current work aims to improve the compressive response of composites by compartmentalizing unstable compressive failure in large fibre-reinforced structures. It proposes a ply-discontinuity feature capable of arresting unstable crack propagation in multidirectional Carbon Fibre-Reinforced Polymer (CFRP) laminates subjected to compressive loading. By replacing 0° oriented plies by carefully selected off-axis ones, the feature is capable of dispersing and dissipating compressive kink-band propagation energy as well as modifying the laminate's failure modes. Consequently, the laminate achieves arrest of rapidly growing unstable cracks (propagating at ~1 km/s) and the specimen's ultimate failure strain is increased. To validate the proposed concept, test specimens were designed and manufactured using IM7/8552 carbon-fibre reinforced epoxy. Through compressive tests, the feature's crack-arrest capability was shown, remarkably increasing by nearly a third the strain tolerance upon final failure, when compared to the respective baseline.

1. Introduction

Compressive performance, particularly in the presence of in-service damage, limits composite design. Factors such as a high sensitivity to manufacture defects and complexity in failure modes cause compressive strength of Fibre-Reinforced Polymers (FRPs) to be significantly inferior to their tensile performance [1-3]. Additionally, if compressive failure initiates in a component, there are no means to arrest such fracture. Thus, composites are currently constrained to a 'no-damage growth' design philosophy. Being able to tolerate and manage compression crack growth ('damage growth tolerance' philosophy) would enable the realisation of composites' full structural potential.

A key component of this design philosophy are crack-arrest methods, which seek to stop unstable failure growth, isolating damage and extending structural life after an initial failure event. Features with these capabilities have already been developed and are widely employed in other fields. In compressed-gas transmission pipelines, ribs are used to contain long tensile cracks in metallic pipes [4,5]. Similarly, in airplane fuselages tear straps are used to stop tear propagation in the composite skin [6]. Nevertheless, little to no study has been done on compression crack-arrest in fibrous composite laminates.

By developing a feature capable of arresting unstable compressive cracks in FRPs, this research aspires to pave the way to successful compartmentalisation of failure in large composite structures. Components designed through this method will remain fit for service after initial failure propagation, enabling safer designs while simultaneously reducing their weight. These developments shall be particularly advantageous in applications where catastrophic failure would lead to loss of lives, as is the case of airplane wings. Figure 1 exemplifies how such a feature would be able to avoid structural collapse in a damaged wing root.

(a) (b)

Figure 1. Visualisation of compressive-crack compartmentalisation on a damaged Airbus A350-1000 wing. (a) Crack propagation from the damaged region without crack arrest mechanisms, unrestrictedly expanding across the wing's chord and causing catastrophic failure. (b) Failure compartmentalisation by periodic crack-arrest bands, allowing the wing to remain in service.

2. Feature concept

Unstable compression crack propagation on CFRPs happens at a rate approaching 1 km/s [7]. Therefore, to stop this growth it is important to implement ways of dissipating or deflecting the energy associated to the propagation process. With that aim, a concept based on the idea of ply-discontinuity was developed. It is known that compressive kink-band failure is the main mechanism of crack growth in FRP compression [8]. This fracture mechanism tends to occur in 0° oriented plies, propagating perpendicular to the loading direction. Thus, by implementing regions where 0° plies are replaced by off-axis ones, the feature seeks to force the failure into following new paths, dispersing energy in the process. Moreover, lay-ups where 0° plies are the main loading component (hard lay-ups) have lower translaminar toughness than those where the load is supported only by off-axis plies (soft lay-ups). Therefore, by inserting discontinuities in the lay-up, the feature also implements regions of increased toughness that assist in fracture containment.

Notably, the feature does not introduce any new material types into the design. The sole presence of materials that have been previously certified and are already in use in the aerospace industry constitutes a remarkable advantage in the mechanism's incorporation into service. Furthermore, the usage of a single type of composite facilitates recycling and disposal processes.

3. Materials and methods

A compression specimen was designed to test the developed crack-arrest feature. The angle of the off-axis plies responsible for replacing 0° in the soft lay-up was defined as ±30°. A sandwich configuration with aluminium honeycomb core and IM7/8552 CFRP skins was chosen to prevent the composite laminate from global buckling during test. A notch was designed to induce initial failure in the gauge

region at an applied strain close to -3100με. This value was chosen for being slightly above the -2500με design limit load typically used in aerospace industry [9]. Figure 2 illustrates the specimen's geometry.

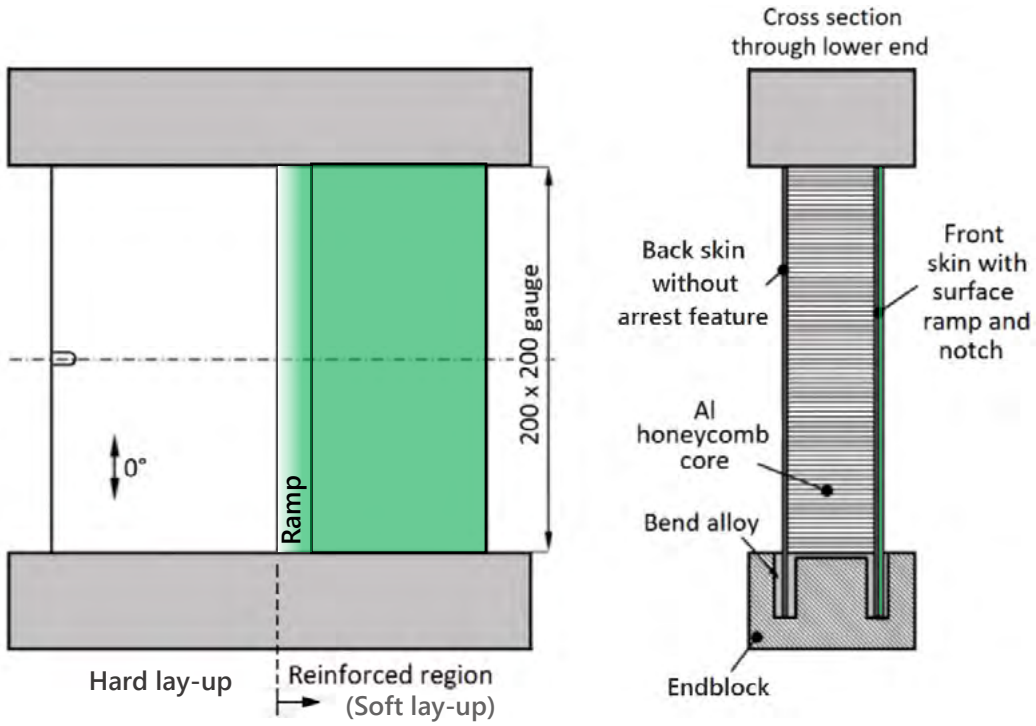


Figure 2. Compression test specimen geometry (crack-arrest region is presented in green).

While defining the skins' lay-up, a series of restrictions was defined to control test variables. Since the hard lay-up is multidirectional, while 0° layers were replaced by ±30°, the remaining plies were maintained continuous to conserve specimen integrity. Moreover, both hard and soft lay-ups were designed to be symmetrical to avoid compression-bending coupling effects. Finally, as a consistent stiffness was desirable throughout the specimen width, additional layers were added to the soft lay-up to compensate for the difference in stiffness induced by changing ply-orientation. To reduce stress concentration, the lay-up transition was designed to happen gradually, assuming the shape of a 'ramp'. Since the front skin of the of the crack-arrest specimen was defined as surface of interest, only this face possessed the arrest feature.

Two specimens were manufactured: a crack-arrest (CA) specimen, with the arrest feature lay-up presented, and a baseline (plain) specimen. The baseline consisted in a sandwich coupon with two hard lay-up skins and no ply-discontinuity, possessing an equivalent stifness to that of the CA specimen.

The specimens were tested in a 250 tonne screw-driven compression test machine under displacement control. Digital Image Correlation and strain gauges remote from the crack region were used to monitor mechanical behaviour and compute applied strain. C-scans and X-ray images of the fractured specimens were taken to achieve deeper understanding of the processes through which failure initiates and is subsequently arrested.

4. Results and discussion

As expected, the baseline specimen suffered an abrupt failure that propagated across the notched face's width, leading to almost complete loss of load-bearing capability. The failure of the CA specimen, however, was successfully stopped upon reaching the beginning of the arrest region. Following this

initial failure, additional strain was endured by the specimen, progressively causing smaller failure steps. Ultimate failure was achieved when the crack front reached the opposite end of the skin's width. Figure 3 represents both specimens after they had reached ultimate failure.

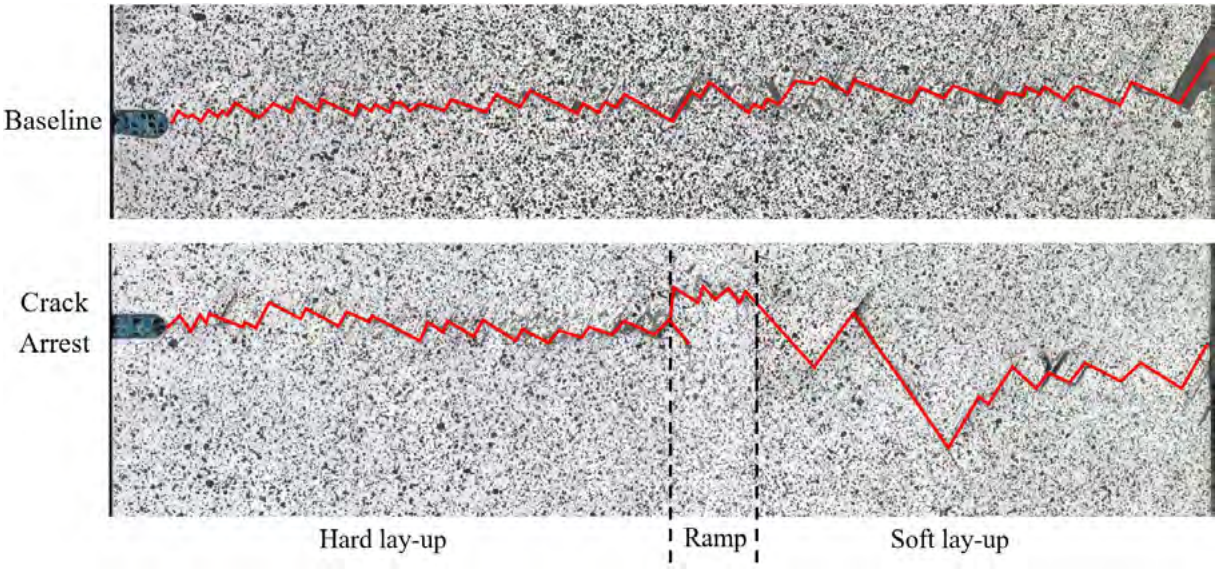

Figure 3. Fractured region of the test specimens, portraying the change in failure path caused by ply-discontinuity. Main visible failure paths are highlighted in red.

It was notable that, as seen in the baseline, initial fracture in the CA specimen grew perpendicular to load application direction. Similar fracture morphology was also observed between these failures, consistent with the baseline's suitability as comparison. Nevertheless, following the initial arrest, the subsequent failure in the CA specimen presented significant changes in both growth direction and fracture morphology. These behavioural changes hint as to the effects of the of ply replacement in obstructing the kink-band propagation.

Figure 4 presents the applied strain versus load of both specimens during test. It's important to note that the specimens' 200x200mm gauge area represents only a very small fraction of the dimensions of the structures they seek to represent. Therefore, even the loss of the entire 200mm section would not represent a significant reduction in the complete structure's load capacity. As of consequence, the most reliable way of analysing the specimens' performance is not through their load capacity but through their strain tolerance. This tolerance represents the structure's capability of being deformed before collapsing.

In Figure 4, it is possible to observe that both specimens showed similar elastic behaviour before initial failure. The baseline's failure happened at $\varepsilon_b^{ult} = -3070\mu\varepsilon$, while that of the CA specimen started at $\varepsilon^{ini} = -3600\mu\varepsilon$. The chart still portrays its subsequent growth steps, up to the ultimate failure at $\varepsilon^{ult} = -4065\mu\varepsilon$. It is notable that, although possessing the same stiffness as the baseline, the CA specimen presented an ultimate strain to failure nearly a third higher than it.

X-rays and C-scans were used to visualise subsurface damage in both specimens. The analyses showed that CA specimen's soft lay-up region presented considerably more extensive delamination than both the hard lay-up region and the baseline. Together with the more tortuous failure path caused by crack deflection, the increase in secondary damage surfaces contributed to energy dissipation, leading to the feature's success.

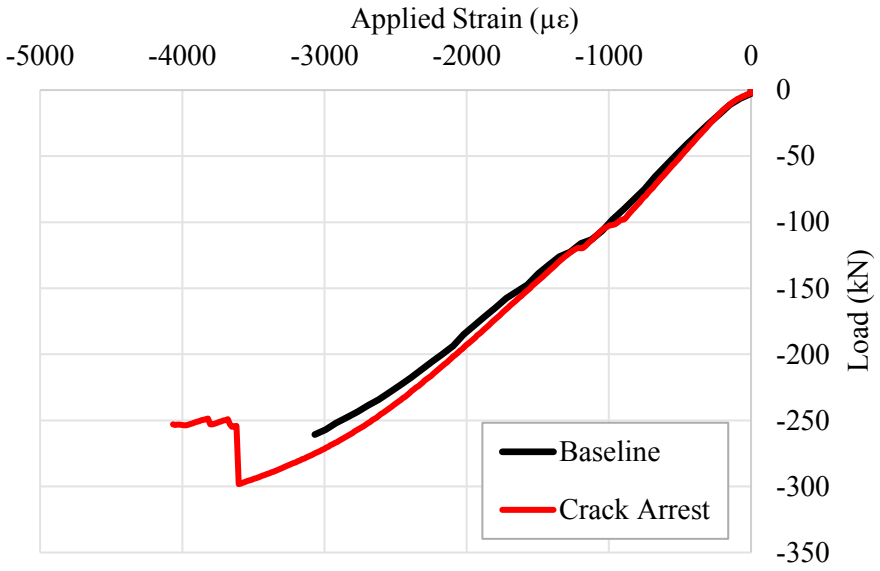

Figure 4. Evolution of applied strain in both specimen tests, evidencing feature-induced crack arrest and increase in strain tolerance.

5. Conclusions

A concept of crack-arresting feature for FRPs under compression was developed and tested. The concept was proven to successfully stop unstable compressive kink-band propagation, considerably delaying the specimen's ultimate failure and improving its strain tolerance. When compared to an equivalent baseline, the crack-arrest specimen showed a one third higher ultimate failure strain.

It was perceived that, by using discontinuity in fibre orientation, the feature can deflect the crack, forcing it to generate longer failure paths. Moreover, the soft lay-up suffered higher levels of secondary failure, contributing to energy dispersion. Therefore, by generating additional failure surfaces and imposing difficulties to crack propagation perpendicular to loading direction, the feature is able of dispersing enough energy to stop kink-band propagation.

Next research steps include fractographic analysis, to deduce the detailed failure mechanisms, followed by optimisation of the ply angles and stacking sequence. Through this process, crack-arrest effects will be maximised, whilst maintaining the same panel stiffness.

Abstract
In this study, we estimate the residual strength of polymer composites after thermal shrinkage by correlating the amount of entropy generation during material deformation with material degradation. We propose a viscoelastic constitutive equation for viscoelastic media, grounded in the principles of irreversible thermodynamics and viscoelastic theory. Numerical simulations are conducted to investigate the residual strength after thermal shrinkage during molding. The results indicate that the residual strength decreases significantly with an increase in temperature difference during cooling due to increased entropy generation. This study highlights the importance of considering thermal shrinkage and its impact on material degradation for accurate residual strength prediction.

1. Introduction

In conventional studies concerning the durability of CFRP, particularly in terms of residual strength, the focus has typically been on assessing durability under specific loading conditions such as constant strain rate, cyclic loading, and creep, each considered independently [1]. To determine the essential durability, it is necessary to measure the residual strength after different load histories. For instance, if the material undergoes creep, followed by cyclic loading, then constant strain rate, and eventually fails, it stands to reason that the initial strength of the material would diminish due to the exposure to various loading conditions (Fig. 1). Utilizing traditional methods, the residual strength after such combined loading scenarios cannot be accurately determined. Therefore, even when the material is subjected to multiple and diverse loading conditions, there is a pressing need for a method capable of calculating the residual strength by establishing a universal failure criterion.

To discuss the lifetime (long-term durability) of composite materials, the viscoelastic properties must be considered because of the viscoelastic behavior of the polymer matrix. In discussing the lifetime of polymer composites, some studies have been conducted to describe their strength degradation by thermodynamic entropy, recently [2, 3]. Inelastic deformation of the material causes an irreversible structural change inside the material. Such an internal structural change is expressed by a thermodynamic internal variable based on Clausius-Duhem inequality (the second law of thermodynamics); i.e., deterioration of the material proceeds with the disorder of the system. The disorder in the system, which causes deterioration of the characteristics, is raised by the mechanical deformation and the entropy increases accordingly. The disorder in the degraded system continues to

increase to the critical state and causes the failure of the materials. Therefore, irreversible entropy in materials can be used as a criterion for evaluating lifetime of materials.

In order to effectively discuss and evaluate the residual strength of materials subjected to various loading conditions, it is imperative to develop a constitutive equation for the resin that comprehensively accounts for these diverse loads. To this end, we propose a viscoelastic constitutive equation for viscoelastic media, which is grounded in the principles of irreversible thermodynamics and viscoelastic theory. As an initial approach, we conduct numerical simulations to investigate the residual strength after thermal shrinkage during molding. It is anticipated that the residual strength after thermal shrinkage will be lower than the static tensile strength. Subsequently, we engage in a detailed discussion regarding the matrerial degradation due to the thermal shrinkage.

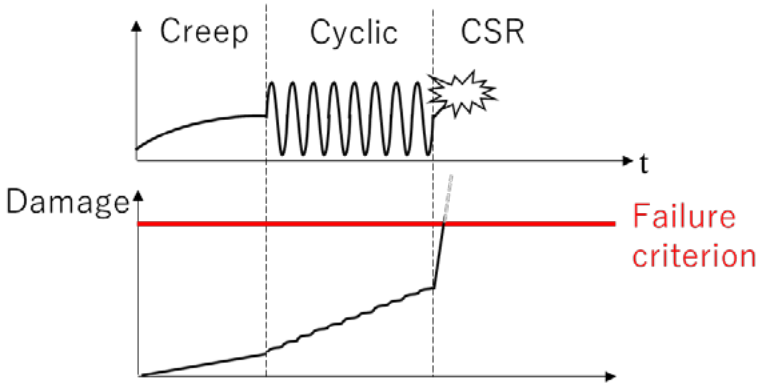

Figure 1. The concept of universal failure criterion.

2. Analysis

2.1 Constitutive equation

The generation of entropy up to the point of material failure (fracture entropy), denoted as s_{cr}, is described by Eq. (1), which is derived using the first and second laws of thermodynamics (Clausius-Duhem inequality) and Helmholtz free energy [4]. In this equation, t_f represents the time of material failure, W_d is the energy dissipated due to non-elastic deformation, T is the temperature, $\dot{\boldsymbol{V}}_k$ is the appropriate set of internal variables, $\boldsymbol{A}_k$ is the generalized thermodynamic force related to the internal variables, and $\boldsymbol{J}_q$ is the heat flux across the boundary. Eq. (1) encompasses mechanical dissipation from non-elastic deformation (the first term), non-recoverable energy such as damage stored within the material (the second term), and thermal dissipation due to heat conduction (the third term). In this study, we assume that the first and second terms are predominant during material deformation, thus defining the dissipated energy W until material failure as the sum of these two terms, as shown in Eq. (2). By using Eq. (2), the entropy generated up to material failure can be determined by measuring the dissipated energy and temperature during the material testing.

$$s_{cr} = \int_0^{t_f} \left(\frac{W_d}{T} - \frac{\boldsymbol{A_k}:\dot{\boldsymbol{V}}_{\boldsymbol{k}}}{T} - \frac{\boldsymbol{J_q} grad T}{T^2} \right) dt \tag{1}$$

$$s_{cr} = \int_0^{t_f} \left(\frac{W_d}{T} - \frac{\boldsymbol{A_k}:\dot{\boldsymbol{V}}_{\boldsymbol{k}}}{T} \right) dt$$

$$= \int_0^{t_f} \left(\frac{W}{T} \right) dt \tag{2}$$

We propose a viscoelastic model, described in Fig. 2, which is derived from Maxwell's model. This model incorporates 15 Maxwell elements. The overall strain, denoted as $\boldsymbol{\varepsilon}^{\mathrm{total}}$, is composed of both a viscoelastic strain, $\boldsymbol{\varepsilon}^{\mathrm{ve}}$, and a viscoplastic strain, $\boldsymbol{\varepsilon}^{\mathrm{vp}}$, as described in Eq. (3). Eq. (4) represents a

viscoelastic constitutive equation that takes into account the stress history, based on the formulation proposed by Schapery [5]. In this equation, D is a damage variable that incorporates the entropy-damage law, and E is the relaxation modulus, as outlined in Eq. (5). In Eq. (5) and Fig. 1, E^n represents the spring stiff ness of the n th Maxwell element, with each element having a stiffness value of 1/15 th of the initial stiffness of the entire Maxwell model. η^n denotes the viscosity coefficient of the nth Maxwell element, t is the time, t' is the time at which the strain is applied, and g is a nonlinear coefficient presented in Eq. (6). σ_{Mises} represents the von Mises stress, σ_0 is a specified stress value, and α_n is a nonlinear coefficient. The second term in Eq. (3) is defined by Eq. (7), where H^{irr} is the viscosity coefficient responsible for inducing irreversible strain. These material parameters are determined through experiments conducted on the matrix resin [3]. The damage variable D introduced by the fracture entropy is expressed by Eq. (8). There, D_{cr} is the critical damage, s is the current entropy and α_d is damage parameter. Matrix properties are shown in Tab. 1.

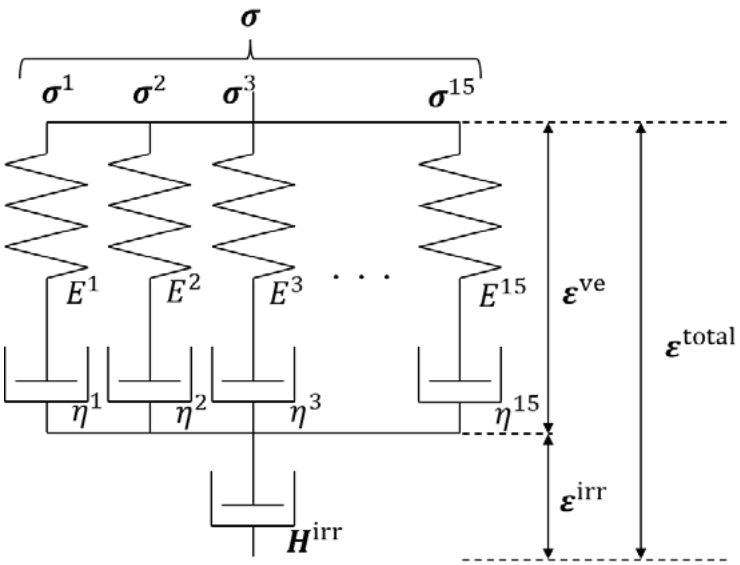

Figure 2. Viscoelastic model.

$$\boldsymbol{\varepsilon}^{\text{total}} = \boldsymbol{\varepsilon}^{\text{ve}} + \boldsymbol{\varepsilon}^{irr} \tag{3}$$

$$\sigma_{ij}(t) = (1 - D)\int_0^t E_{ijkl}(t - t')\frac{g d\varepsilon_{kl}^{ve}}{dt'}dt' \tag{4}$$

$$E_{ijkl}(t) = \sum_{n=1}^{15} E_{ijkl}^n e^{-tE^n/\eta^n} \tag{5}$$

$$g = \frac{1}{1 + \alpha_n\left(\frac{\sigma_{Mises}}{\sigma_0}\right)^m} \tag{6}$$

$$\varepsilon_{ij}^{irr} = \int_0^t \left(H_{ijkl}^{irr}\right)^{-1}\sigma_{kl}dt \tag{7}$$

$$D = D_{cr}\frac{s}{s_{cr}} = D_{cr}\frac{1}{s_{cr}}\frac{W}{T} \fallingdotseq W \times \alpha_d \tag{8}$$

2.2 Micro-scale finite element model

A numerical analysis is performed using the ABAQUS 2020 software package. We create a three-dimensional (3D) unit cell model, as illustrated in Fig. 3, and applied periodic boundary conditions at all edges utilizing the key node method. The representative volume element (RVE) includes 34 carbon fibers with a diameter of 6 μm, embedded within a matrix resin. The dimensions of the 3D unit cell are 39 μm × 39 μm × 0.3 μm, resulting in a fiber volume fraction of 63%. The model consists of C3D15 elements, with a total of 38,322 elements and 173,760 nodes. The carbon fibers are modeled as anisotropic elastic materials (as detailed in Table 2), and the proposed constitutive equation is implemented in the matrix resin via the UMAT user subroutine.

In this study, three types of analysis conditions are performed. The first one involves a static tensile analysis conducted at room temperature (300K) to determine the static strength. The other two analyses consider the thermal shrinkage process during molding. For these analyses, the initial states are set at 400K and 350K, respectively, and the RVE model are cooled to 300K (ΔT are 100K and 50K, respectively). After cooling, the RVE model are left to rest for one hour before performing the static tensile analysis to evaluate the residual strength. The strain rate for the static tensile analysis is set at 0.001/sec. In the analysis of the thermal shrinkage process, the Arrhenius-type time-temperature superposition principle (TTSP) shown in Eq. (9) is adopted. There, α^{TR} is a time-accelerating factor, ΔH

is the activation energy, R is the gas constant, T^{R} is the reference temperature, and T is the current temperature. We assume that $\Delta H = 160$ kJ/mol from the result of dynamic mechanical analysis test, and $T^{\mathrm{R}} = 300$ K in this study.

$$\log\alpha^{\mathrm{TR}}(T) = \frac{\Delta H}{2.303R}\left(\frac{1}{T} - \frac{1}{T^{\mathrm{R}}}\right) \tag{9}$$

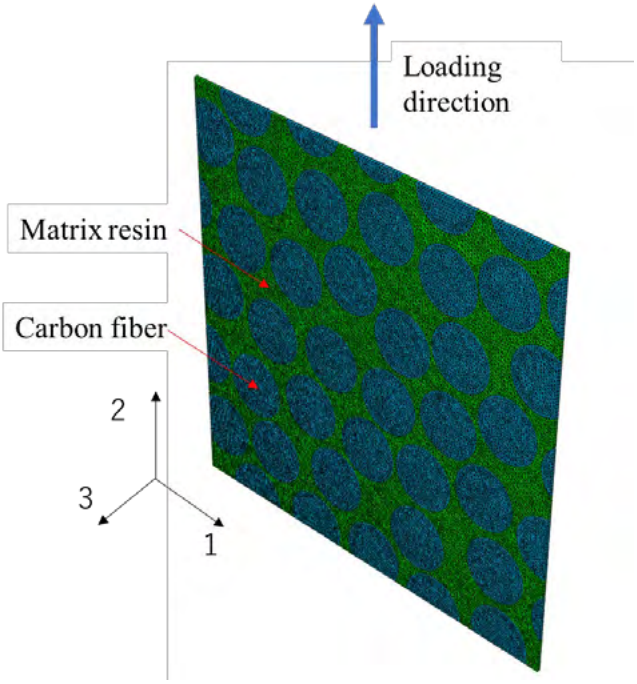

Figure 3. FEA model.

3. Result and Discussion

The results of the three analysis conditions are shown in Fig. 4. The static strength is found to be 68.6 MPa, while the residual strength after cooling with ΔT = 50K is 58.1 MPa, and with ΔT = 100K, it is 51.4 MPa. The greater the temperature difference during cooling, the more entropy (dissipated energy) is generated during thermal shrinkage, resulting in lower residual strength. In cases considering thermal shrinkage, the initial stiffness is reduced compared to the static analysis results due to viscoelastic behavior during cooling. The proposed model is capable of predicting the residual strength while accounting for the damage induced by thermal shrinkage.

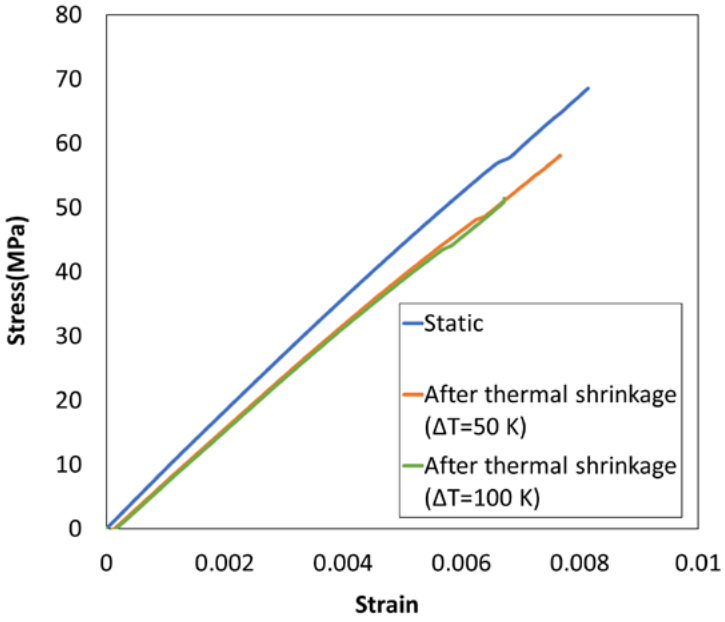

Figure 4. SS curve.

4. Conclusions

The study presented a comprehensive approach to evaluate the residual strength of polymer composites by incorporating a viscoelastic constitutive model based on irreversible thermodynamics and viscoelastic theory. The numerical analysis using ABAQUS revealed that the residual strength of polymer composites decreases as the temperature difference during cooling increases, due to higher entropy generation. The static strength is measured at 68.6 MPa, while the residual strengths after cooling with $\Delta T = 50K$ and $\Delta T = 100K$ are 58.1 MPa and 51.4 MPa, respectively. The proposed model effectively predicts the residual strength by accounting for the damage induced by thermal shrinkage, emphasizing the necessity to consider thermal effects in the design and analysis of polymer composites.

Keywords: Continuous Fiber Additive Manufacturing, Structural Health Monitoring, Self-Sensing, Fiber Optical Sensors, 3D Printing, Carbon Fiber Sensors

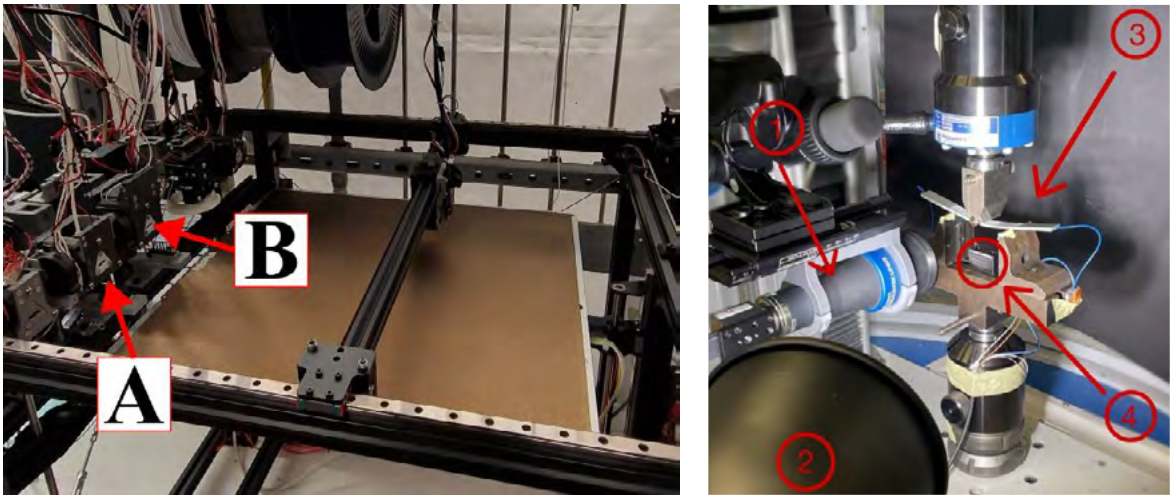
Abstract
This study investigates the automated integration of fibrous sensors, including carbon fiber sensors (CFS) and fiber optical sensors (FOS), into continuous fiber-reinforced additively manufactured parts for enhanced structural health monitoring. Mechanical testing, in the form of tensile and 3-point bending tests, revealed that the presence of integrated CFS and FOS does not significantly impact mechanical properties, highlighting the potential for seamless integration without compromising structural integrity. FOS demonstrated high precision in strain measurements during tensile and bending tests, which strongly correlated with the reference measurement obtained through a video extensometer, even allowing for precise tensile and flexural modulus computation. Meanwhile, CFS exhibited linear piezoresistive behavior up to a particular strain limit, making them suitable for strain-sensing applications. Sensitivity coefficients of different CFS types were determined, which demonstrated the self-sensing capabilities of distinguishing between CFS integrated in different layers of 3-point bending specimens. These findings underscore the potential of additively manufactured sensor-integrated composites for structural health monitoring and multifunctionality across various engineering domains. Further advancements in sensor technology and additive manufacturing techniques hold promise for broader applications in aerospace, automotive, and civil infrastructure.

1. INTRODUCTION

Continuous fiber-reinforced polymer composites are increasingly utilized in various engineering applications due to their superior mechanical properties. To further enhance their functionality, integrating sensors directly into these composites is an area of growing interest. Hereby, fibrous sensors are of superior interest, as they can be integrated without compromising the structural integrity and the mechanical properties of the part. Carbon fibers are widely used as a reinforcement material, but due to their piezoresistive behavior, they can also be used as sensors (CFS), which is also referred to as self-sensing [1]. Some carbon fibers show linear piezoresistive behavior, which is a fundamental property for CFS and is influenced by the micro structure of the CFS as well as geometric effects, as was shown

by Horoschenkoff et al. [2]. CFS are sensitive to strain [3,4], temperature, and humidity [5]. Research on damage monitoring using CFS has also been conducted [6,7].
Likewise, FOS can be used to detect temperature and strain changes. More commonly, Fiber Bragg Grating sensors have been researched [8]. Still, the Rayleigh backscatter measurement technique has emerged in the last years [9,10], allowing the use of cost-effective, single-mode optical fibers as FOS.
In combination with additive manufacturing, FOS have been integrated into additively manufactured parts to measure strain and temperature [11]. With the development of continuous fiber additive manufacturing (CFAM) systems and commercially available systems, self-sensing of 3D printed structures with carbon fiber reinforcement has been in the spotlight of researchers recently [12–14].
In this study, a novel approach is presented for integrating CFS and FOS, using Rayleigh backscattering, into continuous fiber-reinforced parts additively fabricated via Fused Filament Fabrication (FFF). The aim is to evaluate the performance of CFS and FOS in measuring strain under tensile and bending loads.

2. MATERIALS AND METHODS



2.1 Specimen Fabrication

The specimens for the tensile and 3-point bending tests were designed in accordance with the standards DIN EN ISO 527-5 and DIN EN ISO 14125, respectively. A custom-built 3D printer, shown in **Figure 1**, was used to additively manufacture the specimens. The custom 3D printer is equipped with a tool-changer adapted from the concept and mechanisms of the jubilee tool-changer [15]. It can use up to five different tools and switch between them automatically during manufacturing. A continuous fiber printhead, provided by Anisoprint 3D Printing Technology Limited Company, and a direct-drive FFF printhead were used for the specimen fabrication. Anisoprint's Composite Carbon Fiber (CCF) was used as a CFS and as the reinforcement fiber. White PETG by Material4Print was used as a matrix material for the specimens. Thorlabs' SM1550P Polyimide-Coated Single Mode Fiber was used as a FOS.
For the tensile tests, the CFS and FOS were integrated in the mid-plane and centerline of the specimen. The FOS was integrated manually and overprinted by the direct-drive printhead. For the 3-point bending specimen, four different specimen types with sensors were manufactured. For types AN, AS and FO, the CFS and FOS were integrated in the first fiber layer on the tension side of the specimen during testing. For type A2S, the CFS was integrated in the second fiber layer on the tension side of the specimen, therefore being closer to the center of the specimen. The CFS in type AN was printed as one straight line in the centerline of the specimen. The CFS in types AS and A2S were printed as a grid with six gridlines centered around the centerline of the specimen. The CCF reinforcement fibers were printed in straight lines to reinforce the specimen unidirectionally in length direction only. The tensile specimen consisted of three thermoplastic layers on the bottom, mid-plane and top, and four reinforcement layers. The 3-point bending specimens were printed with two thermoplastic layers, bottom and top, and five reinforcement layers. The fiber volume content (FVC) was calculated and experimentally verified by burning the matrix and weighing the specimen using a high-accuracy scale. All specimen types and their respective specifications are shown in **Table 1**.
Each tip of a CFS was printed to extend approximately 20 mm outside the end of the specimen in order to electrically connect them. The matrix at the CFS' tips was removed by burning. The bare carbon fiber was then electrically connected and bonded to copper wires by means of DICO 200-05 highly conductive silver ink. A coreless termination fiber was spliced to one end of the FOS and a Logilink FPSLC01 G627.A2 fiber with an LC/APC connector to the other end.

2.2 Experimental Setup and Analysis

A 100 kN universal test machine by Hegewald & Peschke was used for both tensile and 3-point bending tests. The test machine was equipped with a 10 kN or 2.5 kN load cell for tensile or 3-point bending tests, respectively. LabMaster control software was used to control the test machine and acquire data. A Real-Time Strain Sensor video extensometer (VE) by LIMESS GmbH was used for the reference displacement and strain measurement, as shown in **Figure 1**. The CFS' resistance measurement was conducted via a 4-wire setup by a QuantumX MX840B universal measuring amplifier. The FOS was connected to a LUNA ODiSI-A measurement system. LUNA ODisI-A Control Software v1.3.5 was used for the FOS setup, calibration, and data acquisition. Both tensile and 3-point bending tests were performed at room temperature and displacement-controlled at a speed of 2 mm/min.
The tensile stress and modulus were calculated according to eqs. (1) and (2), respectively.

$$\sigma = \frac{F}{wt} \tag{1}$$

$$E = \frac{\sigma'' - \sigma'}{\varepsilon'' - \varepsilon'} \tag{2}$$

F is the Force, σ is the tensile stress, w the width and t the thickness of the specimen. The Young's modulus or tensile modulus E is calculated between the strains $\varepsilon' = 0.0005$ and $\varepsilon'' = 0.0025$ and the respective tensile stresses σ' and σ'' at these strain values.
The flexural stress σ_f and strain ε_f in the outer surface of the specimen at mid-span, as well as the flexural modulus E_f were calculated according to eqs. (3),(4) and (5) respectively.

$$\sigma_f = \frac{3FL}{2wt^2} \tag{3}$$

$$\varepsilon_f = \frac{6st}{L^2} \tag{4}$$

$$E_f = \frac{L^3}{4wt^3}\left(\frac{\Delta F}{\Delta s}\right) \tag{5}$$

L denotes the span, s is the deflection of the centerline of the specimen at mid-span, Δs is the difference of deflections $s'' - s'$ at $\varepsilon'_f = 0.0005$ and $\varepsilon''_f = 0.0025$, which can be calculated using eq. (4). ΔF represents the difference in Force between s' and s''.
The LUNA ODiSI-A makes use of swept-wavelength interferometry to measure strain or temperature changes along a FOS. This is achieved by cross-correlating the current spectral response of the Rayleigh backscatter with a baseline measurement of FOS' Rayleigh scatter signature [16]. Changes in temperature or strain cause a spectral shift in the Rayleigh backscatter, which can be related to a temperature (ΔT) or strain using eq. (6). With the temperature kept constant at room temperature, the FOS' strain ε_{FOS} can be calculated using eq. (7):

$$\frac{\Delta\lambda}{\lambda} = -\frac{\Delta\nu}{\nu} = K_T\Delta T + K_\varepsilon\varepsilon_{FOS} \tag{6}$$

$$\varepsilon_{FOS} = -\frac{\bar{\lambda}}{cK_\varepsilon}\Delta\nu \tag{7}$$

where λ and ν are the mean optical wavelength and frequency, and K_T and K_ε are the temperature and strain calibration constants, respectively. The center wavelength of the scan is denoted as $\bar{\lambda}$, and c is the speed of light. The FOS strain was captured every 6 mm for the bending and every 10 mm for the tensile tests along the fiber length at approx. 1 Hz sampling rate.
The linear relation of carbon fibers' resistance to strain has already been shown in previous studies. This relation can be expressed as follows:

$$\frac{\Delta R}{R_0} = k\varepsilon \tag{8}$$

where k is the sensitivity coefficient, R_0 is the initial resistance at zero strain, and ΔR is the change in resistance.

3. RESULTS AND DISCUSSION

3.1 Mechanical Properties

Integrating sensors into structural parts may cause lower mechanical properties than non-sensor integrated parts. **Figure 2** denotes the tensile strength, tensile modulus, flexural strength, and flexural modulus of non-sensor integrated, FOS, CFS, and pure PETG specimens. The error bars show the standard deviation. It can be seen that there is no significant difference among the reinforced specimen types, which indicates that the integrated sensors do not significantly impact the mechanical properties. Values for pure PETG without fiber reinforcement were added for reference. The tensile properties were measured in tensile tests; the flexural properties were taken from the literature [17].

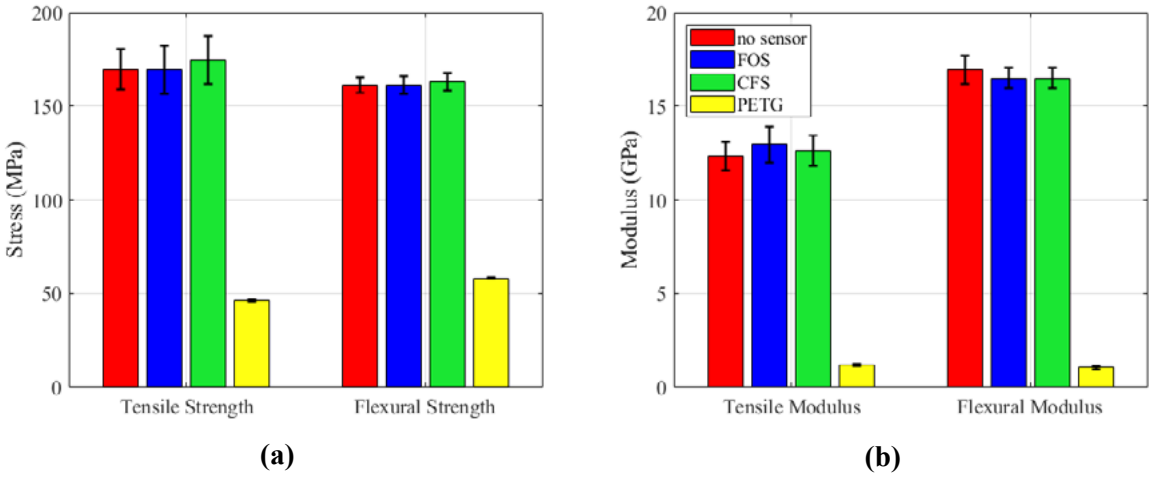

Figure 2: (a) Tensile and flexural strength of all specimen types. **(b)** Tensile and flexural modulus of all specimen types. PETG flexural values from [17].

3.2 FOS

Five specimens were tested in tensile tests. The LUNA ODiSI-A was set to measure the strain every 10 mm, resulting in about 25 measurement points inside the specimens. The strain along the FOS shows that measuring the strain inside the specimens is very precisely possible, as depicted in **Figure 3**. The strain increases over the glued-on tabs, which are used to clamp the specimen into the tensile test fixture of the test machine. The strain in the test region of the specimen has some minor deviations, but is primarily constant, as expected. The FOS strain was averaged to one value at each sampling point for each specimen. Plotting the force against the FOS strain measurement and the video extensometer (VE) strain measurement shows that the two strain measurements only differ slightly from each other when the force approaches the tensile strength of the specimen, as shown in **Figure 3**.

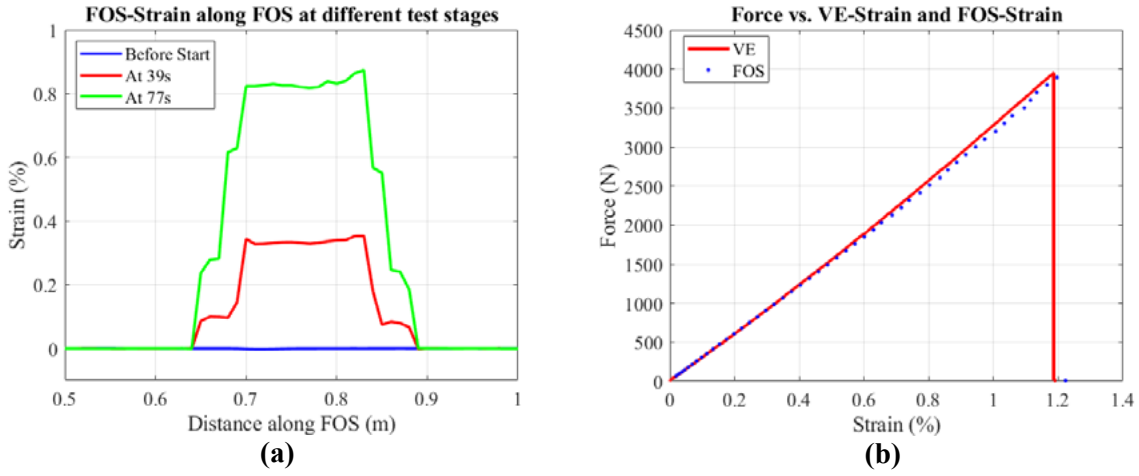

Figure 3: (a) FOS strain measurement at different times during the tensile test. **(b)** Force values plotted against the strain measured by the FOS and the VE.

Similarly to the tensile strain, the strain during the 3-point bending tests was captured, as shown in **Figure 4**. In order to compare the FOS strain measurement to the reference video extensometer strain measurement, the FOS strain was integrated and averaged over the test area. The averaged FOS strain and the reference VE strain were then plotted against time. It can be seen that the FOS is capable of

measuring the strain very well. Due to the LUNA ODiSI-A specifications, the FOS is limited to measuring up to a strain of 1%, which is clearly visible in the form of scatter in **Figure 4**.

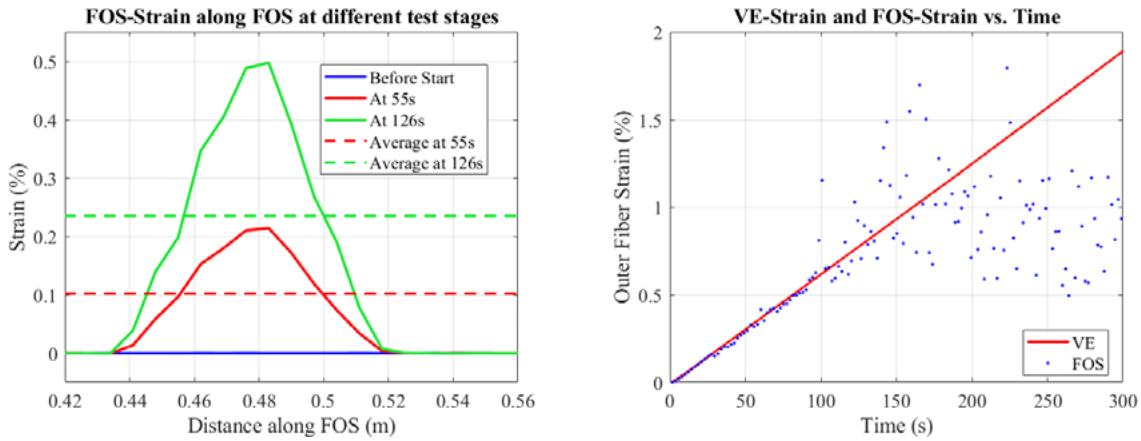

Figure 4: (a) FOS strain measurement at different times during the 3-point bending test. **(b)** Outer Fiber Strain computed by the FOS and the VE plotted against the time.

Considering the excellent correlation of the FOS and reference VE strain measurements, we calculated the average tensile and flexural modulus across all specimens using the VE and FOS strain measurements. The results are shown in **Table 2** and highlight the excellent capabilities of the FOS strain measurement. The modulus deviation is calculated as the difference between the two computed moduli divided by the VE modulus. The value represents the average across all specimens. The standard deviation refers to the modulus deviation across all specimens.

Table 2: Tensile and flexural modulus calculated by the VE and FOS. Modulus deviation and standard deviation refer to the FOS computation.

Specimen Type	VE Modulus (GPa)	FOS Modulus (GPa)	Modulus Deviation (%)	Standard Deviation (%)
FOT	12.402	12.404	-0.045	2.169
FOB	16.498	16.569	2.370	2.430

3.3 CFS

As expected, the resistance of the AT-type specimens increased linearly up to about 0.8% strain, as shown in **Figure 5**. The resistance thereafter started to grow exponentially, which was probably caused by fiber breakage in the CFS. The sensitivity coefficient for the AT-type specimens can be estimated as a linear regression and is denoted k_t along with its R²-value. Three different CFS-type specimens were tested in 3-point bending tests. The relative resistance change for one specimen of each type is plotted over the outer fiber strain (OFS) of the specimen, as shown in **Figure 5**. The corresponding force for each specimen is also shown in **Figure 5**. The sensitivity coefficient was approximated by linear regression and is denoted k_b. No significant difference can be seen between the AN- and AG-type specimens. The A2G-type is clearly distinctive, as it has a smaller sensitivity coefficient. This was expected because the sensor was integrated in the 2nd fiber layer, where the actual strain is less than the outer fiber strain, considering Hooke's law and linear stress distribution in the thickness direction of the specimen. The sensitivity coefficients for all CFS types are shown in **Table 3**.

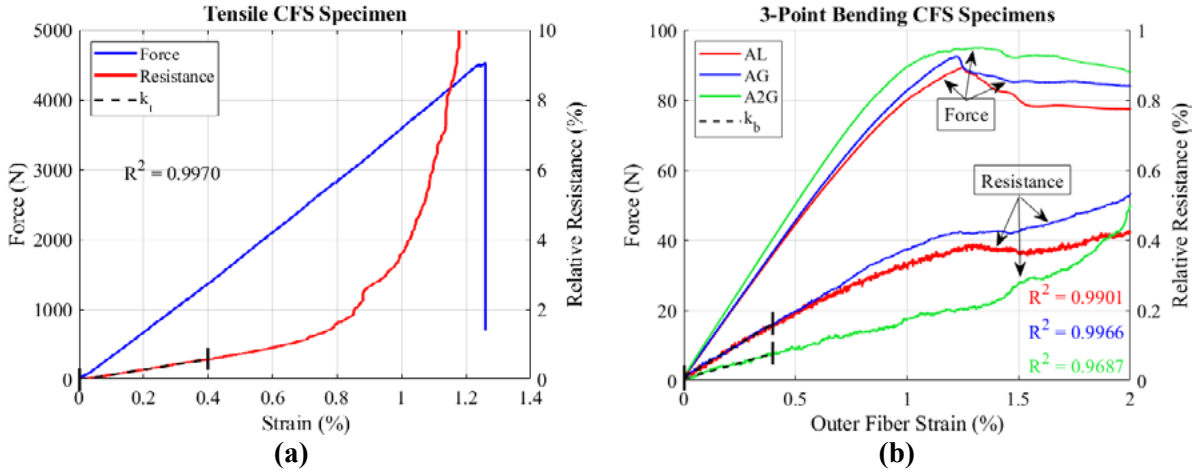

Figure 5: (a) Relative resistance and force plotted over OFS for an AT-type specimen. **(b)** Relative resistance and force plotted over OFS for each CFS-type during 3-point bending tests.

Table 3: Sensitivity coefficients for all CFS-type specimens.

Specimen Type	Sensor type	Sensor location	Sensitivity coefficient (-)	Standard Deviation (-)
AT	CFS (line)	Center plane, centerline	1.470	0.124
AL	CFS (line)	1st fiber layer, centerline	0.329	0.028
AG	CFS (grid)	1st fiber layer, centered	0.316	0.099
A2G	CFS (grid)	2nd fiber layer, centered	0.192	0.063

4. CONCLUSION

This study explored the integration of fibrous sensors, particularly carbon fiber sensors (CFS) and fiber optical sensors (FOS), into continuous fiber-reinforced additively manufactured (CFAM) parts. A custom-built 3D printer was used to fabricate the specimens, using the fully automated manufacturing process and showcasing the capabilities of CFAM. Three different specimen types for tensile and five different types for 3-point bending tests were manufactured to investigate the performance of the integrated sensors and the mechanical properties. The tensile and 3-point bending tests revealed that the presence of integrated sensors did not significantly affect the mechanical properties of the composite specimens. This indicates the potential for seamless integration of CFS and FOS without compromising the overall structural integrity of the composite material. The FOS demonstrated excellent performance in strain measurement during both tensile and bending tests, exhibiting high precision and correlation with the reference strain measurement obtained through a video extensometer. Furthermore, the FOS strain measurement was used to compute the tensile and flexural modulus, which resulted in a deviation of -0.045% and 2.370% compared to the reference tensile and flexural modulus, respectively. This highlights the reliability and accuracy of FOS in monitoring structural deformation and localized strain distribution within composite materials up to strains of 1%, using the LUNA ODiSI-A measurement system. Similarly, the CFS' resistance measurements exhibited linear behavior up to a specific strain limit. The sensitivity coefficients of four different CFS types were determined with high accuracy. The study also identified the influence of sensor location within the composite structure on the sensitivity coefficient values of CFS. It was shown that CFS integrated into different layers in a 3-point bending specimen can be clearly distinguished.

Overall, the findings of this research underscore the potential of integrating fibrous sensors into continuous fiber-reinforced additively manufactured parts. However, further research is necessary to investigate the capabilities of FOS and CFS in structural health monitoring applications, especially regarding fatigue loads and lifetime prediction.

Keywords: glass fibre reinforced polymer, pultrusion, durability, mechanical properties, hygrothermal ageing

Abstract
This paper investigates the durability of 8 mm thick pultruded glass fibre-reinforced polymer (GFRP) composite laminates manufactured with either unsaturated polyester or vinyl ester resins. Over a period of 12 months, a comprehensive set of experiments was carried out to assess the durability performance of these GFRP laminates under accelerated laboratory and natural environmental ageing conditions. The accelerated laboratory ageing included exposure to constant temperatures of -15 °C, 20 °C, 40 °C and 60 °C and water immersion at 20 °C. For natural ageing, four different locations in Portugal were selected to promote different levels of humidity, temperature fluctuations, freeze-thaw cycles, and UV radiation. Mechanical property retentions were evaluated, including tensile strength in the longitudinal pultrusion direction, compressive strength, flexural strength, in-plane shear strength and interlaminar shear strength. The highest reductions in mechanical properties occurred after immersion in water at 20 °C, when the specimens were tested under wet conditions, with the lowest property retentions being 63% for the interlaminar shear strength of the composite with vinyl ester matrix and 69% for the compressive strength of the composite with unsaturated polyester.

1. Introduction

The durability of fibre-reinforced polymer (FRP) composites is particularly critical in civil engineering applications, where the design service life is typically between 50 and 100 years. Furthermore, the assessment of the durability of composites is a complex study, as it depends on several aspects, e.g., polymer matrix, fibres, fibre-matrix interphase, processing method, quality control protocols, details, installation, maintenance and type of use [1, 2]. Among FRP composites, pultruded glass-FRP (GFRP) components are gaining popularity due to their desirable characteristics and relatively competitive cost compared to traditional materials like steel [3, 4].

Typically, composites are exposed to a variety of environmental conditions, frequently experiencing thermal effects (such as thermal cycles and freeze-thaw cycles), moisture, and UV radiation throughout their service life [5]. Thermal aging, involving prolonged exposure to elevated or sub-zero temperatures, and thermal cycling, characterized by temperature fluctuations, can significantly affect the mechanical properties of GFRP materials (CEN/TS 19101:2022). Particularly, elevated temperatures approaching or exceeding the glass transition temperature (T_g) lead to resin softening, contributing to material

degradation and reducing mechanical properties, e.g. [6-8]. Moisture diffusion is another primary cause of GFRP degradation, resulting in resin swelling, plasticization, cracking, hydrolysis, and/or fibre/matrix interface debonding, e.g. [9]. The combined effects of hot and humid climates exacerbate these challenges, while UV radiation accelerates polymer degradation, especially when combined with moisture and elevated temperatures, e.g. [10]. Given these complex interactions, assessing the durability of GFRP laminates requires comprehensive data and careful consideration.

Due to the lack of comprehensive and long-term durability results, targeted research is needed to gather durability data of GFRP composites tailored to civil engineering applications and to develop reliable degradation models for predicting long-term retention of mechanical properties. Furthermore, it is important to note that durability studies of pultruded GFRP laminates under various accelerated laboratory and natural aging conditions are rare, e.g. [11,12[].

To address the gaps identified in the literature, an extensive experimental campaign is being undertaken as part of the Durable-FRP research project. This test program aims to assess the durability of thick pultruded GFRP laminates composed of unsaturated polyester and vinyl ester matrices through laboratory (accelerated ageing) and in-situ field (natural ageing) tests, comprising both unloaded and loaded specimens during ageing. This paper presents selected preliminary results from this program, focusing on two types of pultruded GFRP laminates subjected to accelerated laboratory and natural ageing environments for over 12 months, without loading. The experimental program includes exposure to constant temperatures ranging from -15 °C to 60 °C, immersion in water at 20 °C (for which specimens were tested in “dry” and “wet” conditions), and natural ageing at four different locations in Portugal, characterized by different exposure to moisture, thermal fluctuations, freeze-thaw cycles, and UV radiation. Mechanical properties, including tensile (in the longitudinal direction), compression, flexural, in-plane shear, and interlaminar shear, were evaluated before and after exposure to these ageing environments.

2. Experimental Program

2.1. Materials

As mentioned, pultruded GFRP laminates manufactured with two distinct resin matrices were used: (i) unsaturated polyester (GFRP_UP) and (ii) vinyl ester (GFRP_VE). These laminates are composed of seven reinforcing layers, comprising four layers of chopped strand mat interspersed with layers of rovings in the pultrusion direction. The produced laminates have nominal dimensions of 250 mm of width and 8 mm of thickness.

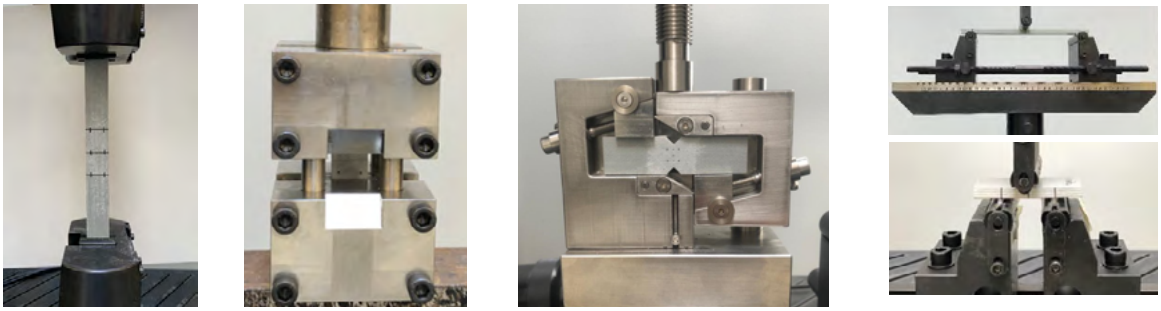
Calcination tests carried out according to ISO 1172:2023 revealed fibre content (by mass) of 59% and 63% for GFRP_UP and GFRP_VE laminates, respectively. For the sake of simplicity in executing the experimental programs, 900 mm × 250 mm × 8 mm (length, width, thickness) plates were used.

2.2. Ageing Protocol

Firstly, all composites underwent a post-cure protocol after manufacturing and before any aging process. This involved exposing the laminates to 80 °C in a climatic chamber for 12 hours. Over 12 months, three types of ageing environments were simulated, both in laboratory and in-situ field conditions. The first group of specimens was subjected to constant temperatures of -15 °C (T-15), 20 °C (T20), 40 °C (T40), and 60 °C (T60) to assess the influence of exposure to those constant temperatures. The second group of specimens was completely immersed in demineralized water at 20 °C (hygrothermal ageing), and their mechanical properties were evaluated in the “dry” state (W20D), after reaching constant mass, and in the wet state (W20S), i.e., removed from water just before performing the mechanical tests. Finally, a third group of specimens underwent natural ageing in four different locations in Portugal, characterized by different exposure to moisture, thermal fluctuations, freeze-thaw cycles, and UV radiation. These locations included: (i) E2 - Elvas (warm and temperate climate; very high thermal amplitudes, the highest temperature in Portugal and UV radiation); (ii) E3 - Lisbon (mild Mediterranean climate in an urban area); (iii) E4 - Serra da Estrela (highest mountain in Portugal; high thermal amplitudes, lowest

temperatures in Portugal, UV radiation and freeze-thaw cycles); and (iv) E5 - Viana do Castelo (maritime moist environment – Atlantic Ocean). Note: E1 corresponds to T20.

2.3. Methods



Several test methods were used to evaluate the durability of GFRP laminates in terms of their thermomechanical and mechanical properties.

The thermomechanical properties of unaged GFRP laminates were assessed using dynamic mechanical analysis (DMA). The DMA tests were conducted using a dynamic mechanical analyser, model Q800 DMA (TA Instruments), following the recommendations of ISO 6721:2019 (parts 1 and 5). Specimens measuring 60 mm × 10 mm × 4 mm were first prepared (in a CNC milling machine to reduce the laminate thickness from 8 mm to 4 mm on one surface) and then heated from 25 °C to 250 °C at a rate of 2 °C/min, while being subjected to a sinusoidal load in a dual cantilever-type clamp system, maintaining a constant frequency of 1 Hz and a strain amplitude of 15 µm. The glass transition temperature, T_g, was determined from the onset of the decay of the storage modulus (E') curve, considering the average from three replicates.

The mechanical properties of GFRP laminates before and after ageing were assessed using an MTS Exceed E45.105 universal testing machine with a load capacity of 100 kN (Figure 1), namely:

- Tensile tests in the 0° longitudinal direction (pultrusion direction), as per EN ISO 527-4:1997, with specimens of 300 mm × 25 mm × 8 mm, loaded at a rate of 2 mm/min.
- Compressive tests (in the 0° direction), as per ISO 14126:1999, with specimens of 153 mm × 25 mm × 8 mm, loaded at a rate of 1 mm/min.
- Flexural tests (in the 0° direction), as per EN ISO 14125:1998, with specimens of 240 mm × 15 mm × 8 mm, loaded at a rate of 5 mm/min.
- In-plane shear (IPS) tests, as per ASTM D5379/D5379M:2012, using specimens of 76 mm × 19 mm × 8 mm, which included a double V-notch at mid-span, loaded at a rate of 2 mm/min.
- Interlaminar shear tests (ILS) in the 0° longitudinal direction, as per ISO 14130:1997, with specimens of 80 mm × 40 mm × 8 mm, loaded at a rate of 1 mm/min.

Each test series comprised six specimens.

(a) (b) (c) (d), (e)

Figure 1. Mechanical tests: (a) tensile, (b) compressive, (c) IPS, (d) flexural, (e) ILS.

3. Results and Discussion

3.1. Initial Characterization

A glass transition temperature, T_g, of 80.6 °C (coefficient of variation, CoV=5.1%) was determined for the GFRP_UP composite, whereas for GFRP_VE a T_g of 101.0 °C (CoV=0.8%) was obtained. Table 1 presents the results of the mechanical properties in tension, compression, flexure, IPS, and ILS for unaged GFRP_UP and GFRP_VE. These results are based on the mean values obtained from six specimens, along with their corresponding CoV. In subsequent sections, these results are then compared with those obtained from the aged series exposed to various thermal conditions.

Table 1. Mechanical properties of references (unaged) series (REF) for both UP and VE matrices.

Test type	GFRP_UP		GFRP_VE	
	Mean value [MPa]	CoV [%]	Mean value [MPa]	CoV [%]
Tensile (0°) strength	426	1.7	456	1.7
Compressive strength	522	8.2	505	9.6
Flexural strength	519	6.1	539	3.4
In-plane shear strength	72.6	5.5	84.6	3.9
Interlaminar shear strength	21.9	3.3	42.1	3.2

3.2. Tensile strength

Figures 2a and 2b show the longitudinal tensile strength retention of GFRP_UP and GFRP_VE laminates, respectively. Overall, relatively low variations of the longitudinal tensile strength retention of the GFRP laminates for the two matrices and across the different laboratory ageing conditions was observed, with retention rates ranging from 86% to 100%. More relevant reductions were observed after exposure to the most extreme conditions, such as constant temperature at 60 °C (T60) and especially water immersion at 20 °C with wet conditions (W20S). Both GFRP_UP and GFRP_VE laminates exhibited relatively similar strength retention levels at different natural ageing environments, with low CoV values.

Under constant temperature exposure (T-15, T20, T40, and T60), the maximum reduction in longitudinal tensile strength was observed at 60 °C for both matrices, resulting in a retention rate of approximately 92%. This highlights the predominant influence of fibre characteristics over matrix properties on longitudinal tensile strength, given the architecture of the fibres used and the fact that literature reports lower degradation of glass fibres to these environments.

Under water immersion at 20 °C, both GFRP_UP and GFRP_VE laminates experienced a decrease in longitudinal tensile strength retention, particularly tested under wet (W20S) conditions, with retention rates of 86% and 89%, respectively. The difference in retention between dry (W20D) and wet (W20S) conditions was approximately 10% for GFRP_UP, while for GFRP_VE laminates, the difference between W20D and W20S was minimal. This may indicate that the degradation of UP composites was irreversible (hydrolysis), whereas in VE some was reversed on drying (plasticisation).

In the natural ageing environments (E2, E3, E4, and E5), both GFRP_UP and GFRP_VE laminates exhibited consistent longitudinal tensile strength retention levels, ranging from 92.9% (E4) to 95.7% (E5) for GFRP_UP and from 92.1% (E5) to 94.1% (E2 and E3) for GFRP_VE, with CoV values consistently below 4%. These results highlight the minor degradation of the pultruded GFRP laminates across diverse natural environmental conditions over a 12-month period.

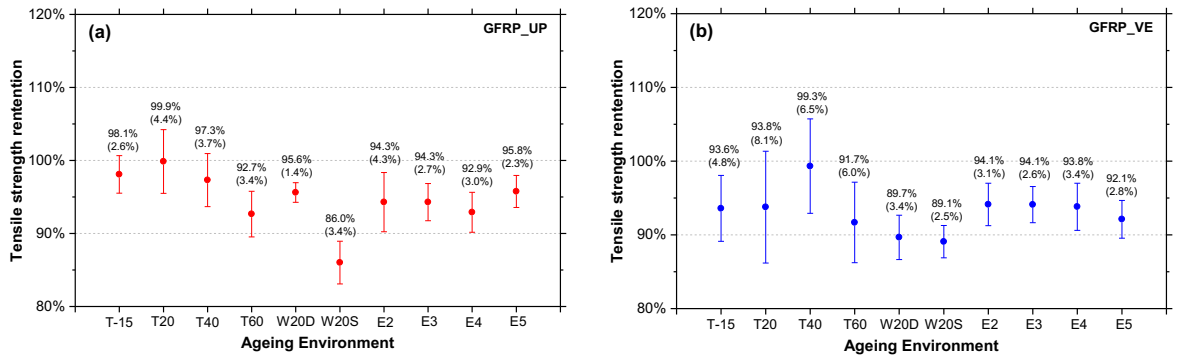


Figure 2. Tensile strength retention: (a) GFRP_UP; (b) GFRP_VE.

3.3. Compressive strength

As shown in Figure 3, both GFRP laminates exhibited an increase in longitudinal compressive strength retention across ageing environments, except for water immersion at 20 °C. GFRP_VE exhibited higher retention rates than GFRP_UP across all environments. Both materials demonstrated better performance at 40 °C, with a notable decline of ca. 15% drop at 60 °C, respect to 40 °C. The results show noteworthy dispersion, with a CoV that frequently exceeds 10%, reaching a maximum of 17.2%. This is consistent with previous studies [8,13]. Sun *et al*. [14] attributed this to local imperfections and material defects that affect compressive strength.

The water immersion at 20 °C resulted in a reduction in the compressive strength retention of both GFRP_UP and GFRP_VE of 31% and 19%, respectively. This reduction underscores the negative effect of moisture on the resin matrix of pultruded GFRP laminates over a period of 12 months. Furthermore, the drying process enabled an almost full recovery of initial compressive strength, for both cases (UP and VE), suggesting a strong impact of plasticization mechanisms on the "wet" condition results. This result is not fully consistent with the observations in section 3.2 (longitudinal tensile strength) and, thus, requires further investigation.

Both GFRP_UP and GFRP_VE laminates showed improved compressive strength retention in the four natural ageing environments, with values ranging from 102% to 118% for GFRP_UP and from 127% to 132% for GFRP_VE. Such increases, also observed in the thermal ageing environments, suggest that a relevant degree of resin post-curing occurred during environmental exposure.

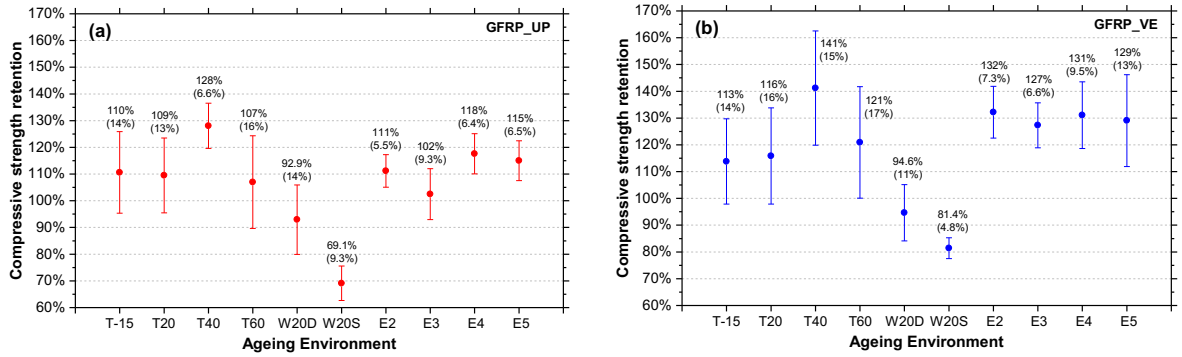

Figure 3. Compressive strength retention: (a) GFRP_UP; (b) GFRP_VE.

3.4. Flexural strength

Figure 4 presents the flexural strength retentions of both GFRP_UP and GFRP_VE composites. The flexural strength retention of a composite is influenced by various factors related to both the matrix and fibre components. In general terms, fibres contribute to tensile strength and stiffness in the tensioned zone (bellow the neutral axis), while the matrix provides support and stability to the reinforcing fibres in the compressed zone (above the neutral axis), with both materials and their interaction affecting the overall performance of the material under bending loads.

After exposure to constant temperatures, both composites (UP and VE) exhibited marginal variations in flexural strength retention, with generally consistent results, with CoV below 6%.

Upon immersion in water at 20 ºC, the GFRP_UP series showed slightly lower flexural strength retentions than GFRP_VE, with minimum retentions of 91% (GFRP_UP) and 93% (GFRP_VE) tested under wet conditions (W20S), with low CoV values.

In terms of natural ageing, the flexural strength retentions for both GFRP_UP and GFRP_VE laminates remained within similar envelopes, ranging from 94% (E2) to 103% (E4) for GFRP_UP and from 94% (E2) to 99% (E4) for GFRP_VE. The highest CoV observed was 7% for E2 in the GFRP_UP laminate.

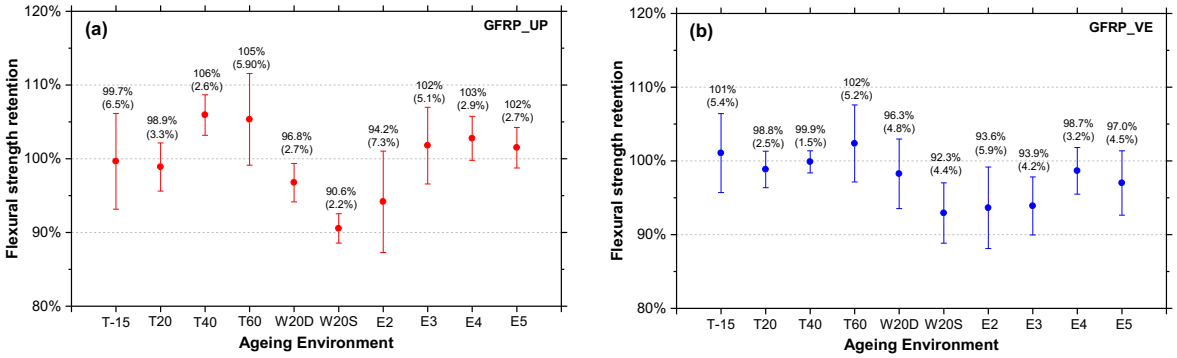

Figure 4. Flexural strength retention: (a) GFRP_UP; (b) GFRP_VE.

3.5. In-plane (IP) shear strength retention

The in-plane shear strength retention of GFRP_UP and GFRP_VE laminates is illustrated in Figure 5a and Figure 5b, respectively. Given the architecture of fibres adopted for the composite plates, this property is strong influenced by the matrix. Across the different environments, all series showed improved in-plane shear strength, except for the water immersion series (tested under wet conditions). Despite minor differences between the two materials, they exhibited similar responses to constant temperature exposure. The results for GFRP_UP showed the highest increase in this property (~17%) at a temperature of 40 °C, while GFRP_VE demonstrated similar increases for the T-15, T40, and T60 series. However, it should be emphasising the relatively high values of the standard deviations obtained.

Regarding water immersion, composites produced with both matrices experienced the highest reduction of IP shear strength tested under wet conditions, with a reduction in the two materials of approximately 8% and CoV values below 5%.

In terms of natural ageing, both GFRP_UP and GFRP_VE laminates displayed a consistent trend of improved IPS strength retention, akin to compressive strength, with values ranging from 106% (E3) to 117% (E4) for GFRP_UP, and from 100% (E5) to 108% (E4) for GFRP_VE.

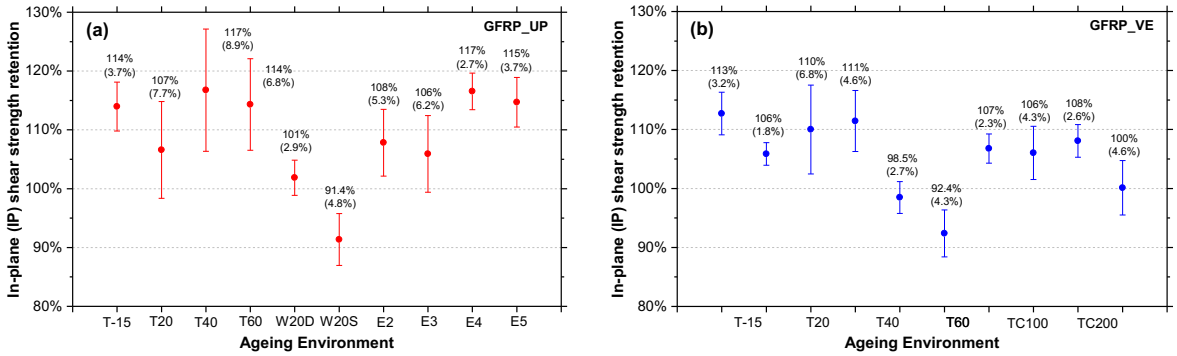

Figure 5. In-plane (IP) shear strength retention: (a) GFRP_UP; (b) GFRP_VE.

3.6. ILS strength response

The interlaminate shear (ILS) strength retention of GFRP_UP and GFRP_VE is depicted in Figure 6a and Figure 6b, respectively. Both laminate types show a trend in ILS strength that is comparable to that observed for compressive and flexural strengths, with minor variations. The ILS strength, reliant on laminae interface adhesion and influenced by fibre bridging mechanisms, is highly dependent on the matrix properties and the fibre-matrix interaction.

Under constant temperature, the ILS strength retention exhibited a nearly linear decrease with temperature rise from -15 °C to 40 °C, and an increase from 40 °C to 60 °C. The GFRP_UP series exhibited ILS strength retentions (slightly) above 100%, for both T-15 and T60 series. In contrast, for all other series, including all GFRP_VE series, strength retentions were below 100%, but above ~90%.

After exposure to water immersion for 12 months and for testing in wet conditions, GFRP_VE laminates experienced significant ILS strength reduction, with a minimum retention of 63%, compared to GFRP_UP laminates, which retained 84% of ILS strength. Notably, GFRP_UP laminates showed a maximum reduction of 69% in compressive strength retention, indicating vulnerability to high moisture content, which is partially reversed upon drying.

Following natural ageing, the ILS strength retention ranged from 90% (E2) to 103% (E4) for GFRP_UP, and from 87% (E3) to 97% (E4) for GFRP_VE.

Finally, the trend observed in ILS strength (higher retention in UP) is somehow opposite to that in compressive strength (higher retention in VE). Both properties are very much influenced by the matrix. Therefore, this requires further investigation.

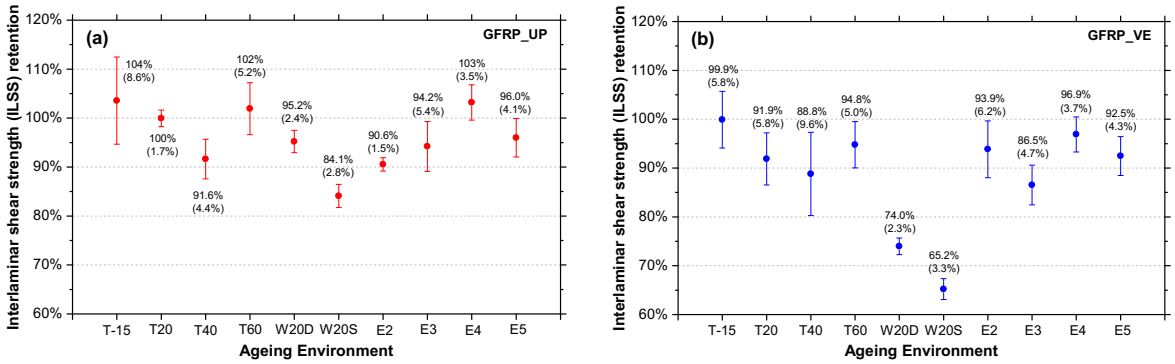

Figure 6. Interlaminar shear strength retention: (a) GFRP_UP; (b) GFRP_VE.

4. Conclusions

This study investigated the durability in terms of the changes in the mechanical properties of pultruded glass fibre-reinforced polymer (GFRP) laminates with unsaturated polyester (UP) and vinyl ester (VE) matrices, under accelerated and natural ageing conditions for 12 months.

Under constant temperature conditions very little reductions were observed for all the properties analysed.

The most significant reductions in mechanical properties were observed following immersion in water at 20 °C, under wet conditions. Notably, the lowest property retentions obtained in this study were found for the interlaminar shear strength of GFRP_VE laminates after water immersion in “wet” condition (63%), and for the compressive strength of GFRP_UP laminates under the same conditions (retention of 69%). However, the drying process allowed the almost full recovery of the initial properties, except in the case of ILS strength of GFRP_VE.

In terms of natural ageing, comprising different climates in Portugal (ranging from relative mild to extreme severe exposure) did not produce, so far, relevant mechanical degradation of both materials across all environments and properties compared to water immersion. The lowest retentions of 87% (GFRP_VE) and 91% (GFRP_UP) were observed in interlaminar shear strength in E3 and E2, respectively. In general, the natural weathering results were more comparable to those obtained in the constant temperature ageing environments, i.e., without water immersion. This highlights the potentially damaging effect of elevated moisture content in GFRP composites, while also suggesting that such high moisture levels may not be easily attained in some outdoor weathering scenarios.

Furthermore, these results highlight the complex interplay between environmental conditions, material characteristics, and mechanical performance of pultruded GFRP laminates. Further analysis and long-

term testing (ongoing) are necessary to deepen the understanding of such phenomena, but these initial findings provide valuable insights into their durability.

Abstract
This research tackles the gap in earthquake-resistant composite pipelines by developing a novel glass fiber-reinforced composite (GRP) pipe connection system. Aligned with seismic guidelines, it introduces an innovative linear and angular deflection solution for GRP pipe joints, ensuring flexibility to endure various deformations during earthquakes. It aims to design a pipe joint capable of withstanding seismic loads and ground deformations by simplifying assembly and disassembly through the omission of bolts in joints. The study involves the mechanical characterization of composite specimens and rings cut from filament-wound pipes to verify the mechanical performance of composite pipes and the structural optimization of earthquake-resistant composite pipes and joints. Notably, finite element models of ring compression tests on filament-wound pipe rings successfully predict stiffness and strength. The methodology integrates composite micromechanics theories and literature to establish initial reference values of material properties, employing an iterative process with the stress homogenization method, validated by comparing simulation results with experimental data. The optimization process includes stress analysis using the Finite Element Method to determine optimal wall thicknesses and improve the position and shape of sealing and lock rings. This proposed pipe joint model aims to advance the engineering design of earthquake-resistant composite pipes, offering valuable insights for assessing the risk of significant ground deformation in pipelines.

1. Introduction

Standardized composite tests offer a general understanding of the strength and stiffness of filament-wound fiber-reinforced pipes but do not account for the behavior of individual layers under load due to variations in fiber orientation and resin type. Specialized tests are necessary to measure individual layer properties for optimized pipe design. Unlike flat composites, acquiring layer characteristics in cylindrical filament-wound composite pipes is more complex. Ply properties are refined through iterative Finite Element simulations and experimental data using initial estimates from literature and micromechanics theories [1]. These refined properties validate material accuracy and predict pipe behavior in various designs.

Designing pipe joints for seismic events necessitates a multidisciplinary approach to address challenges like permanent ground deformation (PGD) caused by faulting, liquefaction, lateral spread, slope failure, or settlement. PGD is most severe at boundary conditions, requiring meticulous design considerations.

This study presents a unique push-on spigot and socket joint for segmented pipelines, designed using Finite Element Analysis. These socket joints allow for elongation, contraction, and rotation during ground deformation, while the boltless design ensures easy assembly.

2. Material and methods

2.1. Determining the in-plane ply properties for finite element modeling

A modeling method is outlined to determine material properties for finite element modeling of Fiber Reinforced Polymer (FRP) pipes. Initially, ply properties are estimated based on previously published studies and available literature on mechanical tests conducted on unidirectional (UD) and angle-ply composite laminates [2] due to the wide range of reported material properties for FRP pipes. Table 1 summarizes the ply properties of the GFRP composites used in piping systems.

Table 1. Material properties of E-glass/UPR epoxy laminate.

E_1 [Gpa]	45.6
E_2 [Gpa]	16.2
G_{12} [Gpa]	5.5
ν_{12}	0.278
ν_{23}	0.4
X_T [Mpa]	1280
X_C [Mpa]	825
Y_T [Mpa]	65.2
Y_C [Mpa]	194
S [Mpa]	51.8

Intralaminar damage properties are assessed using progressive damage analysis, employing continuum damage mechanics principles and Hashin failure criteria [3]. The progressive damage model utilized in the FEA predicts and assesses damage within the plies, requiring additional parameters such as critical energy release rate. Cohesive Zone Modelling is utilized to model the initiation and growth of delaminations. Specific material parameters for cohesive elements are provided in Table 2, emphasizing the influence of Mode-I fracture on transverse matrix cracking and Mode-II fracture on delamination essential for accurate simulations and structural analysis [4-6].

Table 2. Material properties for the cohesive elements.

Direction	Mode I	Mode II, III
Penalty stiffness ($\frac{N}{m^3}$)	10^{14}	10^{14}
Interface strength (MPa)	60	60
Fracture energy ($\frac{J}{m^2}$)	500	800

2.2. Experimental test methods

In this research, a GFRP pipe with a diameter of 200 mm and average thicknesses of 2.5 mm and 5 mm for two different models is selected for the case study. Initially, the pipe is wound with fibers exclusively in the hoop direction, resulting in a unidirectional configuration. For subsequent tests, pipe sections produced by Superlit Boru San. Inc. using filament winding with 20 layers and alternating winding angles of ±55° and ±45° are used, featuring a nominal thickness of 5 mm.

The experimental study examines filament wound GFRP pipes through various tests. The Ring Compression Test, per ASTM D2412-02 standard [7], is conducted to assess compressive transverse

loading resistance. Compression is applied diametrically, with a 10 mm/min test speed, and ring stiffness is calculated to evaluate ovality resistance.

The Circumferential Tensile Test (Split-disk), following ASTM D2290 [8], evaluates ultimate hoop tensile strength using split-ring tests. Stress concentration is induced by a notch, simulating critical defects. Flexural Test (Four-Point Bending) and Short Beam Shear Test, as per ASTM D7264 [9] and D2344 [10], assess flexural characteristics and shear behavior.

The Double-Notch Shear test (ASTM D 3846) [11] evaluates interlaminar and through-the-thickness shear strength. Specimen geometry, especially notch dimensions, significantly affects failure mechanisms. Lastly, tensile tests on specimens cut in the axial direction are performed according to BS ISO 8513:2016 [12], evaluating properties like tensile strength and elongation percentage. Figure 1 shows the test setup for the ring compression, four-point bending, short beam shear, longitudinal tensile, split disk, and double notch shear test for coupon specimens, respectively.

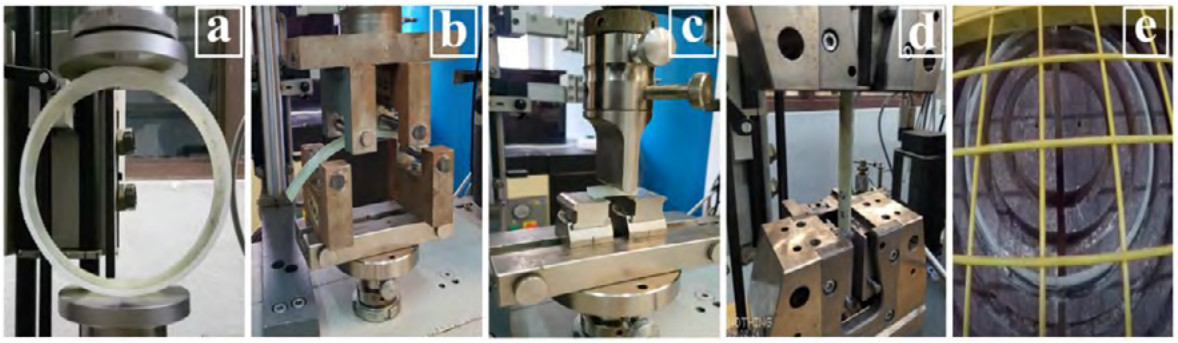

Figure 1. Setup for different tests. (a) Ring Compression fixture, (b) Flexural test with a four-point bending fixture, (c) Short-beam shear test with a three-point bending fixture, (d) Tensile test fixture, (e) Split disc test and Double-notch shear test fixture.

2.3. Damage Analysis using Finite Element Method

ABAQUS software is employed to simulate damage modes across various tests. For ring compression, models represent GFRP pipes with continuum shell elements. Each pipe layer is separately modeled, resulting in 8 and 20-layer pipe specimens with 2.5 and 5 mm thicknesses. Similar modeling approaches are used for flexural, shear, and tensile tests. Longitudinal tensile tests utilize 20 layers of shell elements connected through cohesive zone elements.

Pipe joint simulations assess axial and rotational behavior, incorporating GFRP layers with ±55° angle orientation, an SBR gasket, and a lock ring made of thermoplastic material. Boundary conditions include uniform loads of 600 kN, an inner pipe pressure of 20 bars for axial motions, and a concentrated shear force of 600 kN for rotational movement. General-purpose continuum shell elements ensure an accurate representation of composite behavior.

2.4. Designing of a seismic pipe joint (with locking system)

The spigot and socket pipe ball joint fitting was designed using SOLIDWORKS software, providing resistance to substantial axial and rotational motions while accommodating ground deformation. The design features an EPDM O-ring gasket for sealing, a lock ring for reinforcement, and an assist for rotational freedom. Composite layers are strategically placed for strength, particularly around the lock ring area. The joint's groove for the lock ring is designed to avoid stress concentrations. Figure 2 illustrates the seismic pipe joint model.

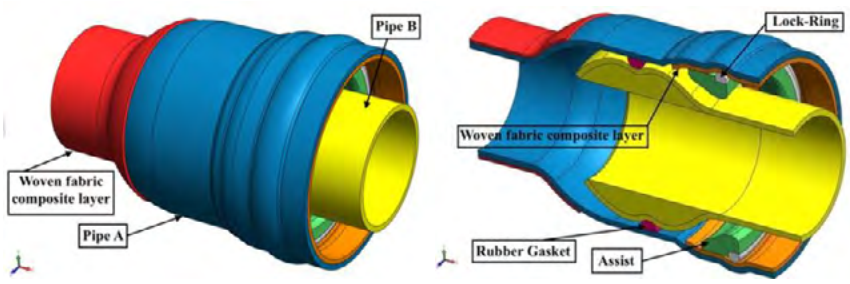

Figure 2. 3D illustration of the seismic pipe joint sleeve model.

The joint allows axial movement and rotation, achieving a secure seal via compression deformation of the rubber ring. The design allows axial flexibility and long-distance deflection, which is crucial for pipeline installation in earthquake susceptible regions. Figure 3 outlines test conditions, demonstrating the joint's ability to withstand diverse forms of deformation. Design parameters include a maximum angle deflection of 12° and an axial extension/contraction deflection of 120 mm, ensuring flexibility without compromising joint integrity.

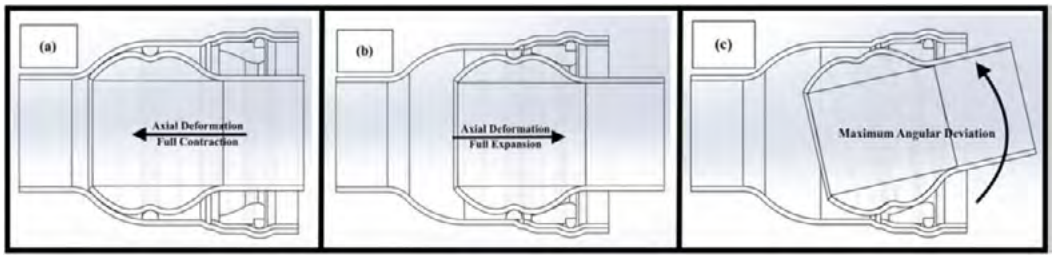

Figure 3. Test conditions (parameters). (a) Full Contraction, (b) Full Expansion, and (c) Maximum Angular Deviation.

3. Results and discussion

Ring compression tests were halted at approximately 50% and 70% diametric deflections for 8T and 20T (UD) specimens, respectively. Visual examination revealed cracking and delamination. The 8T specimen showed extensive delamination within inner plies, starting with matrix cracks and progressing to axial splitting, accentuated by buckling effects. The 20T specimen experienced severe splitting along the fiber winding angle following the pipe's pattern. The reaction force before damage is 1592 N for the 8T model and 6203 N for the 20T (UD) model. For the 20T ± 55° ply orientated model, the inter-ply delamination typically starts from the edges at the top and bottom of the composite pipe before propagating to the sides and other regions of the structure. Upon impact and deformation, buckling and subsequent interlaminar delamination at these regions are observed for all cases. The FEA model estimated the compressive force at damage initiation as 3291 N.

Load-displacement graphs, FEA results, and positions of four diametric deflections for the ±55° ply orientated model are illustrated in Figure 4. Consistency among repeated experimental results across six specimens highlights test reproducibility.

Four-point bending and short-beam shear tests are performed to determine polymer matrix composites' flexural properties and shear behavior. Using three specimens, the flexural tests are conducted on the 20T (UD) model. Table 3 presents the maximum flexural stress, flexural modulus, maximum strain, and short beam strength as determined from experimental and numerical analyses for three composite specimens. Load-displacement graphs are seen in Figure 5 for the 20T (UD) specimens.

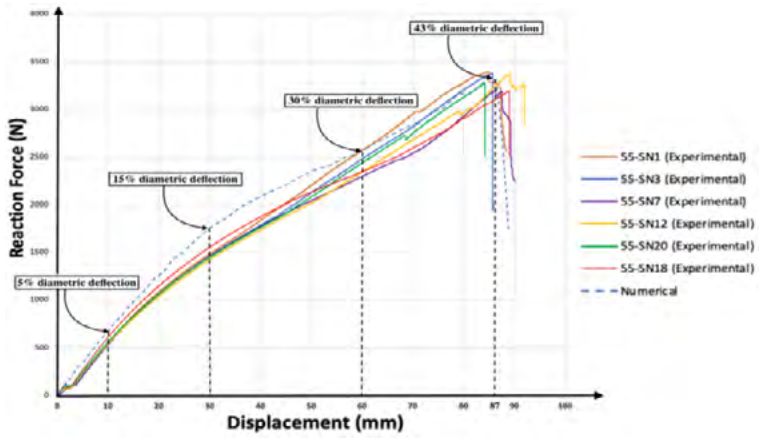

Figure 4. Load-displacement curve for 20T (± 55°) oriented specimens (compression test)

Table 3. Material properties for the 4-Point and Short Beam Shear Tests (UD).

	Flexural Modulus (MPa)	Maximum Flexural Stress (Mpa)	Maximum Strain %	Short Beam Strength (MPa)
20T-1	3497.095	511.95	4.83	49.13
20T-2	3989.872	411.14	4.94	43.35
20T-3	3956.574	419.62	5.72	30.68
Numerical (UD)	4769.37	416.42	4.63	45.41

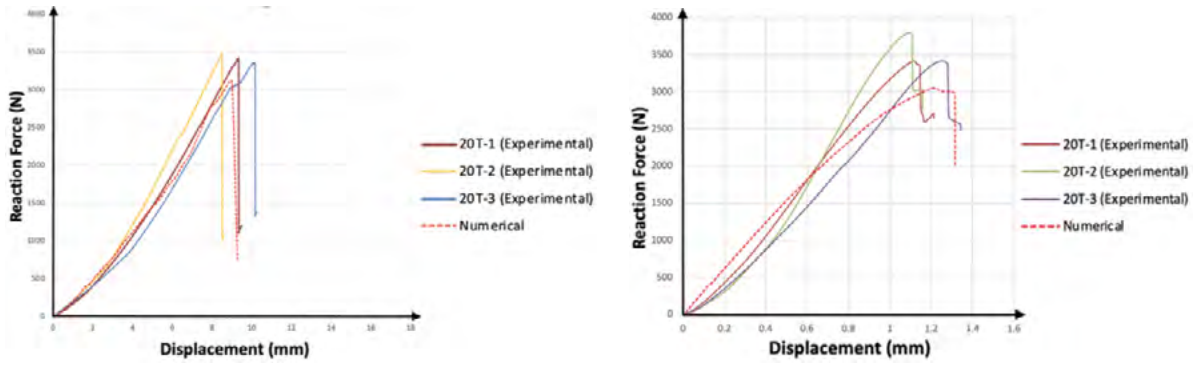

Figure 5. Load-displacement curve. (a) 4-point bending test, (b) 3-point bending test of 20T (UD) model (compression test).

Determining the initial longitudinal tensile strength involves subjecting test pieces, consisting of a specified length of pipe, to longitudinal extension at a constant speed until fracture occurs within a specified timeframe. Observable failure indicators in the tensile test include whitening in the gauge region due to matrix cracks and evident fiber breakage in the test coupons. A comparison of load-displacement curves for experimental and numerical tests is depicted in Figure 6, while Table 4 presents the initial and ultimate tensile strength for the coupon specimens.

The Composite Pipe Split Disc Test is crucial for assessing how well composite pipes withstand internal pressure. Its controlled nature and capability to replicate critical defects make it essential for understanding composite material behavior. In Table 5, there's a comparison of the ultimate hoop tensile stress for ±45° and ±55°orientation between numerical and experimental tests.

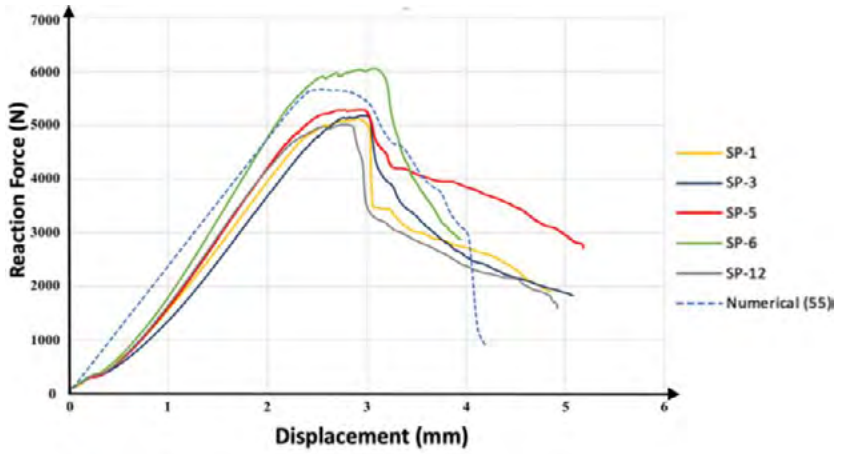

Figure 6. The load-displacement curve for 20T (± 55°) oriented specimens (Tensile test).

Table 4. Tensile test results for for experimental and numerical analysis.

Test Specimen	Initial longitudinal tensile strength (N/mm)	Percentage ultimate elongation (%)	Ultimate tensile Strength (MPa)
SP-1	209.38	1.981	44.54
SP-3	219.61	1.942	42.53
SP-5	219.12	1.921	40.14

Figure 7 depicts the FEM shear damage analysis for Ring compression, Double-Notch Shear, Split-Disk, and Longitudinal tensile test, respectively.

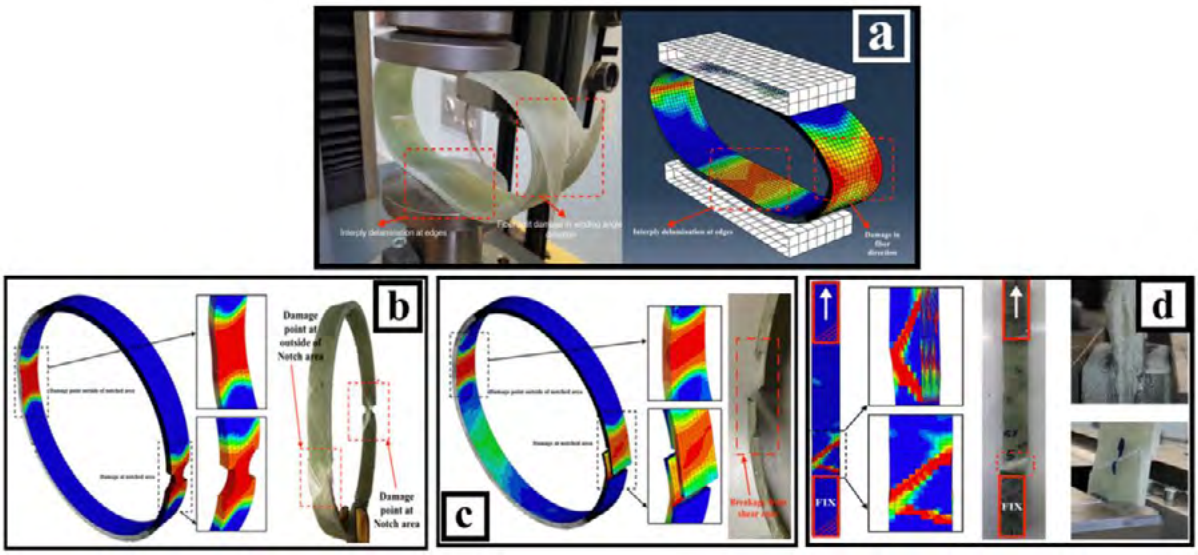

Figure 7. FEM analysis depicting shear damage. (a) Ring-Compression, (b) Double-Notch Shear test, (c) Split-Disk and (d) Longitudinal Tensile test.

Figure 8 depicts the three-dimensional distribution of Hoop stresses for the seismic pipe joint model resulting from a simulation with a 120 mm axial displacement under 600 kN axial load and 20 bar internal pressure for expansion and contraction movements, and 600 kN axial load and 20 bar internal pressure for rotational movement. Vulnerable regions are identified to be around the region where the constriction of the bell pipe's cross-section takes place, along the wall of the pipe bell where the lock ring makes contact for both pull and push movements of the spigot pipe. Examining the stress attributes of the pipeline concerning angular rotation, localized stresses are situated at sensitive locations directly beneath the contact point of the bell mouth with the crown and invert of the spigot. These specific sensitive locations highlight the presence of observable concentrated stress, which shows satisfactory outcomes

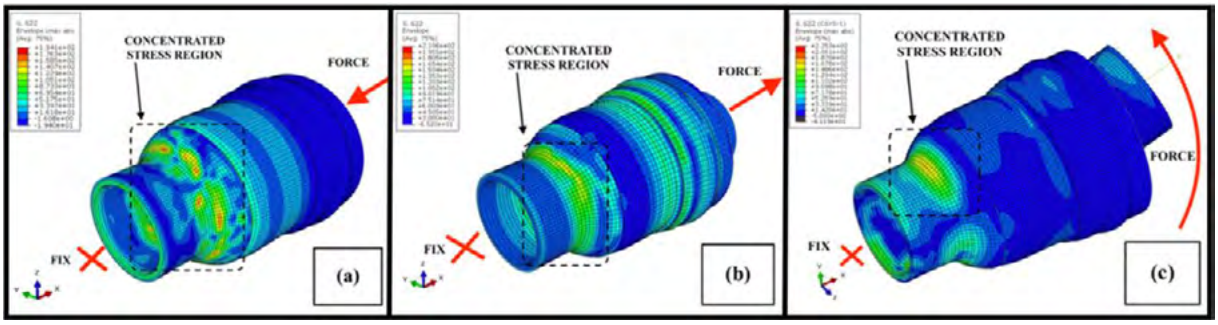

Figure 8. Numerical simulations showing Hoop stress for different movements of the pipe joint. (a) Full Contraction (b) Full Expansion (c) Maximum Angular Deviation.

The tests and results presented here are expected to help tackle some demanding problems related to composite laminate designs, especially for underground composite pipes. Additionally, they aim to emphasize significant challenges and areas of limited understanding in current practices.

4. Conclusions

This research addresses a significant gap in earthquake-resistant composite pipelines by introducing a novel glass fiber-reinforced composite (GRP) pipe connection system. This innovation includes a solution for angular deflection in GRP pipes, enhancing their ability to withstand seismic deformations effectively. Simplifying assembly and disassembly, the system eliminates bolts in joints. The study encompasses the mechanical characterization of composite materials and rings from filament-wound pipes and the structural optimization of earthquake-resistant composite Pipes and Joints. Ring compression tests accurately predict stiffness and strength using finite element models. Integrating composite micromechanics theories and literature, the research refines ply properties through an iterative process validated by comparing simulated outcomes with experimental data. Leveraging these test results, stress analysis via Finite Element Analysis enhances the optimization of pipe joint designs. The proposed socket joints offer advantages in elongation/contraction and rotation during ground deformations, while the absence of bolts in assembly ensures simplicity. The findings of this research contribute to advancing composite laminate designs for subterranean pipelines, addressing significant challenges in existing methodologies, and providing valuable insights for seismic-resilient pipeline engineering. In forthcoming research, the results from numerical analysis used to simulate seismic pipe joints will be further validated through comparison with a physically manufactured model.

Keywords: T-stress, Mode I fracture, Thick adhesive joint, Crack kinking

Abstract

In the present research, pre-cracked double cantilever beam (DCB) thick adhesive joint specimens, manufactured with glass/epoxy composite adherends and a structural adhesive with a bond-line thickness of approximately 10 mm, are tested under pure mode I loading. A Digital Image Correlation (DIC)-assisted in-situ measurement technique is used to determine the T-stress in the test samples, and the crack propagation angles are determined using the second-order crack kinking theory in order to be compared to the experimental values. A good agreement is observed between the experimental and theoretical crack propagation angles. The geometry of the thick adhesive joint causes the T-stress and the crack kinking phenomenon, even if a perfect interface between the adhesive and the adherends exists. In order to validate this observation Polymethyl Methacrylate (PMMA) specimens, in which no interface or voids were present to affect the stress field around the crack tip and cause the crack to deviate from the middle plane of specimens were tested. To accomplish this, two types of specimens, i.e. Compact Tension (CT) and DCB, were manufactured out of (PMMA) and loaded under pure mode I. The same behavior, i.e. deviation of the crack from the middle of the specimen to an oblique path, is observed by changing the specimen geometry from CT to DCB specimens.

1 Introduction

Adhesive joints are used in different industries, including the wind turbine manufacturing, because of their advantages compared to traditional mechanical joining methods. By applying adhesives, there is no need to drill any holes; therefore, the structural integrity of the substrate materials remains intact. Moreover, compared to traditional mechanical joining methods, adhesive joints offer uniform stress distribution as well as more freedom in joining similar and dissimilar materials. In the literature, studies on the fracture behavior of thick adhesive joints are still scarce, even if they are frequently used in the blades of wind turbines. For instance, Miao et al. [1] showed both experimentally and numerically that the crack in thick adhesive joints loaded under pure mode I can initiate in the adhesive; however, the main tendency of the crack is to propagate toward the interface. Similarly, Fernandes et al. [2] and Fan et al. [3] experimentally revealed that the crack trajectory for a joint with a bond-line thickness of about 10 mm is not stable under mode I loading, and that the crack tends to propagate from the middle of the specimen towards the interface. Fan et al. [3] investigated the effect of voids on the performance of thick adhesive joints.

The T-stress is a constant stress acting parallel to the crack plane. It is known that under pure mode I loading, the crack tends to propagate along its initial plane when the T-stress is zero or negative, i.e., the T-stress does not affect the crack trajectory in that condition. A positive T-stress however, causes crack deviation and an unstable crack trajectory [4]. Indeed, finite element simulations were used by Fernandes et al. [5], and it was shown that the positive T-stress in thick adhesive joint specimens is possibly

responsible for the crack kinking from the middle of the specimen. Furthermore, the effect of the specimen geometry on the T-stress and the crack trajectory has been studied by Ayatollahi et al. [6] and Bahadori et al. [7] for notched and cracked DCB specimens made of PMMA. In their analyses, the experimental and analytical predictions were in good agreement regarding the angle of crack propagation.

In-situ measurement approaches based on DIC [8–12] can be used to assess crack tip parameters such as the J-integral, Stress Intensity Factor (SIF), and T-stress for different specimens subjected to mode I loading. These methods, not yet studied for adhesive joints, can be applied in this context to analyze the T-stress of the thick joints under consideration in this study.

Hence, considering the lack of experimental investigations regarding the impact of the T-stress on the unstable crack trajectory in thick adhesive joints, this study employs an in-situ measurement method, validated in [8], to examine the unstable crack path propagation of thick adhesive joints. To do so, the second-order crack kinking theory is used together with experimental data to predict the crack initiation angle. The experimental and analytical methodologies are described hereunder.

2 Materials and methods

A glass fiber reinforced epoxy composite material, manufactured by Vacuum Assisted Resin Transfer Molding (VARTM) and the Sika power®-830 adhesive (Sika Technology AG, Switzerland), were used to prepare the adhesive joints. A unidirectional glass fabric with 425 g/m^2 areal weight was used as the reinforcement, in 0/90 configuration, and the EPIKOTE Resin MGS RIMR 135, together with the EPIKURE Curing Agent MGS RIMH 137, was used as the epoxy resin for manufacturing the composite material. The mechanical properties of the adherend and the adhesive are presented in Table 1 and Table 2, respectively. It has to be noted that, the through-thickness Young's modulus of the composite was estimated based on the test conducted on $[90^o]_8$ specimens. To prepare the joint specimens the procedure outlined in Refs. [3,13] was followed. The specimens had a width of 25.4 mm and a length equal to 356 mm, according to ASTM D3433 [14], and cutting took place using a water-cooled rotating saw. In order to produce pre-cracked specimens, each of them was cut at the middle of the adhesive layer using a thin saw. In the end, the pre-crack was sharpened by a fresh razor blade. Different pre-crack lengths were studied, as will be discussed later. Furthermore, DCB and CT specimens manufactured with PMMA were tested under mode I loading.

Load was applied to the specimens using an Instron universal testing machine (5885). The tests were conducted at a constant crosshead speed of 2 mm/min and DIC was used to monitor the deformation of the specimens during the tests. DIC images were captured both from the undeformed specimens as well as during their loading. After the tests, the images were processed using the VIC3D-9 software [15] to determine the displacement field of the specimens. For that, a subset size of 41*41 pixels was utilized. Section 4 presents the results of the experiments described in this section.

3.1 Theoretical stress field around the crack

The Williams' expansion for the displacement field, considering higher-order singular and non-singular terms, can be expressed as follows [17]:

$$\begin{Bmatrix} u \\ v \end{Bmatrix} = \sum_{n=-(N+2)}^{N} \frac{a_n}{2\mu} r^{\delta_n+1} \begin{Bmatrix} (\kappa + \frac{n}{2} + (-1)^n) cos\left(\frac{n}{2}\theta\right) - (\frac{n}{2}) \cos\left[\left(\frac{n}{2} - 2\right)\theta\right] \\ (\kappa - \frac{n}{2} - (-1)^n) sin\left(\frac{n}{2}\theta\right) + (\frac{n}{2}) \sin\left[\left(\frac{n}{2} - 2\right)\theta\right] \end{Bmatrix} + \sum_{n=-(N+2)}^{N} \frac{b_n}{2\mu} r^{\delta_n+1} \begin{Bmatrix} (-\kappa - \frac{n}{2} + (-1)^n) sin\left(\frac{n}{2}\theta\right) + (\frac{n}{2}) \sin\left[\left(\frac{n}{2} - 2\right)\theta\right] \\ (\kappa - \frac{n}{2} + (-1)^n) cos\left(\frac{n}{2}\theta\right) + (\frac{n}{2}) \cos\left[\left(\frac{n}{2} - 2\right)\theta\right] \end{Bmatrix} \quad (1)$$

in which a_n and b_n are known as Williams' coefficients and are related to mode I and mode II loading conditions, respectively, while u and v represent the displacements in the x and y directions correspondingly, as shown in Figure 1. Moreover, the first-order singular terms, associated with the SIFs K_I and K_{II} are defined as $K_I = \sqrt{2\pi}\, a_1$ and $K_{II} = \sqrt{2\pi}\, b_1$, respectively. Moreover, the T-stress can be derived from the second Williams' expansion as $T = 4a_2$.

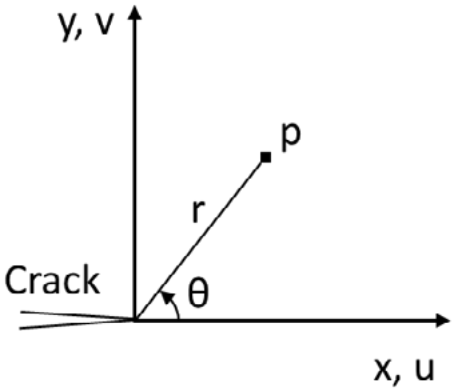

Figure 1. Defined coordinate system at the crack tip

It is worth mentioning that both rigid body translation and rotation are taken into account in Eq. (1), which can be applied to the displacement field derived from DIC [8]. Eq. (1) can be rewritten in a matrix form for a given number of points in the vicinity of the crack as follows:

$$\begin{Bmatrix} u_1 \\ u_2 \\ \vdots \\ u_k \\ v_1 \\ v_2 \\ \vdots \\ v_k \end{Bmatrix} = \begin{bmatrix} F^I_{-(N+2)}(r_1,\theta_1) & \dots & F^I_0(r_1,\theta_1) & \dots & F^I_N(r_1,\theta_1) & F^{II}_{-(N+2)}(r_1,\theta_1) & \dots & F^{II}_0(r_1,\theta_1) & \dots & F^{II}_N(r_1,\theta_1) \\ F^I_{-(N+2)}(r_2,\theta_2) & \dots & F^I_0(r_2,\theta_2) & \dots & F^I_N(r_2,\theta_2) & F^{II}_{-(N+2)}(r_2,\theta_2) & \dots & F^{II}_0(r_2,\theta_2) & \dots & F^{II}_N(r_2,\theta_2) \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ F^I_{-(N+2)}(r_k,\theta_k) & \dots & F^I_0(r_k,\theta_k) & \dots & F^I_N(r_k,\theta_k) & F^{II}_{-(N+2)}(r_k,\theta_k) & \dots & F^{II}_0(r_k,\theta_k) & \dots & F^{II}_N(r_k,\theta_k) \\ G^I_{-(N+2)}(r_1,\theta_1) & \dots & G^I_0(r_1,\theta_1) & \dots & G^I_N(r_1,\theta_1) & G^{II}_{-(N+2)}(r_1,\theta_1) & \dots & G^{II}_0(r_1,\theta_1) & \dots & G^{II}_N(r_1,\theta_1) \\ G^I_{-(N+2)}(r_2,\theta_2) & \dots & G^I_0(r_2,\theta_2) & \dots & G^I_N(r_2,\theta_2) & G^{II}_{-(N+2)}(r_2,\theta_2) & \dots & G^{II}_0(r_2,\theta_2) & \dots & G^{II}_N(r_2,\theta_2) \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ G^I_{-(N+2)}(r_k,\theta_k) & \dots & G^I_0(r_k,\theta_k) & \dots & G^I_N(r_k,\theta_k) & G^{II}_{-(N+2)}(r_k,\theta_k) & \dots & G^{II}_0(r_k,\theta_k) & \dots & G^{II}_N(r_k,\theta_k) \end{bmatrix} \begin{Bmatrix} a_{n-2} \\ \vdots \\ a_0 \\ \vdots \\ a_n \\ b_{n-2} \\ \vdots \\ b_0 \\ \vdots \\ b_n \end{Bmatrix} \quad (2)$$

in which k is the number of points or equations, and N is the number of the higher-order non-singular Williams' expansion terms, including the first-order singular term. It has to be noted that Eq. (1) should be written for each point and since each point has a unique coordinate, i.e., (r,θ) therefore for k number of points there are k equations. Considering that each higher-order non-singular term and its complementary singular term are essential in order to determine the J-integral, for N non-singular terms, N-2 higher-order singular terms are needed when calculating the J-integral using Eq. (2). In Eq. (2), u and v are the displacements of the point P(x,y) as obtained by the DIC. Furthermore, F_N^I, F_N^{II}, G_N^I, and G_N^{II} are functions of r and θ. Additionally, (r_k ,θ_k) corresponds to each (x,y) and can be obtained from the DIC data using the following formula:

$$r_k = \sqrt{(x_k - x_0)^2 + (y_k - y_0)^2}; \theta_k = \tan^{-1}\frac{(y_k - y_0)}{(x_k - x_0)} \quad (3)$$

in which x_0 and y_0 are the coordinates of the tip of the crack. Finally, the unknown coefficients of the Williams' expansion, a_n and b_n, can be calculated using matrix operations and the least square approach [18], which is done in this study through a code implemented in MATLAB [19] in order to calculate the J-integral [8].

3.2 Second-order crack kinking theory

For mode I loading, the tangential stress considering the SIF and the T-stress can be expressed as follows [17]:

$$\sigma_{\theta\theta} = \frac{1}{\sqrt{2\pi r}} \mathrm{K}_I \cos^3\frac{\theta}{2} + T\sin^2\theta \quad (4)$$

in which the first term corresponds to the singular term and the second term corresponds to the T-stress in the Williams' expansion. In order to predict the crack propagation angle, the maximum hoop stress theory or the Generalized Maximum Tangential Stress criterion (GMTS) [4,7] can be utilized. According to the GMTS criterion, the crack will propagate when the tangential stress $\sigma_{\theta\theta}$ reaches its critical value $(\sigma_{\theta\theta})_c$ in a critical distance r_c from the crack tip. Thus, the angle θ_c, corresponding to the propagation angle, can be found as follows:

$$\frac{\partial \sigma_{\theta\theta}}{\partial \theta} = 0 \; and \; \left.\frac{\partial^2 \sigma_{\theta\theta}}{\partial \theta^2}\right|_{\theta = \theta_c} < 0 \rightarrow \theta = \theta_c \quad (5)$$

Using Eqs. (4) and (5) considering the singular term K_I and the T-stress, θ_c can be determined by:

$$\theta_c = 0 \text{ or } \theta_c = 2\cos^{-1}\left[\frac{1}{4\,\bar{T}} \pm \sqrt{0.5 + \frac{1}{(4\bar{T})^2}}\right] \quad (6)$$

in which $\bar{T}$ is the normalized T-stress and is defined as:

$$\bar{T} = \frac{8}{3}\frac{T}{\frac{K_I}{\sqrt{2\pi r_c}}} \quad (7)$$

Eq. (6) predicts fracture for any geometry when K_I and T-stress are known. From Eqs. (6) and (7), it can be deduced that determining the critical distance is necessary for predicting the fracture initiation angle. In the present study, the critical distance as defined by Seweryn [20] is used:

$$r_c = \frac{2}{\pi}\left(\frac{K_{Ic}}{\sigma_u}\right)^2 \tag{8}$$

where K_{IC} is the fracture toughness, and σ_u is the ultimate strength, given in

4 Results and discussions

In all tested thick adhesive joint specimens, unstable crack propagation has been observed, wherein the crack instantly jumps to the interface between the adhesive and the adherend, resulting in a sudden decrease in load. Figure 2 displays an example whereby the crack has jumped to the interface.

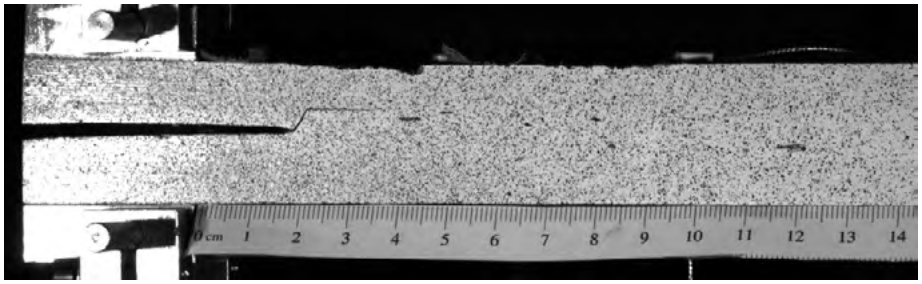

Figure 2. Crack propagation from the middle of the specimen to the interface

The second-order crack kinking theory is employed in this study to predict the crack kinking angle. By employing the Williams' expansion's first and second-order terms, the crack propagation angle of each specimen can be determined and compared with the experimentally measured values. The experimental crack kinking angle values as well as those obtained from the second-order crack kinking theory are presented in Table 3 for each specimen together with the corresponding crack length. Figure 3 shows the crack propagation angle for all specimens, obtained from microscopic observations after the experiment.

Considering the results presented in Table 3, a good correlation can be observed between the experimentally measured values and the theoretical predictions pertaining to the crack propagation angle. Although there are discrepancies between the predicted and measured crack propagation angles, the GMTS criterion indicates the unlikelihood of crack propagation at the middle of the specimen for any crack length.

Table 3. Theoretical and experimental crack kinking angle values

Specimen	Crack length [mm]	Experiment [°]	GMTS [°]
S1	24.0	29	±43
S2	34.0	28	±30
S3	46.5	-40	±37
S4	48.5	39	±62

Each angle is rounded to the closest integer

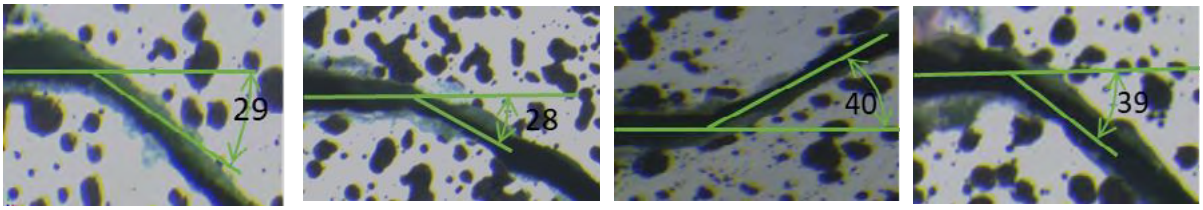

Figure 3. Monitored crack propagation angle of DCB specimens (each experimentally measured angle is rounded to the closest integer)

Ayatollahi et al. [6] investigated the effect of the T-stress on the crack propagation angle on PMMA specimens including CT and DCB as well as Tapered Double Cantilever Beam (TDCB) geometries. They observed that for the DCB specimens, the crack did not propagate in the middle of the specimens under a pure opening mode. In order to reproduce the previous findings DCB and CT specimens made from PMMA are tested. Figure 4 shows DCB and CT PMMA specimens tested in the present research. It can be seen that by changing the geometry, the crack propagation direction under pure mode I loading conditions also changes. Specifically, while the crack propagates at the middle of the CT specimen, it deviates from the middle plane of the DCB specimen and ultimately propagates along an oblique path. The used PMMA specimens did not have any interfaces or voids, which could potentially affect the stress field ahead of the crack tip. Therefore, it is rational to conclude that any deviation of the crack path is due to the geometry.

Figure 4. DCB (left) and CT (right) PMMA specimens under mode I loading

5 Conclusions

The current study investigates the fracture behavior of thick adhesive DCB joints fabricated using composite adherends and subjected to pure mode I loading. It has been observed that in all specimens, the crack propagated instantly from the crack tip towards the interface. It was shown that the positive T-stress at the crack tip due to the DCB geometry is the reason for such a behavior. In order to validate this observation and conclusion and to exclude any effect from voids or other manufacturing defects, DCB and CT PMMA specimens were manufactured and tested under mode I loads. By changing the geometry from CT to DCB in the PMMA specimens, it was observed that the crack tends to deviate from the middle plane of the specimen and then propagates along an oblique path. Hence, it is concluded that the geometry is the primary reason for crack deviations whereas the presence of voids and interfaces in thick adhesive joints can be secondary causes contributing to changes in the crack propagation path. Despite the fact that there are differences between predicted and actual crack propagation angle the GMTS criterion shows that the crack does not tend to propagate at the middle of the specimen for any crack length.

Keywords: Liquid hydrogen pipeline, Cryo-compressed hydrogen, load-bearing pipelines, IVW load introduction, Suspension

Abstract
Efficient hydrogen storage and distribution in aircraft require lightweight construction methods, such as fiber-reinforced plastic (FRP) composites produced through efficient processes. Conventional 'Type 4' pressure vessels are made by winding fiber reinforcement over a liner, but these cylindrical vessels cannot be made arbitrarily small in diameter due to the need for a specific winding angle at the dome area for integration of load introduction elements. If lightweight pressure vessels with selectable diameter and length can be economically produced with axial and circumferential layers, they could also serve as structural components in aircraft, like spars and stringers. To increase volumetric storage density, hydrogen can be stored at cryogenic temperatures as liquid hydrogen (LH_2) or Cryo-compressed hydrogen (CcH_2). The main challenge is maintaining hydrogen at -252°C. A pipeline concept for distributing LH_2 and CcH_2 addresses these challenges using a double-wall CFRP construction. The inner pressure tube stores hydrogen and absorbs internal pressure, while the outer shell provides thermal insulation and system connections. The patented 'IVW Load Introduction' method transfers loads from the outer shell's cylindrical area to the dome or fittings. An effective suspension system mechanically decouples the inner vessel and outer shell, allowing the tank and pipeline to function as structural load-bearing components, potentially replacing existing stiffening components in aircraft.

1. Introduction

The development of liquid hydrogen (LH_2) and cryo-compressed (CcH_2) distribution pipelines is a critical advancement for the aerospace industry, particularly for aircraft applications. Hydrogen as an energy carrier offers numerous advantages due to its high energy density by weight, clean combustion, and potential to significantly reduce greenhouse gas emissions. Transitioning to hydrogen-powered aviation is pivotal for achieving sustainable air travel, given the substantial carbon emissions from conventional aviation fuels \cite {Barthelemy2017}. However, hydrogen's low volumetric density at atmospheric conditions necessitates cooling and/or pressurization to enhance its usability \cite{Massaro 2023}.

Transporting hydrogen in its liquid and cryo-compressed states is beneficial as it occupies significantly less volume than its gaseous form \cite {Klier2017}. Integrating such distribution systems in aircraft poses substantial engineering challenges, particularly in maintaining hydrogen at cryogenic temperatures. Heat ingress can cause hydrogen boil-off, diffusion, permeation, and eventual leakage from the tank. Conventional tanks are double-walled, with an inner tank storing hydrogen and an insulating outer jacket. Efficient and lightweight insulation systems are crucial in reducing boil-off losses while minimizing mass added to the overall vehicle structure. Two materials, foams and Vacuum Assisted Multilayer Insulation (VAMLI), recognized for their excellent thermal resistance properties for aircraft applications \cite {Yin2024}.

Conventional tanks are unsuitable as load-bearing components for tensile, compressive, or bending loads due to the absence of purely axial fibers in the load direction. They also cannot be used in limited design spaces, such as aircraft wings, due to the required minimum diameter of around 200 mm for the winding process. The current research project addresses these limitations by developing small-diameter cylindrical pipelines utilizing the novel 'IVW load introduction' method, which involves fibers applied in purely axial (0°) and circumferential (90°) directions \cite{Motsch-Eichmann2023}.
Current research focuses on developing Type 5 pipelines (without liners) for LH2, where the composite material itself acts as a barrier to prevent hydrogen permeation. The development of insulation systems is not the primary focus of this project.

2. Pipeline design concepts

The main goal is to develop leak tight pipelines for distribution of LH_2 and CcH_2. The pipelines are double-walled, cylindrical and mechanically decoupled by a suspension system. The pipelines are designed be integrated as a structural load-bearing component in aircraft for e.g. as spars or stringers in aircraft as shown in Figure 1.

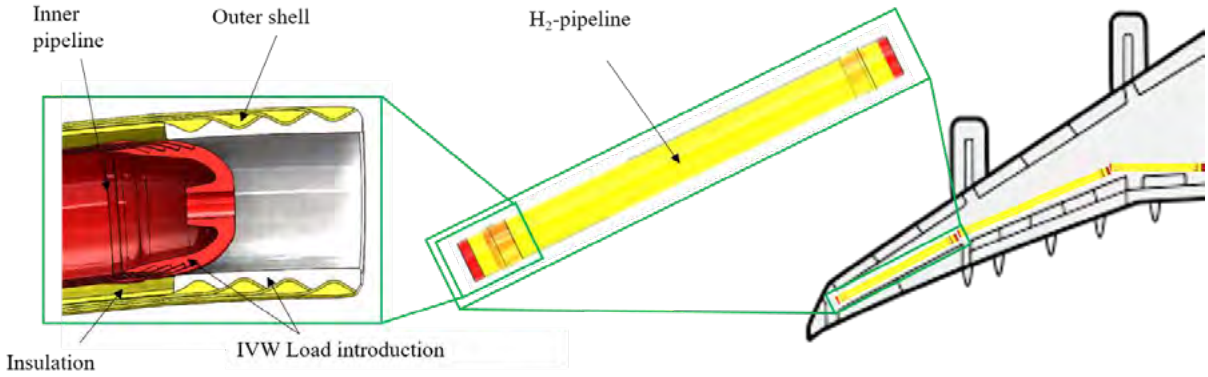

Figure 1. Load-bearing cryogenic hydrogen distribution pipelines.

2.1. Liquid Hydrogen (LH_2) Pipeline

The LH_2 inner pipeline design could incorporate the IVW load introduction, as depicted in Figure 1, but was tailored to meet the geometric and operational specifications outlined in Table 1 (exact dimensions are. Analytical calculations were conducted to determine the requisite minimum wall thickness for the LH_2 inner pipe, utilizing a T300J carbon fiber epoxy laminate with a 60% fiber volume and a strength in fiber direction R_{11} of 1860 MPa. Application of the Boilers formula \cite{Rosen2018} (Eq. 1-3) for pressure vessels yielded a minimum wall thickness requirement of <0.1 mm. While filament winding can achieve such thin wall thickness, stringent attention to manufacturing techniques and quality control is imperative to ensure structural integrity.

Table 1. Geometry and operational specifications for the hydrogen distribution pipeline.

Requirements	Values
Inner Diameter (mm)	35-45
Length (mm)	500
Nominal Pressure LH_2 (bar)	1-10
Nominal Pressure CcH_2 (bar)	200 -350
Operating temperature LH_2 (K)	20
Operating temperature CcH_2 (K)	83

Subsequent investigation explored the viability of a braiding process, reducing the strength in fiber direction R_{11} approximately by 3 times to 500 MPa. This adjustment resulted in a more practical wall thickness of approximately 0.3 mm, a consideration essential for addressing the challenges associated

with connecting metallic end parts to such thin-walled pipes. The first prototype will be produced by biaxial braiding with a braiding angle of ± 54, 7° \cite {Schürmann2005} and Swagelok fitting, which offer reliable vacuum sealing \cite {Glitza2017}.

$$S_{min,u} = \frac{p_i * D_i}{2 * R_{11}} \quad (1)$$

$$S_{min,a} = \frac{p_i * D_i}{4 * R_{11}} \quad (2)$$

$$S_{min,Gesamt} = S_{min,u} + S_{min,a} \quad (3)$$

Due to the applied internal pressure, an axial and a radial load component occurs. Assuming a uniform stress distribution across the cross-section, the stresses for isotropic materials can be determined using the boiler formula (Eq. 4 and 5).

$$\sigma_t = \frac{p_i * D_i}{2 * S} \quad (4)$$

$$\sigma_a = \frac{p_i * D_i}{4 * S} \quad (5)$$

This results in a transverse stress σ_t = 335 MPa and σ_a = 167 MPa.

2.1.1. Outer shell

The outer shell essentially consists of three parts as shown in Figure 2. A metallic boss part, a liner (which in this case acts as a winding aid) and a laminate that absorbs the loads from the boss part. The novel design of the patented IVW load introduction is used \cite{Motsch-Eichmann2023, Nagaraj2022}. The underlying load transfer from the boss part to the laminate works by compressing the axial (0°) layers through the circumferential (90°) layers under the influence of load in axial direction \cite{Motsch-Eichmann2023, Nagaraj2022}.

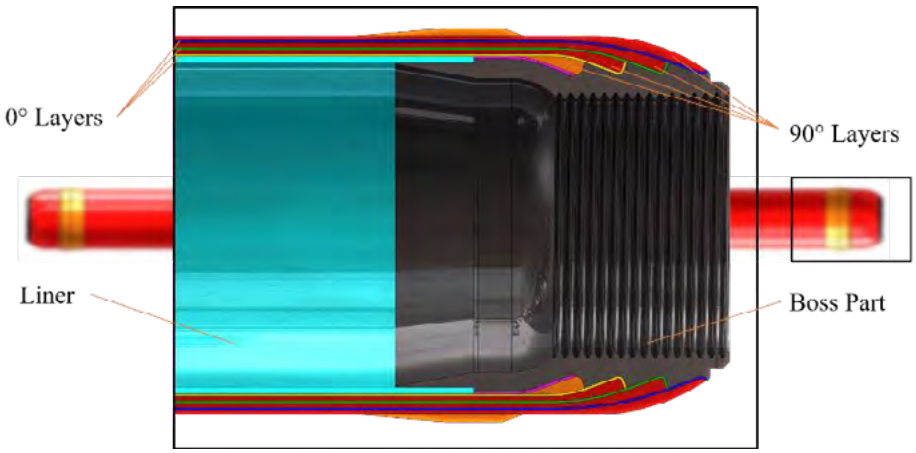

Figure 2. Outer shell for LH_2 and CcH_2 Pipeline employing IVW- load introduction principle. Enclosed view showing the sectional view of the transition area from boss part to CFRP. Adapted from [5] with minor modifications.

Demonstrator production

A demonstrator for the outer shell was produced to assess its load-carrying capacity via initial tensile testing (Figure 4, left view). Aluminum boss parts with IVW load introduction were fabricated and attached to a winding core, which was wrapped with a PVC liner to achieve the desired diameter in the cylindrical area of the pipe. The production process was simplified by employing a unidirectional (UD)

carbon fiber hose, which was pulled over the boss parts and winding core. The UD hose, composed of dry carbon fibers interwoven with an elastomer thread, allows for circumferential stretching and adapts to the contours of the boss parts and winding core. Subsequently, the UD hose was manually impregnated with epoxy resin, and circumferential layers were applied using the wet winding process. Notably, the circumferential layers were applied only in the load introduction area. The results of the tensile test are discussed below.

2.1.2. Suspension concept

The space between the inner tank/pipe and the outer shell is called the interspace, in which the insulation system is installed. The inner diameter of the outer shell depends on the thickness of the required insulation and the geometry of the suspension system. The suspension system is required to keep the mechanical and thermal loads away from being transferred to inner pipe. To this end composite Z-profile springs are designed as shown in Figure 3 to suspend the inner pipe, drawing similarity to the CFRP shell structures developed for pixel detector at CERN \cite {Himmel2003}. As opposed to halfshells in \cite {Himmel2003}, single Z-profile glass fiber laminates will be produced. These individual Z-profiles can be arranged at different points on the surface inner pipe to ensure an effective suspension. The bottom flange of the Z-profile is fixed to the inner tank (for e.g. by gluing). The top flange is flexible and functions like a spring. The Z-profiles are dimensioned such that the flexible top flange can be compressed and pushed into the outer shell where it expands again fixing the inner pipe. The Z-profiles absorb the loads from the outer shell and accommodates the dimensional changes due to its thermal expansion and contraction.

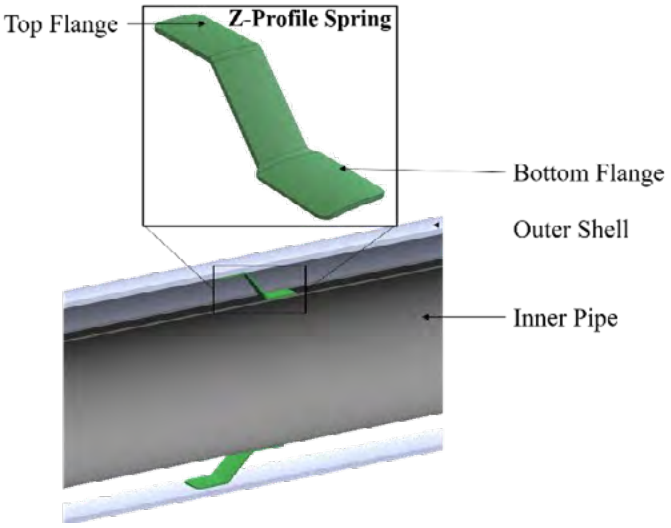

Figure 3. Concept for suspension showing composite Z-profile springs installed at multiple locations on the inner pipe.

2.2. Cryo-compressed Hydrogen (CcH_2) Pipeline

The design of the outer shell can essentially also be used to store or distribute CcH_2. However, the design must be adapted due to the different coefficients of thermal expansion of CFRP and the aluminum boss part. The greater coefficient of thermal expansion of aluminum compared to CFRP would cause the boss part to shrink more than the CFRP when refueling with CcH_2. This would create a gap between the aluminum and CFRP through which the hydrogen could escape. To prevent shrinkage of the boss part, the design of the boss part was revised \cite {Motsch-Eichmann2023}. The revised boss part consists of two parts, an inner cone and an outer cone as shown in Figure 5a. The inner cone design is further modified from \cite {Motsch-Eichmann2023} to enable quick and tightly sealed connection to the On Tank Valve (OTV). No demonstrators are intended to be produced for the CcH_2 pipeline and is only currently considered for a numerical analysis, the results are discussed in this work.

Modelling Approach:
In order to keep the calculation time low, symmetry is utilized and a quarter model is set up in ABAQUS ®. The individual components are meshed using C3D20 Quadratic hexahedral elements. The IMS-65 carbon fiber roving from Teijin and MGS RIMR 135 + MGS RIMH 137 are used as the resin hardener system. The material properties of this composite material are determined from individual components and are shown in Table 2. The liner and metallic boss parts are assigned with material properties of Aluminum 7075. The pressure cylinder model ends shortly after the load introduction as shown in Figure 5. The loads and stresses are evenly distributed in the continuing cylindrical area and therefore are not considered further. The degrees of freedom on the symmetry planes are fixed in the respective directions. The boundary conditions are depicted in Figure 5.

Table 2. Material properties defined in FE-Model.

Material Properties	E_{11} (GPa)	E_{22}, E_{33} (GPa)	E_{33} (GPa)	G_{12}, G_{13}, G_{23} (GPa)	ν_{12}, ν_{13}	ν_{23}	α_{11} (K^{-1})	α_{22}, α_{33} (K^{-1})

Al-7075	70	-	-	-	0.33	-	2.35E-05	-

3. Results and Discussion

Demonstrator tensile test
The total length of the demonstrator produced was 540 mm with a diameter of 66 mm. A laminate thickness of 2.5 mm was achieved with a resulting demonstrator weight of 910 g including the metallic bosses. The adapters were screwed in to the metallic boss at both ends (Figure 4, left view) and subjected to tensile load until failure. The presence of undulations due to interweaving with elastomeric threads introduces local variations in material properties. The first sings of onset of failure was observed around 245 kN (see graph in Figure 4, right view) at which test was terminated because the max load application limit of the hydraulic cylinder (250 kN) was reached \cite {Nagaraj2022}.There was no failure or fracture observed in the demonstrator.

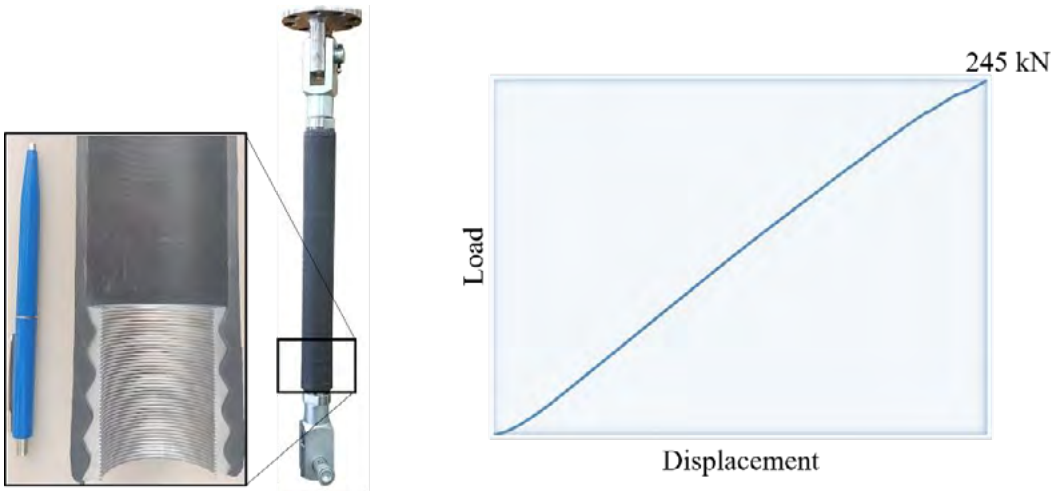

Figure 4. Outer shell demonstrator (left view) with screwed in adapters for the tensile test. Enclosed view showing the sectional view of the load introduction area. Load vs. Displacement curve from the tensile test (right view)

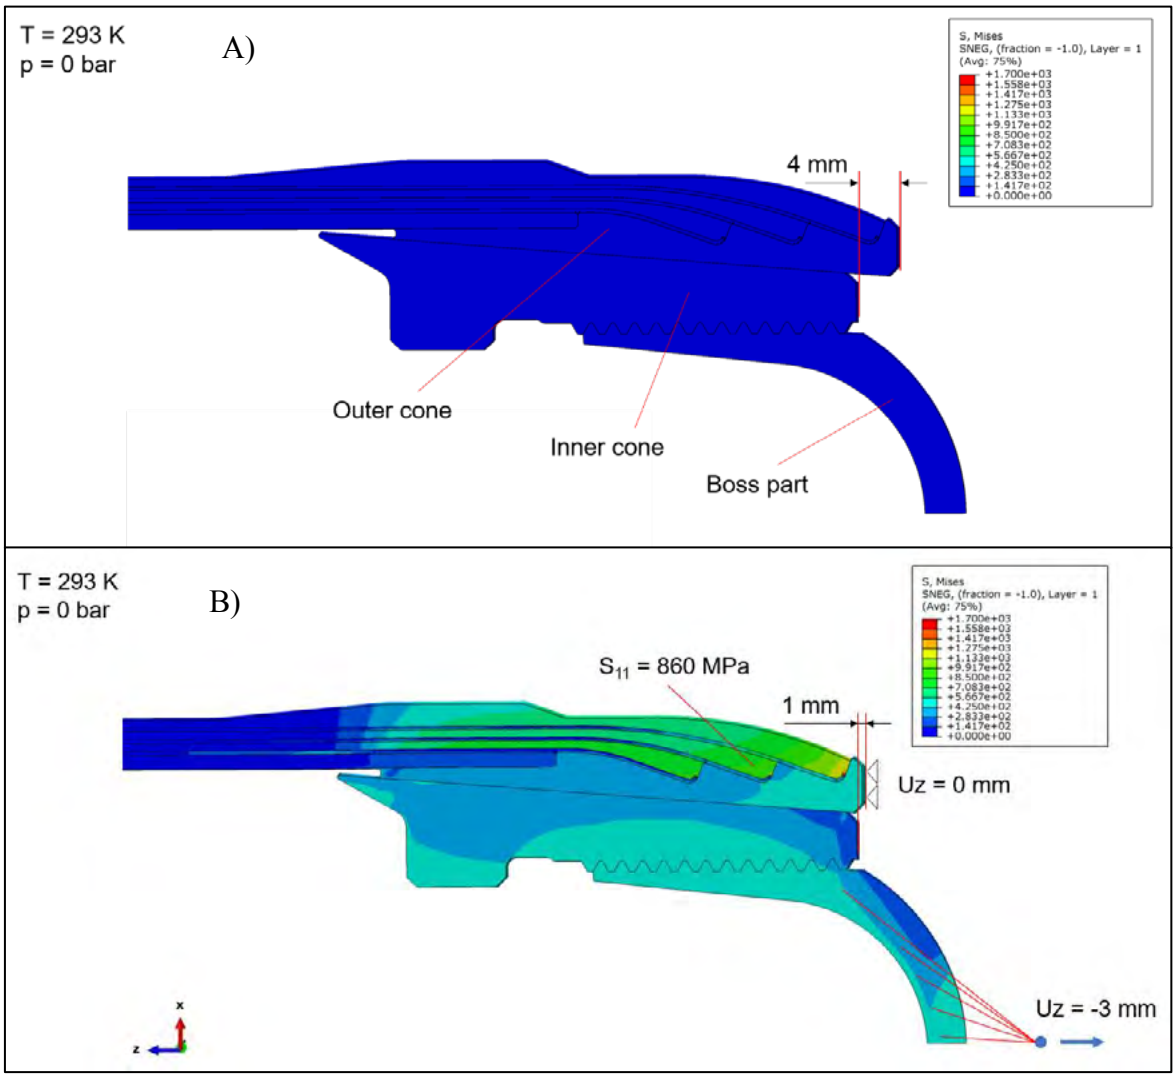
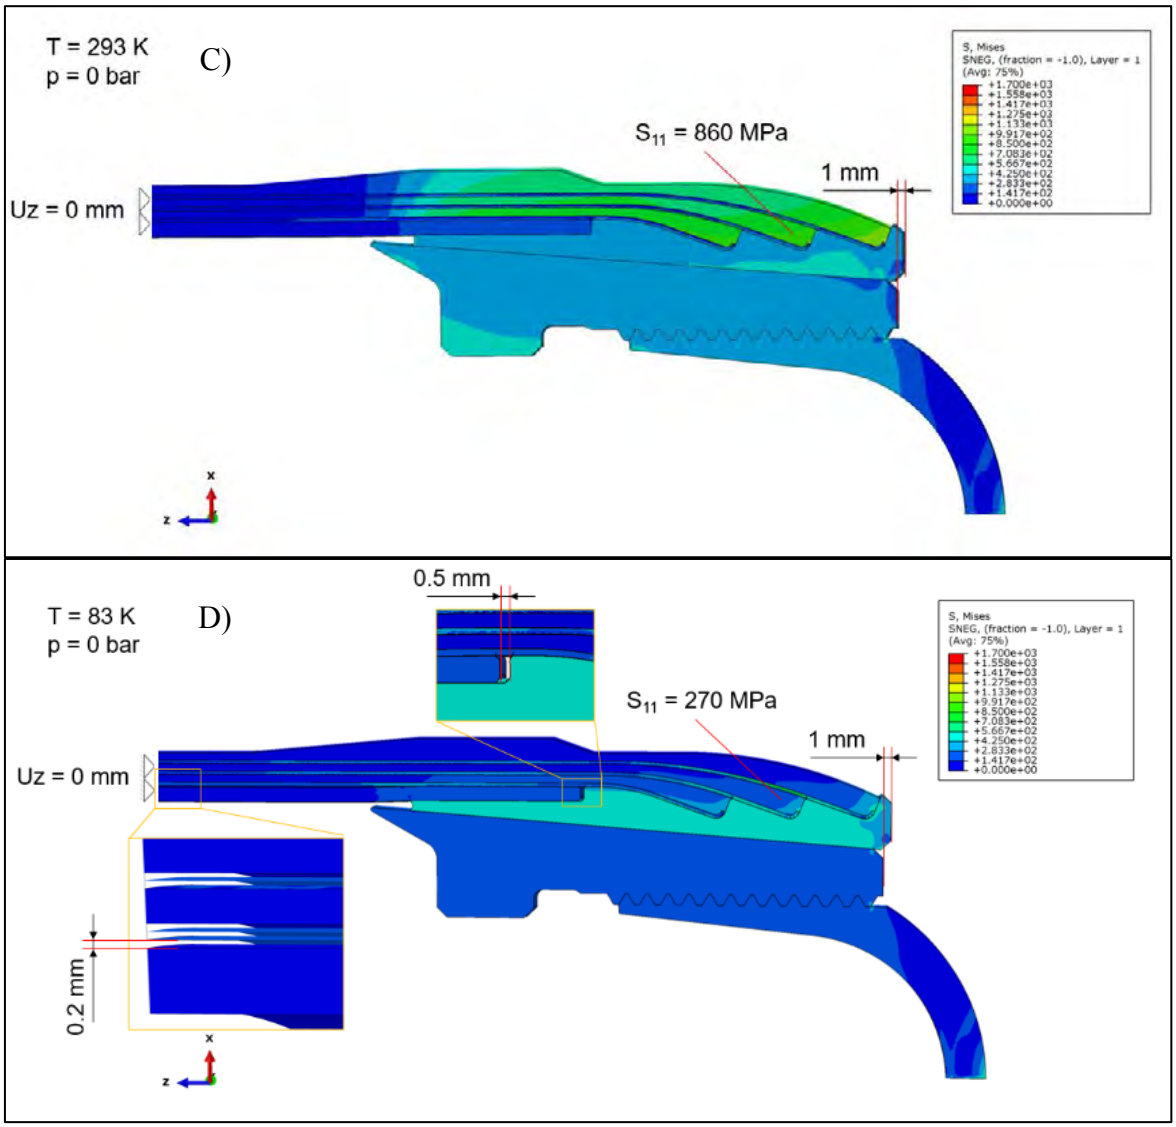
Numerical analysis results for CcH2 pipeline
The numerical analysis consist of four steps. In the first step, the inner cone is displaced relative to the outer cone by an externally applied tensile load. This would be done before installation in the aircraft

(Figure 5b). As a result, the outer cone is stretched in the radial direction and thus also in the circumferential direction. This stretching also elongates the circumferential layers and presses the longitudinal layers against the outer cone. In the second step, the outer tensile load is removed (Figure 5c). Due to the very small angle and the frictional contact between the inner and outer cone, the relative displacement is maintained, and the inner cone does not slip back. The pressure tank or pipeline can now be installed in this pre-stressed state. If the aircraft is now refueled with CcH2 (step three), the hydrogen supply system first cools down before internal pressure builds up. However, the resulting thermal shrinkage of the outer cone is smaller than the expansion caused by the relative displacement between the inner and outer cone. As a result, there is no gap between the CFRP and the outer cone, which means that the tank and the pipeline remain tight throughout (Figure 5d). If the hydrogen supply system continues to be refueled with hydrogen, internal pressure builds up continuously (final step). The internal pressure causes the inner and outer cone to expand in a radial direction and the compression of the longitudinal layers by the circumferential layers increases accordingly. Due to the sufficiently high relative displacement caused by the external load between the inner and outer cone in the first step, there is no further relative movement between the two components during operation (Figure 5e). Consequently, at this pressure, there is no gap between the parts, thereby ensuring that hydrogen leakage is effectively prevented and the pipeline remains leak-proof.





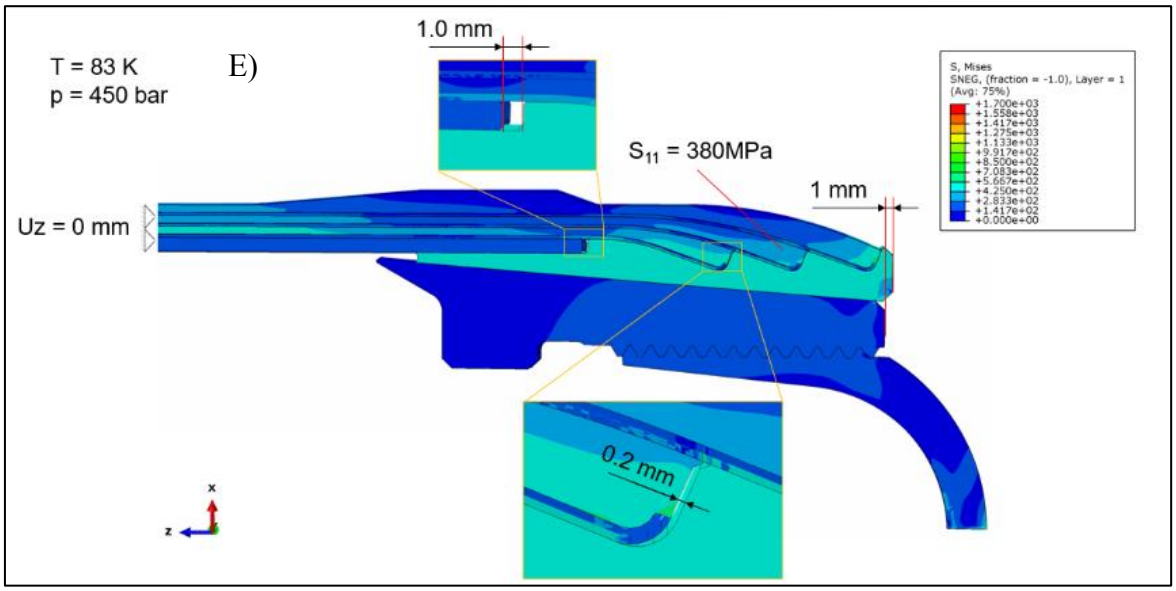


Figure 5. Adapted from [5] with minor modifications. **A):** Further developed design of the boss part [5]. **B):** The inner cone is displaced relative to the outer cone by an external tensile load. As a result, the circumferential layers compress the longitudinal layers.

(Figure 5. Continued): C): The externally applied displacement is released. Due to the relatively flat cone angle, the inner cone does not slip back. **D):** The pressure tank is cooled down during refueling. Due to the pre-tensioning of the outer cone, the thermal shrinkage of the metal parts does not lead to a gap between the CFRP and aluminum.

(Figure 5. Continued): E): The tank is further filled with hydrogen and pressurized. Due to a sufficiently large preload, there is no further relative movement of the two cone parts.

4. Conclusions

As part of the research project, load-bearing hydrogen distribution pipelines are developed. Design concepts for LH_2 and CcH_2 pipelines were presented, utilizing the patented 'IVW load introduction' principle for load transfer. A suspension system with composite Z-profile springs mechanically decouples the inner pipe from the outer shell, enabling its use as a structural load-bearing component in aircraft. Numerical investigations indicate that the developed CcH_2 pipelines can withstand design-operating pressures at cryogenic temperatures. However, further studies under thermo-mechanical cyclic loading at higher temperatures are essential to assess the structure's leak tightness.

Thin-walled braided inner pipes for LH_2 distribution will be produced, followed by burst pressure tests to ensure leak tightness. The first outer shell demonstrator tested with IVW load introduction principle showed high load carrying capacity (245 kN). Production of individual components and bending tests of the double-walled pipelines will be conducted to evaluate the load-bearing capability of the outer shell and the suspension system. Mechanical tests for material characterization at cryogenic temperatures are also planned.

Abstract
Thermoplastic composites with 45% by volume of fibres were prepared by using poly(lactic acid) as matrix and basalt woven fabrics as reinforcement. The effect on the laminate performance of a thermal repairing process after non perforating single or consecutive impact events was investigated. The first impact of a series was characterized by a lower value of the peak force, while the following impacts showed a higher peak and a steeper rise of the force, with a substantial superposition of all consecutive impact responses. The laminates showed some energy dissipation after the first impact at all energy levels, while successive impacts didn't show energy dissipation until 8 J.
The damaged laminates were then repaired at 100 °C and 175°C. Scanning laser Doppler vibrometry (SLVD) and microtomography (microCT) were used to assess the laminate damage. Both SLDV and microCT analyses confirmed that matrix continuity and woven fabric planarity were restored at the higher temperature. A second impact testing campaign on the same points demonstrated the complete recovery of the impact resistance after the thermal repairment at 175 °C.

1. Introduction

The composites market is dominated by thermosets composites, due to their high structural properties, but thermoplastic composites are characterized by better performances in damage tolerance and impact resistance, as well as higher productivity [1]. The high sensitivity of composites to hidden defects or damages can give rise to increasing damage during service life [2] and require continuous structural controls and rapid intervention in presence of damages. Cyclic loads or repeated impacts even of low entity, such as during service life or maintenance, can contribute to the onset and propagation of critical damages. The lower sensitivity to impact loads and the higher difficulty for crack growth, which can lead to unexpected laminate failure, is one of the main reasons for the ever growing interest in thermoplastic composites. Other advantages are the recyclability, high specific strength and stiffness, corrosion resistance, enhanced impact toughness, cost effectiveness and flexibility of design [3]. Conventional repairing approaches for damaged laminates make use of bolts, patches, gouges, or on gluing and stitching parts [4]-[10]. These methods can be expensive, and typically are excluded in case of small or barely visible damages, except that in high demanding applications. Thermoplastic composites allow to use conventional repairing methodologies but also exploit new repairing approaches thanks to the possibility to melt their matrix [11],[12].

Non-destructive evaluation (NDE) methods have an important role in post-manufacturing inspection of structures, for identifying damages during service, maintenance, or after repair. Optical inspection is the most simple, albeit very effective, technique [13],[14] but the most diffuse NDE techniques are based on ultrasounds [15]. Among them, scanning laser Doppler vibrometer (SLDV) can detect matrix damages through the excitation of the laminate by means of a surface bonded piezoelectric transducer and measures superficial strain by using a laser beam [14]. SLDV can precisely identify superficial discontinuities, and, with lower precision, estimate the damage extension through the laminate thickness. A very precise detection of through-thickness damages can be achieved by means of X-ray micro-computed tomography (mCT) [16]. In fibre reinforced composites micro-CT is particularly effective in detecting the internal spatial arrangement of fibres, as well as possible damages like delaminations and microcracking [17],[18].

In this paper a thermal treatment is used to recover not-perforating impact damages in the laminate. A reinforced composite based on poly(lactic acid) and basalt fibres woven fabrics was impacted at low energy and multiple times at the same impact point. A compression moulding process was used to repair the thermoplastic composite, and the effect of heating temperature was investigated by means of optical inspection, scanning laser Doppler vibrometry, and micro-computed tomography.

2. Experimental

2.1. Materials

Poly lactic acid - PLA (Luminy L175 from TotalCorbion NV, The Netherlands) was used as matrix. It has a glass transition temperature of 60°C and peak melting temperature of 175°C. The tensile modulus is 3.5 GPa and the tensile strength 50 MPa, as reported in the datasheet [19]. Basalt fibres (type BAS 220.1270.P) were supplied by Basaltex-Flocart NV (Belgium) in the form of a plain weave fabric with surface weight of 220 g/m^2, yarn count of 7.2 ends/cm (warp and weft) [20]. Basalt fibres density was 2.67 g/cm^3, according to the ASTM D792 procedure.

2.2. Composite preparation and repairing

Composite plates were prepared by using the film stacking process. Layers of reinforcing fabric and PLA, 120 mm x 170 mm in size, were alternatively stacked and then pressed by using an hydraulic hot plate press. Laminates consisting of 10 balanced fabric layers 0°/90°, symmetrically arranged with respect to the middle plane of the laminate ([(0/90)5]s configuration), were obtained with a thickness of 1.80 mm and fibre content target of 45% by volume. Compression at 180 °C at 0 MPa for two minutes and 0.5 MPa for five minutes was applied on the stacking sequence to impregnate the fibres. Composite repairing was performed by hot compacting damaged laminates at 100 °C or 175 °C for 5 minutes at near-zero pressure.

2.3. Laminate characterizations

Flexural properties were determined by using a three point bending configuration set according to ASTM D 790. A universal testing machine (mod. 4304 from SANS Shenzen - China, now MTS Inc., USA) equipped with a 5 kN load cell was used. Out-of-plane impact tests were performed by using an instrumented drop-weight impact testing machine (model Fractovis Plus from CEAST – Italy) equipped with a hemispherical tip (diameter 12.7 mm). All tests were performed putting the specimen on a stainless steel annular ring (internal diameter 40 mm, outer diameter 60 mm). The impactor mass was 1.93 kg, and the impact energy, ranging between 1 and 8 J, was set by changing the impact height. Series of 4 consecutive impacts were also applied to investigate the sensitivity to multiple impacts of the composite. Three samples for each impact condition were tested.

2.4. Damage detection

Optical analysis in reflection mode was carried out by using a microscope (model Z16 APO, Leica Microsystems GmbH, Germany) to investigate the superficial damages induced on the composite. The scanning laser Doppler vibrometry (SLDV) acquisition was made with a single head of the PSV-400-3D vibromter from Polytec (Waldbronn, Germany), measuring the vibration velocity of the sample on

the non-impacted surface at grid points spaced about 2.2 mm. The samples were excited with a surface bonded piezoelectric transducers of 10-mm diameter and 0.5-mm thickness (CeramTec, Germany) that was placed on the impacted face at the middle of one of the short edges. The excitation signal (5-cycle long tone burst with 100 kHz central frequency) for the transducer was generated using an arbitrary waveform generator TGA1241 from TTi (Cambridgeshire, England) then amplified using the EPA-104 Piezo Linear Amplifier from Piezo Systems, Inc (Woburn, MA, USA). The sensed wave signals were filtered in the bandwidth 25-300 kHz by a bandpass filter and the signal root mean square (RMS) was calculated for each grid point [21].

Microtomographic image acquisition has been performed using an UltraTom CT scanner manufactured by RX Solutions (France), equipped with a Hamamatsu micro focus sealed X-ray tube operating at 70kV and 428 µA. A 16 µm spatial resolution was used for the acquisitions. The X-ray shadow projections are digitized with 65536 brightness gradations (16 bits) and recorded in TIFF image format. The image acquisition time was about 2h per specimen. For 3D reconstruction, X-ray images were acquired from 1440 rotation views over 360° of rotation (0.25° rotation step).

3. Results and discussion

The average fibre volume content of laminates was 45.8%. All laminates were free of voids. The absence of voids was qualitatively confirmed through optical microscopy and microCT reconstructed volumes. The prepared laminates exhibited a flexural modulus of 18.6 GPa, flexural stress of 213.3 MPa, and strain at break of 1.34 %. The low strain ad break could be related to the possible low interface strength between PLA and basalt fibres, whose sizing treatment was not specifically developed for the used matrix.

Preliminary impact tests on laminates showed a perforation threshold higher than 8 J, hence that was set as limit for testing. Figure 1A shows the impact points at different impact energies. It is evident the increase in size of the damaged area. The force peak during impacts increased with the impact energy as well (Figure 1B). The widening of damaged area can also be associated with the increased energy dissipation during the impact, as evident from the residual value of the energy-displacement curves, which represent the un-recovered energy (Figure 1C).

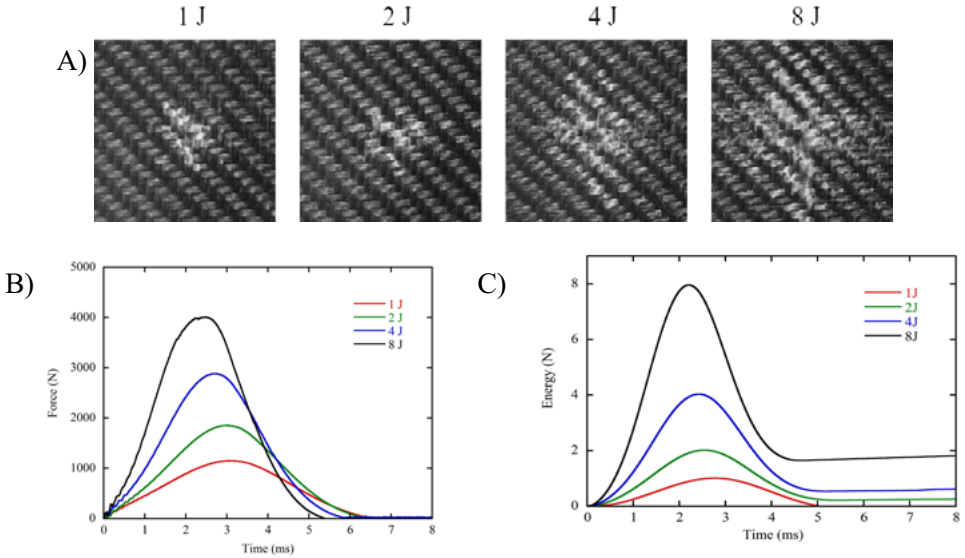

Figure 1. A) Appearance of the impact point at different impact energies; B) Force- and C) Energy-versus time curves as function of the impact energy.

The plots of consecutive impacts show a peculiar behaviour, because the force peak during the first impact is lower than that detected during the subsequent ones (Figure 2A, impacts at 4 J). Additionally, impacts following the first do not show residual dissipated energy up to 4 J (Figure 2B). This verifies at all impact energy values, and has been related to the fact that irreversible phenomena like matrix cracking and delaminations only occur after the first impact, while the subsequent ones do not induce further significant damages until 8 J is used.

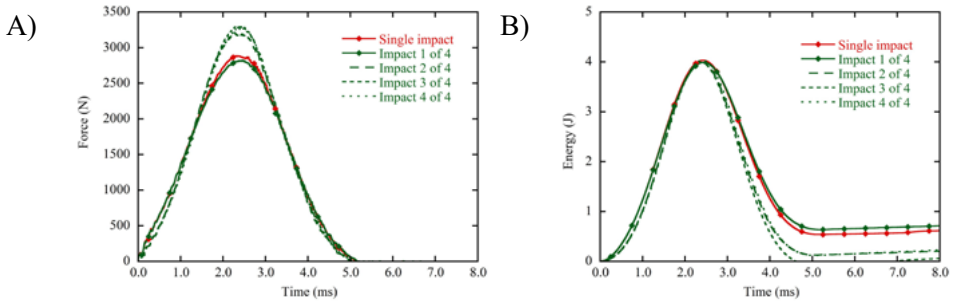

Figure 2. Energy versus time (A) and Force versus time (B) curves after 4 J impacts. Curves from first impacts have a diamond mark.

SLDV analysis evaluated the superficial damaged areas on the impacted surface after one (1x), two (2x) and four (4x) impacts at 4 J (Figure 3A). The damaged area (light grey and white pixels) increases with the impact energy and with the number of consecutive impacts. The optical analysis (Figure 4) shows that laminates processed below the melting temperature of PLA were only able to recover the laminate planarity, while superficial damages were still visible. On the contrary, laminates repaired at 175 °C were completely clean of superficial impact signs. This result is in agreement with the SLDV analysis, which shows residual damages in the laminate repaired at 100 °C (Figure 3B) and no damage pattern in the laminate repaired at 175 °C (Figure 3C). Finally, the microtomographic analysis confirmed the complete recovery of the woven fabrics planarity after both thermal treatments, and no sign of fibres deformation was evident (Figure 5). The combined use of SLDV and microCT results allow to say that thermal treatments were able to recover the reinforcement planarity, but only a temperature high enough to melt the matrix allowed to completely erase any sign of matrix and interface related damages.

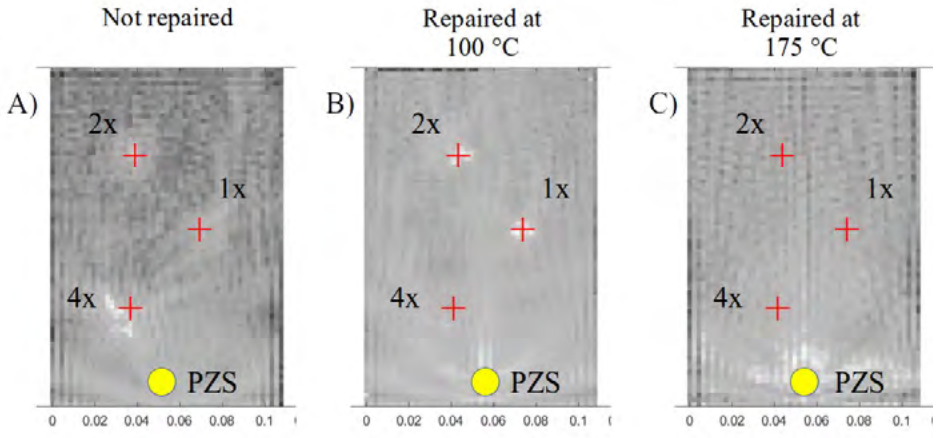

Figure 3. Scanning laser Doppler vibrometric analysis of laminates impacted at 4 J: A) Not repaired, B) repaired at 100 °C, C) repaired at 175 °C. The red cross is the impact point; 1x, 2x and 4x are the number of consecutive impacts. The yellow circle represents the position of the piezoelectric sensor (PZS).

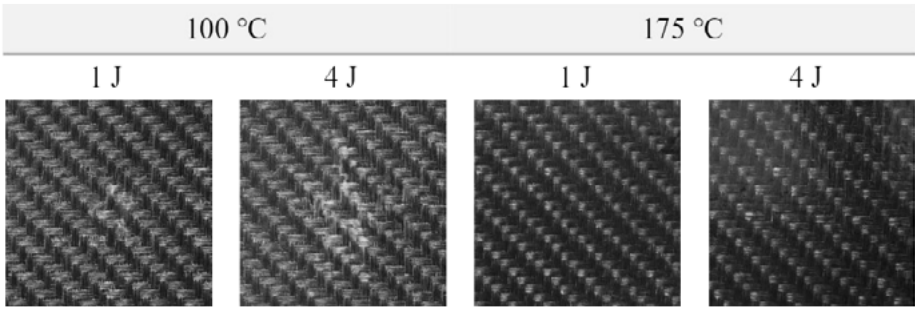

Figure 4. Impact points on front sides of repaired laminates. Square edge is 33 mm.

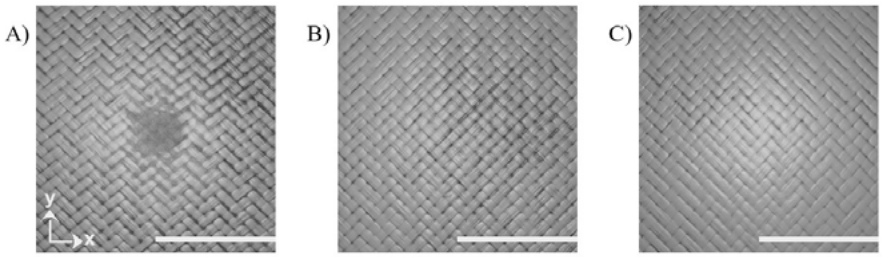

Figure 5. Top surface of microtomographic 3D reconstructions of laminates A) impacted four time at 4 J, b) repaired at 100 °C and c) repaired at 175 °C. White scale bar is 25 mm.

The second impact testing campaign on the same previously impacted points showed that the laminates repaired at 100 °C were still able to show a good performance but force peak values were significantly lower with respect to the first impacts series. On the contrary, the laminates repaired at the matrix melting temperature showed almost the same performances than before repairing, and this is remarkable when considering the fact that each repaired laminate received on each impact point twice the number of impacts with respect to the not repaired laminate.

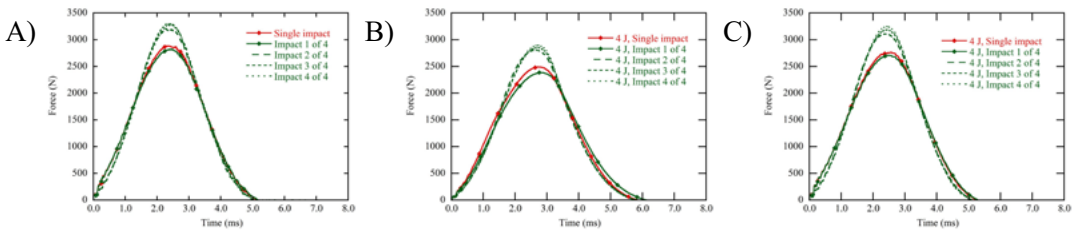

Figure 6. Force versus time curves of laminates impacted at 4 J before and after repairing: A) not repaired, B) repaired at 100 °C, C) repaired at 175 °C.

4. Conclusions

Composites based on PLA and basalt woven fabrics were impact tested at impact energies ranging between 1 and 8 J, and up to four consecutive impacts were delivered. Both front and back surfaces were damaged, and the damaged area increased with the impact energy. The first of each impact series was characterized by a lower peak force and a significant amount of unrecovered energy in proportion to the impact energy. Successive impacts showed a higher peak force and an almost negligible unrecovered energy until impact energy was equal to 8 J.

The laminates were repaired at 100 °C and 175 °C. Microtomographic analysis showed planar woven fabrics at both temperatures. On the contrary, the scanning laser Doppler vibrometry showed that only the higher temperature allowed to erase any visible and instrumental sign of damage. Both techniques combined allowed to assess that a high molecular mobility is needed to successfully restore both matrix continuity and woven fabric planarity.

The effectiveness of the repairing process was finally assessed by a second testing campaign on repaired laminates, and was performed on the previously impacted points. The impact behaviour of laminates repaired at 175 °C was almost superimposed to that of pristine laminates, confirming a complete recovery of the mechanical performance under impact.

Acknowledgments
This study has been carried out within cooperative programme of the agreement on scientific cooperation between the Polish Academy of Sciences (PAS) and the National Research Council of Italy (CNR) within the project “Non-destructive evaluations on repaired fibre reinforced composites (REPCOM)” – Biennium Program 2020-2021 between Institute of Polymers, Composites and Biomaterials, National Research Council (IT) and Institute of Fluid-Flow Machinery, Polish Academy of Sciences (PL).

Abstract
Homogeneous and quasi-homogeneous cell structures, including triple-periodic minimal surfaces (TPMS), are crucial in engineering, particularly in lightweight energy absorption applications. While typically made from metals or polymers, the exploration of polymer composites in cellular systems is increasing, driven by additive manufacturing technologies. High-performance energy-absorbing systems often use continuous carbon fiber–reinforced composites embedded in a thermoset matrix. Despite their potential, current literature focuses on short-fiber composites in TPMS systems, with limited studies on continuous fiber placement. We used a Markforged Mark Two 3D printer to explore various cell structures and reinforcement patterns for continuous fibers. The paper investigates the energy absorption capabilities of these structures to enhance their specific energy-absorbing capability, contributing to the development of modern energy-absorbing structures.

Keywords: 3D printed CFRP, Cellular structures, TPMS, Energy absorption, SEA

1. Introduction

The purpose of energy-absorbing structures is to mitigate the momentary, impulse-like effects of dynamic impact by dissipating energy. This process leads to structural deformation, increasing the duration of the load while potentially reducing its intensity significantly by orders of magnitude as energy is absorbed through various structural transformations. The main design parameters for energy-absorbing devices are maximum force and maximum deceleration which the protected objects are capable of withstanding [1]. Currently, energy absorption applications primarily utilize polymer and metal foams and honeycomb structures, exploiting their adjustable porosity and typically plastic properties within these applications. Additionally, with the emergence of additive manufacturing (AM) technologies, tailorable properties of regular cell structures have become a significant research area in energy absorption applications. Cellular structures respond to compressive loads with a consistent plateau phase, offering a predictable maximum force until critical densification. However, a similar characteristic can also be achieved with materials incapable of plastic deformation, such as fiber–reinforced composites [2–5].

1.1. Composites and energy absorption

The application of composites for energy absorption purposes has been a researched area since the 1970s, with its findings applied in numerous critical areas, including helicopter and race car crash zones [6–9]. These structures typically consist of thin-walled, closed-profile systems, primarily tube-like, oriented with their long axis toward the expected impact [10–12]. During crushing, a progressive mechanism can be initiated to stabilize the otherwise catastrophic and unstable response of fiber–reinforced composite specimens. This mechanism advances synchronously with the propagation of the crush zone, a process referred to as fragmentation. The research by Starbuck *et al.* [13] indicates that in the energy-absorption applications of composites, fiber failure is the dominant energy-absorbing mechanism, followed by various crack propagation and fiber bending mechanisms.

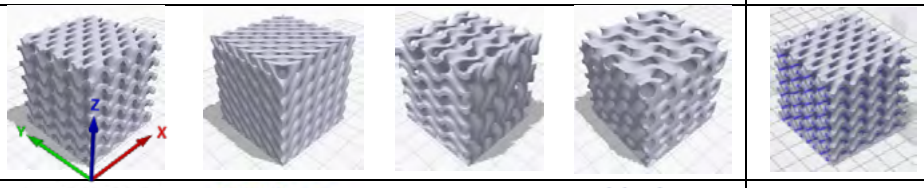
1.2. Applications of triply periodic minimal surfaces (TPMS) in energy absorption

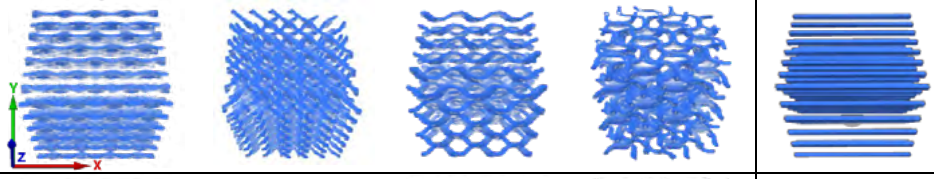
In recent years, the utilization of TPMS structures for energy absorption has emerged as a prominent convergence of AM technologies and high-performance, lightweight structures. In these domains, where spatially adjustable properties are increasingly important, TPMS structures have gained significant attention. [14–17]. We selected these cellular systems for our study due to their self-supporting structures, facilitating support-free printing in subsequent processes. Moreover, the mechanical properties of various TPMS structures are extensively documented in the literature [18, 19].

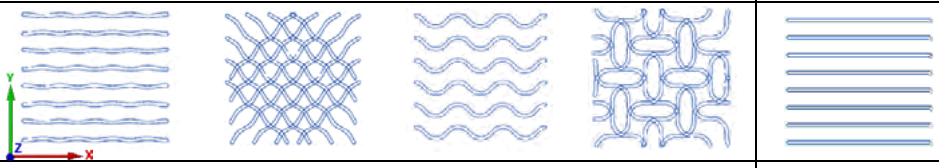
Our objective was to develop hybrid, fiber–reinforced cellular structures that efficiently absorb energy through fragmentation processes, achieved by strategically placed fiber reinforcements. We conducted quasi-dynamic compression tests on various TPMS cell structures using combinations of Markforged's PA6 and Onyx materials alongside continuous carbon fiber to accomplish this. We evaluated the impact of different fiber placement strategies on the energy absorption properties of reinforced structures. We also explored the influence of infill strategies provided by slicing software on unreinforced structures.

2. Methodology

2.1. Selection of test geometry and fiber reinforcement design

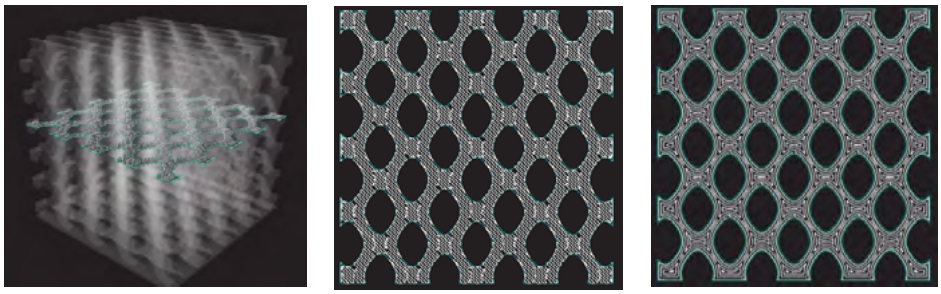






During the TPMS cell structure selection process, we established three key criteria. Firstly, the geometry must be manufacturable without support material, using the chosen material extrusion (MEX) technology. Secondly, the structure should feature longer, uninterrupted cross-sections perpendicular to the main building direction, facilitating continuous fiber placement along its entire length (Table 1). Lastly, we aimed to maximize the geometric energy absorption performance of TPMS cells by selecting structures with optimal specific properties. Building on the research by Kladovasilakis *et al.* [18] and Saleh *et al.* [19], we further analyzed the gyroid (G) and diamond (D) structures to meet these objectives. The compression test specimens were selected as cubes by relevant standards [20]. To mitigate edge effects, we placed 3x3x3 unit cells within these specimens, following literature recommendations [21]. The choice of cube edge length was primarily dictated by the narrowest fiber–reinforced cross-section, determined to be 2.8 mm based on literature data [22] and our own investigations. Consequently, the compression-tested cube had an edge length of 45 mm, with unit cell edges measuring 15 mm, resulting in a relative density of approximately 37%.

Achieving suitable energy absorption characteristics relies on stable, progressive failure processes in the fiber–reinforced region, where continuous fibers break into smaller fragments. In our experiments, we positioned fibers parallel to the loading direction or at angles of ±45 degrees. Fiber placement was restricted to printed layers, ensuring the creation of consistent, identifiable reinforcement with uniform fiber orientation. Thus, for specimens with 0-degree reinforcement, every 60 layers included ten continuous fiber–filled layers spanning the entire cross-section. In specimens reinforced at ±45 degrees, this frequency doubled, with ten continuous fiber–filled layers appearing in every 30 layers, resulting in approximately 8 v% and 16 v% fiber content within the material-filled volume.



To achieve the desired fiber reinforcement orientation, we rotated the elemental cells of the cell structure, resulting in corresponding rotations of characteristic cross-sections where the reinforcement is placed. Consequently, four different reinforced structures were created (Table 1), labelled as D0, D45, G0, and G45, denoting the cellular structure of Gyroid (G) or Diamond (D) and the dominant fiber direction within each cell type (0 or ±45). Here, the loading direction aligns with the 0-degree fiber direction, coinciding with the X-axis in our notation system.

We hypothesized that the progressive failure mechanism heavily depends on the local curvature of reinforcement paths. Slight waviness induces bending-dominated failure in the structure rather than initiating fragmentation-dominated failure modes, leading to more effective energy absorption characteristics. As shown in Table 1 (G0-D45), reinforcements representing dominant fiber directions exhibit varying degrees of waviness in all cases.

Table 1. Various TPMS structures and fiber reinforcement were examined. The X-axis represents the loading direction, while the Z-axis denotes the printing build direction.

		D0	D45	G0	G45	D0 masked
Weight	PA	52.7 g	51.8 g	43.9 g	44.5 g	-
	Onyx	51.5 g	52.5 g	44.2 g	44.6 g	-
	CCF	52.2 g	51.1 g	43.5 g	43.7 g	52.8 g
Cell structure						
Reinforcement paths within the specimen						
Reinforcement repeating unit/layer inside the specimen						
Fiber content		8.53 v%	15.59 v%	8.82 v%	16.51 v%	14.14 v%

To mitigate this effect and enhance energy absorption, we introduced an additional diamond-based structure (D0_masked), where fiber reinforcement was implemented as a separate geometry within the specimen, forming perfectly straight columns. This was achieved by post-merging the unreinforced and reinforced geometries, created separately in the slicing software and consolidated into G-code.
Alongside specimens with continuous fiber reinforcement, we manufactured a series of pure PA and a series of Onyx (short CF-filled PA) specimens to isolate the effect of fiber reinforcement. Markforged's slicing software, Eiger, a closed industrial system, allows for bare fiber reinforcement placement only if the "exposed infill" beta option is enabled. This feature skips the placement of wall layers and prints only the internal structure of the test specimen, possible with raster infill when using 100% infill (Figure 1 (b)). Consequently, the series without fiber reinforcement was also created with the use of raster infill, with the "exposed infill" option enabled. To further investigate the infill strategy, we made additional test specimens from Onyx with a concentric infill strategy (Figure 1 (c)). The effect of the infill strategy was exclusively examined for the D0 specimens. For the printing parameters, refer to Table 2.

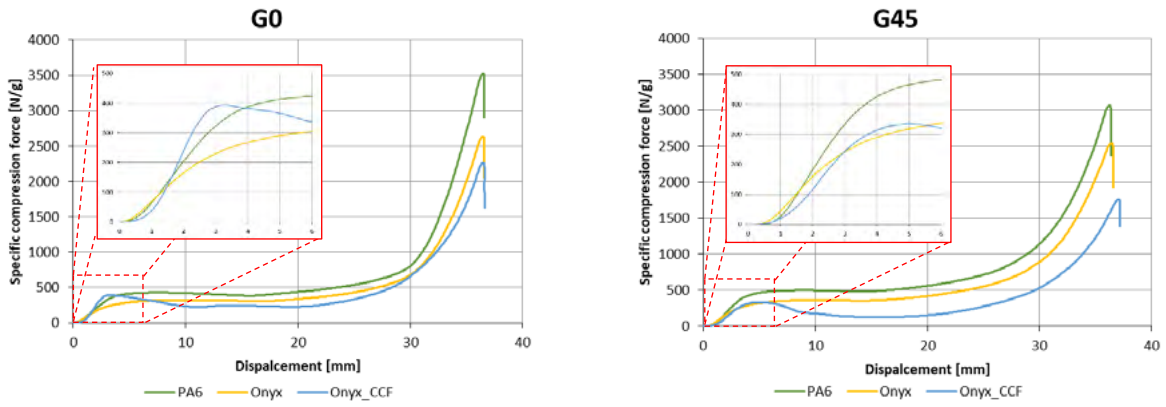
(a) (b) (c)

Figure 1. Infill strategies: A general cross-section (a), which can be filled with a raster (b) or concentric (c) infill pattern.

Table 2. Manufacturing parameters of the compression test specimens

	G0, G45, D0, D0 masked, D45	D0 concentric
Layer thickness	0,125 mm	0,125 mm
Nozzle diameter	0,4 mm	0,4 mm
Infill ratio	100%	100%
Number of walls	0	0
Number of bottom/ top layers	0	0
Reinforcement path-planning strategy	concentric, one loop/-	-
Material deposition strategy in XY plane	raster in ±45°	concentric

2.2. Test environment and parameters



The quasi-dynamic compression tests were conducted on a Zwick Z250 universal testing machine at a maximum achievable loading rate of 600 mm/min. The tests were performed up to 85% engineering strain or a maximum load of 200 kN. The specimens were not conditioned, and air temperature during testing was 21°C with a relative humidity of 48%.
For comparability of the test results, all data is presented normalized to the mass of the respective specimen. Detailed descriptions of the examined parameters can be found in Table 3.

Table 3. Parameters examined during the tests

Designation	Abbreviation	Unit	Determination methodology
Specific energy absorption capability	SEA	J/g	Integration of the force–displacement curve up to the most efficient energy absorption point, followed by normalization with the mass of the specimen (For further information refer to [23])
Specific compression force	F*	N/g	Normalized compressive force with respect to the mass of the specimen.
Specific plateau force	F^*_{plat}	N/g	Average plateau force normalized by the mass of the specimen.
Specific stiffness	E*	MPa/g	The slope of the straight line fitted to the first linear segment of the engineering stress–engineering strain curve, normalized by the mass of the specimen.

3. Results

For better clarity in the presentation of the test results, we depicted the various cell structures on separate diagrams. Additionally, we detailed the initial loading phase in the diagrams. Figure 2 illustrates these compression diagrams.

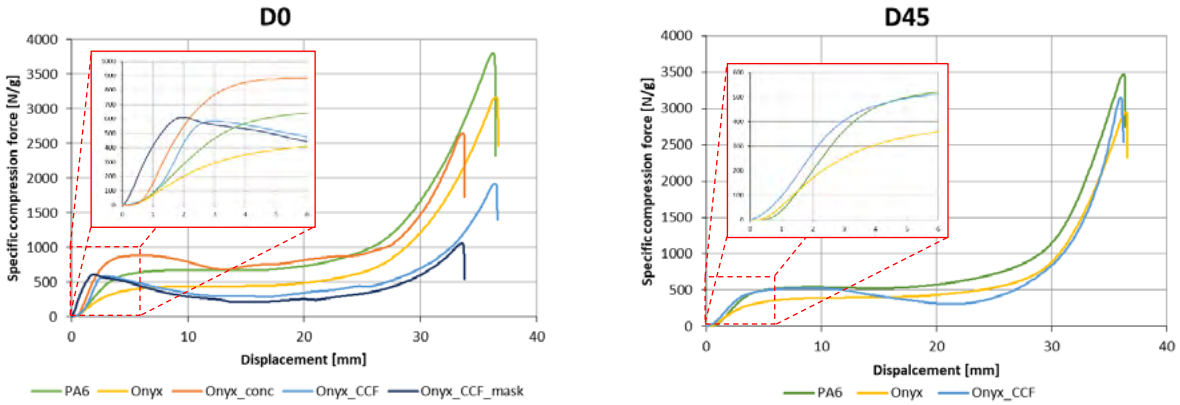


Figure 2. Specific compression force-displacement curves of the test specimens.

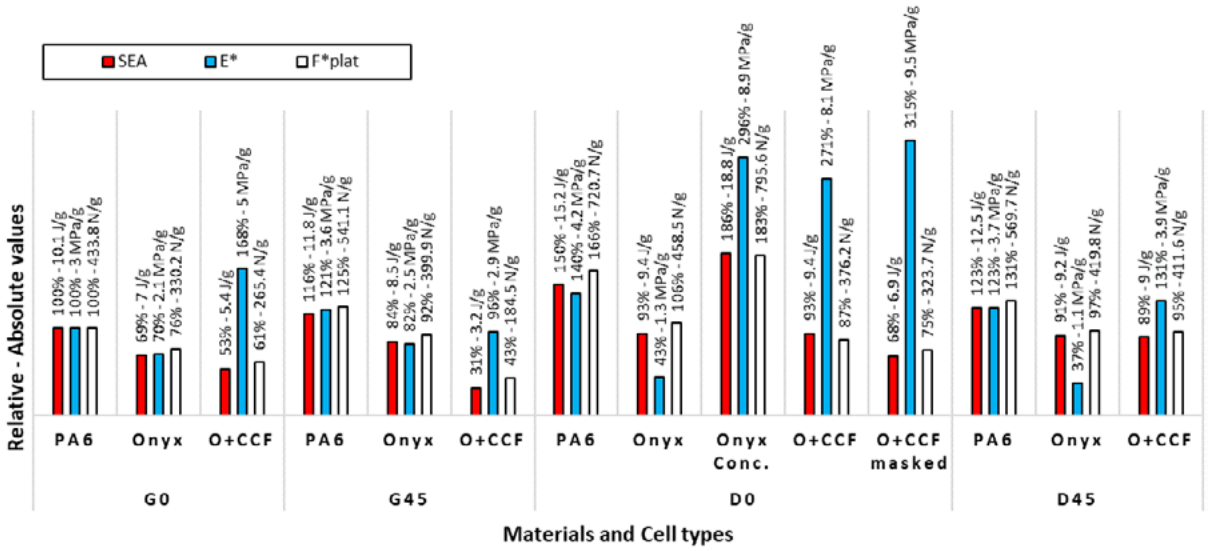
From the curves shown in Figure 2, the parameters listed in Table 3 were then calculated for all test specimens. These were then summarized and displayed in the bar chart in Figure 3. To allow for a common diagram, all metrics were expressed as percentages relative to the G0 specimen made of PA6. However, the absolute values were also indicated on the chart in addition to the relative values.



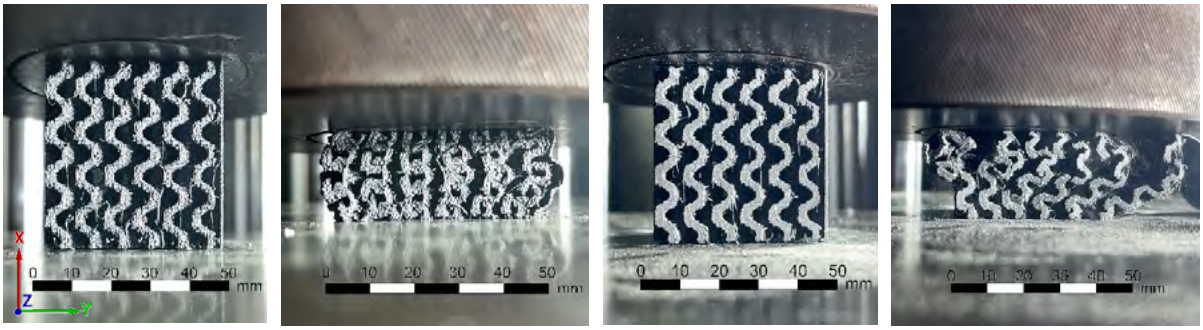


Figure 3. The column chart shows all the results of the tested structures, presenting the relative and absolute performance of each specimen, values normalized to the G0 PA6 structure.

The specimens exhibited consistent failure characteristics across all cell types and orientations, where the PA6 and Onyx specimens remained intact throughout the loading phase, while the fiber–reinforced specimens separated along their length within the reinforced cross-section. Figure 4 illustrates failure typical of matrix-only materials (a, b) compared to the fiber–reinforced structures (c, d).

(a) (b) (c) (d)

Figure 4. Failure characteristic of the axially loaded Schwarz-Diamond cellular structure in the case of short fiber–reinforced PA6 (Onyx) matrix material, where (a) is the undeformed state and (b) shows the ~60% compressive strain state. The axially loaded Schwarz-Diamond cellular structure with continuous fiber reinforcement showed weak interlayer adhesion, where (c) is the undeformed state and (d) shows the ~60% compressive strain state.

4. Discussion and conclusions

Based on the measurement results, the following conclusions were drawn:

1. Clear rankings were established among the examined structural types in cases without continuous fiber reinforcement, extending across all measured parameters. The ranking is as follows: The best was D0, followed by D45, G45 and G0.
2. Fiber–reinforced specimens exhibited a significant average increase of 81% in specific modulus compared to versions made from PA6 for fiber reinforcements corresponding to the 0° loading direction (G0; D0). The structurally regular 0° (D0 masked) fiber–reinforced specimen exhibited an even higher 126% increase in specific modulus.
3. Short-fiber–reinforced Onyx specimens underperformed the pure PA6 structures in terms of all metrics, with average specific modulus reductions of 32% for gyroid (G0, G45) structures and 70% for diamond (D0, D45) structures. In the case of specific plateau forces, this difference averaged 28% across all specimen types while averaging 31% for specific energy absorption. This discrepancy likely stems from the similar ratios between the moduli of pure materials and the lower failure deformation threshold of Onyx, attributed to its high content of inner friction reducers and other additives affecting stiffness.
4. The difference between raster and concentric printing yielded unexpected deviations favoring concentric printing. Among structures made from Onyx material, there was a 585% difference in specific modulus, a 77% difference in specific plateau force, and a 100% difference in SEA values. This significant difference underscores the importance of choosing continuous infill in energy absorption applications, where rasterized infill intermittently builds the cross-section and has a pronounced detrimental effect.
5. The SEA value of the regular 0° (D0 masked) specimen was 37% lower than that of the slightly wavy fiber–reinforced (D0) specimen, likely due to the design created by the combination of two separate pieces on the printing bed during manufacturing, presumably degrading layer adhesion. Additionally, the phenomenon can be explained by the greater lateral force component after stability loss, which caused the structure to separate sooner.
6. Regarding SEA values, the fiber–reinforced specimens consistently underperformed compared to the Onyx and PA6 specimens, with an average value of 47% compared to PA6. This can be explained with the phenomenon presented in Figure 4, where it is clear that while the pure matrix material specimens remained intact throughout the entire loading range, the fiber–reinforced specimens could not resist the simultaneously emerging axial and lateral force components and delaminated and separated due to weak interlayer adhesion. Consequently, they contributed much less to the energy absorption process when deviating from the loading direction. Thus, the desired fiber fragmentation processes fail to initiate properly in the examined specimens,

indicating that continuous fiber reinforcement has not been adequately utilized for energy absorption in the presented cases.

5. Limitations and future improvements

In our study, only one specimen type was manufactured for each test. Thus, our observations and conclusions lack statistical certainty. Supplementary tests would be necessary to establish statistical significance, a task we plan to undertake in the future. Concerning the masked specimen, we relied solely on assumptions regarding interlayer adhesion values, which warrant further investigation under standardized conditions. Moreover, based on the observations outlined in sections 4–6 of Conclusion, it is evident that the most critical parameter requiring development is the integrity of the cellular structure. It ensures adequate support for the fiber reinforcement, even at substantial load states. This may entail enhancing the interfacial adhesion of the fiber reinforcement or implementing macro-level methods, such as radially placed fiber reinforcement. Investigating and improving these parameters could be the foundation for future research.

Keywords: Submodeling, Global-Local, Reissner-Mindlin, Transverse shear, Cohesive zone modeling

Abstract
This paper deals with the development of a numerical approach to study damage initiation in flawed launcher laminated composite structures during pre-sizing phase. It is realised through a novel 2D-3D top-down loose coupling submodeling method adapted to large and complex composite structures. The aim of this numerical strategy is to address defects and damage as early as possible in the development stages of launcher composite structure. A new displacement interpolation based on a fourth order polynomial has been proposed and Reissner-Mindlin theory has been used in addition. Very accurate stress fields are obtained in the local area compared to a refined global model.

1. Introduction

The proportion of composites in Ariane launchers is constantly increasing at each new iteration. Conventional sizing methods of space structures are not suitable for taking into account defects/damage in these structures at the beginning of their development. Indeed, numerical simulations of large damaged composite structures involve high computational costs and are therefore not convenient to rapid pre-sizing loops. Global-local approaches have been developed as a reliable and efficient tool to study the onset and the propagation of damage.

1.1. COLIBRI dimensioning tool

COLIBRI is a platform developed and used by CNES for the design and dimensioning of composite structures for space launch vehicles [16]. This tool sets the critical load threshold before any damage occurs and take into account manufacturing and operational defects via knockdown factors to ensure damage tolerance. More complex methods exist but they come at the end of the development phase, once the architecture is fixed. Therefore, the chosen structure is optimal to meet the specifications but is not necessarily the most efficient to withstand the presence of defects or damage. It is therefore necessary to deal with defects and damage as early as possible in the development phases of the structure.

The composite structures optimised in COLIBRI present large dimensions. In addition, previous studies conducted by CNES and CTI have shown that 3D modeling of the structure, using cohesive elements, is essential to represent damage such as delamination. Due to high computational costs, performing damage calculations on these whole structures is not a feasible solution at the pre-dimensioning stage. In addition, damage initiation and propagation are generally local phenomena that are triggered in stress concentration zones with pre-existing defects such as manufacturing or assembly imperfections, service damage or inadequate maintenance [19].

This dilemma between calculation times adapted to pre-dimensioning and an accurate representation of defects and damage within a composite structure can be addressed by means of submodeling.

1.2. Global-local approach

1.2.1 Global-local methods overview

Widely developed over the last two decades, there are now several categories of global-local approaches. The method most commonly used in industry and commercial software is a top-down loose coupling approach. As shown in Figure 1, it is a two-stage process. First, a simulation is performed on a complete structure with a coarse mesh ("global model"). Then, a new simulation with a refined mesh is carried out on the specific areas to be studied ("local models"). These are two separate models. This is why they are referred to as loose coupling.

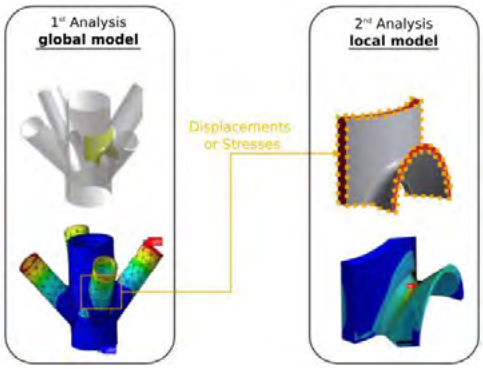

Figure 1. Illustration of top-down approach.

Mechanical quantities are extracted from the global solution and are used as boundary conditions of the local model. Displacements [8, 9, 22] are generally preferred to stresses [15, 30] as prescribed quantities at the boundaries of the local domain because of their higher convergence rate.
Despite its advantages, the top-down approach is limited to cases where the overall response of the structure is not likely to be significantly influenced by the local behaviour. On the other hand, bi-directional submodeling [2, 12, 14, 19, 37] is extremely well suited to damage propagation. Indeed, local information are transferred back to the global model and the global-local process becomes iterative.

1.2.2 Local boundary conditions

After the global static analysis, translations and rotations are known at the global nodes (Figure 2). These data need to be transferred to the local domain interface. The local model has a more refined mesh than the global model. Consequently, intermediate values of displacement along the boundary must be determined. Initially, displacement interpolation was performed using linear shape functions. Later, authors proposed the use of Lagrange interpolation [35] or cubic splines [9].

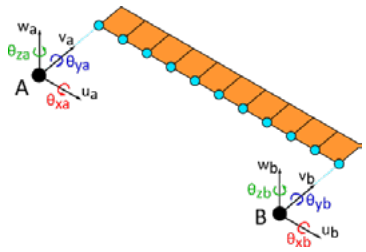

Figure 2. Nodal displacements after global static analysis.

Secondly, the position of the local model boundary is another key point in the success of the global-local approach. As shown by Mao [22], applying displacements at the interface introduces adverse

effects in the accuracy of the solution of the local static problem. They proposed a widely adopted method which involves the use of a transition zone placed around the critical zone, as shown in Figure 3.

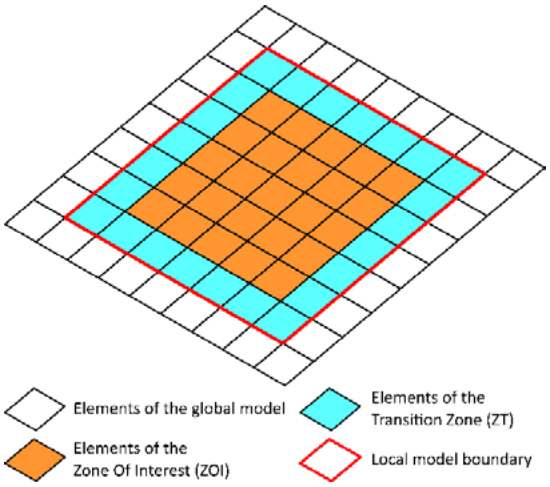

Figure 3. Local model with transition zone.

The suggested size of the transition area is equivalent to a coarse mesh element. As a result, the local model does not correspond exactly to the area of interest, the size of model is increased. [33] studied the effect of interpolation functions on the fidelity of the results obtained for local simulation. Shape functions introduce singularities in the stress field, whereas a cubic spline interpolation generates results in agreement with the exact values. Furthermore, the use of cubic splines would allow to have local boundaries closer to the critical zone. On the contrary, using shape functions would require enlarging the local domain to reduce the impact of singularities at the boundaries.

1.3. Damage modeling

1.3.1 Delamination modeling

Delamination is one of the three main failure mechanisms in laminated composites. This separation of adjacent plies usually occurs in preferred areas and leads to significant decreases in the material strengths. Delamination in composites is often modeled using Virtual Crack Closure Technique (VCCT) or by cohesive interface elements. VCCT is based on linear fracture mechanics and assumes that the energy released during delamination propagation is equal to the work required to close the crack [17, 18, 31]. The main drawback of this technique is that the crack initiation zone must be known in advance, which can be difficult for large complex structures. Cohesive Zone Modeling (CZM), proposed by [4, 20] is another main approach to represent delamination onset and propagation. The behaviour of the cohesive interface is defined by a traction-separation law relating interfacial stresses and displacement jumps at the interface of potential crack. Different forms of cohesive law have been studied in the literature; bilinear, exponential, trapezoidal,...[1, 6, 13]. Both methodologies (VCCT and CZM) have already been studied in the scope of submodeling to represent delamination onset and propagation [2, 5, 17, 34].

1.3.2 Porosity modeling

Voids can be located within a ply (intra-ply voids), as well as in the interface between two plies (inter-ply voids). The presence of voids degrades the mechanical properties dominated by the matrix and the interface [23, 24]. Micro-models are the main category of void modeling [3, 10, 36]. This is mainly because the behaviour of the porous materials is impacted by the location of voids in the laminate but also by their size, shape or distribution [26, 27].
From the point of view of pre-dimensioning, it is not possible to go down to such a small scale and to represent the voids in the material so finely. [20] uses CZM to simulate the presence of inter-ply voids.

Finally, knock-down factors can be used [25] as well as empirical laws to determine the material strength reduction [7, 11, 21, 32].

1.3.3 Matrix cracking modeling

Matrix cracking is one of the first damage modes in composite laminates subjected to mechanical and/or thermal loads. A first way to represent intra-laminar cracking is based on continuous damage mechanics (CDM). Developed over the last two decades, eXtend Finite Element Model (XFEM) allows the modeling of crack initiation and propagation without prior knowledge of the crack path or the need to update the mesh. It has been successfully used in the case of the global-local approach [26, 29]. XFEM can be coupled with CZM, and matrix cracking can also be simulated using cohesive elements [6, 28].

1.4. Objectives

The objectives of the present work is to develop a numerical strategy to take into account the presence of defects and damage in laminated composite structures during pre-sizing stage. The proposed approach allows to go from large dimensional structures represented with 2D shell elements to 3D local areas where defects such as porosity, matrix cracking and delamination have been inserted. Sometimes hard to detect, those damage can lead to a decrease in mechanical properties and a loss of strength. Furthermore, when the structure is loaded, and especially in a reuse scenario, this damage can propagate and lead to final failure with dramatic consequences. For all these reasons, it is important to understand and characterise the behaviour of damaged composite structures:

- At the design level, to improve the performance of structures, challenge mass and cost by accepting to live with damage while avoiding loss of integrity
- At the backup level to be able to confidently predict the propagation of damage and characterise the shape and size of fragments after an accidental event or after neutralisation of the launcher.

This work is a first part in the development of the global/local strategy for modeling damage initiation and propagation in launcher composite structures during pre-sizing phase. The methodology developed focuses therefore on the initiation of damage in the presence of defects.

Most of the works develop their approach via the commercial software Abaqus or use the submodeling module directly implemented in this same software. Here, everything is realized through the numerical solver Nastran only. The automation process is carried out by means of routines written in Python.

2. Developed approach

2.1. Top-down, loose coupling, shell to 3D solid submodeling

The aim of the proposed approach is to detect the onset of damage in laminated composite structures which may have manufacturing or operational defects. Hence the one-way loose coupling global-local methodology is suitable for this problem. As shown in Figure 4, two distinct simulations are performed, one after the other. The information flows from the "global" model to the distinct "local" model.

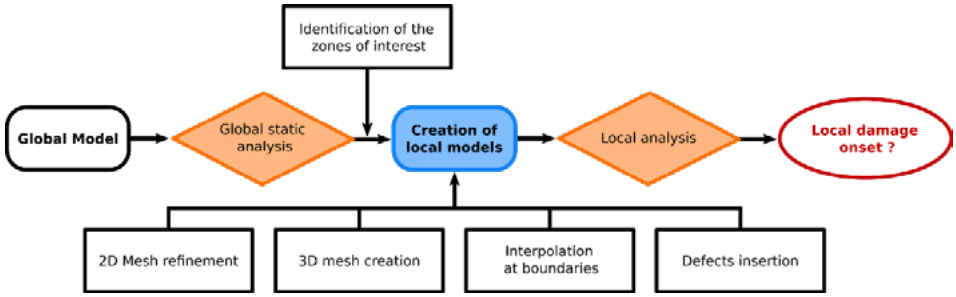

Figure 4. Flowchart of the unidirectional loose coupling procedure.

2.2. Local model's boundary conditions

A key to submodeling is the transfer of information between global and local scales. In the proposed approach, the displacements have been chosen to serve as boundary conditions for the refined local

calculations. The displacements are only known at the nodes of the original mesh. Two steps are then necessary to constrain all the boundaries of the local domain. First, the displacements must be interpolated at the nodes present in the plane on the local mesh boundary. This corresponds to step 1 in Figure 5. In this way, the intermediate values of the displacement between two adjacent nodes of the global mesh (between A and B in the example) are obtained. Because of the three-dimensionality of the local model, a second step is necessary to determine the displacements in the thickness of the boundaries. It is represented in step 2 of Figure 5.

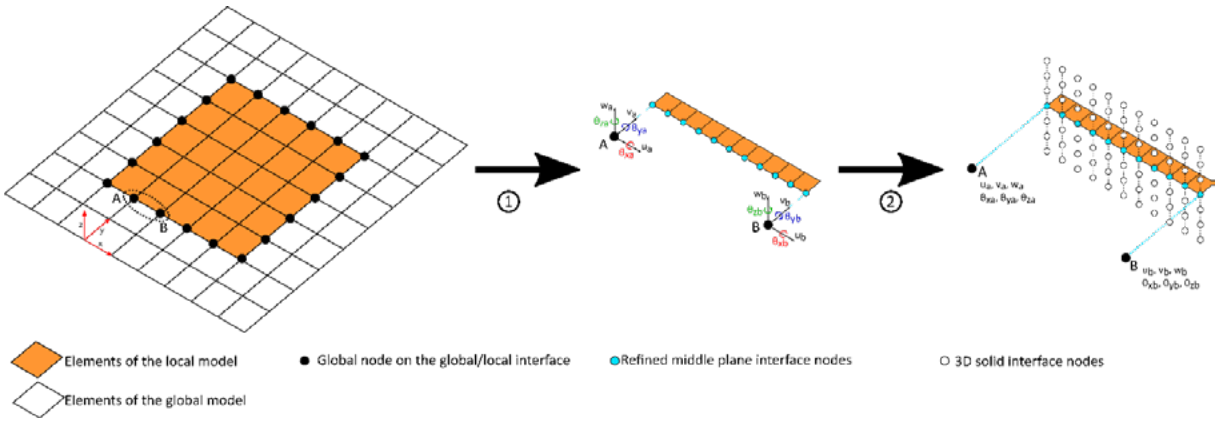

Figure 5. Boundary conditions interpolation steps.

2.2.1 2D shell local model

For the first part of the displacement interpolation, the displacements u and v (in the (x,y) plane) have been linearly interpolated. The interpolation proposed here for out-of-plane displacements w is carried out global element by global element. After the first global simulation, 12 data items are available in each global element: 4 displacements w, 4 rotations around the x axis and 4 rotations around the y axis. A polynomial of order 4 is therefore required to determine w(x,y). As the 4th-order basis is composed of 20 coefficients, truncation was chosen in accordance with the literature:

$$w(x,y)=A_1 x^3 y+A_2 xy^3+B_1 x^3+B_2 y^3+B_3 x^2 y+B_4 xy^2+ C_1 x^2+C_2 y^2+C_3 xy+D_1 x+D_2 y+E \quad (1)$$

According to Reissner-Mindlin theory, the rotations θ_x and θ_y are defined by Eq. 2 and Eq. 3 respectively.

$$\frac{\partial w(x,y)}{\partial y} = k_y \gamma_{yz}^0 + \theta_x \quad (2)$$

$$\frac{\partial w(x,y)}{\partial x} = k_x \gamma_{xz}^0 - \theta_y \quad (3)$$

Where γ_{xz}^0 and γ_{yz}^0 are the mean transverse shear strain of the laminate, k_x and k_y are transverse shear correction coefficients.

2.2.2 3D local model

The proposed approach allows to go from a global model meshed with 2D shell elements to a local model meshed with 3D solid shell Nastran elements. The model will be used in fast optimisation loops during the pre-dimensioning phase of composite structures. Thus, to keep it efficient and to reduce the computational cost, only one 3D element is used in the thickness of a ply. The displacements interpolated at the boundary via the Eq. 1, Eq. 2 and Eq. 3 must then be transformed in pure translational displacement degrees of freedom at each boundary node. For this purpose, the Reissner-Mindlin displacement field defined by Eq. 4 will be used.

$$\begin{cases} u(x,y,z) = u_0 - z\dfrac{\partial w(x,y)}{\partial x} \\ v(x,y,z) = v_0 - z\dfrac{\partial w(x,y)}{\partial x} \\ w(x,y,z) = w_0 \end{cases} \quad (4)$$

Where u_0, v_0 and w_0 are the displacements of the nodes located at the mid-surface.

2.3. Numerical validation

In order to determine the performance of both interpolation steps, multiple simulations have been conducted. Different stacking sequences were studied. The plates were subjected to four loading cases: tension, shear, bending and torsion. All type of loadings are schematized in Figure 6. Local simulations have been carried in presence of transition zone.

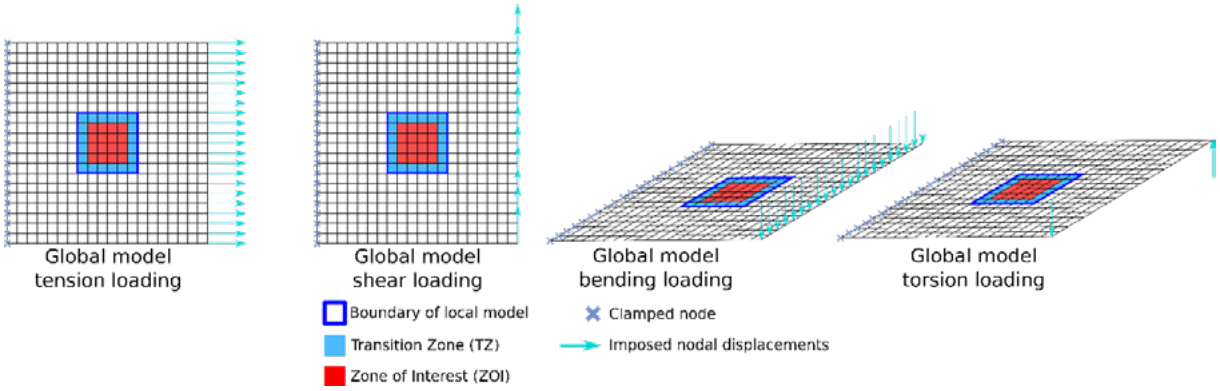

Figure 6. Schematisation of the different modeled loading scenarios.

For each type of solicitations, three models were carried out:

- coarse global model,
- fine global model,
- local model with a mesh size as fine as the fine global model.

The design of experiments was conducted on a 200mmx200mm composite plate meshed with shell elements. The analyses have been done on the following stacking sequences: $[0]_{10}$ and $[45/90/-45/0/0]_s$. The ply thicknesses were all equal to 0,15mm. The material properties are available in the Table 1.

Table 1. Material properties used for analysis.

Material Properties	E_{11} (GPa)	E_{22} (GPa)	E_{33} (GPa)	G_{12} (GPa)	G_{23} (GPa)	G_{13} (GPa)	ν_{12}	ν_{23}	ν_{31}
	160	9.9	9.9	6.1	6.1	3.8	0.33	0.3	0.0178

The elements of the global coarse model have a size of 10mmx10mm. The size of the elements of the fine global model and of the local model is 1mmx1mm. Hence, it corresponds to a factor 10 refinement. The results in the area of interest of the local model were then compared with those of the fine global model. The relative deviation to the ply mean stress has been computed using the Eq. 4.

$$\Delta\sigma_{ij} = \frac{|\sigma_{ij,global}| - |\sigma_{ij,local}|}{|\sigma_{ij,ply,global}|} \quad (4)$$

Where $\Delta\sigma_{ij}$ represents the relative deviations for the stress ij and the index i,j = x,y. $\sigma_{ij,global}$ are the stress ij in the elements of the refined global model and $\sigma_{ij,local}$ are those in the elements of the local model. In this study, the difference is divided by the mean value of the absolute stress in the concerned ply, noted $\overline{|\sigma_{ij,ply,global}|}$. Finaly, $|\overline{\Delta\sigma_{ij}}|$ is the absolute mean values of the concerned $\Delta\sigma_{ij}$. As shown in Table 2, the developed interpolations allows a very satisfying correlation under all types of solicitation

Table 2. Table of relative deviations in stresses for thin 3D model obtained via 3D local and 2D shell fine global simulations for each loading case.

Load cases	Stacking sequences	$\|\overline{\Delta\sigma_x}\|$	$\|\overline{\Delta\sigma_y}\|$	$\|\overline{\Delta\sigma_{xy}}\|$
Tension	$[0]_{10}$	0.002 ± 0.007	X	X
	[45,90,-45,0,0]s	0.04 ± 0.02	0.46 ± 0.41	0.02 ± 0.003
Shear	$[0]_{10}$	1.9 ± 2.47	0.35 ± 0.3	0.04 ± 0.02
	[45,90,-45,0,0]s	0.86 ± 1.36	0.76 ± 1.16	0.82 ± 1.73
Bending	$[0]_{10}$	0.02 ± 0.02	0.16 ± 0.24	16.0 ± 14.6
	[45,90,-45,0,0]s	0.15 ± 0.17	0.37 ± 0.08	0.36 ± 0.44
Torsion	$[0]_{10}$	0.40 ± 0.31	0.39 ± 0.37	0.23 ± 0.04
	[45,90,-45,0,0]s	0.31 ± 0.13	0.29 ± 0.13	0.45 ± 0.43

For instance, the Figure 7 shows the comparison between the stress field σ_x in the zone of interest obtained after a fine global simulation and a 3D local one. The results concern the bending load case of the $[0]_{10}$ plate.

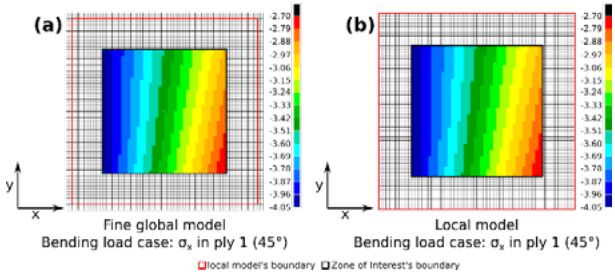

Figure 7. Field σ_x in ply 1 for bending load case

2.4. Local damage introduction

Defects and damage such as porosity, matrix cracking and delamination are inserted into the local model. The onset and progress of delamination will be represented using cohesive elements placed at the interface between plies. These are linear 3D elements with zero thickness. In order to limit the size of the local model, cohesive elements are not inserted between all plies but only at the interfaces where delamination is likely to occur, i.e. between plies of different orientations. Being the most present in the literature, the bilinear cohesive law will been used in the first instance. Currently, porosity and matrix cracking will be modeled via damage variable which will tackle the material properties. Indeed, using cohesive elements to represent matrix cracking could lead to high computational costs and is not in line with the pre-sizing approach. The damage process is automated via Python routines. The proposed approach is illustrated in Figure 8.

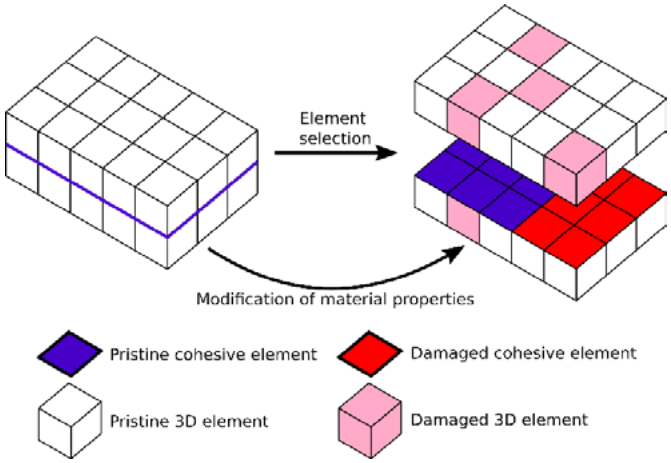

Figure 8. Automated damage process

3. Conclusions

In this paper, a 2D-3D top-down loose coupling submodeling approach adapted to the pre-dimensioning of large composite structures has been formulated. This method is fully compatible with the Nastran solver and allows the local insertion of defects such as porosity, matrix cracking and delamination.
A new displacement interpolation based on a fourth order polynomial and Reissner-Mindlin theory has been proposed. Although this interpolation does not eliminate the need for a transition zone, the very good correlation between the stress fields obtained via the refined global model and the local 3D model demonstrates the effectiveness of the interpolation formulated.
Regarding the insertion of defects and the damage onset, the choice was made to use CZM to represent delamination. Damage variables will be used to model pre-delaminated elements and elements damaged by porosity and matrix cracking.
Finally, the experimental campaign is underway. It will be used to calibrate and validate the insertion of defects into the local model.

Keywords: Thermoplastics, Phase field method, Finite element analysis, Mechanical property

Abstract
Thermoplastic resins used in thermoplastic composite mostly have semi-crystalline properties. It is known that the microscopic structure changes depending on the crystallization temperature and that the mechanical properties change accordingly. In this study, the mechanical properties of thermoplastic resins are predicted by stepwise analysis combining crystallization simulation based on the phase field method, followed by finite element analysis using the obtained crystalline structure. In the crystallization simulation, the effect of crystallization temperature at the isothermal crystallization process is considered. The constitutive equations are based on the assumption that the amorphous phase exhibits elastic or hyperelastic and perfectly plastic behaviors. In contrast, the crystalline phase behaves as an elastic and perfectly plastic solids. Finally, the accuracy of this method is validated by comparing the simulation result with experimentally obtained Young's modulus, Poisson's ratio, and yield stress.

1. Introduction

Recently used in the aerospace industry, Carbon Fiber Reinforced Plastics (CFRPs) have excellent specific stiffness and specific strength. Resins used as base materials for CFRPs are broadly classified into thermosetting resins and thermoplastic resins. The former irreversibly hardens through a cross-linking reaction by heating, while the latter reversibly softens, melts, and solidifies by heating and cooling. CFRPs using thermoplastic resins have been attracting attention in recent years from the viewpoints of productivity and recyclability. Polyphenylene Sulfide (PPS) and Polyaryl Ether Ketone (PAEK), which are thermoplastic resins used as matrices for CFRPs such as aircraft components, have crystalline properties and crystallize upon cooling. These resins have a semi-crystalline microstructure with a mixture of crystalline and amorphous phases, as shown in Fig. 1[1]. The crystalline structure (degree of crystallinity and grain size) varies depending on molding conditions, including crystallization temperature. In addition to this property, the crystalline and amorphous phases are known to have different material properties [2,3,4]. Therefore, to predict the mechanical properties of semi-crystalline thermoplastics, it is essential to consider the molding conditions, the associated crystal structure, and the mechanical properties of each phase.

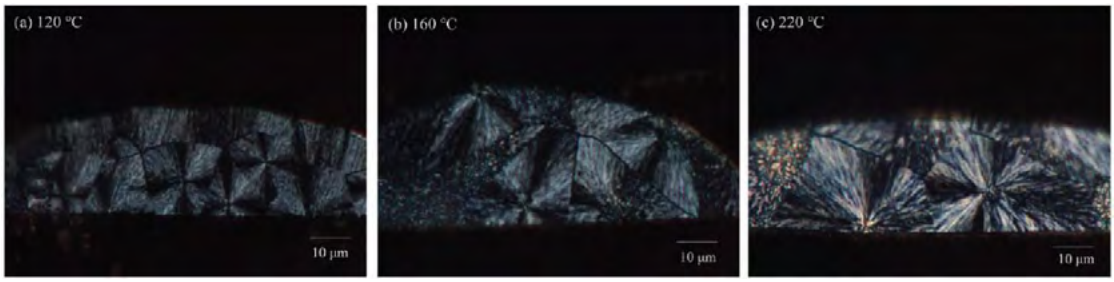

Figure 1. Polarizing optical microscopy image of isothermally melt-crystallized PPS [1].

In this study, PPS, one of the resins with excellent mechanical properties such as stiffness and strength, is studied using a two-step analysis to predict its mechanical properties. First, crystallization simulation with the phase field method is used to obtain the crystal structure that changes with crystallization temperature during the isothermal crystallization process. Next, based on the results of the crystallization analysis, finite element analysis using different material constants for the crystalline and amorphous phases is performed to evaluate the change in mechanical properties as the forming temperature changes. The predicted results are compared with experimental results to verify the validity of the developed method.

2. Crystallization Simulation

2.1. Crystal Growth Model

2.1.1. Phase Field Method

This study uses the phase field method to describe the crystal growth of thermoplastic resin. Interfacial migration is expressed by solving the time evolution equation of ϕ in the phase field method, where $\phi = 0$ is the amorphous phase, $\phi = 1$ is the crystalline phase. This study uses the following governing equations[5,6], where ϕ is a function of position $\boldsymbol{r}$ and time t.

$$\frac{\partial \phi(\boldsymbol{r},t)}{\partial t} = -M_\phi \frac{\delta F(\phi)}{\delta \phi(\boldsymbol{r},t)}. \tag{1}$$

$$F(\phi) = \int f_{\mathrm{cryst}}(\phi) dV = \int \left[f_{\mathrm{local}}(\phi) + f_{\mathrm{grad}}(\phi) \right] dV . \tag{2}$$

$$f_{\mathrm{local}}(\phi, T) = W \int_0^\phi \phi \left(\frac{1}{2} - \phi - m(T) \right) (1-\phi) d\phi . \tag{3}$$

$$f_{\mathrm{grad}}(\phi) = \frac{1}{2} \kappa^2 (\nabla \phi)^2. \tag{4}$$

$F(\phi)$ in Eq. (1) represents the free energy. $f_{\mathrm{local}}(\phi)$ is the local free energy density, $f_{\mathrm{grad}}(\phi)$ is the gradient energy density. M_ϕ in Eq. (1) is the interface mobility, W is a parameter related to the energy barrier, and κ is the gradient coefficient. $m(T)$ is a function of temperature and takes positive values when lower than the melting point. In this analysis, we use the following equation, a dimensionless version of the above equation

$$\tau^* \hat{\varepsilon}^2 \frac{\partial \phi}{\partial t} = \left[\hat{\nabla} \cdot \left(\frac{1}{2} \left(\hat{\nabla} \phi \right)^2 \frac{\partial (\hat{\varepsilon}^2)}{\partial \hat{\nabla} \phi} \right) + \hat{\nabla} \cdot \left(\hat{\varepsilon}^2 \hat{\nabla} \phi \right) - W \phi (\phi - 1) \left(\phi - \frac{1}{2} + m(T) \right) + a \phi (1-\phi) R_{\mathrm{v}} \right] \tag{5}$$

$$\frac{\partial \hat{T}}{\partial \hat{t}} = \hat{\nabla}^2 \hat{T} + \hat{K} \frac{\partial \phi}{\partial \hat{t}}. \tag{6}$$

$$m(\hat{T}) = \frac{a_\mathrm{k}}{\pi} \arctan\left(\gamma(1-\hat{T})\right). \tag{7}$$

with $\hat{T} = (T - T_\mathrm{c})/(T_\mathrm{m} - T_\mathrm{c})$, $\hat{\tau}^* = k_\mathrm{t}/(\rho C_\mathrm{p} \varepsilon M_\phi)$, $\hat{K} = \Delta H_\mathrm{c}/(C_\mathrm{p}(T_\mathrm{m} - T_\mathrm{c}))$, where ρ is density, C_p is constant pressure specific heat, k_t is thermal conductivity, and ΔH_c is latent heat. Also, using representative length D and representative time $\tau = D^2 \rho C_\mathrm{p}/k_\mathrm{t}$, $d\hat{x} = dx/D$, $d\hat{y} = dy/D$, and $d\hat{t} = dt/\tau$ are expressed. $R_\mathrm{v} \in [-1/2, 1/2]$ in Eq. (5) is a random number. $a\phi(1-\phi)R_\mathrm{v}$ denotes the interface noise.

In addition, to introduce the property of temperature dependence of crystallization rate in polymer materials, the simulation model of Bahloul et al [6] is used in Eq. (8). In the analysis, we use the form of Eq. (9), normalized and simplified by the maximum value of the crystallization rate, and treat $\hat{\tau}^*$ and $\hat{K}$ as functions of $\hat{T}$, as shown in Eqs. (10) and (11).

$$G(T_\mathrm{c}) = G_0 \exp\left(-\frac{U}{k(T_\mathrm{c} - T_\infty)}\right) \exp\left(-\frac{K}{T_\mathrm{c}(T_\mathrm{m}^0 - T_\mathrm{c})}\right). \tag{8}$$

$$H(T_\mathrm{c}) = \frac{G(T_\mathrm{c})}{G(T_\mathrm{cmax})} \cong h_0 \exp\left(-\frac{h_1}{T_\mathrm{c} - T_\infty}\right) \exp\left(-\frac{h_2}{T_\mathrm{m}^0 - T_\mathrm{c}}\right). \tag{9}$$

$$\tau^*(T_\mathrm{c}) = \begin{cases} \tau_0^* & (T_\mathrm{g} \le T_\mathrm{c} \le T_\mathrm{cmax}) \\ \tau_0^*/H(T_\mathrm{c}) & (T_{cmax} \le T_\mathrm{c} \le T_\mathrm{m}^0) \end{cases}. \tag{10}$$

$$\hat{K}(T_\mathrm{c}) = \begin{cases} \hat{K}_0/H(T_\mathrm{c}) & (T_\mathrm{g} \le T_\mathrm{c} \le T_\mathrm{cmax}) \\ \hat{K}_0 & (T_\mathrm{cmax} \le T_\mathrm{c} \le T_\mathrm{m}^0) \end{cases}. \tag{11}$$

T_cmax is the temperature at which the crystallization rate reaches its maximum value, and h_1 and h_2 are parameters. The material constants used are shown in Table 1 and the values obtained from the DSC test by Kato et al. were used [7]. Other material constants are taken from a previous study [6].

2.1.2. Parameter Identification

To identify the parameters h_1 and h_2 when using Eq. (9), we first analyzed a single spherical crystal at several crystallization temperatures. For one spherulite with a nucleus placed at the center of the analysis area of 50 μm × 50 μm and mesh size 500 × 500, the average growth rate was obtained from the central nucleus at angles near 0° and 45° to the x-axis as shown in Fig. 2, and $H(T_\mathrm{c})$ was calculated. The Lauritzen-Hoffman equation in Eq. (9), the experimental values from Lovinger et al. [8], and the results of the parameter identification are shown in Fig. 3. In the following analysis, $h_1 = 80$ and $h_2 = 66.73$ obtained from this simulation are used.

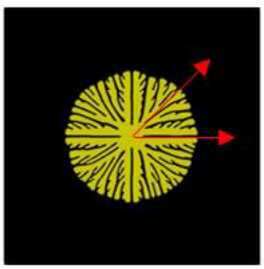

Figure 2. Simulation of PPS crystallization and direction for calculating crystallization rate.

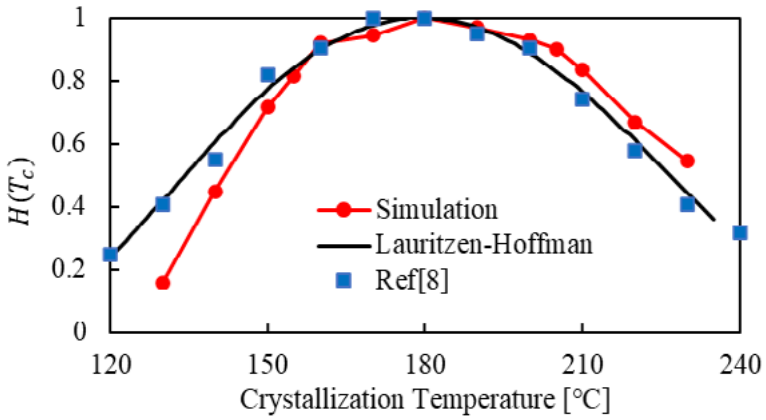

Figure 3. Relationship between crystallization temperature and crystallization rate.

2.2 Multicrystal Simulation

A nucleation model is also introduced since the phase field method can only handle crystal growth. The nucleation rate dN/dt in homogeneous nucleation of polymeric materials is expressed by Eq. (12) using the parameters C_1 for transport of molecular chains and C_2 for primary nucleation [9].

$$\frac{dN(T(t))}{dt} = N_0 \exp\left[-\frac{C_1}{T(t)-T_\infty}\right] \exp\left[-\frac{C_2(T(t)+T_\mathrm{m})}{T(t)^2(T_\mathrm{m}-T(t))}\right]. \tag{12}$$

The nucleation rate is known to affect the size of spherulites as well as the crystallization rate. During isothermal crystallization, spherulites with sizes of 10 μm at $T_\mathrm{c} = 120°\mathrm{C}$, 20 μm at $T_\mathrm{c} = 160°\mathrm{C}$, and 30-40 μm at $T_\mathrm{c} = 220°\mathrm{C}$ have been observed [1], and the values of C_1, C_2, and N_0 obtained by fitting were used in the analysis.

In this study, crystallization analysis is performed on neat PPS. The analysis is performed by discretizing Eqs. (5) and (6) using the finite difference method. The simulation is performed under isothermal conditions at three different temperatures: $T_{\mathrm{cmax}} = 180°\mathrm{C}$, which is the crystallization temperature with the maximum crystallization rate, and $T_\mathrm{c} = 150°\mathrm{C}$ and $210°\mathrm{C}$, which are $T_{\mathrm{cmax}} \pm 30°\mathrm{C}$. The analysis area is $100\ \mu\mathrm{m} \times 100\ \mu\mathrm{m}$ with a mesh size of 1000×1000. Five analyses are performed to account for nucleation and randomness of the crystal structure. Fig. 4(a)-(c) shows results at each crystallization temperature.

3. Finite Element Analysis

Based on the results obtained from the crystallization analysis, homogenized finite element analysis was performed to obtain the mechanical properties. A square mesh was automatically generated using the difference grids used in the crystallization analysis as nodes for FEM.

The results of the crystallization analysis used are those at the time when the change in the average value of the phase field variable over the entire analysis domain is sufficiently small. The dimensioned times t of the results are 1.67×10^{-4} s at $T_\mathrm{c} = 150$ and $210°\mathrm{C}$ and 1.39×10^{-4} s at $T_c = 180°\mathrm{C}$. The mesh size is 1000×1000 and two-dimensional solid elements are used. The finite element method software

Table 1. Material parameters of PPS in crystallization simulation.

$T_\mathrm{g} = 100°\mathrm{C}$	$T_\mathrm{m}^0 = 280.5°\mathrm{C}$	$T_{\mathrm{cmax}} = 180°\mathrm{C}$	$\tau_0^* = 3.0$
$d\hat{t} = 0.1$	$W = 2.0$	$\hat{\varepsilon} = 1/3$	$\hat{K} = 1.4$
$D = 10^{-7}$ m	$a = 0.02$	$a_\mathrm{k} = 0.9$	$\gamma = 10$
$d\hat{x} = d\hat{y} = 1$			

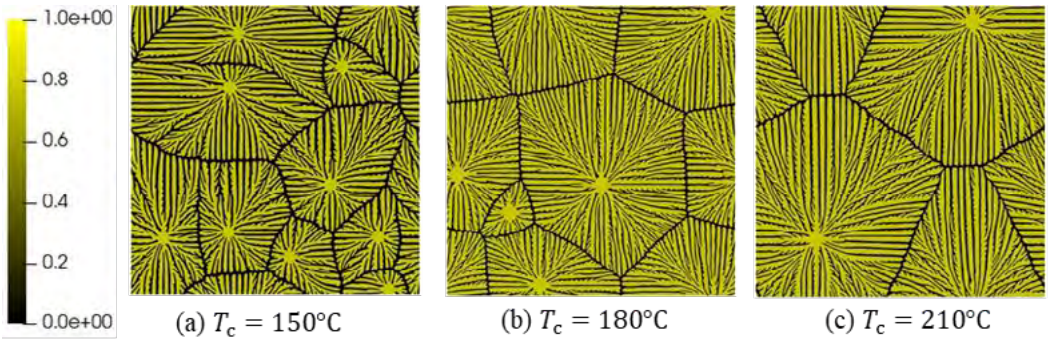

Figure 4. Distribution of phase field variable.
($\phi = 1$ in crystalline phase, and $\phi = 0$ in amorphous phase.)

Abaqus 2019 was used for the analysis.

3.1 Material Model and Boundary Conditions

In the following finite element analysis, the material constants and constitutive equations for the phase field variable $\phi < 0.5$ for the amorphous phase and $\phi \geq 0.5$ for the crystalline phase will be used at each integration point in the finite element.
First, elastic analysis is performed under two assumptions: Model 1: both amorphous and crystalline phases are linearly elastic; Model 2: the amorphous phase is hyperelastic, and the crystalline phase is linearly elastic. The energy density function U is expressed in Eq. (13) using the first-order invariant I_1 of the right Cauchy-Green tensor and the determinant J of the deformation gradient tensor $\boldsymbol{F}$,

$$U = C_{10}(I_1 - 3) + \frac{1}{D_1}(J-1)^2. \tag{13}$$

$$I_1 = \lambda_1^2 + \lambda_2^2 + \lambda_3^2. \tag{14}$$

$$J = \det(\boldsymbol{F}) = \lambda_1\lambda_2\lambda_3. \tag{15}$$

where C_{10} and D_1 are material constants expressed as $C_{10} = G/2$, $D_1 = 2/K_0$ using the initial shear modulus G and volume modulus K_0. Also, λ_i is called the principal stretch and expressed as $\lambda_i = (L_i + u_i)/L_i$ $(i = 1,2,3)$, where L_i is the length before deformation and u_i is the deformation length.
Based on the results of the elastic analysis, the yield stress is obtained by analyzing Model 3: Model 1 with full plasticity based on Mises stress in each phase. Here, 0.2% offset stress is used as the yield stress. Young's modulus to calculate the yield stress is obtained from elastic analysis using the same crystal structure. In both elastic and elastoplastic analyses, the crystal structure is considered to be periodic in a two-dimensional plane, and a periodic boundary condition based on the displacement is added to analyze the plane strain state. In the displacement condition, a macroscopic strain of 3% is applied only in the x- or y-direction. However, if the yield stress could not be obtained in the elastoplastic analysis in the strain range of 3% or less, an macroscopic strain is imposed to the analysis. The macroscopic Young's modulus, Poisson's ratio, and yield stress were obtained from the average stress and macroscopic strain in the analysis region. The material constants used in each finite element analysis are shown in Table 2. The Young's modulus E_c of the crystalline phase was taken from a previous study [10], and the other material constants marked with * were estimated values.

4. Results and Discussion

The relationship between the crystallization temperature and the average values of macroscopic Young's modulus and Poisson's ratio obtained by elastic analysis is shown in Figs. 5(a) and (b). The legend indicates the amorphous/crystalline phase model and the error range indicates the standard deviation.

Table 2. Material parameters of PPS in homogenization simulation.

Amorphous Phase		Crystalline Phase
$E_a^* = 200$ MPa	C_{10}^*=31.25 MPa	$E_c = 28000$ MPa [9]
$\nu_a^* = 0.4$	$D_1^* = 0.006$ MPa^{-1}	ν_c^*=0.3
$\sigma_{Ya}^* = 100$ MPa		$\sigma_{Yc}^* = 400$ MPa

The average values were obtained from the results of x and y tension analyses for each crystallization analyses. Higuchi et al. [11] reported that Young's modulus is higher, and Poisson's ratio is lower at higher crystallization temperatures in experiment. As shown in Fig. 5(a), the tendency that Young's modulus increases with crystallization temperature is consistent to the experiments [11]. The difference grids are used in the crystallization analysis as the nodes for the finite element method. As shown in Fig. 4, the amorphous phase between the spherocrystals at $T_c = 150$ °C is thicker than that at other crystallization temperatures. This cause lower Young's modulus at $T_c = 150$ °C. To solve this, the crystallization analysis needs to be improved. This is a point that needs to be improved in the crystallization analysis. In addition, the large number of spherulite crystals greatly affected the effect of the amorphous phase between the spherulite crystals, resulting in an underestimation of Young's modulus. The Poisson's ratio was greatly affected by the appearance of the spherulites in the analysis region, and the standard deviation was the largest at $T_c = 210$°C, where the number of spherulites was the smallest. We plan to improve this point by expanding the analysis area and using a more coarse-grained model.

The relationship between crystallization temperature and yield stress is shown in Fig. 6(a). The stress-strain diagram obtained from the analysis using Model 3 is shown in Fig. 6(b). In tensile tests [10], it has been reported that yield stress increases as crystallization temperature do. In the present simulation, this tendency was obtained only between $T_c = 150$°C and 180°C. To discuss these results, the phase field variable distribution (crystalline/amorphous phase distribution) is shown in Fig. 4 for each crystallization temperature, one case at each temperature. The total strain, elastic, and plastic strain distributions in the tensile direction are shown in Figs. 7, 8, and 9 respectively. All tensile directions in these results are in the x direction. The yield stresses obtained in simulations are 66.89 MPa at $T_c = 150$°C, 74.85 MPa at $T_c = 180$°C, and 65.02 MPa at $T_c = 210$°C. Areas with compressive strain were found in the amorphous phase between the spherulite lamellae as shown in Figs. 7 and 8. In the amorphous phase between the grains, especially where the amorphous phase is vertically distributed to the tensile direction, the total strain is large, indicating that both elastic and plastic components contribute to the strain. The amorphous phase strain at the spherulitic grain boundaries surrounds the lamellar edge of the neighboring spherulites. On the other hand, the crystalline phase is characterized by a large strain at the nuclei centers of some of the spherulites, where the plastic strain is pronounced.

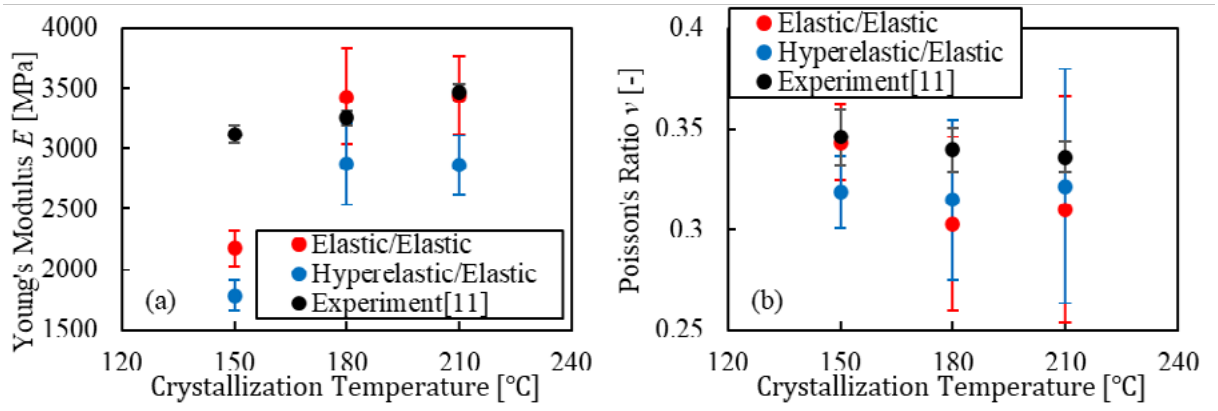

Figure 5. Macroscopic elastic properties gained in FE analysis. (a) Relationship between T_c and Young's modulus (b) Relationship between T_c and Poisson's ratio.

The plastic strain in the spherulite nuclei exists in a direction that connects plastic strain in the nearby amorphous phase. The above confirms the mechanical interaction between the amorphous and crystalline phases. At a crystallization temperature of 210°C, where the yield stress did not match the experimental trend, plastic strain is particularly dominant in the amorphous phase at the grain boundaries due to the low number of spherulites. This causes deformation of the entire region with small plastic deformation of the crystalline phase, resulting in a small increase in stress with increasing strain. This phenomenon is thought to be responsible for the small yield stresses.

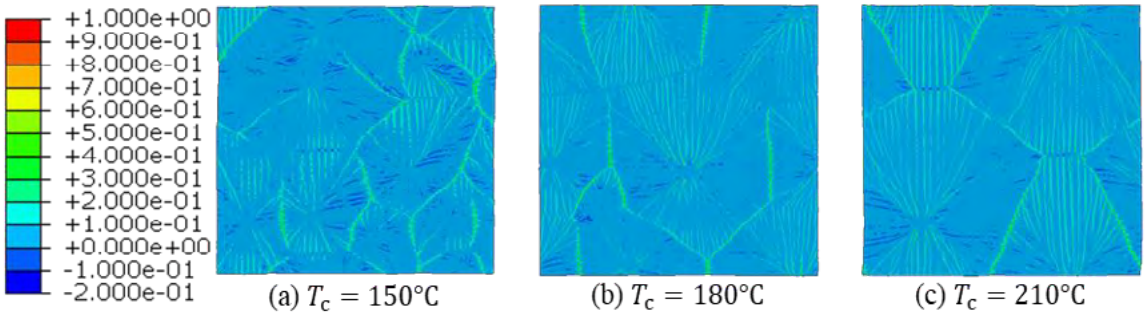

Figure 8. Elastic strain distributions in tension direction at (a) T_c = 150°C, (b) T_c = 180°C, and (c) T_c = 210°C.

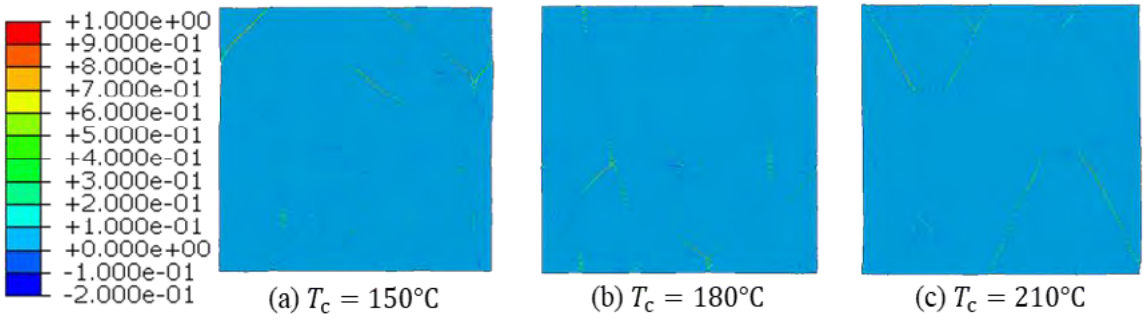

Figure 9. Plastic strain distributions in tension direction at (a) $T_c = 150°C$, (b) $T_c = 180°C$, and (c) $T_c = 210°C$.

5. Conclusion

In this study, isothermal crystallization analysis of PPS, a crystalline thermoplastic resin, was performed at different crystallization temperatures. Parameters related to crystallization and nucleation rate were identified, and the changes in crystal structure with crystallization temperature were captured. Using the microstructures obtained from the crystallization analysis, macroscopic elastoplastic properties were obtained by finite element analysis using different material constants and constitutive equations for the crystalline and amorphous phases. Qualitative agreement with experiments was obtained for Young's modulus concerning crystallization temperature. On the other hand, there were macroscopic mechanical properties and crystallization temperatures that did not capture the trends reported experimentally. In the future, not only crystallization analysis using the phase field method but also the development of constitutive equations used in finite element analysis and the introduction of elastic anisotropy are required to improve the accuracy.

Keywords: Carbon fibers, Topology optimization, Anisotropy, 3D printing

Abstract
This paper investigated the challenges and methodologies in anisotropic topology optimization for 3D printing, focusing on improving the mechanical properties of structures produced by fused deposition modeling (FDM). The study addressed the significant performance gap between theoretically optimized designs and their physical counterparts. The research adopted a dual optimization approach, utilizing scalar and vector functions to represent topology and fiber orientation, respectively. These functions are smoothed using a Helmholtz type partial differential equation to avoid common problems like checkerboard patterns in design. Optimization targets minimizing compliance to enhance structural stiffness, implemented using finite element methods (FEM). The design variables were updated by the method of moving asymptotes (MMA). Significant findings included the impact of design binarization, where densities were adjusted between solid and void, affecting the structure's compliance. Although a low-density region minimally affected overall compliance, it was critical for global optimal stiffness. The study demonstrated a substantial discrepancy between theoretical and actual design results for 3D printing, suggesting a need for refined optimization and design methods.

1. Introduction

3D printing technology has revolutionized the design and manufacturing fields in terms of its ability to create complex shapes and quickly give shape to ideas by importing CAD data. In particular, the fused deposition modeling (FDM) is one of the most popular methods for manufacturing prototypes. However, structural parts fabricated by the FDM method using polymer and short-fiber reinforced composites have relatively low mechanical properties, limiting their application to structural components [1]. In recent years, continuous fiber-reinforced composites have been focused on in the FDM method to improve mechanical properties.

Carbon fiber-reinforced plastics (CFRP), which have excellent mechanical properties such as specific strength and specific stiffness, have been applied in the aerospace, automotive, and marine fields. Among them, much attention has been paid to designing the structures with continuously varying fiber orientation by anisotropic topology optimization because those structures can effectively utilize the anisotropic nature of composites [2].

However, the design of CFRP in the context of 3D printing spans over different domain such as materials, structures and manufacturing and there are several challenges. One of the challenges is a big gap in mechanical performance between optimized continuous carbon fiber-reinforced composite structures and ones manufactured by the FDM method due to current limitations such as feasible printing curvature of continuous fibers and insufficient impregnation of reinforced fibers by matrix during printing [3]. Therefore, it is necessary to contrive ways to prevent the mismatch and improve the mechanical properties.

This study aims to quantitatively track the mismatch of mechanical properties in a series of design processes of continuous carbon fiber-reinforced composites for manufacturing by 3D printing, and to predict accurate mechanical properties. We hope to provide a new insight for enhancement of mechanical properties from the standpoint of computational mechanics.

2. Formulation

In this section, we first present the topology design representation by using a scalar function and a filter based on a Helmholtz type partial differential equation. Then, we similarly present the orientation design presentation by a vector function. Finally, optimization problem is introduced.

2.1. Topology design representation

To represent the topology, we defined a fixed design domain D and a scalar function $\phi \in [0,1]$ in D. Since ϕ can take arbitrary values for each point, problems such as checkerboard patterns can occur if it is used as a design variable that represents the topology as it is. Therefore, we considered a new scalar function φ that satisfied the following Helmholtz-type partial differential equation and the Neumann boundary condition to smooth the topology. This method is known to have implementation advantages in that it can utilize the already existing framework of finite element methods (FEM) such as geometry and mesh [4, 5].

$$-R_{\varphi}^{2}\nabla^{2}\varphi + \varphi = \phi, \tag{1}$$

$$\frac{\partial \varphi}{\partial \boldsymbol{n}} = 0. \tag{2}$$

R_{φ} is the filter radius with respect to the topology and functions like a low-pass filter by setting an appropriate value for R_{φ} [5]. Also, $\boldsymbol{n}$ is the normal vector to the boundary Γ. Then the material density function ρ can generally obtained by generally introducing a Heaviside function $H \in [0,1]$ and interpolating with a smoothed scalar function φ, so that ρ is forced to approach 0 or 1.

$$\rho(\varphi) = H(\varphi). \tag{3}$$

Since $\phi \in [0,1]$ in this study, $\varphi \in [0,1]$ is satisfied for any φ. Therefore, $H(\varphi)$ was defined by the following equation.

$$H(\varphi) = \varphi. \tag{4}$$

$\rho(\boldsymbol{x}) = 1$ denotes the solid domain Ω_D and $\rho(\boldsymbol{x}) = 0$ denotes the void domain $D \backslash \Omega_D$. The operation to clarify the boundary between 0 and 1 was performed after the optimization calculation, allowing for grayscale.
In addition, the following equation was assumed to hold between the material density $\rho(\boldsymbol{x})$ and the stiffness tensor $\mathbf{C}(\boldsymbol{x})$.

$$\mathbf{C}(\boldsymbol{x}) = \{\varepsilon + (1-\varepsilon)\rho(\boldsymbol{x})^P\}\mathbf{C}_{\boldsymbol{s}}. \tag{5}$$

$\mathbf{C}_{\boldsymbol{s}}$ is the solid stiffness tensor when $\rho(\boldsymbol{x}) = 1$, ε is a very small positive lower bound set for avoiding singularity and P is the density penalty parameter. In this study, $\varepsilon = 10^{-3}$ and $P = 3$ were set.

2.2. Orientation design representation

To represent the orientation design, we defined a vector function $\boldsymbol{\vartheta} = [\xi, \eta]^T, \{\xi,\ \eta \in [-1, 1]\}$ in D. We introduced an isoparametric shape function N and considered a vector function $\tilde{\boldsymbol{\vartheta}}$ that was defined by the following equation to obtain the fiber orientation vector $\boldsymbol{\theta}$.

$$\tilde{\boldsymbol{\vartheta}} = N(\boldsymbol{\vartheta}). \tag{6}$$

An isoparametric shape function N is such a function that transforms a square region in a 2D plane to a circular region in coordinates. The projected vector function $\tilde{\boldsymbol{\vartheta}} = \left[\tilde{\xi}, \tilde{\eta}\right]^T$ satisfies $\tilde{\xi}^2 + \tilde{\eta}^2 \leq 1$. For details on the formulation of this shape function N, please refer to the literature in Nomura [6]. The fiber orientation vector $\boldsymbol{\theta} = [\varsigma, \zeta]^T$ was defined as a vector function satisfying the following Helmholtz-type partial differential equation and the Neumann boundary condition as in the previous section.

$$-R_{\boldsymbol{\theta}}^2\nabla^2\begin{bmatrix}\varsigma\\ \zeta\end{bmatrix} + \begin{bmatrix}\varsigma\\ \zeta\end{bmatrix} = \begin{bmatrix}\tilde{\xi}\\ \tilde{\eta}\end{bmatrix}, \tag{7}$$

$$\frac{\partial \varsigma}{\partial \boldsymbol{n}} = 0, \qquad \frac{\partial \zeta}{\partial \boldsymbol{n}} = 0. \tag{8}$$

R_θ is the filter radius with respect to the fiber orientation. If the fiber orientation angle $\psi \in [0, 2\pi]$ was defined as the angle between $\boldsymbol{\theta}$ and the unit vector $[1, 0]^T$, the stiffness tensor $\tilde{\mathbf{C}}(\boldsymbol{x})$ rotated by ψ around any point $\boldsymbol{x}$ satisfied the following equation.

$$\tilde{\mathbf{C}}(\boldsymbol{x}) = \mathbf{T}(\psi)\mathbf{C}(\boldsymbol{x})\mathbf{T}^{\boldsymbol{T}}(\psi). \tag{9}$$

$\mathbf{T}$ is the rotation tensor. In combination with the previous section, the stiffness tensor $\tilde{\mathbf{C}}(\boldsymbol{x})$ considering anisotropy at a point $\boldsymbol{x}$ is determined by the material density $\rho(\boldsymbol{x})$ and the fiber orientation angle $\psi(\boldsymbol{x})$, and is expressed as

$$\tilde{\mathbf{C}}(\boldsymbol{x}) = \{\varepsilon + (1-\varepsilon)\rho(\boldsymbol{x})^P\}\mathbf{T}(\psi)\mathbf{C}_{\boldsymbol{s}}\mathbf{T}^{\boldsymbol{T}}(\psi). \tag{10}$$

2.3. Optimization problem

The considered optimization problem is the minimization of the compliance, which means the maximization of the global stiffness. The objective is to find a material distribution in the fixed design domain D, which minimizes the compliance for a given set of loads and boundary conditions. The material behavior is liner elastic.

Formulation of the problem is expressed as

$$\min_{\phi,\vartheta} f = \int_D \boldsymbol{\varepsilon} : \tilde{\mathbf{C}} : \boldsymbol{\varepsilon}\, d\Omega, \tag{11}$$

subject to

$$\phi \in [0,1], \tag{12}$$

$$\xi \in [-1,1], \tag{13}$$

$$\eta \in [-1,1], \tag{14}$$

$$\int_D \rho\, d\Omega - \bar{V} \leq 0, \tag{15}$$

$$\begin{cases} -\nabla \cdot \boldsymbol{\sigma} = 0 & \text{in } D \\ \boldsymbol{u} = \bar{\boldsymbol{u}} & \text{in } \Gamma_d \\ \boldsymbol{\sigma} \cdot \boldsymbol{n} = \boldsymbol{t} & \text{in } \Gamma_n \end{cases}, \tag{16}$$

$$\boldsymbol{\sigma} = \tilde{\mathbf{C}} \cdot \boldsymbol{\varepsilon}, \tag{17}$$

$$\boldsymbol{\varepsilon} = \frac{1}{2}(\nabla \boldsymbol{u} + (\nabla \boldsymbol{u})^T), \tag{18}$$

where $\bar{V}$ is the upper boundary for the volume of the material and $\bar{V} = 0.5$ was set in this study. $\boldsymbol{u}$ is the displacement vector fixed as $\boldsymbol{u} = \bar{\boldsymbol{u}}$ on the Dirichlet boundary Γ_d, $\boldsymbol{t}$ is a traction vector defined on the Neumann boundary Γ_n, $\boldsymbol{n}$ is the normal vector to the boundary Γ_n, $\boldsymbol{\sigma}$ is the stress tensor and $\boldsymbol{\varepsilon}$ is the strain tensor.

3. Optimized topology and orientation design

We treated the Messerschmitt-Bolkow-Blohm (MBB) beam problem in 2D plane stress state as a benchmark for single load optimization. In this study, we focused on the process of acquiring the CAD geometry before designing printing path for 3D printing of the structural parts.

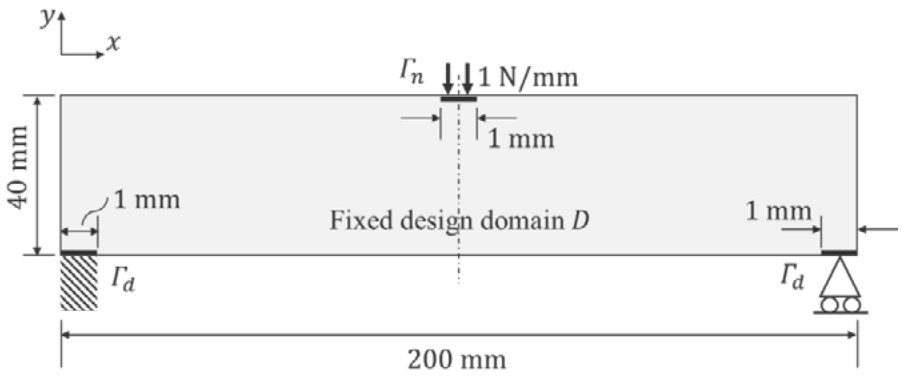

Figure 1. Desing domain and boundary conditions for MBB beam problem.

Table 1. Material properties.

		CF/PA12
E_1 [GPa]	Tensile modulus 0°	130
E_2 [GPa]	Tensile modulus 90°	6.6
G_{12} [GPa]	In-plane shear stiffness	2.2
ν_{12} [-]	In-plane Poisson's ratio	0.33

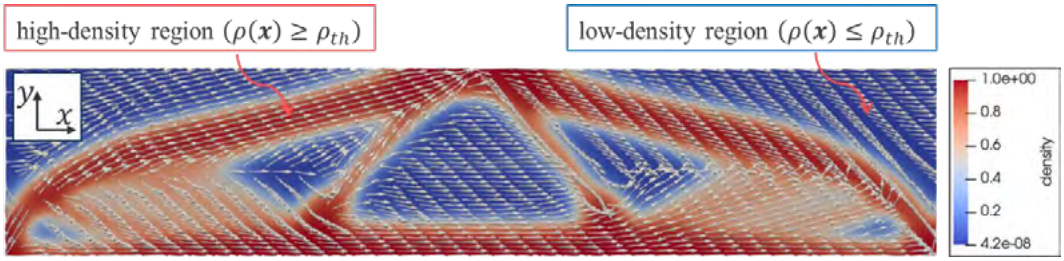

Figure 2. Optimized density and fiber orientation distribution, $f = 0.00293$, Iter.:500.

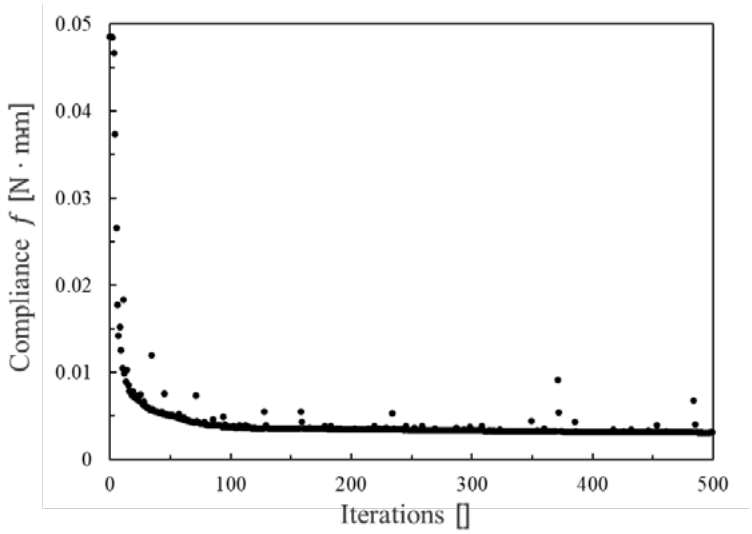

Figure 3. Optimization histories

3.1. Numerical implementation

All formulations were discretized based on the FEM. The design variables were updated by the method of moving asymptotes (MMA), based on the sensitivities of the objective and constraint functions. All of the program was implemented in Python using a combination of FEniCS (a FEA framework), pyadjoint (a generic algorithmic differentiation framework) and nlopt (a library of nonlinear optimization).

Figure 1 shows the fixed design domain D, boundary conditions, and loading conditions of the compliance minimization problem for the MBB beam under volume constraints.
The design domain was divided into (200×40) elements using a square four-node linear element with a side length of 1 mm, consisting of two pasted triangles.
Table 1 shows the material properties used in this study. These are based on the material properties of CF/PA12 at $v_f = 60\%$.

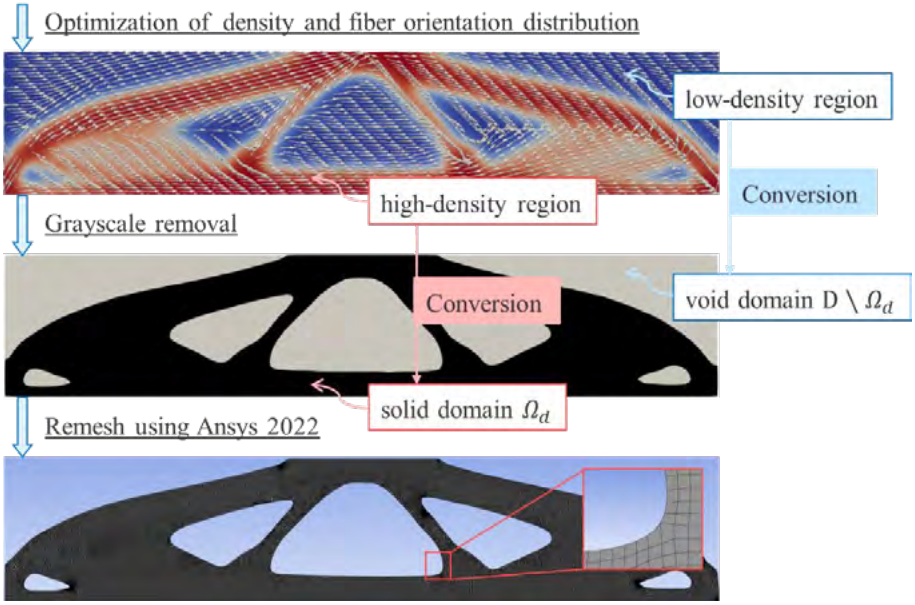

Figure 4. Flow to obtain remesh of the high-density region from optimization results.

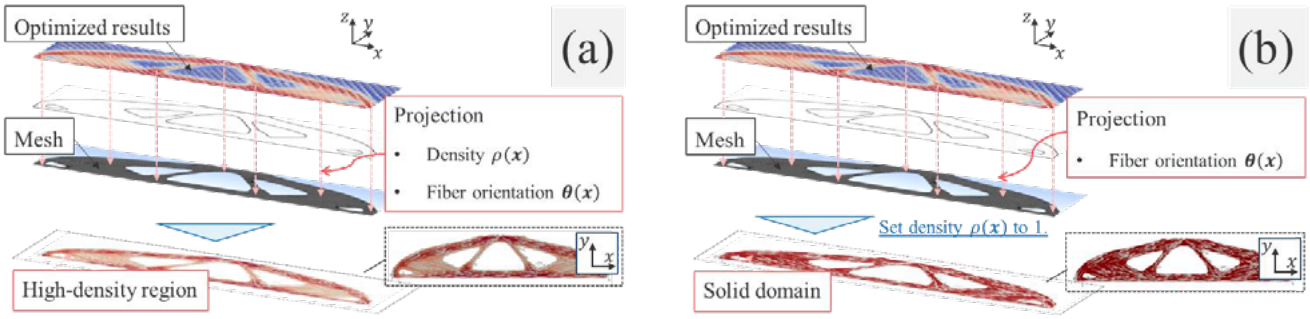

Figure 5. Flow to obtain (a) the remeshed high-density region with the same density and fiber orientation distribution as the optimized results, (b) the remeshed solid domain with the same fiber orientation distribution as the optimized results.

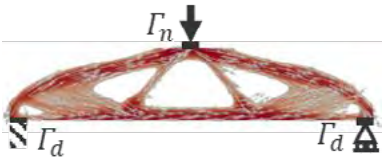
3.2. Optimization results

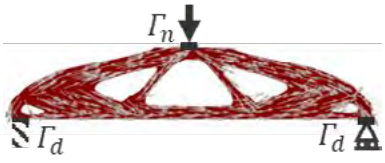
Figure 2 and 3 show the optimized results for the case where the filter radius R_φ and R_θ were set to (5.0, 5.0). No checkerboard pattern was observed although only the linear elements was used for the discretization.

In order to obtain the CAD geometry, the grayscale of the optimized results at iterations = 500 was removed, which means binarizing densities that take intermediate values between 0 and 1 to 0 or 1. The density threshold for removing grayscale, ρ_{th}, was set to 0.5. Regions with density lower and higher than ρ_{th} were defined as “low-density region” and “high-density region”, respectively, and the low-density region was converted to the void domain and the high-density regions was converted to the solid domain, as shown in Figure 4.

To obtain the mesh of the high-density region, the geometry was imported into Ansys 2022 and automatically remeshed, as shown in Figure 4. The elements were all triangular or rectangular linear elements with 147492 elements and 75415 nodes.

3.3. Discussion about binarization





Structural analysis was performed on the two models to investigate the effects of binarization on compliance, as shown in Table 2. One model was the high-density region with the same density and fiber orientation distribution as the optimized results and the other was solid domain with the same fiber orientation distribution as the optimized results. The way to obtain each model from the optimized results is shown in Figure 5. The remeshed high-density region had both optimized density and fiber orientation vectors, while the remeshed solid domain had only the optimized fiber orientation vectors and the density of the entire domain was set to 1. The same boundary and loading conditions as in the problem setup was imposed on both the high-density region and the solid domain models. Here, it was assumed that stiffness was proportional to density. The volume of the material of the high-density region was 8.8 % lower than the upper boundary, $\bar{V} = 0.5$, and the volume of the material of the solid domain 10.6 % was higher than the upper boundary.

The compliance value for the high-density region, 0.00290 N·mm. was higher than that of the solid domain, 0.00261 N·mm. This indicates that the high-density region undergoes slightly more deformation under the same loading conditions, suggesting marginally lower stiffness compared to the solid domain. However, note that the volumes of materials of the two models were different. The volume of material of the solid domain was 22.6% larger than the one of the high-density region, while the compliance of the solid domain was only 10.0% less. This suggests that the solid domain model has the potential to reduce weight.

The maximum and minimum principal stress distribution was comparable between the two models. This suggests that there is no significant difference in their ability to handle tensile and compressive stresses. The high-density region, despite using less material, does not show significant differences in stress distribution compared to the solid domain, indicating that it can effectively handle the applied loads without substantial variations in stress levels.

The discussions so far indicate a large range of gaps from the initial optimization results. These results indicate that binarization has a significant impact on compliance and requires appropriate filtering to reduce the compliance change at each stage of the design process.

Table 2. The comparison of structural analysis results between the high-density region and solid domain.

	High-density region	Solid domain
Volume of the material [%]	45.1	55.3
Boundary conditions		
Compliance f [N·mm]	0.00290	0.00261
Maximum principal stress [MPa]		
Minimum principal stress [MPa]		

4. Conclusions

In this study, anisotropic topology optimization was used to obtain the geometry and fiber orientation distribution, which were then utilized to acquire the CAD geometry for 3D printing of the continuous carbon fiber-reinforced structural parts.
The weight and compliance were investigated during the design process, and it was found that there was a large gap between the initial optimization results and the ones which removed gray scale.
In the future, we will design printing paths based on the geometry, 3D print them and actually test the manufactured structure so as to track the compliance in the whole design and manufacturing process. Another future work is to introduce filtering to binarize the appropriate density to reduce the error of the objective function during the design process.

Keywords: Polymer matrix composites, Mechanical testing, Optical light microscopy, Fibre/matrix interface, Debonding

Abstract
The characteristics of the fibre/matrix interface govern the growth of debonding cracks, which frequently originate from the tips of fibres in short fibre composites. In this regard, off-axis fibres may be exposed to mixed-mode loading, which causes interactive debonding growth in both sliding and opening modes. Polarized light microscopy is a versatile technique to visualize these debonding cracks and their interactions. In this study, single short-fibre specimens were produced by imbedding glass fibres in an epoxy matrix using an innovative manufacturing technique. Utilizing an in-stu micromechanical testing frame, debonding lengths were extracted versus remote stress levels. This method can also be employed in cyclic loading to see the effects of ageing and temperature on debonding progression.

1. Introduction

Since fibre-matrix interface serves an important function in transmitting load from the matrix to the fibre, several studies have been undertaken to investigate its characteristics. Some of the well-known characterization techniques for examining the fibre/matrix interface include the pull-out test [1, 2], the microdroplet test [3, 4], the single fibre fragmentation test [5, 6], the Broutman test [7, 8] and the transverse single fibre test. These tests measure the interfacial shear strength of fibre/matrix interface except the Brutman test and the transverse single fibre test which determine the transverse interfacial strength. Regarding the pull-out test, Nirmal et al. [1] measured the interfacial strength of betelnut fibres in polyester and epoxy matrices using the pull-out test. They examined the effect of different treatment solutions to improve the corresponding interfacial shear strength. Yue et al. [2] evaluated the interfacial shear strength of E-glass/nylon 66 and E-glass/nylon 11 using the single fibre pull-out test and determined the interfacial shear strength, interfacial friction coefficient and matrix shrinkage pressure using this technique. With regard to the microdroplet test, Kang et al. [3] studied the interfacial shear strength of carbon/epoxy using the microdroplet test. They utilized different finite element models of sphere, cylinder and droplet to determine the shear stress distribution at the fibre/matrix interface. Bellil et al. [9] investigated the interfacial shear strength of flax fibres with different polymers using the microdroplet test. They determined the best and worst performing systems as flax/PLA and flax/PP, respectively.

For the transverse single fibre tests, Tandon et al. [10] used different geometries for making transverse fibre specimens including edge-to-edge fibre, short fibre and cruciform specimens. They obtained higher normal interfacial strength values in the cruciform specimens compared to the other geometries. Using cruciform specimens has enabled researchers to examine debonding in the transverse single fiber test

without the problem of specimen edge effects. Foster et al. [11] examined the interfacial strength of steel wire/epoxy using cruciform specimens. They also examined the effect of inter-fibre spacing on the debonding initiation and matrix cavitation using 3D finite element models.
Ogihara and Konayagi [12] employed cruciform specimens with different fibre angles to determine the interfacial shear and normal strength in E-glass/epoxy. They found out that the interfacial shear strength is higher than the interfacial normal strength for this material system. Koyanagi et al. [13] utilized cruciform specimens to determine the effect of temperature on the interfacial strength of glass/epoxy and concluded that this property is independent of testing temperature.

Different techniques can be used to observe the initiation and propagation of debonding cracks such as optical microscopy (OM), scanning electron microscopy (SEM), and transmission electron microscopy (TEM). Optical microscopy has been widely used for examining the debonding initiation and propagation of composites. Scanning electron microscopy has also been utilized to observe the evolution of debonding cracks at specimen edges and surfaces. In this regard, Totten et al. [14] measured the load at the onset of debonding initiation in glass fibre/epoxy composites. They also determined the associated stress state using a 3D finite element model. Bourmaud et al. [15] employed SEM in situ to determine the load at debonding initiation. They captured different failure modes such as void nucleation, debonding and fibre bundle decohesion. Since SEM observation is limited to the specimen surface which is the location of stress singularity, other visualization methods might better represent the damage evolution inside the specimen.
Testing temperature and hydrothermal ageing can affect interfacial bonding in polymer composites. For instance, Thomason and Yang [16] showed that the interfacial shear strength of E-glass/epoxy decreases as testing temperature increases particularly in the glass transition region. They concluded that the interfacial shear strength is affected significantly by compressive residual stresses and static friction between the fibre and matrix. Conversely, Koyanagi and Ogihara [13] studied the effect of temperature on the normal interfacial strength of E-glass/epoxy using cruciform specimens. They concluded that the effect of temperature on the mentioned property is insignificant.
Ageing of fibres and composites can affect debonding evolution. Gaur et al. [17] examined the effect of hydrothermal ageing on the interfacial strength of E-glass, carbon and Kevlar 49 fibres with epoxy as the matrix. They concluded that the interfacial strength of carbon/epoxy is less affected compared to the other material systems. Be et al. [18] investigated the hydrothermal ageing behaviour in E-glass/epoxy composites with different sizing reactivity. They examined the corresponding effect using AFM and DMA.
After reviewing the literature, It was found that most of the research studies on the interface have been focused on the interfacial shear strength of composites. The current paper considers mixed-mode debonding evolution in single fibre E-glass/epoxy composites at different fibre angles, and the effect of ageing and temperature under fatigue loading.

2 Materials and experimental set-up

EPIKOTE™ RIMR 135 and EPIKURE™ RIMH 137 were used as the epoxy resin and its hardener, respectively and mixed at the weight ratio of 10:3. E-glass fibres including StarRov® PR 220 1200 090 from Johns Manville were chopped and compounded with epoxy mixture. The mixture was degassed for 15 min at full vacuum. Short fibre E-glass/epoxy panels with randomly oriented fibres were fabricated. Further details regarding the fabrication process can be found in Refs. [19, 20].

The tensile tests were conducted at a displacement rate of 1 mm/min using an in-house micromechanical tensile stage. A BX51 Olympus microscope was used for the visualization of the fibres and monitoring damages during loading. The setup is shown in Figure 1.

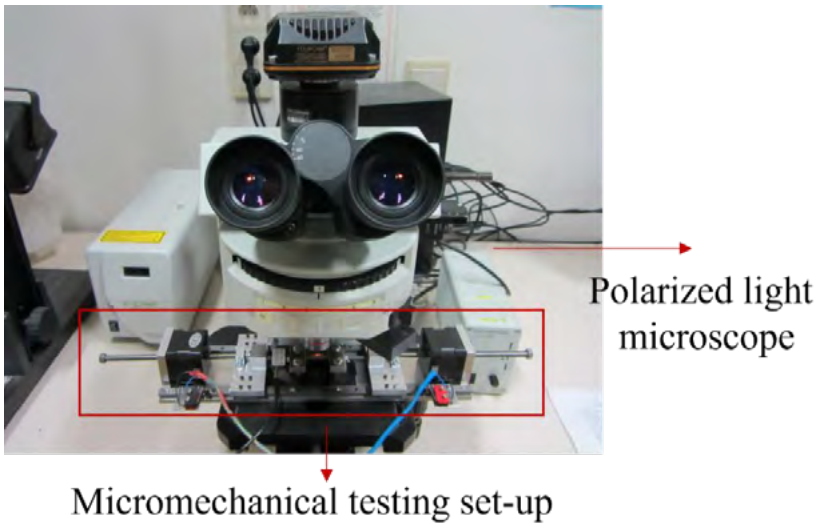

Figure 1. Micromechanical test setup under the polarized light microscope.

The geometry of the specimens and the associated dimensions are indicated in Figure 2 and Table 1, respectively.

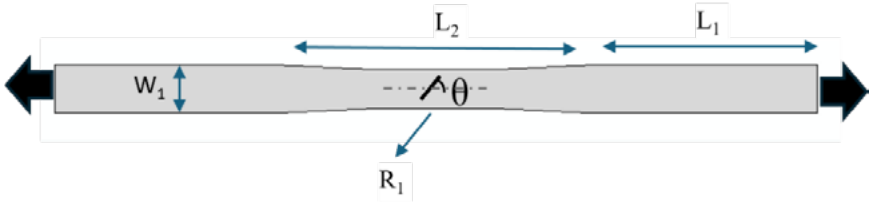

Figure 2. Dog-bone geometry utilized for the micromechanical tensile tests.

3. Mechanical testing results and discussion

As the load is applied to the specimen, voids are nucleated at the tips of fibres. Following the void nucleation, debonding cracks are initiated and propagate from the fibre tips and the debonding lengths can be recorded versus remote stress levels. As seen in the figure, the debonding crack is not symmetric relative to the fibre axis and is not cylindrical compared to the debonding cracks in the horizontal fibres in the single fibre fragmentation tests [5].

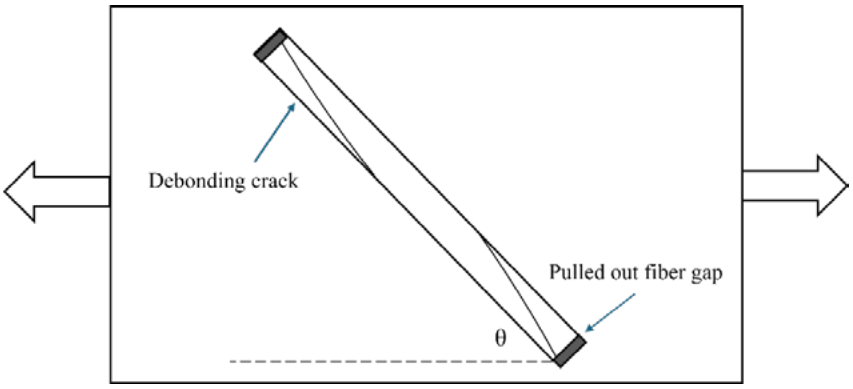

Figure 3. Schematic of debonding growth in an off-axis E-glass/epoxy specimen.

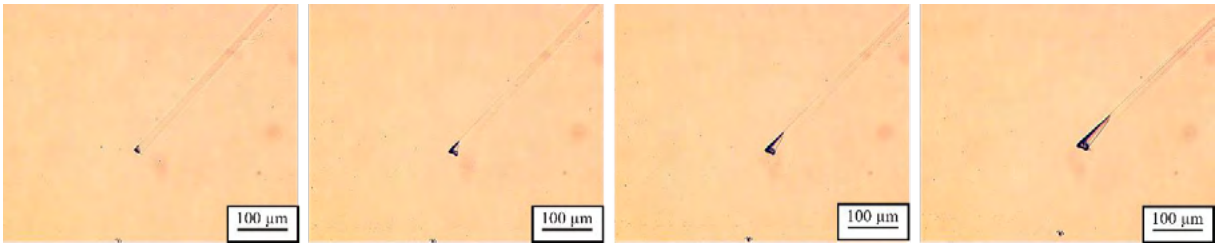

Figure 4. Successive progression of debonding at different remote stress levels for a 45° E-glass/epoxy specimen.

Data on debonding length can be extracted for different remote stress levels. For instance, the plots of debonding lengths versus remote stress levels are shown for (90° and 45°) E-glass/epoxy in Figure 5 and Figure 6. Accordingly, the maximum debonding length is less than 100 µm for the two fibre angles. Meanwhile, the remote stress at void nucleation for the 45° E-glass/epoxy specimens is 44.13 ± 4.01 MPa.

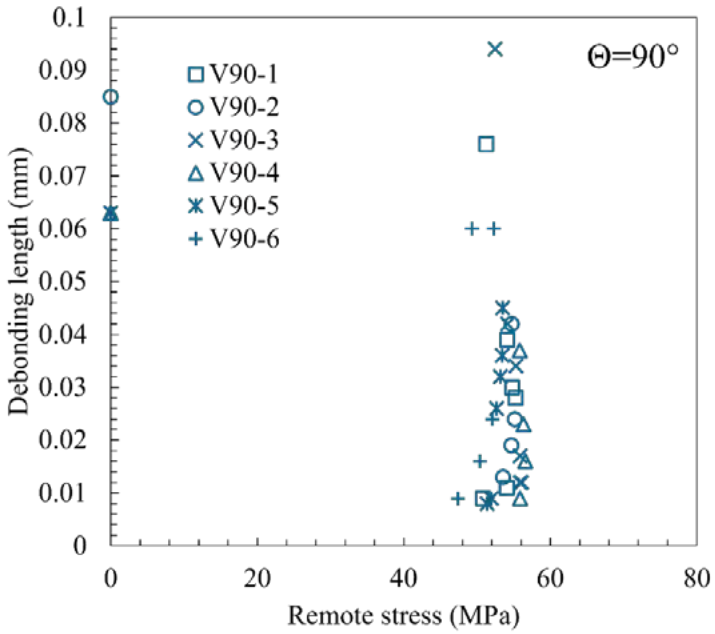

Figure 5. Debonding length versus remote stress for 90° E-glass/epoxy.

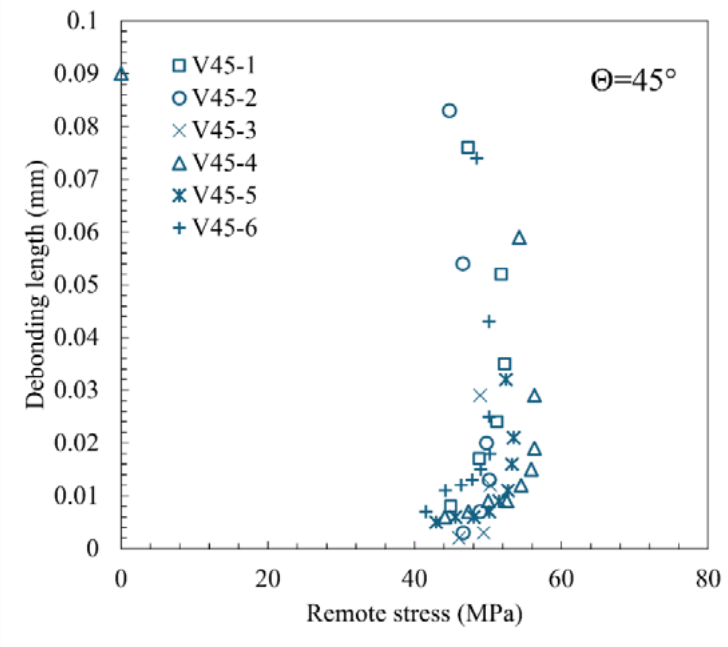

Figure 6. Debonding length versus remote stress for 45° E-glass(090)/epoxy.

For the 0° E-glass/epoxy, debonding cracks are self-similar and symmetrical since the evolution of the cracks occurs in pure shear as seen in Fig. 7 and 8. Pull-out in these specimens is more clear compared to the off-axis fibre specimens.

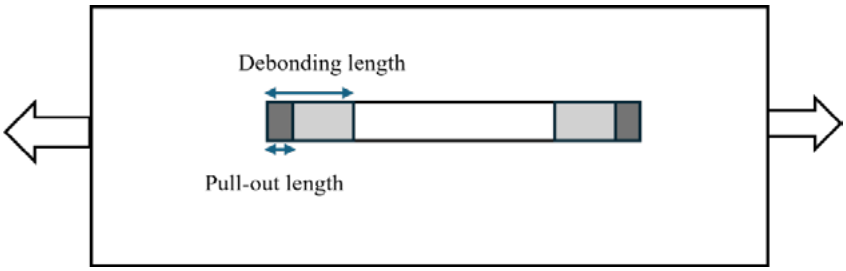

Figure 7. Schematic of debonding growth in a 0° E-glass/epoxy specimen.

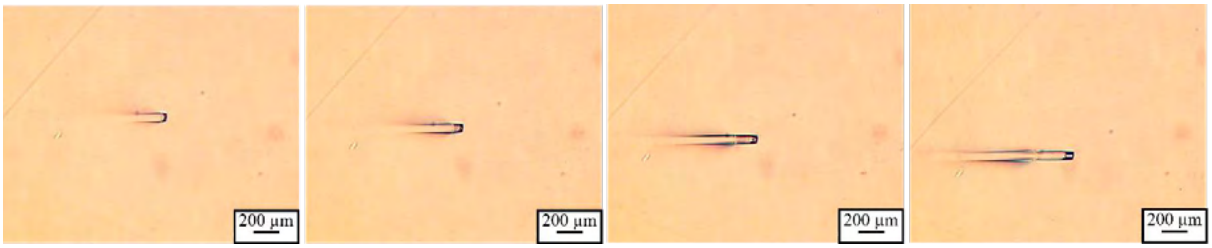

Figure 8. Successive progression of debonding at different remote stress levels for a 0° E-glass/epoxy specimen.

Debonding lengths versus remote stress levels are shown for 0° E-glass/epoxy specimens in Fig. 9. The primary observation in Figs. 5, 6, and 9 is that there are two stages corresponding to the debonding growth: stable and unstable progressions. Debonding growth is relatively slow in the stable phase yet fast in the unstable phase.

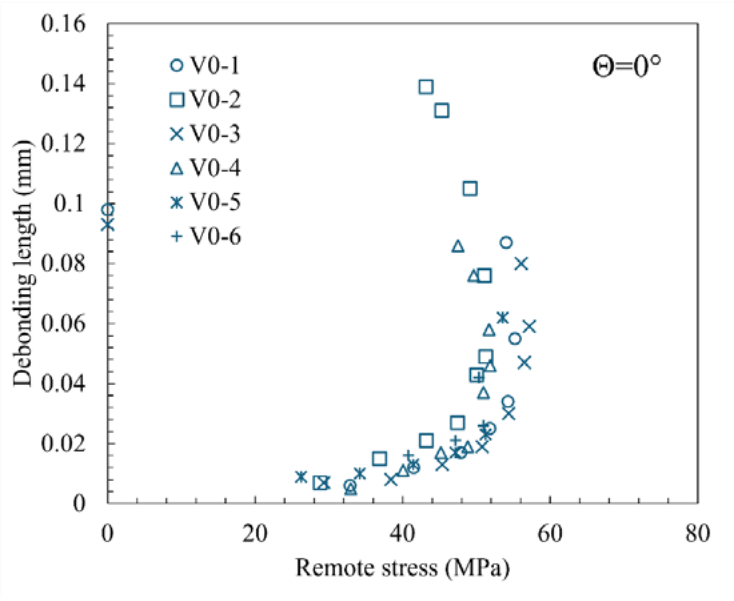

Figure 9. Debonding length versus remote stress for 0° E-glass(090)/epoxy.

Cyclic loading can be utilized to see the effects of fibre ageing on the debonding progression at low stress levels. The progression of debonding cracks at different number of cycles can be clearly seen for virgin (V) and four-week aged fibres (A) in Figure 10(a). An analogous comparison can be performed between 45° virgin E-glass/epoxy at room temperature and 50 °C in Figure 10(b). The difference between the debonding lengths at the two conditions can be readily seen in this Figure.

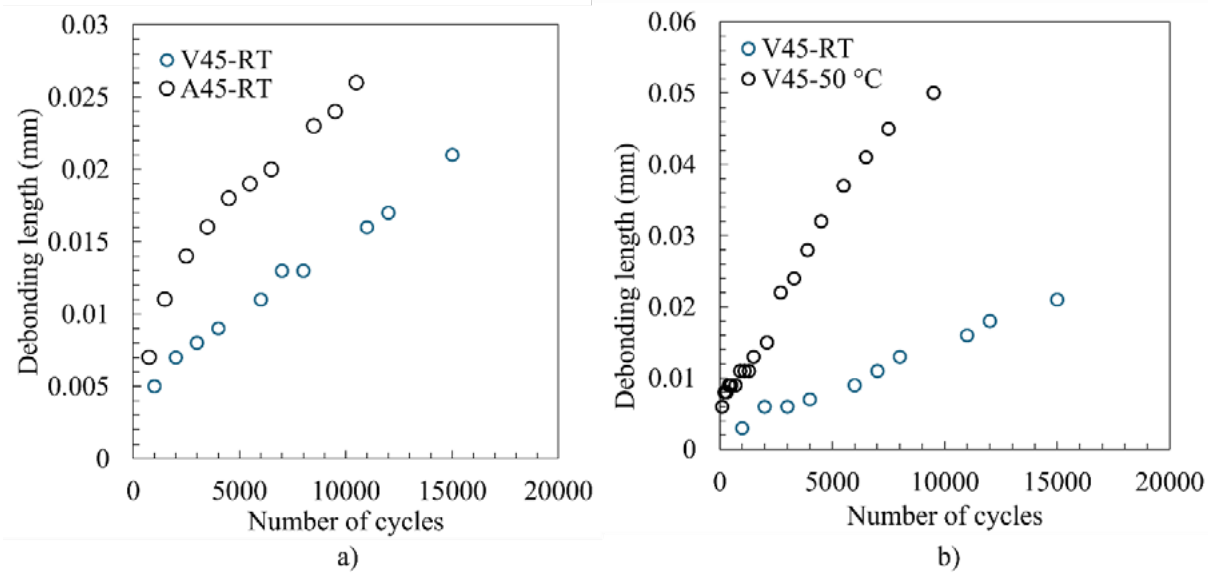

Figure 10. Debonding length versus number of cycles for a) 45° virgin and four-week aged E-glass/epoxy b) 45° virgin E-glass/epoxy at room temperature and 50 °C.

4. Conclusion

Single short fibre E-glass/epoxy specimens were fabricated and loaded under tension using a micromechanical testing setup. Debonding cracks were visualized in real-time using a polarized light microscope. Debonding lengths versus remote stress levels were extracted for 0°, 45° and 90° fibre angles. These debonding lengths can be further utilized by a numerical model to extract the corresponding interfacial strengths and fracture toughness values. This method was also used in cyclic loading to see the effects of ageing and temperature on debonding progression.

Abstract
Depending on their use, thermoplastic polymers can be processed using different methods, including Additive Manufacturing (AM) and Injection Moulding (IM). This study aims to investigate the impact of the manufacturing process on the behaviour of High-Impact Polystyrene (HIPS) material during service life, simulated via accelerated aging. HIPS is commonly used in different home appliances, such as inner liner in refrigerators. In this work, HIPS coupons were produced by AM and IM, resulting in coupons with different internal structure. To reproduce the real service environment, and by that be able to assess durability, freeze-thaw cyclic aging was adopted. The effects of freeze-thaw aging on the mechanical, physical, and chemical performance of the HIPS material, were assessed by means of tensile testing, assessing the mechanical properties evolution during accelerated aging. To study the evolution of coupon internal structure as a function of aging, a total of 384 freeze-thaw cycles, between -20°C and 50°C were employed, assessing the properties of the material after 3, 6, 12, 24, 48, 96 and 192 days, time intervals. A link between physical, mechanical and chemical properties evolution was developed, in an attempt to develop an understanding of the material's degradation in time and of the effects of the processing method on the durability and long-term performance.

1 Introduction

Plastic production in Europe constantly increases, supported by the evolving needs of consumers and industries. 53,9MT of plastics were produced in 2020, while 57,2MT of plastics were produced in 2021, accompanied by a stagnation of the amount of post-consumer recycled plastics used, close to 10% of the total produced plastic. In 2021, the majority of the plastics produced were used for packaging applications, representing 39,1% of the produced plastics, while the fourth biggest consumption of plastics goes to the industry of electrical and electronics, representing 6,5% of the total produced plastics [1]. Among this 6,5% representing 3,72MT of plastic used for electrical and electronics applications, it was observed that High Impact Polystyrene (HIPS) is the second most used polymer behind ABS, representing 26% of all the polymers found to be used in these applications [2]. The second most used process for plastic manufacturing in any application combined and the first most used in the field of electrical and electronics application is IM, one of the most important processes for mass-production of thermoplastic parts [3-5]. However, traditional manufacturing processes for plastics nowadays give space to AM, a process emerging in different industries for both large and small scale series production. AM is perceived as an emerging manufacturing process with great potential to limit the environmental impact of plastic objects manufacturing, by decreasing the amount of waste and energy consumption [6-8]. This paper focuses on material extrusion Fused Filament Fabrication (FFF) AM. When comparing samples produced in AM or in IM, different properties are obtained after production, in relation to the difference in the parameters used as well as the process itself. For example, F. L. Garcia et al. compared the mechanical properties of Acrylonitrile Butadiene Styrene samples produced by IM and by AM, and found that for an AM sample produced with 100% infill density and 45° printing orientation, the tensile strength and strain were recorded to be 19% higher, for the case of IM samples [6], which render IM samples more resistant to external mechanical loads. In another study comparing AM and IM of

PolyLactic Acid (PLA) material, Acrylonitrile Butadiene Styrene (ABS) and Nylon 6 (PA 6), M. Lay et al. highlighted the lower mechanical properties of AM samples for the three polymers, in comparison to IM produced ones. The tensile strength values were found to be 48, 34 and 37% lower for printed PLA, ABS and Nylon 6, in comparison to the same material produced by IM. This was, according to the authors, attributed to the presence of voids in AM samples observed by Scanning Electron Microscopy (SEM) and through density measurements, but also to the benefit of the injection pressure present during the IM process creating excellent entanglement of the polymers chain and thus ultimately increasing the mechanical performance of the IM samples compared to AM ones [9, 10]. Numerous studies have been reported comparing AM and IM and their impact on the material's properties, as well as studies optimizing AM process parameters to improve the properties of the final produced part. However, no studies have been dedicated to evaluate the impact of the manufacturing process on the sample behaviour throughout its lifetime, by means of accelerated aging.

In this work, we focus on HIPS, and more particularly on HIPS used for refrigerator applications (electronics). As such, freeze-thaw accelerated aging cycles were used to simulate, compare and understand the degradation mechanisms of HIPS produced by AM vs. IM. To understand the impact of the manufacturing process on the polymers' long-term properties, aged coupons were tested in terms of physical, mechanical and chemical properties. Herein, we present preliminary tensile test results of coupons cyclically aged between -20°C and 50°C, for 3, 6, 12, 24, 48, 96 and 192 days intervals. The results presented are preliminary results in the framework of PRecycling Horizon Europe project, aiming to suggest a mechanism of degradation of HIPS material when subjected to different aging conditions.

2 Methodology and materials

2.1 Materials

This work was deployed on recycled HIPS material (rHIPS) supplied by Coolrec, Netherlands, and processed with AM by BIOG3D, Greece and with IM by R-NANO lab, National Technical University of Athens, Greece. For the needs of the study, tensile coupons were manufactured using AM and IM, according to the ISO 527. The AM samples were produced with a 0° orientation, a bed temperature of 60°C, a nozzle temperature of 240°C and a printing speed of 30mm/s. The IM samples were produced with a barrel temperature of 210°C and residence time in the barrel of 10 min to ensure the homogeneous melting of the pellets and a mould temperature of 60°C. The different pressures used at different steps of the process were between 10 and 12 bars.

2.2 Accelerated aging protocol

To simulate real use, freeze-thaw cyclic aging was performed using a Freeze-Thaw Chamber (LIB Industry, China) through repeated cycles, with one cycle corresponding to 6h of exposure to -30°C followed by 6h of exposure at 50°C. Figure 1 illustrates the freeze-thaw cycles performed. All coupons were subjected to freeze-thaw cycles for 3, 6, 12, 24, 48 and 96 days, corresponding to a total of 6, 12, 24, 48 and 192 cycles, respectively.

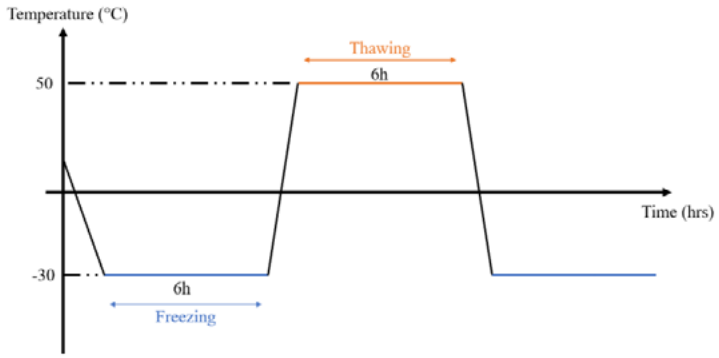

Figure 1. Freeze-thaw cyclic programme

2.3 Material characterisation

After freeze-thaw exposure, coupon's degradation was assessed through the tensile mechanical properties evolution. In specific, preliminary results of the mechanical properties evolution as a function of the aging time are reported, presented changes in Young's modulus evolution and Strain at break values. Uniaxial tensile was performed on coupons following the ISO 527-2 using an Instron 5966 (Instron, Norwood, USA) at a 5mm/min loading rate. An AVE2 video-extensometer was used to measure the mechanical strain. The tensile modulus was determined by analyzing the force-displacement curves. The behaviour of the material was assessed by examining changes in its stiffness (Young's modulus, E) and strain at break.

3 Results and discussion

Preliminary tensile test results are presented as properties retention vs. the number of Freeze-Thaw Cycles (FTC). The average tensile property values obtained for IM and AM samples are presented in Table 1.

Table 2. Average Young's modulus and strain at break for IM and AM samples during FTC

FTC	Injection molding				Additive manufacturing			
	Young's modulus (Gpa)	Standard deviation (Gpa)	Strain at break (mm/mm)	Standard deviation (mm/mm)	Young's modulus (Gpa)	Standard deviation (Gpa)	Strain at break (mm/mm)	Standard deviation (mm/mm)
0	1.736	0.090	0.260	0.026	1.532	0.532	0.064	0.027
12	1.875	0.057	0.259	0.078	1.758	0.131	0.041	0.031
24	2.105	0.516	0.121	0.023	2.600	0.122	0.037	0.013
48	1.958	0.036	0.278	0.092	1.729	0.165	0.027	0.002
96	1.680	0.066	0.255	0.057	1.717	0.219	0.026	0.007
192	1.578	0.037	0.297	0.031	1.535	0.057	0.030	0.005

The results of the mechanical properties presented in Figure 2 show a strong increase in the Young's modulus until 24 FTCs. This stiffness increase is more pronounced for the AM samples than for the IM samples. This can be attributed to a possible crosslinking from radical formation in link to the polymer's oxidation, or a chain relaxation phenomenon resulting in an increase in the crystallinity and embrittlement of the material [11, 12]. It is likely that the HIPS material contains a polybutadiene phase, of which the double bonds are likely to be subjected to oxidation during degradation and this form radicals. However, the stiffness of the material decreases for both AM and IM samples after 24 FTCs, stabilizing around a value close to that of the unaged material. This can be attributed to the polymer chain scission phenomenon occurring through oxidation throughout the degradation process [11-14].

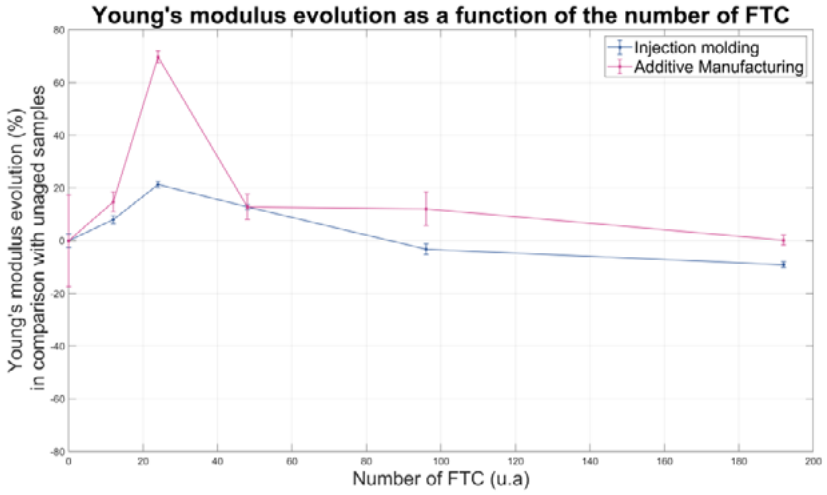

Figure 2. Young's modulus evolution as a function of the number of FTC

In the context of IM samples, the second hypothesis linked to possible chain scission is confirmed by the strain at break values evolution, shown in Figure 3, where the increase in the Young's modulus until 24 FTCs is happening simultaneously with a decrease in the values of strain at break. In this precise case, the chain scission phenomenon occurring with oxidation and radical formation can be observed through the decrease in the strain at break. Later, the decrease in the values of Young's modulus between 24 and 48 FTCs is simultaneous with an increase in the values of strain at break, even if both properties' evolutions are not proportional. The strong increase in the values of strain at break cannot be attributed to a crosslinking reaction, as this increase corresponds to a decrease in the values of Young's modulus. However, other internal structural re-organizations may occur simultaneously. In the case of AM samples, an exponential decrease in the values of strain at break is observed throughout the degradation process highlighting a different impact of FTC aging from this AM process compared to the IM process. The overall decrease in the values of strain at break can for AM samples be attributed to the chain scission phenomenon occurring during the degradation process.

The aging in its globality showcases a more significant and negative impact on the values of strain at break of AM samples than IM samples. The manufacturing process is therefore affecting largely the mechanism of degradation as well as its kinetic and degree.

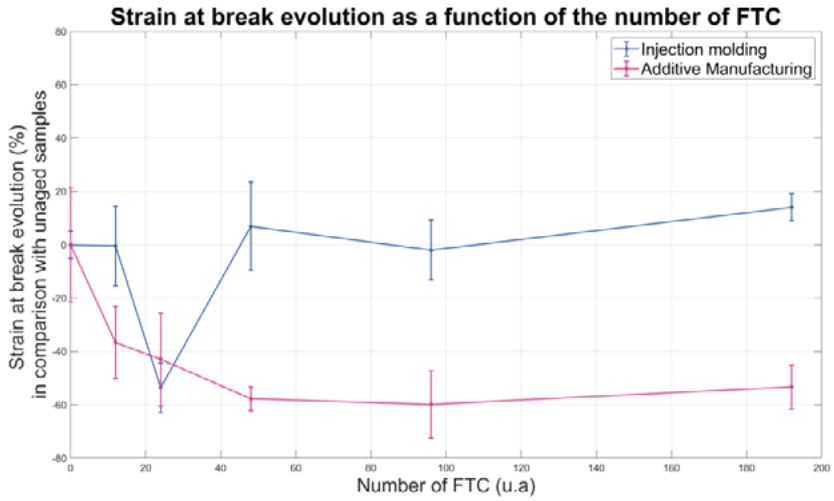

Figure 3. Strain at break evolution as a function of the number of FTC

4 Conclusion

This work focused on the understanding of the impact of the manufacturing process on the durability of additively manufactured and injected moulded recycled HIPS samples. Freeze-thaw aging was used to simulate the real environment and conditions to which HIPS materials are used in white good applications. Preliminary results were shown, presenting the evolution of Young's modulus and strain at break values after FTC aging, highlighting the negative impact of the AM process vs. IM, on the durability of the tested material. An evolution in the Young's modulus values corresponding to an opposite evolution in the strain at break values was observed for both AM and IM samples, highlighting a possible crosslinking followed by a chain scission mechanism. In conclusion, preliminary results on the impact of the manufacturing process on the long term properties of HIPS material were presented, while the degradation mechanism will be further investigated through physico-chemical testing.

Acknowledgments

The authors acknowledge the company Coolrec for the recycled HIPS supply, the National Technical University of Athens (NTUA) for the manufacturing of the IM samples and the company BIOG3D for the manufacturing of the AM samples. This study was part of the PRecycling project funded from the European Union's Horizon Europe research and innovation program under grant agreement No 101058670.

Abstract
Smart self-regulating heating devices utilizing the positive temperature coefficient (PTC) effect have shown great potential in advancing applications across healthcare, soft robotics, and energy-efficient manufacturing. However, achieving homogeneous resistive heating within such temperature self-controllable nanocomposites remains a significant challenge. This study explores and evaluates multiple innovative strategies to enhance the temperature uniformity of PTC nanocomposites. By identifying the primary physical mechanisms behind the inhomogeneous heating observed in conductive polymer composites, we have proposed and evaluated a series of strategies, with an improved temperature uniformity (from 32.6 to 2.7 % variation at 125 °C), providing valuable insights for the design and development of advanced self-regulating heating devices based on conductive polymer nanocomposites.

1. Introduction

The PTC effect in CPCs describes the increase in electrical resistance of conductive nanocomposite upon increased temperature [1]. When utilizing CPC for Joule heating, the passage of electrons through the material generates heat, causing the temperature of the material to increase. As the temperature increases, the material's electrical resistivity also increases due to the mismatched thermal expansion between the polymer matrix and conductive fillers [2], limiting the current flow and reducing the heat generation, hence causing the material to self-regulate its temperature. The temperature of self-regulation is usually determined by the matrix polymer's melting or softening point [1, 3]. The PTC effect in CPCs has been extensively studied for its potential applications in a wide range of industries, including electronics and heating systems, taking advantage of using PTC-CPCs for self-regulating heating and providing precise temperature control in addition to an energy-efficient and cost-effective solution for heating systems [2].

However, a few challenges remain in such self-regulating heating materials that may affect their wider adoption and utilization. One of the most important problems is the temperature uniformity of the self-regulating heating devices. According to the PTC mechanism [1], a conductive filler loading near the percolation threshold can provide the highest PTC intensity, as the number of contact points between the conductive nanofiller particles is relatively low rather than homogeneously distributed throughout the matrix. This results in a non-uniform heat generation, where the heat will be generated mainly along the connected network pathways followed by heat dissipation to other areas. An ideal combination of the filler size and dispersion for homogeneous heating throughout the specimens is often difficult to achieve in practice [3, 4], especially for self-regulating heating films without any high thermal conductivity substrate to homogenize the temperature.

This study addresses the critical issue of temperature non-uniformity that often occurs at the self-regulating heating stage, which is of great importance for practical applications when using such novel materials. Two fundamental interconnected physical mechanisms causing inhomogeneous heating in CPC, namely the mismatch in heat dissipation between the edges and the central areas, and the mismatch in resistivity within the nanocomposites, have been identified and discussed, with a range of strategies proposed and evaluated to address these two challenges towards homogeneous heating of self-regulating heating nanocomposites. By tailoring the materials formulations and utilizing distinct electrode layouts and configurations, an enhanced heating homogeneity with a significantly reduced temperature variation across the heating film can be achieved at the self-regulating heating stage. A systematic analysis and comparison have been performed for all strategies, to provide insightful knowledge and perspectives to design and develop novel self-regulating heating devices based on conductive nanocomposites.

2. Experimental

2.1. Materials

Graphene nanoplatelets from XG Science (GNP, Grade M25) and a relatively high aspect ratio carbon nanotube (CNT) from Nanocyl (NC7000) were used as conductive nanoparticles. Boron nitride (BN) powder with an average particle size of ~1 μm and a purity of 98% from Merck Life Science UK Limited was used as received for thermal conductivity enhancement. The polymer matrix chosen for this research was high-density polyethylene (HDPE) (INEOS, RIGIDEX HD5218EA). Aluminium foil with a thickness of 0.1 mm was used as a 2nd thermal conductive layer in certain strategies. Copper wire with a diameter of 0.15 mm, copper mesh with a wire dimension of 0.056 mm, and recycled carbon fiber veil (Technical Fibre Products Ltd.) were used as electrodes embedded in the nanocomposites.

2.2. Preparation of self-regulating heating film

The nanocomposites were melt-compounded in a Micro Compounder (Xplore MC 15 HT) using a screw speed of 50 rpm at 200 °C with desired filler concentrations as detailed in **Table 1**. The melt-compounded nanocomposite pellets were then compression moulded (Dr Collin GmbH, Presse P300E) at 200 °C with 60 bar to obtain a rectangular shape with a lateral dimension of 100×100×0.15 mm^3. Electrodes were embedded through a 2nd compression moulding with final dimensions in **Figure 1**.

Table 1 Filler concentration and resistivity at room temperature of nanocomposites in each strategy.

No.	Film Strategy	PTC nanocomposites	Resistivity (Ω·m)		Secondary materials	Resistivity (Ω·m)

2.3. Characterization and Measurements

The electrical conductivity of CPCs and contact resistance at electrodes were measured by a two-point method consisting of a voltage power source (Agilent 6614C) and a picometer (Keithley 6485). The electric current value was measured under an applied voltage range of 0-20 V with a step of 0.5 V. The resistance was then calculated from the I-V curve obtained.

The pyroresistive behavior (temperature-dependent resistance) of nanocomposites was characterized by measuring the electrical resistance of the specimen via a two-probe method inside a convection oven. The electrical resistance of the specimen with dimensions 25 × 5 × 1 mm^3, was measured using a digital multimeter (Agilent 34410 A) and simultaneously recorded by a custom-built LabView program, while the temperature was recorded by a data logger (Pico Technology TC-08).

The Joule heating behavior of the nanocomposites was measured by applying a direct voltage (Fisherbrand PowerPro 300) to the sample with a data logger (Pico Technology TC-08) to record temperature data. A layer of calcium-magnesium silicate thermal insulation wool (Calcium Magnesium Silicate, RS Components, thickness of 38 mm) was placed on the top and bottom of the film. A thermal infrared camera (FLIR, TG165-X) was used to capture thermal images of uncovered CPC.

3. Challenges and Approaches

To achieve a homogeneous Joule heating of conductive polymer nanocomposite films, two interconnected key aspects need to be considered with equal importance: (i) uneven thermal dissipation within the specimen, where the heat preservation area (often the center) reaches the switching temperature first, therefore, leading to a further uneven resistivity; (ii) resistivity distribution among the

specimen, especially at or near the interface between electrodes and conductive polymer composites, which could affect the Joule heating performance at various locations of the film. This is of particular importance for conductive polymer nanocomposites with PTC effect, where sequential heating from the first triggering area can significantly affect the local resistance hence the electric current that goes through other areas, resulting in inhomogeneous heating across the film.

Many heating devices would have electrodes positioned at both ends to maximize the heating areas and materials used (as shown in **Figure 2**a). However, as the heat loss at the edge is normally more pronounced than the central areas of the heating materials, a "hot line" can often be observed near the center of the CPC film (as shown in the IR image in **Figure 2**a). Consequently, the temperature of the hot line would reach the melting point first, resulting in a higher resistivity than other areas during the Joule heating process due to the PTC effect [3], hence further affecting the temperature uniformity of the nanocomposites with reduced heating close to the edges. This uneven heating would be further magnified when the heating devices are scaled up.

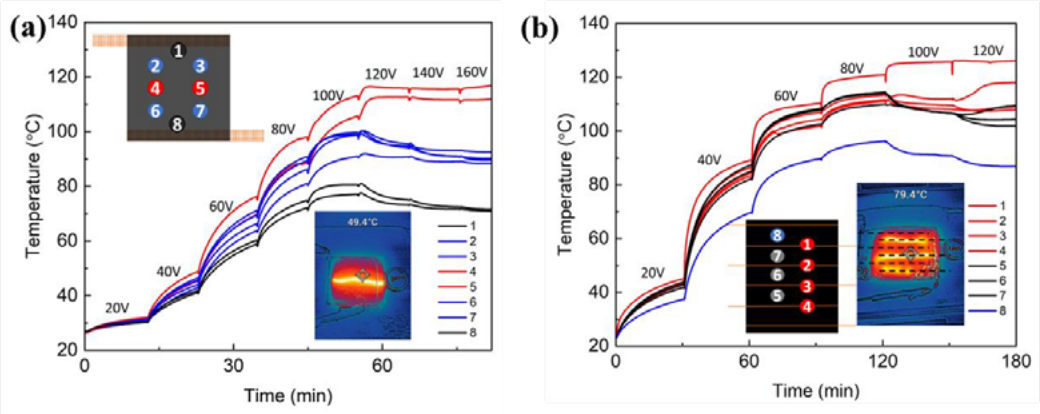

Figure 2: Two main challenges causing the non-uniform heating in GNP/HDPE film: (a) two electrodes with a middle "hot line" resulting from a rapid heat loss at the edges and (b) multiple parallel electrodes with a heat accumulation near copper wire electrodes due to the contact resistance.

With multiple electrodes embedded in the nanocomposite film with reduced distance between electrodes (**Figure 2**b insert), an improved temperature uniformity has been achieved compared to the single pair of end electrodes. However, a clear temperature difference between the maximum and minimum points remains, with multiple hot lines appearing in the IR image. As shown in **Figure 2**b, the temperature of four thermal couples on the copper wire electrodes (red lines of points 1-4) was higher than that of areas between electrodes (black lines of points 5-7), which resulted from the contact resistance between nanocomposites and copper wire electrodes, whereas the lowest temperature was recorded at the edges (blue line of point 8) due to the accumulated effect of rapid heat dissipation. However, with a reduced distance between electrodes, the mismatch of resistance (Ch2) between nanocomposites and electrode contact resistance becomes a dominating factor, resulting in a more pronounced heating close to the copper electrodes.

To address these two challenges causing inhomogeneous heating, several strategies have been proposed and explored: (i) adjusting the resistivity of non-PTC heating areas according to the PTC switching unit at self-regulating temperatures, ensuring sufficient current flow throughout the specimens at elevated temperatures (Strategy 1-2, addressing the sequential heating problem and Ch2); (ii) increasing the film thickness to achieve more consistent resistivity across the film hence to avoid undesirable heating initiation before the temperature equilibrium process (Strategy 3, addressing Ch2); (iii) utilizing additional thermally conductive layers to facilitate the heat transfer (Strategy 4, addressing Ch1); (iv) adjusting and tailoring the initial heating locations to mitigate the heat dissipation issue (Strategy 5,

addressing Ch1); (v) using novel electrode materials to replace copper, reducing the mismatch in electrode contact resistance and nanocomposites (Strategy 6, addressing Ch2).

4. Results and Discussion

4.1. Introducing ZTC heating elements

Considering the pyroresistive feature of the materials, ensuring most areas can be heated before triggering self-regulating heating is essential to allow sufficient heat dissipation to solve the temperature uniformity issue. Therefore, a zero temperature coefficient (ZTC) heating element has been introduced to avoid early triggering of the PTC effect in the central area, which addresses Challenge 1 with the hot line at the center. The sections with a higher resistivity will convert more electrical energy to heat energy, leading to earlier heating once the specimen is subject to an applied current. Therefore, the resistivity of each heating element (CNT/HDPE and GNP/HDPE) at the terminal temperature (120 °C) should be the same to obtain homogeneous heating, while the resistance of CNT/HDPE should be higher than GNP/HDPE at room temperature to initiate the heating (detailed values in **Figure 3**a). In theory, it is expected that the whole system can reach a steady state of self-regulating heating after the GNP/HDPE sections (point 5-6) reach the switching temperature, as shown in Figure 3a, although a temperature drop can be observed in CNT/HDPE sections (point 1-4) due to reduced current from the resistivity increase (PTC effect) in GNP/HDPE units.

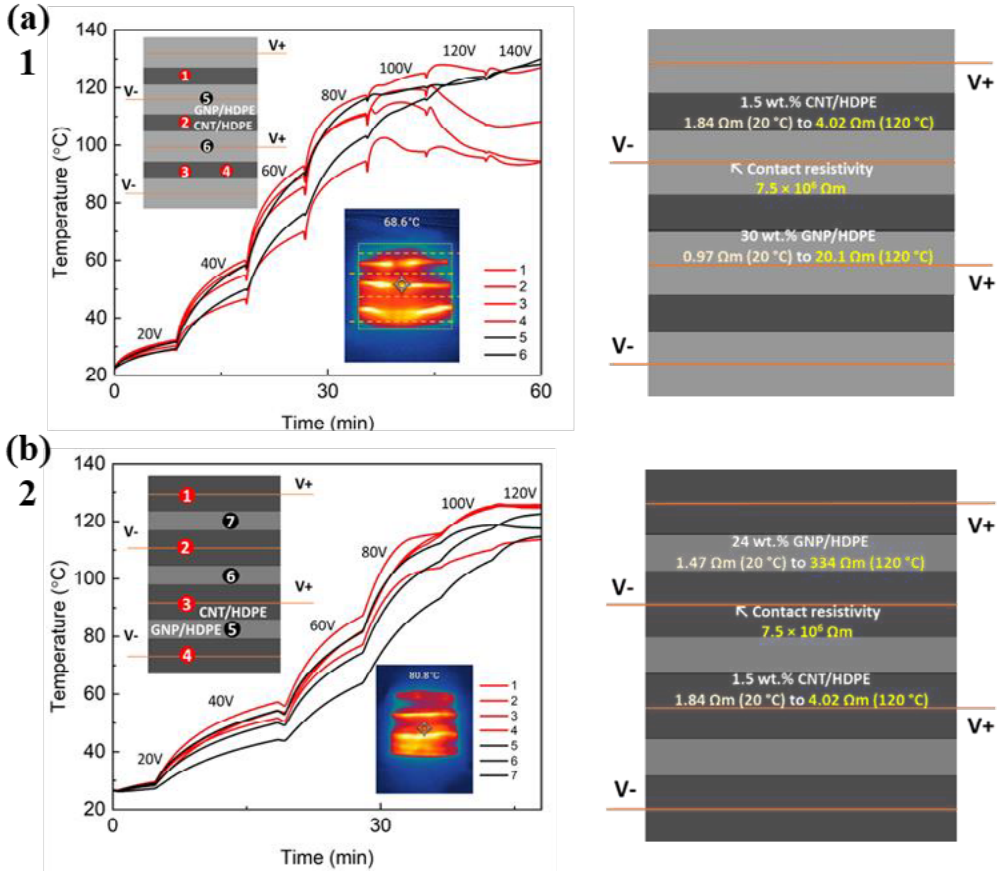

Figure 3 Temperature profile with IR images of self-regulating heating film with resistivity values of each section at room temperature and self-regulating temperature, in introducing ZTC elements strategies with electrodes embedded in either (a) GNP/HDPE sections, or (b) CNT/HDPE sections.

As shown in **Figure 3**a, by embedding electrodes in the GNP/HDPE phase with the CNT/HDPE section joined in between, it is expected that the middle CNT/HDPE ZTC unit with relatively high resistivity (compared with the GNP/HDPE phase) will heat up first, as shown in the three areas between the four dash lines in the IR image. A relatively homogeneous heating process can be found, until the copper wires areas with high contact resistivity in two GNP/HDPE sections (points 5-6, black lines) in between ZTC heating sections reach the switching temperature, triggering the PTC effect and restricting the current with a relatively stabilized temperature apart from two edge sections (point 1, grey line) due to more pronounced heat dissipation. A temperature difference (ΔT) of 56 °C has been recorded across all thermocouples, without improvements compared to previously recorded ΔT of 46 °C in Ch1 and 43 °C in Ch2.

Three different resistance values can be expected, CNT/HDPE, GNP/HDPE, and contact resistance on the copper wire surfaces, which will heat up sequentially. To achieve an ideal process starting with simultaneous heating by contact resistance and CNT/HDPE phase, followed by the GNP/HDPE phase triggered at the end, embedding the electrodes in the CNT/HDPE phase has been explored in Strategy 2 (**Figure 3**b). A significantly reduced ΔT of 12 °C was obtained, achieving an almost 80% reduction compared with Strategy 1. It is worth noticing that the self-regulating performance in Strategy 2 at the switching temperature is also more pronounced than in Strategy 1, attributed to the use of 24 wt.% GNP/HDPE for their desirable resistance range in the design.

4.2. Thickness increase strategy

A slightly increased film thickness has been examined as shown in **Figure 4**a. With applied voltages, all areas in the film started heating with a slight temperature variation, until the first areas reached the melting temperature (points 1, 7, 8, red lines), leading to reduced heating with a temperature equilibrium process. With further increased voltages (from 50V to 90V), a clear self-regulating heating can be observed, with a relatively uniform temperature distribution after the heat transfer.

A significantly reduced ΔT of ~11 °C has been recorded across the surface of the film, especially compared with the same electrode design but thinner 300 µm film in Challenge 2 (**Figure 2**b) with a ΔT of 43 °C. Considering the copper electrode diameter of 150 µm, the current thick film (600 µm) can provide a more consistent film thickness with a well-surrounded area for a more consistent contact resistance. More importantly, heat dissipation through the in-plane direction can facilitate temperature homogeneity in this strategy.

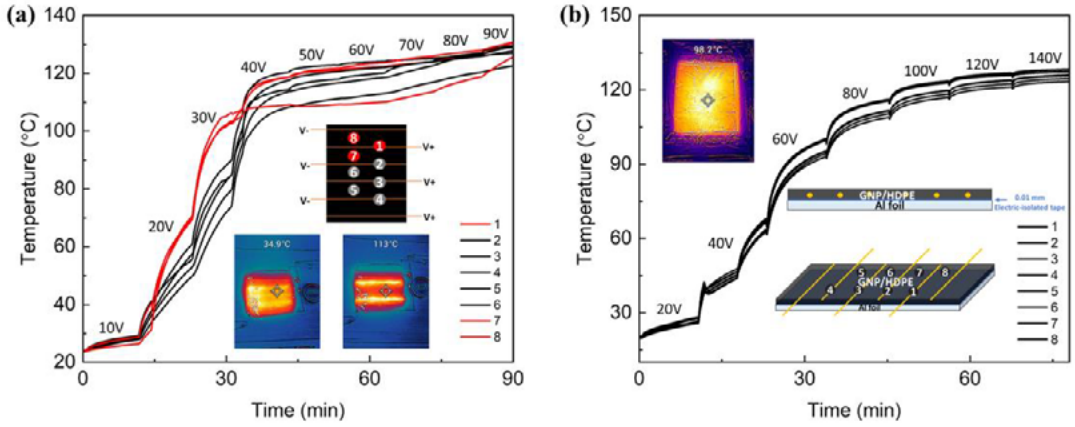

Figure 4 Temperature profile with IR images of the self-regulating heating film in (a) increasing thickness strategy (Strategy 3) and (b) the heating film with 0.1 mm Al foil layer (Strategy 4).

4.3. Additional thermally conductive layer

As indicated by the previous increased thickness strategy, apart from tuning the material compositions and constructions of the PTC and ZTC units, another way to facilitate heat dissipation and temperature homogeneity is to have an efficient heat dissipation layer within (or on top of) the nanocomposite film. Therefore, a heat dissipation layer with a high thermal conductivity has been attached to the nanocomposites, as illustrated in **Figure 4**b insets. This could be an effective alternative to previously examined thick films, especially for end electrode design with relatively large distances between electrodes. A heat-dissipation layer of thin Al foil (100 µm) with a thermal conductivity of ~ 240 W/mK [6], has been attached to previously examined Ch2 nanocomposite films. As shown in **Figure 4**b, an improved temperature uniformity has been achieved with a $\Delta T < 7$ °C. Upon reaching the self-regulating heating stage, a clearer temperature difference has been observed in **Figure 4**b without obvious temperature differences between the contact resistance area near copper wires and the nanocomposites. Despite this fact, a highly thermally conductive layer such as thin Al foil can efficiently facilitate the heat dissipation of the PTC film, achieving more homogeneous heating both before and after the self-regulating stages. This relatively small ΔT agrees with our previous finding when having a continuous layer of materials attached to the heating film for improved heat dissipation [7]. A ΔT of 9 °C has been achieved successfully with clear self-regulating heating observed.

4.4. Sandwich electrode structure

Rather than treating the contact resistance as an uncontrollable heating area, utilizing it as a heat generation area is another approach to address the temperature uniformity problems. **Figure 5**a illustrates a design featuring two layers of copper mesh serving as top and bottom electrodes. As the voltage increased from 80 V to 200 V, the PTC nanocomposites with sandwich-structured electrodes exhibited relatively homogeneous heating and yielded a ΔT of only 11 °C. A stable self-regulating heating can be found, even at increased voltages from 100 V to 200 V, confirming the effective heat dissipation in the current design. However, it is worth noting that although the copper mesh with a wire dimension of only 0.056 mm is relatively flexible, it may result in increased rigidity and additional weight in the sandwiched film for heating devices.

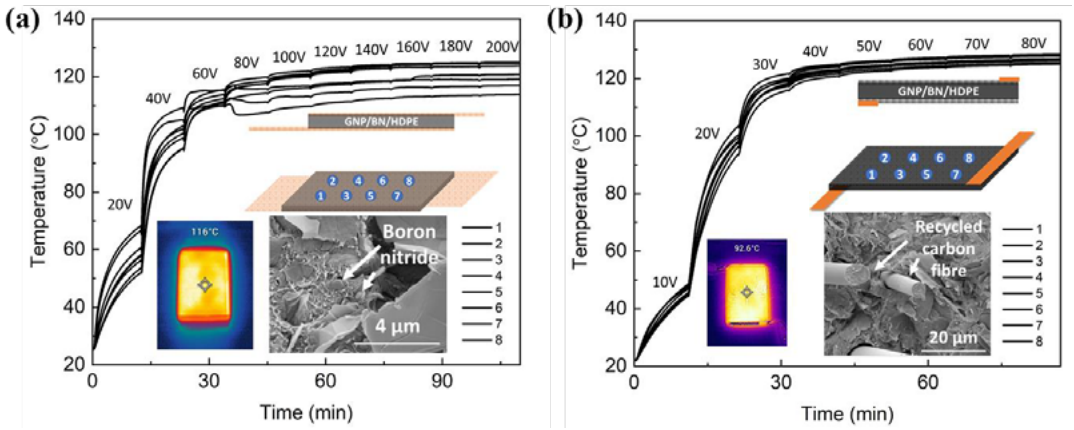

Figure 5: Temperature profile, IR images, schematic illustrations, and morphology images of sandwich electrode strategy with electrodes of (a) copper mesh and (b) rCF veils.

To avoid weight penalty while exploring the potential of upcycling recycled composite wastes as functional and smart materials, lightweight recycled carbon fiber (rCF) veils were evaluated as top and bottom electrodes in sandwich structures. Surprisingly, **Figure 5**b reveals a significantly enhanced heating homogeneity with a minimal ΔT of only 3 °C, surpassing the performance of all previously tested strategies, alongside a stable self-regulating heating with increased voltages from 40 V to 80 V.

Compared to copper mesh electrodes, rCF veils, offers a much larger surface area, leading to a significantly increased total contact area between electrodes and the nanocomposites. In addition, the inherent carbon composition of rCF electrodes contributes to a reduced difference in contact resistance when interfaced with GNP-based PTC nanocomposites.

5. Conclusion

This study aimed to understand and address an issue of inhomogeneous heating which resulted in hot lines in pyroresistive conductive polymer composite heating devices. Two fundamental interconnected physical phenomena causing the inhomogeneous temperature profile have been identified and discussed. Several strategies were proposed and examined to enhance the temperature uniformity of PTC-based self-regulating heating devices, with equivalent simulation performed for most performing strategies. A comprehensive summary showcasing the performance of each strategy has been presented, highlighting the effectiveness of the sandwich electrode structure and the increase in nanocomposite film thickness. A temperature difference of only 3 °C has been achieved successfully at the self-regulating heating stage (125 °C). More interestingly, the use of recycled carbon fibres has been proven an efficient element in smart heating devices, while guidance has been provided for filler selections and electrode designs to enhance the overall functionality of these heating devices.

Keywords: COMBOO, Bamboo, Honeycomb, Lightweight composite, Sandwich

Abstract
In this paper the results of an initial compression test of the composite sandwich structure CCLT – "COMBOO cross laminated timber", COMBOO being a honeycomb pattern of cut bamboo – compared to conventional CLT are presented and discussed.
CLT is a massive timber plywood usually made of pine boards in several layers aligned under an angle of 90 degrees (fibre orientation) with dimension of up to (W x L x H) 7 m x 13 m x 450 mm. It is widely used in civil engineering and architecture to build even high rise wooden buildings. The consumption of large amounts of timber with its density of 0.45 g/cm^3 can somehow be a disadvantage.
COMBOO has many interesting technical properties and a very low density of 0.2 g/cm^3. The combination of both provides the properties of a sandwich structure and could be an alternative material for CO_2 friendly construction.
The stresses measured ranged from 3.1 - 3.97 MPa at 10% compressive deformation perpendicular to the fibre, an average value of 3.5 MPa, and a standard deviation of 0.36 MPa for CLT samples, and 3.39 - 3.42 MPa, an average value of 3.40 MPa with a standard deviation of 0.01 MPa for conventional CLT samples.

1. Introduction

Composite materials integrate the advantageous properties of various substances to achieve superior functionalities. Often, core layers of sandwich composites include environmentally problematic materials like polymer or metallic foams, aramid honeycomb, or balsa wood. These materials pose significant disposal challenges and carry a heavy CO_2 and energy footprint during production. In response, natural and renewable materials with remarkable mechanical properties are being considered. Bamboo, for instance, not only has a high CO_2 storage capability while growing, akin to timber, but it also grows at the impressive rate of up to one meter per day and can be harvested within about seven years. [1] With its low production energy consumption and non-toxic impact on the environment, bamboo offers a sustainable alternative with a significantly positive ecological footprint.

Earlier research on the combination of a bamboo core layer with outer layers of GFRP as a lightweight structure element for partitioning walls or in transport applications not only showed very promising mechanical properties but also resulted in a decoratively translucent element. The next lightweight component to be tested was a COMBOO core with plywood panels as outer layers. The potentially very interesting combination of properties – a lightweight structure with high stability with respect to

compression and bending based on a renewable material – led to an expansion of scope into the area of civil engineering from partitioning walls to wall and ceiling elements where timber is often used, by envisioning a variation of outer layer material. Integrating the new bamboo structure into elements composed of Cross Laminated Timber (CLT) turned out to be a very promising approach [2, 3, 4, 8].

Bamboo has been a trusted construction material for millennia, praised for its high compressive and tensile strengths. When incorporated into construction materials like CLT, bamboo enhances these composites by leveraging its superior compression strength and lighter density owing to its hollow structure. Bamboo's composition – cellulose, hemicellulose, and lignin – is similar to timber but boasts a more favorable CO_2 impact, stronger material properties, and a lower overall density, enhanced by its rapid growth and short harvest cycle.

COMBOO Cross Laminated Timber (CCLT) innovatively replaces the inner timber layers of CLT with a honeycomb structure made from cut bamboo rings. This creates a lighter yet robust sandwich material with bamboo layers encapsulated by traditional CLT. This composite not only reduces the weight of large-scale construction elements – making it advantageous for high-rise building projects – but also maintains essential mechanical properties. Additionally, substituting timber with bamboo in the honeycomb structure significantly lowers the CO_2 footprint due to the reduced energy requirements and CO_2 emissions associated with bamboo production.

The synergy between timber and bamboo in CCLT allows for environmentally benign construction solutions. By incorporating bamboo, the overall density of construction elements decreases while their crucial characteristics are preserved, demonstrating bamboo's capacity to rival traditional materials like steel in tensile strength and stability thanks to its unique hollow cylindrical structure.

This paper covers the manufacturing of test samples of CCLT as well as conventional CLT and describes the results of first compression tests.

2. Materials and Methods

CLT is composed of an odd number of spruce board layers, beginning at 3 layers, each layer being oriented at an angle of 90° compared to previous/next. For the tests, the number of layers was set to 5, in order to be able to replace the core layer while maintaining the CLT characteristics in the outside layers. The comparison of 5 layered conventional CLT and 5 layered CLT with a COMBOO core layer instead of spruce shows the advantages of the enhanced CLT element compared to its conventional counterpart. In this case only one layer of spruce was replaced by bamboo rings, limiting the weight reduction effect to that layer. The length and diameter of the bamboo rings directly impacts the potential weight reduction. Using a thicker COMBOO layer, with longer bamboo rings and also larger diameters would augment the weight reduction effect even further which may well go beyond 20 percent.

2.1. Manufacturing and Materials

Two types of elements were produced for the compression test: 5-layer CLT, made of 5 layers of spruce boards, and 5-layer CCLT (COMBOO-CLT) in which the middle layer was replaced by a layer of COMBOO. Spruce boards with the dimensions (L x W x H) 450 mm x 150 mm x 20 mm, and bamboo culms of similar diameter were selected for the COMBOO layers, in order to obtain a regular honeycomb structure. Before assembling and gluing the spruce boards, these were processed for smoothing and leveling using a jointer and thickness planer. The bamboo rings were cut using a band saw equipped with a linear guide ensuring a constant length as well as parallel edges. The PU glue used in the production process is certified for the gluing of load-bearing wooden components.

For the 5 layer CLT elements a total of 15 spruce boards was used. The first layer of three spruce boards was placed and arranged on an even and plane surface so as to obtain a square with the dimensions of 450 mm by 450 mm. Glue then was spread over the surface in an approximately 3 mm thick layer and the second layer of boards was placed perpendicularly to the boards in the first layer. After pressing the

boards together manually the second layer of glue was applied and the third layer of boards arranged perpendicularly to the boards below. This procedure was repeated for the last two layers after which a load 1584 kg (block of metal cased concrete) was placed on top for the required hardening time of 60 minutes.

The five layer CCLT elements were made using 12 spruce boards making up four layers of spruce board and cut bamboo rings arranged in a honeycomb structure as the middle layer. The first two layers were made in the same way as for the CLT elements. After applying pressure manually, they were covered with a separator film and the second set of two layers was made in the same manner on top of the first. The load of 1584 kg was then placed on top. During the hardening of the CLT layers (60 minutes) the bamboo with a diameter of approximately 80 mm was cut into rings with a height of slightly more than 20 mm. After the hardening of the two CLT layers, the upper two layers were removed, a layer of glue was applied on top of the remaining two CLT layers, and a total of 34 rings was arranged on top and weighed down individually with weights between 2 and 5 kg instead of using the concrete block because the irregular height of the bamboo rings would not have allowed an even weight distribution. After further 60 minutes of hardening, the weights were removed and the element was placed into a CNC machine and the bamboo ring layer was milled over to remove irregularities and assure an even height of 20 mm. Finally a last layer of glue was applied on the upper side of the bamboo rings and the upper two CLT layers placed on top. For the duration of the hardening the load of 1584 kg was applied.

From these CLT and CCLT elements, a total of 10 test samples with varying dimensions were made: samples 1-3 with the dimensions (L x W x H) 80 mm x 80 mm x 100 mm, samples 4-6 with the dimensions 76 mm x 76 mm x 100 mm, and samples G1-G4 with the dimensions 200 mm x 200 mm x 100 mm. A communication problem with the workshop resulted in the samples 4-6 being cut to the dimensions of 76 mm by 76 mm instead of 80 mm by 80 mm yet an adaptation of the calculations allowed to compensate for the resulting differences.

2.2. Methods – Compression Test

The compression tests were performed in accordance with DIN EN 408 using a compression testing machine by TESTING Bluhm & Feuerherdt GmbH (Berlin, Germany) with a maximal load of 300 kN.

Preliminary tests testing the compressive strength of bamboo rings had resulted in high values [8] which lead to the smaller dimensions of the test samples prepared for the compression test in order to be able to stay below the load-limit of the testing machine during the experiment. Yet the high compressive strength resulted in the bamboo being pressed into the upper and lower CLT layer, so that the samples needed to be re-dimensioned, which led to sample sizes of 200 mm by 200 mm instead of 80 mm by 80 mm.

Before the tests were run, all samples were weighed in order to determine the differences in weight between the CLT and the CCLT samples. In these initial tests with a very limited number of samples weight reduction was about 4.54 % for the small samples (1, 2, 3 vs. 4, 5, 6) and about 8.45 % for the larger ones (G1, G2 vs. G3, G4) [7].

3. Results

The compression tests yielded the following results for the CCLT samples: between 3.1 and 3.97 MPa with an average of 3.5 MPa and a standard deviation of 0,36 MPa for the small samples (samples 1-3), between 3.39 and 3.42 MPa with an average of 3.40 MPa and a standard deviation of 0.01 MPa for the larger ones. In comparison, the testing of the CLT samples yielded between 3.49 and 4.14 MPa with an average of 3.76 MPa and a standard deviation of 0.24 MPa [7].

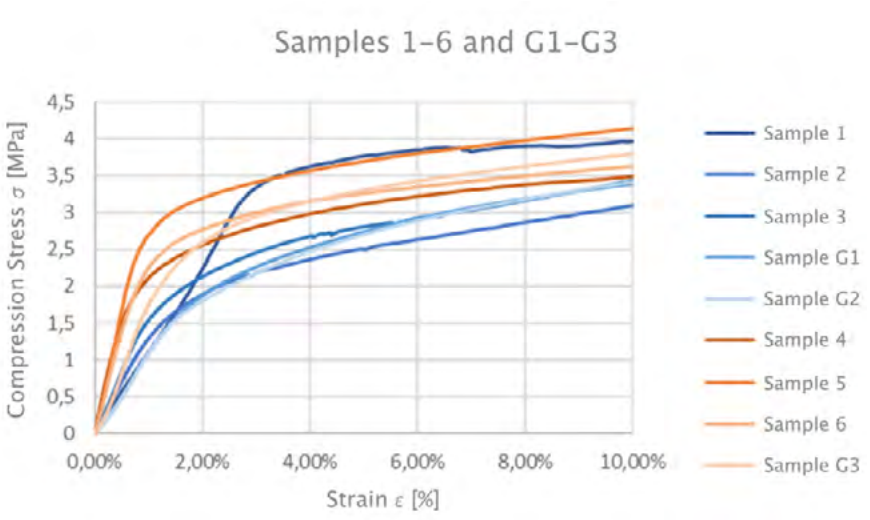

Figure 1. Stress over compression ratio for samples 1-6 and G1-G3 [7, translated into english]

When comparing the samples after the compression tests different failure modes became apparent at 10% compression: penetration of the board layers by the bamboo rings, deformation of board layers, cracks withing the deformed board layers as well as leaked resin from within the boards.

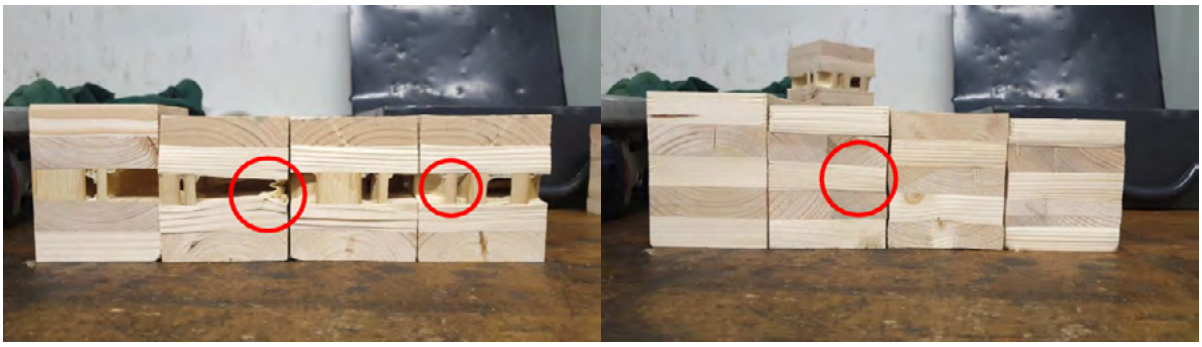

Figure 2. *Deformations in samples 1-3 (left) and 4-6 (right) at 10% compression [7]*

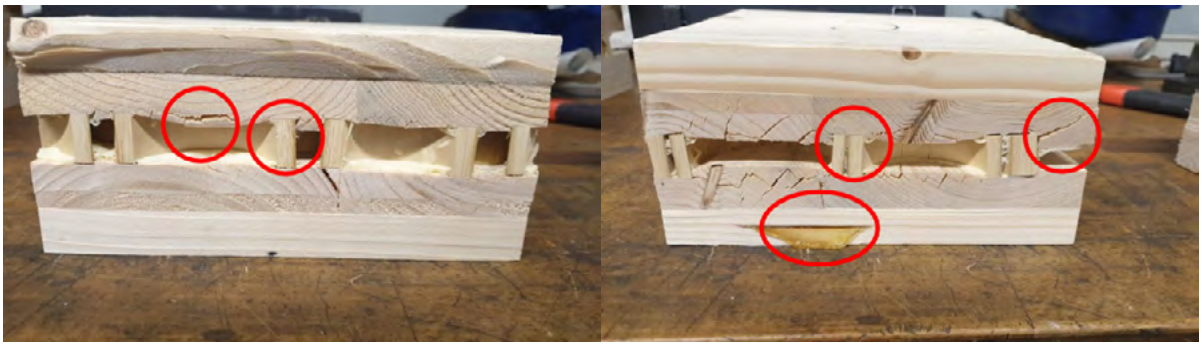

Figure 3. Deformations in sample G1 (left) and G2 (right) at 10% compression [7]

4. Discussion

The obtained results show similar compression strengths of the CLT and the CCLT samples in spite of technical difficulties during sample production. Some of the spruce boards were slightly warped and also the applied pressure using the available load of 1584 kg was much too low compared to what the gluing requirements are: the resulting pressure resulting from the applied load of 1584 kg was at around 0.076 MPa when at least 0.6 MPa would have been required. This probably did not affect the compression test, but might very well affect bending tests, so it is an issue which needs resolving in the future. Additionally the limited available manpower made it impossible to respect the open time of the glue. Considering these difficulties, resulting compression strengths above specification values of industrial CLT (2.7 MPa) are very promising. [6] The compressive strength of the COMBOO layer lies far beyond the compressive strength of the outer CLT layers as it is composed of bamboo rings. The compressive strength of MOSO bamboo which was used to build the COMBOO core reached values between 68.5 MPa and 87 MPa with an average of 75 MPa in earlier compression tests [8], which nearly twentyfold compared to the values obtained for CLT.

5. Conclusion and Outlook

As has already been shown in earlier works involving COMBOO [2, 3, 4], the bamboo layer brings with it the advantages of bamboo, it provides superior mechanical properties when integrated as a core layer into CLT which in this case are high compressive strength, low density due to its hollow structure resulting in lower weight as well as environmental advantages. Ongoing research will provide further insight for example concerning the effect of optimized production processes, on the compression strength and also other properties such as bending strength. Sample production is an issue, which will need to be addressed. This includes an optimized way of applying glue to the bamboo rings within the specified open time, applying a defined pressure to an irregularly shaped surface (when first gluing the bamboo rings to the CLT) in order to be able to apply the required pressure for the gluing process as well as a way to efficiently transfer compressive forces from the COMBOO layer to the CLT layers and vice versa which would allow for even greater compressive strength.

Keywords: Bio-inspired, 3D printing, sacrificial bonds and hidden lengths, toughness

Abstract

Aiming to aid the sustainable transition to fossil fuel-free epoxy materials and enhance the toughness of bio-based epoxies, here we integrate an overlapping curl microstructure consisting of coiling fiber with sacrificial bonds and hidden lengths into a bio-based epoxy matrix. Inspired by natural material, where exceptional properties are achieved at low environmental cost, the microstructure mimics the molecular structures of spider silk, known for its exceptional fracture resistance. The 3D-printed overlapping curl shows a saw-tooth mechanical response with continuous load-carrying ability thanks to the break of sacrificial bonds and unfolding of the hidden lengths. By embedding the overlapping curl into the compact-tension configuration of the bio-based epoxy, an extrinsic toughening mechanism is triggered as the hidden length unfolds. Experimental results show that a single-sided overlapping curl structure is able to improve the toughness of bio-based epoxy by 19%.

1. Introduction

The demand for a sustainable transition in load-bearing structures in the mobility and energy sector, with low carbon emissions and high safety requirements, drives the need for the replacement of fossil fuel-based materials with bio-based materials. Despite being more sustainable, bio-based epoxies, for example, face strong limitations in engineering applications due to their low mechanical properties such as fracture resistance [1] when compared to their fossil fuel-based counterparts. Through evolution over millions of years, natural materials provide a wealth of sophisticated and hierarchical structures with high fracture resistance at low environmental costs, including spider silk, bone, and nacre [2,3,4]. One of the key features that contribute to the high fracture resistance of these biological materials is the presence of sacrificial bonds and hidden length (SBHL) in their organic structures. Upon stretching, the sacrificial bonds will first break and then the hidden length unfolds, providing a residual load and avoiding the sudden fracture.

Drawing inspiration from these biological structures, this work presents a bio-inspired microstructure named overlapping curl (OC) containing coiling fiber with sacrificial bonds and hidden lengths to mimic SBHL features to delay crack propagation in a bio-based epoxy matrix and improve its intrinsic fracture resistance. Fused filament fabrication 3D-printing was adopted to fabricate OC with polylactide (PLA) material and its mechanical behavior was first characterized through tensile tests. Subsequently, the OC structure was embedded into a bio-based epoxy and tested under Compact tension (CT) tests.

2. Experiments

2.1 3D-printing fabrication of overlapping curl

As shown in Figure 1, the overlapping curl structure containing coiling fibers with sacrificial bonds and hidden lengths was produced using a polylatic acid filament (PLA, ReFormTM – rPLA, Formfutura BV, Nijmegen, Netherlands) with a commercial Prusa i3++ 3D printer. The molten PLA material was firstly extruded from the printer nozzle at the temperature ***T***. With the nozzle moving horizontally with the speed ***F***, the extruded PLA filament coiled under the buckling effect [5] and then intersected itself. By controlling the printing parameters (nozzle height ***Z*** and filament extrusion ***E***) to a specific ratio region, the coiling fibers with different curl sizes and orientations (single-sided and double-sided) can be fabricated and are listed in Table 1.

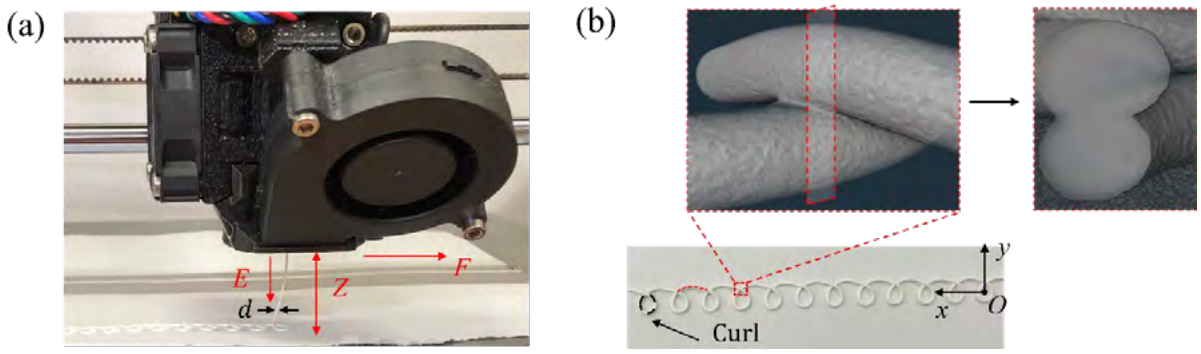

Figure 1. (a) The 3D-printing process and (b) the OC structure contains coiling fiber with sacrificial bonds and hidden lengths.

Table 1. 3D-printing parameters and structures of overlapping curl. ***T***: temperature of the printer nozzle, ***F***: nozzle horizontal speed, ***Z***: nozzle height, and ***E***: filament extrusion.

OC type	***T*** (°C)	***Z*** (mm)	***F*** (mm/min)	***E*** (mm/min)	Structures
Single_Z10	275	10	750	75	
Single_Z5	275	5	750	75	
Double_Z10	275	10	1000	60	
Double_Z5	275	5	1000	60	

2.2 Compact-tension sample manufacturing

A silicon mold was designed for manufacturing compact-tension (CT) samples with consistent geometry shapes, as shown in Figure 2. A two-component bio-based epoxy (SR GreenCast 160) was mixed at a mixing ratio of 1:0.42, before being placed into a vacuum chamber for degassing for around 1 hour. After that, the bio-based epoxy was poured into the mold with the overlapping curl (represented as the blue dashed line in Figure 2) embedded in the vertical direction regarding the crack path and cured for 7 days at room temperature. The thickness of the CT sample was controlled around 8 mm. The CT samples are designated as CT-pure and CT-OC without and with overlapping curl, respectively.

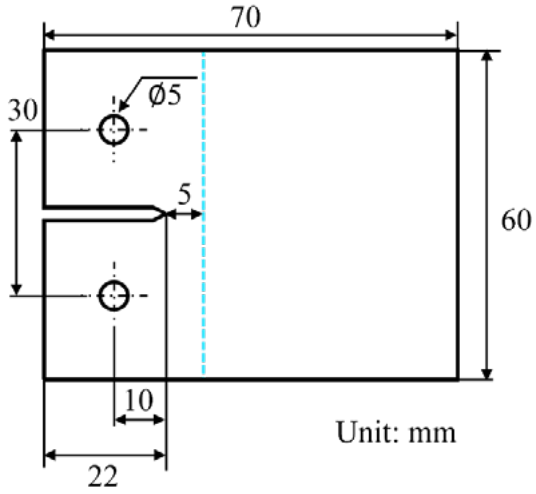

Figure 2. The geometry and dimensions of the CT specimen (thickness of 8 mm). The blue dashed line represents the position of the embedded overlapping curl structure.

2.3 Mechanical testing and characterization

The tensile test and compact-tension test using a universal Zwick loading frame were performed to obtain the corresponding mechanical response of the OC and CT samples. A 100 N load cell was used for loading OC under tensile at a speed of 5 mm/min. During the test, a high-resolution camera is used to capture the deformation process of the OC. Also, a mechanical extensometer is attached to measure the actual separation displacement. For CT tests, a 10 kN load cell is adopted and the tensile loading is applied at a rate of 2 mm/min. Besides, a high-resolution camera and a traveling microscope are set from both sides of CT samples to record the crack advance in the CT testing. The energy release rate (toughness) of the CT samples is obtained from the following equation (Eq. 1) [6],

$$G_I = \frac{P^2}{2t}\frac{dC}{da} \tag{1}$$

Where $\boldsymbol{P}$ is the load, $\boldsymbol{t}$ is the thickness of the sample, $\boldsymbol{C}$ is the fitted compliance of the load-displacement curve, and $\boldsymbol{a}$ is the crack length.

3 Results and discussions

3.1 Overlapping curl mechanical response

Figure 3 shows the representative mechanical response and deformation process of OC under the uniaxial tensile test. With the displacement extension, the load increases until the first sacrificial bond breaks (i) and a load drop happens accordingly. As the curl unfolds (ii), the load rises again reaching the

force limit of the next sacrificial bond (iii). This process continues after all the sacrificial bonds break and a subsequent final failure of the straightened OC (v). This feature leads to the typical saw-tooth curve of the OC structure.

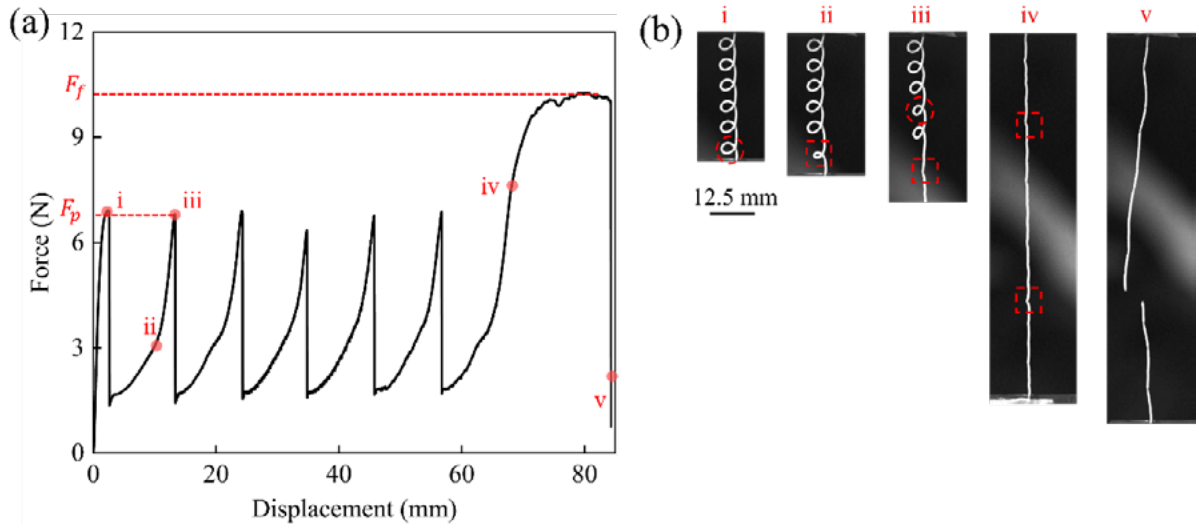

Figure 3. (a) The representative saw-tooth mechanical response curve of Single_Z10 OC and (b) the corresponding deformation process. The red dashed ellipse indicates the broken sacrificial bond and the red dashed rectangle outlines the remaining hidden lengths.

From the load-displacement curves of OC in Figure 4(a), the single-sided overlapping curl structures (Single_Z10 and Single_Z5) show full extension, i.e., all the sacrificial bonds break and hidden lengths unfold. There is also some necking of the filament before the final failure as seen in the final plateau in the load-displacement curve. For the double-sided overlapping curls (Double_Z10 and Double_Z5), they break early, the hidden length is not fully unfolded, and the extension is truncated. To better characterize the mechanical parameters, the sacrificial bonds peak force $\boldsymbol{F_p}$ and failure force $\boldsymbol{F_f}$ of OC, as defined in Figure 3(a), are compared.

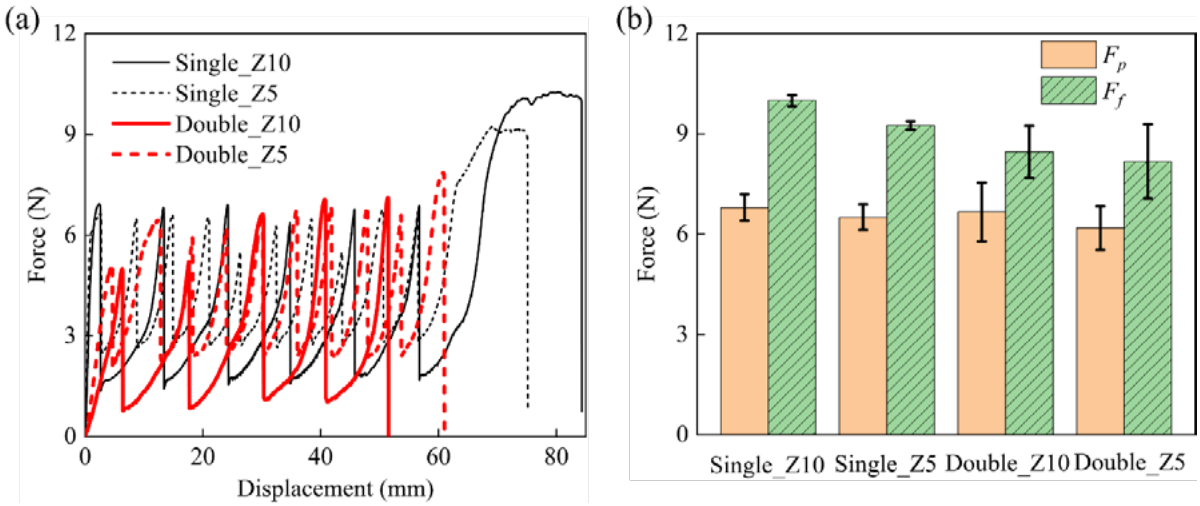

Figure 4. (a) The representative load-displacement curves of the four coiling fiber patterns. (b) The averaged sacrificial bonds peak force $\boldsymbol{F_p}$ and failure force $\boldsymbol{F_f}$ of the coiling fibers.

The average values and standard deviations of F_p and F_f values are shown in Figure 4(b). It can be observed that the F_p values are similar across the four types of structure, while the F_f varies. Both single and double Z5 structures show smaller F_f than their Z10 counterparts. This may be due to the smaller curl size of the Z5 overlapping curl, possibly resulting in more stress concentration while unfolding, causing an early failure and hence lower F_f when compared to Z10. Furthermore, the double-sided structures show lower F_f than the single-sided structures, which may also relate to the higher stress concentration in the double structure since during the manufacturing process, the extruded filament shifts the orientation direction [7].

3.2 Compact-tension test results

To study the effect of the integrated structure on the toughness of bio-based epoxy, CT samples with and without overlapping curl were tested. Figure 5(a) shows the representative load-displacement curves (the load is normalized by the sample thickness). Six typical points in the curve are picked to analyze the OC/epoxy interaction during fracture. Immediately after reaching the peak load, the load decreases faster in the sample with the OC (CT-OC) than without the OC (CT-pure). At point 2 of the CT-OC, the slope in the load-displacement curve changes as the OC starts to affect the crack advance. In Figure 5(b), the delay in crack advance is unnoticeable around point 2 but becomes evident starting from point 3. Figure 5(c) shows the toughness values vs crack length, from point 3 until point 6. An average of 19% toughness improvement is observed. In Figure 6 the fracture process is captured to help illustrate the extrinsic toughening mechanism. Based on Figure 6 - point 2, it can be observed that there is already a gap between the coiling fiber and the epoxy (indicated by the red arrow) indicating that at this point the sacrificial bond has already broken and the hidden length started to unfold. From this point onwards, the OC is believed to start affecting the crack propagation. When the crack tip reaches the position of the overlapping curl (point 3), the hidden length unfolds further, posing a residual load behind the crack tip which delays the crack propagation. The curl completely unfolds at point 4 and breaks at the crack advance of 23mm (point 6). It is also observed an epoxy ligament (highlighted by the red ellipse in Figure 6 - point 6) is also triggered, possibly delaying the crack propagation, and enhancing further the toughness values.

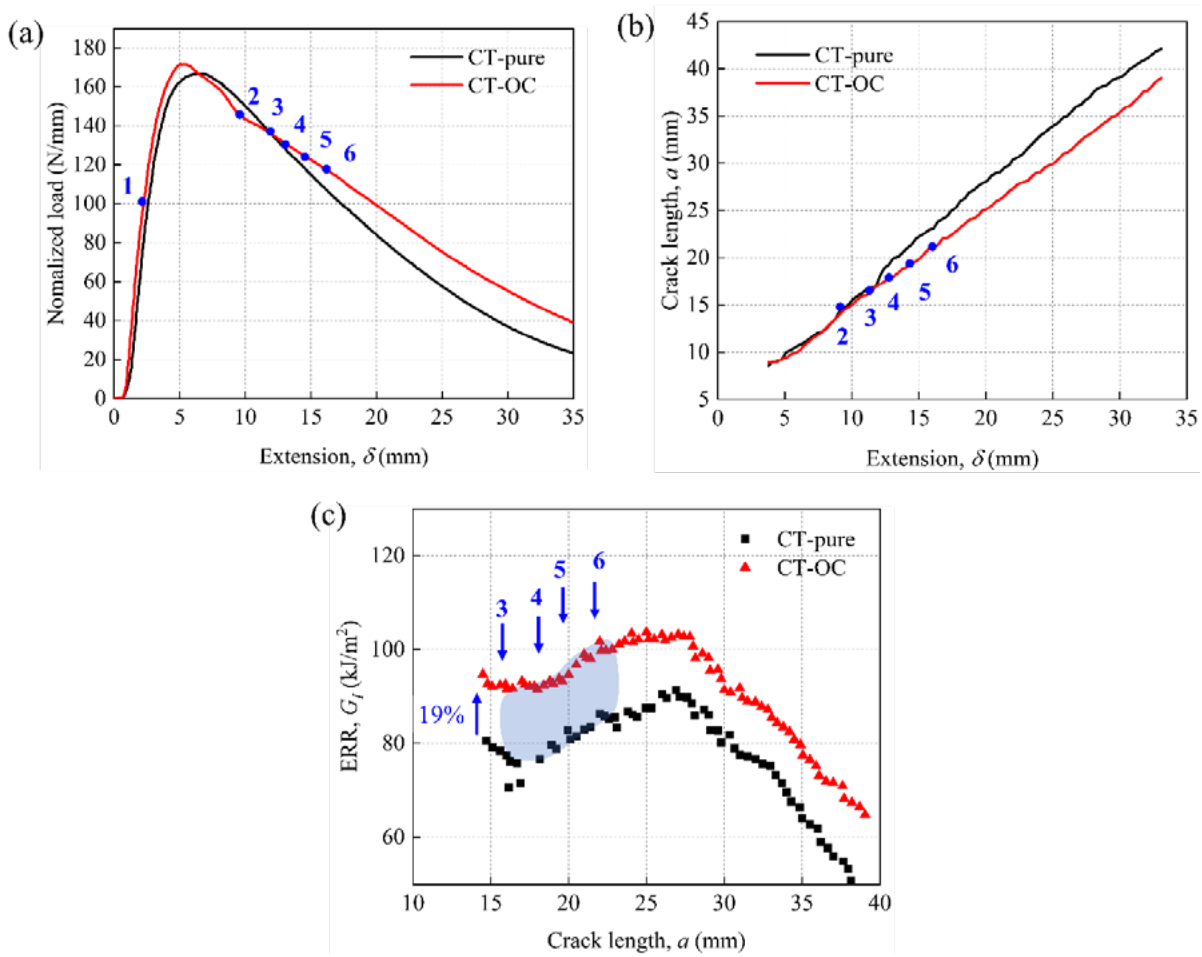

Figure 5. (a) Typical load-displacement curves of CT-pure and CT-OC samples. The load is normalized by the sample thickness. (b) Crack length vs extension curve, and (c) toughness R curve.

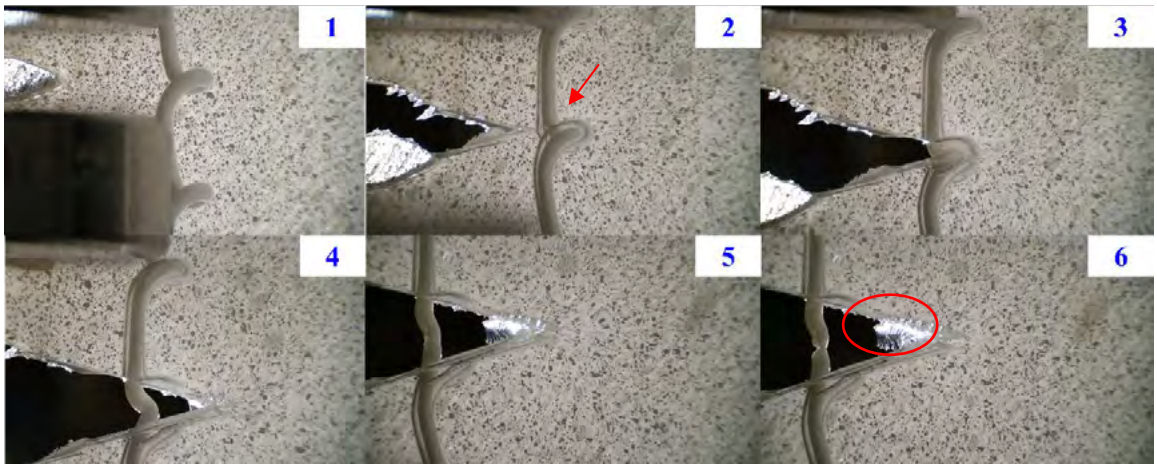

Figure 6. Snapshots during crack propagation of CT-OC sample. The red arrow indicates the gap between the coiling fiber and epoxy. The red ellipse highlights the epoxy ligament.

4. Conclusions

A bio-based epoxy reinforced with a spider silk-inspired overlapping curl consisting of coiling fiber with sacrificial bonds and hidden lengths was designed and tested. The 3D-printed overlapping curl alone shows the typical saw-tooth curve attributed to the break of the sacrificial bonds and unfolding of the hidden lengths. The single-sided overlapping curl structure shows longer extensions than the double-sided ones. Compact tension test of the single-sided overlapping curl structures embedded in the bio-based epoxy shows an average 19% toughness increase when compared to pure bio-based epoxy. As the crack crosses the coiling fibers, and the hidden length unfolds, it is expected that a reinforced load is applied to the crack path delaying crack propagation and contributing to the mechanical performance increase.

Keywords: Polypropylene composite, Cellulose nanofiber, Talv filler, 3D printing, Multiscale FEA

Abstract

Hybrid reinforced composites with talc fillers and cellulose nanofibers (CNFs) were proposed as a new fused filament fabrication for polypropylene (PP), which is an important thermoplastic polymer widely used in mass-produced products such as automobiles. The effect of filler addition was clarified by multiscale finite element method (FEM). A multiscale FEM scheme for printed hybrid reinforced PP composites by three-step homogenization was developed in computational simulation. Cross-sections of 3D printed specimens were observed with an optical microscope, and multiscale FEM based on a microstructural model constructed from the binarized images was performed. The effects of voids due to poor filling and interfaces between solidified filaments in the heterogeneous structure formed by printing were quantified, and the mechanism of mechanical property degradation was elucidated.

1. Introduction

Polypropylene (PP) is widely used mainly in the automotive industry because of its excellent mechanical properties and moldability, low cost, thermoplasticity, and high recyclability. In general, PP is reinforced with short glass and carbon fibers, natural fibers such as hemp and yellow hemp, and mineral fillers such as talc and calcium carbonate to improve stiffness and strength. In general, PP products are mass-produced by injection molding. In recent years, however, there has been an increasing demand for prototyping using PP itself instead of alternative materials such as ABS or PLA in the product development process, and for personal production as an alternative to injection molding. PP printing by fused filament fabrication (FFF) is also gaining momentum [1]. However, compared with engineering plastics, PP has lower thermal, electrical, and mechanical properties, and has many points to be improved, such as large warpage after fabrication. In addition, the mechanical properties of PP are lower than those of injection-molded materials due to the generation of internal voids caused by its nature in 3D printer modeling [3]. In order to achieve the multiple objectives of adding desirable properties to the base resin in the 3D printing process and at the same time suppressing the degradation of mechanical properties, it is effective to add multiple fillers with different properties instead of a single filler. In such hybrid reinforced composites, the design parameters of mechanical properties are doubled and the influence of each factor becomes more complex, making the introduction of mathematical and numerical analysis essential. In general, multiscale simulations are effective in characterizing composite materials and elucidating the strengthening mechanism [4-7].

In this study, hybrid reinforced PP composites were proposed as a new PP printing material, and the effects of filler reinforcement were investigated by multiscale finite element analysis based on homogenization theory. Talc, commonly used in the automotive field, was selected as a filler along with CNF, which is increasingly utilized as an environmentally friendly material. Furthermore, by employing a three-step homogenization process, an analytical scheme for the nonlinear mechanical properties of printed hybrid reinforced PP composite structures was developed. The cross section of the 3D printed specimen was observed with an optical microscope, and a multiscale analysis based on the microstructural model constructed from the binarized images was performed. The effects of voids due to poor filling and the interface between melted and solidified filaments on the inhomogeneous structure formed by printing were quantified, and the mechanism of degradation of mechanical properties was elucidated.

2. Computational methods

2.1. Materials

In the creation of hybrid reinforced composite filaments, block PP (J707G, Prime Polymer), a thermoplastic polymer, was employed as the base material, and talc and CNF as reinforcement. For the former, PP masterbatch (MB) mixed with 70% talc was used, and MB mixed with 15% CNF was assumed to be used for the latter. 10 g of talc MB and 10 g of CNF MB were blended with 100 g of MB of PP, and three types of composites, PP/Talc, PP/CNF, and PP/Talc/CNF, were prepared. Three types of composite materials, PP/Talc, PP/CNF, and PP/Talc/CNF, were prepared.

2.2. Multiscale finite element analysis

For hybrid reinforced polymer composites, in addition to heterogeneous structures in which CNF and talc are dispersed, it is necessary to consider heterogeneous structures with inherent voids and interfaces due to printing. Since it is difficult to treat these heterogeneities in a single microstructure, three heterogeneous structures were homogenized hierarchically, as shown in Fig.1. First, we consider the microstructure with talc filler dispersion and the sub-microstructure with CNF dispersion. In the case of injection-molded specimens, the micro- and sub-microstructures are targeted, dealing with homogenized macrostructures in which the microstructures are periodically arranged. On the other hand, in the case of 3D printed specimens, meso-heterogeneous structures formed by melt-glued filaments are also considered. In the meso structure, we consider not only the printed phase, but also the void phase due to poor filling and the interfacial phase between melt-glued filaments. Homogenization theory is employed for scale coupling in macro and meso structures, meso and micro structures, and micro and sub-micro structures. In homogenization theory, scale ratios are introduced and displacements are expressed as asymptotic expansions of the displacements of the global structure and the perturbed displacements of the local structure, allowing the derivation of scale-coupled equations that are mathematically consistent for both structures.

In the first stage of the homogenization process, the homogenization properties of the base material region of the microstructure with talc filler dispersed as the global structure are calculated, with the CNF-dispersed sub-microstructure as the local structure. In the second stage of the homogenization process, the homogenization properties of the printed phase of the 3D printed specimen are obtained using the microstructure with talc filler dispersed as the local structure and the global structure as the global structure. In the third step of the homogenization process, the homogenization properties of the macrostructure are obtained by taking the mesostructure of the 3D printed specimen as the local structure and the global structure as the macrostructure. In addition, the mechanical response of the macrostructure to external loading is analyzed. Multiscale.Sim was used for scale coupled analysis based on homogenization theory, and ANSYS was employed as the FEM solver.

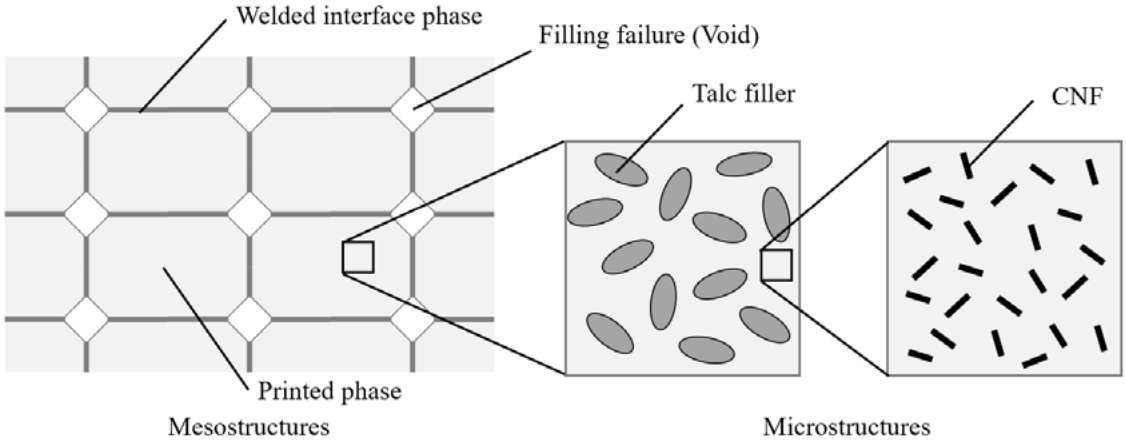

Figure 1. Multiscale modeling of 3D-printed hybrid reinforced composites.

An example of a representative volume element model employed for micro and sub-micro structures is shown in Figure 2. From left to right in the figure below, the RVE models are PP/Talc, PP/CNF, and PP/Talc/CNF. Based on SEM observations of composite cross sections, the Talc shape was a disk with a diameter of 4.0 μm and a thickness of 0.39 μm, and the CNF was 0.03 μm in diameter and 1.5 μm in length based on the published values of the raw material manufacturer. Talc and CNF were assumed to be elastic materials, with Young's modulus of 17.2 GPa and 140 GPa, respectively, and Poisson's ratio of 0.27 and 0.30, respectively, for PP. The mechanical properties of PP/CNF were obtained through the first homogenization process. Next, the obtained mechanical properties of PP/CNF were input to the base material of the RVE model in which only Talc was distributed, and the mechanical properties of PP/Talc/CNF were obtained through a second homogenization process.

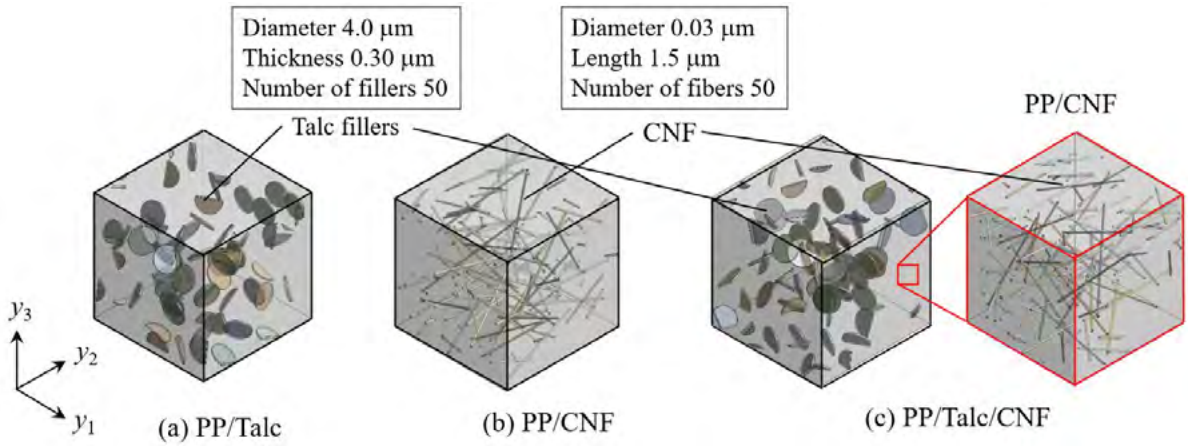

Figure 2. RVE models of PP composites with talc fillers and CNFs dispersed.

3. Result and discussion

Figure 3 shows a microstructure model of a 3D printed body considering the meso-homogeneous structure formed during printing. As shown in (a), an assembly of four melt-glued quarter filaments is considered as the unit cell of the heterogeneous structure, with a diamond-shaped void in the center due to poor filling and an interface phase between the four filaments. First, a general-purpose 3D printer (MF2500EP2, MUTOH) using the FFF method was used to print specimens for cross-sectional observation. The specimens were placed in the xy-plane of the printer table so that the thickness direction coincided with the z-axis in the stacking direction and the longitudinal direction was parallel to the x-axis. The specimens were printed with a fill rate of 100% and a printing angle of 0 degrees, i.e., with the longitudinal direction aligned with the x-axis. A nozzle with a diameter of 0.4 mm was used. After

searching for optimal printing conditions through trial and error, the extrusion nozzle temperature was 235°C, the table temperature was 115°C, the extrusion width was 0.4 mm, and the layer thickness was 0.2 mm. The cross section of the printed specimen was observed under an optical microscope, and the obtained cross-sectional image was binarized to identify void areas. From this, the area percentage and rhombic dimensions of the void areas were statistically calculated and reflected in the unit cell. As shown in (b), the cross section of the unit cell was divided into three regions, A, B, and C, and the possible effects of printing were reflected in these regions as mechanical properties. The PP composite material was set in region A, voids in region B, and one-tenth of the Young's modulus of PP in region C. The interface between the filaments is formed by molten PP, but the degree of entanglement of the PP molecular chains is mild, and a weak interface is assumed to form, different from the original mechanical properties.

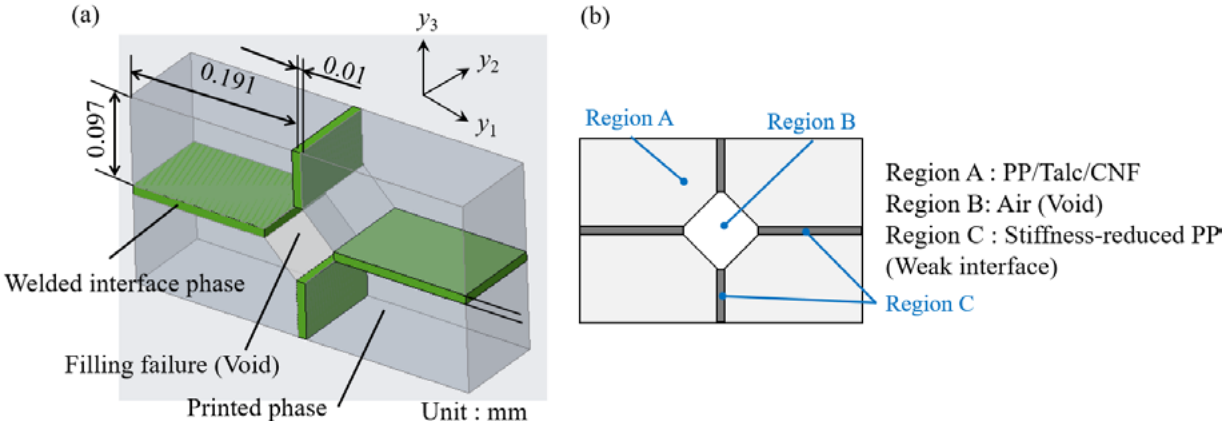

Figure 3. Meso heterogeneous structures formed during printing. (a) Unit cell model and dimensions of the heterogeneous structure; (b) Factors that degrade mechanical properties

Figure 4 shows the stress-strain relationship obtained from multiscale FEA with meso-homogeneous structure in Figure 3 for each of the printed composites. For all composites, the tensile stress increased linearly with increasing applied strain, and then the nonlinearity became significant after the applied strain exceeded 1%. This is because the nonlinear properties obtained from tensile tests of injection-molded PP were input to the base material PP in multi-scale FEA to analyze the mechanical properties of the PP composites. The influence of the filler was significant as the loading increased. At all loading strains, tensile stresses were higher for PP, PP/Talc, PP/CNF, and PP/Talc/CNF in that order, with the hybrid reinforced PP composite having the highest initial modulus and tensile stresses.

To quantitatively confirm the reduction in mechanical properties due to printing, Figure 5 then compares the Young's modulus and tensile strength of the PP composites obtained from the analysis using the injection-molded and 3D-printed models. In (a), Young's modulus of both injection-molded and 3D-printed composites improved in the order of PP, PP/Talc, PP/CNF, and PP/Talc/CNF. The Young's modulus of CNF was about 8 times larger than that of talc filler, which is considered to be due to its greater reinforcing effect. Furthermore, the Young's modulus of the 3D-printed specimens was about 10% lower than that of the injection-molded specimens. The maximum stress of both injection-molded and 3D-printed specimens increased in the order of PP, PP/Talc, PP/CNF, and PP/Talc/CNF in (b), and the maximum stress of the 3D-printed specimens was about 10% lower than that of the injection-molded specimens. These results indicate that voids and fragile interfaces reduce the mechanical properties of the 3D-printed specimens, and that Young's modulus and maximum stress are affected by the printed heterogeneous structure to the same extent.

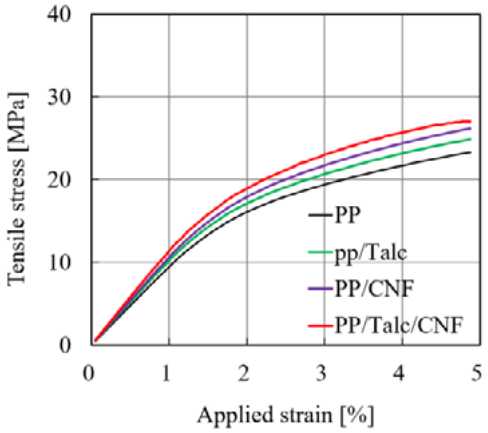

Figure 4. Comparison of computational results of stress-strain relationship of injection molded PP composites.

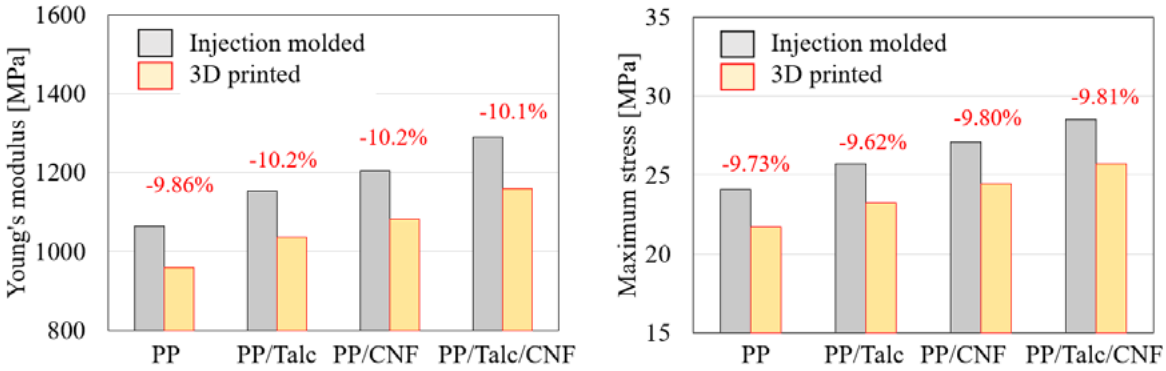

Figure 5. Comparison of mechanical properties of four different injection molded and printed models obtained from the analysis. (a) Young's modulus, (b) Maximum stress.

4. Conclusions

Hybrid reinforced PP composites with talc and CNF were proposed as a new FFF for PP composites, and the effect of filler addition was clarified by multiscale FEA. In the numerical analysis, a multiscale FEM scheme of printed hybrid reinforced PP composites with three-step homogenization was developed. It was found that the addition of talc and CNF was effective in improving Young's modulus and maximum stress, and the hybrid composites with both additions showed further reinforcing effects. For the inhomogeneous structure formed by printing, the effects of voids due to poor filling and the interface between melted and solidified filaments were assumed, and the mechanism of degradation of mechanical properties was clarified.

Keywords: Laser ablation, Linear regression, Buckingham-Pi, 4D-Imaging, Fiber reinforced polymer composites.

Abstract: The study of laser ablation in fiber-reinforced composites extends beyond machining, offering insights into material behavior in high-heat environments, such as aerodynamic heating in high-speed aircraft, atmospheric re-entry and laser weapon on composite drones, unmanned air vehicles (UAVs) and missiles. Laser ablation, replicating high heat flux rapidly, is pivotal for exploring thermal shock and ablation resistance. Key parameters include ablation depth and the heat-affected zone (HAZ). Initial analysis, utilizing optical microscopy and image processing, revealed a correlation between laser power, energy input, and HAZ size. While HAZ area remains nearly constant with energy input for varying laser power, ablation depth increases proportionally with laser power due to the laser burning off material beyond its diameter, leaving contact with the pit's sidewall. Distinctive heat-affected volumes were observed using a four-dimensional X-ray microscope. The study aims to link ablation performance, material properties, and laser parameters for damage prediction. Methodology focuses on ablation depth and HAZ area, incorporating material properties and non-dimensional terms derived using the Buckingham-pi method. Empirical formulas predicting ablation depth an in GFRP and CFRP was found through linear regression using dimensionless terms.

1. Introduction

Fiber reinforced polymer (FRP) composites is being used extensively in aircraft and drone industry owing to it's high specific strength and stiffness, lightweight design causing fuel savings and lower carbon footprint than traditional material. However, when exposed to high heat flux it undergoes thermal degradation due to low degradation temperature depending upon the type of fiber and matrix used. High heat flux is experienced in cases of laser machining, directed energy system being used to attack UAVs, missiles and during aerodynamic heating in high speed aircraft. The major damage parameter in all of these cases are - heat affected zone and ablation depth. In laser machining of FRPs different laser parameters affect area of heat affected zone and ablation depth, this in turn will affect the quality of machined part [1].

Composite materials were initially used in military aircraft to reduce weight, allowing for increased weapon capacity and extended range. Recently developed directed energy systems are being deployed on battlefields, particularly targeting UAVs and helicopters, with potential for wider adoption as they advance [2]. Carbon-Carbon/Silicon carbide composites are used in hypersonic aircraft and rocket nozzles where they have to withstand sudden extreme heat during their service life, enduring high heat flux for short periods, with the combined effect of aerodynamic forces can cause unprecedented material damage [3,4]. In all these cases, it is evident that there is a need to understand the effect of high heat flux on FRP composites [4]. In laser ablation experiments, high heat flux can be emulated by adjusting both the power and diameter of the laser beam. Therefore, understanding laser material removal and predicting the size of the heat-affected area and depth of material removal is crucial.

In this paper, laser ablation experiments have been conducted on both carbon fiber and glass fiber reinforced polymer composites. The morphological study of the damaged specimen was carried out using four-dimensional X-ray microscope. Non-dimensional framework is introduced that predicts ablation depth (dependent term) given material properties and laser parameters (independent terms).

2. Materials and methods

2.1. Materials

Unidirectional carbon fiber reinforced composite (figure 1(a)) was manufactured using hand lay-up in the composite fabrication lab. It is a 7 layered laminated composite of 5.0 mm thickness. It was made using T-300 carbon fibers with LY 556 epoxy and HY 951 hardener as matrix in 10:1 ratio by weight. The sample was cured for 24 hours under pressure load. It was cut using water jet into rectangular pieces of 100 mm × 20 mm.

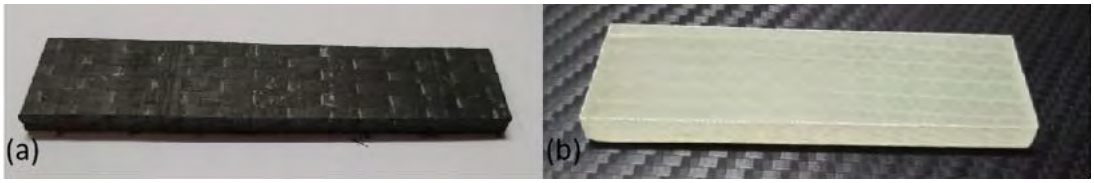

Figure 1. Laminated (a) carbon and (b) glass fiber reinforced composite.

Glass fiber composite (figure 1(b)) was manufactured by Fibrotech Composites. It has e-glass fiber by Owens Cornins and epoxy resin HSC 7600 with hardener HSC 8575 as matrix. It is a unidirectional laminated composite with 6 bundled-layer and a total thickness of 5.0 mm. Each layer has six fiber bundles in it stacked horizontally.

Table 1. Composite material properties

Specimen Type	Density (Kgm^{-3})	Specific heat capacity ($JKg^{-1}K^{-1}$)	Thermal Conductivity ($Wm^{-1}K^{-1}$) (Through thickness)	Melting temperature of fibers(K)
CFRP	1513	1021	0.636	3473
GFRP	2015	672	0.479	1978

2.2. Experimental setup

For the ablation experiment, SIL laser engraving machine and cutting machine AccuCut 1212 model was used. It is a near infrared laser. It has Co_2 DC Glass Laser Tube, pulse laser with a wavelength of 106nm. For ablating UD-GFRP/CFRP composite, laser power was varied as 20W, 26W, 39W, 40W, 52W, 65W while time for irradiation was varied till the laser just ablates through the entire thickness. The laser ablates the composites normal to it's surface. Laser diameter is 0.1 mm.

2.3. Non-dimensional framework

Dimensional analysis is a powerful technique for explaining complex system behaviors, such as laser ablation in polymer composites. It simplifies problems by reducing them to a manageable set of independent variables, offers physical interpretability through dimensionless terms, guides

experiments by identifying key influencing factors, and establishes scaling laws to relate behaviors across different scales. This approach also aids in developing empirical relationships using statistics and machine learning.

Buckingham pi method is one such method that is used to obtain non-dimensionless numbers to explain complex physical phenomenon [5,6,7,8]. The key idea behind the Buckingham Pi theorem is that physical phenomena can often be described by dimensionless groups or parameters, which are combinations of the original variables in a system such that the resulting expression is dimensionless (i.e., it has no units). These dimensionless parameters help in understanding the relative importance of different variables and how they affect the behavior of a physical phenomena [8].

Table 2. Set of fundamental parameters chosen for non-dimensional terms.

Parameters	Symbol	Dimension
Density	p	ML^{-3}
Thermal conductivity (through thickness)	k_1	$MLT^{-3}C^{-1}$
Thermal conductivity (along fibers)	k_2	$MLT^{-3}C^{-1}$
Specific heat	c	$L^2T^{-2}C^{-1}$
Fiber melting temperature	T	C
Material thickness	h	L
Power	P	ML^2T^{-3}
Irradiation time	t	T
Ablation depth (dependent)	d	L

Ablation depth prediction	
Power ratio	$\frac{Thk_1}{P}$
Diffusivity ratio	$\frac{h^2pc}{tk_1}$
Depth ratio	$\frac{d}{h}$
Repeating variable	K_1,h,c,t

Using these set of variables, we end up with 51 sets of π terms for both ablation depth and damage area prediction. To reduce this set of π terms to a unique choice of set that could explain the system behaviour, statistical consideration such as correlation among independent non-dimensional terms, correlation between dependent and independent non-dimensional terms, p-value (significance of independent parameters in predicting dependent terms) and interpretability of the dimensionless terms are considered. The repeating variables in table 2. are not apparent based on the dimensionless numbers since 'Diffusivity ratio' arises due to ratio of two other numbers and 'Conductivity ratio' is dropped due to it's weak correlation with the depth ratio.

3. Results and discussion:

3.1. Experimental:

Area of the heat affected zone (figure 2 (a)) and ablation depth (figure 2 (b)) was calculated in Image J software from the image taken in optical microscope at 16X magnification.

In surface view as shown in figure 3(b), Carbon Fiber Reinforced Polymer (CFRP) exhibits an elliptical profile, while Glass Fiber Reinforced Polymer (GFRP) in figure 3(d) showcases a circular profile. When subjected to damage as shown in Figure 3(a), CFRP typically displays a spheroidal damage profile within the Heat Affected Zone (HAZ), whereas in figure 3(c) GFRP exhibits a conical damage profile within the HAZ. This can be attributed to high thermal conductivity, high melting point of carbon fibers as compared to glass fibers and unidirectional nature of the composites.

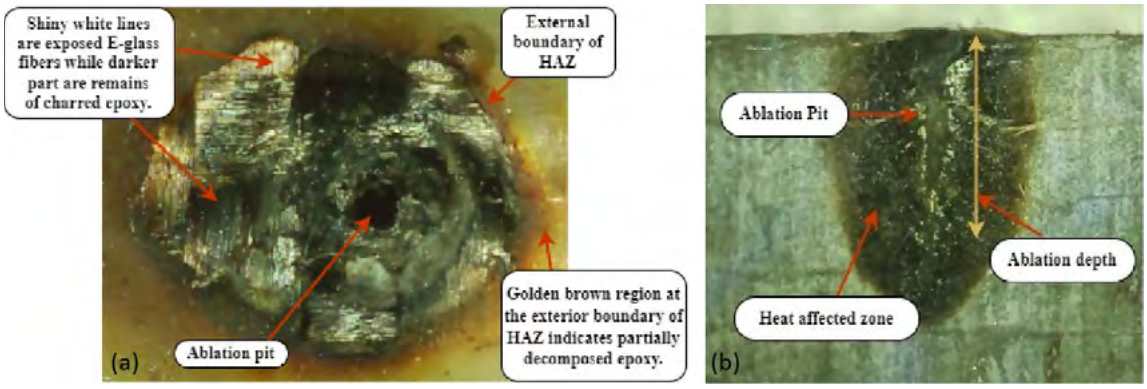

Figure 2. (a) Heat affected zone and (b) ablation pit morphology in case of GFRP.

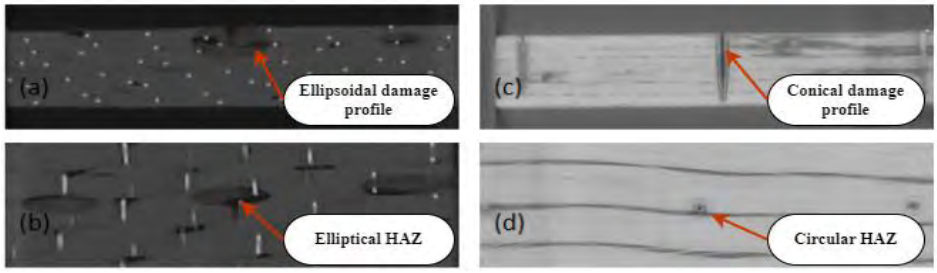

Figure 3. Ablation pit morphology comparison between (a) CFRP & (c) GFRP and heat affected zone profile comparison between (b) CFRP & (d) GFRP.

From figure 4, it can be seen as the area of the heat-affected zone is increasing with increasing power for the same irradiation time because more energy is applied per unit time. For the same power, more irradiation time results in more HAZ area since more energy is being applied. However, for 26W and 39W laser power, after a certain time, the area of HAZ doesn't increase. This could be due to the fact that once more area around the laser diameter region gets vaporized, there is no contact left for heat to be conducted in the in-plane direction of the composite laminate. This is more prominent in the case of low-power lasers since it requires more time to ablate the GFRP laminate completely. This leads to the deepening of the ablation pit without any further increase in the HAZ area. Therefore, in order to observe no further increase in HAZ area with irradiation time for a 52 W laser, we need a thicker composite. For a 65 W laser, the irradiation time to completely ablate the composite is too short; therefore, very few data points are seen in the plot.

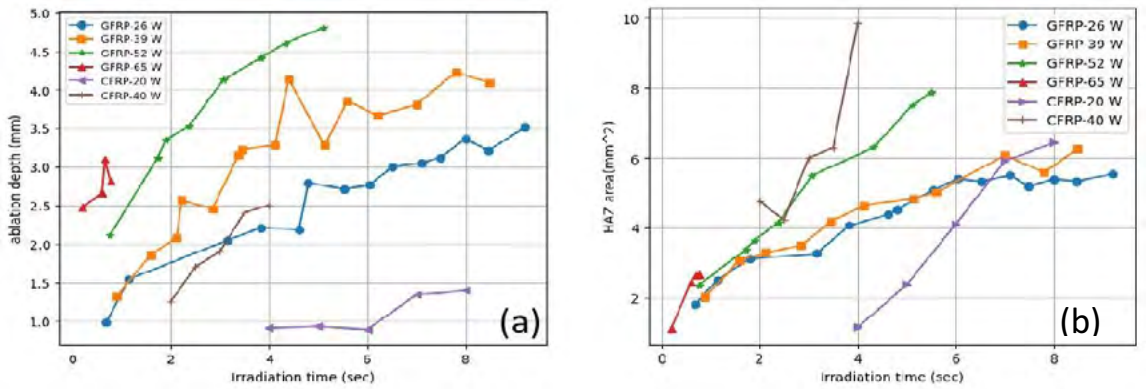

Figure 4. (a) Heat affected zone vs irradiation time plot and (b) ablation depth vs irradiation time for both GFRP and CFRP

For CFRP, higher power does less damage than low power in GFRP. Even a lower laser power will cause a large heat affected zone due to comparatively higher thermal conductivity in the in plane direction along fibers. Any discrepancy with the above-mentioned trend can be attributed to whether laser strikes fibre bundles (more HAZ area) or the interface between the fibre bundles. It is observed that ablation depth is more for higher laser power for the same energy. Here, diameter of the laser is kept the same therefore, higher laser power is also the higher laser intensity which is the critical parameter affecting laser ablation depth. Ablation depth should increase with increasing irradiation time for the same laser power, however, this is not true always in the figure 3(a) for laser power of 26W, 39W and 65W. This results in more depth for lesser time in some of the cases. Another observation that can be made from the figure 3(b) is that as laser power is increasing effective slope of ablation depth vs irradiation time plot is also increasing which suggests that ablation rate is higher for high power laser.

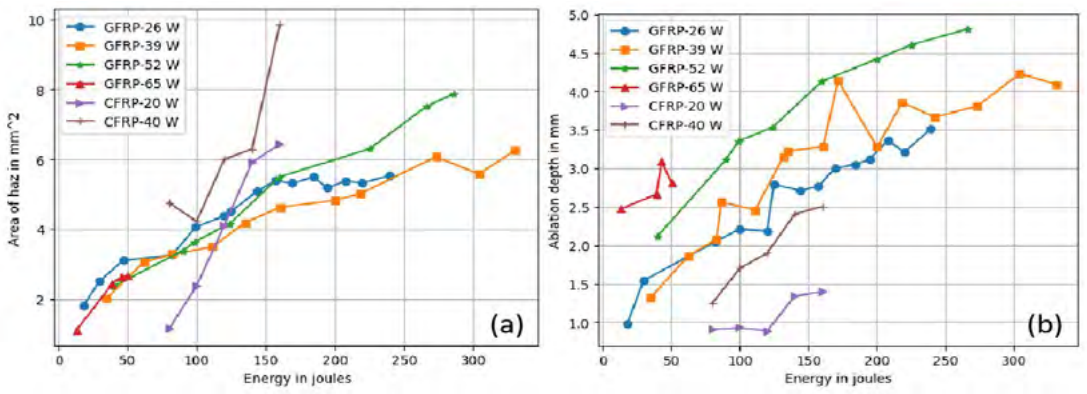

Figure 5. (a) Area of haz at the exposed surface vs energy plot (b) ablation depth vs energy plot for both CFRP and GFRP.

Increasing laser energy increases ablation depth for the same laser power, however ablation depth for high power laser is higher for same energy input. Area of heat affected zone increases with the increase in laser energy. For the same energy, varying laser power level does not change the area of the heat affected zone for GFRP (figure 5(a)) but this cannot be said for the CFRP material (figure 5(b)) owing to less sample points.

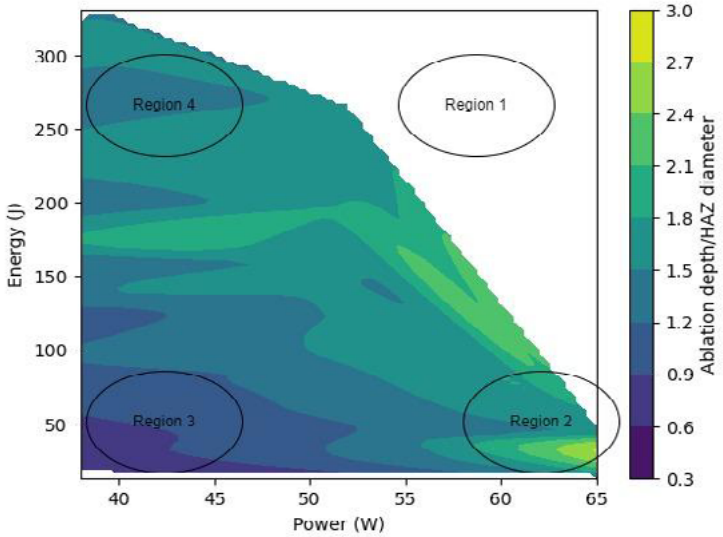

Figure 6. Ablation depth to heat affected zone ratio vs energy input and laser power for GFRP

In figure 6, the plot is divided into 4 regions, region 1 (in white) is for that combination of laser power and energy which results in almost complete ablation of the composite laminate. Region 2 refers to the region of high power and low energy which results in high ablation depth as compared to the width of the heat affected zone. As we move from region 2 (high power) to region 3 (low power) for the same energy, a lower depth to haz diameter ratio is observed since lower power leads to low depth however for large irradiation time (to maintain same energy) results in more heat transfer as melting point of material around laser reaches slowly. From region 3 to region 4, for the same power, energy (irradiation time here) increases which causes ablation depth to dominate as enough time exists for material removal however once material around laser looses contact with laser beam haz stops increasing leading to a higher depth to damage diameter ratio.

3.2. Non-dimensional framework:

For predicting depth ratio, diffusivity ratio and power ratio turns out to be the most important parameters. Linear regression was performed in log-log domain as it linearizes the data that helps to capture non-linear trends by using linear regression which is the simplest model to implement and easily interpretable. Figure 7(a). shows comparison between actual and predicted ablation depth for CFRP and GFRP. The 3D plot in figure 7(b). shows regression plane and scatter points between dependent and independent dimensionless ratios in the log-log domain. The equation for the regression plane for predicting ablation depth is,

$$\frac{d}{h} = 0.286 \times \left(\frac{h^2 pc}{tk_1}\right)^{-0.35} \times \left(\frac{Thk_1}{P}\right)^{-0.7276} \quad (1)$$

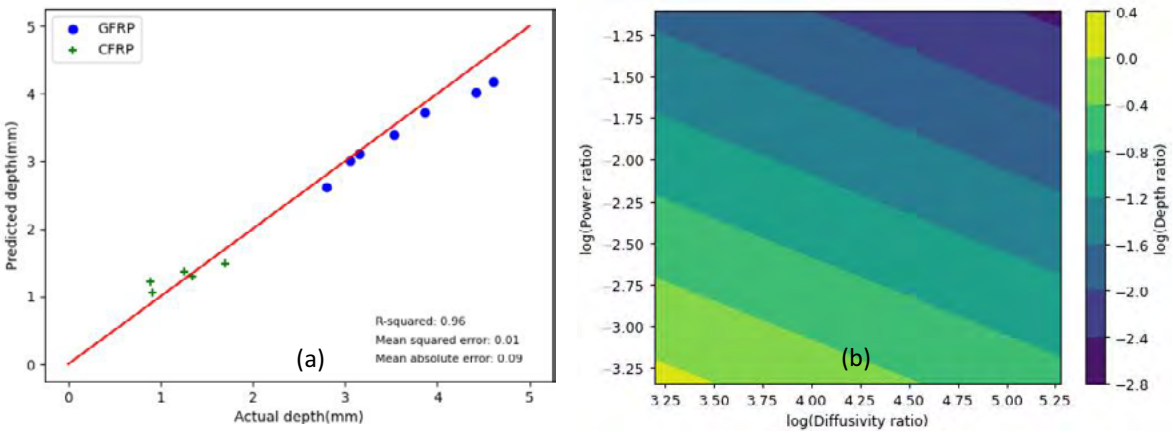

Figure 7. Regression plot (a) predicted depth vs actual depth (b) 2D contour plot for 'Depth ratio' prediction for a combination of 'Diffusivity ratio' and 'Power ratio'.

From figure 7(b) we can observe the parallel shades of colors that represent values of depth ratio for various power and diffusivity ratios. The depth ratio is inversely related to power and diffusivity ratios.

4. Conclusion

Laser ablation damage comprising ablation depth and heat affected zone was investigated for unidirectional carbon and glass fiber reinforced polymer composite. Damage profile was studied under 4D X-ray microscope. Area and depth of the damage was measured in image J software. Experimental data was analyzed to study the effect of laser parameters and material properties on ablation depth and area of heat affected zone. Non dimensional framework was used to predict laser ablation depth. The following conclusions could be drawn:

1. Unidirectional CFRP composite yielded an elliptical heat affected zone surface and ellipsoidal damage profile while unidirectional GFRP composite yielded a circular heat affected zone surface and a conical damage profile.
2. Laser ablation depth increases for the same energy input for the increasing laser power however, area of heat affected zone remains nearly the same for same energy input while laser power is increasing.
3. Ablation depth vs irradiation time plot shows greater slope for higher laser power implying higher ablation rate for high power laser ablation.
4. Buckingham-pi method yielded an empirical formula that relates depth ratio to power and diffusivity ratios.

Abstract

The failure behavior of carbon fiber/poly(ether ketone ketone) (CF/PEKK) composites manufactured via automated fiber placement (AFP) followed by subsequent consolidation in autoclave is studied. Multi-instrumental structural health monitoring (SHM) approaches are used to analyze damage development stages and and damage types in high performance thermoplastic composite laminates. Void analysis, and density measurement, and optical microscopy reveal the effect of secondary consolidation through autoclave on the microstructure of the composite laminates. An interlaminar void reduction from 5.65% to 0.46% are observed. Acoustic emission (AE), digital image correlation (DIC), and infrared thermography (IRT) techniques during tensile tests provide complementary understanding of the physics behind the critical damage types occurring in the material, such as edge splitting. Slope of the cumulative AE counts and percentage of total number of hits signify two distinct stages of failure, each associated with a dominant failure mode. Also it is evident that the high energy AE hits are corresponding to macro level damage events which are captured by the IRT in the form of various edge splitting. The initiation of these damage events can be anticipated through concurrent monitoring of DIC strain maps.

1. Introduction

High-performance thermoplastic matrix composites (TPCs) are increasingly favored for aerospace applications due to a multitude of advantages, such as notable strength-to-weight ratios, expedited molding processes, exceptional resistance to environmental factors, recyclability, and the capability for room temperature storage [1,2]. Within the realm of TPCs, Polyetherketoneketone (PEKK) stands out for its remarkable structural advantages, characterized by high mechanical toughness, favorable formability, low moisture absorption, and strong bonding properties [3,4].

Understanding damage onset and evaluation in composites is crucial for ensuring structural integrity and facilitating safer design practices. There is a growing need for alternative and complementary monitoring methods to investigate damage accumulation in composite materials [5,6]. This research integrates a comprehensive structural health monitoring system with mechanical testing to analyze the characterization of damage mechanisms, including their development and classification, in high-performance thermoplastic composites (TPCs) produced through Automated Fiber Placement (AFP) technology, specifically those composed of Carbon Fiber/Polyetherketoneketone (CF/PEKK).

2. Materials and Methods

Three unidirectional laminates are produced using a robotic laser-assisted Automated Fiber Placement (AFP) system (Coriolis C1), with a feed rate of 0.2 m/s and a consolidation force of 400 N (see in **Figure 1a**). The visible nip-point temperature is recorded at 400±10 °C. After the lay-up process, the laminate is cooled down to room temperature and removed. Consolidation of the AFP CF/PEKK thermoplastic lay-up occurs in an autoclave environment using the ASC autoclave system, with a consolidation temperature of 377 °C, heating, and cooling ramps of 5 °C/min and 11 °C/min, and a pressure of 8 bars maintained constant for 40 minutes (see in **Figure 1b**).

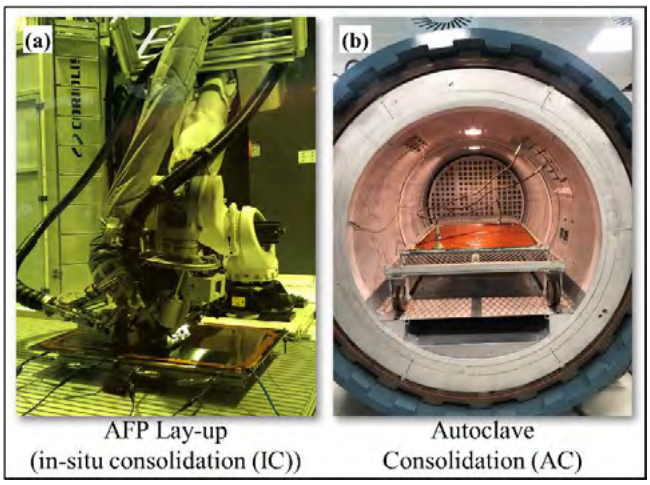

Figure 1. CF/PEKK Composite Manufacturing

To obtain the void content of in-situ and autoclave consolidated CF/PEKK laminates, fiber, matrix, and void contents of these specimens are measured based on the ASTM D3171 standard method 1. Also, the effect of secondary consolidation on the microstructure of the composite is thoroughly investigated using a Nikon, ECLIPSE LV100ND model microscopy.

2.1. Multi-instrument Structural Health Monitoring Techniques

Tensile tests are conducted on CF/PEKK composite specimens at a speed of 1.5 mm/min using an INSTRON 5982 universal testing machine. A bi-axial strain gauge is affixed to the specimen surface to measure the Poisson ratio. Throughout the tests, specimens are monitored using multi-instrument structural health monitoring techniques, including AE, DIC, and passive IRT, as depicted in **Figure 2**.

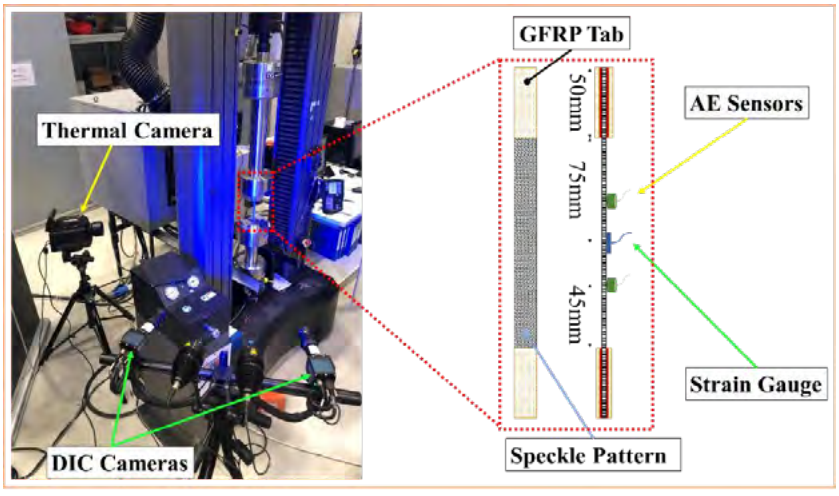

Figure 2. Multi-instrument Structural Health Monitoring.

3. Results

3.1. Impact of secondary consolidation on the microstructure of the composite

The average densities of three samples from in-situ and autoclave consolidated CF/PEKK composite plates are 1.49 and 1.58 g/cm3, respectively. **Table 1** presents the corresponding average weight fractions of fiber (W_f) and matrix (W_m), along with the volume percent contents of fiber (V_f), matrix (V_m), and void (V_v) for both consolidation methods.

Table 1 Fiber, matrix, and void contents of in-situ and autoclave-consolidated laminates.

	W_f (%)	W_m (%)	V_f (%)	V_m (%)	V_v (%)
In-situ consolidated (IC) CF/PEKK	65.04 ± 0.26	34.96 ± 0.26	54.22 ± 0.20	40.13 ± 0.31	5.65 ± 0.13
Autoclave-consolidated (AC) CF/PEKK	65.29 ± 0.14	34.71 ± 0.14	57.47 ± 0.16	42.07 ± 0.15	0.46 ± 0.04

As seen in **Table 1** the void content of autoclave consolidated CF/PEKK composite is less than 1%, i.e. minimum acceptable range in high performance composite laminates. As seen in **Figure 3** the large portion of voids in the microstructure of in-situ consolidated composites are pseudo-interconnected interlaminar voids at intimate contact lines. Autoclave processing not only helps to reduce the size of voids but also provides a network of pathways for removal of trapped air via bleeding. As a result, the void content decreases from 5.65% to 0.46%.

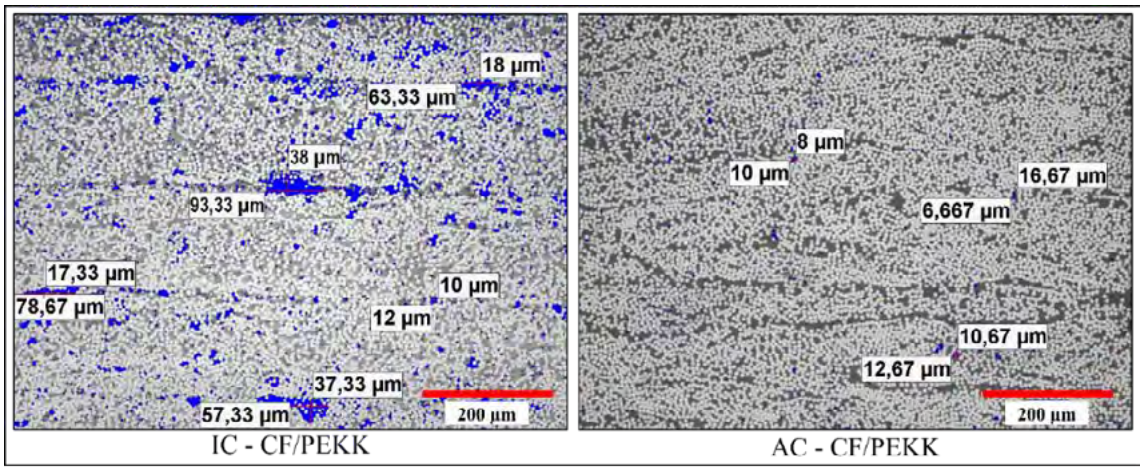

Figure 3. Optical microscope images of in-situ and autoclave consolidated laminate.

3.2. Multi-instrument Nondestructive Monitoring

The identified types of failure have been categorized based on their Weighted Peak Frequency (WPF) [7–9], spanning from low to high, as outlined in **Table 2**. The representative clustering of AE hits tensile samples of CF/PEKK is given in **Figure 4a.** Partial Power 2 indicates to the percentage of signal power in the frequency range of 300–600 kHz. WPF is calculated using Equation (1) as:

$$WPF = (f_c \times f_p)^{1/2} \quad (1)$$

where f_c and f_p indicate the frequency centroidand peak frequency, respectively.

Table 2 WPF range and related failure type.

WPF Range (kHz)	Failure Type
50-190	Matrix Cracking (MC)
190-360	Interface Failure (IF)
360-550	Fiber Failure (FF)

In **Figure 4b**, the amplitude of AE hits and the cumulative AE counts versus time graphs for CF/PEKK composite specimens are depicted. Notably, the cumulative AE count curve reveals two distinct stages called as stage I and stage II, respectively. In the region designated as Stage I, the AE counts demonstrate a linear increase, suggesting a consistent progression of damage within the laminate. In this stage, the AE hits associated with matrix cracking and interface failure exhibit both high and low amplitudes. Contrary to Stage I, Stage II displays a non-linear rise in cumulative AE counts over time, predominantly consisting of low-amplitude AE events. Notably, the frequent incidence of high-amplitude interface failures, such as delamination events observed in Stage I, is absent in Stage II. Although low- and high-amplitude delamination failures are evident in thermoplastic laminates, their occurrence frequency varies depending on the severity of accumulated damage within the material. **Figure 4c** illustrates the percentage of failure in these two stages, indicating a transition from matrix failure to fiber failure.

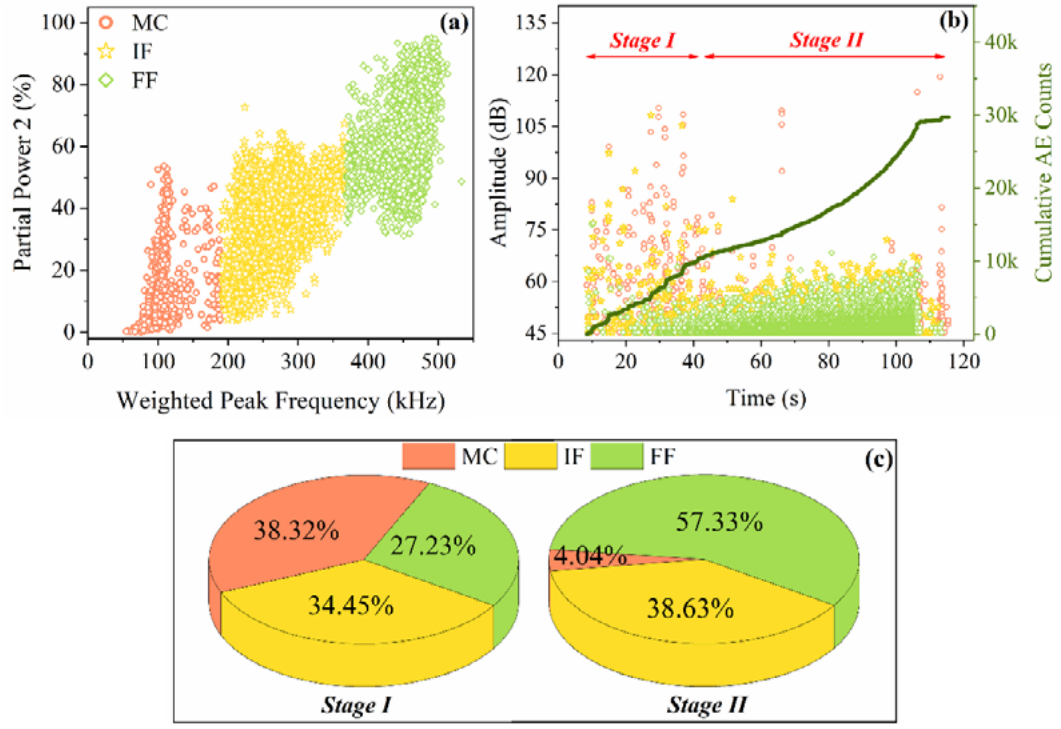

Figure 4. (a) Representative k-means clusters for tensile samples and **(b)** variations of time versus amplitude and cumulative AE counts, and **(c)** number of hits for various damage types

Figure 5 presents the plot of cumulative AE energy and load versus time. The fact that the axial strains-over time obtained from SG and DIC are the same with each other, which means that the DIC method is reliable for this study. Also, there is a deviation between axial strain curves and load curve at the end of the Stage I. At this stage, fiber-dominant failures control the material fracture, concomitant with a reduction in slope observed in the strain-time curve, indicative of an augmented stiffness in the laminates. There are five significant changes in the load versus time curve, marked as i, ii, iii, iv and v. All points (i-v) are also detected by AE, SG, DIC and IRT system, however, after point ii, AE sensor failed to record data.

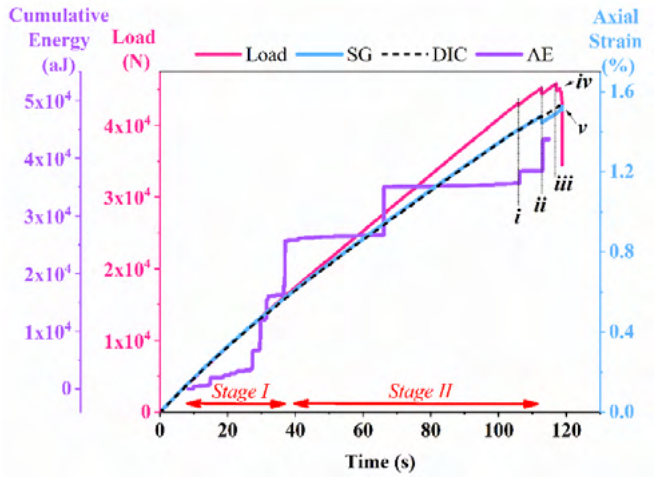

Figure 5. Plots of total AE cumulative energy, load, and axial strain over time. Note: Points (i), (ii), (iii), (iv), and (v) are marked to show the activity at 106, 113, 117, 118 and 119 s, respectively.

Thermal maps and strain maps corresponding to the time intervals (i-v) are depicted in **Figure 6**. Edge splitting, attributed to fiber misalignment at the edges of the composite specimen, is clearly observed from the beginning to the final stages of the tensile test in the IRT maps. Additionally, as depicted in the DIC map, localized high strain regions encircled in the specimen's edges are more pronounced. This suggests that the edge regions of the specimen are more susceptible to damage initiation and growth. Despite the expectation of greater deformation and earlier failure in regions with higher strain regions, it is noteworthy that the top left side of the specimen fails at an early stage, while the lower left region remains unaffected. The comparison between DIC strain maps and corresponding thermal maps indicates that the high strain gradient region at the lower left edge of the sample emerges at 67% of the maximum stress, while thermography maps do not exhibit any relevant activity in the same region until 90% of the ultimate tensile strength is reached. This observation underscores the capability of DIC results to identify failure-prone areas in TPCs well in advance compared to other techniques.

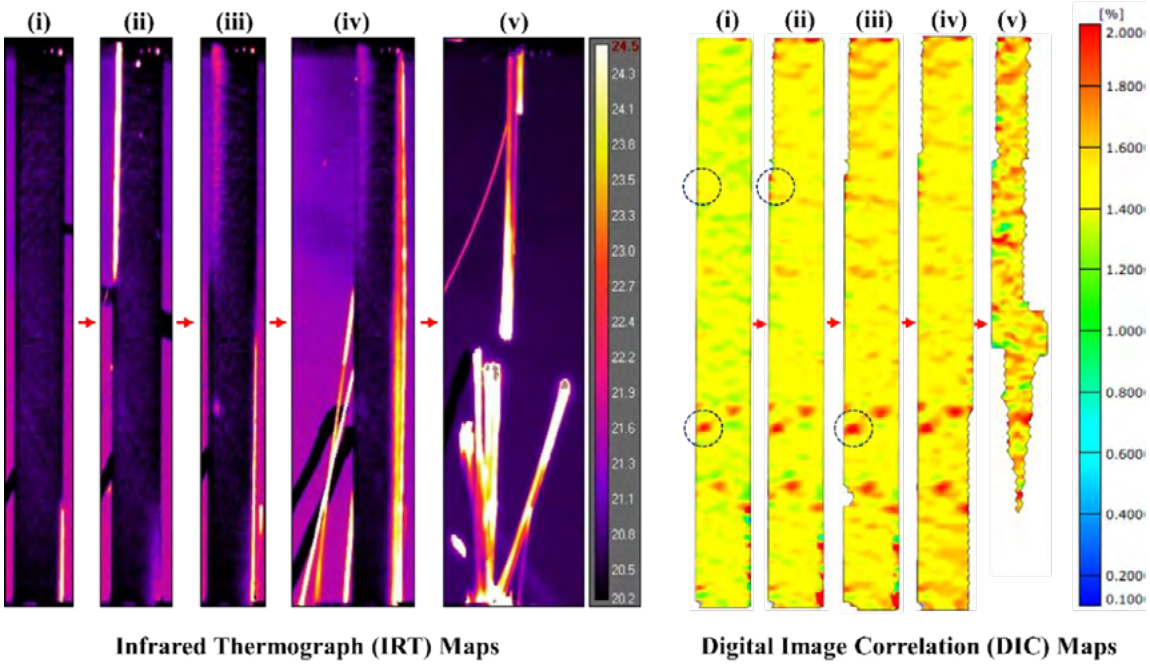

Figure 6. Thermograms and DIC in-plain strain fields for CF/PEKK specimens at (i) 106, (ii) 113, (iii) 117, (iv) 118, and (v) 119 s corresponding to the points marked in **Figure 5.**

4. Conclusions

This study investigates the impact of autoclave consolidation following in-situ consolidation on the microstructural properties of unidirectional CF/PEKK TPCs and examines damage mechanisms under tensile loading using multi-instrumental monitoring techniques. Microscopic observations reveal a reduction in voids within in-situ consolidated laminates post-autoclave consolidation, enhancing material intimacy. Analysis of AE hits and counts demonstrates a shift in tensile failure behavior from matrix-dominant to fiber-dominant failure modes, coinciding with a gradual stiffness increase. This change in AE hits may serve as a damage index in thermoplastic laminates, aiding in assessing composite structure longevity. Correlation between AE energy upsurges and macro-level damage detected by thermal imaging links to edge splitting, predictable through DIC strain maps. However, DIC maps provide insufficient data on the likelihood of these macro damage events due to the stochastic nature of fiber failures in carbon fiber-reinforced laminates. Furthermore, DIC allows susceptible failure areas in thermoplastic materials to be identified much earlier than IRT methodologies.

Abstract

Injection-moulded short-fibre composites are lightweight materials suitable for high-volume applications; however, current simulation methods for these materials are based on failure initiation criteria only, and cannot yet predict ultimate failure accurately. This work proposes an improved methodology to predict the progressive failure of injection-moulded short-glass-fibre reinforced PA66 composites, from coupon level to component level, based on experimentally-measured properties. The material's fracture toughness was characterised for different fibre orientations and environmental conditions, and these values were used as the input for cohesive zone modelling in Finite Element analyses, coupled with the fibre orientation fields predicted by an injection-moulding process simulation. The coupled process/structural simulations using cohesive zone modelling presents excellent agreement with the expeimental data of the coupons/subcomponents/components, highlighting the importance of accounting for the fracture toughness of the material to accurately predict the ultimate failure of injection-moulded short-fibre reinforced PA66 composites.

1. Introduction

Injection-moulded (IM) short-glass fibre reinforced thermoplastics (SFRPs) have three key advantages over conventional materials: they are lightweight, they have short production cycles, and they can be moulded into complex 3D-shaped components. The injection-moulding process creates a skin-core micro-structure with complex fibre orientation states, as the fibres align along the flow direction in the skin, and along the transverse direction or randomly in the core (as shown in Figure 1). This microstructure leads to anisotropic and heterogeneous mechanical properties and failure modes, which complicate the design of SFRP components.

When designing SFRP components, it is necessary to predict when and where failure will occur. However, existing failure criteria for SFRPs (e.g. based on the Tsai-Hill criterion [1]) underestimate the ultimate failure load of components, because they consider failure initiation only and neglect the finite toughness of the material. The objective of this work is therefore to develop a Finite-Element methodology to predict failure of IM-SFRP subcomponents and components, by accounting for the material's progressive failure using properties measured experimentally from coupon testing.

2. Manufacturing

Polyamide 6.6 reinforced by 50% (wt) glass-fibres (PA66-GF50) from Asahi Kasei Corporation was used to injection-mould plates (Figure 1). Dog-bone specimens (based on ISO8256) and Compact-Tension (CT) specimens (Figure 2) were machined at several angles from the IM-plates [2,3]. Subcomponents (Figure 3(a), representing a simplified geometry of an automotive component [3]), and components (Figure 3(b), representing a real geometry of an automotive engine mount) were also manufactured with the same material as used for IM-plates. These samples were kept dry as moulded (DAM), or conditioned under 50% of relative humidity (RH50, according to ISO1110 [4]).

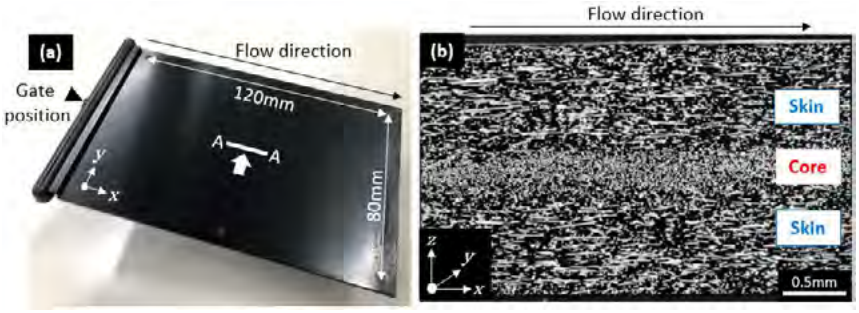

Figure 1. (a) Photograph of an injection-moulded PA66-GF50 plate (2 mm thick). (b) Optical micrograph across the A-A section defined in Subfigure (a) [2,3].

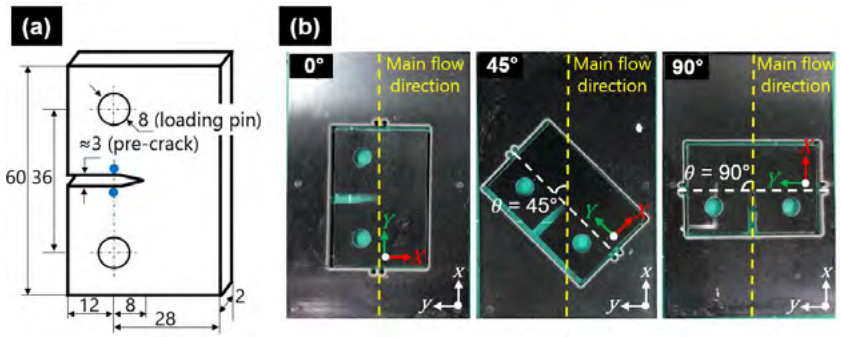

Figure 2. Design of CT specimens: (a) details of the geometry (dimensions: mm), (b) definition of the machining angles [2].

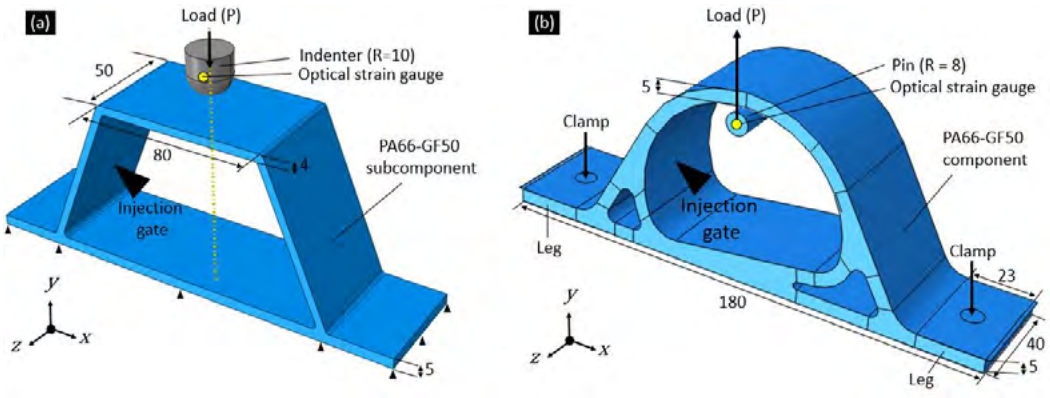

Figure 3. Geometry of (a) subcomponents [3] and (b) components (dimensions: mm).

3. Characterisation of fracture toughness

CT tests were conducted using specimens machined at several angles from the IM plates; all experimental details have been published elsewhere [2]. Representative load-displacement curves of the CT specimens tested at different machining angles and environmental (temperature and moisture) conditions are shown in Figure 4. All specimens exhibited a stable crack propagation (with a gradual decrease in the load after the peak). The value of the peak load was the highest for the specimens machined at a 0° angle, and progressively decreased with increasing machining angles. The value of peak load also decreased with an increase in moisture content or temperature.

These load-displacement curves of CT specimens were transformed into R-curves (using compliance calibration or the J-integral method [2]), and the value of the plateau region in the R-curves were regarded as the overall fracture toughness (or critical strain energy release rate) of the PA66-GF50 material; these are plotted against the machining angles in Figure 5(a). The fracture toughness was maximum at 0° (i.e. for fracture across the preferential fibre orientation direction), and decreased as the machining angle increased up to 90° (i.e. for fracture along the preferential fibre orientation). Moreover, the fracture toughness increased under hotter/wetter conditions. These fracture toughness plots were transformed to functions of the fibre orientation tensor α_{YY} along the loading direction, as shown in Figure 5(b) (the procedure is shown elsewhere [2]).

The fracture surfaces of CT specimens after testing were observed using scanning electron microscopy (SEM) to characterise the damage mechanisms. Representative SEM images (in the skin region) after the tests under 23°C-DAM conditions, for different machining angles, are shown in Figure 6. Large deformation of the PA66 matrix with good interfacial adhesion was observed in all angles. It was also noted that failure mechanisms in the skin region was dominated by fibre tension in the 0° specimens, then shifting to matrix shear failure in the 45° specimens (where the fibres were preferentially aligned diagonally with respect to the crack faces), and to matrix transverse tension failure in the 90° specimens.

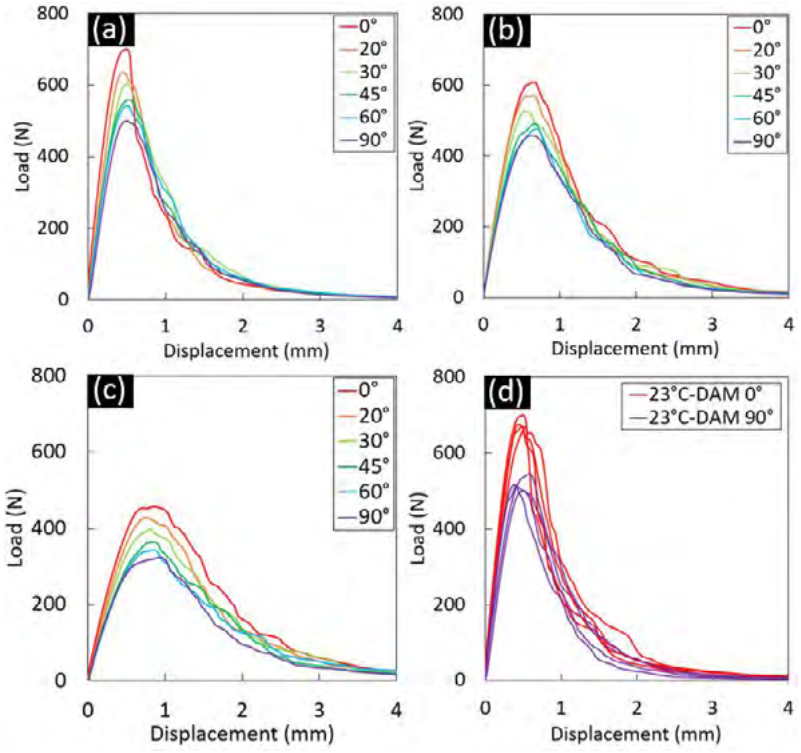

Figure 4. Load-displacement curves of CT specimens: representative curves at different machining tested under (a) 23°C-DAM, (b) 23°C-RH50, and (c) 80°C-RH50; (d) all four load-displacement curves for 0° and 90° tested under 23°C-DAM [2].

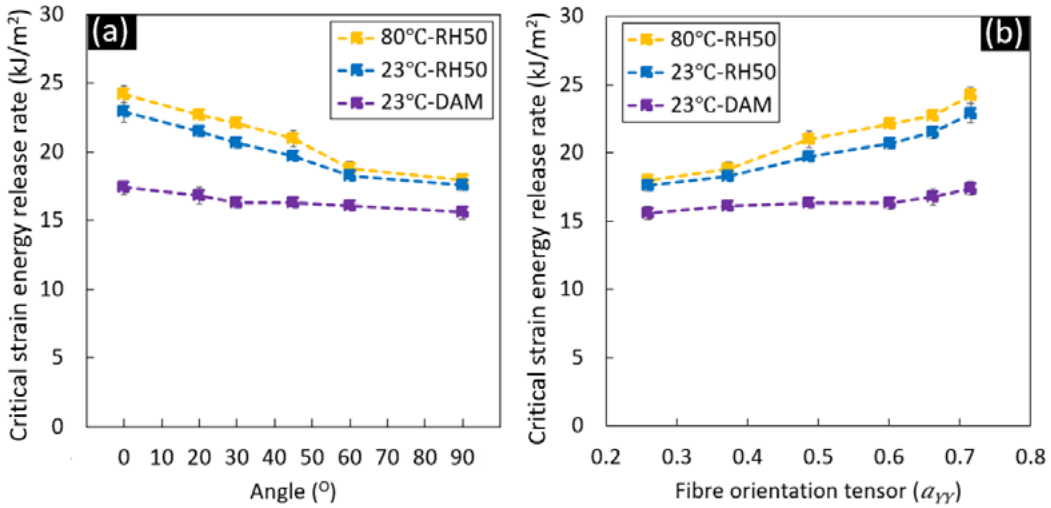

Figure 5. Fracture toughness of PA66-GF50 material as a function of machining angle (a) and fibre orientation tensor along the loading direction a_{YY} (b), under different environmental conditions [2].

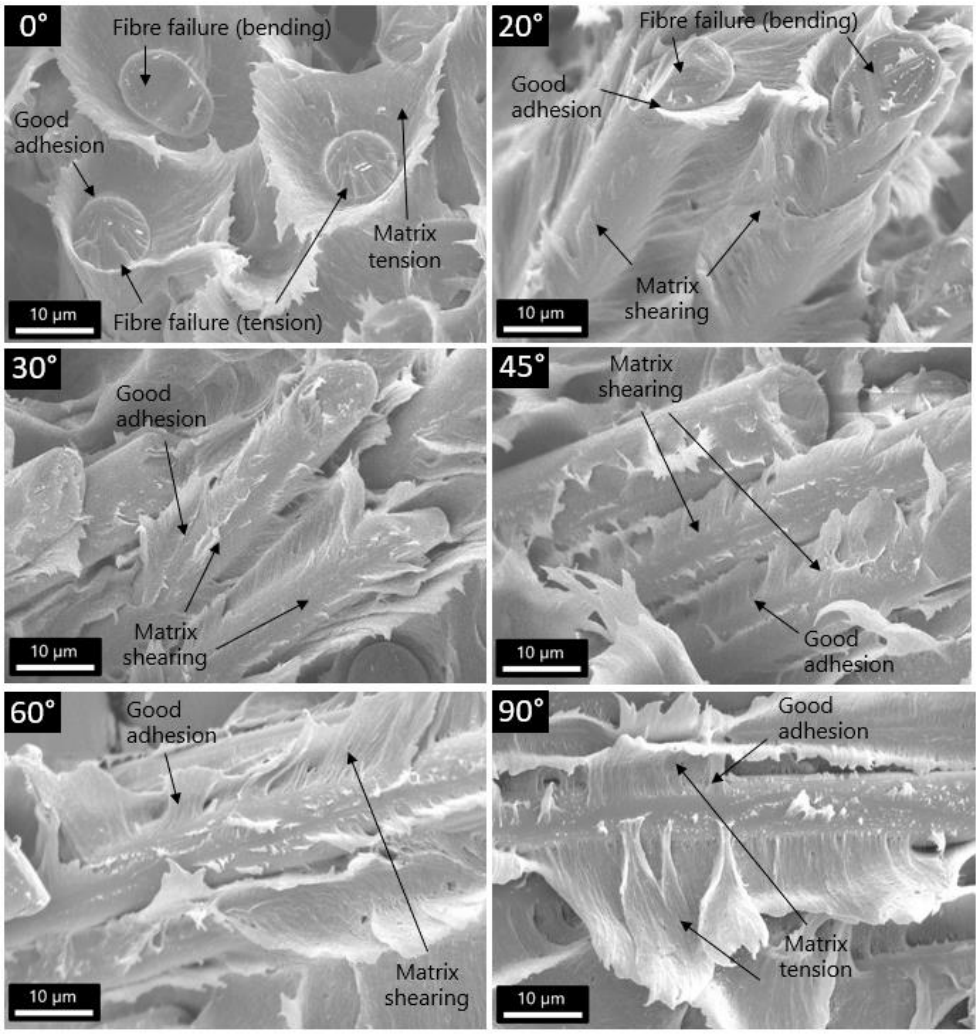

Figure 6. Scanning electron micrographs of the fracture surfaces of CT specimens (in the skin region) after testing under 23°C-DAM conditions: (a) 0°, (b) 20°, (c) 30°, (d) 45°, (e) 60°, (f) 90° [2].

4. Testing and simulations of subcomponents

PA66-GF50 subcomponents (with geometry and loading conditions shown in Figure 3a) were tested under quasi-static conditions at 23°C-DAM, 23°C-RH50 and 80°C-RH50, and the load-displacement curves are shown in Figure 7. A softer and weaker response was observed under wetter or hotter conditions. The crack initiated at the backface of the loading point, then it propagated through-the-thickness along the y-z plane. This crack propagation direction and the fracture plane were consistently observed for all the tested subcomponents regardless of the environmental conditions.

To predict the fibre orientation fields in the subcomponents, the injection-moulding process was simulated using Moldflow software [5]. The obtained fibre orientation tensor fields were then mapped onto an Abaqus [6] Finite Element Analysis (FEA) model of the subcomponent under quasi-static condition, using Digimat-MAP [7]. The PA66-GF50 material was modelled using Digimat's elastic-plastic material model (based on orientation averaging, Mori-Tanaka/Voigt mean-field homogenization and J_2-plasticity model), calibrated with the dogbone tensile testing data under several machining angles, accounting for the anisotropy and material nonlinear-response [7]. We present full details of these coupled process/structural simulations ("coupled FEA") elsewhere [3].

Load-displacement curves of the subcomponents under different environmental conditions from the coupled FEA, using two approaches to predict failure, are also shown in Figure 7:

(i) The conventional approach: failure initiation predicted by the Tsai-Hill ("TH") criterion [1]. The failure point corresponds to the moment when the Tsai-Hill criterion is first met.

(ii) Accounting for the fracture toughness of the material: progressive failure predicted by cohesive zone modelling ("CZM") using the CT test results (Figure 5) as inputs, mapped according to the complex skin-core fibre orientation states predicted by the process simulation (further details are shown elsewhere [3]).

A good agreement was observed regarding the initial stiffness and progressive softening in all simulation results. However, the coupled FEA with the TH criterion predicted onset of failure about 20% earlier than the failure load observed in the tests, under all environmental conditions. These results clearly demonstrate that the failure models currently implemented in commercially-available software, based on failure initiation criteria only, are not sufficient to accurately predict the maximum load in the tests.

To improve failure predictions, the finite fracture toughness of the material (Figure 5) was then introduced in the simulations (in the "FEA (CZM)" approach) of the subcomponents. This approach showed excellent agreement of the failure points between the simulations and the test results, within less than 3% error in the failure load for all environmental conditions.

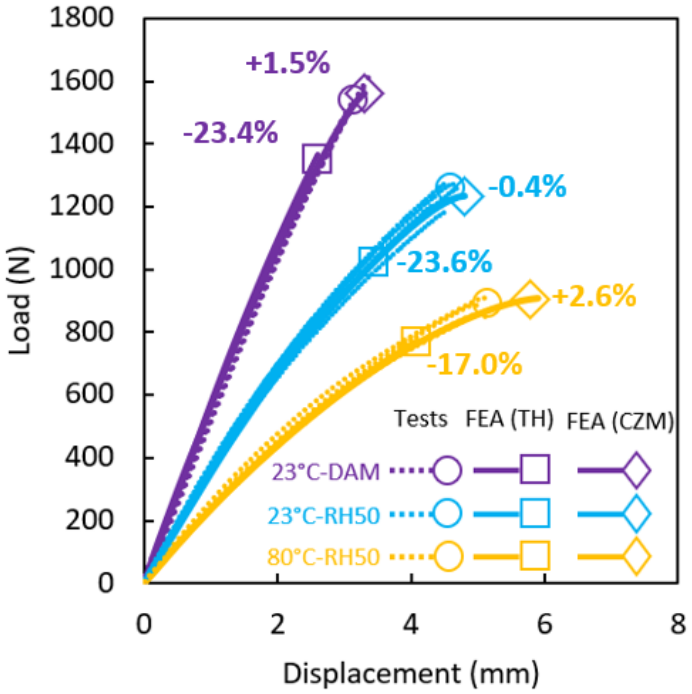

Figure 7. Load-displacement curves of the subcomponents from the tests and the simulations under the three different environmental conditions [3].
The numbers indicate the difference between predictions and experimental results.

5. Testing and simulations of components

PA66-GF50 components (with geometry and loading conditions shown in Figure 3b) were tested under quasi-static conditions at 23°C under DAM conditions, and the load-displacement curves are shown in Figure 8. The crack initiated at the top of the components, from the front edge, and then it propagated through-the-thickness and towards the back of the component (along the *y-z* plane), consistently for all the tests.

The same FE simulation methodologies as used for the subcomponents (with the TH criterion or CZM, described in Section 4) were applied to the PA66-GF50 components; the corresponding outputs are also shown in Figure 8. Both methodologies showed good agreement regarding the initial stiffness and progressive softening compared to the test results; however, the coupled FEA with the TH criterion predicted failure about 14% earlier than observed in the tests. In the coupled FEA with CZM, the predicted failure point showed excellent agreement with the test results (error: -0.6%). This demonstrates that the existing failure initiation criteria are insufficient to simulate the full response of automotive components, and accounting for the finite fracture toughness of the material is essential to accurately predict those maximum failure loads.

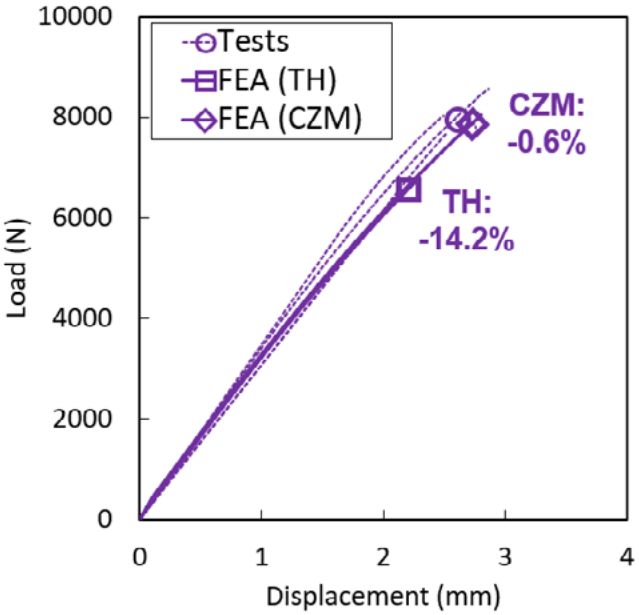

Figure 8. Load-displacement curves of the components from the experimental tests and the simulations. The numbers indicate the difference between predictions and experimental results.

6. Conclusions

PA66-GF50 composite coupons, subcomponents and components were tested under quasi-static conditions; coupled process/structural simulations using CZM calibrated with measured fracture toughness showed excellent agreement of failure points with the test results (within 3% error). This work demonstrates that accounting for the finite fracture toughness of IM-SFRPs is required to overcome the limitations of conventional methodologies, and accurately predict the ultimate failure of IM-SFRP components. The output from this research will provide more confidence in the design of safer and more efficient damage-tolerant IM-SFRP components.

Acknowledgments

This research was funded by Asahi Kasei Corporation under the “Material Modelling of Short-Fibre Reinforced Composites” project.

Abstract
This work deals with the fatigue of laminates under interlaminar shear stresses. It aims to establish an approach for characterizing the fatigue life of the material using a short beam shear test fixture, identifying the failure mechanisms and establishing a relevant fatigue analysis for such out-of-plane loading conditions. To achieve this objective, high-speed optical camera and digital microscope imaging were used to observe the onset of delamination. Finite element simulations were carried out to refine test analysis.

1. Introduction

Numerous studies have been conducted to characterize the fatigue behavior of carbon/epoxy laminates under in-plane cyclic loadings [1]. However, only few studies address the fatigue of laminates subjected to out-of-plane loadings. Out-of-plane cyclic loadings can occur due to a drastic change in ply orientation in laminates, a complex geometry or the applied loading, and can lead to delamination. A few number of test fixtures are available for such purpose [2-4]. All of them introduce a multiaxial stress state into the laminate, which complicates the interpretation of test results and the adaptation of the test for cyclic loadings. Among them, a 3-point bending short beam shear test fixture is adopted, considering that optical and thermal imaging (for future analysis) are key experimental techniques in this study: fewer metallic pieces are in contact with the sample than for other test standards, reducing friction and heat exchange during cyclic loading, both detrimental to thermal imaging. Short beam shear test fixtures and standards are designed for monotonic loading and, at the day of publication of this paper, no specific standard exists for cyclic loading on laminates. Nonetheless, it has been used in the literature for fatigue testing [5-7], some precautions being needed to correctly analyze test results. The objective of this work is to develop an experimental methodology for characterizing the fatigue of laminates under cyclic interlaminar shear loading using 3-point bending test on a short beam.

2. Material and methods

The material under investigation is a unidirectional (UD) laminate, composed of AS7 carbon fibers and 8552 epoxy resin matrix from Hexcel®. It is approximately 3.27mm thick, and composed of 24 plies stacked in one direction, $[0]_{24}$. The laminate is cured in an autoclave, following the manufacturer's recommended curing cycle. Before curing, a counter plate is placed on top of the stacked plies in order to obtain the same post-cure surface finish on both sides of the panel. The test samples were water-jet-cut, and have dimensions of 30mm x 15mm (length x width). The geometry proportions follow the NF EN 2563 [2] standard. A MTS® servo-hydraulic tension-compression testing machine, with load capacity up to 50kN, was used for testing. A WTF ASTM D790 3-point flexure test fixture is considered.

©2024 | 3_ZIMMERMANN DE ALMEIDA_Otavio_7WJX7.pdf

The distance between the lower loading rollers is half the specimen length (15mm), as recommended in [2] to allow sufficient interlaminar shear and reduce bending stresses in the gauge section. Quasi-static monotonic and fatigue tests were carried out until sample failure. For monotonic loading, a constant crosshead displacement speed of 1mm/min is applied. Cyclic loading is applied in the form of a sinusoidal signal, with a applied compression-compression loading ratio that represents a specimen equivalent stress ratio of $R = \frac{\tau_{13min}}{\tau_{13max}} = 0.1$, where τ_{13min} and τ_{13max} are the minimum and maximum values over the cycle of the maximum out-of-plane shear stress; 1 is the fiber direction and 3 is the out-of-plane direction (**Figure 1**). The number of cycles to failure N is given by the moment where at least one delamination is present in half-length of the specimen. This can be detected as a remarkable variation in the machine loading. The interlaminar shear stress τ_{13} is calculated at the sample neutral axis assuming a parabolic shear stress distribution through the specimen thickness, according to equation (**1**), where P is the load, w the sample width and t the sample thickness. For fatigue testing, a loading frequency of 5Hz is adopted. A Nova FastCam® S9 high-speed camera is used to follow the fast delamination onset during monotonic tests. The lateral surface of the sample observed was painted in white to allow better visualization of cracks. Acquisition frequencies of 1kHz and 10kHz were used. High-speed camera images are linked to the loading cell measurements. They are triggered at a specific force, corresponding to 94% of the mean shear stress at failure measured from monotonic tests. The samples were observed after testing with a Keyence vhx5000® digital microscope.

In order to analyze the results, finite element (FE) simulations of the test were performed using Abaqus®. The specimen mechanical behavior is defined as orthotropic linear elastic; the used coefficients are presented in **Table 1**. Rollers have the same diameter and position of the test fixture. Only half of their volume is represented. Their behavior is isotropic linear elastic, with a Young modulus E_{roller}=210GPa and a Poisson's ratio ν_{roller}=0.3. The lower rollers are clamped. The displacement of the upper roller along the 3 direction is imposed (the displacements along directions 1 and 2 are forbidden). A frictionless contact condition is defined between the rollers and the specimen. Two symmetry planes were used (the first one parallel to the 1-3 plane at half-width, and the second one parallel to the 2-3 plane at half-length) so that only one eighth of the system is modelled. 8-node linear brick elements are used, with an aspect ratio of 4x4x1 (length x width x thickness), each ply having only one element on its thickness.

Table 1. Orthotropic linear elastic ply properties (Ei is the Young's modulus along direction i, Gij is the shear modulus in direction j on the plane whose normal is in direction I, and vij is the Poisson's ratio relative to directions i and j).

3. Results

May and Hallet [5] have shown that damage initiates inside the specimen and propagates for a certain number of cycles before sample failure (whereas it breaks abruptly under monotonic loading), and that the failure mode differs from quasi-static monotonic tests. The number of cycles between instants when damage is observable inside the specimen and when its failure occurs is into account in this work, but a stress corrective factor is proposed to take into account the difference in failure modes between monotonic and cyclic loading**.**

3.1. Monotonic loading

Eight specimens have been tested under quasi-static monotonic loading, resulting in a mean interlaminar shear strength of τ_{13}^{u}=122MPa. Failure occurs, on average, close to the specimen's mid-height (**Figure 3**). The captured images reveal that delamination initiates inside the specimen and propagates towards

the exterior faces. All delamination occur exclusively on one half of the sample length. The image where delamination is first visible corresponds to the end of the drop on the loading data, and therefore to the point where a damage effect is first detected. In some of the tested specimen, as illustrated in **Figure 1**, two almost simultaneous delaminations appear on the thickness of the sample. For other cases, only one main delamination is visible.

$$\tau_{13} = \frac{3.P}{4.w.t} \quad (1)$$

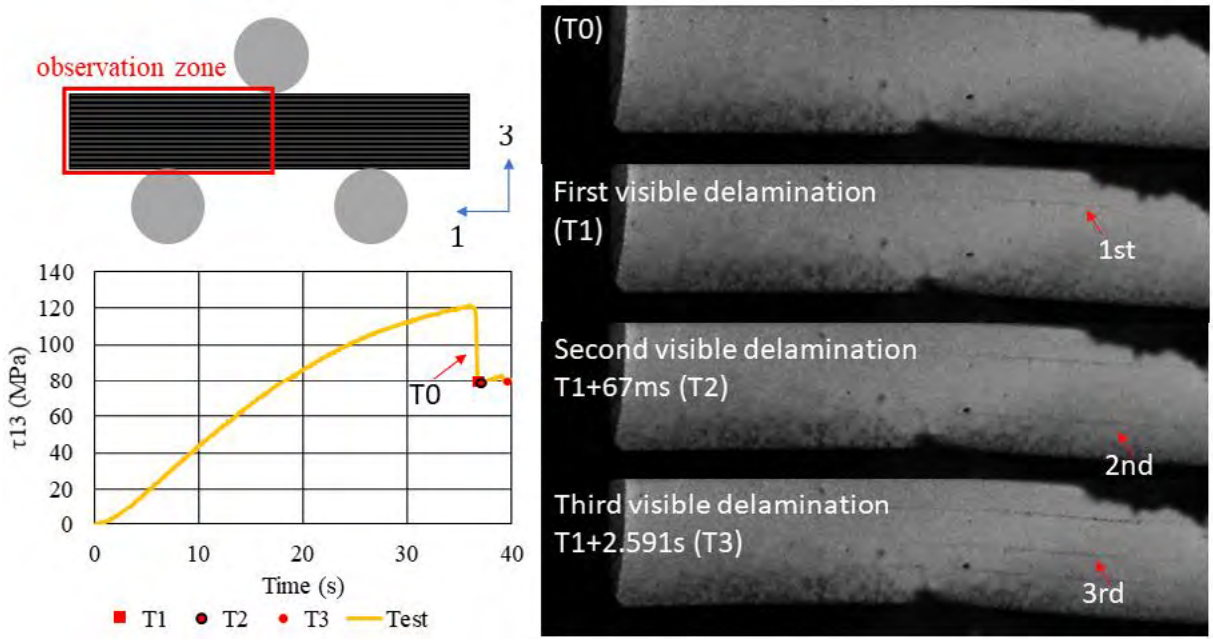

Figure 1. Delamination apparition on the free surface of sample during a monotonic test and comparison with the loading curve.

3.2. Fatigue

Delamination during fatigue tests occurs above the neutral axis, on average. It therefore does not occur in the same place as during monotonic tests (as shown in **Figure 2**). In **Figure 3**, the average position of cracks for each case, with the associated standard deviation, is represented on the observable "length x thickness" face of the FE model: they are named $p_{fatigue}^{delamination}$ for fatigue and $p_{monotonic}^{delamination}$ for monotonic test. The τ_{13} stress distribution shown is calculated through a monotonic loading step up to the equivalent of τ_{13}^{u} in rollers' applied force.

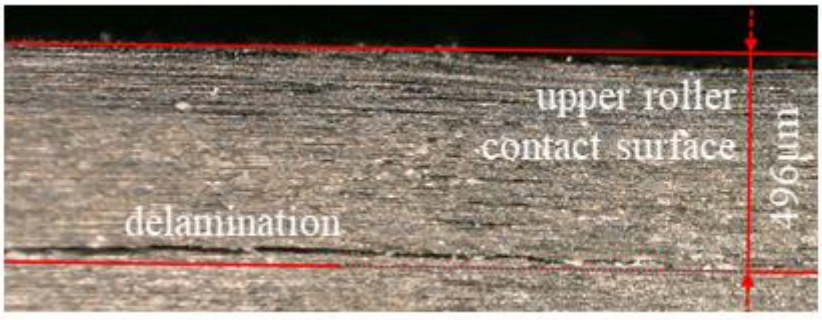

Figure 2. Delamination observed on one length-thickness free surface after fatigue test.

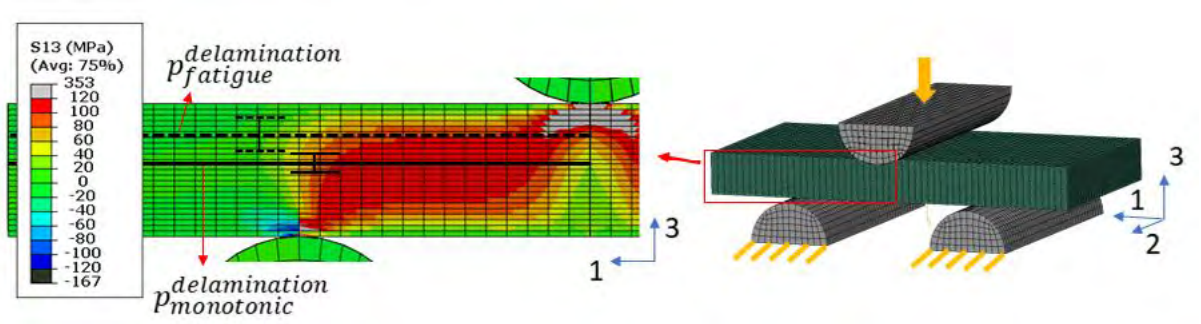

Figure 3. Average delamination location for monotonic and fatigue loadings over an out-of-plane shear stress field calculated by FE simulations.

As the location of delaminations is not the same for monotonic and fatigue tests and the stress distribution over the region of interest is non-homogeneous, fatigue and monotonic data cannot be treated in the same way. The parabolic distribution hypothesis for interlaminar shear stress over the thickness (equation (**1**)) is only valid in the middle of the red zone of the shear stress map seen in **Figure 3**. In order to estimate the effective failure stress $\tau_{13}^{p,fatigue}$ where delamination is observed after fatigue tests from the stress τ_{13} calculated at mid-thickness (equivalent to the stress calculated with equation (**1**)), a stress correction factor is determined from the results of FE simulations: the peak shear stress $\tau_{13}^{p,fatigue}$ in the plane at the position $p_{fatigue}^{delamination}$ is estimated and a constant correction factor f is calculated according to equation (**2**). This correction factor is calculated for all fatigue tests, as the samples were scanned on the microscope and the position $p_{fatigue}^{delamination}$ of each one is known. In **Figure 4**, the stress-corrected S-N curve is compared to the S-N curve obtained when the shear stress is calculated from equation (**1**). For a given number of cycles at failure, the effective maximal interlaminar shear stress is higher than the one calculated near the neutral axis of the sample.

$$f = \frac{\tau_{13}^{p,fatigue}}{\tau_{13}} \quad (2)$$

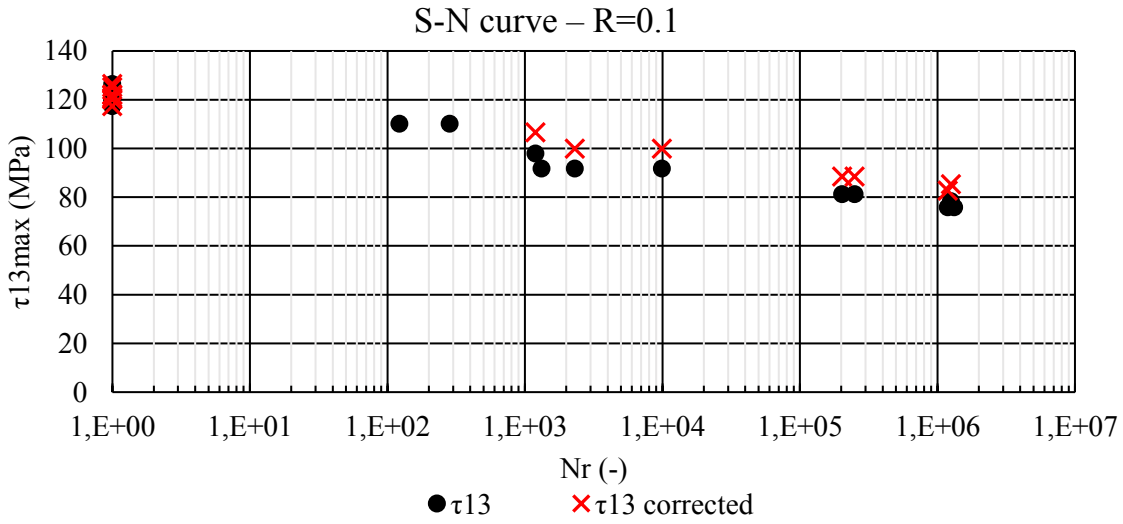

Figure 4. S-N curve considering parabolic stress distribution hypothesis and considering the corrected stress values.

3.3. Discussion of delamination location

Under monotonic loading, delamination occurs on the half-thickness plane, while out-of-plane shear stress is the highest under the upper roller. This could be linked to the significant out-of-plane compression stresses under the roller. Indeed, an increase in the interlaminar shear strength in the presence of out-of-plane compression has been reported in the literature [8,9]. Under cyclic loading, delamination does not occur at mid-height. Cohesive element-based FE simulations have been conducted in [10,11] to explain the difference observed between the failure locations. In this work, an interpretation of the problem is made on the basis of the coupled stress and energy criterion proposed by Leguillon [12]. This criterion has already been used to predict delamination in composites [13]. According to the criterion, for a crack to appear and propagate over a surface ΔS, both stress and energy criterion must be met (**Figure 5**). Under monotonic loading, on the one hand, the stress concentration zone under the upper roller exceeds the critical stress, but the region concerned is too small for the energy developed to be sufficient to reach the critical value. In the half-thickness region, on the other hand, both the stress and energy criteria are met so that crack propagation is expected. Under cyclic loading, the shear stress in the half-thickness plane is never high enough to meet the stress criterion. It is assumed that, over a number of cycles, the stress concentration zone under the upper roller is damaged and the mechanical properties of the matrix degrade, leading to a decrease in the critical strain energy release rate G_c. When the energy release rate meets G_c, delamination occurs.

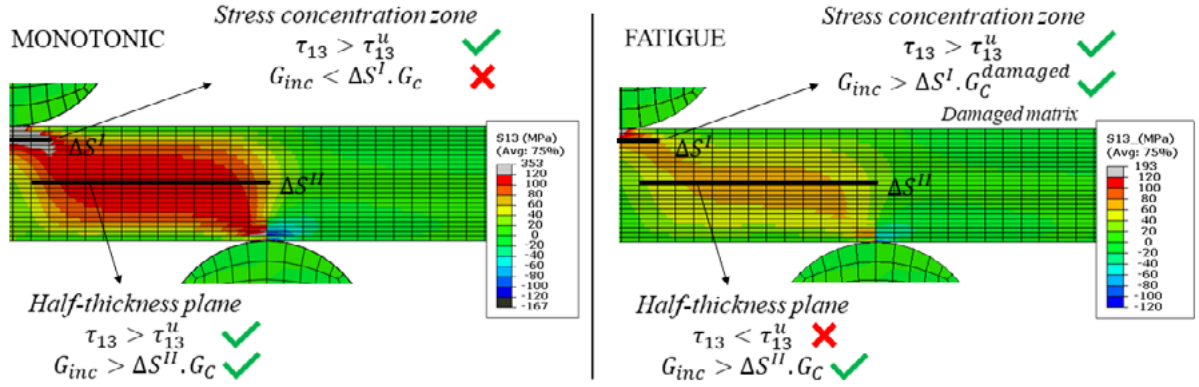

Figure 5. Interpretation of fatigue and monotonic failure cases according to the coupled criterion.

4. Conclusions

The presented work aimed to establish an experimental methodology to characterize the fatigue behavior of an UD laminate under interlaminar shear cyclic loading. A 3-point short beam shear test fixture is used. As observed in the literature, the failure modes induced by monotonic and fatigue loadings are different. High-speed camera films allowed to better understand the process of delamination: where the crack probably starts and how it propagates. *Post-mortem* digital microscope analysis was used to measure the position of delamination over the sample thickness. This information was related to the stress field in the samples calculated using a FE model. These results were used to determine the failure stress at the fatigue crack location from the test data. A S-N curve was then obtained for R=0.1. The difference between failure locations for monotonic and fatigue tests can be explained with the coupled criterion (energy and stress).

Keywords: natural fiber-reinforced materials, compressive load, laminates

Abstract
Objective of a current research project at the University of Applied Sciences in Darmstadt is to investigating whether paper laminate is a sustainable material for lightweight design. Therefore thick-walled material examined here consists of thin layers and, due to the fiber reinforcement, exhibits a slight anisotropy in relation to the production direction.
Under compressive loads, this material exhibits a complex failure in the form of symmetrical or asymmetrical layer buckling due to its layered structure. In our opinion (thesis), this instability results in a local reduction in stiffness caused by these layer buckling. On the other hand, there is an increase in stiffness with increasing specimen length.
In order to understand the failure behaviour, compression tests in the form of face crush tests with defined strain rates were carried out on air-conditioned, thick-walled samples (50x10 mm) of different lengths. Calculability is generally required of materials used in light weight design.
The paper presents and discusses the test and calculation results obtained. The aim is to generate a first material model for compressive loads that takes into account the special features of the failure of paper composites.

1. Introduction

A current research project at the University of Applied Sciences in Darmstadt is investigating whether paper laminate is a sustainable material for lightweight design. This project continues the work of the LOEWE project BAMP (Building with Paper) founded by the LOEWE program of the State of Hessen. The aim of BAMP was to provide scientific and technical foundations for the use of paper in building applications and to develop new approaches to solutions. One application for paper is columns or beams subjected to pressure loads, which is why this work focuses on compressive loads. For tensile loads, comprehensive investigations and a suitable material model for paper laminates are presented in [4].

2. Experimentell Investigation

2.1. Paper Material and Semifinished Products

Paper fibers are processed for the production of paper, which, according to [2], are mainly obtained from annual plants, thinned wood and sawmill waste. In contrast to other short-fiber-reinforced plastic composites (FRP), in which carbon or glass fibers are usually used, the fibers of paper laminates are renewable and recyclable. As shown in Figure 1, paper is a renewable, random fibre-reinforced material. The investigated material was cut out of an L-shaped angular edge protector (150x150x10mm). The angular edge protector itself consists of glue and approx. 15 layers of paper produced continuously in a rolling/drying process. These thin layers of paper are then cut to size, placed on top of each other and formed into an L-shape and glued together in several steps using a moulding rolling process [5].
Therefore the thick-walled material examined here consists of thin layers and, due to the fiber reinforcement, exhibits a slight anisotropy in relation to the production direction (MD).

2.2. Sample Manufacturing and Preparation

Samples of different lengths were cut from a commercially available angular edge protector in the longitudinal direction (//), i.e. in the production direction (MD) and transverse to the production direction (⊥ or CD) using a band saw or circular saw. The following samples were analysed: 150x50x10mm (//) ; 100x50x10mm (//) ; 50x50x10mm (//) ; 15x50x10mm (//) ; 50x50x10mm (⊥). Figure 1 shows an example of the 50x50x10mm (//) with its microstructure and layer structure.

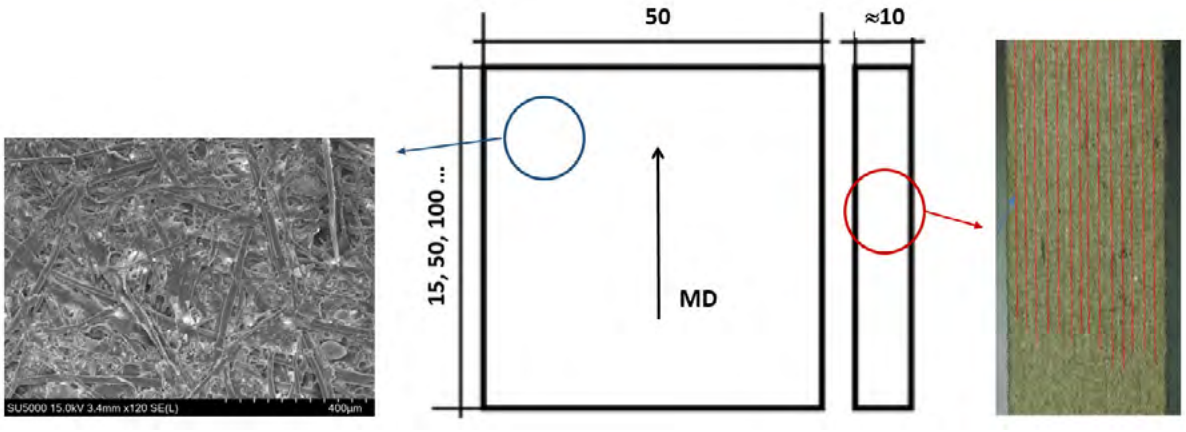

Figure 1. Microstructure of the Paper, the geometry of the 50x50x10mm samples and there layup.

Before carrying out the compression tests, it was necessary to prepare the samples cut from the semi-finished product for the tests. As paper is very hydrophilic and swells as it absorbs moisture, all samples were stored in a climate chamber at 23°C and 50 % relative humidity for a week after being graded, measured regularly and their weight determined. After one week, the weight remained constant, which means that the moisture exchange was complete.

2.3. Carrying out Experiments

Due to the 'column' application, the compression tests were carried out as a forehead compression test using a Zwick&Roell Z050 universal machine in a climatic chamber. DIN EN ISO 604 [3] was used as the basis, although the specimen geometry and test speeds deviated from the standard. The material paper reacts to an applied force, similar to plastics or wood, by yielding to reduce the external stress (creep) [1]. Due to the application as a support with primarily static loads, a rather slow strain rate of 0.0005 was selected for the test series despite the tendency of the paper to creep. The test procedure could explain failure type A due to the transverse strain on the load introduction plates prevented by friction. Figure 2 shows the test setup and failure mode A.

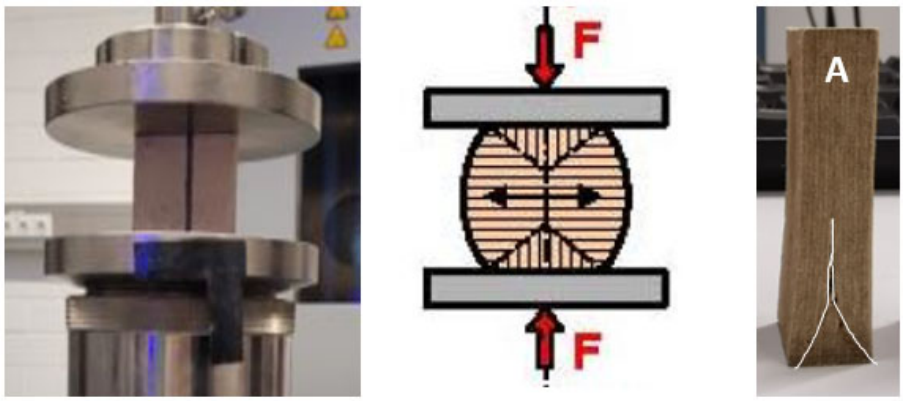

Figure 2. Experimental setup.

2.4. Results of the Experimental Investigations

To determine the optimum specimen geometry and to avoid buckling of the specimens, both the length and the width of the specimens were varied. Figure 3 shows examples, only the length differs here, of the stress-strain curves of specimens measuring 15x50x10 and 50x50x10mm as well as typical damage modes.

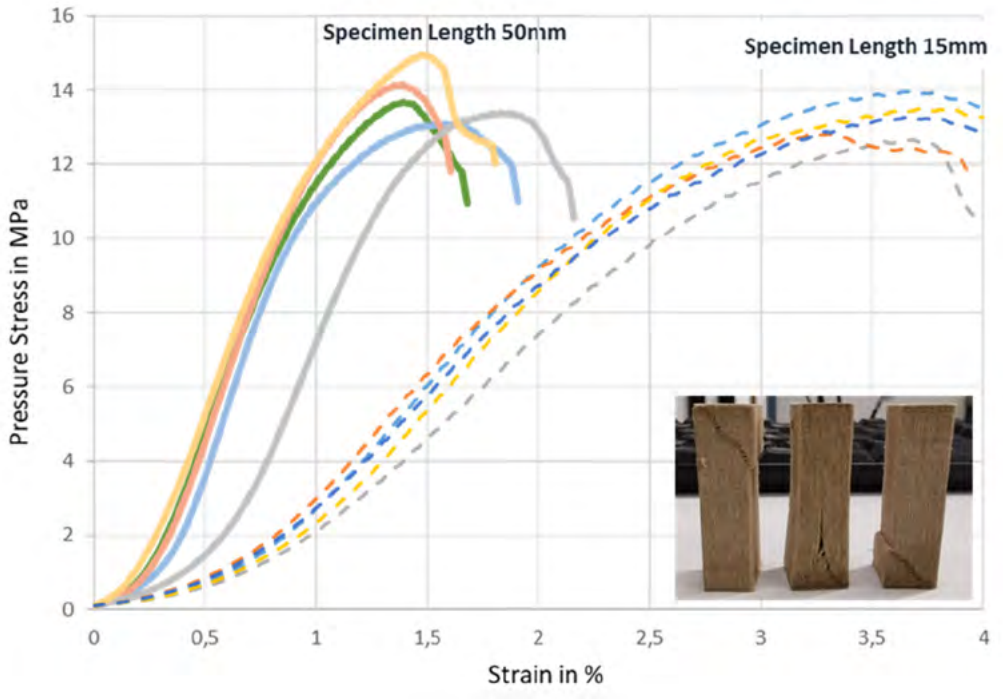

Figure 3. Stress-strain diagrams for samples of different lengths and typical damages modes
First measurement campaign

A comparison of the stress-strain curves shows that the modulus of elasticity increases with length. As far as the strength is concerned, it is on average at the same level for both sample lengths. Furthermore, it can be seen that there is a distinct and in part quite different running-in phase. For the further analyses, the greatest gradient after the running-in phase was determined as the modulus of elasticity.
Figure 4 summarises the moduli of elasticity determined in this way for the first measurement campaigns. The compression modulus of elasticity is compared as a function of the sample length (left) and the sample width (right). The compressive modulus of elasticity increases as the sample length increases. However, a dependence of the modulus of elasticity on the width could not be reliably proven due to the scattering.

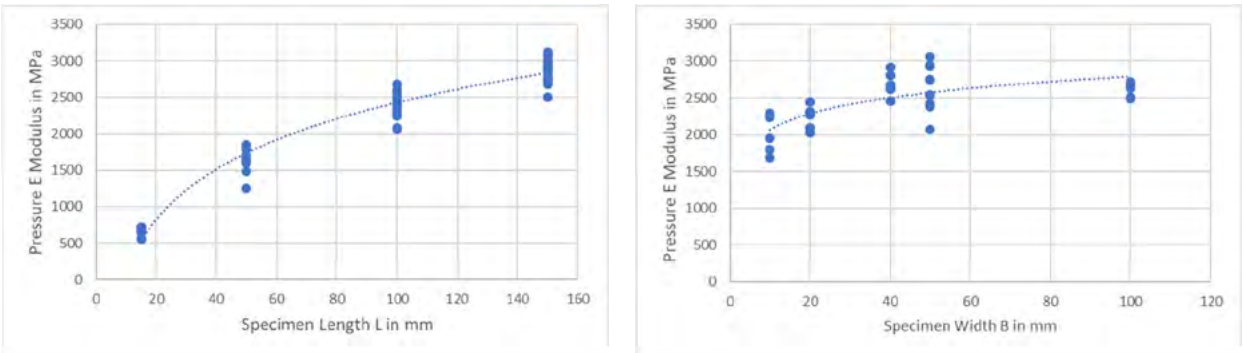

Figure 4. Pressure E-modules: as a function of sample length (left) and sample width (right)
First measurement campaign

The measurement results shown in Figure 5 occurred during further tests of the same delivery batch of the angular edge protector material. With the exception of the tester, an attempt was made to keep all test parameters constant. In relation to the first series of measurements, these measurement results show differences both in the scatter and in the position of the mean values (Figure 6).

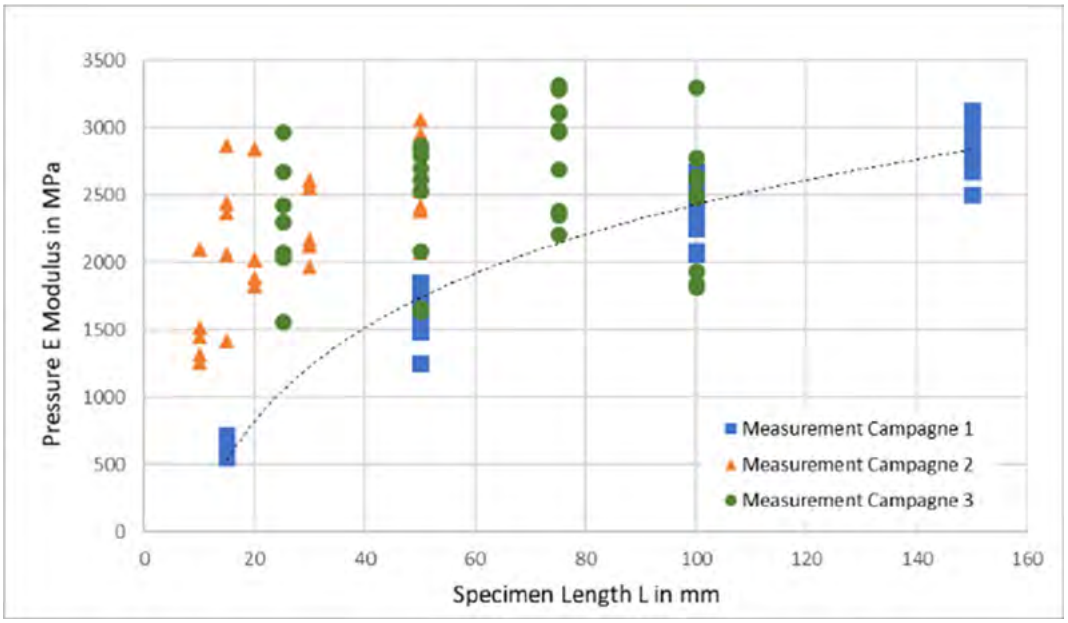

Figure 5. Results of various measurement campaigns

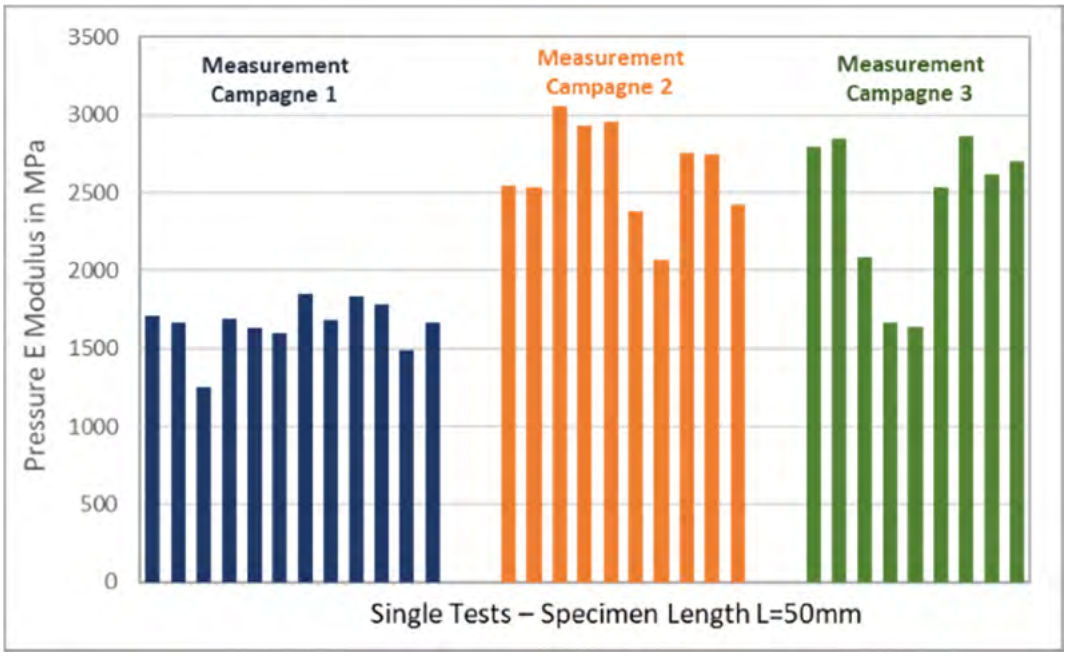

Figure 6. Comparison of the results of various measurement campaigns

3. Material Model based on a "*Spring Approach*"

Even if only indicated by the scattering, one cause of the length dependence of the modulus of elasticity is asymmetrical layer buckling (failure mode B). The layer buckling leads to a reduced stiffness C_f. in

the damaged area. If damage over the entire cross-sectional area is assumed, the total stiffness C_{res} of the specimen can be described by a series connection of the spring stiffness of the damaged area C_f with that of the undamaged area C_{non}, as shown in Figure 7.
The following equation (Eq. 1) describes the series-connected stiffnesses of the specimen (Figure 7) with A for the cross-sectional area, l_f for the length of the damaged area (*right*) and L-l_f as the length of the undamaged area (*left*):

$$C_f = \frac{E_f A}{l_f} \quad \text{and} \quad C_{non} = \frac{E_{non} A}{L - l_f} \tag{1}$$

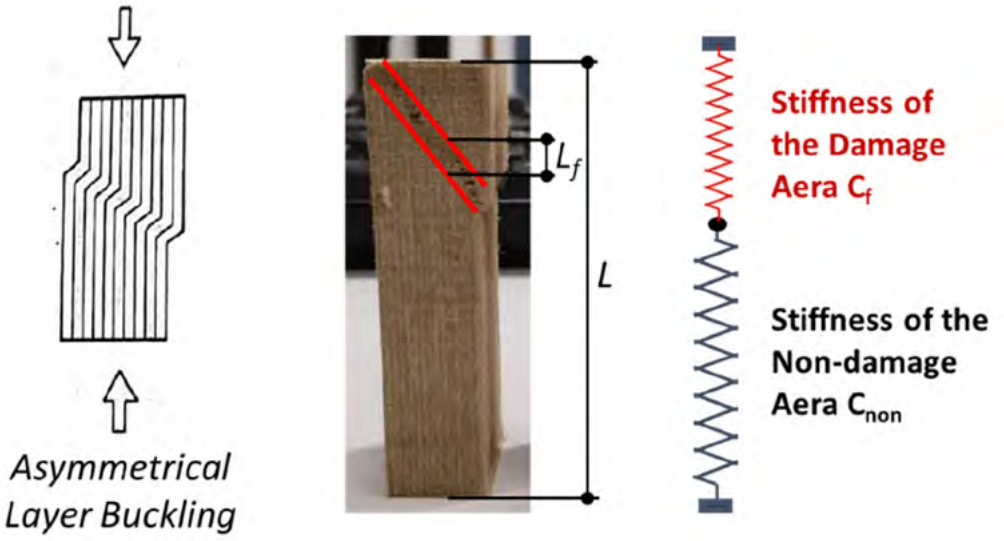

Figure 7. Spring Approach for Asymmetrical Layer Buckling [6].

E_{non} is the modulus of elasticity of the undamaged material and E_f that of the damaged material. Analogous to (Eq. 1), the resulting overall stiffness can also be calculated using L, A and E_{res}, whereby it can also be calculated by connecting the springs specified in (Eq.1) in series:

$$C_{res} = \frac{E_{res} A}{L} = \frac{C_f \; C_{non}}{C_f + C_{non}} \tag{2}$$

If (Eq.1) is set in (Eq.2), ones get Eq.3. (Eq.3) shows the resulting modulus of elasticity of the hole sample E_{res}. This equation can be simplified as a function of L. The parameters a and b are fitting parameters that can be determined from test data.

$$E_{res} = \frac{L \, E_{non}}{L + \left(\frac{E_{non}}{E_f} - 1\right) L_f} = \frac{L \, a}{L - b} \tag{3}$$

Figure 8 shows the test results of the first measurement campaign and the adapted fitting curve. As the measured values can be mapped very well using the two fitting parameters, it can be seen that the series connection approach is very well suited to explaining the length dependence of the modulus of elasticity.

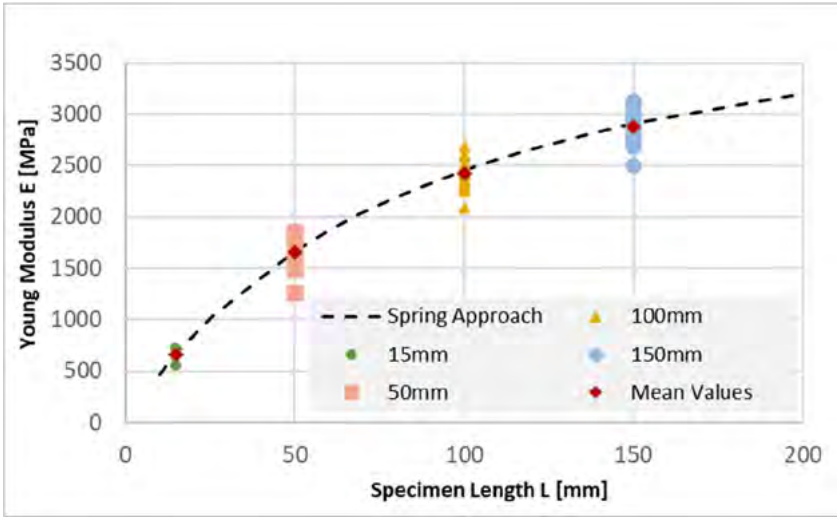

Figure 8. Testing Results fits with adapted fitting curve based on the spring approach.

Furthermore, a reduction factor f_{red} for the modulus of elasticity of the undamaged material can also be derived from (Eq.3).

$$E_{res} = \frac{1}{1+\left(\frac{E_{non}}{E_f} - 1\right)\frac{L_f}{L}} E_{non} = f_{red}\, E_{non} \tag{4}$$

The value (L_f/L) describes the geometric size of the damage in relation to the total length L of the sample. The value (E_{non}/E_f) describes the 'severity' of the damage by the ratio of the modulus of elasticity of the undamaged material to that of the damaged material. If $E_{non}/E_f = 1$, this means that there is no damage. In the case of $E_{non}/E_f = \infty$, this means that the stiffness in the damage area is zero (extreme damage). Figure 9 shows the reduction factor f_{red} over (L_f/L). With a damage length of approx. $l_f = 1$ to 2 mm and the analysed sample lengths of 15 to 150 mm, the values for the factor (L_f/L) are between 0.133 (short samples) and 0.007 (long samples). As we do not know the 'severity of damage' (value: E_{non}/E_f), various values from 1 (no damage) to 100 (damage) were selected. Whether $E_{non}/E_f = 100$ is a realistic damage value is not yet known. Perhaps the value is also greater.

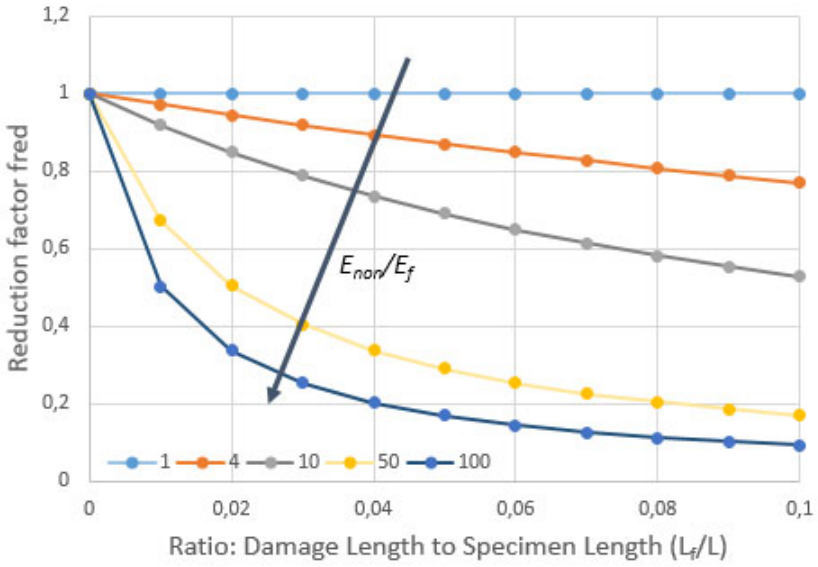

Figure 9. Influence of Damage on the Testing Results.

Figure 9 clearly shows why the short samples in particular scatter strongly. Small differences in the damage (value: E_{non}/E_f) lead to large changes in the reduction factor f_{red} and thus the measured modulus of elasticity.

3. Conclusions

The test results show that this material exhibits a complex failure in the form of symmetrical or asymmetrical layer buckling under compressive load due to its layer structure. In our opinion, this instability leads to a local reduction in stiffness caused by layer buckling. This hypothesis also explains the measured increase in the compressive E-modulus with increasing sample length, as has been shown.

The scattering of the measurement results that occurs with the different measurement campaigns is problematic for the use of paper as a lightweight construction material. One explanation for the scattering of the measured values is the drop in stiffness in the local failure area. How great is the damage (E_{non}/E_f) and what influences it? Subsequent series of tests should shed further light on the reasons for the scattering of the measured values. The aim is to derive measures that reduce the scattering and possibly also improve the performance of the material.

Acknowledgments

First of all, we would like to thank the state of Hesse for the funding that laid the foundation for this work with the LOEWE project BAMP! and enabled further work through the Hessian University Pact 2021-2025. Furthermore, our students: Schneider, Eydt, Kling, Khoder Waffo, Mirza, Tozan, and many others should not go unmentioned, who have made this work possible through their contribution.
