Editorial

This collection contains the proceedings of the 21st European Conference on Composite Materials (ECCM21), held in Nantes, France, July 2-5, 2024. ECCM21 is the 21st in a series of conferences organized every two years by the members of the European Society of Composite Materials (ESCM). As some of the papers in this collection show, this conference reaches far beyond the borders of Europe.

The ECCM21 conference was organized by the Nantes Université and the Ecole Centrale de Nantes, with the support of the Research Institute in Civil and Mechanical Engineering (GeM).

Each volume gathers contributions on specific topics:

Vol 1. Industrial applications
Vol 2. Material science
Vol 3. Material and Structural Behavior – Simulation & Testing
Vol 4. Experimental techniques
Vol 5. Manufacturing
Vol 6. Multifunctional and smart composites
Vol 7. Life cycle performance
Vol 8. Special Sessions

Nantes, the birthplace of the novelist Jules Verne, is at the heart of this edition, as are the imagination and vision that accompany the development of composite materials. They are embodied in the work of numerous participants from the academic world, but also of the many industrialists who are making a major contribution to the development of composite materials. Industry is well represented, reflecting the strong presence of composites in many application areas.

With a total of 1,064 oral and poster presentations and over 1,300 participants, the 4-day event enabled fruitful exchanges on all aspects of composites. The topics that traditionally attracted the most contributions were fracture and damage, multiscale modeling, durability, aging, process modeling and simulation and additive manufacturing.

However, the issues of energy and environmental transition, and more generally the sustainability of composite solutions, logically appear in this issue as important contextual elements guiding the work being carried out. This includes bio-sourced composites, material recycling and reuse of parts, the environmental impact of solutions, etc.

We appreciated the high level of research presented at the conference and the quality of the submissions, some of which are included in this collection. We hope that all those interested in the progress of European composites research in 2024 will find in this publication sources of inspiration and answers to their questions.

AUTHORS'S INDEX | *COUNTRY*	TOPIC	ARTICLE TITLE	PAGE
ABREU FILHO Marco A. | *PORTUGAL*	Durability, ageing, environmental effects	Experimental and numerical analyses on the thermal distribution within hybrid FRP sandwich panels under different climatic conditions	**976**
ACOSTA CORREA Jose David | *UNITED KINGDOM*	Poster	Promises and challenges of using electrical resistance change to detect damage in carbon fibre composite laminates	**435**
AHMADVASHAGHBASH Sina | *BELGIUM*	Bio-inspired designs	Intermittent Interfaces in Fiber-Reinforced Composites: Optimising the Balance Between Strong and Weak Fibre-Matrix Interfaces	**1085**
AL-RAMAHI Nawres | *SWEDEN*	Poster	Analysis of electrical performance of carbon fiber composites for heat generation in deicing applications	**1091**
ANTONIOU Alexandros | *GREECE*	Buckling & stability	A novel test load frame for characterizing the buckling resistance of thick sandwich panels	**808**
AOKI Ryoma | *JAPAN*	Fatigue	Numerical prediction of fatigue damage progress and residual strength after fatigue in composite pressure vessel	**1099**
ARRESE Ainhoa | *SPAIN*	Poster	Characterization of fatigue-driven delamination in mode	**1113**
ATHIRA ANIL KUMAR Athira Anil | *UNITED KINGDOM*	Textile composites	Implementation of Second-Order Homogenisation using Shell Elements for Woven Composites	**1120**
AZADI Shain | *ITALY*	AI-based methods	Delamination classification in composite plates using guided waves and 1D-CNN	**101**
BAEK Jeong-Hyeon | *SOUTH KOREA*	Multiscale modeling	Prediction of Mechanical Behavior of Carbon Fiber Braided Composites: A Multi-Scale Simulation-Based Progressive Failure Model	**191**
BA El Hadji Amadou | *FRANCE*	Sandwich structures	Influences of mechanical and water aging on changes in mechanical behavior and damage mechanisms on sandwich structures used as windturbine blades in marine environment (EMR)	**840**
BANGARU Ashish Kumar | *DENMARK*	Fatigue	Understanding fatigue delamination crack growth in a wind turbine rotor blade through an element testing	**1132**
BENDER Marcel | *AUSTRIA*	Textile composites	Influence of Fluid Properties on Transverse Fabric Compressibility During In-Situ Impregnation	**1140**
BOLD Jens | *GERMANY*	Keynote Lecture	Analytical and Numerical Modeling of Aramid Honeycomb Cores	**826**
BOND Emily | *UNITED KINGDOM*	Lightning Strike, fire behavior and fire retardance/ resistance of composites	Finite Element Modelling of Lithium-Ion Battery Fires on Composite Structures	**1**

Table of Contents

AUTHORS'S INDEX | *COUNTRY*	TOPIC	ARTICLE TITLE	PAGE
BONE Jasmine | *UNITED KINGDOM*	Durability, ageing, environmental effects	Micromechanical Property Characterisation of Water Absorption in Carbon Fiber Epoxy Composites using Nanoindentation	1148
BRUYNEEL Michael | *BELGIUM*	Fracture and damage	Modelling coupons at dome area of composite pressure vessels: from a 2D-shell to a 3D-solid formulation, with comparison to test results	109
BUTLER Richard | *UNITED KINGDOM*	Joining & joints	An efficient method to predict skin-stiffener debonding in post-buckled panels	207
CANTWELL Wesley | *UNITED ARAB EMIRATES*	Maintainance & repair	The Repair of Interlaminar Fracture in Thermoplastic-matrix Composites	32
CAPRETTI Monica | *ITALY*	Hybrid composites	On Design and Optimization of Flax and Hybrid Composite Tubular Structures Subject to Axial Crushing	847
CARDONA Carlos | *LUXEMBOURG*	Fracture and damage	Mechanical behaviour of bamboo fibres at the micro scale by applying digital image processing analysis	1156
CARMINE Contaldi | *DENMARK*	Fracture and damage	A semi-analytical model for crack kinking out of the interface of bimaterial anisotropic layers	1172
CHANDRAKAR Prateek | *INDIA*	Buckling & stability	Stochastic thermal buckling investigation of optimized variable stiffness composite laminates incurred internal flaws	199
CHAO Luo | *JAPAN*	Multiscale modeling	Multiscale study on nonlinear properties of cellulose nanofiber-reinforced thermoplastic polymer composite filaments	214
CHARKIEH Ahmad Shawki | *BELGIUM*	Short & long fibre composites	Mechanical performance of 3D printed fibre-reinforced triply periodic minimal surfaces structures	39
CHAUDHARY Amit | *INDIA*	Fracture and damage	A new semi-discrete continuum damage modelling framework for composites with focus on open-hole compression failure	443
CHEBBO Hussein | *FRANCE*	Durability, ageing, environmental effects	Accelerated ageing of a pultruded FRP composite PA6/GF: Characterisation and modelling of hygrothermal ageing	1164
CILENTO FABRIZIA | *ITALY*	Material by design	Investigation on GNP layer as protection against high thermal fluxes in CFRP composites	1204
CORREA Elena | *SPAIN*	Interfaces	Experimental and numerical comparison of fibre/matrix debond extension in ultra-thin plies after tension-tension cyclic loading	1178
DADABO Koami Pierre | *FRANCE*	Multiscale modeling	Eshelby's inhomogeneity problem in complete Mindlin's first strain gradient elasticity theory	775
DAGHIA Federica | *FRANCE*	Keynote Lecture	Mechanism-based modelling of the viscoelastic response of a unidirectional composite ply: validation of a new transversely isotropic model through analytical and numerical homogenisation	113
DE ANTUNES E SOUSA Guilherme | *PORTUGAL*	Poster	Cork-based Composite Materials Suitable to Protect Type I Hydrogen Tanks	783

Table of Contents

AUTHORS'S INDEX | *COUNTRY*	TOPIC	ARTICLE TITLE	PAGE
DEBARRE Antoine | *FRANCE*	Fracture and damage	Experimental and numerical study of the mechanical behaviour of an oxide/oxide ceramic-matrix-composite at high temperature	358
DEMIR Serdar | *TURKIYE*	Poster	THE INFLUENCE OF THE CRUSH PLUGS ON THE ENERGY ABSORPTION OF CARBON/EPOXY COMPOSITE CIRCULAR TUBES UNDER AXIAL CRUSHING	675
DEMOULIN Leyne | *FRANCE*	Fracture and damage	Identification of local to global mechanical properties of clear wood peeled veneers from off-axis tensile tests using full-field local displacement measurements	451
DEYDIER Maxime | *FRANCE*	Fracture and damage	Design assessment of composite patch repair on steel structures based on toughness tests using a newly designed non-standard "equivalent interface" specimen	984
DIMASSI Adli | *GERMANY*	Sandwich structures	Investigating load introduction methods for aircraft floor panels made of foam core sandwich	458
DOITRAND Aurélien | *FRANCE*	Fracture and damage	Simulation of transverse cracking and subsequent acoustic emission in laminates	118
DORIAT Aurélien | *FRANCE*	Durability, ageing, environmental effects	Thermo-Oxidation Aging of Carbon-Fiber Reinforced Epoxy Polymer Composite under High-Speed Air Flow	992
DROUIN Thomas | *FRANCE*	Fracture and damage	Thermo-mechanical study of oxide/oxide CMCs using in-situ micro-ct tests and digital volume correlation	1182
DUBARY Nicolas | *DENMARK*	Fracture and damage	On the use of modeling to assist experimental issues and method development for compressive characterization determination of pultruded carbon fiber specimen	464
DUSHIMIMANA Aloys | *PORTUGAL*	Durability, ageing, environmental effects	Modelling of short- and long-term bond behavior in concrete structures strengthened with externally bonded CFRP composites	683
ECKRICH Maximilian | *GERMANY*	Topological optimization	Anisotropic topology optimization considering multiaxial fiber orientations for composite truss structures with improved intersection point design	8
ELMAS Sinem | *TURKIYE*	Poster	Annealing Effects on Mechanical Performance and Failure Characteristics of CF/PEKK Aerospace Composites: A Thorough Exploration	691
ERIVES ANCHONDO Ruben | *DENMARK*	Fracture and damage	Influence of large-scale fibre bridging in the crack growth rate of mixed-mode delamination of a unidirectional glass-epoxy composite	1196
FACHTAN Robin | *GERMANY*	Design of parts	Robust skin: a multidisciplinary approach to robust membrane wing design for sustainable urban mobility	1211
FAN Jialiang | *SWISS*	Joining & joints	Fatigue Investigation of Self-healing Adhesives for Wind Turbine Applications	1219
FARROKHABADI Amin | *BELGIUM*	Acoustic Emission & ultrasonic method	Investigation of energy absorption and ultrasound-based damage response of 3D printed composite star hourglass shaped lattice structures	1339

Table of Contents

AUTHORS'S INDEX | *COUNTRY*	TOPIC	ARTICLE TITLE	PAGE
FAWAZ Arij | *FRANCE*	Durability, ageing, environmental effects	Moisture Absorption Comparison Between Bulk Adhesives and Adhesively Bonded Joints in different environments	1227
FERNANDES Pedro | *PORTUGAL*	Topological optimization	Topology optimization and numerical modelling of structural batteries	1235
FERNBERG Patrik | *SWEDEN*	Fracture and damage	Modelling of transverse cracking resistance reduction at elevated temperatures and after isothermal heat treatments	1245
FIKRY M. J. Mohammad | *JAPAN*	Fracture and damage	Suppression of delamination in CFRP laminates with ply discontinuities using polyamide mesh material	471
FINAZZI Daniele | *BELGIUM*	Short & long fibre composites	Tensile behaviour of short glass fibre-reinforced polyamide-6: combined effect of temperature, moisture content and strain rate	122
FIORE Vincenzo | *ITALY*	Poster	Effect of alternating salt fog and dry conditions on the behavior of flax fiber reinforced epoxy composites	479
FOTOUHI Sakineh | *FRANCE*	Poster	Finite element modelling of composite materials under impact loading, challenges and potential ways forward.	855
FUJITA Yuki | *UNITED KINGDOM*	Short & long fibre composites	Failure prediction of injection-moulded short-fibre composites: characterisation and prediction from coupons to components	1737
GERMAN Guillaume | *FRANCE*	Durability, ageing, environmental effects	Aging mechanisms of ceramic matrix composites	485
GERRITZEN Johannes | *GERMANY*	AI-based methods	Direct Parameter Identification for Highly non-linear Strain Rate Dependent Constitutive Models using Machine Learning	1252
GIBHARDT Dennis | *GERMANY*	Durability, ageing, environmental effects	Effects of Temperature, Water Absorption, and Weak Interphase Strength on the Damage Tolerance of GFRP	697
GIORDANO Michele | *ITALY*	Structural health monitoring and control	Hierarchical highly electrically conductive nanocomposites for strain sensing device in Structural Health Monitoring	386
GIRARD Hugo | *FRANCE*	Fracture and damage	Fiber-matrix interface fracture characterization by the Coupled Criterion and dual-vision system	366
GIUSEPPE ROMANO Giuseppe | *UNITED KINGDOM*	Poster	On the transverse shear failure in unidirectional fibre-hybrid composite laminae using periodic microstructures	705
GOMEZ Arturo | *DENMARK*	Multiscale modeling	Multi-scale level prediction of crack growth in wind turbine blade shear-web joints applying cohesive zone modelling	734
GORDE Shubham Shahaji | *GERMANY*	Short & long fibre composites	Warpage modelling of carbon fibre-reinforced SMC components in automotive applications	1260
GORTNER Florian | *GERMANY*	Lightning Strike, fire behavior and fire retardance/ resistance of composites	Development of translucent epoxy-based Sheet Molding Compounds with flame retardant properties for aircraft applications	492

Table of Contents

AUTHORS'S INDEX | *COUNTRY*	TOPIC	ARTICLE TITLE	PAGE
HACKER Gereon | *GERMANY*	Fatigue	An Energy Conserving Cycle Jump and Load Application Technique for High-cycle Fatigue Simulations under General Loading Conditions	713
HAILUN ZHOU Hailun | *UNITED KINGDOM*	Topological optimization	Topology optimization method based on minimal surface lattice structure for the lightweight design	61
HAO Jianqun | *BELGIUM*	Structural health monitoring and control	Remaining useful life prediction of flax fibre composites under creep load by acoustic emission and deep learning	1269
HASAN Tarikul | *PORTUGAL*	Durability, ageing, environmental effects	Durability under hygrothermal exposure of vacuum infused GFRP composites produced with polyester and vinyl ester resins	1277
HASAN Tarikul | *PORTUGAL*	Durability, ageing, environmental effects	Effects of thermal cycles and thermal ageing on the mechanical and thermomechanical behaviour of vacuum infused GFRP composites	1285
HASELBACH Philipp Ulrich | *DENMARK*	Multiscale modeling	Quantifying the accuracy of different modelling techniques and element types to predict the structural performance of the DTU 12.6m wind turbine blade	1293
HAWKINS Aidan | *UNITED KINGDOM*	Fracture and damage	Investigating Homogenisation, Mechanical Performance and Compression After Impact of Double-Double Laminates	130
HEDVARD Michelle | *GERMANY*	Fracture and damage	Numerical method for fracture modelling of lattice interface materials in composite structures	226
HERMASSI Nahed | *FRANCE*	Poster	Effects of continuous glass fiber incorporation to recycled PA6 polymer: An interfacial approach	1301
HIGUCHI Ryo | *JAPAN*	Integrated testing and modelling of composite structures	Effects of ply thickness and 0-degree layer ratio on failure mode and strength of notched composite laminates: Experiment and high-fidelity simulation	1310
HIRSEKORN Martin | *FRANCE*	Multiscale modeling	Multi-scale modeling of time-dependent thermal expansion and chemical shrinkage during the curing process of polymer matrix composites	232
HO-NGUYEN-TAN Thuan | *SOUTH KOREA*	Forming & stamping	An effective simulation method for the laminated composite fan blade structure with fiber-draping analysis	500
HORN Alexander | *DENMARK*	Sandwich structures	Temperature-dependent changes in thermo-plastic sandwich core properties and failure mechanisms using short four-point tests with short specimens	1318
HOSOI Atsushi | *JAPAN*	Joining & joints	Enhancement of Interlaminar Fracture Toughness by Micro-Bridging at Crack Tip in Bonded Dissimilar Materials	506
HOSSEIN ABADI Ramak | *BELGIUM*	Multiscale modeling	Numerical fiber reorientation modeling for in-plane shear behavior of woven thermoplastic composite laminates	1000
HUAIXIANG Sun | *CHINA*	Fracture and damage	Structural damage identification of composite reinforced siding panels based on machine learning	718

Table of Contents

AUTHORS'S INDEX | *COUNTRY*	TOPIC	ARTICLE TITLE	PAGE
HUANG Weizhao | *JAPAN*	Durability, ageing, environmental effects	Structural health monitoring of CFRTP under thermo-oxidative ageing by non-destructive vibrational method	138
ISHAN MANOJ Ishan | *INDIA*	Joining & joints	Novel joint interface design strategies for strength improvement in fdm printed single lap adhesive joints	726
ISOZAKI Minori | *JAPAN*	Joining & joints	Comprehensive Evaluation for Joint Strength of Ultrasonic-Welded CFRTP involving Interface and Resin Strengths	512
JACKSTADT Alexander | *GERMANY*	Hybrid composites	Revisiting Constrained-layer Damping in Hybrid Lightweight Laminates: Characterisation, Modelling and Design Guidelines	1323
JADHAV Prakash | *INDIA*	Dynamic	Wear analysis of microstructure image-based 3D models to help design the best abradable coating composition.	146
JEON Min-Hyeok | *SOUTH KOREA*	Fracture and damage	Compressive energy absorption of 3D printed continuous fiber reinforced composite with different printing path	519
JEON Na-Hyun | *SOUTH KOREA*	Buckling & stability	Study on buckling behavior of composite sandwich structure with 3D-printed corrugated core under hydrostatic pressure	741
KANDARE Everson | *AUSTRALIA*	Lightning Strike, fire behavior and fire retardance/ resistance of composites	Engineered mycelium for fireproofing flammable composite materials and structures.	1331
KASHTALYAN Maria | *UNITED KINGDOM*	Multiscale modeling	Effect of stiffness variation in the adhesive on performance of composite-metal tubular joints	1347
KAWAI Masamichi | *JAPAN*	Fatigue	Fatigue Notch Sensitivity of Woven CFRP Laminate Under Different R-ratio Loadings - Experiment and Modeling -	753
KHANDAR SHAHABAD Peiman | *TURKIYE*	Design of parts	Design and fabrication of variable stiffness composite laminates with enhanced dynamic behavior	524
KHAN Kamran A. | *UNITED ARAB EMIRATES*	Multiscale modeling	FLEXURAL RESPONSE OF REAL WOVEN COMPOSITE ENABLED VIA XCT-DRIVEN FINITE ELEMENT MODELING	246
KIM Doyoung | *SOUTH KOREA*	Poster	Challenges in characterizing and modeling 3D woven composites	532
KITAMOTO Kazuya | *JAPAN*	Poster	Modeling Moisture-induced Deformation in CFRP Based on Two-Phase Diffusion Theory	761
KLEIN Timothée | *FRANCE*	Interfaces	Virtual testing of the transverse cracking mechanisms of thin ply thermoplastic and thermoset matrix laminated composites under cryogenic thermomechanical loading	816
KOBEISSI Alaa | *FRANCE*	Fracture and damage	Static and fatigue multi-axial traction/torsion loading of 3D reinforced composite materials	1005
KONDAGUNTA Nagendra Gopal | *INDIA*	Sandwich structures	Vibration analysis of syntactic foam core sandwich composites using an exact state-vector formulation	536

Table of Contents

AUTHORS'S INDEX | *COUNTRY*	TOPIC	ARTICLE TITLE	PAGE
KORFF Maximilian | *GERMANY*	Design of parts	Sustainable Integration Strategy for Recycled Carbon Fiber Nonwovens within CFRP Boss Structures for Pressure Vessels	**544**
KOYANAGI Jun | *JAPAN*	Fatigue	Numerical simulation for fatigue failure by randomly variable loadings for a viscoelastic material based on entropy damage criterion	**252**
KRAUKLIS Andrejs | *NORWAY*	Durability, ageing, environmental effects	Modular framework for lifetime prediction of composite materials affected by the environment	**1354**
KUDO Natsuko | *JAPAN*	Fatigue	Numerical simulation of fatigue damage accumulation of orthotopically viscoelastic CFRP laminates considering temperature elevation caused by energy dissipation	**1012**
KULKARNI Anish Niranjan | *LATVIA*	Textile composites	FE modeling of damage development in hybrid carbon/ steel fiber textile composites using fracture mechanics and cohesive zone approach	**1362**
KUMAR Manish | *INDIA*	Fracture and damage	A Kinematically Enriched Directed Continuum Damage Mechanics Approach to Model Low-Velocity Impact Damage in Composites	**550**
KWAK Minjun | *SOUTH KOREA*	Poster	Physics-informed neural network for efficient prediction of the mechanical behaviour of short fiber-reinforced composites	**257**
LAMMING François | *FRANCE*	Poster	Comprehensive Analysis of Fatigue and Creep Relationships in Thermoplastic Composites: Towards Innovative Structural Design Approaches.	**1369**
LARQUEMIN Tiffany | *FRANCE*	Poster	Numerical Modelling and Experimental Comparison of a Tensile Test on Flax Roving	**1375**
LASEN Matias | *NETHERLANDS*	Fatigue	Hybrid Paris-Erdogan laws estimation from high frequency testing in T700/M21 composites	**218**
LAURENTZI Aretxabaleta | *SPAIN*	Dynamic	Design, manufacturing and testing of 3D printed variable-stiffness laminates for optimum dynamic response	**1107**
LECOINTRE Lea | *JAPAN*	Poster	Lightning strike induced and impact induced delamination investigation using advanced Non-Destructive Testing methods	**1383**
LEE Se-Min | *SOUTH KOREA*	Dynamic	Revolutionizing Airbag Deployment Predictions: Study of Dynamic Properties of TPO and PP in Automotive Safety Modeling	**263**
LIEBAU Alex | *GERMANY*	Lightning Strike, fire behavior and fire retardance/ resistance of composites	Investigation how the Flame-Retardant Content Affects the Mechanical Properties of GFRP for Lightweight Ship Constructions	**558**
LIN Lanhui | *FRANCE*	Poster	Translaminar fracture behavior of hybrid woven-ply PEEK thermoplastic laminates under isothermal and kerosene flame exposure	**378**

Keywords: Carbon Fibre-Reinforced Polymer (CFRP), Finite Element Analysis (FEA), Lithium-Ion Battery Thermal Runaway, Battery Enclosure, Intumescent Coatings

Abstract
The use of composite materials, for lightweighting, and lithium-ion batteries (LIB), for electrification, has expanded across the transportation industry. A common failure mechanism for LIBs is thermal runaway (TR), i.e. when a battery enters a state of uncontrolled, self-heating which can result in very high temperatures, smoke, and even battery fire. Battery fire containment is generally achieved with metallic structures, but to-date Carbon Fibre Reinforced Polymer (CFRP) containment structures have not been investigated. This paper presents Finite Element (FE) models to assess thermal and mechanical damage and failure during and after a lithium-ion battery (LIB) thermal runaway (TR) event impinging on a CFRP composite specimen. A loading approach is developed using published experimental data for a cylindrical 18650 LIB fire. A trio of sequential simulations including heat transfer, thermo-mechanical and Compression after Thermal Runaway (CaTR) models are linked with python scripts to transfer damage states. Results have shown, for unprotected specimens, the presence of thermal damage from a single cell runaway can potentially reduce the residual strength by 20%. Application of a 0.5 mm coating reduced the thermal damage area from 10,587 mm^2 to 1431 mm^2.

1. Introduction

The use of composite materials, for lightweighting, and lithium-ion batteries (LIB), for electrification, has expanded significantly in aerospace, maritime, and automotive sectors. The combination of these technologies presents new and emerging design challenges. Carbon Fibre Reinforced Polymer (CFRP) composites are more susceptible to thermal damage (softening, deformation, and failure) than traditional metallic structures due to lower thermal conductivity [1].

Thermal runaway (TR) describes the phenomenon when a battery enters a state of uncontrolled, self-heating which can result in very high temperatures, smoke, and even battery fire [2–4]. While TR mechanisms are largely well known, containment of such events is less well understood, but remains a prominent safety concern. It is standard practice for batteries to be housed in a metal enclosure, typically aluminium or steel, which contains the batteries and enables extinguishment in the event of TR. However, the interest in composite battery enclosures has been growing in recent years, as a means of lightweighting battery assemblies.

Research on the effects of fire on composite structures is relatively well established [5,6]. However, research on the effects of battery fires on composite structures is less well developed [1]. Due to the

inherent susceptibility of composites to thermal damage, barrier coatings have been proposed with the potential to protect these structures. While there exists a range of protective coating types each with advantages and disadvantages, intumescent and gel coatings have become a common choice due to their flame-retardant properties [6–9]. Intumescent coating systems, when expanded, provide a low thermal conductivity protective layer that limits heat transfer to the underlying composite structure [7]. Intumescent coatings have been used to protect composite structures from the effects of fire but none are recorded to have been tested under exposure to a battery fire, whether experimentally or computationally [6].

This work develops finite element (FE) models of thermal loading experienced during an 18650 battery thermal runaway event on composite specimens. Experimental data for a cylindrical cell fire was studied and used to define representative thermal loading patterns and behaviours for single-cell load cases. Once validated, the loading profile was applied to a composite specimen to appraise thermal damage, predict the reduction in residual strength and assess the merits of an intumescent coating.

2. Methodology

A trio of sequential simulations; heat transfer modelling, thermo-mechanical modelling and Compression after Thermal Runaway (CaTR) were established to model and predict damage to composite structures during and post thermal runaway fire, as shown in Figure 1.

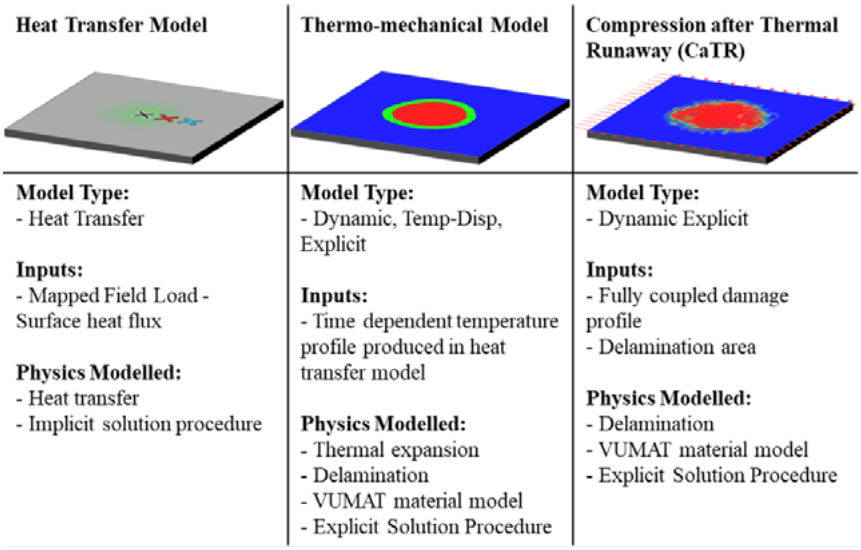

Figure 1. Model flow scheme

Prior to the modelling of composite structural damage a validated loading approach was required. Therefore, a representative loading profile, varying both spatially and temporally, for a single-cell 18650 runaway event was created based on data from Shen [10] and Zhang et al. [2]. This was applied to a 6061-T6 aluminium alloy specimen. The heat flux distribution was applied to the model using a mapped analytical field, with more details given by Sterling et al. [1]. Three thermocouples, attached to the rear of the specimen, at 0 mm, 50 mm, and 100 mm from the centre of the specimen were used to check the accuracy of the loading profile. The accuracy of this loading approach is shown in Figure 2.

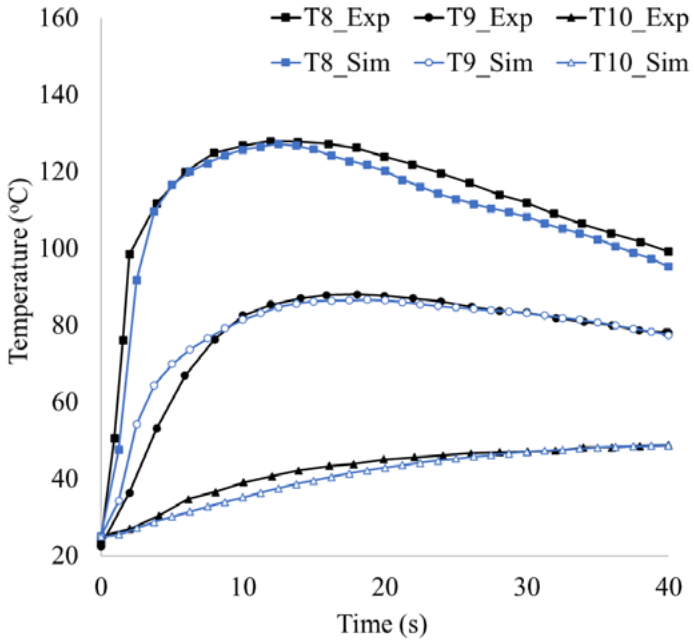

Figure 2. Comparison of measured (from ref. [11]) and predicted back face temperature on aluminium plate

It can be seen there is generally good agreement between the measured and predicted temperature peaks with some discrepancy around three seconds into the simulation. The predictions can still be considered acceptable given that no two fires will be identical there will be some inherent variation in results from test to test. Once this loading approach had been created and validated, it could then be applied to composite specimens.

2.1 Heat Transfer Model

Firstly, modelling of the heat transfer behaviour, due to heat flux loading, was completed. All models in this work replicated the specimen geometry used in preceeding experimental work by Zhang et al. [2]. The specimen measured 400 mm x 400 mm x 4.704 mm and was meshed with DC3D8 8-node linear brick solid heat transfer elements. The laminate stacking sequence was $[45/0/-45/90]_{4s}$. Temperature dependant material properties for the CFRP used are shown in Table 1, from ref. [12].

Table 1. Temperature dependent CFRP material properties

Temperature (°C)	Density (kg/m^3)	Specific Heat (J/kg°C)	Thermal Conductivity		
			Fibre (W/m.K)	Transverse (W/m.K)	Through-Thickness (W/m.K)
25	1520	1065	8.00	0.67	0.67
500	1520	2100	4.39	0.34	0.34
800	1100	2100	2.61	0.18	0.18
1000	1100	2171	1.74	0.10	0.10
3316	1100	2500	1.74	0.10	0.10
3334	1.11	5875	1.74	0.10	0.10

2.1.2 Intumescent coating modelling

The intumescent coating used in this work was derived from the work of Mouritz et al. [6] with properties shown in Table 2.

Table 2. Intumescent coating material properties from ref. [6].

Property	Material State	Value
Thermal conductivity (W/m°C)	Virgin	0.4
	Intumesced/Charred	$3.00 \times 10^{-4}T + 0.1$
Specific heat capacity (J/kg °C)	Virgin	2200
	Intumesced	$1.5T + 3000$
Density (kg/m^3)	Virgin	1392

2.2 Thermo-mechanical modelling

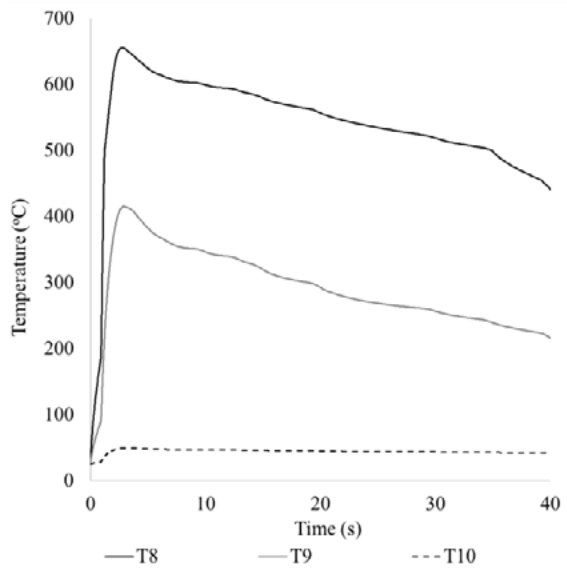
A thermo-mechanical model, was completed with a dynamic, temperature-displacement, explicit analysis step in Abaqus/Explicit using C3D8RT elements. The temperature profile from each node of each element of the FE mesh in the heat transfer simulation was transferred using Python scripts, as discussed in previous works [12,13]. Intralaminar damage was captured using a VUMAT material model developed by Millen et al. [14], with material properties shown in Table 2.

Table 2. Mechanical properties for thermo-mechanical model [14]

Temperature (°C)	E_1 (MPa)	E_2=E_3 (MPa)	G_{12}=G_{13} (MPa)	G_{23} (MPa)	ν_{12}= ν_{13}	ν_{23}	α11 (x10^{-8})	α22= α33 (x10^{-5})
25	161,000	11,400	5170	3980	0.32	0.44	1.8	3
200	161,000	9120	4136	3184	0.32	0.44	5.4	5.25
260	161,000	114	41.36	31.84	0.32	0.44	5.4	5.25
600	161,000	5.7	2.068	1.592	0.32	0.44	5.4	5.25
3316	161,000	5.7	2.068	1.592	0.32	0.44	5.4	5.25

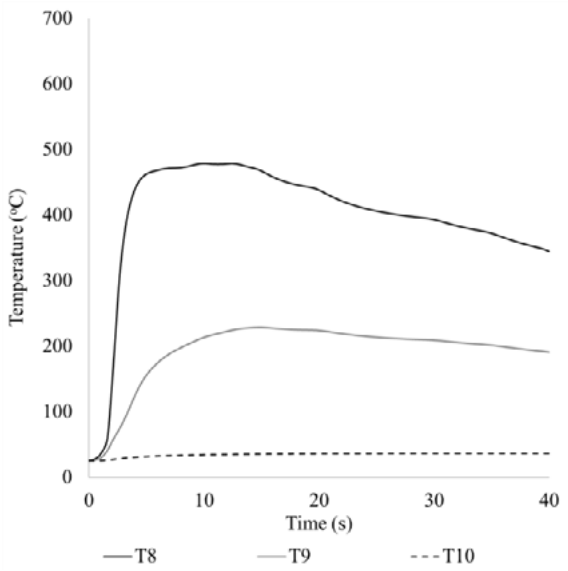
This temperature distribution was then transferred to structural models to predict mechanical damage (i.e., fibre/matrix failure or delamination), considering strain and heating rates, with a VUMAT subroutine. Finally, CaTR simulations were completed, after damage mapping with python scripts, to determine the residual strength of the specimen.

2.3 Compression after Thermal Runaway (CaTR)



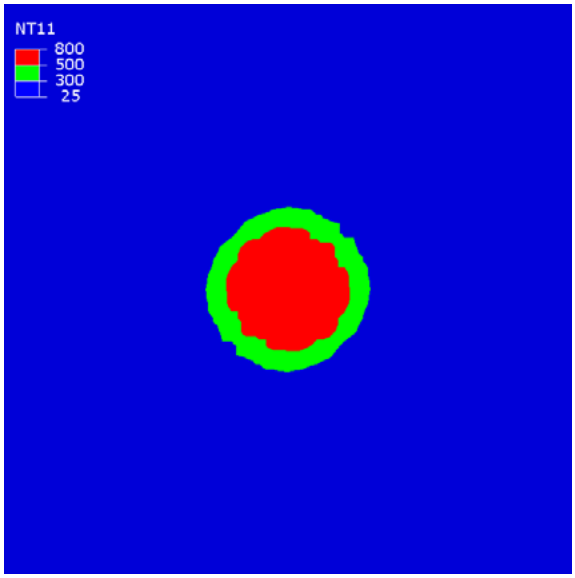
CaTR was completed using Abaqus/Explicit. Boundary conditions in the CaTR models were derived from the typical compression-after-impact (CAI) arrangement. As such, the side of the specimen opposite the compression load was fixed in all directions. The two sides perpendicular to loading were constrained to avoid buckling. The intralaminar and interlaminar damage from the preceeding thermo-mechanical model was transferred to the the CaTR using the same approach proposed in ref. [15].

3. Results

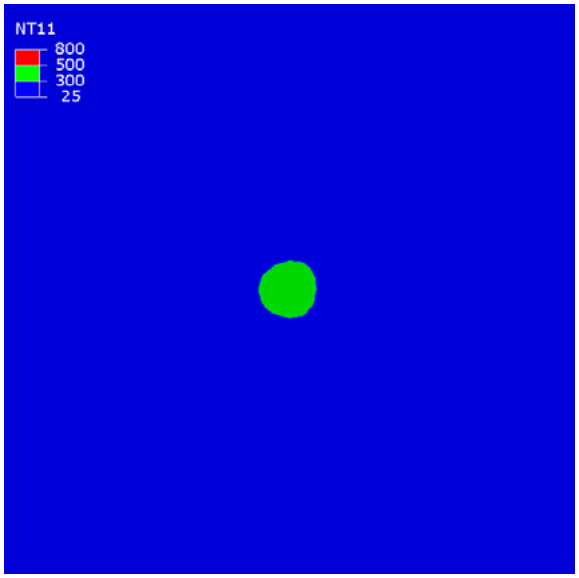


3.1 Thermal damage

Figure 3 shows the thermocouple measurements and predicted damage profiles for both unprotected and protected composite specimens. In the unprotected case, Figure 3a, the temperature rises rapidly at approximately 14,000 °C/min reaching a peak of 656 °C. This temperature then gradually drops as the flux from the battery runaway decreases and conduction and emissivity occur. Alternatively, in Figure 3b it can be seen that the addition of a 0.5 mm thick intumescent coating reduced the peak temperature to 479 °C (~5500 °C/min).



Looking at the predicted thermal damage area, a similar trend is observed, where the addition of an intumescent coating reduces the overall damage. In the unprotected case the moderate damage area (areas where 300 °C ≤ T < 500 °C) was 10,587 mm^2 and extended four plies deep or 0.588 mm while the severe damage area (areas where T ≥ 500 °C) was 5413 mm^2 and was confined to the top ply. The addition of a 0.5 mm thick intumescent coating eliminated the severe damage area and reduced the moderate thermal damage area to 1431 mm^2.



a) Thermocouple measurements on unprotected composite specimen

b) Thermocouple measurements on protected composite specimen

c) Top surface predicted thermal damage profile on unprotected composite specimen

d) Top surface predicted thermal damage profile on protected composite specimen

Figure 3. Thermocouple measurements and predicted damage profiles for both unprotected and protected composite specimens

3.2 Mechanical damage

In the thermo-mechanical models, delamination was the dominant failure mode. Under the influence of a single-cell runaway event, the predicted delamination area and depth were 9930 mm^2 and six plies

(0.88 mm), respectively. This represented an increase of 6% over the moderate thermal damage area predicted previously. The delamination depth was two plies or 0.3 mm deeper than the predicted moderate thermal damage, due to the combined effects of mechanical and thermal strains.

3.2 CaTR results

Figure 4 compares the CaTR strength after a single cell exposure and the strength of an undamaged specimen. The strength of the undamaged specimen was 333 MPa but after a single cell runaway event this reduced to 265 MPa.

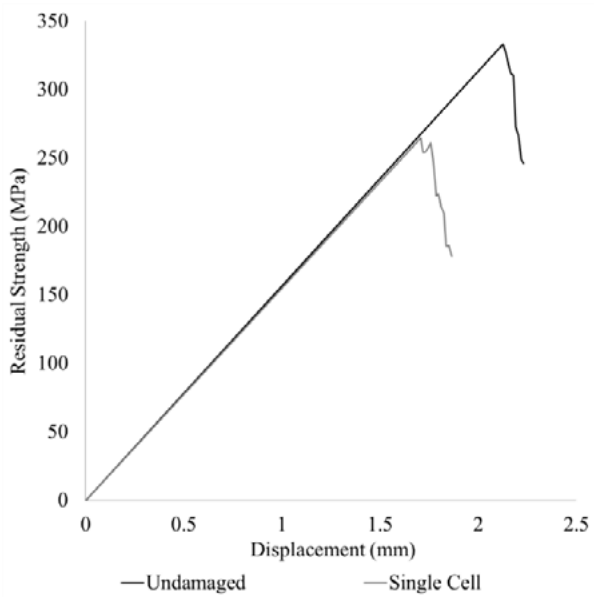


Figure 4. CaTR plots for undamaged and single cell specimens

4. Conclusions

The models presented herein have been used to predict thermal and mechanical damage during and after a cylindrical 18650 lithium-ion battery thermal runaway fire on a composite specimen. A thermal loading profile was developed, based on published experimental data, which could replicate the spatial and temporal variation of the fire. Initial validation was completed on an aluminium plate specimen before being applied to a typical aerospace composite. Results have shown, for unprotected specimens, the presence of damage from a single cell runaway can potentially reduce the residual strength by 20%. An intumescent coating was also modelled in heat transfer simulations, with material properties derived from literature. Application of a 0.5 mm coating reduced the thermal damage area from 10,587 mm^2 to 1431 mm^2 following a single cell thermal runaway event. Further details of the models used herein and results can be found in ref. [1].

Keywords: Topology Optimization, BESO, Fiber Placement

Abstract
Modern fiber placement technologies for continuous fiber reinforced polymer composites allow for manufacturing of parts with complex shapes and load-adapated fiber orientation. For design of corresponding structures, anisotropic topology optimization is promising as it results in very light truss-structures with optimized fiber orientation. However, most anisotropic topology optimization approaches are limited towards exclusively unidirectional fiber orientations that are not suitable for intersection points with multiaxial stress states. Therefore, a bi-directional evolutionary structural optimization approach that uses unidirectional fiber orientations at regions with unidirectional stress states and biaxial fiber orientations where needed is developed. Results show that the proposed topology optimization approach produces fiber orientations at intersection points that are more suitable for manufacturing by fiber placement technologies such as Wet Fiber Placement compared to optimization with purely unidirectional fiber orientations. In addition, by adding a second fiber orientation at intersection points during the optimization procedure the probability for inter-fiber failure at those regions is reduced.

1. Introduction

Wet Fiber Placement (WFP) is a novel fiber placement process in which continuous fiber rovings are in-line impregnated with a thermoset resin system, conveyed to a placement head by a system of driven rollers, and – almost tension-free – placed directly into cavities of a mold. After placement, the molds can be demounted and transferred to a press for curing of the final part by applying temperature and pressure [1]. Since the freshly impregnated rovings are rather limp compared to preimpregnated tapes they can be placed in curved pathways [2], which allows for load-adapted placement and manufacturing of complex-shaped parts.

For design of such complex-shaped, lightweight structures, topology optimization is a promising approach. While material optimization and topology optimization have been combined by a wide number of researchers to account for the anisotropic material properties of continuous fiber reinforced polymer composites (CFRPC), those approaches are, in many cases, limited to exclusively unidirectional fiber orientations. Topology optimization usually results in truss structures, in which the trusses carry unidirectional tension or compression loads, whereas the intersection points between the individual trusses are subject to more complex, multiaxial stress states. For such regions, a unidirectional fiber orientation is not reasonable. Therefore, anisotropic topology optimization based on unidirectional fiber orientations may yield a design that is not feasible for manufacturing and for load transfer at intersection points. To overcome these issues a bi-directional evolutionary structural optimization

(BESO) procedure that accounts for unidirectional but also biaxial fiber orientations is developed and studied on benchmark test cases.

2. Materials

In our topology optimization procedure, we distinguish between solid, CFRPC material and void material representing the elements that are removed from the design space. For CFRPC we assume the material properties presented in Table 1. For the void material, we consider a Young's modulus of E_{Void} = 0.0001 MPa and a Poisson's ratio μ_{Void} = 0.3. [3]

Table 1. Elastic material properties for CFRPC [3].

E_{11} (MPa)	E_{22} (MPa)	E_{33} (MPa)	G_{12} (MPa)	G_{13} (MPa)	G_{23} (MPa)	μ_{12}	μ_{13}	μ_{23}
140,000	9,000	9,000	5,000	5,000	3,000	0.3	0.3	0.4

While it is not a direct objective of the optimization procedure, we also evaluate failure criteria for the optimized structures. For this Puck's failure criteria [4] is used together with the strength values provided in Table 2 [3].

Table 2. Strength values for CFRPC [3].

$R_{\parallel}^{t}$ (MPa)	$R_{\parallel}^{c}$ (MPa)	$R_{\perp}^{t}$ (MPa)	$R_{\perp}^{c}$ (MPa)	$R_{\perp\parallel}$ (MPa)
1750	1200	40	175	60

3. Methods

3.1. Anisotropic BESO

For topology optimization we use the anisotropic BESO procedure as presented in [5]. In this, the topology optimization problem is formulated as a compliance minimization subject to a volume constraint [5]:

$$\text{min:} \qquad \boldsymbol{C} = \frac{1}{2}\boldsymbol{F}^{\boldsymbol{T}}\boldsymbol{U} \tag{1}$$

$$\text{subject to:} \qquad V^{*} = \sum_{i=1}^{N} v_i x_i \tag{2}$$

In those equations, $\boldsymbol{C}$ is the compliance, which is the objective function to be minimized, $\boldsymbol{F}$ are the applied forces, and $\boldsymbol{U}$ the displacements. Furthermore, V^{*} is the target volume fraction of the design space that should be filled by CFRPC material, v_i is the volume of element i and x_i is its relative density. The relative density can either take values of 1 for CFRPC material or 0.001 for void material [5]. The decision, whether an element will contain CFRPC or void material is based on the element sensitivity α_i that can be calculated according to Eq. 3 [6]:

$$\alpha_i = -p\frac{E_i}{x_i} \tag{3}$$

In Eq. 3, E_i is the element strain energy that is directly obtained from finite element analysis (FEA) and p is a constant that is called penalty exponent. In the BESO procedure, the element sensitivities are filtered spatially and by their history from previous iterations. In this study the filtering scheme as described in [6] is applied. The BESO procedure starts with a design space completely filled with CFRPC material. The volume fraction of the CFRPC material is then subsequently decreased according to Eq. 4 [5]:

$$V_k = V_{k-1}(1 - ert) \text{ for } V_k > V^* \quad (4)$$

Here, ert is an evolution rate to be specified. Based on the volume fraction of the current iteration V_k a sensitivity threshold value α_{th} is determined using a bisection method [7]. Elements with a sensitivity that is larger than the threshold are assigned CFRPC material, while the other elements are assigned void material. When the target volume fraction is reached, the optimization procedure continues until a convergence criteria for the objective function is met [5].

In order to account for anisotropic material properties, the BESO procedure is coupled with computer aided internal optimization (CAIO) [8]: In each iteration of BESO, the elements are not only switched between CFRPC and void material, but their material orientation is aligned with the direction of the maximum absolute principal stress in the element. More detailed descriptions for this can be found in [5,6].

3.2. Consideration of biaxial fiber orientations

In order to consider not only unidirectional fiber orientations, but also biaxial fiber orientations at regions were this is necessary, we consider models that are build from two layers of shell elements as shown in Fig. 1 for the example of a plate clamped at its left end and subject to a vertical force at its right bottom corner. The first layer will be denoted as “master layer”. On this, we will perform most of the calculations needed for the anisotropic BESO procedure. The second layer referred to as “slave layer”, on the other hand will be only activated at regions of multiaxial stress states in order to add a second fiber orientations at such areas. Both layers are ideally connected by using a tie-constraint. For a symmetric laminate, a symmetry boundary condition (not shown in Fig. 1) can be added optionally. [3]

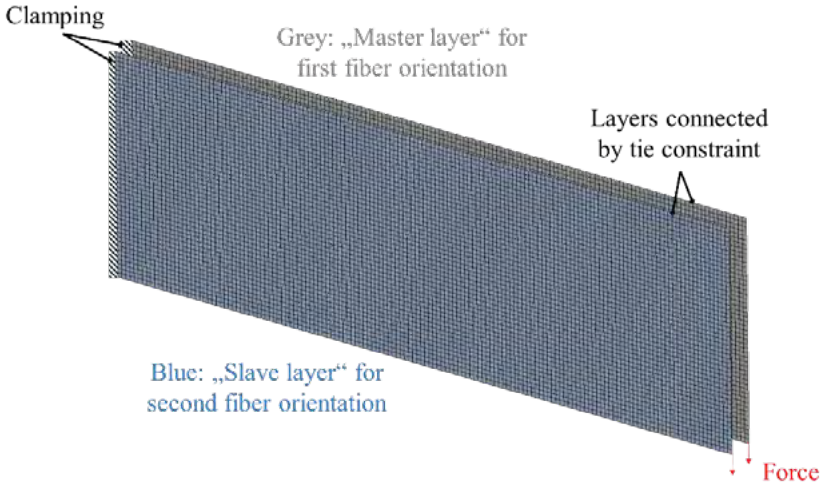

Figure 1. Finite element model of a plate consisting of two shell element layers.

To decide at which regions a second fiber orientation should be introduced, we define a variable sr that describes the stress ratio of an element i in the master layer m [3]:

$$sr_i = \frac{|\sigma_{I_{i,m}}|}{|\sigma_{II_{i,m}}|} \quad (5)$$

In Eq. 5, $\sigma_{I_{i,m}}$ is the first principal stress of element i in the master layer m and $\sigma_{II_{i,m}}$ is its second principal stress. Elements for which sr_i is smaller than a threshold sr_{th} are saved in a list and considered

as candidate elements for adding a second fiber orientation by activation of the corresponding element in the slave layer. To create smooth regions in which a second fiber orientation is added, the candidate elements are filtered: The slave layer element is only activated for candidate elements if more than half of the surrounding CFRPC elements in the master layer are also candidate elements. [3]

Of course activation of elements in the slave layer increases the overall volume fraction of CFRPC material in the design space. To account for this and to guarantee, that the overall CFRPC volume fractions between different optimization results are equal for comparability, we extent the variable space for the relative element density x_i: The relative element density x_i will therefore be 0.001 for void elements, 1 for elements in the master layer with unidirectional fiber orientation (corresponding slave element is deactivated) and 2 for elements in the master layer with biaxial fiber orientation (corresponding slave element is activated). The relative element densities are then considered in Eq. 2 for calculation of the solid material volume fraction. The volume fraction is only calculated based on the elements in the master layer. [3]

By choice of the threshold value sr_{th} the amount of material with a second fiber orientation can be controlled. However, large values for sr_{th} in an early stage of the optimization procedure – at which many regions with multiaxial stress states exist compared to a truss-like structure at a later stage of the optimization process – can lead to optimization instabilities, as "more material is removed" with respect to the plane design space in order to meet the volume fraction criteria. To avoid those, we start the optimization procedure with sr_{th} = 1 and subsequently increase sr_{th} after the target volume fraction is reached according to Eq. 6 [3]:

$$sr_{th,k} = sr_{th,k-1} + ert_{sr} \quad \text{for} \quad (sr_{th,k} < sr_{th}^{*} \; and \; V_{k-1} = V^{*}) \tag{6}$$

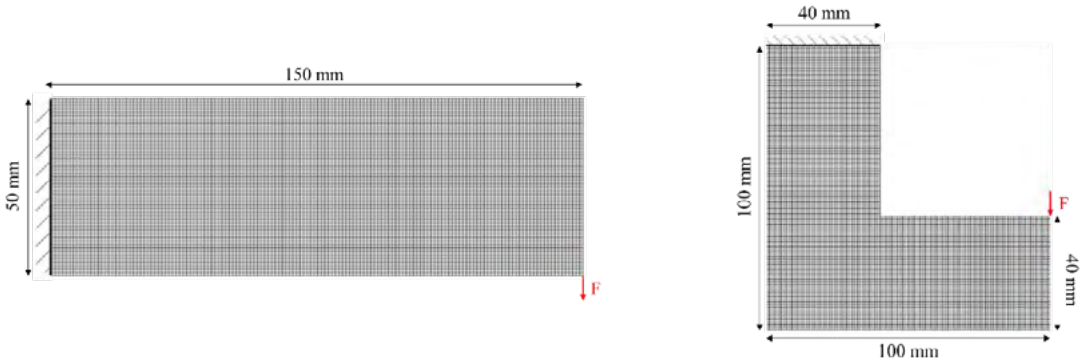
In this, $sr_{th,k}$ is the threshold value in iteration k and $sr_{th,k-1}$ is the threshold value from the previous iteration. ert_{sr} is an evolution rate for the stress ratio threshold and sr_{th}^{*} is a target value for the threshold. [3]

While in the master layer the element orientations are aligned with the direction of the maximum absolute principal stresses, a second (different) fiber orientation is required at regions of multiaxial stress states. To calculate the fiber orientation angle in the slave layer we utilize composite net theory, which is considered one of the first tools for design of composite structures [9]. By this we can simply calculate the fiber orientation angle of an active element in the slave layer by [3]:

$$\beta_2 = \arctan\left(-\frac{\sigma_{II_{i,m}}/\sigma_{I_{i,m}}}{\tan\beta_1}\right) \tag{7}$$

Where $\sigma_{II_{i,m}}$ and $\sigma_{I_{i,m}}$ are the principal stresses in the underlying element of the master layer, β_1 is the fiber orientation angle of the underlying element in the master layer and β_2 is the fiber orientation angle of the corresponding element in the slave layer [3].

Activation of elements in the slave layer s with a second fiber orientation of course affects the stress state and the strain energies obtained for the corresponding elements in the master layer m. To account for this Eqs. 3, 5, 7 are replaced by Eqs. 8, 9, 10 in case that the slave layer element is activate for a corresponding master element [3]:



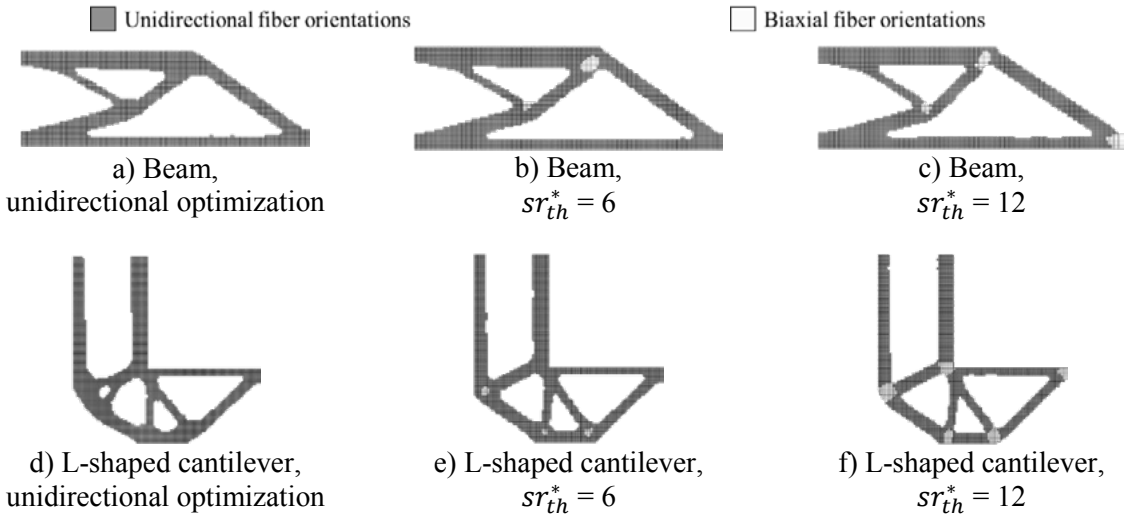
$$\alpha_{i,m} = -p\frac{(E_{i,m} + E_{i,s})}{x_{i,m}} \tag{8}$$

$$sr_i = \frac{|\sigma_{I_{i,m}}|}{|\sigma_{I_{i,s}}|} \tag{9}$$

$$\beta_2 = \arctan\left(-\frac{\sigma_{I_{i,s}}/\sigma_{I_{i,m}}}{\tan\beta_1}\right) \tag{10}$$

3.3. Test cases

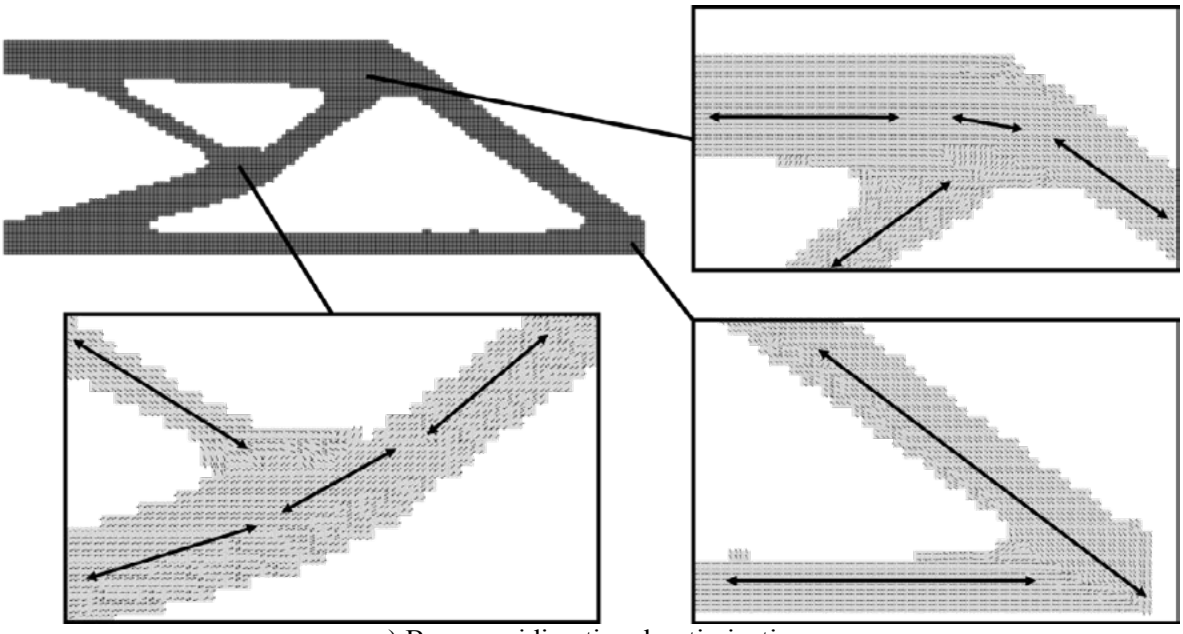
Two numerical test cases are shown in order to evaluate the optimization procedure. The first one is a beam clamped on its left end and subject to a vertical force on its bottom right corner, the second one is a L-shaped cantilever (Fig. 2). For both test cases, a filter radius of 4 mm and a target volume fraction of 40% is used. As the parameter sr_{th}^* affects how much material with a second fiber orientation is added, for this parameter the values 1 (exclusively unidirectional optimization), 4, 6, 8, 10, and 12 are tested. [3]



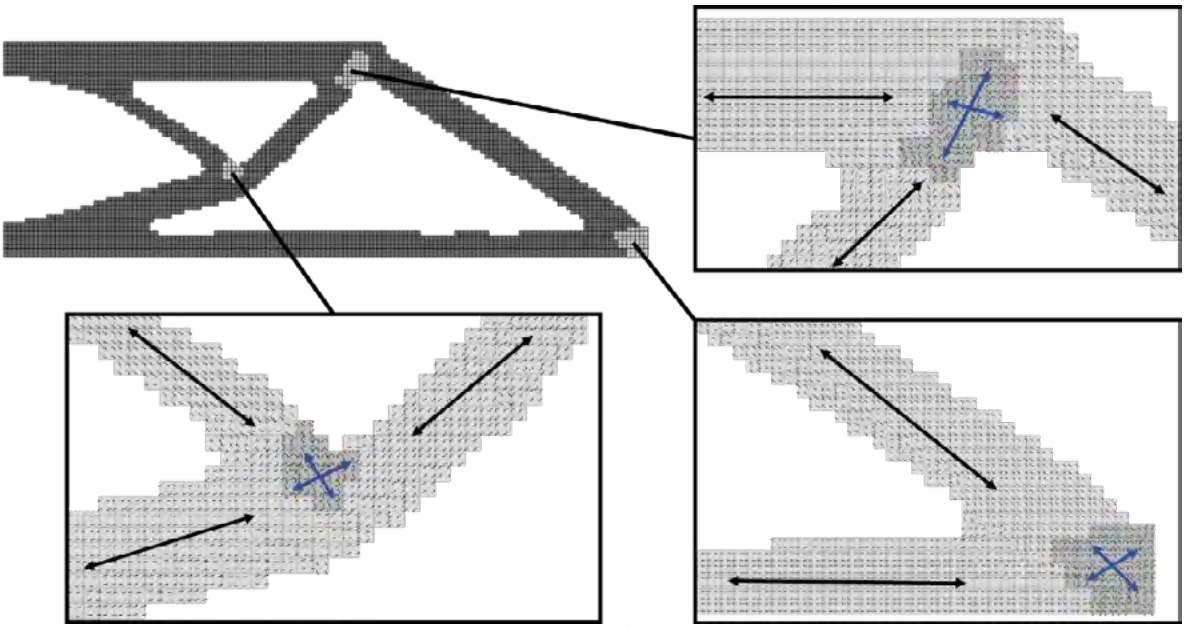
a) Beam test case b) L-shaped cantilever test case

Figure 2. Numerical test cases for topology optimization [3].

4. Results



In the following, selected results from our studies are presented. For more detailed results, the reader is referred to [3]. Fig. 3 shows the material distribution for the optimization results considering sr_{th}^* values 1, 6, and 12. In this, the dark grey colored elements represent unidirectional fiber orientations and the light grey colored elements represent regions where a second fiber orientation is added. From Fig. 3, it can be obtained that, as expected, increasing values for sr_{th}^* lead to more and larger regions at which a second fiber orientation is added.



a) Beam, unidirectional optimization
b) Beam, sr_{th}^* = 6
c) Beam, sr_{th}^* = 12
d) L-shaped cantilever, unidirectional optimization
e) L-shaped cantilever, sr_{th}^* = 6
f) L-shaped cantilever, sr_{th}^* = 12

Figure 3. Optimization results and material distribution [3].

At the example of the beam test case, the fiber orientation distributions at intersection points are studied in more detail in Fig. 4 by comparing the unidirectional optimization result and the result for sr_{th}^{*} = 12. Regarding the unidirectional optimization result, the fiber orientations at intersection points are dominated from the higher stressed truss member. Therefore, there is no fiber continuity at intersection points and it is unclear, how the fiber bundles should be placed in the WFP process. For the biaxial optimization result on the other hand, the fiber orientations obtained indicate, that overlapping fiber bundles should be placed above each other. This is considered a feasible design, as by that small placement radii, that would very likely lead to placement defects [2], are avoided.

a) Beam, unidirectional optimization

b) Beam, sr_{th}^{*} = 12

Figure 4. Fiber orientations at intersection points for beam test case.

While it is not a direct objective of the optimization process, the biaxial fiber orientations are also found to be beneficial for structural strength. Fig. 5 shows the results for fiber failure (FF) stress exposure

factors and inter-fiber failure (IFF) stress exposure factors utilizing Puck's failure criteria at the example of the L-shaped cantilever considering a load of 2000 N [3]. Regarding FF stress exposure, there is little difference between the unidirectional and biaxial optimization result – in both cases FF stress exposure factors can be considered uncritical. However, the optimization considering exclusively unidirectional fiber orientations leads to critical IFF values > 1 at all intersection points. Therefore, the resulting fiber orientation is not feasible to achieve sufficient strength. IFF stress exposure is clearly improved when adding a second fiber orientation during topology optimization (Fig. 5 e) and f)). Therefore, the approach leads to designs that require less redesign in such regions compared to topology optimization considering only one fiber orientation.

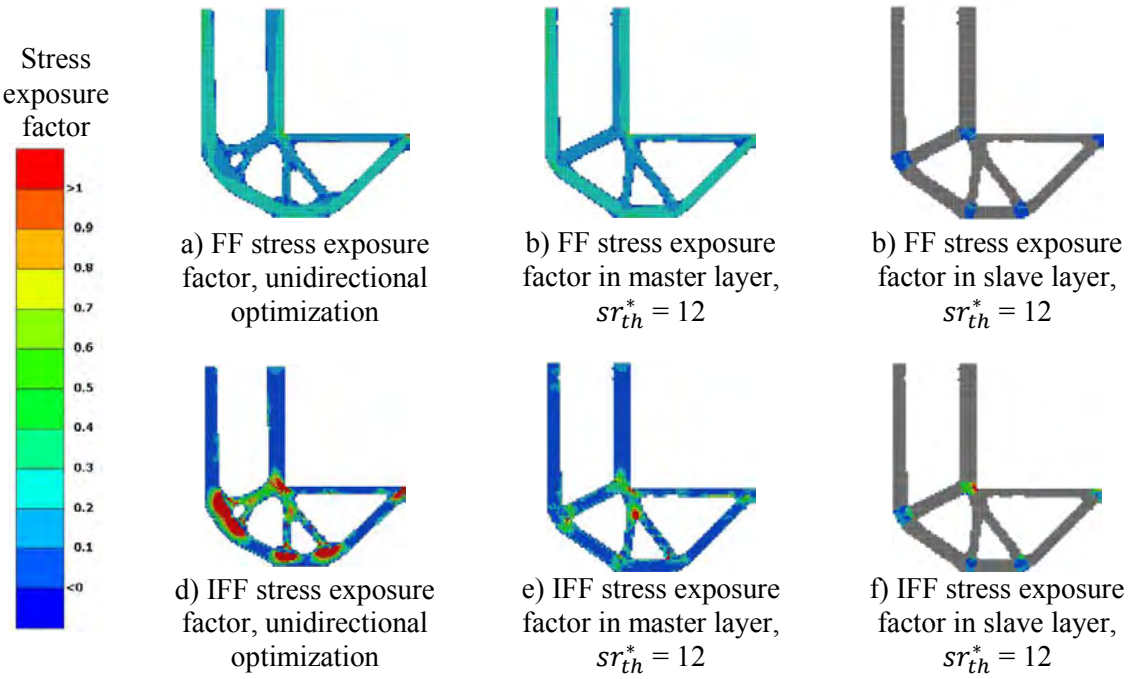


Figure 5. FF and IFF stress exposure factors for L-shaped cantilever test case.

In [3], the impact of adding a second fiber orientation on structural compliance is also discussed. It was found that the approach can lead to improved structural compliance, but whether an improvement is achieved depends on the specific test case and also on the target volume fraction.

5. Conclusions

In this study, an anisotropic BESO algorithm that adds a fiber orientation at regions in which a multiaxial stress state is present is developed. The choice where a second fiber orientation is added is made based on the stress state within the finite elements. It could be shown that a parameter describing the stress ratio in the finite elements can be used to control the number and size of regions in which a second fiber orientation is added. From numerical test cases, it was observed that the fiber orientation distribution at intersection points is improved regarding the manufacturability of topology-optimized structures and also structural strength is improved by reducing the probability of inter-fiber failure.

Keywords: molecular dynamics simulation, graphene, nanocomposites, mechanical behaviors

Abstract
The study aimed to characterize the mechanical behaviors of graphene nanocomposites using molecular dynamics (MD) simulation. Both monolayer graphene and multilayer graphene were considered as reinforcement in the epoxy matrix. The influences of surface functionalization and graphene waviness on the behaviors of the nanocomposites were also examined. The moduli of the nanocomposites were evaluated from simple tension simulation. In order to explicate the load transfer efficiency between the graphene and the surrounding matrix, the local stress of the graphene was calculated. Moreover, the pullout simulations were also carried out to characterize the interfacial behavior of the graphene and the epoxy matrix. Results indicated that the increase in the number of graphene layers reduced the Young's moduli of the nanocomposite. The reduction of moduli for the nanocomposites was attributed to the poor interfacial properties.

1. Introduction

In recent years, with the advancement of nanotechnology, nano-materials with the characteristics of high surface area-to-volume ratio have been applied in composite materials, forming nanocomposites. Graphene with excellent mechanical properties has been introduced in nanocomposites as reinforcement. In graphene nanocomposites, graphene often exhibited a multilayered or curved morphology [1-3], and these different forms of graphene may influence the mechanical properties of the nanocomposite. Moreover, the mechanical properties of nanocomposites are closely related to the interfacial properties between the reinforcement and surrounding matrix. Thus, understanding the influence of the graphene morphology and the interfacial properties between nano-reinforcements and the matrix on the mechanical properties of nanocomposites has become an essential topic in the society of nanocomposites [4-6]. This study utilized MD simulations to investigate a model of multilayer graphene/epoxy resin nanocomposites. By analyzing mechanical properties, and local stress distribution on graphene, we aimed to understand the effects of different forms of graphene on the moduli of nanocomposites and further explore the underlying physical mechanisms.

2. Molecular dynamics simulation

2.1. Generation of atomistic model

In MD simulation, the atomistic interactions between molecular were described using potential function. In this study, the Polymer Consistent Force Field (PCFF) [7] potential was adopted to model the bonded and non-bonded interactions. This is because that this potential has been widely used in MD models for epoxy resin and graphene [8, 9]. Regarding the epoxy resin molecular chains, a structure representing a cross-linked resin with a crosslink density of 50% was constructed using 9 EPON862® resins and 3 TETA® hardeners [10]. For multilayer graphene, the initial stacking was done in an A-B-A configuration. Concerning surface modification of graphene, carboxyl (-COOH) and amine (-NH2) groups were introduced based on experimental measurements [9], with

modification proportions of 4.7% and 9.7%, respectively. The modification proportion was defined as the number of functional groups divided by the number of carbon atoms in a single-layer graphene. The Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS) [11] was utilized for MD simulations.

In the MD simulation, the atomistic models for graphene/epoxy nanocomposites need to be established. The graphene length and width in x and y directions was 100 Å and 21 Å, respectively, with periodic boundaries in the y direction. The graphene was placed in the middle of the simulation cell, and constraints were applied to maintain its rigidity and to prevent the effect of external forces. Epoxy resin molecules were randomly distributed throughout the cell. The length of the cell in the y direction was then compressed to 150 Å, and the density in the z direction is compressed to approximate experimental values under NVT ensemble at 800 K. Subsequently, the temperature was reduced from 800 K to 300 K within 90 ps under NPT ensemble at zero atmospheric pressure, and the constraints on graphene were removed. Finally, the system was equilibrated at 300 K for 300 ps to reach a stable state of the graphene/epoxy resin nanocomposite model. Figure 1 illustrates the atomistic model for the nanocomposites containing monolayer, two-layer and four layer graphene. In these atomistic models, the volume fractions of graphene were the same.

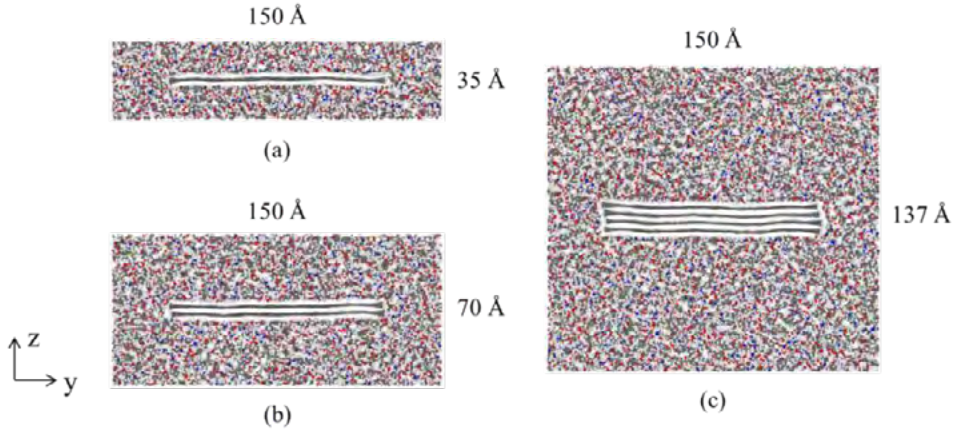

Figure 1. Atomistic model of graphene nanocomposites
(a) monolayer (b) two layers (c) four layers

On the other hand, for the nanocomposites with wavy graphene, the sinuous form of graphene was described using a sine function to quantify the degree of curvature of graphene as follows

$$z = a\sin\left(\frac{2\pi x}{L}\right) \tag{1}$$

where a is the amplitude and L is the wave length of the sine function. The waviness ratio of graphene is defined as α=a/L. In this study, α = 0.05, 0.1 and 0.15 were considered. By following the equilibrium procedure described early, the atomistic models of nanocomposites with two-layer wavy graphene were generated as shown in Figure 2.

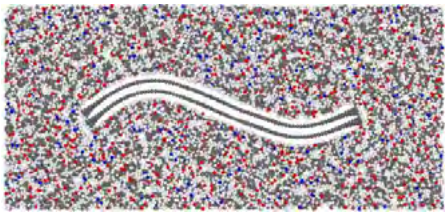

Figure 2. Atomistic model of wavy graphene nanocomposites (α = 0.1)

2.2. Simple tensile simulation

The mechanical properties of the nanocomposites were characterized through tensile loading simulation. The atomistic model was placed under the NPT ensemble with zero pressure in all directions and the temperature was reduced from 300 K to 0.1 K within 40 ps. Subsequently, equilibrium was conducted at 0.1 K for 10 ps to obtain a nanocomposite model close to absolute zero. Next, an amount of strain was applied in the graphene plane direction (y-direction) of the simulation cell. Each time a strain of 0.005 was applied, stress relaxation was performed simultaneously in the x and z directions, followed by a 50 ps equilibration process. This process was repeated for uniaxial tensile simulation until the strain reached 2%, and the corresponding stress of the nanocomposites was recorded for each strain. Stress was calculated using the Virial stress [12] which calculated the average stress components in all directions of the simulation cell. However, to further investigate the load transfer efficiency and mechanism between graphene and epoxy resin within the nanocomposites, it is necessary to perform local stress calculations. Lutsko [13] and Cormier et al. [14] developed the Lutsko stress, which calculated the average stress within a chosen Lutsko volume to analyze the local stress distribution in the materials. In this study, the local stress within graphene was calculated and the load transfer efficiency was defined as the ratio of the average Lutsko stress to the Virial stress along the tensile direction of the nanocomposites.

2.3. Pullout simulation

To further investigate the influence of the interfacial properties on the load transfer between graphene and epoxy resin, we also conducted graphene pull-out simulations and calculated the corresponding average interfacial shear stress. This simulation methodology was used by many researchers to explore load transfer behaviors between different materials [15-17]. The pullout simulation involved the calculation of the graphene pull-out energy, which was defined as

$$U_{pullout} = U_2 - U_1 \tag{2}$$

Where U_2 is the energy when the graphene was completely pullout. On the other hand U_1 is the energy, when the graphene was fully embedded with the nanocomposites. Figure 3 depicts snapshots before and after the pull-out process of two-layer graphene. Based on the pullout energy, the averaged interfacial stress was then evaluated as

$$\tau_i = \frac{U_{pullout}}{wL^2} \tag{3}$$

where w and L denote the width and length of the graphene, respectively.

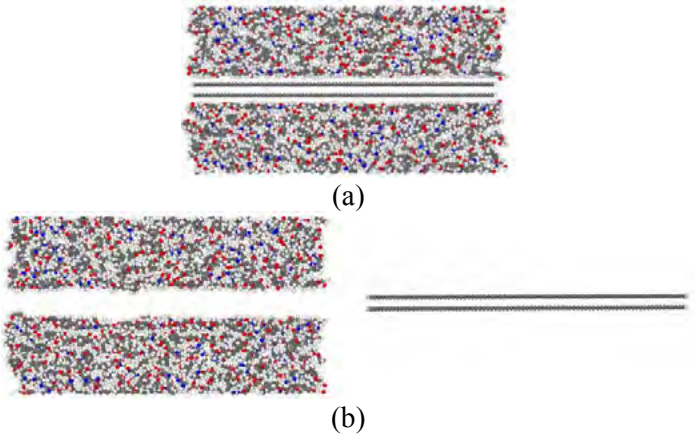

Figure 3. Schematic of graphene pull-out simulation

3. Results and discussion

The results of the Young's moduli for different numbers of layers and levels of curvature are presented in Table 1. It can be observed that surface modification can effectively enhance the mechanical properties of the nanocomposite material compared to the unmodified case. Specifically, for single-layer graphene, the Young's modulus increases from 8.48 GPa to 10.26 GPa after modification. Regarding the number of layers, it is noticeable that as the number of graphene layers increases, the Young's moduli of the nanocomposite material decreases, indicating that aggregation of graphene reduces the mechanical properties of the nanocomposite. When the curvature increases, regardless of modification, there is a significant decrease in the Young's moduli of the nanocomposite material. For unmodified single-layer graphene, the Young's modulus decreases by nearly 50% at $\alpha = 0.15$, indicating a significant impact of this curvature effect on the mechanical properties of the nanocomposites. Additionally, comparing the α values from 0 to 0.15 for one-layer, two-layer, and four-layer graphene, it can be observed that as the α value increases, the difference in Young's moduli in terms of different-layer graphene nanocomposite materials is becoming minor. At $\alpha = 0.15$, there is no significant difference in the Young's moduli between single-layer and multi-layer graphene nanocomposite materials. For the practical applications, when using graphene, it is essential to maintain its flatness to achieve a more significant enhancement in the Young's moduli of the nanocomposites.

Table 1. Young's modulus of graphene nanocomposites

Layer number	Young's modulus of nanocomposite (GPa)							
	Pristine graphene				Functionalized graphene			
	α=0	α=0.05	α=0.1	α=0.15	α=0	α=0.05	α=0.1	α=0.15
1	8.48	5.97	5.13	4.38	10.26	8.43	6.69	5.43
2	6.64	6.48	5.28	4.35	8.29	6.89	6.60	5.21
4	5.86	5.70	5.03	4.42	7.22	5.92	5.52	4.72

Table 2. Load transfer efficiency of nanocomposites with four layer graphene

	Pristine graphene		Functionalized graphene	
	outermost layer	inner layer	outermost layer	inner layer
Average Lutsko stress(GPa)	0.384	0.278	0.909	0.386
Load transfer efficiency	4.22	3.05	7.97	3.39

Load transfer efficiency of nanocomposites with four layer graphene is listed in Table 2. It can be seen that the outer layer of graphene exhibits better load transfer efficiency than the inner layer. This may

be due to the phenomenon of loss of stacking between layers during stretching, as mentioned in previous literature [18], where the shear strength between graphene layers is lower than the shear strength at the polymer/graphene interface, resulting in reduced load transfer efficiency for the inner layers of multi-layer graphene. In addition, Table 2 illustrates that surface modification can significantly increases the load transfer efficiency of the outer layer of graphene from 4.22 to 7.97. However, the increase in load transfer efficiency for the inner layer of graphene is lower, only rising from 3.05 to 3.39. This phenomenon demonstrates that surface modification can effectively enhance the load transfer between the outer layer of graphene and the epoxy resin, with a lower increase in efficiency for the inner layer. The stress values of the inner and outer layers of four-layer graphene were averaged and the corresponding load transfer efficiency was calculated. The results for the four layer case were compared with the results for one and two layers in Table 3. It can be observed that single-layer graphene has a higher load transfer efficiency compared to multi-layer graphene, primarily because of the lower load transfer efficiency of the inner layers in multi-layer graphene. These results can explain the reduction in the Young's moduli of the nanocomposites with multi-layer graphene.

Table 3. Load transfer efficiency of nanocomposites

	Pristine graphene			Functionalized graphene		
	1 layer	2 layer	4 layer	1 layer	2 layer	4 layer
Average Lutsko stress(GPa)	0.796	0.380	0.331	1.413	0.822	0.648
Load transfer efficiency	5.65	3.92	3.64	8.94	6.63	5.68

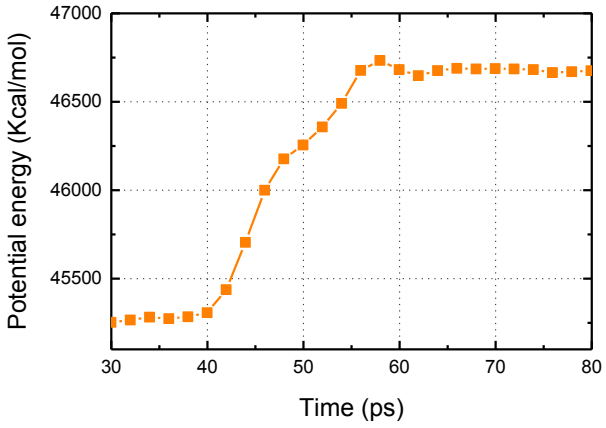

Figure 4. Energy variations during graphene pull-out simulation

Figure 4 shows the variation of potential energy during the pull-out process. Subtracting the potential energy U_1 before 40 ps from the potential energy U_2 after 60 ps yielded the graphene pull-out energy, and the corresponding interfacial shear stress is listed in Table 4. The results indicate that the interfacial shear stress between graphene and epoxy resin decreases with an increase in the number of graphene layers. For single-layer graphene, the interfacial shear stress is 46.4 MPa, whereas for four-layer graphene, it decreases to 39.2 MPa. This further demonstrated that adding single-layer graphene to epoxy resin can result in better mechanical properties as compared to multi-layer graphene.

Table 4. Interfacial shear stress in graphene nanocomposites

Layer number	Pullout energy (Kcal/mol)	Interfacial shear stress (MPa)
1	1397	46.4
2	1234	40.9
4	1182	39.2

4. Conclusions

The mechanical properties of graphene nanocomposites were examined using MD simulation. The moduli of the nanocomposites were calculated and the load transfer efficiency between the graphene and the surrounding matrix was evaluated. Moreover, the pullout simulations were also carried out to characterize the interfacial behavior of the graphene and the epoxy matrix. Results illustrated that the increase in the number of graphene layers reduced the Young's moduli of the nanocomposite, which was mainly due to the low load transfer efficiency of the graphene inner layer. The pullout simulation revealed that the interfacial shear stress of the multilayer graphene was lower than that of the monolayer graphene. In addition, graphene surface functionalization can effectively improve the load transfer efficiency between graphene and epoxy matrix, thereby improving the Young's moduli of the nanocomposites, wherein the enhancement of the outermost layer is more significant than the inner layer. In addition, the phenomenon that wavy graphene would dramatically reduce the Young's modulus of the graphene nanocomposite was observed in our simulation.

Abstract
Ceramic materials, known for their strength, often lack the flexibility and energy absorption required for diverse applications. This study dives into the static and cyclic flexural properties, including energy absorption, stiffness, and strength, of bioinspired ceramic-polymer composites. Specifically, we explore how different micro-patterns influence these properties. Utilizing ultra-short pulsed picosecond lasers in a subtractive manufacturing process, we engrave an array of micro-patterns onto alumina tiles, mimicking the designs found in natural armors. These laser-engraved tiles are then layered with an interlayer of Surlyn®, a commercial monomer, to create the composites. Our findings highlight the intricate relationship between the composites' performance and the bioinspired surface patterns. Certain macro architectures result in significant improvements in energy absorption, with enhancements of up to 85%. These improvements are attributed to mechanisms such as crack deflection, interfacial friction, and plastic deformation of the soft phase. This research not only advances our understanding of natural armor structures but also lays the groundwork for a new era of ceramic composites with superior properties.

1. Introduction

Ceramics are vital materials across various industries, prized for their exceptional thermo-mechanical properties, hardness, durability, and low electrical conductivity. However, their inherent brittleness presents a significant challenge, limiting their damage tolerance. Despite efforts to enhance impact resistance and toughness through strategies like nano-material dispersion and microstructure control, significant improvements have been elusive [1-5].

In materials like nacre, significant energy dissipation occurs due to inelastic deformations around cracks, a primary toughening mechanism. Complex interfaces in natural materials lead to outstanding combinations of stiffness, strength, and toughness. For instance, the heterogeneous architecture of beetle cuticles initiates localized toughening mechanisms, enhancing mechanical performance while reducing weight [6-10].

Recent efforts have integrated bioinspired architectures with ceramics to achieve optimized stiffness, strength, and toughness balances. However, unlocking the full potential of bioinspired materials requires scalable manufacturing technologies capable of producing complex structures [11-15]. To address this, we've developed a digital manufacturing platform enabling precise control over 3D architecture, including micro-pattern cut depth. This platform fabricates multilayered ceramic composites with bioinspired hard building blocks and soft interlayers. Through experimental investigation, we compare the static and cyclic mechanical performance of these ceramics with and

without patterns. This innovative approach yields a new class of ceramics offering predictable, high-performance responses, essential for advanced composite development [16-18].

2. Materials and Methods

2.1. Material Fabrication

High-tolerance nonporous alumina ceramic tiles (96-99.8% Al_2O_3, 3875 kg/m^3 density, McMaster-Carr, No. 8462 K45) with a thickness of 635 µm serve as the rigid component. A 100 µm thick Surlyn® thermoplastic film acts as the soft polymer interface between the ceramic tiles. Four beams are created by circular diamond saw-cutting the ceramic tiles, each measuring 25 mm wide and 114 mm long. Laser machining is performed on the tiles before lamination, using established parameters for alumina laser machining. An Ytterbium picosecond fiber laser (YLPP-25-3-50-R, IPG Photonics, USA) with 50 W maximum average power, emitting 3 ps pulses at 1030 nm wavelength, is used. The laser can operate at up to 1.83 MHz repetition rate and generates a Gaussian beam profile.

A 45° oriented micro-pattern (Figure 1a) and a hexagonal pattern penetrating the entire ceramic thickness with 5 mm length (Figure 1b) are applied. The micro-patterns, designed for precise surface engraving, achieve a depth of 20 µm in a single pass with a 200 µm kerf width matching the spacing between patterns. Each beam consists of two ceramic tile layers with the same engraved hexagonal pattern and an intermediate Surlyn® layer. One group of beams includes micro-patterns, while the others do not. Components are assembled using vacuum bagging and subjected to a 5-hour heat treatment at 146 °C for proper bonding and desired properties.

2.2. Experimental Setup

All specimens undergo 3-point bending tests with an 80 mm fixed span length (Figure 1e). In static tests, a constant displacement control at 1.3 mm/min rate is applied until 12 mm deflection. For cyclic tests, a combined control strategy is used. Loading phase maintains a 6 mm/min rate for 1 mm/cycle over 12 cycles. The control mode transitions to load control during unloading to capture specimen behavior under cyclic loading, providing a comprehensive assessment of material response in static and cyclic conditions.

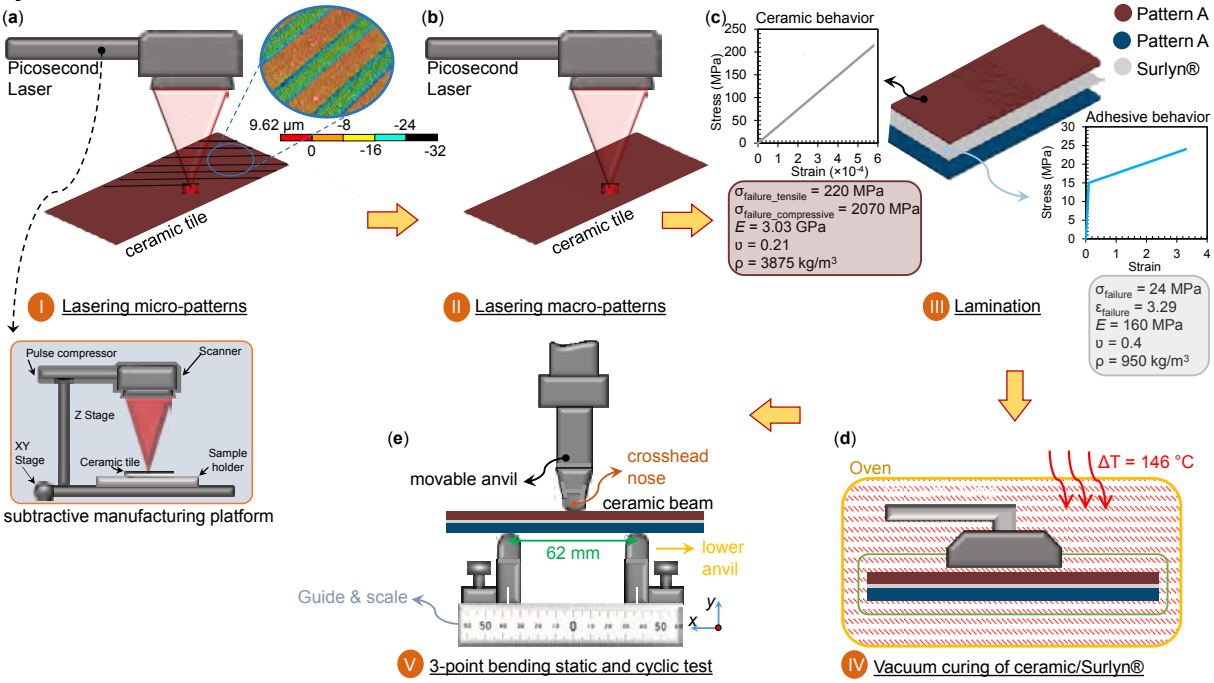

Figure 1. The manufacturing process of the bi-layer architectured ceramic beams: (**a**) Micro-patterning of ceramic tiles using the picosecond laser and subtractive manufacturing platform, (**b**) Macro-patterning of ceramic tiles using the picosecond laser, (**c**) Lamination of ceramic tiles and

commercial monomer Surlyn, (**d**) Vacuum bagging and curing of ceramic composite beams, and (**e**) Configuration for static and cyclic 3-point bending tests.

3. Results and Discussion

The architectured ceramic beams were subjected to 3-point bending static load testing to evaluate the impact of stacking sequences (Back-to-back (BB), Side-down (SD), Side-up (SU), and Face-to-face (FF)), along with micro-patterns, on their mechanical performance. The main parameters assessed included maximum load, flexural stiffness, and energy absorption. The energy absorbed by the structures in the static analysis was determined by the area under the force-displacement curves, while the cyclic analysis was represented by the loop area.

3.1. Static Loading

Figure 2 shows how micro-patterns significantly enhance the ceramics' mechanical properties under static load. Micro-patterns improve energy absorption, with Ceramic FF increasing by up to 140%. Maximum load is also boosted, with Ceramics SD and FF increasing by up to 140% and 130%, respectively. Flexural stiffness sees notable improvements, particularly in Ceramics FF (up to 300%) and SD (up to 80%).
Enhancements stem from:

1. Enhanced interfacial bonding: Micro-patterns strengthen bonding between ceramic units, improving cohesion and robustness.
2. Optimized stress distribution: Specific micro-patterns disperse stresses more evenly, reducing localized failure risk and improving overall strength and stiffness.

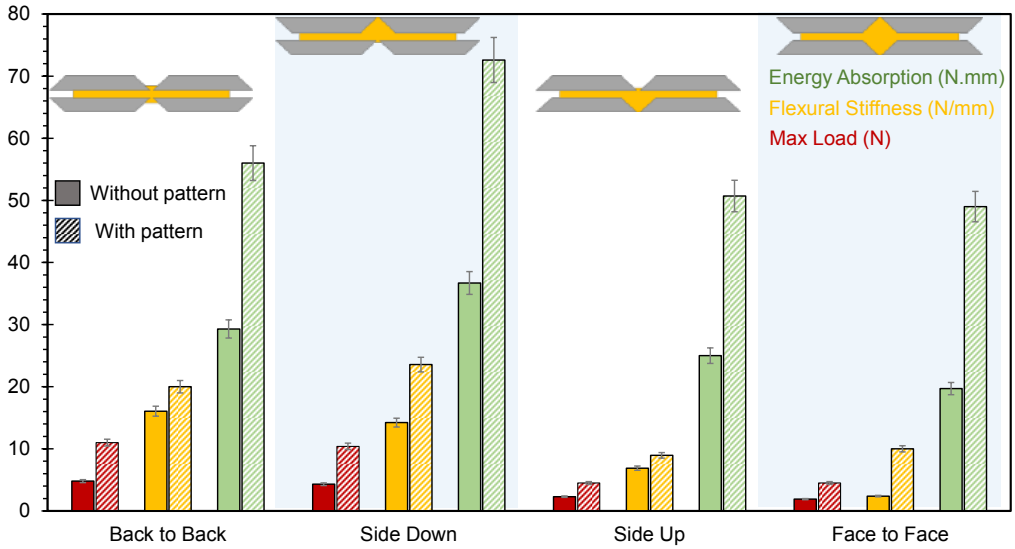

Figure 2. Static 3-point bending mechanical performance of the architectured ceramic beams with different stacking sequences (Back-to-back (BB), Side-down (SD), Side-up (SU), and Face-to-face (FF)) and micro-patterns: Maximum load, flexural stiffness, and energy absorption of the ceramics under static load with and without micro-patterns.

3.2. Cyclic Loading

Figure 3 illustrates the hysteresis force-deflection curves of architectured ceramic beams with varying stacking sequences (BB, SD, SU, and FF) and micro-patterns. Introducing micro-patterns on ceramic surfaces generally enhances the cyclic mechanical performance of the multilayered ceramic beams, improving both energy absorption and stiffness. However, the extent of this enhancement varies among the different stacking sequences. Notably, micro-patterns had a significant impact on Ceramics FF and SU, where Surlyn primarily influences the mechanical characteristics (controlled by shear force), emphasizing their role in these enhancements. For instance, the total cyclic energy absorption for

Ceramic FF increased by up to 85%, whereas for Ceramic BB, this improvement was only 14%, as shown in Figure 3. Several factors contribute to the varying improvements in cyclic mechanical performance with the introduction of micro-patterns:

Interfacial bonding enhancement: Micro-patterns promote better bonding between ceramic units and the Surlyn matrix, improving load transfer and energy dissipation. This bonding is particularly beneficial for Ceramic FF, enhancing adhesion and interaction between layers.

Crack deflection and propagation: Certain micro-patterns, like grooves or ridges, act as crack arrestors, deflecting cracks and preventing propagation. Ceramic FF may benefit more from crack deflection mechanisms due to its configurations.

Stress redistribution: Micro-patterns redistribute stress concentrations, preventing localized high-stress areas that could lead to failure. Ceramics FF, SU, and SD with intricate micro-patterns may show more significant improvements in stress redistribution compared to Ceramic BB.

Energy dissipation pathways: Micro-patterns create additional pathways for energy dissipation, allowing the material to absorb more energy before failure. Unique patterns on Ceramic FF offer effective pathways for energy dissipation.

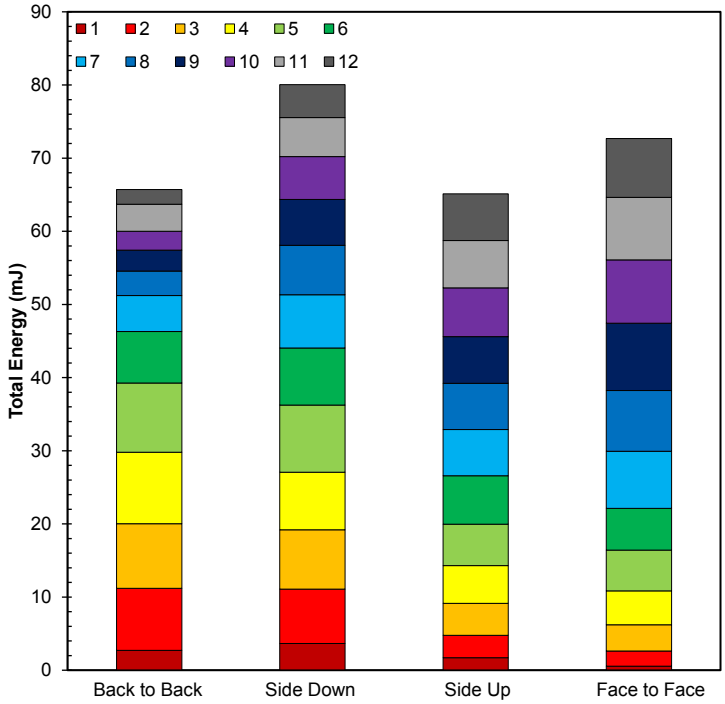

Figure 3. Cyclic 3-point bending mechanical performance of the architectured ceramic beams with different stacking sequences (BB, SD, SU, and FF) with micro-patterns: Total energy absorption as well as energy absorption, flexural stiffness, and plastic deformation of each cycle.

After cyclic 3-point bending tests, each ceramic system exhibited plastic deformation, evident in the increase in residual deflection with each cycle. Up to the third cycle, all ceramic groups, micro-patterned or not, showed similar levels of plastic deformation. Beyond this point, Ceramics BB and SD underwent significantly greater plastic deformation, indicating enhanced energy dissipation mechanisms and damage accumulation. Conversely, Ceramics FF and SU displayed higher durability and resistance to plastic deformation but lower energy dissipation capabilities under cyclic bending. Micro-patterned specimens exhibited comparable plastic deformation levels but at higher load capacities, suggesting improved interfacial strength and stress distribution.

4. Conclusion

In this study, we investigated bioinspired ceramic-polymer composites' static and cyclic flexural properties using an advanced subtractive manufacturing platform. Alumina tiles were engraved with

micro patterns and stacked with Surlyn® interlayers to create the composites. Micro-patterns significantly improved properties, enhancing energy absorption, maximum load, and flexural stiffness. Ceramic FF showed up to 85% more cyclic energy absorption due to crack deflection, better bonding, stress distribution, and energy dissipation. Cyclic behavior insights showed FF's stability, SD and BB's higher energy dissipation potential, and BB's initial energy absorption loss. In summary, micro-patterns further improved properties, particularly in energy absorption and bonding. This study highlights tailoring ceramic properties for various applications by choosing stacking sequences and micro-patterns carefully.

Keywords: 3-Dimensional reinforcement; Damage tolerance; Weaving; I-sections; weave pattern

Abstract

The design of composite I-sections in aerostructures faces a significant challenge with conventional laminates because they are prone to delamination under out-of-plane loads. This study investigates the design, manufacture, and mechanical properties of 3D woven near-net-shaped composite I-sections to address this issue. The study also compares their advantages with equivalent laminates and examines the influence of weave patterns on their mechanical behavior. Specimens were manufactured using the vacuum-assisted resin transfer molding technique, and quasi-static tensile, compressive, and bending tests were conducted to assess the properties of I-sections with three different weave patterns. It finds that the ultimate strength and damage tolerance of the 3D woven I-sections is superior to that of the laminated counterparts, and different weave patterns play a significant effect in damage mode and load-bearing capacity. In addition, using 3D woven preforms to manufacture composite I-sections also exhibits shortened production time in terms of layup and resin infusion.

1. Introduction

Delamination is common in traditional laminated composites when subjected to out-of-plane loads due to weak interlaminar properties. This poses significant challenges in designing and manufacturing aerostructures like clips, airframe joints, or aeroengine vanes, prone to catastrophic failures under operational loads [1]. 3D woven composites provide better structural integrity and higher strength due to interlaced yarns [2].

3D woven composites are gaining popularity in the aerospace industry due to their superior mechanical properties, cost-effectiveness, and high production efficiency. They are ideal for structural components such as fan blades and casings in aeroengines and have potential for other structures. Various composite manufacturing techniques, including z-pinning [3], braiding [4, 5], and weaving [2], have been employed to improve the load-bearing capacity of structures typically dominated by interlaminar strength. Different methods for composite manufacturing have their limitations. For example, z-pinning is effective against mode I crack only. Braiding can reduce structural stiffness due to fiber waviness. 3D woven composites, however, offer advantages in near-net-shaped manufacturing and mechanical properties, especially with 3D angle-interlock and orthogonal weaving techniques.

The design of bifurcated preforms using 3D weaving is categorized into on-loom [6] and off-loom [7] methods. On-loom methods weave preforms directly without the need for unfolding but have size and thickness limitations. Off-loom methods involve unfolding flat-woven fabrics to form near-net-shaped structures, with ongoing research to improve mechanical properties through fabric pattern design. Recent advancements [8-10] in off-loom design methodologies, particularly through 3D angle interlock and orthogonal weaving, have significantly improved the in-plane mechanical properties by increasing the fraction of straight fibers. Research [10, 11] has shown that 3D woven bifurcated structures, such as T-joints and I-sections, exhibit improved structural performance, including better damage tolerance and ultimate strength than traditional laminated counterparts.

To further promote the application of 3D woven composites, extensive research has been conducted on evaluating their mechanical properties, focusing on the effects of weave pattern design. Innovations in yarn orientation and weave patterns at the junctions of these structures have led to notable enhancements in strength and failure resistance, crucial for preventing crack initiation and propagation under operational loads.

2. Materials, manufacture, and experiment setup

The I-section composites in this study were formed using near-net-shaped preforms, which were woven with three distinct regions using a Jacquard loom. The preforms were bifurcated during the forming process (**Figure 1** left)to create flanges and a web. The key to designing this structure is in the appropriate bifurcation design, which is achieved by reinforcing the bifurcated region with separate non-through-thickness binders. The composites were fabricated using the VaRTM process.

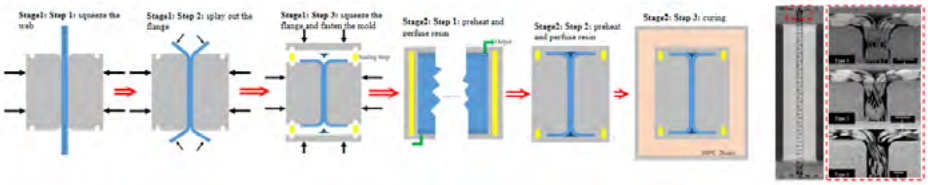

Figure 1. Schematic representation of the I-section manufacturing process.

This study explores the mechanical properties of different bifurcation techniques by manipulating the arrangement of weft yarns in the bifurcation region. Three distinct weft yarn paths were incorporated to create crossed or entangled weft structures, resulting in different mechanical properties (Figure 1 right). Types 1, 2, and 3 represent unchanged weft yarn order, crossed weft yarns, and entangled pattern weft yarns respectively. The areal density of three types of 3D woven preforms are 3474 g/m^2, 3481 g/m^2, and 3394 g/m^2. Ten layers of 400 g/m^2 plain-woven fabrics made of T700 spread tows were used as a control group for specimen manufacturing, due to availability in the lab.

We studied the mechanical behavior of 3DWOC near-net-shaped I-sections under three loading conditions: tension, compression, and bending. Tension and compression tests simplified the out-of-plane loads experienced by the I-sections, while the bending test approximated the anticipated distributed aerodynamic force on the web. We used a 10kN universal testing machine with a uniform loading rate of 1mm/min. Three specimens were tested for Type 1, Type 2, Type 3, and Type L at a constant room temperature and relative humidity until the specimen fractured.

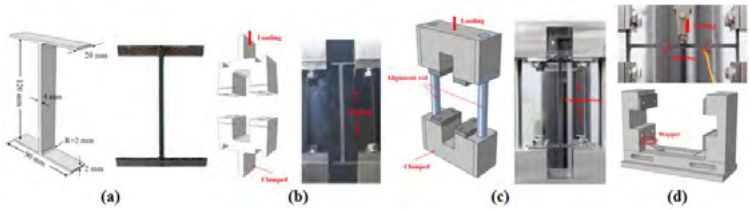

Figure 2. Testing layout for composite I-sections; (a) Specimen dimensions; (b) Tensile test layout; (c) Compressive test layout; (d) Bending test layout.

3. Results and discussion

3.1. Load-displacement responses

Representative load-displacement responses for the four types of I-sections under tension, compression, and bending are plotted in **Figure 3** The mean value derived from three sets of valid data of the initial stiffness, damage onset load, and ultimate failure load are compared in **Table 1**, where the initial damage load is defined as the first significant load drop and the ultimate failure load is defined as the maximum load. Good consistency in load-displacement responses under all three loading conditions was observed for the four types of specimens

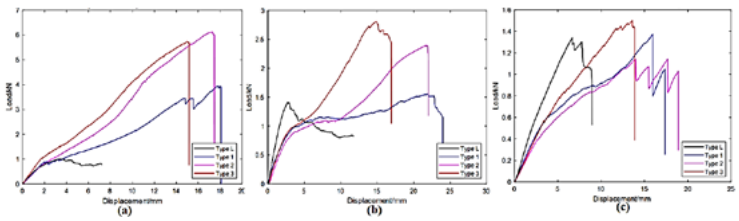

Figure 3. Load-displacement responses for each test; (a) Tension; (b) Compression; (c) Bending.

Table 1. Stiffness, initial, and ultimate failure loads (averaged) of the four types of specimens.

Test	Type	Initial Stiffness (N/mm)	Initial damage load (N)	Ultimate failure load (N)
Tension	1/2/3/**L**	460/478/629/**500**	836/778/911/**412**	3481/6481/5392/**1027**
Compression		411/338/415/**665**	414/557/745/**1255**	1345/2166/2724/**1441**
Bending		184/151/148/**242**	423/375/451/**525**	1255/1297/1471/**1302**

The 3D woven specimens have enhanced damage tolerance and increased load improvement potential after initial damage. Compared to laminates, 3D woven composite I-sections have much higher loading-bearing capacity. During the compressive test, the Type L specimen experienced a notable drop in compressive load after ultimate failure followed by persistent load fluctuations throughout the stage. Type 2 and Type 3 specimens saw their compressive loads increase during the damage-evolving stage. Under bending loads, the Type L specimen has a higher initial stiffness of 242N/mm and a smooth curve. The 3D woven specimens have lower initial stiffness but can withstand different ultimate loads. Type 3 shows the best ultimate strength with a 13% increase.

3.2. Characterization of failure modes

Neat matrix cracking, yarn transverse cracking, delamination, and yarn rupture are the primary failure modes of the four types of specimens. The nomenclature utilized to denote these failure modes are outlined in **Table 2**. The failure mode of laminated I-section Type L in tensile test is delamination. The delamination starts from the noodle and extends to the web and flange until the test parts fail. The primary difference in the fiber architecture between Type 1 and Type L is the presence of binder yarns. The binder yarns in the 3D orthogonal woven specimens enhance the preform integrity, resulting in a higher ultimate strength than the Type L specimens.

Table 2. Nomenclature of failure modes in the test.

Damage type	Neat matrix crack	Yarn transverse crack	Delamination	Yarn ruptures
Code	C	Cy	D	R

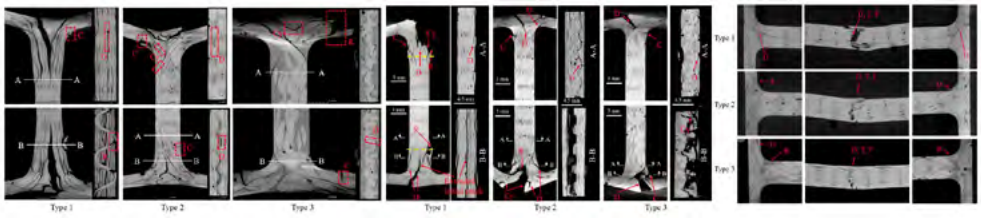

Figure 4. The images from μCT scan of fractured tension (left), compression (middle), and bending (right) specimens

The failure mode of 3D woven I-section Type 2 under tension has limited delamination propagation due to the crossing structure of the weft yarns in the noodle. Type 2 only showed transverse cracking in the flange. Similarly, Type 3 exhibited matrix cracking and delamination in the junction, but tightly entangled weft yarns limited the delamination propagation and improved the ultimate strength of the I-section. The 3D woven specimens with through-thickness yarns and featured weft yarn paths improved the structures' ultimate strength and damage tolerance under tension. Type 1 and Type 2/3 with binder and crossed-weft yarns limited the crack propagation, with crossed-weft yarns being more effective. Type 2/3 maintained the webs' integrity, and the fracture of flanges led to ultimate failure rather than propagated cracks of Type 1/L.

The images from the μCT scans of the fractured compression specimen are shown in **Figure 4** (middle). Delamination occurs similarly in the three types of 3D woven specimens. In Type 1, severe delamination occurs along the weft yarn interfaces extending to the web's middle plane. Neat matrix cracks, transverse cracks, and yarn fractures occur around the top and bottom binders in the web. (marked with yellow dashed lines in **Figure 4**(middle-a)). Type 2 and Type 3 specimens both had minor delamination along weft yarns in section A-A. Crossed weft yarns in section B-B prevented initial cracks from propagating but caused resin-rich regions leading to neat matrix cracking. Overall, both types showed similar failure modes including neat matrix cracks, minor delamination, and yarn ruptures.

μCT results show that Type 3 noodle specimens with intricate cross structures have better load-bearing capacity and less damage area than other weft yarn architectures.

CT scan images of the three types of 3D woven specimens after bending tests are shown in **Figure 4** (right). The 3D woven specimens had damages in the noodles and middle of the web, with delamination along weft yarns, transverse cracks within warp yarns, and ruptures of the weft yarns. The three types of 3D woven specimens in the noodle showed different failure modes. Failures were observed in Type 1, while Type 2 and Type 3 showed matrix cracks and slight delamination in resin-rich areas. Noodle failures do not determine the ultimate failure of the structures. However, 3D woven I-sections may show enhanced ultimate strength due to delamination resistance in the junctions. All noodle failures occurred near the top flanges, which withstand the tensile stress caused by bending loads.

4. Conclusions

This study explored the use of 3D woven composite I-sections for aeronautical applications. Three types of I-sections with junction variations were tested for mechanical properties. Results showed that adding binder yarns and crossed weft yarns improved strength and damage tolerance under pull-off load. The test results show that the ultimate strength of the three tests has been enhanced by 531%, 89%, and 13% respectively using different designs, compared with 2D counterparts. Crossing weft yarns is more effective in maintaining the integrity of webs, limiting crack propagation, and improving load-bearing capacity. This means manipulating yarn paths can help tailor the mechanical properties of I-section composites. Moreover, the 3D woven specimens exhibited superior damage tolerance and ultimate strength compared to the laminated specimens, as well as a fast production cycle. This highlights the potential of 3D weaving technology in the development of high-performance composite structures.

Keywords: Repair 1, delamination 2, thermoplastic 3, fracture 4, Elium 5

Abstract
In this study, pre-cracked carbon fiber-reinforced composite laminates based on an infusible thermoplastic resin (Elium®) were manufactured via the vacuum-assisted resin transfer molding process. These pre-cracks were subsequently repaired using a hot press by heating the laminates above the glass transition temperature of the cured liquid thermoplastic resin. The Mode I interlaminar fracture toughness (G_{Ic}) was investigated by conducting a series of double cantilever beam (DCB) tests and the precise contribution of each processing parameter towards the measured fracture toughness was determined using an analysis of variance (ANOVA) approach. The bonding mechanisms were investigated through microscopic analyses and X-ray Computed Tomography (XCT) and the mechanical performance of the repaired composites was also investigated through four-point bending tests.

1. Introduction

Thermoplastic-matrix composites have, at times, attracted significant interest from the aerospace industry for use in load-bearing aircraft parts. Thermoplastic-matrix composites are typically associated with a high impact resistance, superior solvent resistance, the possibility to recycle, and relatively good formability characteristics. Limitations to the greater use of these materials in aircraft composites are linked to the high melting temperature of the polymeric matrix and its elevated melt viscosity. For example, poly-ether-ether-ketone, a semi-crystalline thermoplastic that has attracted significant attention over the years has a processing temperature of between 380 and 400°C, excluding it from many traditional manufacturing processes [1,2]. Producing large, potentially complex structures using this material is, therefore, challenging. Attempts to overcome these challenges have resulted in the recent development of liquid resin systems, such as Elium® from Arkema, with a very low melt viscosity, rendering it compatible with out-of-autoclave techniques such as RTM/VARTM as well as the possibility of being cured at room temperature [3-5]. A number have studies have recently highlighted the ease of manufacturing of Elium-based composites as well as their resulting mechanical properties. Thermoplastic-matrix composites also offer the benefit of ease of repair since the polymer can be softened at elevated temperatures, leading to molecular interdiffusion across the crack or delamination. It is well–established that strong molecular bonds can be formed via an interdiffusion mechanism with the associated movement and entanglement of chains across the interface precipitating crack-healing and toughness restoration [6,7]. Research has shown that polymer molecules diffuse across the crack

boundary via a mechanism termed reputation that was first proposed by de Gennes [6] and later investigated by Doi and Edwards [7].

Currently, there is very little information on the interdiffusion and crack-healing mechanisms that take place in Elium®-based composites at elevated temperatures. Having such information available would enable engineers to potentially repair damaged composites, such as wind turbine blades that have been impacted during operational service.

In this study, the possibility of repairing carbon fiber reinforced polymer (CFRP)/Elium® laminates containing delamination is investigated. Here, cracked laminates are repaired under different pressures and temperatures for different time periods and the resulting toughness of the interface is measured by conducting Mode I double cantilever beam (DCB) tests at quasi-static rates of loading.

2. Experimental Procedure

The reinforcement material used in this investigation was based on a 2x2 twill weave carbon fibre fabric with an areal density of from Gurit Ltd. The fabrics were infused with a low viscosity thermoplastic polymer (Elium 1880 from Arkema, China) and an benzoyl per oxide initator was used to trigger the polymerization process. Further details regarding these constituent materials are given elsewhere [8].
Pre-cracked laminates, suitable for double cantilever beam (DCB) testing, were manufactured using the vacuum assisted resin transfer molding technique, Figure 1. Here, twelve layers of the carbon fabric were stacked in preparation for resin infusion. A nylon film was placed at the interface between the 6th and 7th plies in order to create a pre-crack for subsequent testing, Figure 1. The polymer film covered approximately 75% of the total length of the plate, thereby allowing sufficient area for subsequent repair. Resin infusion was undertaken at 23°C, then allowed to cure for 24 hours and finally post-cured at 60°C for 24 hours. Double cantilever beam test specimens with length and width dimensions of 250 × 20 mm respectively were removed from the plates using a diamond slitting wheel. Futher details of the manufacturing process are given elsewhere [8].

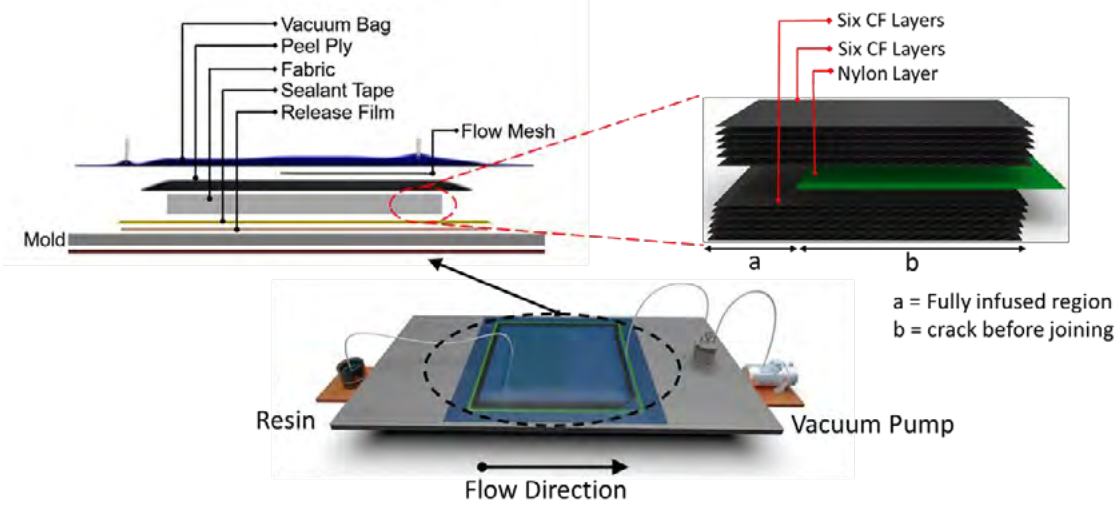

Figure 1. Schematic of the VARTM process and the position of the artificial defect [8].

The test samples containing very long artificial pre-cracks were healed in a Meyer hot press for different periods of time and at different temperatures and pressures. Here, an 80 mm long aluminum foil was inserted at the mid-plan to act as a pre-crack, leaving sufficient area for subsequent repair. The specimens were subsequently healed at temperatures of 150, 180, and 210°C for periods of 30, 60, and 90 minutes at pressures of 4.7, 7.0, and 9.3 bar. After the healing process was completed, the press was opened and the specimen was left to cool.

Mode I DCB testing was conducted according to the ASTM D5528-13 standard. The tests were conducted on an Intron-5969 universal testing at a crosshead displacement rate of 5mm/minute. The load (P) and resulting crosshead displacement (δ) were recorded during each test. The Mode I interlaminar fracture toughness (G_{Ic}) was determined using the following equation:

$$G_{Ic} = \frac{3P\delta}{2b(a+|\Delta|)} \quad (1)$$

Where b is the specimen width, a is the crack length and Δ represents a correction factor to account for the fact that the beam halves do not act as if they are fully built-in at the crack tip [9]. The experimental results were also corrected for large displacements.

3. Results and Discussion

Inspection of the DCB samples after being subjected to a healing process indicated that in all cases, the application of pressure and temperature for different periods of time resulted in the formation of a bond between the upper and lower portions of the test sample. This bond was primarily created due to the flow of the polymer resin across the interface at higher temperature. Figure 2 shows the polymer melt flow across the interface in the repaired specimens. DCB tests were then conducted to measure the Mode I interlaminar fracture toughness and edge views of several samples are presented in Figure 3.

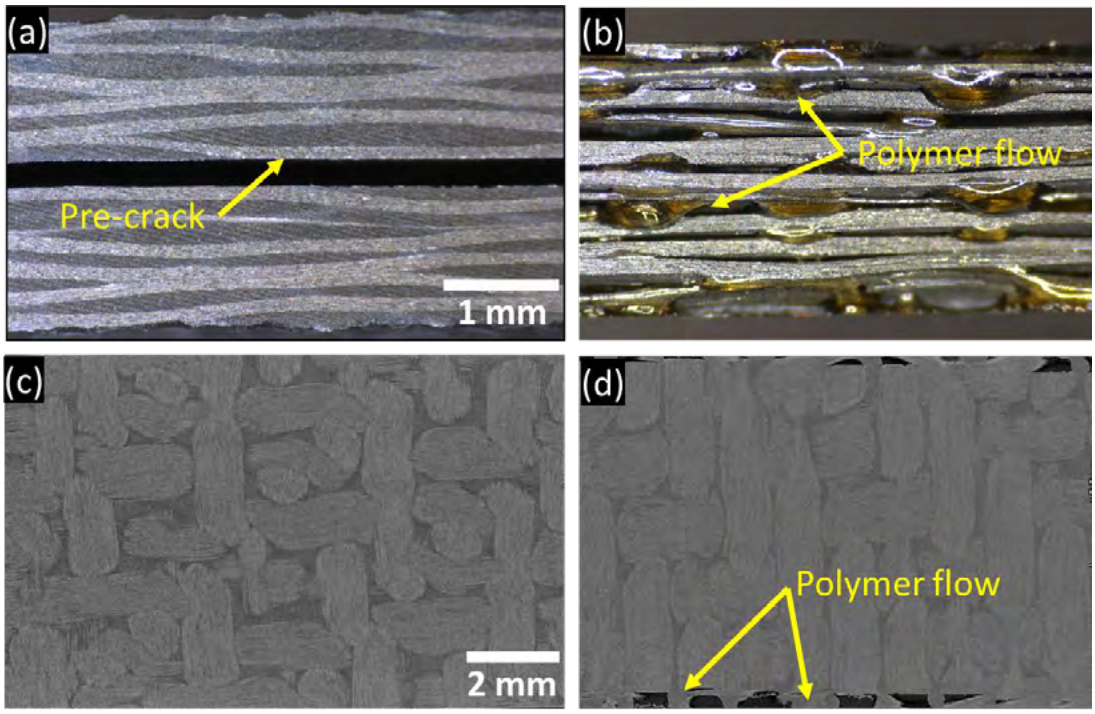

Figure 2. (a) Cross-sectional optical micrograph a pre-cracked specimen, (b) Cross-sectional optical micrograph of the specimen repaired at 210C for 90 min., (c) Raw XCT image of the reference specimen (top view), and (d) Raw XCT image of the specimen repaired at 210C for 90 min.

Figure 3 clearly highlights an increase in fiber bridging as the healing temperature is increased. The presence of fiber bridging is known to increase the stability of the crack and also increase the measured fracture toughness. During delamination growth, fibers on the upper and lower sides of the interface are pulled out and the fracture surface is stabilized. This increases the resistance to failure, leading to an increase in the interlaminar fracture toughness. Many studies have reported fiber bridging to significantly improve the delamination resistance of composites [10,11].

Figures 3c and 3d show that these samples healed at 180°C and 210°C exhibited greater levels of fiber bridging relative to their S150 counterparts. The amount of fiber bridging was also observed to increase with time for a given healing temperature.

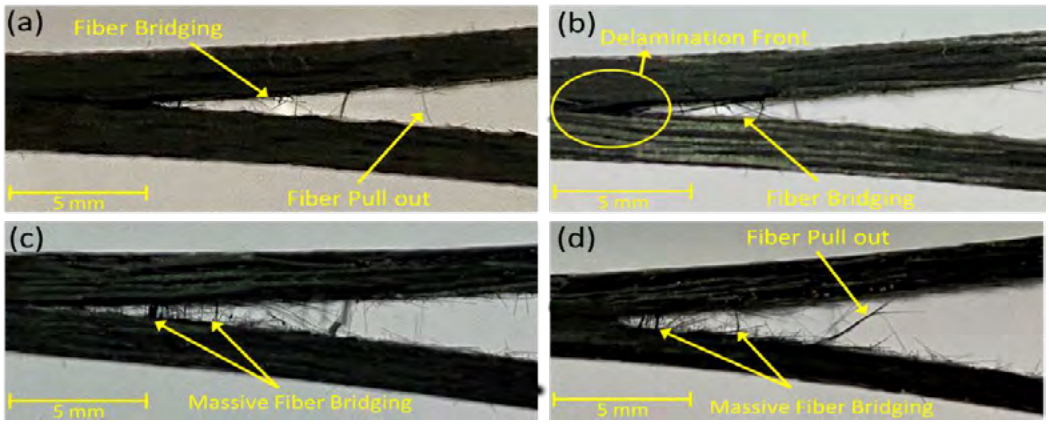

Figure 3. Edge view of DCB specimens showing the crack front in the following samples (a) S_O (b) S150-90-4, (c) S180-90-2 and (d) S210-90-3.

Table 1 summarizes the resulting values of Mode I interlaminar fracture toughness, G_{Ic}. Included for comparison is the average value measured following tests on as-manufactured DCB samples, i.e. the baseline value. From the table, it is clear that The contribution of each of these processing parameters to the measured interlaminar fracture toughness was identified using an ANOVA analysis. The ANOVA analysis showed that temperature and time contributed 84 % and 12 %, respectively, whereas the applied pressure was shown to have only a small effect (Figure 4a). Additionally, the ANOVA interaction plots shown in Figure 4b revealed that the effect of temperature was independent of other parameters (i.e., time and pressure). In other words, the repair of the specimens could be optimized by changing the temperature while keeping other two parameters constant.

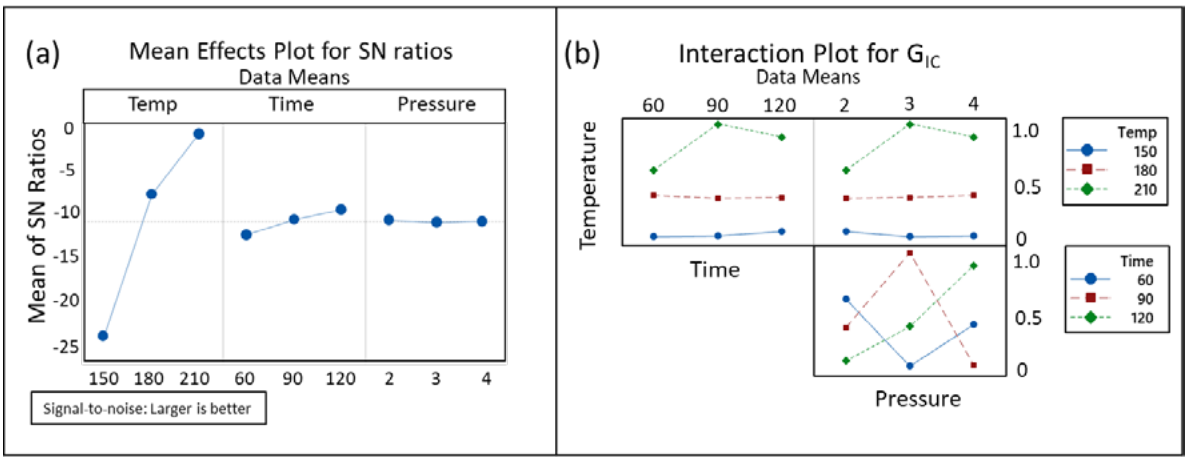

Figure 4. Main effects plot for G_{IC}, and (b) Interaction plot for G_{IC}.

Table 1. Average values of the different healing temperatures, times and pressures.

Specimen Code	Temperature (°C)	Time (min)	Pressure (Bar)	G_{Ic} (J/m^2)
S150-30-2	150	30	2	19
S150-60-3	150	60	3	60
S150-90-4	150	90	4	69
S180-30-3	180	30	3	67
S180-60-4	180	60	4	422
S180-90-3	180	90	3	406
S210-30-4	210	30	4	521
S210-60-2	210	60	2	625
S210-90-3	210	90	3	749
S_o	–	–	–	**1160**

As noted above the value of G_{Ic} exhibited a strong dependency on the contact time, t, increasing continuously as the sample was exposed to high-temperature healing. The effect of healing time was investigated more closely via a series of experiments conducted at 210°C involving healing times ranging from 10 to 120 minutes whilst being subjected to a constant pressure of 4 bar. The resulting variation of G_{Ic} with the square root of the healing time $t^{1/2}$ (in seconds) is shown in Figure 5 where a reasonably linear relationship between these two parameters is evident. This linear increase in G_{Ic} with $t^{1/2}$ aligns well with de Gennes's interdiffusion theory [6] and Wool's crack healing theory [7]. Based on these theories, the interlaminar fracture toughness is related to the healing time by the following relation:

$$G_{Ic} = G_{Ic}^{*} \, (t/\tau)^{1/2} \tag{2}$$

Where, G_{Ic}^{*} is the fracture toughness of the base material and τ is the reptation time.

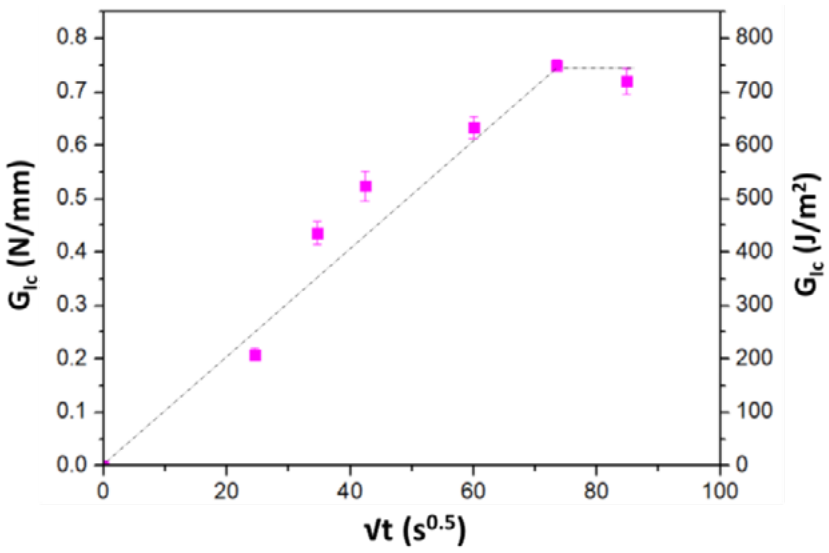

Figure 5. The plot of G_{Ic} vs. $\sqrt{t}$ ($s^{0.5}$) for specimens healed at 210°C at 4 bar.

This repair technique was also utilized to repair artificial cracks representing impact-induced delamination. The performance of the repaired laminates was investigated by subjecting them to four-point bending tests and an ANOVA analysis. The mechanical tests revealed that the samples repaired at the same optimum parameters exhibited the highest residual flexural strength (96%) of the pristine specimens [12]. A dominant delamination failure mode was observed in all the repaired specimens. As all the specimens were observed to fail in an opening mode at the crack tip during the flexural tests, their residual strength was compared to the G_{IC} values. Based on Figure 6, a linear increase in the residual strength was observed as the fracture toughness was increased. In addition, both the fracture toughness and the residual flexural strength were increased by increasing the repair time.

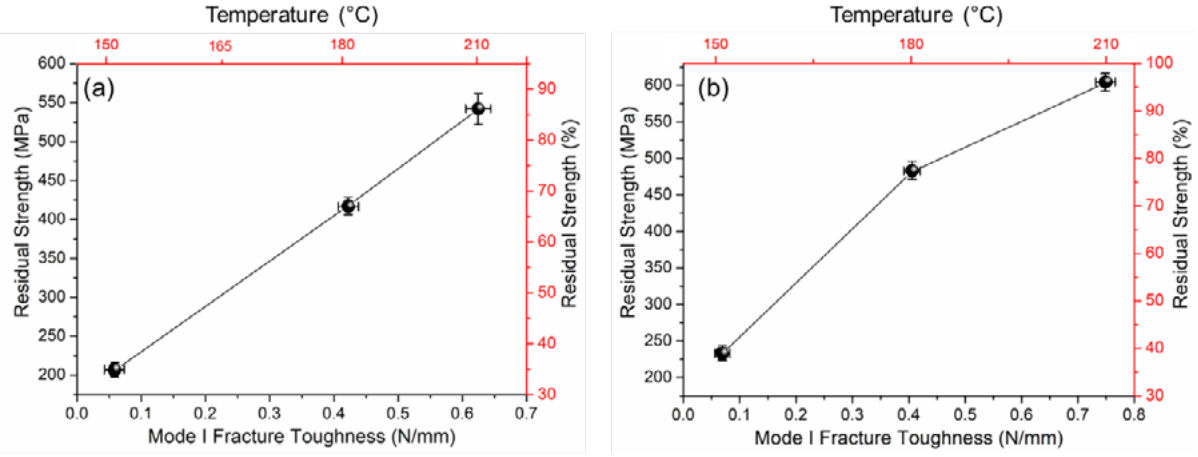

Figure 6. Residual strength as a function of the Mode I fracture toughness for specimens repaired for (a) 60 min and (b) 90 min [12].

3. Conclusions

This possibility of repairing delamination-type cracks in an infusible thermoplastic-matrix composite has been investigated experimentally through a series of DCB tests. Optical micrographs of test samples after healing showed that the level of healing was influenced by both temperature and time. In contrast, the level of applied pressure had very little effect on the quality of the interface. It is believed that the bonding mechanism responsible for removing the crack was associated with the interdiffusion of the polymeric molecules across the crack, as well as chain bridging and interface bonding. The Mode I fracture toughness of the healed DCB specimens was high at 750 J/m^2, corresponding to approximately 65% of the value of the standard reference specimens. An observation of the test sample during fracture highlighted the presence of significant fiber bridging, which failure mechanism that served to increase the interlaminar fracture toughness and stabilize the crack front. Finally, the measured interlaminar fracture toughness exhibited a linear relationship with the square root of the healing time ($t^{1/2}$), agreeing with the predictions of earlier interdiffusion crack healing theories.

Abstract

This study focuses on geometric optimization of short-fiber composite 3D printed Triply Periodic Minimal Surfaces (TPMS) structures. It evaluates their performance in compression, assesses their energy absorption capabilities, and examines the impact of geometric grading.
Owing to its material versatility and support for complex geometries, the fused filament fabrication (FFF) 3D printing technique is used to print a set of TPMS structures. This experimental study covers a series consisting of a strut-based canonical lattice structure in addition to skeletal and sheet gyroid TPMS structures, with attention to the influence of relative density grading and cell size grading.

1.Introduction

Additive manufacturing (AM), facilitating the production of geometrically challenging customized components from digital input, has seen intriguing developments, including the production of lattice structures [1]. The production of low-density, strong lattice cores opens the door to the implementation of such design in sandwich structures providing promising lightweight load-bearing units [2]. Demonstrating a uniform stress distribution throughout the material and enhanced energy absorption with minimal surface area, Triply Periodic Minimal Surfaces (TPMS) structures exhibit superior strength-to-weight ratios [3]. Grading, which is limited and less achievable in conventional lattices, holds promise in design and fabrication of functionally enhanced TPMS structures, featuring anisotropy and controlled deformation characteristics [3][4]. Studying compression and energy absorption characteristics of the core serves as a foundation preceding our broader investigation into hybrid sandwich structures.

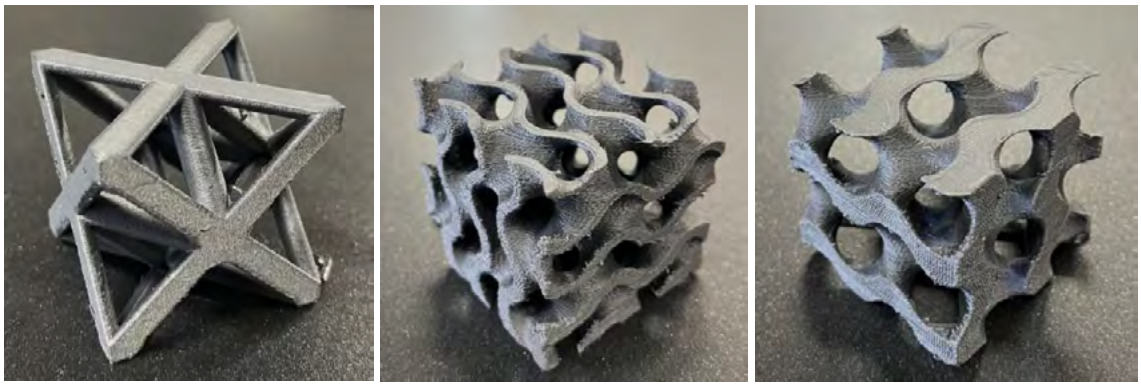
2. Methodology

2.1 Design

The designs chosen for this study include the strut-based lattice, in the form of an octet lattice structure, in addition to skeletal and sheet gyroid TPMS structures. The octet truss lattice is a complex three-dimensional lattice structure made of interconnected octahedral and tetrahedral units, where the repeating pattern ensures both structural stability and the ability to bear loads [2]. TPMS, which are mathematical surfaces with zero mean curvature at every point, are here studied in the form of skeletal and sheet structures. Skeletal gyroid TPMS structures are made up of interconnected struts or beams, resembling a skeletal framework. On the other hand, sheet gyroid TPMS structures have more continuous surfaces, creating a sheet-like geometry with minimal thickness.

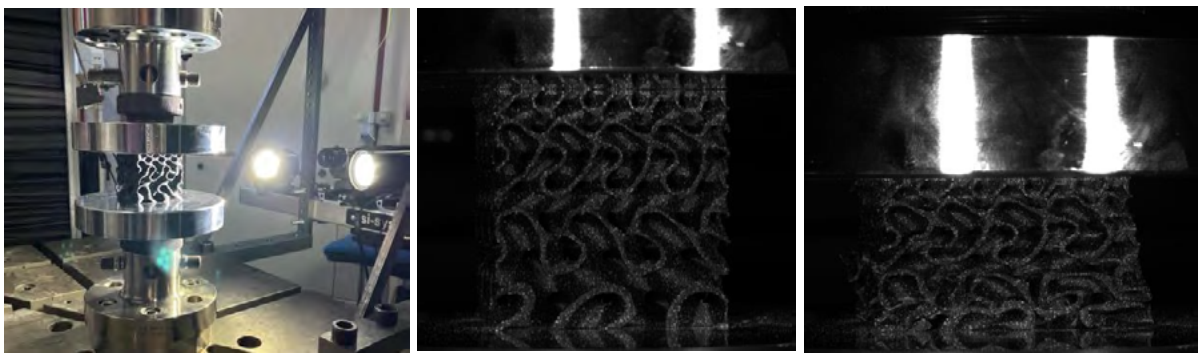


Following the design and the production of the preliminary prints, the structures undergo optimization in cell size, and specific weight, which is defined as the weight per unit volume of a substance. The gradation applied to these structures is along their vertical dimension with the printing direction. By introducing this variation in the strut size or thickness, the relative density of the structure can be tailored to achieve application-specific mechanical behaviors. Optimization of gyroid structures has shown a promising avenue for enhancing energy absorption capacity through gradation using both conventional fabrication and additive manufacturing [5][6]. In this study, the best performing structure between the three initial uniform designs undergoes gradation in cell size and specific weight. Two uniform TPMS structures are produced and studied in compression to find the stiffer structure, and as a result, this better performing geometry was graded. This helps understand the effect of gradation and the potential for improvement in terms of stiffness and energy absorption. Starting initially with uniform TPMS design as shown in figure 1-a, a new structure was created by employing gradation, with a specific weight ranging from 0.5 at one extreme to 0.2 at the other as shown in figure 1-b. In another specimen the gradation ratio used for relative density was also applied to the cell size, as shown in figure 1-c. The gradation implemented ensured that the total material volume remained consistent between the uniform and graded structures. The purpose was to optimize the distribution of material throughout the structure to enhance its performance.

(a) (b) (c)

Figure 1. Sheet gyroid TPMS design
(a) Uniform | (b) Relative density gradation | (c) Cell size gradation

The samples were created through fused filament fabrication using a Prusa i3 MK3S+. The layer height was set to 0.2 mm, ensuring precision in each layer, at a controlled printing speed of 40 mm/s. Following supplier's recommendation, the nozzle and print bed temperatures were set to 285°C and 100°C, respectively, to ensure proper filament flow and adhesion. The filament material used is polycarbonate with short carbon fiber reinforcement. All the samples are made up of an array of unit cells and have dimensions of 5x5x5 cm^3. Figures 2 depicts the 3D printed samples.



(a) (b) (c)

Figure 2. 3D printed samples analyzed in this article
(a) Octet | (b) Sheet gyroid TPMS | (c) Skeletal gyroid TPMS

2.1 Testing

The investigation of the compressive properties of the 3D-printed samples was carried out experimentally using an Instron 5885 electromechanical testing system. The compression tests were performed perpendicular to the build direction and according to the ASTM D695 standard [7]. The quasi-static compression tests were displacement controlled at a rate of 1 mm/min. A stereo digital image correlation (DIC) system was employed for the strain measurement with two 24 megapixels Basler cameras. Figure 3 shows the test set-up for the compression of a sheet TPMS with cell size gradation. White paint was sprayed evenly across the surface of the structures, forming a random pattern of contrasting specks, as seen on the specimens in figures 3-b and 3-c. The speckle serves as a reference to measure displacement during testing. A thorough comparison is established to compare strut-based lattices to TPMS structures, in terms of compressive strength and energy absorption with focus on the effect of grading.

(a) (b) (c)

Figure 3. Deformation monitoring in compression by DIC.
(a) Compression test and DIC set-up | (b) Test sample before loading | (c) Test sample after loading

3. Results

The data obtained from both the Instron electromechanical testing system and DIC were post-processed. The strut-based lattice is compared to the TPMS structures giving insights into both compressive strength and energy absorption capacities of these structures. The following results were normalized and rescaled using Eq (1) to facilitate comparison and analysis. The normalization is applied to each property studied, such as E modulus, SEA, or ultimate strength, across all tested specimens, with **x** representing the selected property value, $\mathbf{min}\ (\boldsymbol{x})$ indicates the minimum value of this property observed among all the tested specimens and $\mathbf{max}(\boldsymbol{x})$ comes from the highest value. $\boldsymbol{x'}$ is the normalised and rescaled value and it falls between 0 and 1. In terms of strain, the maximum value shown is 1, which in full scale refers to an upper limit of 20% strain in the structure.

$$\boldsymbol{x'} = \frac{\boldsymbol{x} - \mathbf{min}\ (\boldsymbol{x})}{\mathbf{max}(\boldsymbol{x}) - \mathbf{min}\ (\boldsymbol{x})} \tag{1}$$

Given its porous structure, the octet truss structure exhibited the lowest stiffness, compared to sheet and skeletal TPMS structures. The uniform sheet TPMS structure scoring 0.2 outperformed the skeletal structure scoring 0.08. This can be attributed to the improved load distribution and material efficiency in sheet structures. The continuous shell geometry in the sheet structure promotes a more uniform stress distribution, minimizing the likelihood of localized stresses and failure. Figure 4 shows that sheet TPMS structures tend to withstand higher stresses compared to the other two structures reflecting its promising strength as well. While TPMS structures show a ductile behavior, the octet trusses in this case can be classified as brittle according to Gibson and Ashby reproduced curves [8]. An octet structure consists of interconnected beams or struts that are prone to sudden failure following straight crack propagation, in contrast to tortuous propagation in TPMS structures. Plate-based structures have been proven to outperform truss lattices in terms of Young's modulus [1], and TPMS sheet structures are akin to plate lattices. As lateral expansion of the octet is not prohibited by the boundary conditions, stress concentrations around the hinges initiated shear failure.

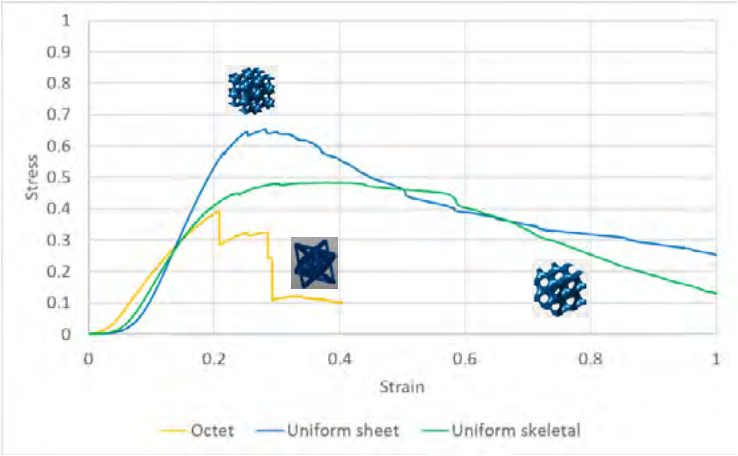


Figure 4. Normalized stress-strain curve of the uniform structures under quasi-static compression

Building on previous results where sheet TPMS structures showed superior performance, it was chosen to undergo gradation in relative density and cell size. Figure 5 depicts the normalized stress-strain curves for a uniform sheet TPMS structure, a TPMS that underwent relative density gradation (RD-sheet), and another with cell size gradation (CS-sheet). Referring to the same figure and to table 1, the TPMS structure with cell size gradation shows no improvement in stiffness, but rather a minor decrease. The change in the cell size throughout the height of the specimen may have altered the load distribution, where smaller cells deformed redistributing the loads to more voluminous cells below, which is shown in figure 3-c. On the other hand, gradation in relative density shows potential with a substantial increase in stiffness of around 400%, from a Young's modulus of 0.2 before gradation to around 1 post gradation. This is attributed to the material distribution gradient within the specimen. Strategically redistributing the material density can be useful in tailoring the load distribution and optimizing the load-bearing capacity.

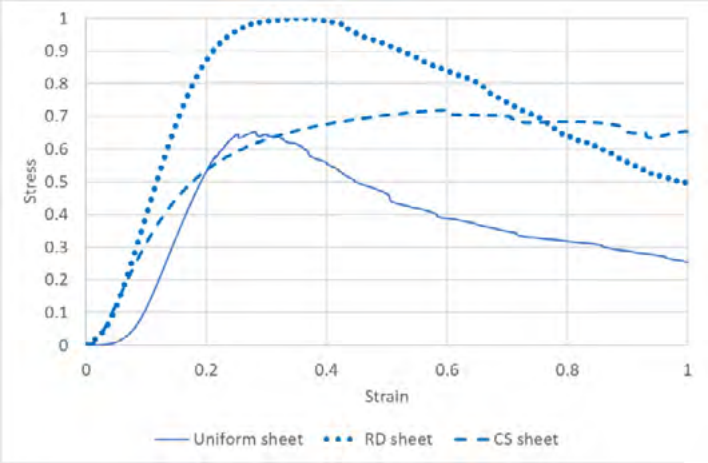

Figure 5. Normalized stress-strain curve of the sheet TPMS structures under quasi-static compression

For energy absorption calculations, it is a common practice in literature to transform load-displacement curves into engineering stress-strain curves. The energy absorption (EA) per unit volume is determined by the numerical integration of the stress-strain curve during compression, consisting of the area under the curve. Energy absorption capacity is highly influenced by localized densification [6][9].

Energy absorption: $$EA = \int \boldsymbol{\sigma}(\boldsymbol{\varepsilon})\boldsymbol{d\varepsilon} \quad (2)$$

where σ, the engineering stress, denotes the ratio of applied force $\boldsymbol{f}(x)$ to stressed area, and ε is the engineering strain which is the ratio of the displacement to the total height of the sample.

The Specific Energy Absorption (SEA) is defined as the work per unit mass when the material is quasi-statically compressed [9]. By examining table 1 and its visualization in figure 6, it is observed that gradation in sheet TPMS structures notably enhances the energy absorption with around 200% increase, which is consistent with literature findings on the effect of gradation [10]. By optimizing the material distribution within the structure, critical regions can be reinforced to withstand higher stresses, improving the overall structural robustness. The structures thus effectively absorb and dissipate energy, withstanding a larger stress envelope while undergoing deformation. However, this gradation effect is not as pronounced in skeletal TPMS structures, where the increase in energy absorption is relatively minimal. While sheet TPMS owe their superior performance to the continuous shell-like topology, skeletal TPMS structures are closer to strut-based structures featuring larger voids throughout its cells.

While gradation in cell size of sheet TPMS improved specific energy absorption substantially, there is no improvement in the mechanical properties. Load bearing capacity of larger cells and deformation in smaller cells balance each other, leading to a plastic behavior. As the smaller cells deform, the structure can sustain the loads for a longer duration, which delays the drop in stresses. Consequently, this results in a larger envelope under the stress-strain curve as shown in the stress-strain plot in figure 5.

Table 1 and figure 6 summarize the results of all tested structures, normalized and falling between 0 and 1, with 1 being for the highest scoring structure in each category. The results consist of the Young's modulus (**E**), the ultimate strength (**σ**) and the specific energy absorption (**SEA**).

Table 1. Mechanical properties and energy absorption capacity of tested structures – normalized (0-1)

Specimen	*E*	σ	SEA
Octet	0	0	0
Sheet TPMS	0.2	0.15	0.47
Skeletal TPMS	0.07	0.43	0.4
RD-sheet	**1**	**1**	**0.9**
RD-skeletal	0.09	0.71	0.49
CS-sheet	0.07	0.24	1

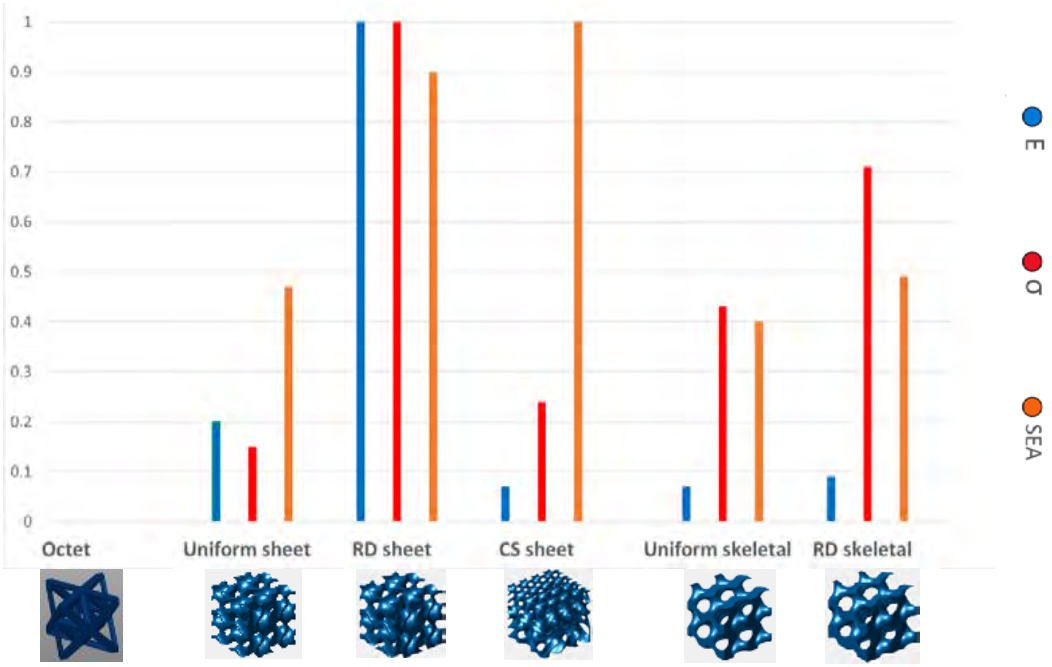

Figure 6. Overview of the mechanical performance and energy absorption of tested structures

4. Conclusion

The observed mechanical behavior in compression of the tested structures can be attributed to the intricate interplay between the lattice topology and material distribution employed in the design process. The octet truss structure exhibited the lowest stiffness displaying a brittle behavior, while the sheet TPMS structure showed superior performance due to improved load distribution and material efficiency.

Gradation in relative density notably enhanced the performance of sheet TPMS structures, particularly in stiffness and energy absorption. However, while gradation in cell size improved energy absorption thanks to the larger area under the stress-strain curve because of larger plastic deformations, it didn't lead to improvements in Young's modulus and ultimate strength in compression. Overall, these findings underscore the importance of material distribution and gradation strategies in optimizing the mechanical performance of lattice structures.

Exploring the potential of TPMS lattices with gradation could offer exciting avenues for tailoring mechanical properties to meet specific performance requirements. The influence of relative density gradation and morphological variations on the structural response to loading conditions can lead to diverse mechanical behaviors optimized for different applications. While our study demonstrates the influence of gradation on the mechanical properties and energy performance, future research could delve into targeted functional gradation to explore the versatility and tunability of TPMS-based lattice structures for various engineering applications.

Abstract
Bicycles must resist loads without failure or excessive deflection but also be lightweight. Constructing a bicycle frame from carbon fibre rather than metal allows design freedom to maximally benefit from the higher specific strength and stiffness of the composite material. However, determining the best composite lay-up is non-trivial. This paper presents a case-study computational optimization of a CFRP mountain bicycle frame. Multiple load cases were considered (impact, jumping, pedalling and cornering) with a combined weighted compliance value as the objective to minimise. Key constraints were a maximum frame mass and a factor of safety (FOS) greater than two for each load case. Laminate stresses were determined by finite element analysis with ply failure predicted by the Hoffman criterion. The analysis was validated by comparison with a published test to failure of a similar composite frame. An initial design had excessive strength under some load cases (FOS of up to 7) and deflections of up to 10 mm. After optimization, all FOS were within a range of 2 to 3.5 and deflections were less than 6 mm. Although load-case definition and weighting remain significant subjective manual tasks this case study demonstrates the benefit of computational optimization for a designer of a composite bicycle.

1. Introduction

Off-road cycling is a sport that is demanding of both athlete and equipment. Bicycles must endure a range of high-magnitude load scenarios without failure or excessive deflection but also be as light as possible. Constructing a bicycle frame from carbon fibre reinforced plastic (CFRP) allows much more design freedom than metal tube construction and an opportunity to take advantage of carbon fibre's high specific strength and stiffness. However, determining the best distribution of composite material is a non-trivial task. This paper presents a case study investigation into the use of computational optimization of the composite laminate lay-up for a frame of a full-suspension “mountain” bicycle (Figure 1). The aim is to maximise stiffness whilst achieving adequate strength and low weight.

2. Methods

2.1. Load cases

Although some standards do exist for bicycle design, e.g. [1,2], they do not define a full set of operating load cases that can be used to optimize the design of a high-performance off-road bicycle. Indeed, such loads, along with resulting composite lay-ups, may be industrial proprietary knowledge and thus unpublished. Consequently, the load cases used for this case study were partly determined from first principle analysis of the bicycle and cyclist system with reference to published data where available. In general it is intended that this bicycle design be suitable for up to ASTM “condition 4” cycling (i.e.

jumps under 1.22 m and speeds under 40 km/h) [1]. Four main scenarios were considered: frontal impact, jump landing, pedalling and cornering. Key assumptions included:

- A rider mass limit of m = 120 kg
- Factor of safety (FOS) > 2 for all load cases
- Fatigue life > 100,000 cycles for repeated load cases
- Maximum seat post extension of 400 mm, minimum insertion of 120 mm

A FOS of 2 was selected because carbon fibre composites fracture without yield and consequently a failure could be potentially catastrophic for the rider. Fatigue life was determined from the ASTM Standards for mountain bicycles [2] resulting in an allowable stress/strength value of 0.55 for quasi-isotropic laminates [3] to be applied to repeated load cases. The load cases are summarized in Table 1.

Figure 1. Full-suspension mountain bicycle.

2.1.1 Frontal impact

The frontal impact load case was based on a published test by Santa Cruz Bicycles [4] in which a CFRP full-suspension mountain bicycle frame failed at a force of approximately 9000 N applied between the front fork axle and the crank axle (bottom bracket).

2.1.2 Jump landing

The jump landing load case assumes a total drop height of 1.22 m with a constant landing force resisted by compression of the rider's legs through a distance of 0.24 m; this gives a total force of 5.1mg = 6000 N applied vertically to the crank axle. These values are in good agreement with measured jump landing forces [5] and also match Pole Bicycles' internal testing procedure [6].

2.1.3 Seated pedalling fatigue

This load case simulates the fatigue loading of a 120 kg rider pedalling while seated. The repeated force is taken as the complete weight, mg = 1200 N, of the rider acting on the seat. This force is in agreement with the ASTM standard for Condition 3 mountain bike use [2], as well as Pole Bicycles' test procedure [6]. The load is applied with 400 mm of seatpost extension for the given maximum assumption and 70 mm rearward according to the ASTM test specification [2], with the virtual seat post constrained 120 mm into the frame to give the minimum insertion depth. As this load is cyclic, the actual load to be applied is: 1200 N / 0.55 = 2200 N.

2.1.4 Maximal pedalling

This load case simulates the overloading of a 120 kg rider applying maximal torque during a race start. In previous work [7] the forces applied to the frame by cyclists in a racing standing start were calculated as 2.1*mg* at the left pedal and -0.5*mg* at the right pedal (or vice versa). As this maximal load is not expected to occur often fatigue amplification was not applied.

2.1.5 Cornering fatigue

This load case simulates the fatigue loading of high-speed cornering. A 10 m radius corner and speed of 10 m/s were assumed [8] giving a centripetal acceleration of approximately 1*g*. The corresponding horizontal centripetal force acts simultaneously with the vertical rider weight. To allow for the possibility of the rider's centre of mass not being aligned with the plane of the bicycle frame whilst cornering the centripetal and weight forces were treated as separate horizontal and vertical forces applied at the crank axle. Since this load case is repeated, the actual loads applied are each: mg / 0.55 = 1.8mg = 2200 N.

Table 1. Summary of load cases.

Load Case	Description	Parameters	Optimization weighting
1	Frontal impact	4500 N between fork and crank axles	0.1
2	Jump landing	6000 N vertically at crank axle	0.1
3	Seated pedalling fatigue	2200 N vertically on virtual saddle	0.1
4A & 4B	Maximal pedalling	2500 N vertically at left/right pedal -600 N vertically at right/left pedal	0.4
5A & 5B	Cornering fatigue	2200 N vertically at crank axle +/- 2200 N horizontally at crank axle	0.3

2.2. Frame loads

To determine the forces applied to the frame front triangle (Figure 2) during load cases 1-5, the bicycle-rider system and rear suspension mechanism were each analysed in static equilibrium. This firstly allowed ground reaction forces to be found; subsequently chain tension and suspension pivot contact forces were calculated.

2.3. Material properties

The material properties for the carbon fibre prepreg to be used in the frame were adapted from the Gurit SE 84LV datasheet [9] with reference to standard properties [10]. Two materials were used: 300 gsm HEC unidirectional and 200 gsm RC200T 3K weave HEC with assigned properties as listed in Table 2.

2.4. Initial frame design

A candidate bicycle frame geometry was defined using SolidWorks (Dassault Systèmes) software (Figures 1 & 2). To define an initial frame lay-up the thickness of carbon fibre laminate required for a FOS of 2 under load case 1 was determined by an approximate hand calculation. The load applied through the front fork axle and bottom bracket was assumed to be resisted only by bending in the circular cross-section of the 58 mm diameter down tube. For an approximately isotropic 0/90°, +/-45° lay-up of Gurit 200 gsm RC200T 3K twill weave HEC [9] this gave a required wall thickness of 2.9 mm. The initial laminate design adopted was therefore a quasi-isotropic carbon fibre lay-up of thickness 2.8 mm (12 0.23 mm plies of RC200T weave) in the main tubes and 5.5 mm (24 plies of RC200T weave) in reinforced areas around bearings (suspension, pedal cranks, steering) and the seatpost (Figure 2). The mass of this initial design was 1.1 kg.

Table 2. Material properties.

Property	Description	300 GSM HEC UNIDIRECTIONAL	200 GSM RC200T 3K WEAVE HEC
	Cured ply thickness (mm)	0.3	0.23
E1	Longitudinal Modulus (MPa)	130000	61000
E2	Lateral Modulus (MPa)	8300	61000
NU12	Poisson's Ratio	0.26	0.06
G12	In-plane Shear Modulus (MPa)	5600	5200
G1Z	Transverse Shear Modulus in 1Z Plane (MPa)	5600	4100
G2Z	Transverse Shear Modulus in 2Z Plane (MPa)	3000	3300
XT	Allowable longitudinal tensile stress (MPa)	2458	719
XC	Allowable longitudinal compressive stress (MPa)	1354	759
YT	Allowable lateral tensile stress (MPa)	39.2	662
YC	Allowable lateral compressive stress (MPa)	1354	731
S	Allowable in plane shear stress (MPa)	86.6	74.8

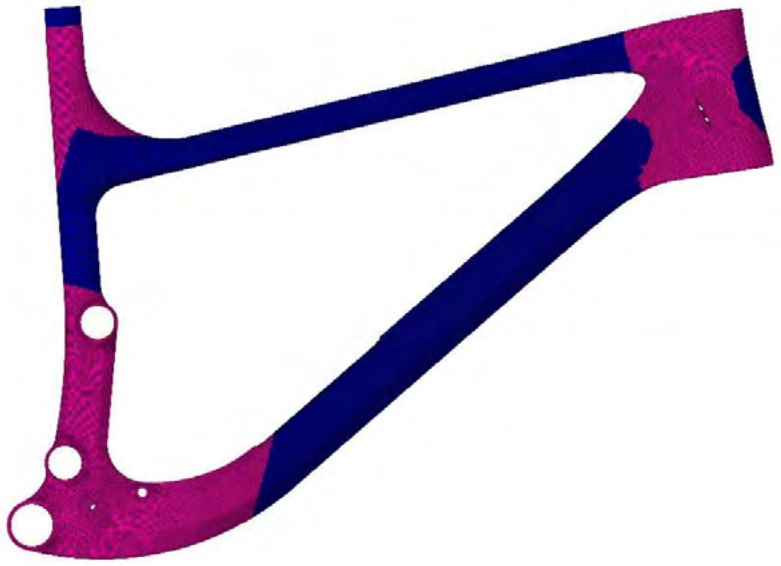

Figure 2. Frame front triangle design showing initial boundaries of reinforced areas.

2.5. Finite element analysis

Calculation of laminate stresses was performed using the HyperWorks (Altair Engineering) finite element analysis programme [11]. The frame geometry was imported as a surface and meshed with shell elements. Ply failure was predicted using the Hoffman composite failure criterion.

2.5.1 Boundary conditions

The frame was constrained in all 6 degrees of freedom via RBE3 (load-transfer) semi-rigid body elements between the upper and lower headsets to simulate the fork constraint. RBE3 elements distribute

the load applied at the independent node while allowing local deflections [11]. Each suspension pivot, the bottom bracket, and the seat mounting interface were also connected with RBE3 elements.

2.5.2 Mesh convergence study

A mesh convergence study was conducted to determine the required element size for accurate results. Both maximum nodal displacement and minimum composite strength ratio were considered for load case 5. A suitable mesh density was determined when the results did not change by more than 0.1% while further decreasing element size. Convergence occurred at 83400 nodes, with a 2 mm nominal mesh element size (Figure3).

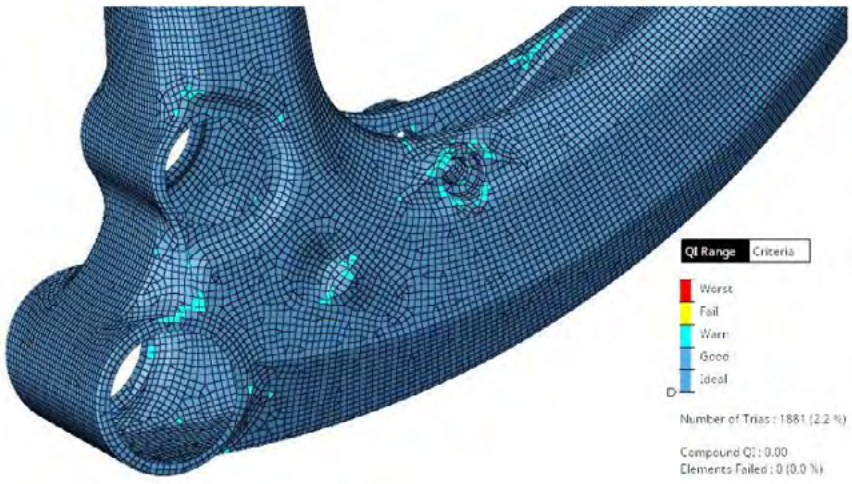

Figure 3. Detail of finite element mesh in the bottom bracket area.

2.5.3 Validation

The finite element modelling approach was validated by comparison of predicted strength with the published Santa Cruz test to failure of a similar composite frame [3].

2.6. Optimization

The multiple load cases considered present a multi-objective optimization problem. This was tackled by assigning selected weights to each load case and using a weighted compliance value as the objective to minimise. Stiffness under maximal pedalling loads was selected as most important and the largest weight (0.4) was therefore assigned to load case 4. To further prioritise the lateral stiffness of the frame a weight of 0.3 was assigned to cornering (load case 5) whilst the remaining load cases were assigned weights of 0.1 (Table 1). Key constraints for optimization were that the frame mass did not exceed that of the initial design (1.1 kg) and that a factor of safety (FOS) of at least two was achieved for each load case. Optimization of lay-up was performed using the HyperWorks (Altair Engineering) software in two steps: an ideal free-size optimization and a subsequent manufacturable size optimization to produce a practical laminate with discrete ply thicknesses and boundaries.

2.6.1 Free-size optimization

Free-size optimization was used to determine the ideal thickness of specific ply orientations and types in each element of the model, in particular allowing unidirectional plies to be used in the lay-up. For this optimization the design variables were defined as the thickness of plies in each element. A “super-ply” concept was adopted, in which each available fibre orientation was assigned to a super-ply whose thickness was free-sized. In addition the “smear” option was used in order to neutralise the effect of stacking sequence (giving an ABD stiffness matrix that is stacking sequence independent and assumes a symmetric lay-up) [12].

Plies of +/-45 and 0/90 3K twill weave; and 0, 45, 90, and -45 degree unidirectional fibres were used. Lay-up constraints were used so that, for each element, the +/-45° unidirectional plies should be balanced, the surface 3K twill weave plies should have a minimum thickness of 0.23 mm each, and the total laminate thickness should be >1.6 mm. The unidirectional plies were balanced to minimise the effects of warping. The twill weave constraints were added to keep a surface aesthetic/protective layer intact. The total minimum thickness was defined to keep some strength in the non-structural regions to mitigate impact damage, e.g. rock strikes. The responses measured at each iteration were the mass of the frame (< 1.1 kg), the composite failure index for each ply in each element (strength ratio > 2) and the compliance of the frame under each load case. The objective of the optimization was to minimise the combined weighted compliance value.

2.6.2 Size optimization

Following the Free-Size Optimization a Size Optimization was performed to define a practical (i.e. manufacturable) laminate with discrete ply thicknesses and boundaries. This took the lay-up schedule generated by the free-size optimization and refined the thickness and boundaries of each ply. The thicknesses of the 300 gsm unidirectional plies and 200 gsm 3K woven fabric were defined to be 0.3 mm and 0.23 mm, respectively.

3. Results and discussion

3.1. Initial laminate & validation

For the initial frame lay-up the HyperWorks calculation gave a minimum composite strength ratio of 2.1 at the joint of the headtube and downtube for load case 1 (an applied load of 4500 N between the front fork axle and bottom bracket). This magnitude and location were in good agreement with the failure at 9000 N in the Santa Cruz test [3] and was therefore considered an adequate validation of the overall approach. The initial design was found to have adequate strength under all load cases with a minimum FOS of 2.1 (load case 1) but an excessive maximum of 7.0 (load case 5). The greatest deflection was under load case 1 with a magnitude of 10 mm.

3.2. Optimization

The free-size and subsequent size optimization resulted in adjusted displacements and FOS values for all load cases. These are plotted in Figs. 4 & 5, respectively. Small increases in displacement and FOS are seen after the final size optimization step due to the additional constraints applied to produce a manufacturable lay-up. After optimization deflections for all load cases were reduced, the largest to less than 6 mm. In particular, the average stiffness for cornering and pedalling (load cases 4 &5) increased by 30%. The optimized FOS for all load cases are in the range of 2 to 3.5. The final optimized total laminate thickness is plotted in Figure 6.

Table 3. Displacement and strength for all load cases, initial and optimized laminates.

Load Case	Description	Initial laminate design		Free-Size Optimization		Size Optimization	
		Max. Disp. (mm)	Min. FOS	Max. Disp. (mm)	Min. FOS	Max. Disp. (mm)	Min. FOS
1	Frontal impact	10.0	2.14	5.53	2.10	5.95	2.02
2	Jump landing	1.58	2.54	1.61	2.05	1.67	2.01
3	Seated pedalling	5.32	2.60	2.89	1.97	3.25	2.05
4A	Max. Pedal Left	2.22	4.37	1.72	2.34	1.73	2.47
4B	Max. Pedal Right	1.33	5.69	0.83	3.54	0.87	3.61
5A	Cornering Left	1.45	6.94	1.20	3.00	1.19	3.37
5B	Cornering Right	1.44	6.92	1.19	3.28	1.17	3.28

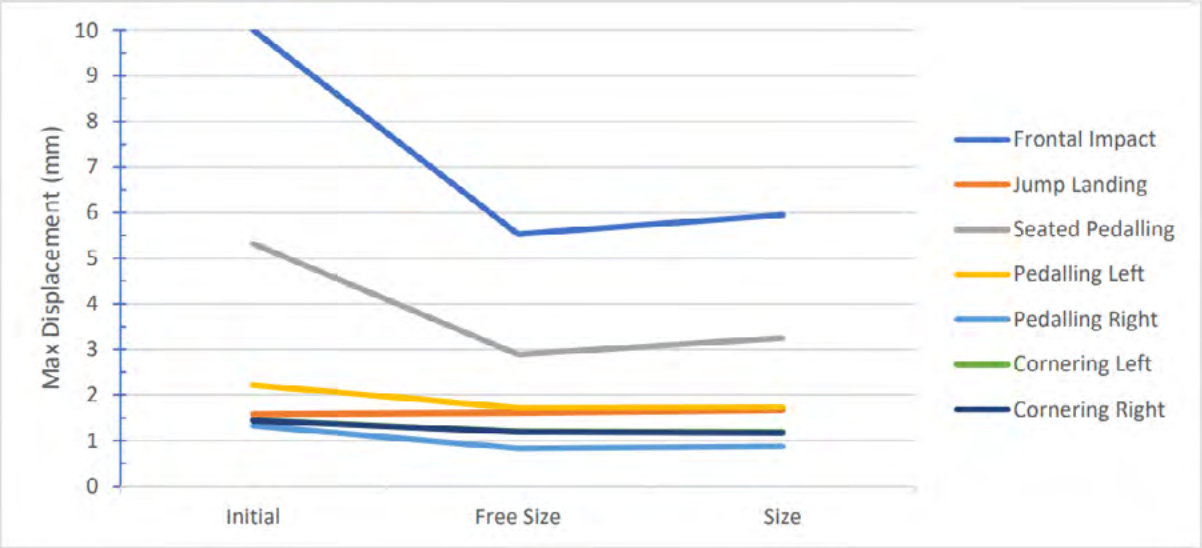

Figure 4. Maximum displacement (mm) under each load case for initial and optimized lay-ups.

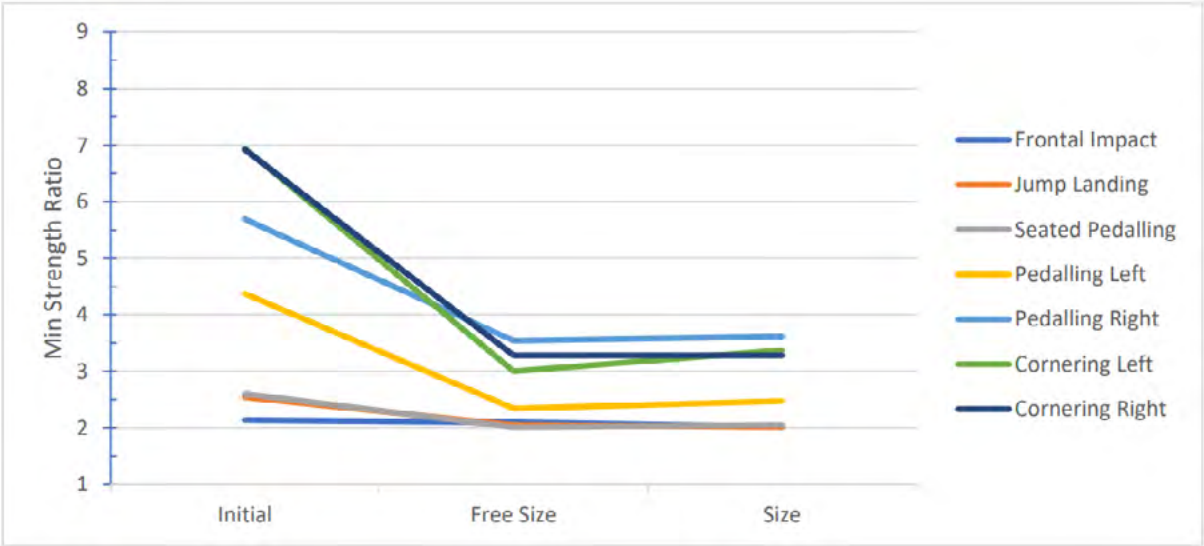

Figure 5. Minimum strength ratio (FOS) under each load case for initial and optimized lay-ups.

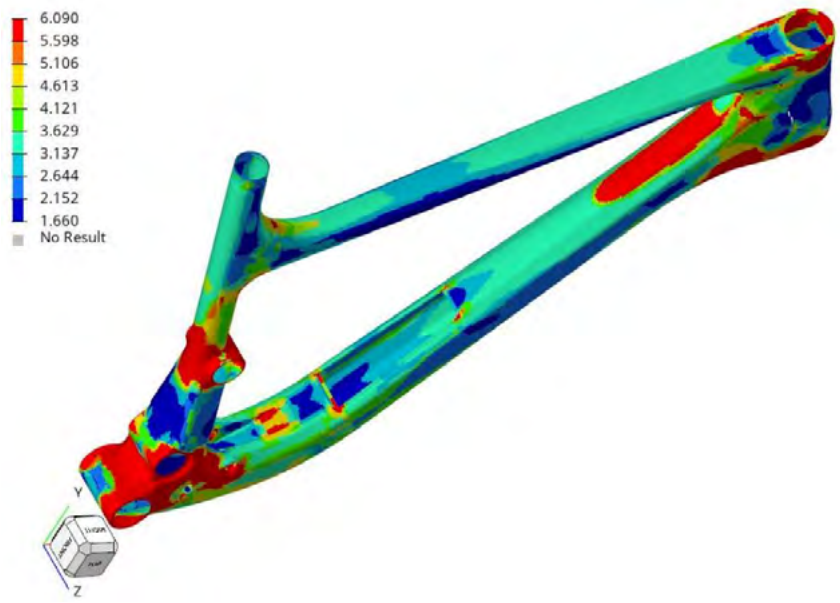

Figure 6. Total laminate thickness (mm) after size optimization.

4. Conclusions

The optimization process carried out for this case study has produced a laminate design that maximises stiffness whilst achieving adequate strength and low weight. Although load-case definition and weighting remain significant subjective manual tasks, the case study demonstrates the benefit of computational optimization for designers of composite bicycles.

Keywords: Tailored Fiber Placement, variable-axial, structural vane, jet engine

Abstract
This paper presents a virtual-physical testing methodology for the design and dimensioning of a variable-axial structural guide vane manufactured by Tailored Fibre Placement (TFP). Within the context of a jet engine, a validation pyramid based on the building block approach is developed, considering different levels of complexity from coupon- up to system-level. Both virtual and physical sections of the validation pyramd are defined. Focussing on the coupon- and element-level, a method to determine a material model for the TFP structural vane is proposed, considering the complex environment of the jet engine. A work flow for the specific TFP element-specimen design process using the software EDOstructure for variable-axial components is developed.

1. Introduction

The use of lightweight materials in the aerospace sector can significantly contribute to the European Union's ambitious goal of reducing CO2 emissions by 75% by 2050 [1]. This potential is especially evident when employing innovative technologies such as TFP to produce stress-adapted structures [2]. However, designing novel tailored, variable-axial (VA) carbon fibre reinforced polymer (CFRP) structures presents complex challenges. The assessment of their load-bearing capacity is particularly demanding due to the intricate relationship between geometry, composition, and the manufacturing process [3]. Figure 1 illustrates the evolution of the intermediate case (IMC) in the Rolls-Royce Pearl engine architecture: transitioning from the traditional function-separated intermediate case on the left, through the newer generation of IMC with a function-integrated metallic design in the center, to a future architecture featuring a hybrid metal-composite design on the right [4]. In this hybrid design, CFRP is utilised in areas where load transmission is indirect and straightforward, while metal is employed in regions subjected to complex loads due to its isotropic properties.

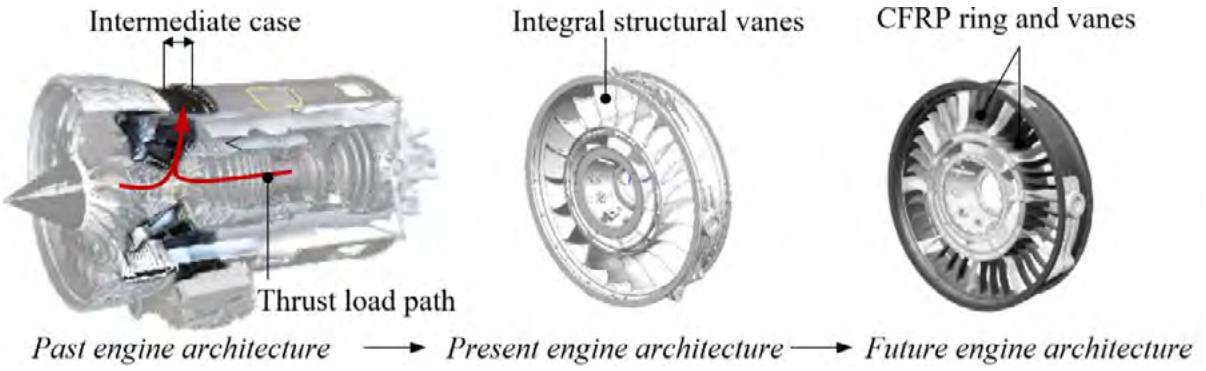

Figure 1. Intermediate cases of Rolls-Royce jet engines [4]

In order to increase the efficiency of the Engineering Design Process, it is essential to use reliable mechanical properties that take the influence of TFP process into account. For a complex system such as a jet engine and its different scales, the material scale provides important input parameters for the higher scales that follow. Furthermore, the modelling of tailored structures proves to be challenging when conventional simulation software is used [4, 5].
The TFP technology, designed for creating curvilinear fiber patterns, was invented and developed at the Leibniz Institute for Polymer Research Dresden e.V. [6] and is shown in Figure 2 [5]. The adjustable process parameters are the stitch width, stitch distance (R-value), oscillating movement of the roving placement, roving distance, number of layers and the deposit radius.

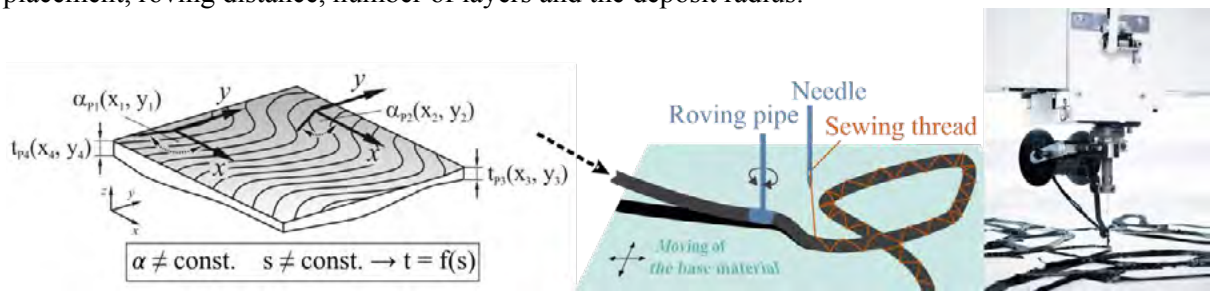

Figure 2. Principle of a VA composite design (left), TFP manufacturing principle (center), and TFP fibre placement head (right) [5]

Preliminary experimental research on how TFP process parameters affect the tensile modulus and strength was carried out by Spickenheuer [7]. Uhlig et al. demonstrated in one work [8] that variations in TFP parameters significantly influence local fiber volume content and in-plane waviness of composite materials. In a further work [9] they concluded, that the stiffness reduction due to the TFP process is minor compared to a unidirectional (UD) material, but can be significant for strength properties.

2. Development of a physical-virtual testing methodology

This paper presents a virtual-physical testing methodology to efficiently determine the material properties of variable-axial structural vanes for future jet engines. The developed validation strategy is based on the building block approach [10] as shown in Figure 3.Various levels are defined in a validation pyramid (VP) to determine the material model at the coupon- and element-level, analyse the structural behaviour from the virtual component- to system-level, and validate the numerical models with a physical test campaign extedning from the physical element- to system-level. This work specifically focuses on the two lower levels—coupon and element—which provide critical input parameters for the subsequent levels. The levels above the element level are included in the VP for completeness only.

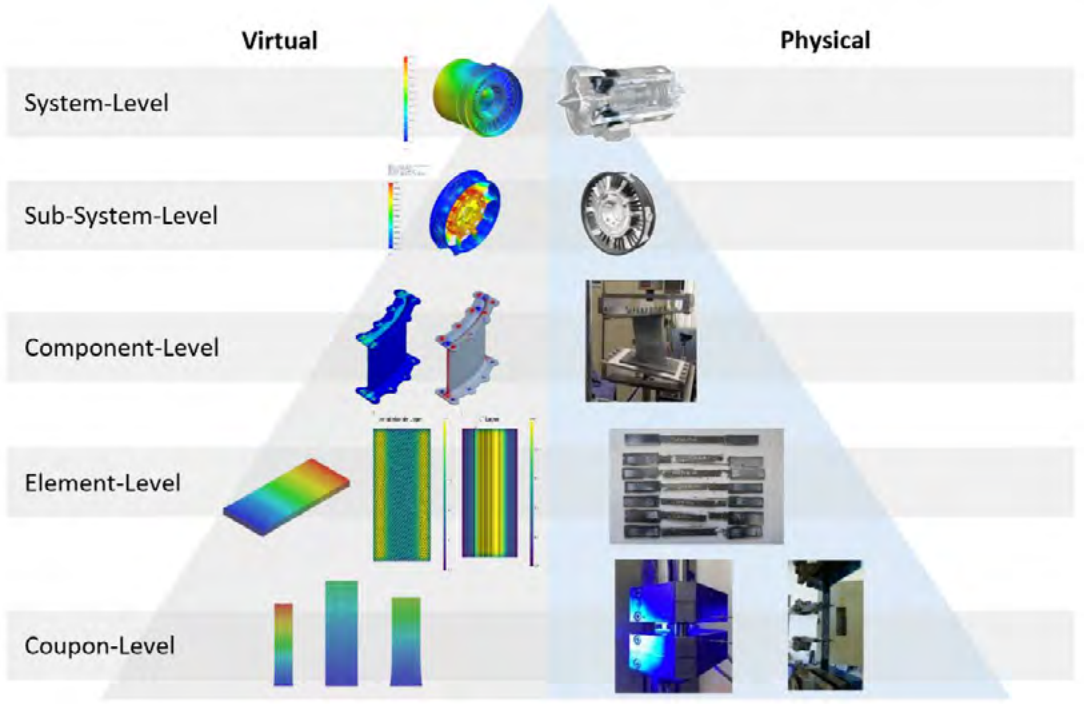

Figure 3. Virtual-physical validation pyramid

For VA structures, it is necessary to capture the influence of the TFP process parameters on the material properties. On the coupon-level, the material parameters are determined to define the initial material model. Two material models are determined: one without the TFP influence considered, which serves as a baseline, and another one with TFP influence considered. By that, a knock-down factor is determined for the TFP process influence on the material properties. Subsequently, the component simulation is solved in Ansys APDL with an isotropic shell model including load and boundary conditions as an input. The result file .rst format is the compatible file format for the TFP component strcutrual vane design process. Here, a specific TFP software called EDOstructure from Complex Fibre Structures GmbH [11] is used (version 1.0.2193). A vane TFP pattern is realised, which is used to derive an element specimen design. The pattern is exported as a DXF file and transmitted to Hightex Verstärkungsstukturen GmbH [12] to manufacture the specimen. Furthermore, the element test is performed and the initial material models are calibrated. Finally, the calibrated material model is implemented in the vane simulation model and further analysis can be performed. The process flow chart is shown Figure 4.

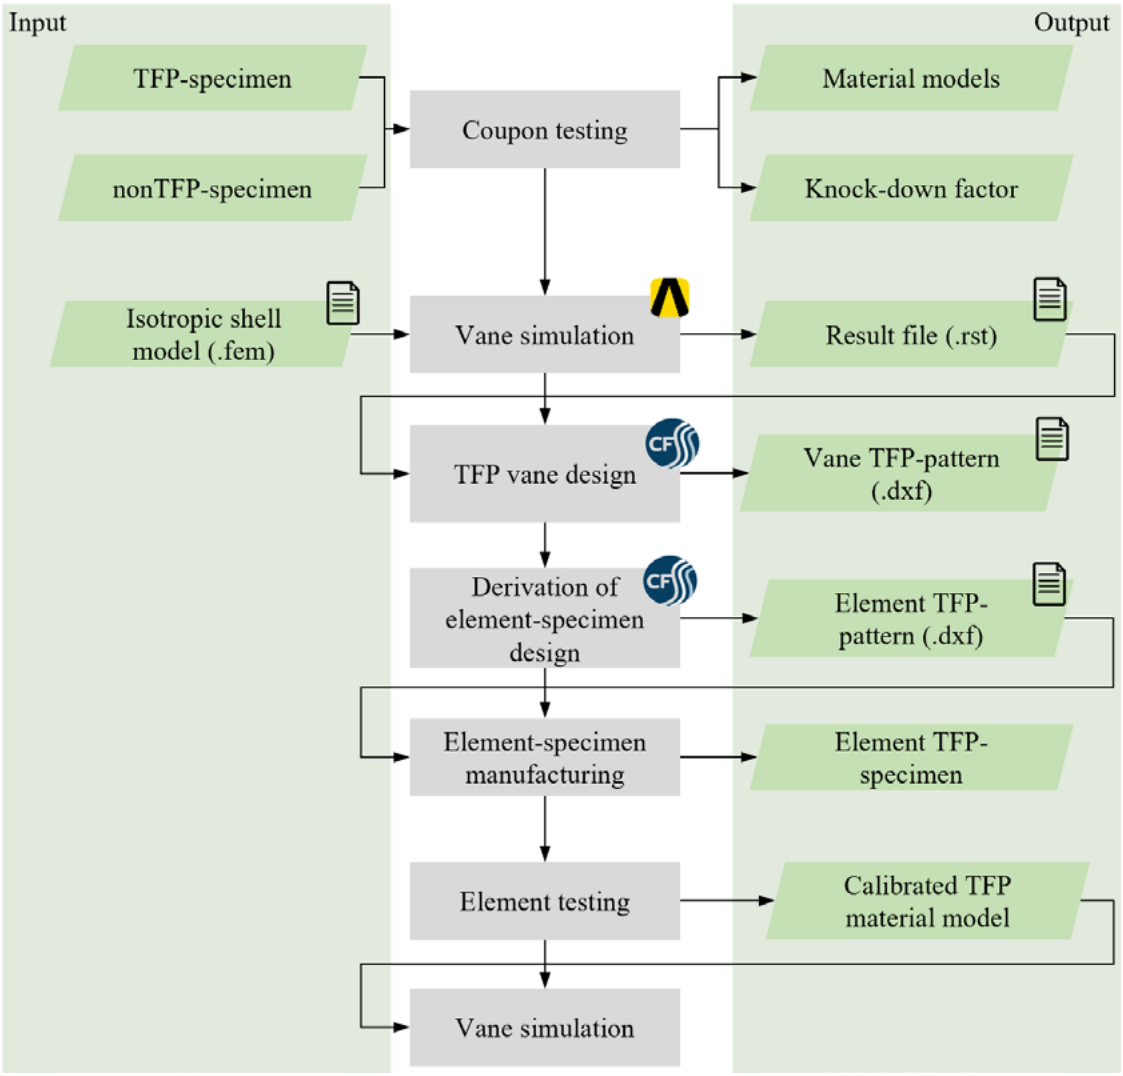

Figure 4. Process flow chart for the determination of the TFP material model

3. Results

Specific TFP element-specimens were designed, considering component, sub-system- and system-level factors (cf. Figure 5). The design parameters were derived from the component model. From the sub-system, relevant interface information was obtained, and from the engine system, load and boundary conditions were extracted. An isotropic shell model was developed and solved; its solution was imported into EDOstructure. The VA pattern for the vane was generated, and a specific design feature, referred to as the S-curve, was identified. To accurately map the fibre orientations on the mesh of the vane finite element (fe) model, a mesh size equal to half of the roving width was selected.

Subsequently, a simple specimen model was created to project the S-curve pattern from the vane onto a plate model. Load and boundary constraints were appropriately set, and the .rst file was imported into EDOstructure to verify the directional field and generate the DXF pattern for producing the TFP element-specimen.

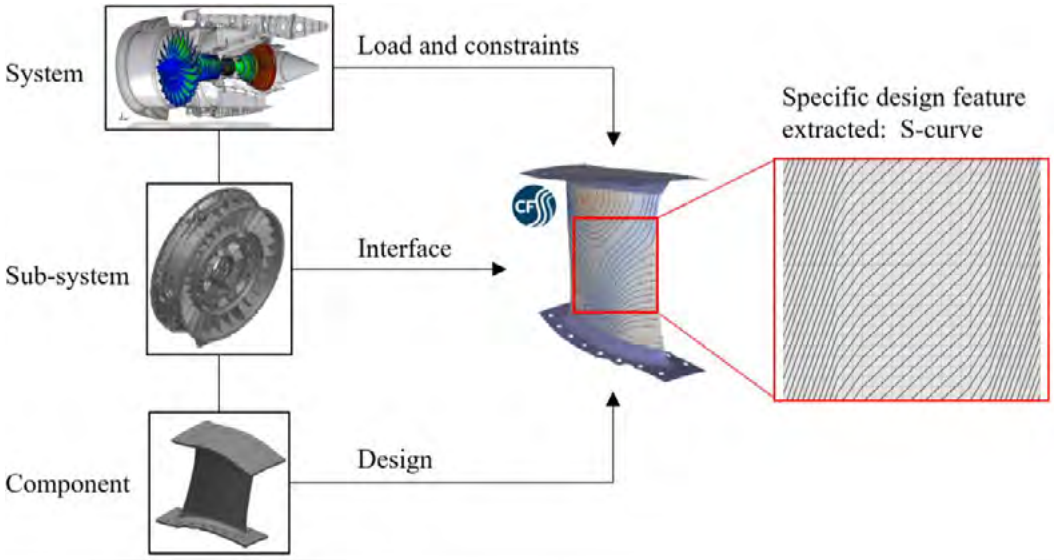

Figure 5. TFP element design determination considering component, sub-system and system-level

The pattern was modified by Hightex into a manufacturing-oriented design, and the adaptations were retransferred and mapped onto the specimen model by re-importing an HGT DXF file into EDOstructure. The preform for the TFP element-specimen was produced and infiltrated using a Resin Transfer Moulding plate tool. The consolidated plate was cut by a water jet into the specimens. The process of designing the specimen and plate preform, as well as the actual preform, is shown in Figure 6. The green frame marks the TFP specimen.

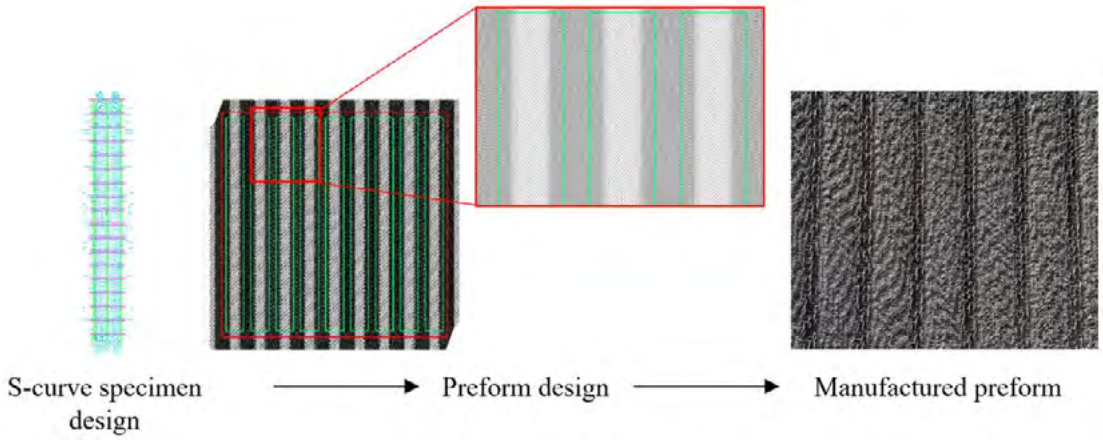

Figure 6. Process from specimen design to manufactured preform

While the input file for EDOstructure must be an Ansys .rst file, several export options for the fe-model export were available. Here, the fe-model was exported as a bulk data file (bdf) and imported into Siemens NX.

4. Conclusions and outlook

This paper successfully introduced a virtual-physical testing methodology for determining the material properties of variable-axial structural vanes for jet engines, integrating both TFP technology and a multi-level validation strategy. By effectively considering the influence of TFP parameters on material properties through both theoretical and experimental approaches, this research provides insights for optimising the design and manufacturing of lightweight, efficient aerospace components, supporting the broader goal of reducing environmental impact in the aviation industry. The presented numerical methods enable an efficient modelling of the tailored structures by plotting the fibre patterns (as DXF files) from the manufacturing process directly on the model as initially explained in [13]. This paper also shows the needed interacting process steps as well as the data flow between the different software

tools used. The proposed method facilitates an effective and efficient design and dimensioning of variable-axial engine structures based on reliable data for future applications.
Further work should focus on comparing physical and virtual test results within the developed framework. Moreover, analysing the higher levels in the validation pyramid will allow for the capture of additional effects of the developed material model on those levels. Through this analysis, the required structural behaviour at the component, sub-system, and system level could be investigated by appropriately setting the TFP process parameters.

5. Acknowledgments

The work took place as part of the projects "Development of a highly efficient linked product engineering process (PEP) for hybrid lightweight structures in the context of Industry 4.0" (PEP4.0, funding code 20X1717B) and “Load-appropriate fiber paths on curved structures using the example of a design space-conforming and aerodynamic Type-V hydrogen pressure tank and an engine ring structure with a development process-accompanying validation strategy” (LaSt, 20M2118F). The projects are funded as part of the fifth and sixth Luftfahrforschungsprogramm of the Bundesministerium für Wirtschaft und Klimaschutz BMWK.

Topology optimization method based on minimal surface lattice structure for the lightweight design

Hailun Zhou[a], David Zhang[a,*]

[a]*Faculty of Environment, Science and Economy, University of Exeter, North Park Road, Exeter, EX4 4QF, , UK*

Abstract

The lattice structure is regarded as the ideal structure in various applications such as energy absorption, bone implants, and lightweight design for aerospace. Compared to traditional lattice structures, novel lattice structures designed by triply periodic minimal surfaces (TPMS) based on mathematical methods exhibit a high stiffness-to-weight ratio. In my research, the design method of the I-graph-wrapped package (IWP) TPMS-based lattice structure will be proposed, especially the continuous change in the volume of the graded IWP structure. To investigate the relationship between its mechanical properties and structural relative density, the elastic matrix constants of the IWP lattice are calculated via the homogenization method. The homogenization method will be applied to obtain the relationship between elastic properties and the design parameter of IWP lattice. Furthermore, the topology optimization based on Simple Isotropic Material with Penalization (SIMP) algorithm was investigated to solve the optimal density distribution of IWP lattice filling structure. The results show that the overall stiffness of IWP lattice filling structure is higher than that of traditional BCC lattice filling structure with equivalent total volume. This research will guide the designers in choosing the appropriate structures with predictable mechanical properties during the process of structural optimization.

Keywords: lattice structure, topology optimization, Triply periodic minimal surfaces (TPMS), homogenization method

1. Introduction

Lattice structure is widely employed in structural optimization due to its high strength-to-weight ratio. The design method based on triply periodic minimal surfaces (TPMS) allows the lattice structure to be defined by a mathematical equation, free to select different types of unit cells and architectural details including cell repetitions and relative density. The minimal surfaces, which have a mean curvature of zero that resembles the surface curvature of the trabecular bone [1], are frequently regarded as excellent structures of biometric tissues. The TPMS-based lattice structures have a high surface-to-volume ratio [2] and pore connectivity [3]. The biocompatibility of bone implants can be enhanced by the smooth convergence of TPMS-based structures that can minimize the effect of stress shielding [4]. Furthermore, this design approach has received much attention in the application of designing continuous functionally graded materials by altering the relative density parameters [5] and even connecting several different types of TPMS structures smoothly [6]. Dawei Li et al. [7] presented a novel optimization strategy for designing functionally graded TPMS-based cellular structures with desired mechanical properties, which was used in lightweight design for aerospace applications.

Compared to the traditional body-centred cubic (BCC) lattice structure, the I-graph-wrapped package (IWP) lattice, one of the TPMS lattice structures, exhibits superior mechanical properties such as elastic modulus, yield strength, and energy absorption ability. The IWP lattice structure has a smoother external structure compared to the BCC structure. The lattice structure topology optimization (LSTO) method is to design lattices in-fill components with exceptional directional tensile or shear properties, considering various relative density limits. The optimized lattices

are then filled into the design space based on optimization results. The Simple Isotropic Material with Penalization (SIMP) algorithm is one of the most widely implemented methods. It interpolates Young's modulus of the material to the scalar selection field to solve the topology optimization (TO) problem with continuous variables. The intermediate densities are penalized due to the high cost of realizing these results. However, this artificial penalization implies that the topology is less optimal than if the intermediate densities had not been penalized. If there were a method to replace these intermediate regions, there would be no need to penalize them. Several previous studies attempt to tackle the TO problem by using multiple materials, including composites [8] and discrete regions of different materials [9, 10]. Additive manufacturing has been considered a manufacturing route for the intermediate density results by using a multi-material 3D printing technology, but there are a lot of constraints in the technology of multiple metal materials. Another approach that changes the architectural features of structures made of the same material was investigated. Since the relative density of the lattice unit cell is a variable, it can be used to replace the intermediate regions according to a relationship between the variable density of TO results and the variable relative density of the lattice. To get a continuous merging of structure, the relative density of these lattice unit cells should vary continuously.

The intermediate densities can be considered as materials with varying relative densitys of TPMS lattice structure. Thanks to the mathematical parametric design approach, lattice structures with different relative densitys can be smoothly interconnected through a functional equation. This research proposes an LSTO method based on the IWP lattice structure and improves the global stiffness under the requirement of total relative density. The finite element analysis was implemented to compare the stiffness of proposed IWP lattice filling structure with traditional BCC lattice filling structure. The research in mechanical properties of the continuously functionally graded lattice will lay a foundation for potential applications.

2. Design method of IWP lattice structure

The boundary between solid and void of the IWP lattice structure is described as implicit equation. Therefore, the solid IWP lattice region can be expressed as follows [11]:

$$\begin{aligned}\varphi_{IWP} = 2[&cos(\omega x)cos(\omega y) + cos(\omega y)cos(\omega z) + cos(\omega z)cos(\omega x)] \\ &- [cos(2\omega x) + cos(2\omega y) + cos(2\omega z)] - t \leq 0\end{aligned} \tag{1}$$

where ω is the parameter to control the unit size of lattice structure, t is the design variable used to adjust the relative density ρ of the IWP structure, which can be calculated by the following equation:

$$\rho = \frac{\iiint_{(\varphi_{IWP}\leq 0)\cap(|x|\leq \frac{L}{2})\cap(|y|\leq \frac{W}{2})\cap(|z|\leq \frac{H}{2})} dxdy}{LWH} \tag{2}$$

where L, W, and H are the length, width, and height of the lattice structure, respectively. In order to investigate the relationship between the offset parameter t and relative density, a polynomial fitted equation and the curve were shown in Fig.1. This would provide an approach allows that designer to obtain desired lattice structures rapidly by modifying the parameter t.

3. Topology optimization of lattice filling structure

3.1. Homogenization method

The finite element analysis is used to investigate the mechanical properties of IWP lattice structure with different relative densitys. Given the periodic arrangement of lattice structures, a single lattice unit cell was chosen as the representative volume element (RVE) for simulating their mechanical properties [12]. Subsequently, periodic boundary conditions (PBCs) were implemented on the RVE to account for the influence of surrounding unit cells. To apply the PBCs, it was essential to ensure an equal number of nodes with corresponding coordinates on opposite surfaces. Consequently, a finite element model with a symmetric mesh (C3D10 element) was created by mirroring the 1/8 subdivision. EasyPBC, which is an Abaqus plugin developed to estimate the homogenized effective elastic properties of RVE, is applied in this work to calculate the equivalent mechanical properties of the IWP lattice structure. The equivalent mechanical properties were determined using the homogenization method with the imposition of PBCs. The material model for simulation employed a linear elastic model, where the elastic modulus was determined as 2200 MPa and Poisson's ratio was set at 0.35. Considering the cubic symmetry of the RVE, the constitutive properties of interpenetrating lattice structures were assumed to be linearly elastic and orthotropic. Therefore, the homogenized equation of Hooke's law can be simplified as:

$$\begin{bmatrix}\sigma_{11}\\ \sigma_{22}\\ \sigma_{33}\\ \sigma_{23}\\ \sigma_{12}\\ \sigma_{13}\end{bmatrix} = \begin{bmatrix}C_{11} & C_{12} & C_{12} & 0 & 0 & 0\\ C_{12} & C_{11} & C_{12} & 0 & 0 & 0\\ 0 & 0 & 0 & C_{44} & 0 & 0\\ 0 & 0 & 0 & 0 & C_{44} & 0\\ 0 & 0 & 0 & 0 & 0 & C_{44}\end{bmatrix} = \begin{bmatrix}\varepsilon_{11}\\ \varepsilon_{22}\\ \varepsilon_{33}\\ 2\varepsilon_{23}\\ 2\varepsilon_{12}\\ 2\varepsilon_{13}\end{bmatrix} \tag{3}$$

where σ_{ij}, $varepsilon_{ij}$ are the equivalent stress and equivalent strain, respectively. C_{11}, C_{12}, and C_{44} are the independent elastic constants which can be calculated by FEA analysis under PBCs [13]. The elastic modulus E can be calculated as:

$$E = \frac{C_{11}^2 + C_{11}C_{12} - 2C_{12}^2}{C_{11} + C_{12}} \tag{4}$$

The relationship between elastic constants and offset parameter t are plotted in Fig.2. The regression model employs a first-order exponential function, and the fitting results align well with the data values. The fitting equations are shown in Eq.5, which are then utilized in the following optimization model to capture the mechanical properties

©2024 | 3_HAILUN ZHOU_Hailun_3776J.pdf:3

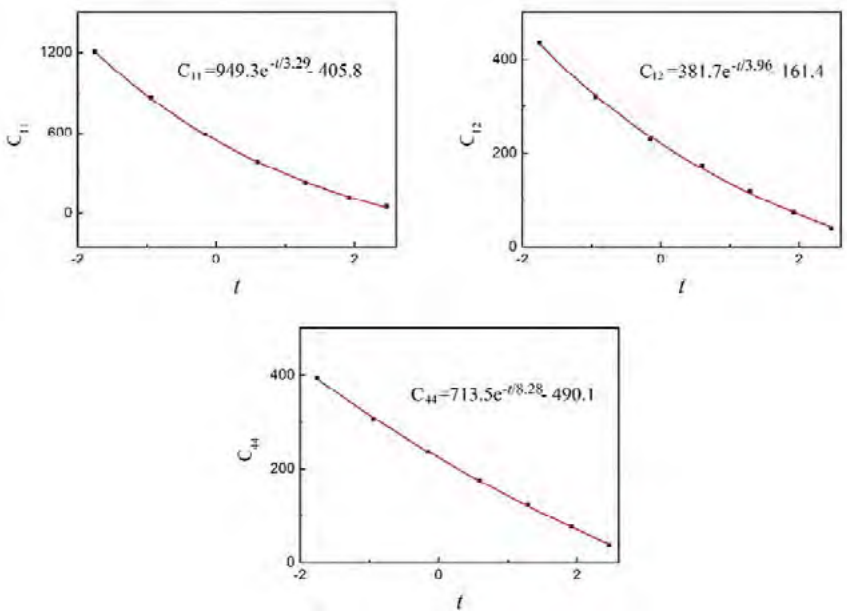

Fig. 2. The elastic constants C_{ij} versus offset parameter t for IWP lattice structure and the exponential fitting curves.

Table 1: Elastic properties of lattice structures.

Lattice type	Relative density	Elastic modulus E (MPa)
BCC	15%	9.88
BCC	25%	41.24
BCC	35%	84.13
IWP	15%	15.85
IWP	25%	63.84
IWP	35%	150.28

of IWP lattice structures with distinct relative densitys. The fitted data intersected with the simulated results, and all the R^2 values were greater than 0.99, indicating the high accuracy of the regression results.

$$\begin{aligned} C_{11} &= 949.3e^{\frac{t}{3.29}} - 405.8 \\ C_{12} &= 381.7e^{\frac{t}{3.96}} - 161.4 \\ C_{44} &= 713.5e^{\frac{t}{8.28}} - 490.1 \end{aligned} \tag{5}$$

As indicated in Table 1, it can be observed that at the same 15% relative density, the elastic modulus of the IWP lattice structure is 60% higher than that of the BCC structure, indicating superior load-bearing capacity. As the relative density of the IWP lattice structure increases, both the elastic modulus and shear modulus significantly rise, while the Poisson's ratio experiences a slight decrease.

3.2. LSTO model

The mechanical properties and deformation behaviour of the IWP lattice structure are influenced by the relative density ρ. To investigate the application of this lattice structure in structural design, a topology optimization method based on this lattice structure is studied to address the optimization problem of compliance. In this section, the optimization mathematical model can be represented by the following equations:

©2024 | 3_HAILUN ZHOU_Hailun_3776J.pdf:4

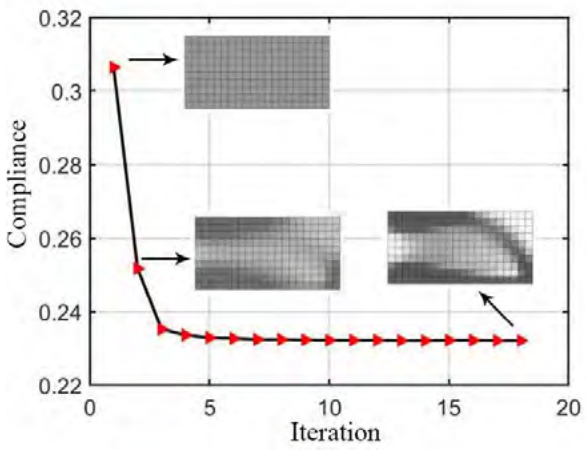

Fig. 3. The iterative curve of topology optimization based on IWP lattice without penalty.

$$\begin{aligned} Find \quad & :\rho = (\rho_1, \rho_2, ..., \rho_n) \\ Minimize \quad & :f(\rho) = U^T K(\rho) U \\ Subject\ to \quad & :F = K(\rho) U \\ & V = \sum_{i=1}^{N} \rho_i v - V_{max} \leq 0 \end{aligned} \tag{6}$$

where ρ represents the spatial distribution of the design variables, f is the compliance of the lattice in-fill structure, $K(\rho)$ is the global stiffness matrix, V and V_{max} denote the volume of optimized structure and the permissible maximum relative density (50%) of the entity structure, respectively. The flowchart of the topology optimization process based on the IWP lattice structure is depicted in Fig. 3. Firstly, the IWP lattice structures with varying design parameter, relative density ρ, is generated using the mathematical TPMS-based design method. Subsequently, the effective elastic constants C_{ij} of the IWP lattice are calculated via the homogenization method as mentioned in the previous section. Then, the design space for topology optimization is meshed by the hexahedral element type. The homogenized material model based on the elastic constants is implemented into the simulation analysis. In the next step, the objective function and constraints as indicated in Eq.6 are established and the final distribution of the design variable was optimized using the Solid Isotropic Material with Penalisation (SIMP) algorithm. The IWP lattice structure can be parametrically controlled for relative density, which can be applied to SIMP optimization processes to replace intermediate density results. Lastly, the 3D model of the IWP lattice filling structure will be generated based on the solved optimal distribution of relative density. The stiffness of a non-optimized traditional BCC lattice filling structure with the same total volume will be compared to that of the optimized IWP lattice structure. All optimization processes were implemented using MATLAB code.

3.3. Optimization results

The iteration curve of SIMP's topology optimization is shown in Fig.3. The design domain is discretized into finite element grids corresponding to unit cells of the lattice structure, and its grayscale value representing its relative density. It can be observed that the convergence shows a great outcome after more than 5 iterations, and the grayscale image of the optimized lattice filling structure can be obtained. The IWP lattice structure can change its relative density by controlling parameters. As shown in Fig.5, the controlling points were defined in the grayscale image grid, setting the control parameters t as functions that vary with these points enables the design of variable-density lattice filling structures. As shown in Fig.6, the IWP lattice filling structure obtained through the proposed optimization method is compared with the BCC lattice filling structure. In terms of stress distribution, high stress is mainly concentrated at the intersections of the support rods in the BCC structure, while in the IWP structure, the stress concentration phenomenon

BCC	3563.33	10	0.604
IWP	3204.57	10	0.147

is mitigated due to the transitional structure being arc-shaped. The stiffness of the IWP lattice filling structure has also been enhanced. Under the same constraints and external loads, the maximum displacement is reduced by 76% compared to the BCC lattice filling structure, as shown in Table 2.

4. Conclusion

This study achieves parametrical design of lattice structure through mathematical equations, allowing for the adjustment of the structure's relative density by changing parameters. Additionally, a function relationship between the design parameter of the IWP structure and its mechanical properties is obtained through the homogenization method and applied to topology optimization. Subsequently, an optimization filling method for IWP lattice structures based on the SIMP algorithm is established using a case study of cantilever beam, optimizing the structural stiffness under total volume constraints. The results show that the optimized IWP lattice filling structure reduces the maximum displacement by 76% compared to the traditional BCC lattice filling structure under the same load condition, which indicates the stiffness performance is significantly improved.

Abstract

The research focuses on the simultaneous deformation of uncured metal-composite laminates under the press forming process of a double-curved dome part. The study is designed to evaluate the influence of material type, inter-ply friction and clamping force by the use of a finite element modelling method. The result shows that the main failure mode for aluminium-based hybrid materials is metal cracking while prepreg buckling dominates the failure of stainless steel-based hybrid materials. The increase of clamping force contributes to the deformation of fibre reinforced prepreg layer and decrease the risk of prepreg buckling, but the simultaneous increase of plastic deformation tends to induce the failure of metal cracking. The variation of friction coefficient at the metal-prepreg interface affects the inter-ply sliding displacement during the forming process. This work provides a numerical method on the material selection and process parameter optimisation where compatible deformation of the individual layers can be achieved through its own mechanisms.

1. Introduction

The Metal-composite laminates, which are also known as fibre metal laminates (FMLs), are one of those lightweight composite materials made by alternating thin sheets of metal alloys and layers of fibre reinforced polymers [1,2]. This hybrid combination creates a material which has excellent specific strength, higher stiffness, and superior fatigue resistance than the monolithic metal sheets as well as better impact strength and damage tolerance compared with full composites [3,4]. Traditional method for the manufacturing of metal-composite laminates is through layup techniques followed by autoclave curing, which is applicable for the product with a relatively simple shape, having large radiuses like aircraft fuselages [5]. As for the forming of small and medium sized part with relatively small radii and complex shapes, the concept of press forming is proposed where the hybrid laminates are pressed using a die and shaped by the deforming force [6]. However, there are some limitations for the press forming of hybrid laminates especially for the epoxy-based hybrid materials because of the needs for various forming and curing stages as well as for the complex deformation mechanisms. Therefore, this study puts forward a hot-pressing cycle involving a laminate preparing and preheating stage, forming of uncured laminate, consolidation or (partial) curing in a same mould as well as the cooling and removal of the component as shown in **Fig.1**. This approach contributes to a better formability of metal-composite laminates based on the understanding of different deformation mechanisms for both layers as well as the optimisation of processing parameters in the hot-pressing cycle.

The forming of metal sheet into the desired shape involves the elastic-plastic deformation of the material by bending, stretching and drawing. Typically, the deformation induces in-plane strain ratios from pure shear to biaxial stretch and the failure strain for the metal alloy materials is in the range of 10% to 50% [7,8]. Therefore, the deformability of the metal sheet is mainly determined by the metal

constituent and the failure mode is dominated by the metal cracking in the forming process [9]. The wrinkling may occur for metal sheet which caused by the increase of compressive stress, but the increasing thickness and clamping force contribute to the delay of such phenomenon [10]. For the deformability of composites, fibre reinforcements and prepregs are particularly prone to wrinkling due to the fibre composition and the possible slippage in-between the fibre tows [11,12]. The wrinkling of woven fabrics is related to intra-ply shear in studies based on the "shear locking angle", which is the maximum angle between warp and weft yarns [13]. Besides, the wrinkling of unidirectional (UD) fibres occurs due to the large differences in rigidity between the fibre orientation and its transverse direction. Therefore, the wrinkles are related to the bridging of the rigid ply and the ply-ply friction during forming [14]. Larberg [15] found that the stacking sequence of UD-prepreg laminates have a significant effect on wrinkle development when forming a spar geometry. He explained this effect as that the combination of 0° and 45° layers may reduce the material deformability through shearing. Akermo et.al [16] further discovered that the inter-ply friction improves the forming behaviour of cross-plied UD prepregs by serving as a connection between the plies, but also introduce wrinkles if not properly controlled.

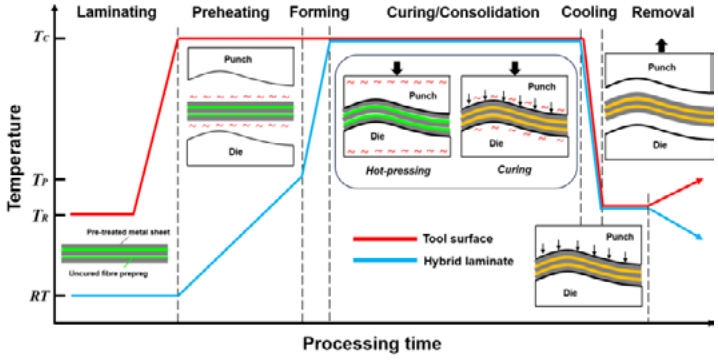

Fig.1: Processing temperature-time profile of the tool surface and hybrid laminates

The numerical modelling of metal-composite laminates can be approached mainly in three ways: micro-level, meso-level and macro-level. As for the micro-level approach, individual materials are differentiated in the model consisting of fibres and matrix. This is the most complex but realistic approach as it requires partitioning the model into different pieces [17]. The meso-level method regards the laminate as a system of independent layers with specific homogenized mechanical properties. This approach results in an effective modelling for all type of hybrid laminates as it requires relatively limited number of elements. Although there are some simplifications which skips the issue of layer boundary conditions, it would not affect the laminate performance unless delamination or other failure phenomena occur [18,19]. The macro-level approach describes the entire hybrid laminate as a homogenized material with anisotropic properties. This approach can be described as a simple generalization since only a few engineering constants are needed. The biggest problem for this method is to obtain the data of the homogenized material as the replacement for the hybrid laminate. One of the possible solutions is the application of Classical Laminate Theory which enables the description of their behaviour under external loads according to the engineering constants, representing membrane, bending and coupling behaviour, or by the uniaxial tensile test of the specimen in order to obtain the constant data in the theory [20,21]. Moreover, process simulation of the hot-pressing of fibre metal laminates requires an accurate mathematical description of the main deformation mechanisms like intra-ply shear, inter-ply sliding as well as bending [22]. None of these mechanisms is negligible or dominant, as the laminate deformability is supposed to be a result of a delicate balance among them [23,24]. Therefore, more advanced material constitutive models and boundary conditions of each deformation mechanisms are required to improve the predictive quality for manufacturing.

This paper aims to develop a homogenised meso-level model for simultaneous deformation in a hot-pressing process and implement it into numerical software Abaqus for analysis. A set of forming tools for the forming of double-curved hemisphere part are designed and the meso-level approach coupled

with the friction contact model for finite element simulation is established. The novelty of the research is to study the "harmony" deform of the individual layers with its own deformation mechanisms when applying the initial circle and square shapes for metal sheet and uncured fibre prepreg, respectively. The simulations are conducted with various material constituents, as well as the clamping forces and inter-ply friction coefficients to evaluate what combinations would be good for a maximum deformability. Then, the numerical model is capable of predicting the local strain distributions and the maximum draw depths for the uncured hybrid materials.

2. Materials and methods

2.1. Materials

The hybrid laminates involved in the research are the metal sheets of aluminium alloy 2024-T3 (Al) and stainless steel 304L (Ss), as well as the fibre reinforced prepregs of S2-glass/FM-94 (GFRP) and T300-carbon/MTC510 (CFRP). The metal-composite materials consist of two layers of 0.5-mm thick metal sheet and one layer of fibre prepregs which are known as a 2/1 layup. Each fibre layer includes two cross-plied unidirectional (UD) prepregs with a total thickness of 0.3mm. The UD fibre ply oriented at 0° corresponds with the rolling direction of metal sheet. The mechanical properties of the material constituents in hybrid laminates are shown in **Table 1** and the behaviour of the metal sheet cannot be affected under the studied temperature ranges. Two parameters of elastic modulus and ultimate strength for the UD reinforced fibre prepregs represent the properties in the fibre orientation of 0° and 90°, respectively.

Table 1 Mechanical properties of the material constituents in hybrid laminates [25,26]

	Density (g/cm^3)	Elastic modulus (GPa)	Poisson's ratio	Shear modulus (GPa)	Yield strength (MPa)	Ultimate strength (MPa)	Shear strength (MPa)	Elongation at break (%)
Aluminium alloy 2023-T3	2.7	71	0.33	28	320	480	283	16.2
Stainless steel 304L	8.0	200	0.30	77	210	574	378	45.6
UD glass fibre prepreg-FM94	2.6	54.0/9.4	0.33	5.5/2.6	-	1870/50	38.5	3.8

2.2. Concept design

The concept of simultaneous deformation of uncured metal-composite laminates came from the design of an integral forming and curing cycle in the proposed hot-pressing process as exhibited in **Fig.1**. In order to investigate the three-dimensional (3D) deformations of the individual layers and the metal-prepreg interfaces, a double-curved hemisphere forming tool concept with draw bead is designed as the schematic graph shown in **Fig.2(a)**. The hybrid laminate with a circle shape of 70mm radius for metal sheet layer and a square shape of 100×100mm for fibre prepreg layer is placed symmetrically on the die surface and clamped by blank holder. As the schematic graph presented in **Fig.2(b)**, the metal sheet and fibre prepreg deforms independently through bias-stretch and intra-ply shear, and the different shape design contribute to the study of "harmony" deform for the individual layers. Furthermore, the concept of draw bead with the depth of 1mm and length of 5mm is proposed to constrain the material flow as well as to achieve a part without cracks and wrinkles. The hemisphere punch with a radius of 42.5mm moves vertically down the centreline of the laminate to a special displacement. In addition to the different material constituents studied in the research, the effects of clamping force and intra-ply friction are compared as well. **Table 2** presents the test parameters used for the forming simulation and the model is conducted varying one parameter at a time while keeping the other parameters at the baseline value. To simplify the hot-pressing temperature condition, the friction coefficient (μ) of 1 is regarded as

the forming condition of room temperature (RT). Then, the frictional contacts where μ= ∞(Tie), 0.5, 0.2 are created as the state of full-cured, medium-friction as well as low-friction, respectively.

Table 2 Test parameters used for the hybrid laminate hot-pressing concept

Test parameter	Baseline value	Additional values investigated
Clamping force (kN)	0	0.1, 1, 2
Inter-ply friction (μ)	1 (RT)	∞(Tie), 0.5, 0.2

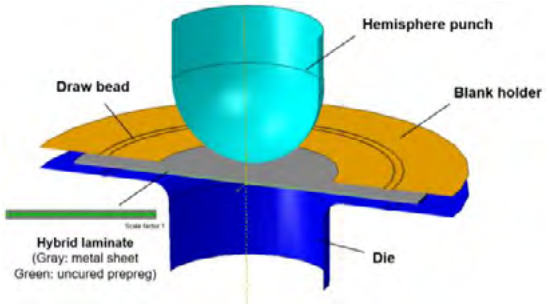

Fig.3: Finite element model of the hot-pressing process for uncured hybrid laminates

2.3. Finite element model

The application of finite element model (FEM) made it efficient to analyse the simultaneous deformation of uncured hybrid laminates and provide guidance for actual experimental testing. In the research, finite element analysis software Abaqus is used to simulate the forming process of the uncured laminates by using the stress-strain distributions of the metal sheet and the unique anisotropic properties of the fibre reinforced prepreg. **Fig.3** exhibits the simulation model established for the study and all the materials as well as tool geometries followed by the concept design. The elastic-plastic properties of the metal sheets and the elastic constants for the uncured prepreg lamina as shown in **Table 1** are imported into the material property module in Abaqus. In the finite element model, all tools including the hemisphere punch, die and blank holder are modelled as discrete rigid shell elements with a mesh size of 2 mm. Metal sheets and the uncured fibre prepreg are created as four-node doubly curved conventional shell element with reduced integration (S4R) in the same mesh size. The laminate structure in the simulation model is represented in the composite layup module where all layers and their parameters such as orientation, thickness, property and relative location are defined and assembled into the forming simulation. As for the interactions and boundary conditions in the model, the value of clamping force and punch displacement can be set, and the contacts between the fixed tools and the uncured laminates are set as penalty friction in a constant value of 0.15. The interaction at the metal-prepreg interfaces is also defined as friction contact as shown in **Table 2**.

3. Results and discussion

3.1. Effect of material composition

During the laminate press forming process, the metal and composite type both play a significant role in the deformability and failure modes of the hybrid materials. **Fig.4** shows the numerical results of the vertical displacement (U3) before failure for Al/GFRP laminate at room temperature and zero clamping force. The metal cracking which dealt by element deletion when the element exceeds the forming limits is the main failure mode as shown in the figure. It is observed that the lower aluminium sheet cracks first at the displacement of 25.08mm and the failure occurs at the centre regions of the metal material. The GFRP material, which is not shown in the figure, stays in contact with the outer metal layers and has no failure at such displacement. Also, the type of fibre prepreg has limited effect on the metal cracking and maximum depth for the aluminium-based hybrid laminates as the prepreg changes from GFRP to CFRP. The reason is due to the fact that the aluminium alloy has lower failure strain than the stainless steel while the fibre prepreg in the middle has not experienced large intra-ply shear strains nor failure at the same depth. When replacing the metal type from aluminium alloy to stainless steel, the failure mode for hybrid materials is totally different. The CFRP and GFRP material in the stainless steel-based hybrid laminate undergo prepreg buckling while the outer metal layers have no failure of metal cracking as exhibited in **Fig.5**. In this case, the numerical result on the vertical displacement (U3) before failure under room temperature and zero clamping force condition for the Ss/CFRP and Ss/GFRP laminates are 39.81mm and 44.64mm, respectively. The prepreg buckling is caused by the layer overlaps due to the increase of intra-ply shear strain which exceeds the locking angle. The locking strain for the GFRP is higher than the CFRP under the same condition which results in a larger failure depth during the forming process.

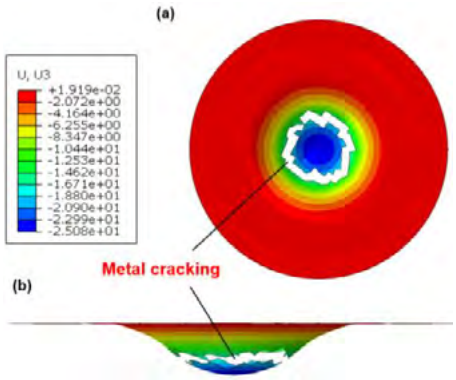

Fig.4: Numerical simulation on vertical displacement (U3) at the maximum value at room temperature and zero clamping force for Al/GFRP laminates: (a) XY plane-Al; (b) XZ plane-Al

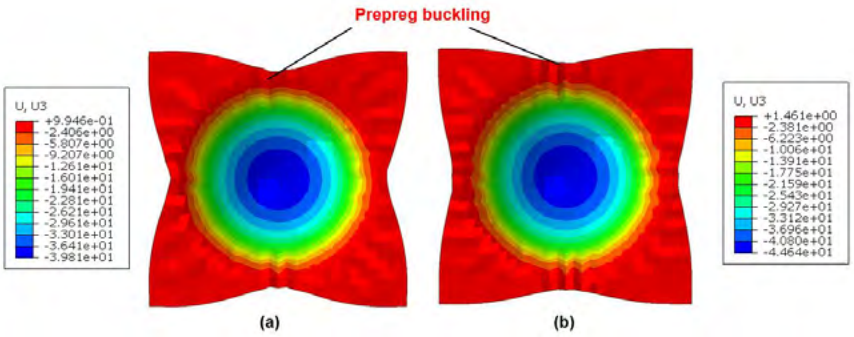

Fig.5: Numerical simulation on vertical displacement (U3) at the maximum value at room temperature and zero clamping force for stainless steel based hybrid materials: (a) CFRP; (b) GFRP

3.2. Effect of clamping force

Fig.6 shows the simulation results on maximum draw depth and its corresponding failure mode under four clamping force conditions at room temperature. For the aluminium-based hybrid laminates with both CFRP and GFRP materials, the increase of clamping force tends to decrease the maximum draw depths even though the influence is limited. The reason is mainly due to the increase in biaxial stress which induces earlier cracking of the aluminium sheet. Besides, the main failure mode for such laminates is metal cracking and the prepreg layer witnesses no prepreg buckling. However, the larger draw depth with less clamping force does not mean a better formability for Al/CFRP and Al/GFRP laminates as the metal wrinkling may occurs at the flange regions. For the stainless steel-based hybrid laminates, the failure mode is complex under various clamping forces. The increase of clamping force from 0kN to 1kN increases the maximum draw depth and the failure of metal cracking occurs coupled with prepreg buckling. As the clamping force reaches 2kN, the metal cracking is dominated with lower failure depth while the phenomenon of prepreg buckling does not exist anymore. This indicates that the increase of clamping force delays the prepreg buckling. A more detailed graph on the different failure modes for Ss/CFRP laminates under 1kN and 2kN is exhibited in **Fig.7**. It is obvious to see that higher clamping force lowers the maximum failure depth and metal cracking occurs at the inner radius regions. The firm clamping on the four-square corners for CFRP reduces the occurrence of prepreg buckling by inducing tension forces in the prepreg layers through friction between draw bead-metal and blank holder-metal interfaces. In order to investigate the friction effects, the comparison between two clamping forces against the initial and final prepreg shapes for Ss/CFRP laminates at room temperature and draw depth of 40mm is presented in **Fig.8**. When the clamping force is 0 kN, the CFRP is easier to flow into the central region which increase the possibility of prepreg buckling. However, the four-square corners of CFRP have nearly no movement when the clamping force is 2kN. Since the clamping force only applies on the four-square corners of the CFRP layer, the effect on the deformability of the 0°/90° CFRP at four central edge regions is limited as the relative displacement is measured to be almost the same. Therefore, the clamping force at 1kN can be seen as an optimised value for a better deformability.

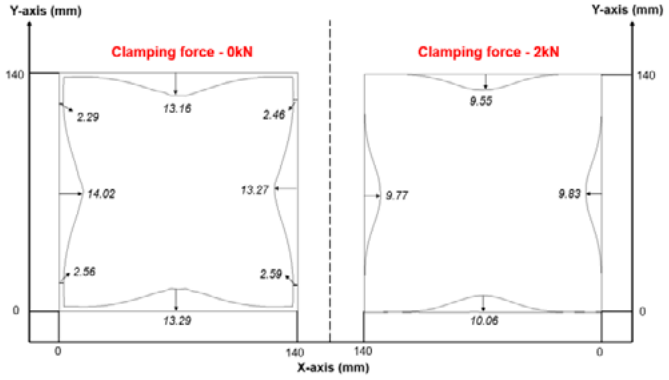

Fig.8: Comparison between two clamping forces against the initial and final prepreg shapes from the numerical simulation for Ss/CFRP laminates (Draw depth=40mm)

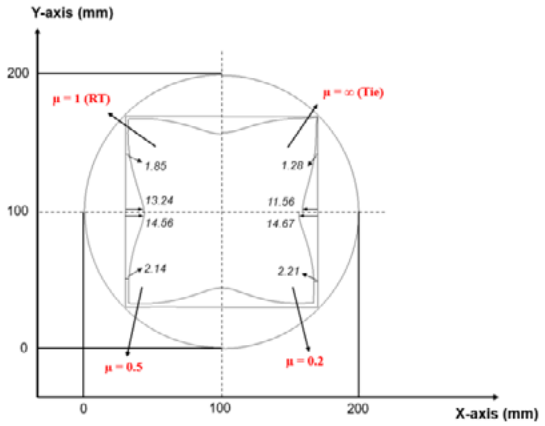

Fig.9: Comparison between inter-ply frictions against the initial and final laminate shapes from the numerical simulation for Ss/CFRP laminates under the clamping force of 1kN (Draw depth=40mm)

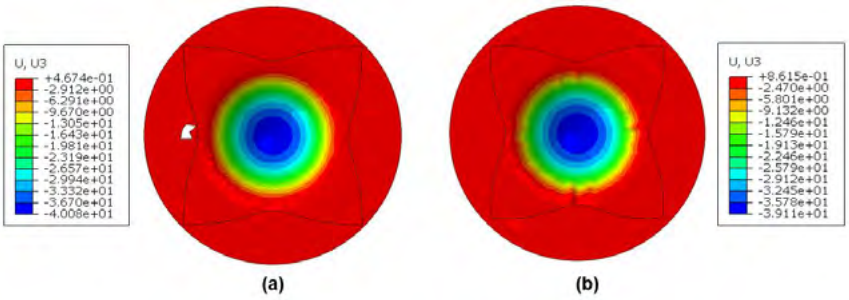

Fig.10: Numerical simulation on vertical displacement (U3,mm) before failure for Ss/CFRP laminates under the clamping force of 1kN and two inter-ply friction coefficients: (a) μ =∞; (b) μ =0.2

3.2. Effect of inter-ply friction

The importance of inter-ply friction can be underlined by conducting a "tie" constraint and simulations with different frictional coefficients. **Fig.9** shows the laminate shapes before and after forming at the draw depth of 40mm from the numerical simulation for Ss/CFRP laminates. The effect of friction on the inter-ply sliding is analysed by looking at the position of the edge of the prepreg layer. When the metal-prepreg interface is constrained which denotes a cured laminate, the maximum horizontal displacement for CFRP is 11.56mm and the horizontal gap at the centre location is small. With the decrease of inter-ply friction, the corresponding horizontal displacement and gap increases. This means that higher friction induces a limited sliding which constrain the deformation and delay the buckling of the CFRP

material. However, the high friction and low friction condition seems to have distinct influence on the failure mode. **Fig.10** presents the numerical results at the maximum vertical displacement for Ss/CFRP laminates under the clamping force of 1kN. It is seen that the metal-prepreg interfaces with a "tie" constraint witness a higher failure depth with metal cracking, while the failure of prepreg buckling is dominated when the inter-ply friction coefficient is 0.2. Therefore, the result demonstrates that a proper selection of inter-ply friction coefficient may help to increase the uncured laminate formability without the failure of either metal cracking or prepreg buckling.

4. Conclusions

The simultaneous deformation of uncured metal-composite laminates is numerically investigated under different material composition, inter-ply friction and clamping force conditions. The proposed method applies a initial circle and square shape for the metal sheet and uncured fibre prepreg, respectively. The main conclusions are:

(1) The failure mode of the uncured hybrid laminates depends on the type of metal composition. The aluminium-based materials with a lower fracture strain exhibit a lower maximum forming depth with aluminium cracking. While for the stainless steel-based materials, the prepreg buckling dominates the laminate failure with a higher maximum forming depth. In addition, the Ss/GFRP undergoes a higher forming depth than the Ss/CFRP under the same condition, but the effect of fibre reinforced prepreg layer on aluminium-based materials is limited.

(2) The increase of clamping force contributes to the deformation of fibre reinforced prepreg and decrease the risk of prepreg buckling, while the increase of baixial stress as well as the hinder of sliding and material flow tend to induce metal cracking for the stainless steel-based materials. A medium clamping force of 1kN is regarded as a compromise forming parameter since the effect of clamping on metal sheet and fibre prepreg is opposite.

(3) A proper heating of the uncured hybrid laminates under a medium temperature and friction condition increase the laminate deformability without the failure of either metal cracking or prepreg buckling.

Abstract

Considering the existing challenges involved in the transfer of flame retardant (FR) formulations from epoxy (EP) resins to glass fiber reinforced composites (GFRCs), obtaining data on the post-fire flexural properties of such composites is even more challenging as this involves balancing test parameters with potential composite delamination. In this study, solvent-free FR additives: ammonium polyphosphate (APP), and inorganic silicate (InSi) were added at 10, 30% and 50% w/w loading to a Bisphenol A diglycidyl ether (DGEBA)-dicyandiamide (DICY)-Urone resin matrix. These resin formulations were transferred to bidirectional (BD) glass fiber composites via prepregs. A novel, but facile approach was developed to prepare the composite samples for furnace tests at 400 ºC. The composites were also subjected to fire exposure at different heat fluxes and times via a bench-scale test and subsequently tested via three-point bending. At approximately 3.5% P content, the FRs significantly improve the fire performance of both the resins and composites. However, they also degrade the systems' pre- and post-fire flexural modulus and strength. Therefore, improving the flame-retardant mode of action of the FRs in the composites, contrastingly reduces their structural integrity post-fire leading to a trade-off effect.

1. Introduction

Epoxy (EP)/glass fiber reinforced composites (GFRCs) are vital for lightweight structural applications in the construction and transport sector [1]. However, many epoxy resins, such as diglycidyl ether of bisphenol A resin (DGEBA), are not inherently flame retardant [2]. Data on the transferability of flame-retardant mode of actions from neat resins into fiber-reinforced composites prepared via prepregs is less available than adapting additive-based FRs for improving the flame retardancy of the resin alone. The use of intumescent FRs such as ammonium polyphosphate (APP) to improve char formation [3] can be further enhanced with the use of barrier formers such as inorganic silicates (InSi) [4] [5]. However, when such combinations are transferred to composites the modes of action of the FRs may be maintained [6] or hindered [3]. The presence of the thermally inactive glass fibers in the composite structure can eclipse the activity of the FRs, notably in intumescent systems [7]. Studying the post-fire flexural properties of such composites is also difficult as it involves balancing test parameters while preventing potential composite delamination due to resin burn-off effects that can make testing unviable. Of the existing studies on the post-fire flexural mechanics of epoxy-fiber-reinforced composites, only a limited few [8] [9] [10] involve mechanical characterization post-ignition, in a heat flux range of 30-50 kW/m^2

normally used in cone calorimeter tests. The reproducibility of the post-fire mechanical analysis used in these investigations is low, since the resin matrix burn-off and subsequent fiber delamination effects occur in a narrow test parameter range with a fire exposure time of less than 5 minutes. To the best of the authors' knowledge limited data is available on correlating flame retardancy with post-fire flexural behavior of the composites and investigating the potential tradeoffs therein. Here, the improvement in the fire performance using three loading levels of APP + InSi FRs in a DGEBA-dicyandiamide (DICY)-urone resin matrix is studied using their corresponding glass fiber composites. Thereafter, using a novel but facile method to ensure a universal sample preparation and testing method following fire exposure of reinforced composites, the post-furnace and post-fire properties of these composites are correlated with their fire performance.

2. Materials and Methods

A schematic summary of the materials and methods used in this investigation is given in Figure 1. DGEBA with an epoxy equivalent weight of 182-192 g/eq, was combined with a DICY hardener and a urone accelerator in the stochiometric ratio 100:6.5:1. APP and InSi were added in the ratio 8:2 at 10%, 30% and 50% w/w loading in the resin matrix. These formulations were then transferred to BD GFRCs with a fiber volume content of ~ 55% and a glass fiber aerial weight of ~ 600 g/m^2 via prepregs. The BD GF prepregs, containing equal densities of glass fibers in the 0 and 90^o orientations, were stacked and cured in an autoclave with a constant ramp rate of + 5 ^{o}C/min to 100 °C for 2 hours, followed by a second ramp to 140 °C with a ramp rate of + 5 ^{o}C/min for an additional 2 hours, and finally, a cooldown ramp of - 5 ^{o}C/min to room temperature over a minimum of 4 hours.

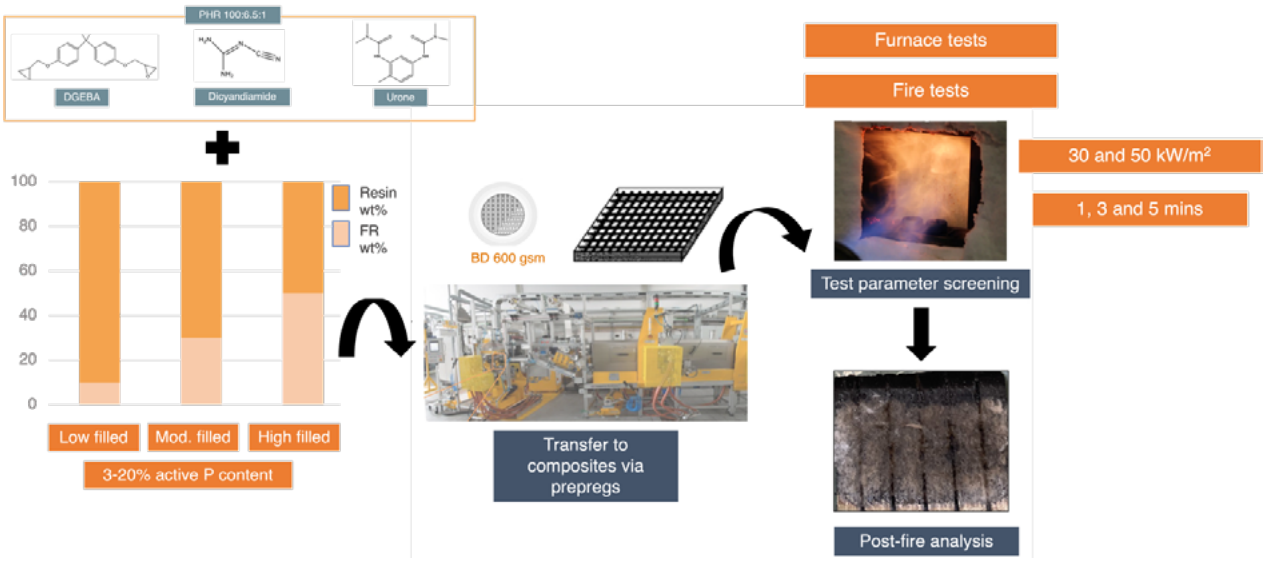

Figure 1. Summary of the materials and methods

A summary of the sample naming convention is given in Table 1. The overall GF content is maintained at ~ 70 wt.% to ensure high thermal inertness of the composite. The peak heat release rate (pHRR) composites are obtained via cone calorimetry measurements performed on specimens sized at 100 mm x 100 mm x 4 mm under an external heat flux of 50 kW/m^2 following ISO 5660-1 guidelines.

Table 1. Summary of composite formulations prepared via prepregs

Specimen name	*APP content in resin (%wt)*	*InSi content in resin (%wt)*	*BD GF content in composite*
E100:GF-BD	0	0	73
E90InSi2APP8:GF-BD	8	2	71
E70InSi6APP24:GF-BD	24	6	70
E50InSi10APP40:GF-BD	40	10	70

2.1 Sample preparation configuration for furnace, bench-scale tests and flexural testing

This study introduces an adapted sample preparation method for composite laminate specimens, which is analogous to the segmental division found in several commercial chocolate bars. A laminate with a uniform thickness of 4 mm was initially dimensioned into a square shape measuring 100 mm x 100 mm on each side. Before mechanical testing, each specimen was subjected to a partial cutting process. The cutting was executed so that approximately 0.1-0.3 mm of the laminate remained intact on one face, effectively leaving a thin, uncut layer that connects the sections. The rationale behind this technique is to significantly reduce the influence of edge effects, which are known to impact the mechanical performance during bending tests. Post-cutting, the specimen's partially cut side was exposed to a controlled fire to simulate realistic conditions of flame spread as described in Section 2.1.6. One set of samples was directly exposed to the fire at heat fluxes of 30 kW/m^2 for 3 mins and 50 kW/m^2 for 5 mins as shown in Figure 2. A bench-scale testing apparatus described in [11] was used to expose the composites to a controlled flame following the 14 CFR 25.856 Appendix F Part VII; 2003 guidelines. A second set was exposed to radiation in a muffler furnace at 400 ^{o}C for 1, 2 and 3 minutes.

Figure 2. Partially cut samples before exposure to the flame (left) in the bench-scale test and post fire exposure at 50 kW/m^2 for 5 mins (right). The lower half of the composite is left unburnt due to coverage by the clamps in the bench-scale apparatus to prevent complete edge delamination

After the fire or radiation exposures, the specimens were entirely separated from the main body of the composite plates using a diamond saw. Each separated specimen was subjected to three-point bending tests with the load applied on the burnt face of the material. For the analysis of the flexural behaviour of the composites pre-exposure and post-radiation/fire exposure, the machine was set up according to the DIN EN ISO 14125 standard using a crosshead speed of 2 mm/min on a Zwick Roell Z020 originally from Zwick Roell GmbH & Co. KG. The capacity of the load cell used was 20 kN. The dimensions of the composite samples used were 100 mm x 15 mm x 4 mm. For all the burnt/radiated samples the load was applied to the burnt side during testing.

3. Results and Discussion

3.1 Trade-offs in fire performance and pre-fire flexural modulus

From Figure 3, it is evident that the increased loading of the FRs results in improved fire performance via a decline in the pHRR obtained from cone calorimetry data. However, they simultaneously also cause a decrease in the pre-fire flexural moduli of the composites with an increase in the FR content. This implies that the flame retardants are effective in their primary role. They likely promote char formation, which acts as a barrier to heat and mass transfer, thus slowing down the combustion process. Here, APP catalyzes charring in the presence of heat and releases non-flammable gases that dilute the flammable gases near the combustion zone, contributing to lower pHRR values. Additionally, InSi can act as a heat sink, absorbing some of the heat generated during combustion, contributing to lower pHRR values. The high FR content can disrupt the continuity of the resin matrix and introduce defects or stress concentrators, particularly if the distribution of the flame retardants is not uniform [12] or due to a high P content [13]. These results will be verified in a future in-depth study using scanning electron microscopy (SEM) imaging. Thus, adding the FRs, specifically InSi increases the brittleness of the composite which decreases its ability to deform elastically under stress.

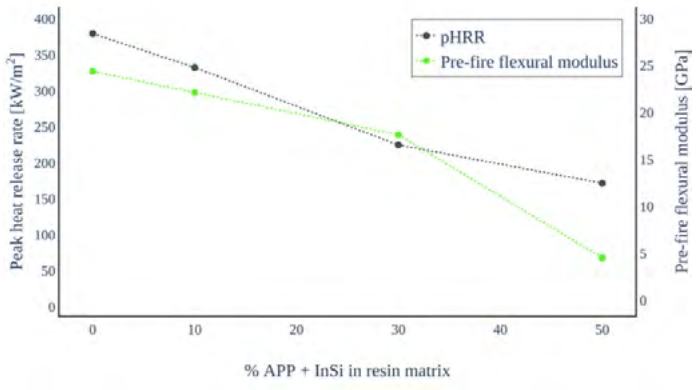

Figure 3. Simultaneous decline in the pHRR and the pre-fire flexural moduli of the composites with increasing FR content in the resin matrix

3.1 Comparison of pre- and post-furnace flexural properties

The flexural strength, strain and modulus of the BD GF composites with varying amounts of FRs are depicted in Figure 4 (a), (b) and (c) respectively. It is clear that the flexural strengths of the composite decrease not only with an increase in the furnace exposure time, but also with an increase in the FR content. A similar trend is observed in the case of the flexural strain of the composites. Thus, the exposure to radiation at 400 ^{o}C for 1 and 2 minutes causes a decline in the flexural strength, presumably via increasing degradation of the matrix-fiber interface. The increase in the FR content, especially at 50% loading, can lead to agglomeration or poor interfacial bonding causing stress concentration sites to form. The formation of char was also observed on the surface of the composites post-furnace exposure, which results in a brittle structure leading to a decrease in the flexural strain with exposure time and This is mirrored in the flexural moduli for E100:GF-BD and E90InSi2APP8:GF-BD, but not for E70InSi6APP24:GF-BD and E50InSi10APP40:GF-BD. In the latter two composites, a sudden recovery of the flexural modulus occurs after furnace exposure. This result can be explained by a potential barrier formation due to the InSi content in these composites, similar to the consolidation of fire residues via melting and sintering of nano-silica particles incorporated into novolac-based glass fiber composites [14].

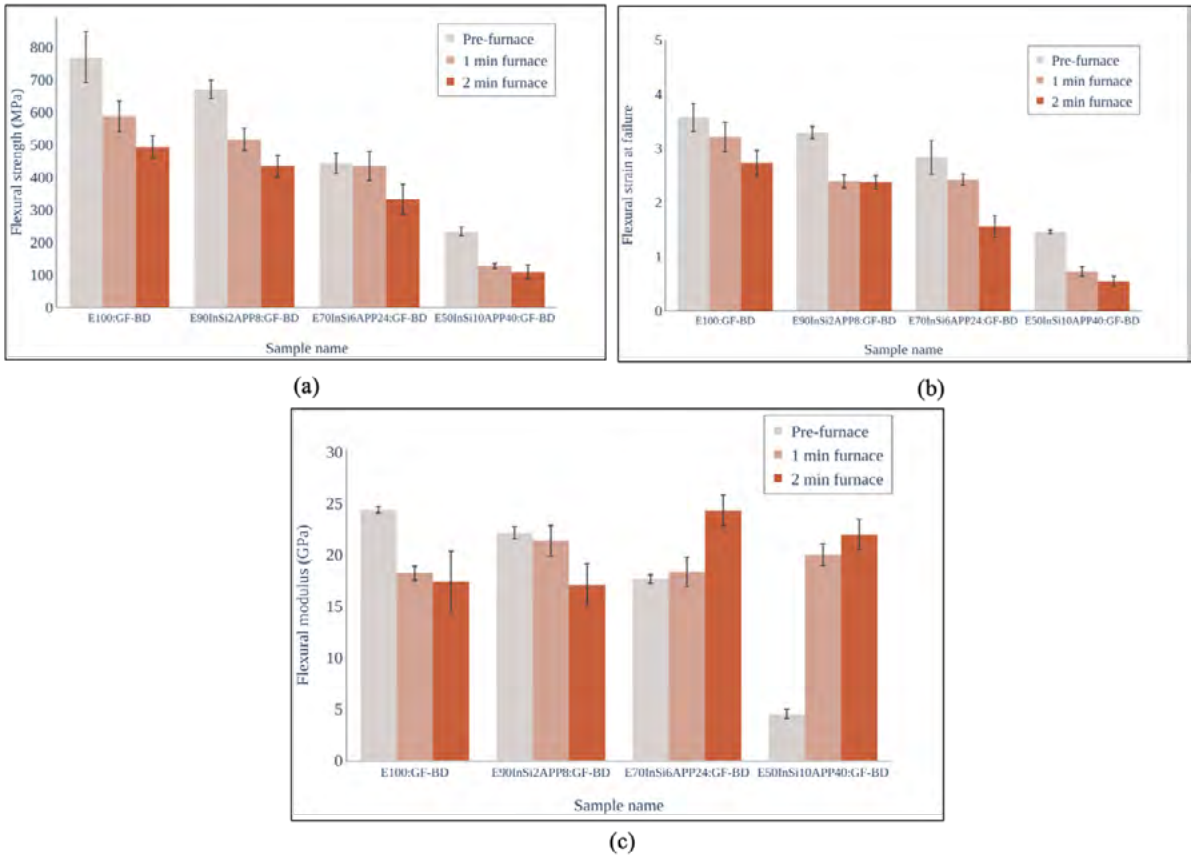

Figure 4. Pre- and post-furnace flexural strength (a) strain (b) and moduli (c) of the BD GF composites with increasing FR content

3.1 Comparison of pre- and post-fire flexural properties

Figure 5 depicts a three-dimensional image of the decline in the flexural strength and moduli of the BD GFRCs with increasing FR content and with increasing heat flux and time of exposure. The standard deviation for the data of the samples with 30 kW/m^2, 3 mins exposure is high due to the inhomogeneity of the burnt surfaces; the flame causes more concentrated burning towards the center of the composite compared to the edges. The residual flexural moduli after 50 kW/m^2 for 5 mins for the composites with 0%, 10%, 30% and 50% FR content are 13%, 9%, 6% and 1% respectively.

This result implies that the post-fire residues are not further stabilized by the addition of the FRs as in the case of the furnace-exposed samples. This result is potentially due to the char and pore formation overpowering the barrier formation effects contributed by InSi that caused a recovery of the post-furnace flexural modulus. Similar effects have been shown in past studies in literature with heat fluxes up to 10 kW/m^2 causing interlaminar damage, followed by decreases in mechanical strength already beginning at fluxes of 20 kW/m^2. With a further increase in the heat flux at 30 and 50 kW/m^2, matrix cracking increases, followed by complete resin burn-off and delamination [15] [16] [17]. However, in comparison to the literature, the residual post-fire flexural moduli for the composites are comparable to vinyl ester composites of similar compositions and higher than that of epoxy-glass fiber composites, potentially due to the higher GF content at 70% [18].

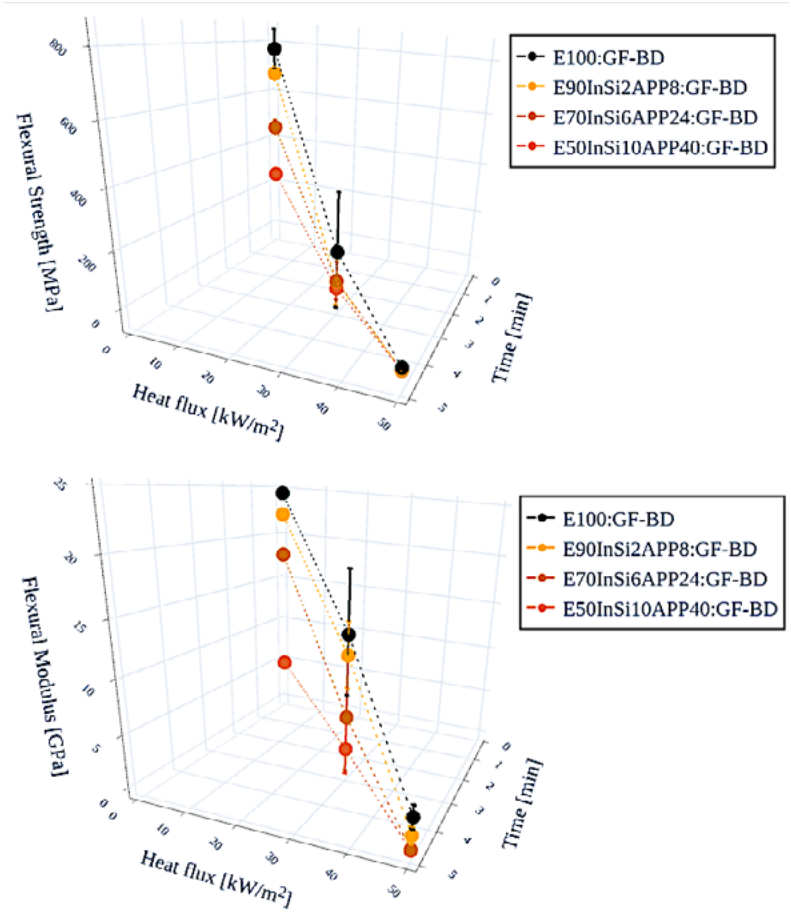

Figure 5. Comparison of the pre- and post-fire flexural strength (left) and moduli (right) after a fire exposure at 30 kW/m^2 for 3 mins and 50 kW/m^2 for 5 mins

3. Conclusions

In this investigation, a novel but facile approach was implemented to prepare and test the post-furnace and post-fire epoxy glass fiber composites (EP GFRCs) based on a Bisphenol A diglycidyl ether (DGEBA)-dicyandiamide (DICY)-Urone resin matrix and bidirectional glass fiber composites with a fiber weight content of 70%. The suggested method prevents undesirable edge effects and enables testing of the composites at a heat flux of up to 50 kW/m^2 and an exposure time of 5 minutes. These results show a significant improvement to the current state of the art where there are limited reproducible experimental studies on the post-fire flexural properties of EP GFRCs that involve actual ignition of the composites. The exposure to radiation at 400 °C for 1 and 2 minutes causes a decline in the flexural strength, presumably via increasing degradation of the matrix-fiber interface. In comparison to the literature, the residual post-fire flexural moduli for the composites are comparable to vinyl ester composites of similar compositions and higher than that of epoxy-glass fiber composites, potentially due to the higher GF content at 70%.

Abstract
This study investigates how pre-existing surface craters of leading edge protection coating used against rain erosion of wind turbine blades affect the maximum strains during impacts of rain droplets. Surface craters in the form of pinholes can form during the coating application process. The investigation is carried out by using finite element models of droplet impacts on surfaces with craters, where the impact velocity, droplet size, and crater position and size are varied. The simulations predict that the maximum strain is located at the crater walls and increases as the impact velocity and droplet size increase, and that craters closer to the central impact axis experience larger strains than craters placed farther away. The size of the crater was not predicted to have an influence on strains. The position of the maximum strain value was at the crater walls for all cases, and it was larger than for an impact on a flat surface. Observations from rain erosion tests suggest that some fractures initiate from pre-existing craters which act as weak points of otherwise highly resistant coatings.

1. Introduction

A reduction in the annual energy production (AEP) of wind turbines has been observed due to leading edge erosion (LEE) of rotor blades [1, 2]. One of the main drivers of LEE is repeated impacts of rain droplets near the tip of the blade, which occur at high impact speeds (80 – 120 m/s) [3]. The water inside the impacting droplets enters its compressible region at such impact speeds and may exert large contact pressures on the protective coating materials, in the order of hundreds of MPa. The impact load causes stress waves to propagate through the coating material which results in the initiation and propagation of cracks. Eventually, the cracks lead to the gradual erosion of the surface of the leading edge, and to a reduction of the aerodynamic efficiency of blades (Figure 1). Apart from AEP losses, LEE increases maintenance costs as repairs are required once erosion breaks through the protective coating layer and propagates into the composite substrates. The composite substrates have a much lower erosion resistance than the polyurethane-based protective coatings and thus damage may propagate unpredictably fast after breakthrough of the coating layer. If erosion of the composite layers becomes severe, even the entire blade may have to be replaced. It is thus important to have predictive models [4] for the erosion of the coating layer to be able to predict how much time is needed until erosion propagates into the composite substrate. To make accurate predictions, it is necessary to understand how erosion damage initiates. Observations from rain erosion tests suggest that damage initiates from areas with surface anomalies or defects and recent numerical studies have predicted elevated impact stresses in such areas [5, 6]. This study investigates the effect of pre-existing surface craters of the coating layer on maximum strains during rain droplet impacts, by using finite element simulations. The effects of impact velocity, droplet size, surface crater size and positions on the maximum principal strain values and their location are explored and then compared with observations from tests. The maximum strain values for impacts on

flat surfaces are also calculated and are predicted to be much smaller than those for surfaces with craters, suggesting that erosion damage initiates from areas with surface irregularities.

2. Methods

2.1. Impact finite element model

A finite element (FE) model that simulates the impact of a single water droplet on the coating layer of the leading edge is used to study the effect of pre-existing surface craters. The simulation is performed with the commercial code ABAQUS. A time-dependent explicit analysis that uses the coupled Eulerian-Lagrangian approach for the fluid-solid interaction is used and more details about the model can be found in references [7, 8]. Figures 2A and 2B present the element mesh of the model and how surface craters are included. The polyurethane-based coating is modelled with a combined hyperelastic and viscoelastic model to consider the loading rate effect. The coating's density is 1200 kg/m^3 and the parameters of the Yeoh model for the hyperelastic behavior are C_{10} = 292.271·10^6 Pa and D_1 = 2.0498·10^{10} Pa. The viscoelastic behavior is modelled with time domain Prony series with parameters that are given in Table 1. This material model is obtained by fitting the master curve from a dynamic mechanical analysis (DMA) test using the MCalibration software by PolymerFEM. For the water inside the droplet, a Us-Up equation of state with constants c_0 = 1483 m/s, s = 0 and Γ_0 = 0 is used. The thickness of the coating layer was 0.5 mm for all simulations. Quarter symmetry is used to reduce the computational cost.

The maximum tensile principal strains are used to study areas which are loaded more than others, since this quantity has been used in literature to predict lifetimes of rubber-like components [9], which behave similarly to polyurethane coatings. Impacts on flat surfaces are also studied to see how strain values change when including surface craters. Figure 2C presents a contour plot of the maximum tensile strain at every location of a cross section of the coating layer, for a flat impact surface.

2.2. Mesh sensitivity study

The sensitivity on mesh size is checked for two cases. For the first case, the impact surface is flat and for the second case, a surface pit is included in the model. The surface pit has a half-spherical shape of radius 0.1 mm, and its center is placed 0.2 mm away from the central impact axis. The impact velocity was 100 m/s and the droplet diameter was 2 mm for both cases. The element size is expressed as the number of elements per drop diameter (EPD). The results of the mesh sensitivity study are presented in Figure 3, where the time history of the maximum principal strain is plotted at the coating location where the maximum value is experienced. For both cases, a mesh size of 200 EPD provided sufficiently converged results and at the same time led to an affordable computational cost. This value was used to produce all the following results of this study.

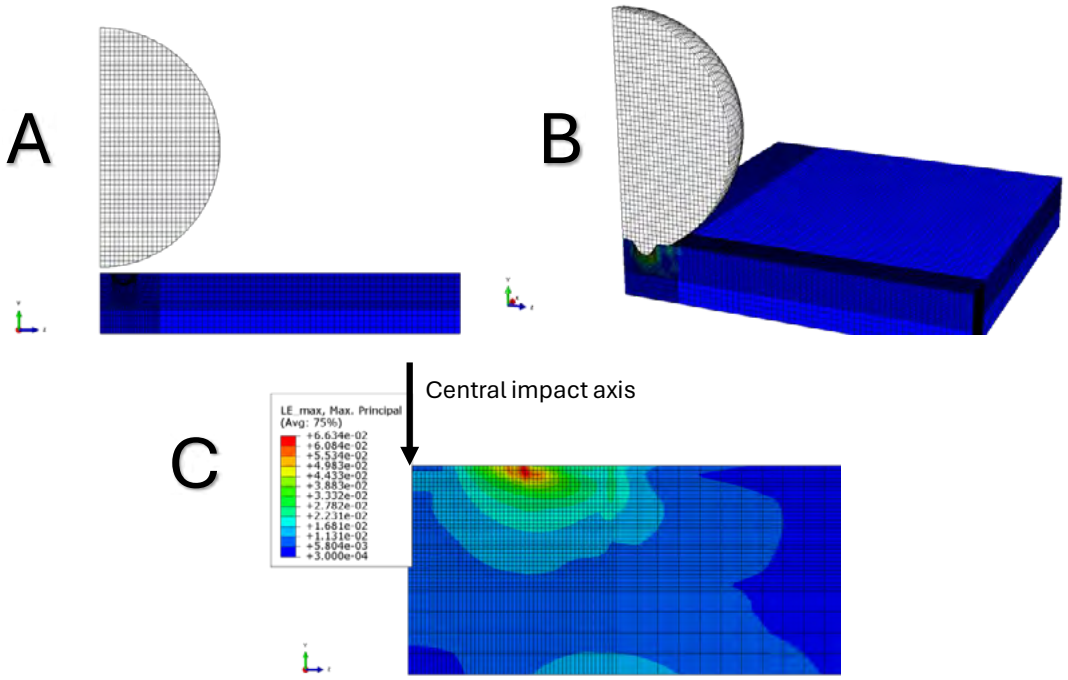

Figure 2. Finite element model of droplet impact on the protective coating layer (A), image during simulation as the water flows into a pre-existing surface defect (B) and the maximum tensile principal strains contour plot for an impact on a flat surface with a 2 mm droplet diameter and 100 m/s impact velocity (C).

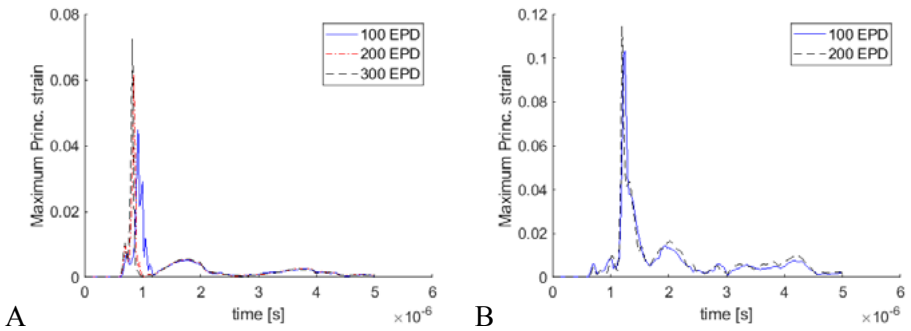

Figure 3. Mesh sensitivity study for impacts on a flat surface (A) and a surface with a pit (B). The impact velocity was 100 m/s, and the droplet diameter was 2 mm for both cases.

3. Results

3.1. Effect of impact velocity and droplet size

A half-spherical surface pit with a radius of 0.1 mm was used to check how the impact velocity affects the maximum principal strain (MPS) values. The pit center was placed 0.2 mm away from the impact axis and a droplet diameter of 2 mm was used for all impact velocity cases. The contours of the maximum MPS value at each point on a cross section of the coating layer that contains the surface pit are presented in Figure 4, for four impact velocities. The same contour plot is used in Figure 5, where now the droplet size varies, and the impact speed is 100 m/s for the four examined cases. The main observation for all of the cases is that the largest MPS values are located at approximately the same location at the wall of the surface pit. The maximum MPS values are examined in more detail in section 3.3.

3.2. Effect of pit location and size

Now the distance between the center of surface pit from the central impact axis is varied. The radius of the pit is again 0.1 mm while the impact velocity and droplet diameter are 100 m/s and 2 mm, respectively. The contour plots of the maximum MPS for four different locations of the pit are presented in Figure 6. The location of the largest MPS values now changes with the distance of the pit. When the pit is directly below the impacting droplet, the maximum MPS value is found at the base of the tip. The location of the maximum MPS rotates to the side of the wall of the pit as the distance from the impact axis increases. The effect of the pit size is also examined by varying the radius of the pit. The distance from the impact axis is 0.2 mm for all cases and the impact velocity and drop size are the same as the for Figure 5. The contours for this case are presented in Figure 7. Again, the maximum MPS values are found at the right side of the pit walls, and their location with respect to the parametric circumferential position seem to be independent of the pit radius.

3.3. Graphs of maximum tensile strain values versus the examined parameters

To check how each of the examined parameters influence the maximum MPS, the maximum MPS value is plotted against each parameter value in Figure 8. The maximum MPS value for the flat impact surface is also plotted in Figure 8A and 8B, for comparison. The simulations predict that the maximum tensile principal strain inside the pit increases as the impact velocity increases. The same trend is predicted for increases in droplet diameter values. The maximum strains for the surfaces with pits are larger than those of the flat impact surface, by a factor of approximately 1.5 for the same impact speed and droplet size. The distance of the surface pits is also predicted to be important as smaller distances led to larger strains in Figure 8C. The simulations do not predict a dependence on the size of the pit for the examined geometry, as observed in Figure 8D.

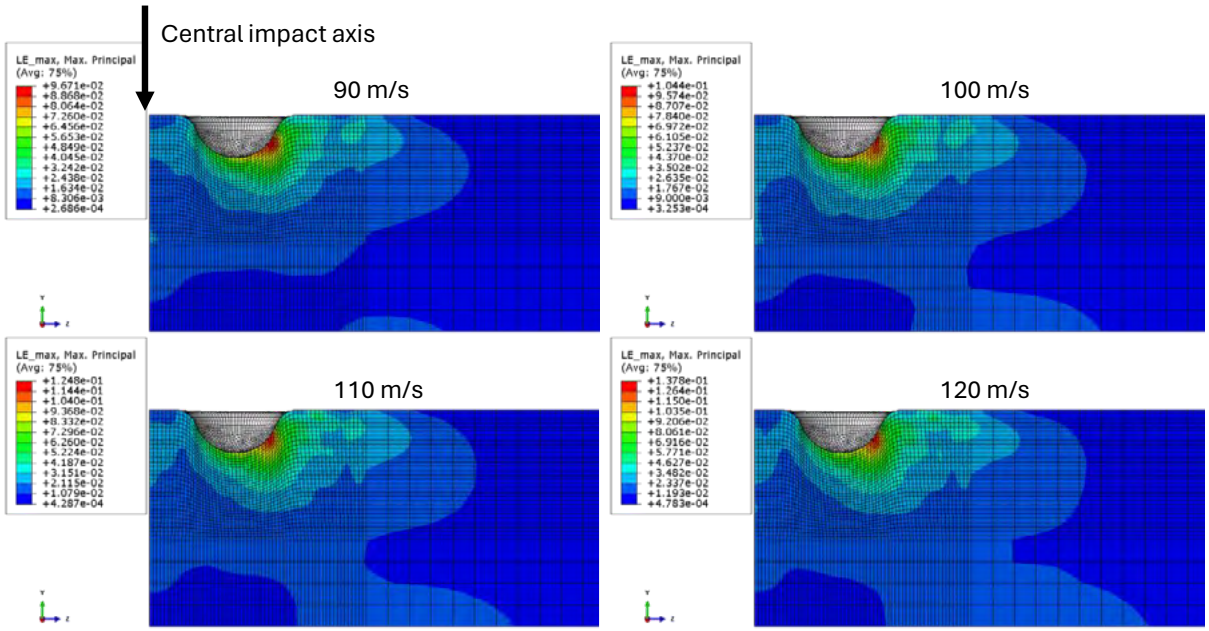

Figure 4. Contour plots of the maximum tensile principal strain value on a cross section of the coating layer which contains a surface pit. Four impact velocity cases: 90 m/s, 100 m/s, 110 m/s and 120 m/s. Droplet diameter 2 mm.

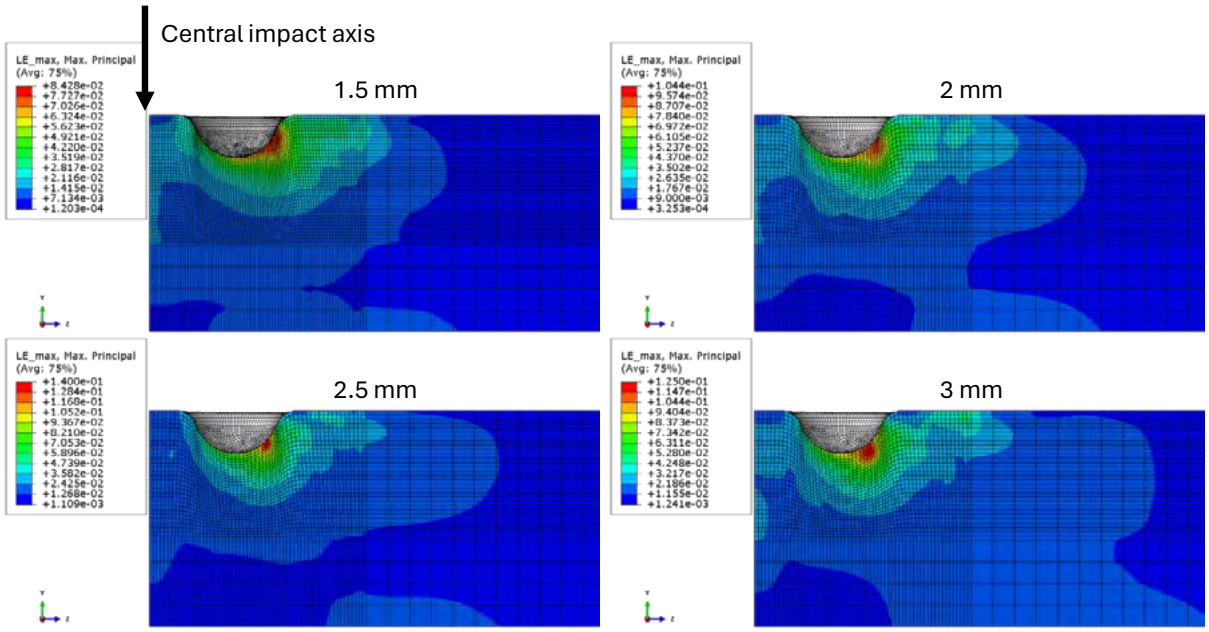

Figure 5. Contour plots of the maximum tensile principal strain value on a cross section of the coating layer which contains a surface pit. Four droplet diameter cases: 1.5 mm, 2 mm, 2.5 mm, and 3 mm. Impact velocity 100 m/s.

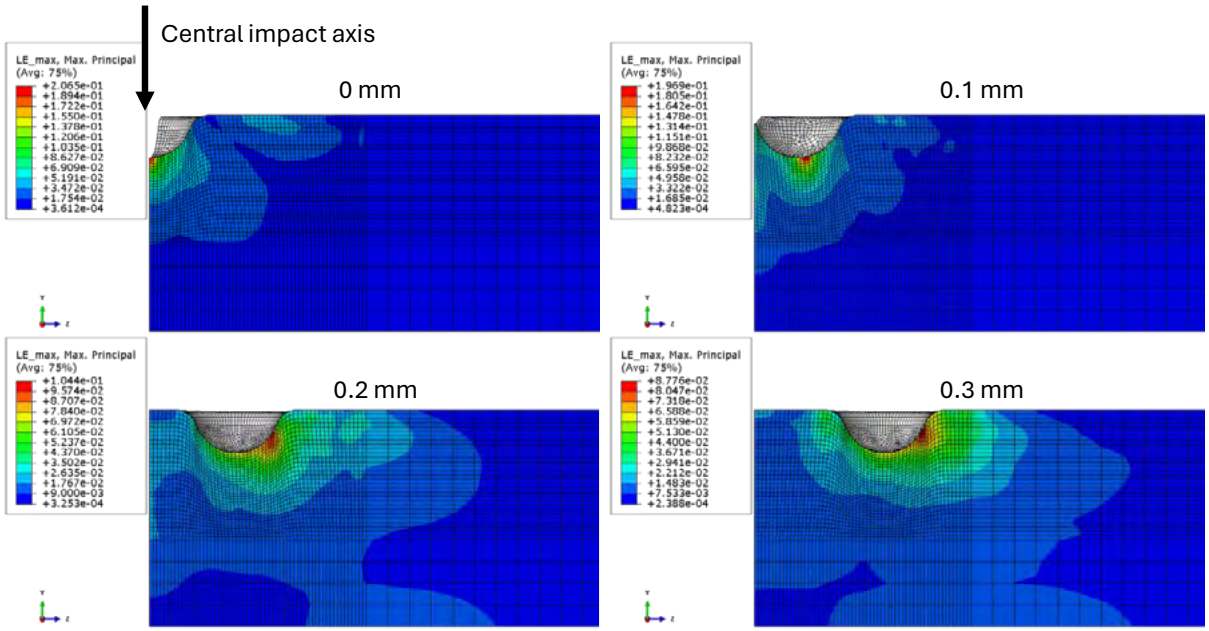

Figure 6. Contour plots of the maximum tensile principal strain value on a cross section of the coating layer which contains a surface pit. Four distance values between the pit and the impact axis: 0 mm, 0.1 mm, 0.2 mm, and 0.3 mm. Impact velocity 100 m/s and droplet diameter 2 mm.

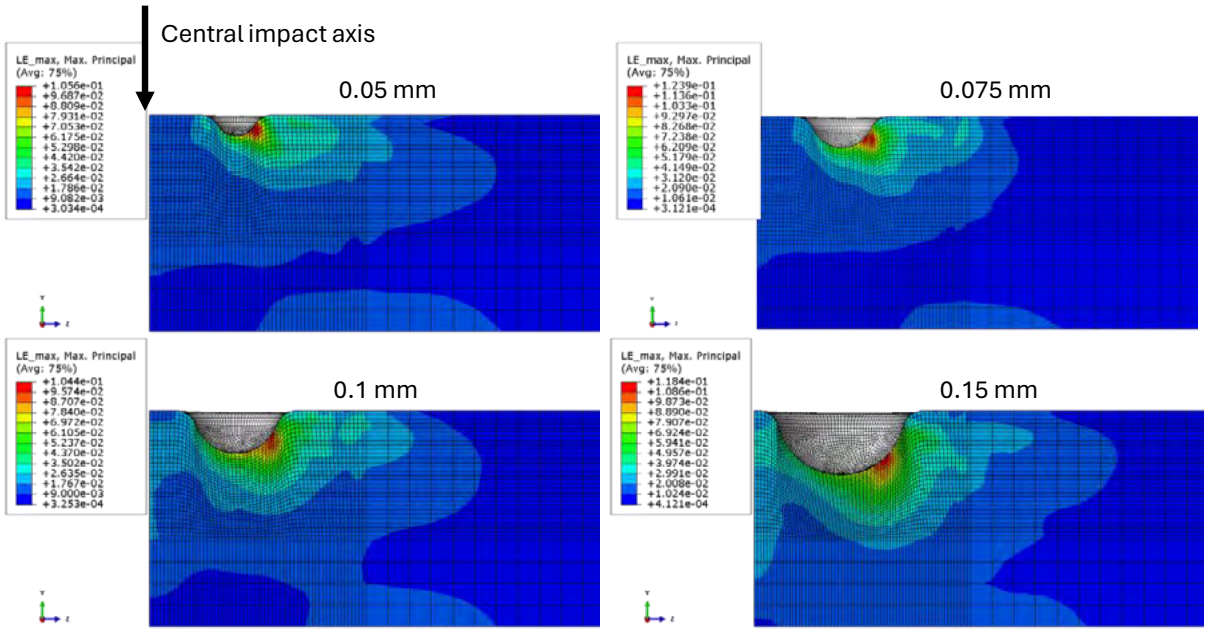

Figure 7. Contour plots of the maximum tensile principal strain value on a cross section of the coating layer which contains a surface pit. Four pit radius values: 0.05 mm, 0.075 mm, 0.1 mm, and 0.15 mm. Impact velocity 100 m/s and droplet diameter 2 mm.

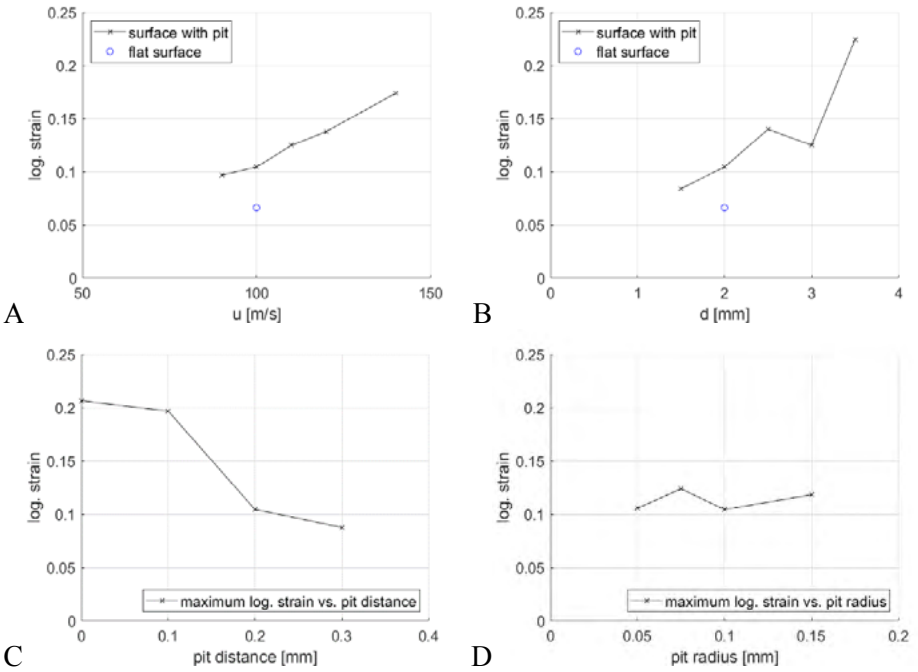

Figure 8. Maximum tensile principal strain versus impact velocity for drop diameter 2 mm (A), droplet diameter for impact velocity 100 m/s (B), pit distance for impact velocity 100 m/s and drop size 2 mm (C), pit radius for impact velocity 100 m/s and drop size 2 mm (D).

4. Experimental observations

Experimental images from rain erosion tests where failure seems to have initiated from pre-existing surface craters are presented in Figure 9. The locations of the pre-existing craters are indicated by arrows and the location where failure seems to initiate is at the walls of craters, similar to the observations from the simulations. Once failure initiates, the propagation direction seems to cause craters to grow in width and in some cases, cracks propagate deep into the coating layer and reach all the way down to the substrates.

5. Conclusions

In this study, the effect of pre-existing surface defects during rain droplet impacts on leading edge protection polyurethane coatings was investigated. A coupled Eulerian-Lagrangian approach was used to account for the large deformations of the droplet and study the fluid-solid interaction. The simulations predicted that the walls of surface craters experience the largest tensile strains during the impact, possibly due to the outward flow of water during the droplet splash. The effects of impact velocity, droplet size, crater position and size on the maximum principal strains at the walls of pre-existing surface craters were investigated. It was predicted that strain values at those locations increase with the impact velocity and droplet size. The location of the craters relative to the central impact axis was also predicted to influence strain values and the location of the maximum. More specifically, craters closer to the impact axis experienced larger strains than craters placed further away, and the position of the maximum value rotated from the base of the crater to the side of the crater walls as the crater moved away from the impact axis. The size of the crater was not predicted to have a strong influence on the maximum strain. Images of failed coating locations from rain erosion tests suggest that fracture initiates from pre-existing surface craters, and this could be justified by the results of the simulations. Coating surfaces with craters experienced larger strains than flat surfaces in the simulations, and this suggests that the state of the surface when performing lifetime calculations or tests should be considered.

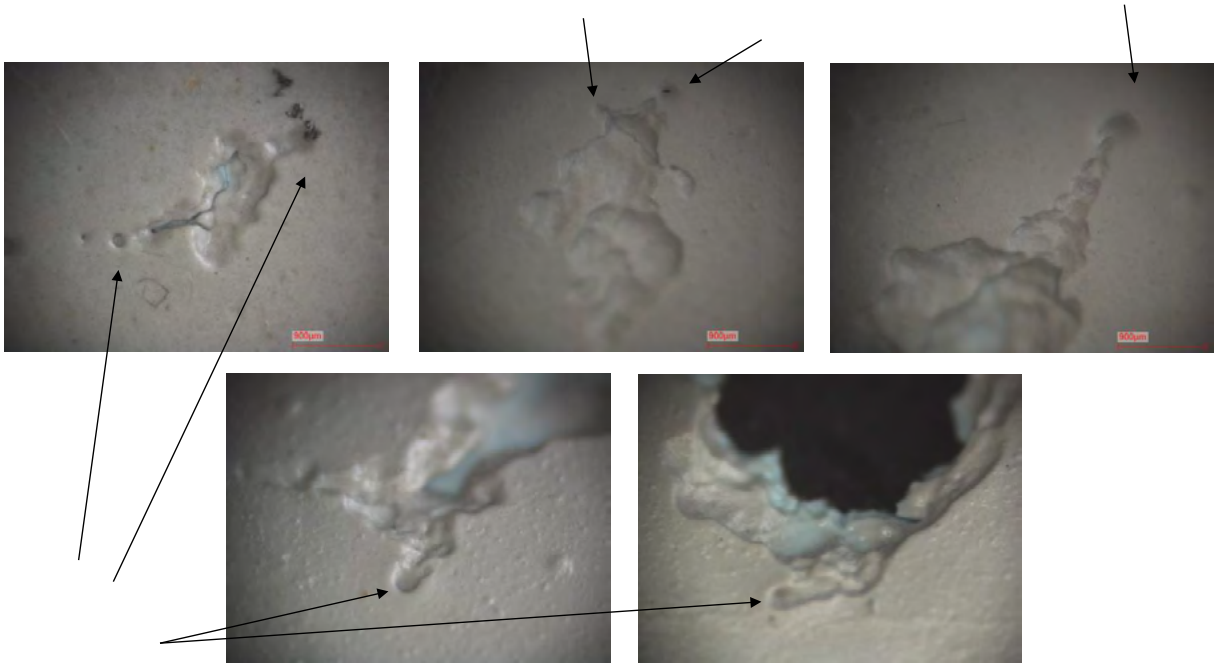

Figure 9. Images of failed locations from rain erosion tests. Failure seems to have initiated from pre-existing surface pits. The location of the pre-existing pits is shown by arrows.

Acknowledgments
The authors would like to acknowledge the project DURALEDGE for providing the rain erosion test samples from which the failure images in this work were extracted.

Abstract
Fibre-reinforced polymers (FRPs) are increasingly used for mobility applications due to their excellent properties in lightweight design. In addition to adequate mechanical properties, flame retardancy is often a critical requirement. Because FRPs are usually combustible, flame retardants (FRs) are required. However, they can impair the properties of composites and should be used as little as possible. Typically, the surfaces of structural components are exposed to flames, therefore this work focuses on the protection of the outer layers with red phosphorus (RP). This study introduces a process containing a pre-curing of modified layers based on thermokinetic models. Thereby, the RP remains in the desired layers and its content can be kept minimal. In addition, three-point bending tests showed an adequate bonding of the pre-cured and non-pre-cured plies. There are several standardised fire tests for FRPs, but these usually require large test specimens and special devices. As part of this study, flame tests were developed to enable a qualitative comparison of different laminates using as little material and equipment as possible. Within those, it was found among other things that despite a saving of up to 82.5 wt.% RP related to homogeneously flame-retardant FRPs, significant improvements were achieved compared to unmodified configurations.

1. Introduction

Particularly in mobility applications, the protection of people is the priority. Fires must be delayed long enough to allow people to evacuate out of the danger zone. FRPs are now increasingly used to save resources and fuel, as their high specific strength and stiffness offer great potential for lightweight construction. However, compared to metal materials, most FRPs are not intrinsically flame-retardant, which means that flame retardants have to be added. Epoxy resins are widely used as matrix materials for FRPs. Without the use of FRs, epoxies ignite at approx. 375-425 °C [1].

The required factors for the development and maintenance of a fire can be visualised in a fire tetrahedron (Figure 1, left). A fire is caused by an external HEAT source, which decomposes the polymer in the pyrolysis zone. In the polymer, chemical bonds are decomposed and short-chain pyrolysis gases are produced, which serve as FUEL. The volatile component then forms a highly flammable air-gas mixture with atmospheric OXYGEN. Heat is released in the process and partially fed back into the polymer material. The process produces highly reactive OH and H radicals, which again generate new radicals (CHAIN REACTION). By reaching the auto-ignition temperature, the polymer ignites itself, which results in new heat and the process progresses. This thermal feedback is shown in Figure 1 (right). Over time, the pyrolysis zone moves continuously through the polymer material. The combustion produces carbon monoxide, carbon dioxide, carbon and water. If there is a lack of fuel or oxygen or if heat is

removed from the system, one of the necessary factors is no longer present and the fire extinguishes itself. Flame retardants can also interrupt the combustion process by suppressing at least one of the necessary parameters.

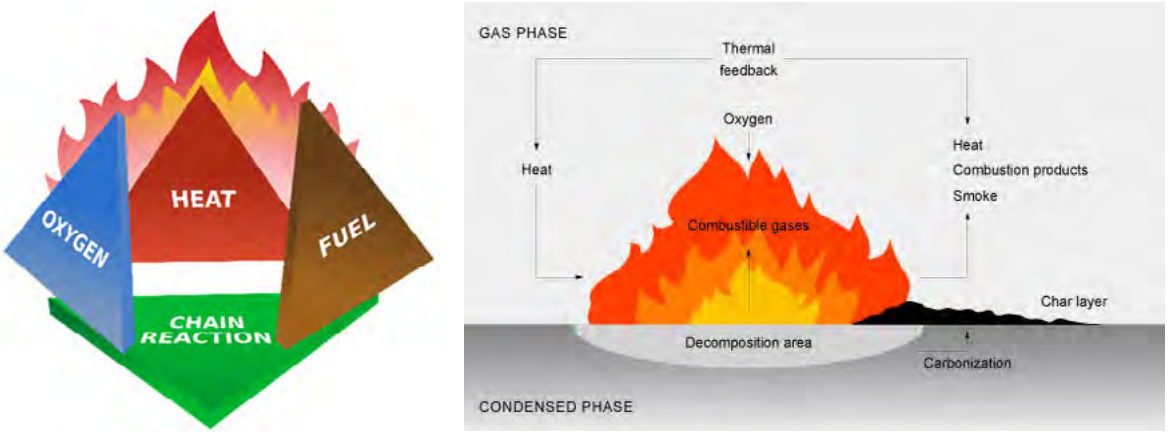

Figure 1. Left: Fire tetrahedron [2]. Right: Combustion process [3].

The mechanisms of FR are based on chemical and/or physical processes which occur in the gas and/or solid phase [4]. For example, the thermal decomposition of additivated red phosphorus above approx. 300 °C leads to a conversion to phosphoric acid, which extracts water from the pyrolysing substrate. In the solid phase, the phosphoric acid and the polymer substrate esterify to form a char (carbonisation), shielding heat and oxygen transport [5].

Various tests can be carried out to assess the fire behaviour. However, the real fire behaviour of materials depends on many other factors, such as ventilation, heat transport, the component itself or storage conditions. However, real room fire tests are very time-consuming and expensive. The fire behaviour of small test specimens can be tested on lab scale under ideal conditions. The influencing parameters of specimen geometry, ignition source, oxygen supply and heat yield can be controlled. UL 94 flame tests are frequently used, in which samples of the matrix material are flamed twice for 10 seconds with a defined Bunsen burner flame e.g. in a vertical flame test. After each flame treatment, the afterflame time is noted and the dripping of the material is analysed, allowing different classifications of the material as a result. In cone calorimetry, a sample is exposed horizontally to a constant heat flow for the duration of the test. In addition, a spark igniter is used, which ignites the material as soon as an ignitable mixture is created in the gas phase. The aim is to determine the heat release rate through oxygen consumption. In addition, the time-to-ignition (tti) and the mass loss of the sample, as well as the total amount of heat released and the maximum heat release rate are determined. In contrast to the UL 94 test, in which flammability and burning behaviour are examined, the fire process is determined energetically. In aircraft construction, test specimens are tested for their flame resistance following the "aircraft materials fire test handbook". The sample is clamped horizontally over a Bunsen burner and flamed for 15 seconds. The burn rate is determined. A metal mould with specified internal dimensions is used as a holder, which itself is non-combustible and corrosion-resistant. When positioning the mould, the side that is exposed to the flames in the real application must be placed towards the flame. Other standards, such as ASTM F776 according to DOT/FAA/AR-00/12 and DIN EN 60695-11-10, also provide methods for analysing horizontally tested test specimens, whereby different fire lengths are examined.

For mobility applications, these horizontal tests are more realistic, as FRPs are usually only exposed to potential flames on the surface and not over their cross-section. This study deals with the realisation and evaluation of FRs only at the surface and not over the entire cross-section of the FRP, thus reducing the overall amount of flame retardants. For instance, most flame retardants generally have a negative

influence on mechanical properties [6], which is why a reduction in the FR content is accompanied by a less pronounced influence on mechanical performance. In industrial practice, surface flame retardancy is sometimes achieved using gel coats or coatings [4]. Due to the additional material, this minimises the lightweight construction potential. The method investigated in this study examines the direct FR modification of individual layers of the FRP.

2. Materials and Methods

In the present study, the DGEBA resin 827 (*Epikote™ 827*, Westlake, Houston, USA) is cured with the amine curing agent 137H (*EPIKURE™ MGS™ RIMH 137*, Westlake, Houston, USA). RP (Red Phosphorus, Exolit RP 607, Clariant, Muttenz, Suisse) is added as a flame retardant. Composites were manufactured using 600 g/m² unidirectional glass fibre fabrics with 10 % backing fibres (R&G Faserverbundwerkstoffe GmbH, Waldenbuch, Germany). A 30 g/m² non-woven (R&G Faserverbundwerkstoffe GmbH, Waldenbuch, Germany) was partly added to the surfaces. As a release agent, Mikon® W64+ (Münch Chemie International GmbH, Weinheim, Germany) was used.

Stochiometric mixtures of 827 and 137H (weight shares: 100:28.57) are mixed and degassed in a Thinky Mixer ARE-250 (THINKY U.S.A., INC., Laguna Hills, USA) and a vacuum stirrer at 200 min^{-1} for at least 30 min. For the modified epoxies, RP was mixed into the epoxy system before. In the following, given percentages of RP refer to the relative mass of RP related to the total mass of resin and curing agent. To manufacture 4 mm thick plates, handlaminates were manufactured and cured vacuum-assisted for 8 h at 50 °C with a heating mat (msquare GmbH, Stuttgart, Germany) and post-cured for 16 h at 80 °C in a convection oven. Commercial prepregs are pre-cured to approx. 25 – 35 % which is described in the literature as *B-stage* [7; 8]. Various temperatures can be selected to realise the desired degree of curing. In this work, pre-curing is carried out at 50 °C, analogous to the complete curing, introduced before. Thermokinetic methods were conducted and validated via FTIR and DSC as described in [9] to determine the required time for pre-curing. After an initial study, 90 min at 50 °C (≈ 40 % pre-curing) is necessary to achieve a prepreg that is easy to process. Fibre-volume contents are approx. 40%, determined on four specimens for each configuration via calzination at 600 °C for 4 h. Table 1 gives an overview of the manufactured plates and their nomenclature.

Table 1. Manufactured Configurations with their amount of RP per plate (250 mm x 250 mm). NW: Non-woven fabric, *: pre-cured, x%: mass-related amount of RP.

Configuration	*Scheme*	*Absolut RP content (g)*	*Global RP fraction (wt%)*
$[0]_8$		0	0
$[NW,0_8,NW]$/ $[NW^*,0^*,0_7,NW]$		0	0
$[NW,0_8,NW]^{3\%}$		4	3
$[NW,0_8,NW]^{12\%}$		16	12
$[NW^{12\%*},0^{12\%*},0_7,NW]$		2.8	2.1

Specimens were cut with an ATM Brillant 265 saw (ATM Qness GmbH, Germany) and all specimens were conditioned in a vacuum oven at 40 °C for 48 h before testing. Three-point bending tests were performed based on DIN EN ISO 14125. Unmodified hand laminates with pre-curing [NW*,0*,0_7,NW] were tested to eliminate the influence of RP on mechanical properties. Five specimens were tested with the pre-cured part on the tensile side as well as on the compression side with a universal testing machine *Allroundline Z10* (Zwick Roell, Ulm, Germany).

The conducted flame tests were tailored to the flame-retardant surface modifications of the laminates considering methodical approaches of conventional test methods (see introduction). The 40 mm flame of a bunsen burner (0,7 kW, methane gas, technical grade) was applied centred at a distance of 25 mm to the surface of 100 mm x 100 mm specimens. Considering various flame tests, described in the introduction, *Test A* used ten flame applications of 60 s. A 180 s flame treatment was added afterwards. Between every flame treatment, the mass loss and the burning and afterflame times were evaluated via postprocessing of video recordings during the tests. The more, as a second test (*Test B*), a single flame treatment over 180 s was conducted. To prevent the flame from spreading over the edges, a steel frame was utilised. In addition, three temperature sensors (type K, Figure 2, left, 1-3) were installed to continuously measure the temperature development during flame treatment on the top (centred) and bottom (edge area) of the test specimen and on the frame. The tests are conducted in a *HVFAA Horizontal Vertical Flame Chamber* (Atlas Material Testing Technology, Mount Prospect, Illinois, USA).

3. Results and Discussion

3.1 Pre-curing of the modified layers

Vacuum-assisted hand lamination is a simple process to manufacture composites with changing matrices. One typical problem while curing plies with and without flame retardants is the convey of particles into unmodified layers (Figure 3, left). As a result, the desired particle content on the surface is lower than intended. By pre-curing the modified plies, it was possible to ensure that the RP remained in the desired layers so that the filler content could be kept as low as necessary (Figure 3, right).

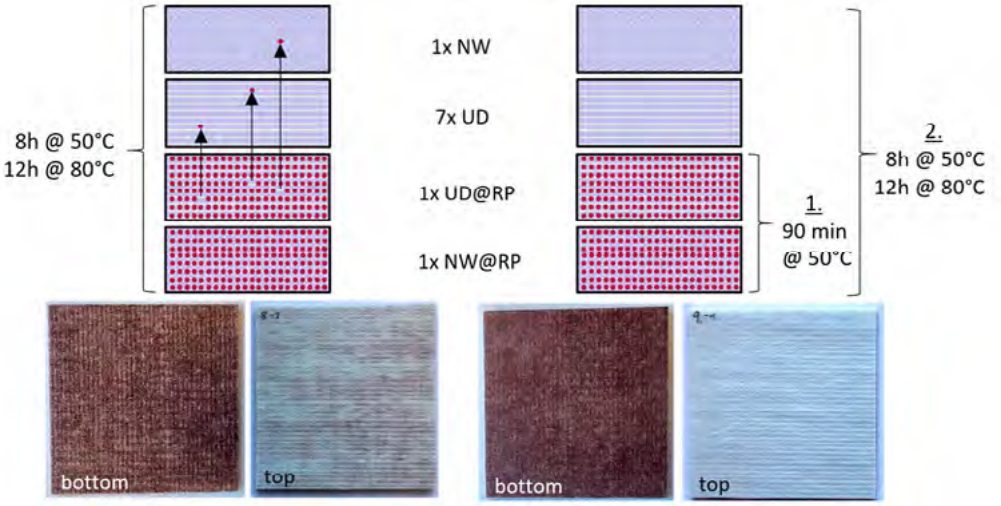

Figure 3. GFRPs containing partially modified layers without pre-curing (left) and pre-cured (right). NW: Non-woven fabric, UD: Unidirectional glass-fibre fabric; RP: Red Phosphorus.

3.2. Three-point bending tests

To verify an adequate bonding between the pre-cured and non-pre-cured layers, three-point bending tests were conducted. The configuration [NW*,0*,0_7,NW], tested with the pre-cured plies under compression load on the top of the test setup achieved bending strengths of 650.32 ± 39.10 MPa. With the pre-cured layers under tensile load, bending strengths of 641.66 ± 30.23 MPa were reached which means that no difference exceeding the standard deviation could be found. Furthermore, the specimens delaminated at other interfaces than between the pre-cured and non-pre-cured plies. This is shown in Figure 4 exemplary for the configuration [$NW^{12\%}$*,$0^{12\%}$*,0_7,NW], because the pre-cured layers are visually distinguishable in this case. Therefore, it can be stated, that the bonding is adequate and the pre-curing has no significant negative influence on the mechanical properties. For the flame tests performed in this study, it is sufficient that the adhesion is not so poor as to result in significant mechanical weakening. Therefore, additional tests to vary the stress ratios in the target interface (e.g., interlaminar shear strength, short beam shear) or cost-intensive double cantilever tests are not performed.

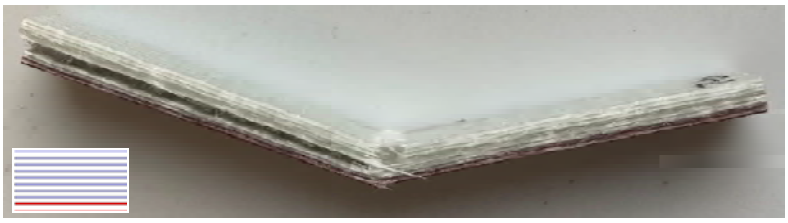

Figure 4. Specimen of configuration [$NW^{12\%*}$,$0^{12\%*}$,0_7,NW] after three-point bending test.

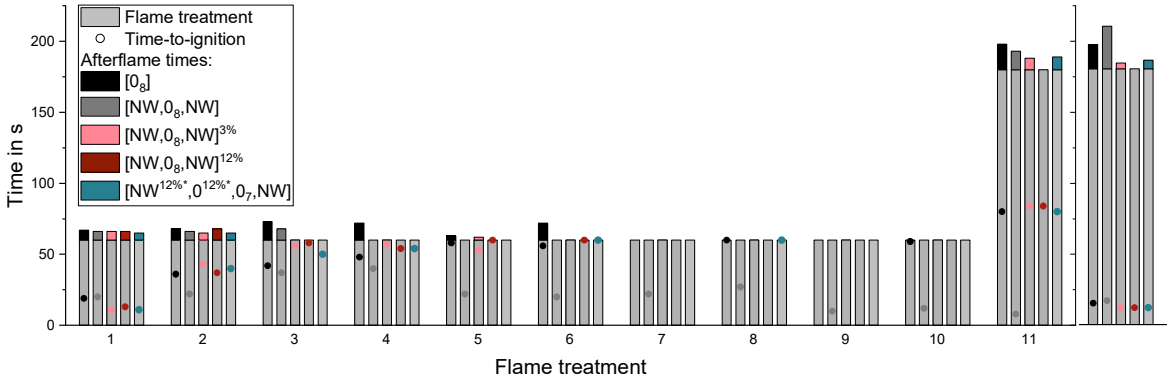
3.3. Tailored flame tests

Figure 5 (left) shows the results of the eleven flame treatments of *Test A*, while Figure 5 (right) displays the single 180 s flame treatment of *Test B*. The dots demonstrate the time-to-ignition (tti) within the flaming time (60 s or 180 s, grey column). On top of this column, the afterflame time is shown.

Firstly, the influence of the NW is analysed by comparing [0_8] with [NW,0_8,NW]. In addition to the positive influence on the surface quality, the non-woven fabric is beneficial for the GFRPs behaviour against fire, because it prevents the afterflame time after A3 while without NW six flame treatments

lead to an afterflame time. Considering the images of the flame-treated surface of the specimens (Table 2), it is noticeable that the fibres without the NW are already exposed after the first flame treatment, so that the matrix of the lower layers is more freely accessible, while the NW forms a closed layer above the load-bearing fibre layers. The matrix content is comparatively high in the NW, so more carbon is present, which can carbonise and form a char. If the number of flame treatments increases, the glass fibre non-woven cannot withstand any more, which is additionally noticeable in an afterflame time of 13 s after *A11*. It is also noticeable that the ttis with NW are significantly lower than without, however this does not have a negative influence on the afterflame times.



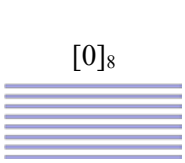


Figure 5. Afterflame times and tti in *Test A* with several flame treatments (left) and *Test B (right)*.

When using RP, no afterflame times can be observed for any of the configurations analysed from the third flame treatment onwards. The configurations only differ in the three-minute flame treatments. While no afterflame times can be determined for the 12 % modified configuration in *Test A11* and *B*, the configuration modified with 3 % RP throughout burns for eight seconds (*A11*) resp. four seconds in *Test B*. The only locally modified configuration is in a comparable range in terms of afterflame times. However, Table 2 shows that fewer fibres are exposed after *A11* than with [NW,0$_8$,NW]$^{3\%}$. On the other hand, *Test B* leads to comparable surfaces. Table 2 also shows that the modified configurations have a different char structure to the unmodified configurations due to the reaction of the RP described in the introduction. In general, *Test B* leads to a different visual impression. The load-bearing fibres are less exposed without prior flame treatment for all configurations with NW.

Table 2. Flamed surfaces after first, fifth and last flame treatment of *Test A* and after *Test B*.

Configuration	*A1*	*A5*	*A11*	*B*
[0]$_8$				
[NW,0$_8$,NW]				

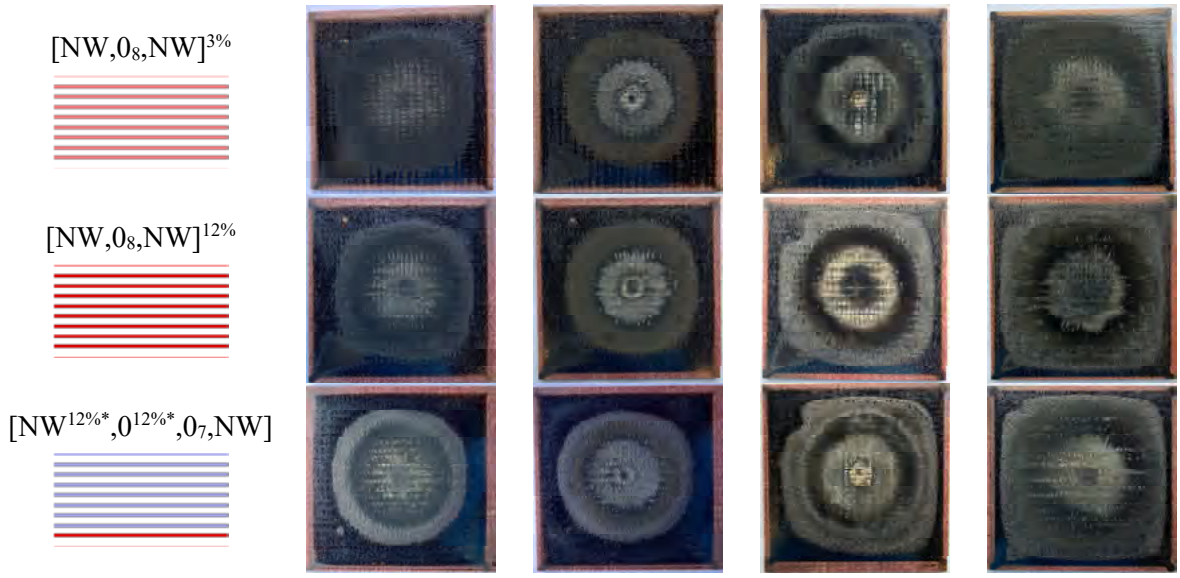

Figure 6 shows the temperature development over three minutes (*A11* and *B*) exemplary for the configuration [NW,0$_8$,NW]. However, in qualitative terms, the curve can be observed in the same way for all configurations. The temperature on the upper side initially rises more slowly, but the maximum measured value then exceeds that of test B as the flame exposure time increases. As described in the introduction, the shielding due to the formation of a char by the individual flame treatments therefore leads to a change in heat conduction. As the duration of the flame treatment increases, the heat conduction across the cross-section appears to increase proportionately more. The reason for this may be the 'failure' of the NW and thus the loss of the char built up on it. On the bottom side, the temperature is measured at the edge as described. In contrast to *Test B*, in *Test A11* a plateau at a comparatively lower temperature level is formed. In this case, the temperature also rises to a higher maximum value with further flame treatment.

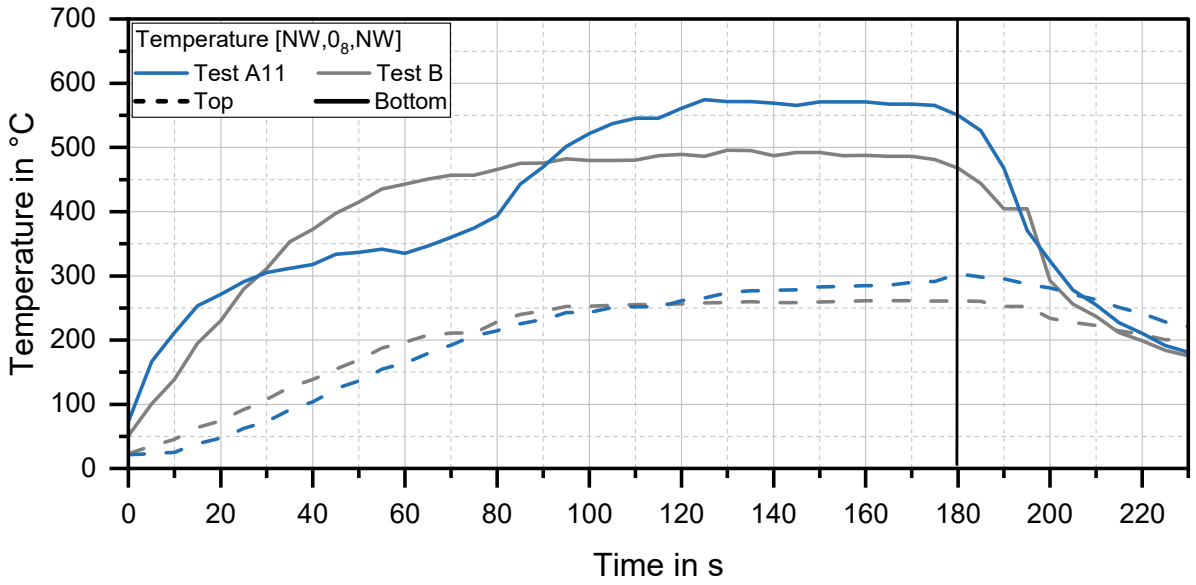

Figure 6. Temperatures on the flamed surface (bottom) and the top of the specimen [NW,0$_8$,NW]. 180 s flame treatment after 10 x 60 s (*Test A11*) and *Test B*.

4. Conclusions

With the methodology used, it was possible to show that the pre-curing determined from thermokinetic methods ensures that the modification remains in the desired plies and that the FR content can be kept as low as necessary. In addition, mechanical properties were not changed beyond the standard deviation. The test scenarios developed from various existing flame tests provide a screening method for making qualitative comparisons between different flame retardants or flame retardant proportions and their distribution in the laminate. It could be shown that the modification of individual layers with a small amount of FR already shows great improvements in fire behaviour compared to unmodified configurations. In a direct comparison of the heterogeneously modified configuration $[NW^{12\%*},0^{12\%*},0_7,NW]$ with the configuration $[NW,0_8,NW]^{3\%}$, approx. one third of FR can already be saved and similar results can be achieved concerning afterflame times. According to optical analyses, the heterogeneously modified specimen is even less affected. Compared to the configuration modified with 12 % throughout, 82.5 wt.% RP can be saved. Only with increasing fire load (180 s flame exposure), differences are recognisable. In addition, the use of a NW is not only useful for uniform surface qualities but also for fire protection applications, as the high matrix content leads to a more pronounced char.

It should be noted that the results are comparable within the study, but a quantified comparison, for example when using other burners, is not possible. As flame retardancy is highly component-dependent, it is necessary to examine the required amount of modificated plies by using suitable large-scale tests for the desired application.

Keywords: guided waves, delamination, CFRP, 1D-CNN, damage detection

Abstract
This study assesses the effectiveness of Ultrasonic Guided Waves (UGWs) combined with a 1D Convolutional Neural Network (1D-CNN) for detecting and classifying delamination in carbon fiber reinforced polymer (CFRP) laminates. A dataset of 912000 waveforms from undamaged and damaged CFRP plates was analyzed using a shallow 1D-CNN with two convolutional blocks and a fully connected layer, designed for computational efficiency and robust generalization. The model processed data with a 70-30-10 split for training, validation, and testing, achieving an average accuracy of 90.27%. The analysis showed high recall and precision rates - over 90% in about 75% of classes and over 95% in about 40% of the classes. These metrics were particularly significant when the waveforms propagated parallel to the fiber direction: averaging Precision, Recall, and F1-Score at 96.2%. They highlighted the effectiveness of the model over a range of delamination depths and orientations. However, performance differences were observed in cases with deeper delamination and perpendicular wave propagation due to suboptimal wave excitation. These results highlight the potential of 1D-CNNs to effectively classify complex UGW signals for real-time health monitoring of structural composite components.

1. Introduction

Lightweight and resilient, Carbon-Fiber Reinforced Polymer (CFRP) laminates are essential in aerospace, energy, and automotive industries due to their superior mechanical properties [1]. However, these composites are susceptible to impacts, fatigue, and latent defects over their service life [2], requiring real-time monitoring and rapid damage detection.

Ultrasonic Guided Waves (UGWs) have emerged as a leading method for detecting, localizing, and classifying such damages, providing reliable identification of invisible flaws and critical insights into material integrity [3, 4]. However, traditional damage assessment using UGWs relies heavily on expert analysis, which can be slow, costly, and error-prone. These are problematic in safety-critical environments where fast and accurate assessments are critical.

To overcome these challenges, Convolutional Neural Networks (CNNs) have been used for their data analysis capabilities, although they require significant computational resources and large training datasets. In contrast, recently developed 1D Convolutional Neural Networks (1D-CNNs) offer a more efficient alternative to 2D-CNNs for analyzing one-dimensional signals, such as patient ECGs, bearing vibrations and waveforms. With simpler kernel structures, 1D-CNNs are less computationally demanding, facilitating deployment on consumer-level hardware, and enabling real-time applications in structural health monitoring and anomaly detection [5].

UGW-based 1D-CNNs have recently been applied to damage detection in aluminum [6] and metal [7] plates. However, their use in composite laminates, which exhibit more complex multimodal and dispersive behavior, has not yet been reported.

In this research, a 1D-CNN is used to detect and classify 20 mm x 20 mm square delamination in eight-layer CFRP cross-ply laminates with a $[90_2/0_2]_S$ stacking sequence. One intact and three artificially flawed specimens were prepared with delamination located at different depths (0.28 mm, 0.56 mm, and 0.84 mm). The CFRP plates were examined using a laser ultrasonic visualization inspector. One-dimensional waveforms were recorded using a wideband piezoelectric transducer. The resulting dataset, after Z-Score normalization, contained 228000 waveforms per plate, totaling 912000 signals.
The designed 1D-CNN architecture, with two convolutional blocks and one fully connected layer, inputs normalized data directly from the sensors to closely mimic real-time monitoring. The output layer categorizes twelve classes, assigning three classes per plate based on the direction of waveform propagation.
The organization of this paper is as follows: Chapter 2 provides a comprehensive overview of the materials used and the experimental setup. Chapter 3 describes the 1D-CNN architecture developed for this study. Chapter 4 examines and discusses the classification results achieved by the model. Finally, Chapter 5 outlines the conclusions derived from this research.

2. Materials and experimental setup

This study utilizes a UGW-based 1D-CNN to detect and classify delamination in eight-layer CFRP cross-ply laminates with a $[90_2/0_2]_S$ stacking sequence, as shown in Figure 1a. The anisotropic stiffness matrix components and thermal properties of the 0° ply, assuming 60% fiber volume fraction, are detailed in Table 1 [8].
Laminate plates, measuring 200 mm x 200 mm with a total thickness of 1.12 mm and individual plies 0.14 mm thick, were produced in four variants. The undamaged specimen is labeled "IO", while the other three contain a central 20 mm x 20 mm delamination at varying depths: "R1" between the 4th and 5th ply (z=0.54 mm), "R2" between the 6th and 7th ply (z=0.84 mm), and "R3" between the 2nd and 3rd ply (z=0.28 mm), as shown in Figure 1b.
A piezoelectric sensor (AE-900S-WB, NF CO., LTD.) with a bandwidth from 0.3 MHz to 1.5 MHz was attached to the top surface of the specimen outside the scanned area to detect the temporal waveforms generated by the laser ultrasonics (Figure 1c). The sensor positions were adjusted to vary the wave propagation directions relative to the fiber direction of the top ply, allowing for the collection of UGW waveforms in three orientations: perpendicular (0°, "PA"), diagonal (45°, "PB"), and parallel (90°, "PC") to the top ply fiber orientation, detailed in Figure 1d.

Table 1. Thermo-mechanical properties of the homogenized CFRP unidirectional ply with 0° fiber orientation (T700SC/2500 Toray)

Elastic Stiffness Coefficient		Specific Heat	Heat Conduction Coefficient		Thermal Expansion Coefficient	
C_{ij} (i,j=1...6) [GPa]		C [J/kg/K]	K_i (i=1...3) [W/m/k]		α_i (i=1...3) [W/m/k]	
C_{11}	133.0	923	K_1	60	α_1	4.8x10-7
$C_{12}=C_{13}$	4.978		$K_2=K_3$	0.59	$\alpha_2=\alpha_3$	4.0x10-5
C_{23}	5.345					
$C_{22}=C_{33}$	10.71					
C_{44}	2.700					
$C_{55}=C_{66}$	4.800					

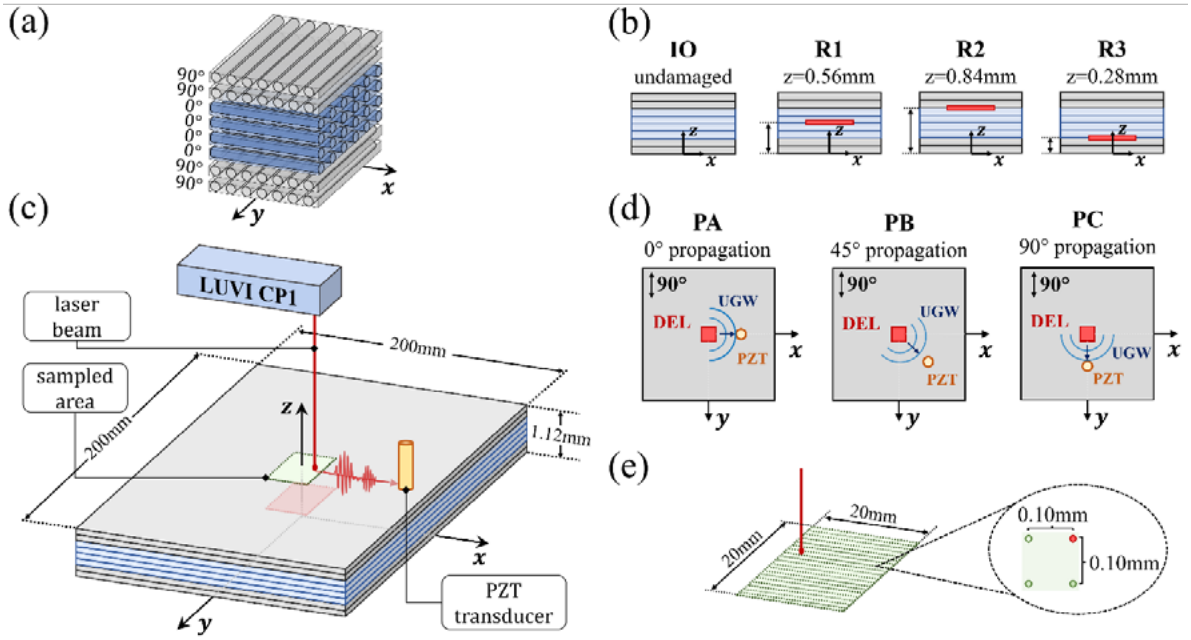

Figure 1. Experimental setup and configurations for UGW testing in CFRP Laminates. (a) cross-ply stacking sequence of the CFRP plate; (b) cross-sectional views of the laminate variants, illustrating intact and delaminated conditions at varying depths; (c) overview of the LUVI-CP1 system scanning a CFRP plate via laser-induced UGW excitation; (d) UGW propagation directions with respect to the fiber orientation in the laminate: 0° (PA), 45° (PB), and 90° (PC); (e) scanning area and grid details.

Surface vertical displacement is measured using a laser ultrasonic visualizing inspector (LUVI-CP1, Tsukuba Technology Co., Ltd). The LUVI system uses an Nd:YAG laser to induce rapid thermal expansion and contraction in the target area, creating broadband UGWs that propagate through the material. This system scans a 20 mm x 20 mm high-resolution area centered on the specimen with a 195x195 scan grid, spacing of d=0.103 mm between illumination points, and produces approximately 38000 waveforms per scan with a scan density of 100 points per mm². The laser parameters include an absorbed pulse energy (E_p) of 1e-4J, a pulse duration of 1e-8s and a beam radius of 5e-4m, with no gain applied to the recorded data.
Once collected, the data is normalized using Z-Score normalization [9], a statistical method that standardizes the scale of different variables by transforming the data to be normally distributed, which often leads to improved performance in machine learning algorithms. Each waveform in the dataset is transformed using the formula:

$$z = \frac{(x - \mu)}{\sigma} \tag{1}$$

where x is the original value, μ the mean of the waveform and σ its standard deviation.
Once normalized, the waveforms are associated with a categorical vector (*label*), randomly shuffled, and placed in indexed data containers. This process is repeated for each combination of plate type and UGW propagation direction, after which all sub-datasets are merged into the final dataset and then randomly shuffled.

3. Description of the 1D Convolutional Neural Network

CNNs typically consist of input, hidden, and output layers. The hidden layers, where learning takes place, include a series of convolutional layers, activation layers, normalization layers, and pooling layers, culminating in a fully connected layer and a classification function that outputs probabilistic values between 0 and 1 for object classification.

A convolution layer is defined by several key parameters: i) the filter (or kernel) size, which refers to the dimensions of the filter that passes over the input to compute dot products and extract features to produce a feature map; ii) the number of filters that pass over the input; iii) the stride, or the number of positions the filter moves as it passes over the input; and iv) the padding, which involves adding zeros (or using other techniques) to adjust the spatial dimensions of the output feature map produced by the convolution. The activation layer introduces non-linearities, enabling the network to learn complex patterns. The normalization layer standardizes network inputs or normalizes previous layer activations, enhancing training efficiency and stability. The pooling layer reduces computational demands by down-sampling, thus reducing the number of parameters. A fully connected layer learns non-linear combinations of high-level features, with each neuron connected to those in the previous layer to effectively integrate learned features for the final output. Finally, the classification function maps the processed inputs to predicted class labels, completing the model's learning process.

The model for this study is implemented in MATLAB® (R2024a). It features a 1D-CNN architecture consisting of two convolution blocks, each containing a 1D convolutional layer, an activation layer, and normalization layers. These are followed by a Global Average Pooling layer and a Fully Connected layer linked to a Classification Function. This architecture, which was refined after experimenting with different layer configurations, uses a shallow design. While this design minimizes computational demands and reduces the risk of overfitting, it may slightly compromise accuracy compared to deeper models.

The model processes time-series data from the Training Dataset, which includes 638820 waveforms, each with 1000 data points across a single channel. The first 1D-Convolution layer employs 32 size-5 filters that passes over the input with a stride of 1 and 'causal' padding, transforming the input into a 1000x32 feature map. This layer is followed by ReLU activation and layer normalization, chosen for its efficiency in handling non-linearities and its suitability for small batch sizes. A subsequent convolution block applies 64 filters of the same size and stride, enhancing the data into a 1000x64 feature map, also followed by ReLU activation and layer normalization. Following the convolutional blocks, a global average pooling layer reduces each feature dimension from 1000 to 1, condensing the feature map to a 1x64 representation. This condensed feature representation is then fed into a fully connected layer, which reduces the dimensionality to 12. The final output layer uses a Softmax activation function in the fully connected layer to classify the outputs into different classes, ensuring that the sum of the output probabilities is equal to 1. Figure 2 shows a schematic of the implemented 1-D CNN architecture.

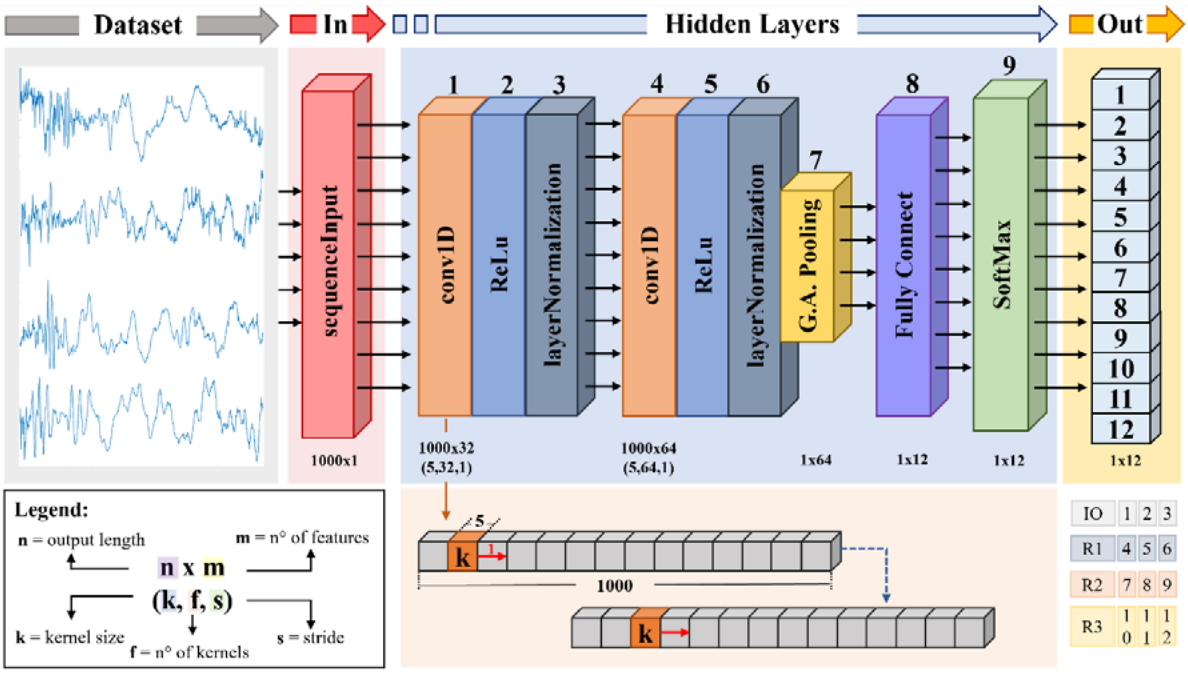

Figure 2. Architecture of the implemented 1D-CNN.

The model underwent training on an Intel(R) Xeon(R) W-2265 CPU with a dataset split of 70% training, 20% validation, and 10% testing. The training configuration for this study uses the Adam (Adaptive Moment Estimation) optimizer, which is known for its efficient handling of sparse gradients and adaptive learning rate capabilities that enhance convergence speed. The training is designed to run for a maximum of 10 epochs to balance computational efficiency with adequate exposure to the training data. The initial learning rate is set at 0.01 to foster rapid convergence without the risk of early overshooting of minima. 'Accuracy' is the primary metric monitored during training and serves as a quantitative measure of the model's performance in correctly predicting labels. Figure 3 illustrates the statistical variation in training accuracy over the 10 epochs.

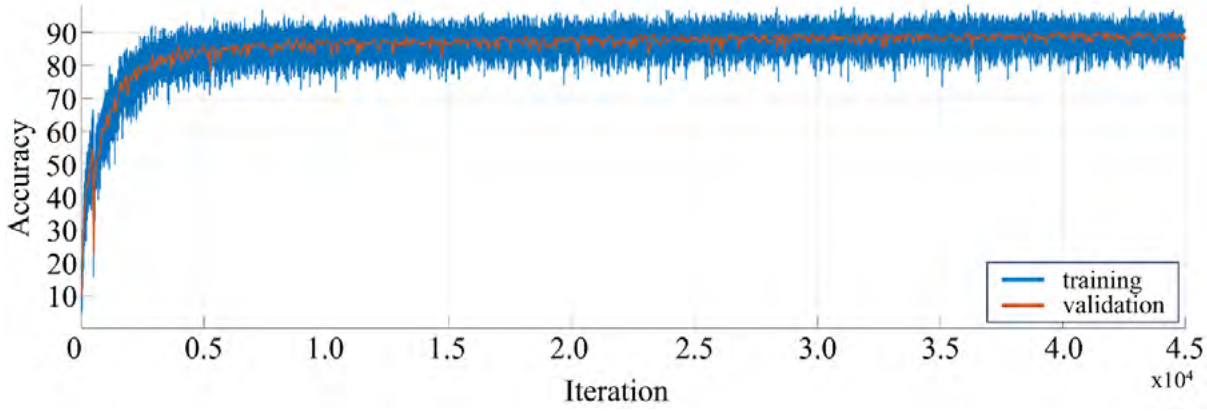

Figure 3. Accuracy evolution during training for a total of 10 epochs and 45000 iterations.

4 Results and discussion

After training is completed using the Training Dataset (70% of the total) and the Validation Dataset (20% of the total), the model's effectiveness is evaluated using the Test Dataset, which comprises the remaining 10% of the collected data. This testing phase is crucial as it assesses the general ability of the model to ensure a high level of performance on new, unseen data, thus confirming its robustness and applicability to real-world scenarios.

4.1. Confusion Matrix

The Confusion Matrix (CM) is a key tool used in predictive analytics to visualize and assess the performance of classification models, such as the 1D-CNN developed in this study.

Presented in a tabular format, the CM contrasts true class labels with predicted ones, clearly distinguishing correct from incorrect predictions. Each row of the matrix corresponds to instances of a True Class, and each column to instances of a Predicted Class. Correct predictions are shown along the diagonal, where the predicted classes match with the true classes. Conversely, off-diagonal elements highlight errors, indicating where the model confuses one class with another.

To effectively interpret a CM, the concepts of True Positive (TP), where the model correctly predicts the positive class; True Negative (TN), where it correctly identifies the negative class; False Positive (FP), where it incorrectly predicts the positive class; and False Negative (FN), where it fails to identify the positive class, are introduced.

Figure 4 displays the CM for the model predictions. The left vertical axis lists the True Classes from IO to R3, while the bottom horizontal axis shows the Predicted Classes. Errors (FN) are shown in off-diagonal row elements, with the Recall, ratio of TP to total elements per class (TP+FN), noted at the end of the row. Similarly, off-diagonal column elements show errors (FP), with the Precision, ratio of TP to total column elements (TP+FP), indicated at the bottom of each column.

Significantly, plates R1 and R3 in the PA direction were frequently misclassified, resulting in Recall and Precision rates of 73.5% and 70.5% for R1, and 68.0% and 71.2% for R3, respectively. Conversely, for the same plates in the PC direction, both Recall and Precision were consistently high, with R1

achieving 97.0% and 93.6%, and R3 scoring 95.3% and 97.2%, respectively.

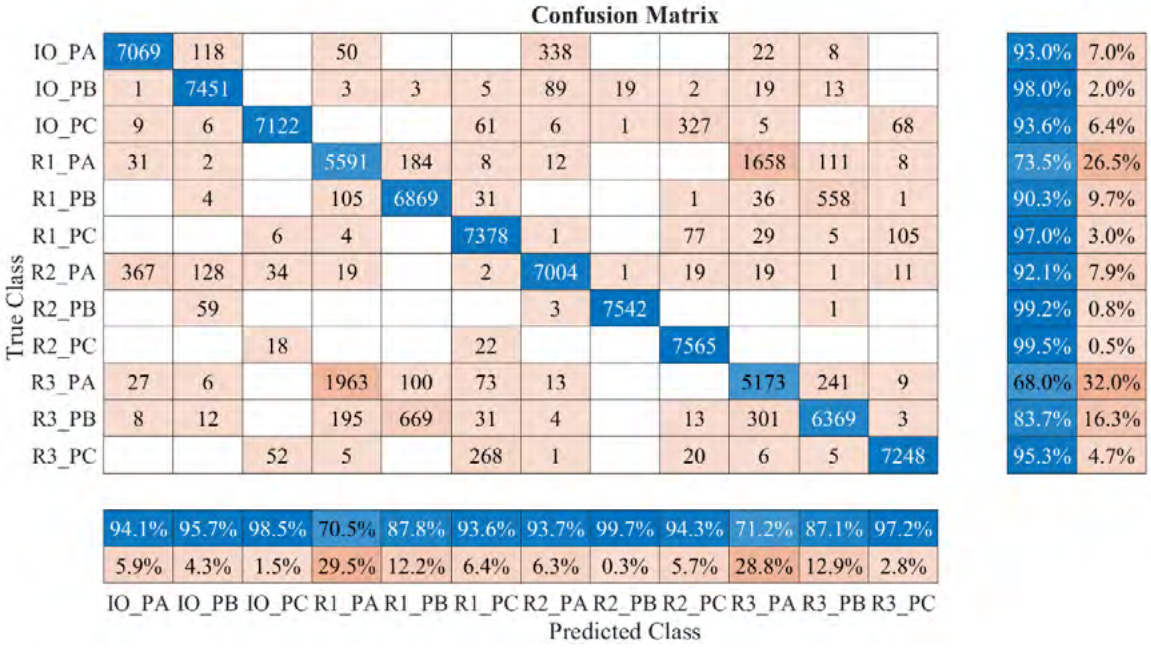

Figure 4. Confusion Matrix displaying the classification results for each class under UGW-based 1D-CNN analysis. The matrix illustrates the true class labels (rows) vs. the predicted class labels (columns). Each cell shows the count of predictions, with diagonal cells indicating correct classifications. The right and bottom margins show the Recall and Precision percentages for each class, respectively.

4.2. Evaluation Metrics

Having defined the key concepts of True Positive (TP), True Negative (TN), False Positive (FP), and False Negative (FN), the performance of the 1D-CNN architecture was evaluated using the following metrics:

i. Precision (P) is the ratio of correct positive predictions to the total predicted positives, calculated as:

$$P = \frac{TP}{TP + FP} \tag{2}$$

ii. Recall (R) measures the proportion of actual positives correctly identified by the model, given by:

$$R = \frac{TP}{TP + FN} \tag{3}$$

iii. F1-Score (F) is a statistical measure used to evaluate the accuracy of a test by calculating the harmonic mean of precision and recall.

$$F = \frac{2 \cdot P \cdot R}{P + R} \tag{4}$$

Precision (P), Recall (R), and F1-Score (F) metrics, estimated for each class in the confusion matrix, are analyzed by grouping the average results per plate type (Figure 5a) and UGW propagation direction (Figure 5b) to gain deeper insights. The performance analysis reveals that the intact IO plate and the R2 plate, with delamination close to the inspected surface at z=0.84 mm, give superior results with average scores of 96.1% and 96.4%, respectively. Conversely, the R1 and R3 plates, which have deeper

delamination at z=0.56 mm and z=0.28 mm, respectively, have lower scores of 85.4% and 83.7%. These results suggest that the absorbed pulse energy (Ep) of the laser used in the study results in reduced UGW excitation effectiveness for deeper delamination. Frequent misclassifications between R1 and R3, as observed in Figure 4, are likely due to their similar waveform characteristics resulting from the greater delamination depth.

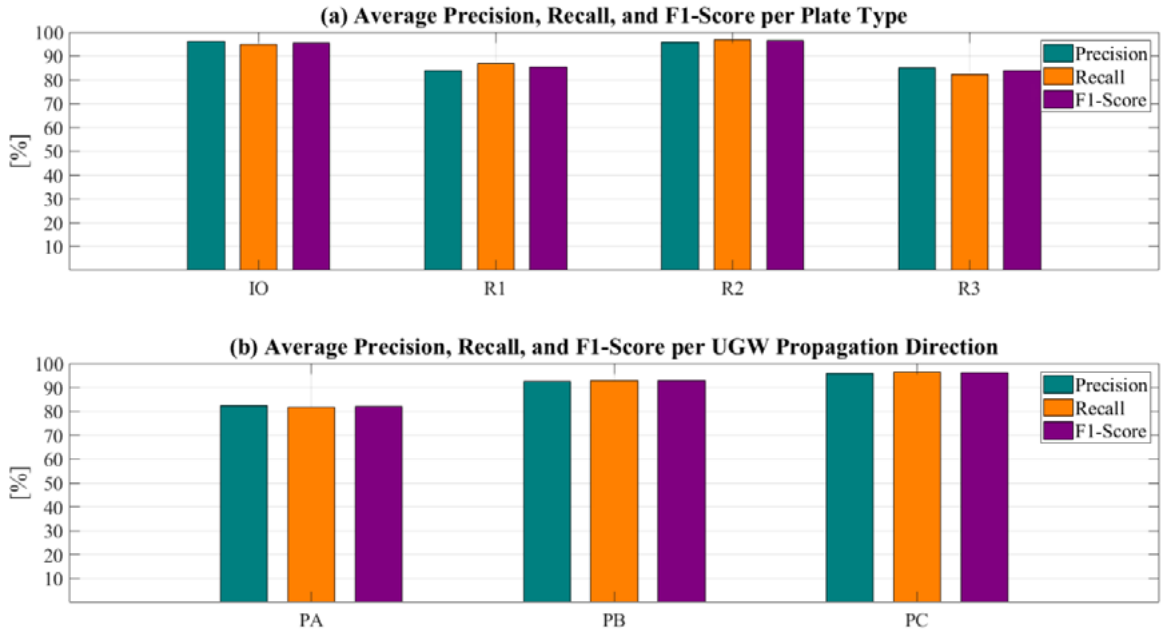

Figure 5. Comparative analysis of 1D-CNN metrics: Average Precision (teal), Recall (orange), and F1-Score (purple) (a) for four types of CFRP laminate plates: IO, R1, R2, and R3; (b) for three UGW propagation directions: PA (0°), PB (45°), and PC (90°). Each bar represents the average percentage of these metrics computed across all tests.

When analyzing model performance in relation to the direction of UGW propagation (Figure 5b), the scores show a significant dependence on the direction of wave propagation. For PA, where the waves propagate at 0° and perpendicular to the fiber direction of the top ply, the average score for all metrics is 82%. For PB, at 45°, this rises to 92.7%. It is noteworthy that for PC, where the wave propagation is 90°, parallel to the fiber orientation, the score peaks at 96.12%. This result indicates that the UGW is highly effective when the wave propagation direction is parallel to the fiber direction of the top ply illuminated by the laser, irrespective of the delamination depth.

5. Conclusions

This study demonstrates the effectiveness of a UGW-based 1D-CNN as a diagnostic tool for the detection and classification of delamination in cross-ply CFRP laminates. The research involved an extensive experimental campaign using an undamaged specimen and three damaged laminates, representing 12 classification classes. UGW waveforms for different damage scenarios and propagation directions were collected using a laser ultrasonic visualization inspector (LUVI-CP1) and a broadband piezoelectric transducer, resulting in a dataset of over 900000 waveforms. This dataset was pre-processed using Z-Score Normalization.

The dataset was then divided using a 70-20-10 split to ensure an equal representation of each class in each segment. A shallow 1D-CNN, consisting of two one-dimensional convolutional blocks and one fully connected layer, was designed to minimize computational effort while maintaining good model generalization. The model, which used “accuracy” as a training metric, was trained over 10 epochs and achieved an overall average accuracy of 90.27%.

Detailed performance analysis showed that the Recall for 9 out of 12 classes exceeded 90%, with 5 classes above 95%. Similarly, the Precision for 8 out of 12 classes was over 90%, with 5 classes above

95%. Data analysis by plate type revealed frequent misclassification between plates with deeper delamination (R1 and R3), probably due to insufficient laser energy to effectively excite deeper delamination. However, when considering the direction of wave propagation, it was observed that misclassifications occurred mainly when waves propagated perpendicular to the fiber direction of the top ply (PA). In contrast, for directions parallel to the fiber orientation (PC), both Recall and Precision were significantly high, reaching 97.0% and 93.6% for R1, and 95.3% and 97.2% for R3 respectively. In conclusion, the proposed 1D-CNN model accurately classifies UGW signals from damaged CFRP laminates using a shallow, efficiently implemented architecture.

Abstract
This paper describes a methodology developed to accurately model the material properties in the dome area of composite overwrapped pressure vessels (COPV). First, a COPV is produced on a hexagonal-shaped so-called "soccer ball" mandrel, which has cleverly-designed flat faces in the dome and in the cylindrical regions. Coupons with specific dimensions and stacking sequences are extracted from the cylindrical region of the COPV and are tested, in order to identify the parameters of an advanced intra-laminar damage model for orthotropic plies. Coupons in the dome area are then extracted in longitudinal and circumferential directions. These coupons are flat on one side (the one in contact with the mandrel), and non-flat on the other side. They present a (complex) variable thickness pattern. Starting from a shell model of the coupons developed in a previous paper, a 3D solid-elements model is here developed, in which each layer is represented with its geometrical thickness. We then come up with a 3D model with variable thickness that represents the interlacements of the tapes resulting from the filament winding process. Four-point bending physical tests are conducted on the coupons, and the corresponding FEM simulations are performed. A good agreement is obtained between simulations and tests in terms of stiffness and strength.

1. Introduction

We are in the context of the analysis of carbon fiber reinforced plastics (CFRP) high-pressure vessel (COPV - Composite Overwrapped Pressure Vessel) of type 4, manufactured by filament winding (FW).

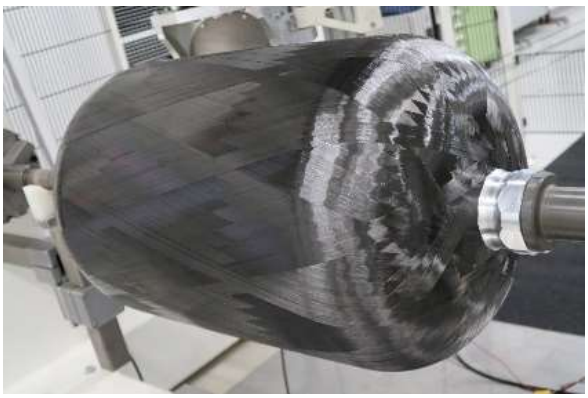

Figure 1. COPV produced by filament winding.

As it is the case for aerospace and automotive applications, efficient design and sizing of COPV must rely on advanced FEM modeling and simulation, on top of physical testing. There is therefore a need for accurate failure analysis in the context of COPV. Classically, the parameters of material models are identified based on flat UD-laminate coupons with specific predetermined fiber orientations (e.g. 0°, 90°, +45°), and based on standards like the ones of ASTM relevant for flat coupons made of UD plies. CFRP manufactured by FW has a unique and complex laminate structure, which presents curvatures, ply interlacements and variable thickness, that make testing and modeling difficult tasks. However, in practice, it is important to use coupons produced with the final manufacturing process for the parameter identification of the material models; if classical coupons produced by e.g. ply lamination are used, the effect of FW structure cannot be accounted for, and cannot be introduced in the material models. In [1], an efficient approach to create representative flat coupons based on the FW process is developed and explained. Flat coupons are created in the cylindrical part of the COPV, as well as in the dome area.

Figure 2. Specific mandrel with flat faces: detail of the filament winding process and tape interlacement at the dome area

In the philosophy of the pyramid of tests, coupons extracted from the cylindrical part are used to characterize the composite material and to determine the parameters of the material model, while coupons coming from the dome area are useful to validate the model and to better understand the damage mechanisms and strength of the material in the dome area, where variable thickness and complex interlacements of the tapes resulting from the filament winding process are present.

2. Material characterization and calibration of the intra-laminar material model

The flat coupons extracted fom the cylindrical part are used to determine the parameters of an advanced material model including non linear behavior and damage propagation [2]. That material model, which is an extension of the Ladeveze CDM model for UD plies [3], is implemented in LS-Dyna via user routines. Standard (ASTM-like) testing (tension, compression, …) is conducted, with cyclic loading when necessary. Next Figure illustrates some results of the parameter identification process (calibration of the material model).

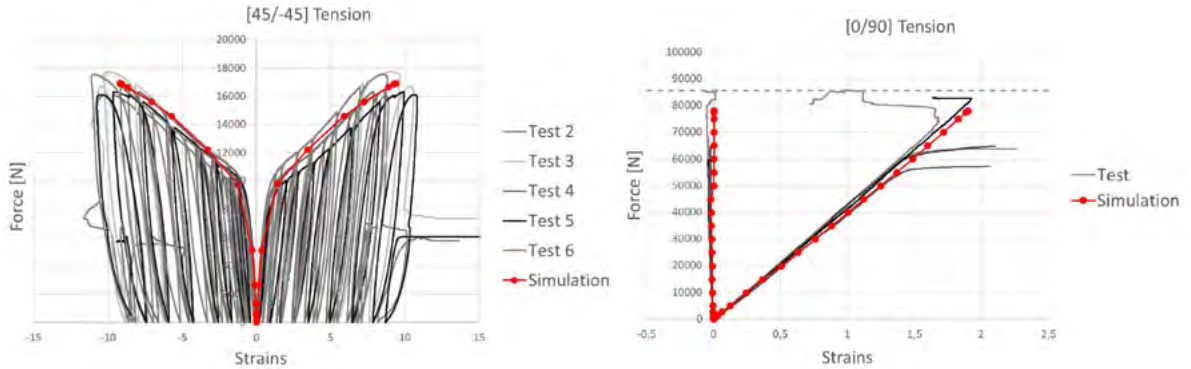

Figure 3. Comparison between test and simulation for the material model parameters identification

3. Modeling methodology of coupons at dome area

3.1. 2D-shell models

In [4], a specific numerical procedure is set up in order to model coupons in the dome area of a COPV. Coupons in the longitudinal and circumferential directions are considered. For modeling, first the tape pattern from the filament winding process is reproduced, and groups of finite elements are defined. The local fiber orientations are then assigned to each group of elements. 2D-multi-layer shell elements are used.

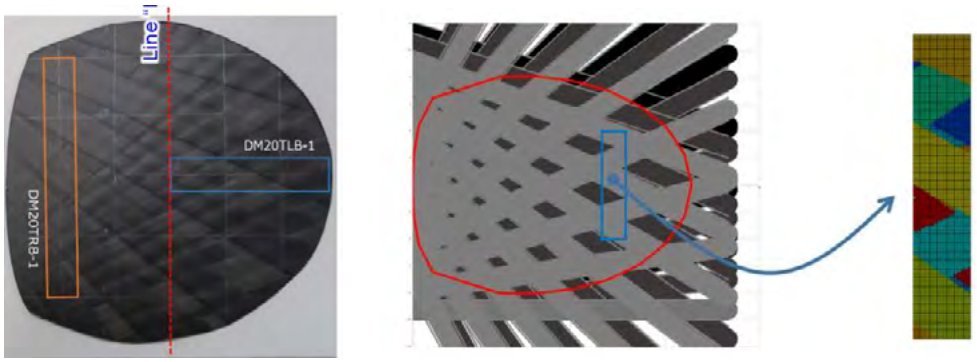

Figure 4. Flat part at the dome area, with indication of locations of longitudinal and circumferential coupons ; complex interlacement of tapes at the dome area of a COPV, and creation of a 2D-shell elements model of a circumferential coupon

3.2. Extension to 3D-solid elements models

Shell models of the previous section are now inflated, in order to create full 3D models built with solid elements. The geometric thickness can now be observed in the finite element model. A typical mesh is illustrated in the Figure below. The material model with parameters identified in Section 2 is assigned to each element, with local fiber orientations coherent with what was defined in the 2D-shell model.

Figure 5. 3D – solid elements FEM model of a coupon at the dome area of a COPV

3.3. Extension to 3D-solid elements models: comparison between tests and simulation

Four-points bending tests are conducted on coupons extracted in the longitudinal and circumferential directions (see Figures 4 and 6). It can be seen in the Figures below that depending on the orientation mechanical responses are very different, bending for circumferential coupons leading to very large dispalcements. We note a good agreement between tests and simulation, as shown in Figure 7 where force-displacement curves are compared.

Figure 6. Physical testing on coupons extracted from the dome area (left: longitudinal direction; right: circumferential direction)

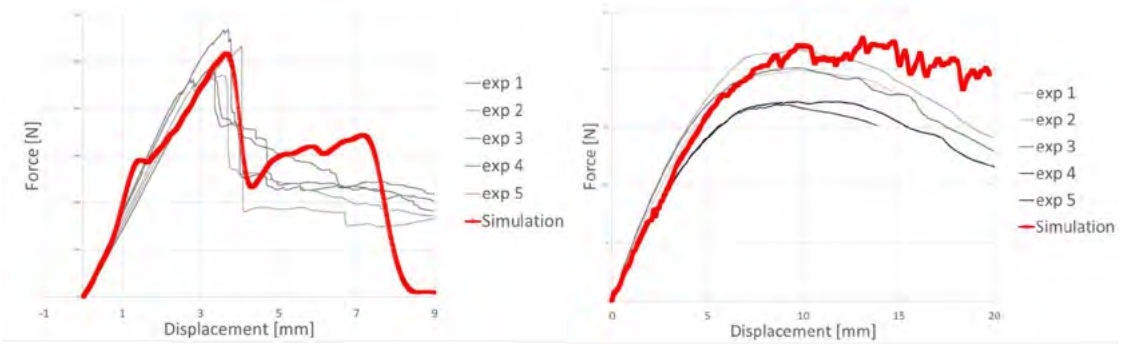

Figure 7. Comparison between test and simulation for 3D – solid elements FEM model of a coupon at the dome area of a COPV (left: longitudinal direction; right: circumferential direction)

4. Conclusions

In this paper, we derived an efficient modeling methodology for coupons extracted from the dome area of a composite pressure vessel. The models are based on 3D-solid elements meshes. Experimental and numerical results are compared for four-points bending ; a good agreement is observed in terms of stiffness and strength.

Keywords: viscoelasticity, transverse isotropy, homogenisation

Abstract
The viscoelastic response of long fibres, polymer matrix composites is mainly due to the deviatoric response of the matrix. This single microscale mechanism, however, results in different amount of viscous relaxation for the elastic constants defining the transversely isotropic behaviour at the scale of the composite ply. In a recent work, some of the authors proposed a reformulation of transverse isotropy based on the Cartan decomposition. This geometrical formulation of the constitutive law leads to a set of five elastic parameters which is different from those commonly used in the formulation of constitutive laws, but which is easier to relate to the underlying constituents. In particular, only two of the parameters are significanly affected by the deviatoric response of the matrix, thus largely simplifying the formulation of the viscoelastic constitutive behaviour at the composite scale. Analytical and numerical homogenisation procedures are used to evaluate the pertinence of the proposed model.

1. Introduction

The constitutive behaviour of a composite depends on the behaviours and on the arrangement of its elementary constituents. For long fibres, polymer matric composites, the fibres response can be considered elastic in a large range of temperatures, while the matrix has a viscoelastic response, especially involving its deviatoric part [1]. At the scale of the composite ply, on the other hand, the constitutive response can be considered as transversely isotropic, defined by five independent elastic parameters. The single relaxation mechanism at the microscale can potentially affect all of these elastic parameters, thus leading to the demultiplication of the viscous relaxation functions which need to be identified at the composite scale (see for example [2]).

In a recent work [3], some of the authors proposed a reformulation of transverse isotropy based on group representation theory, and in particular on an irreducible decomposition of the stress (resp. strain) tensors, also known as the Cartan decomposition. Such reformulation gives rise to a set of five elastic constants which is different from those commonly used in transverse isotropy, but it is easier to relate to the behaviour of the underlying constituents. In particular, the viscoelastic response was assumed to

affect only the longitudinal and transverse shear moduli, thus simplifying its description. The key points of the proposed formulation are recalled in Section 2 of the paper.

The assumptions introduced in [3] were challenged through analytical and numerical homogenisation in a follow-up work [4]. In particular, analytical results derived by Hashin [5] with a cylindrical model enabled us to formulate the five elastic constants of the composite as a function of the constituents' properties and volume fraction. Based on these formulas, presented in Section 3, the matrix shear modulus affects all of the five parameters for transverse isotropy, but only two of them go to zero when the matrix shear modulus goes to zero. This shows that the assumptions made in [3] are indeed an approximation of the viscoelastic behaviour of the composite, but that only a small error is introduced when typical behaviours for carbon fibres and polymer matrix are assumed. Finally, Section 4 shows some numerical homogenisation results, using periodic boundary conditions on a Representative Volume Element (RVE). In particular, relaxation tests are used for identification of the elastic and viscoelastic parts of the homogenised composite behaviour, while creep tests are used to compare the RVE response to the one of the homogenised model. The presented work confirms that the key features of the RVE response can be captured by the new transversely isotropic model based on Cartan decomposition.

2. Tranversely isotropic model based on Cartan decomposition

The new transversely isotropic model is recalled below. For details on its derivation, see [3].

The Cartan decomposition of the stress (resp. strain) tensor is given as

$$\boldsymbol{\sigma} = s_f \boldsymbol{M}_f + s_h \boldsymbol{M}_h + \boldsymbol{s}_{fs} + \boldsymbol{s}_d, \tag{1}$$

where $s_f \boldsymbol{M}_f$ is the stress in the fibres' direction, $\boldsymbol{s}_{fs}$ are the shear components involving the fibres' direction, $s_h \boldsymbol{M}_h$ and $\boldsymbol{s}_d$ are the hydrostatic and deviatoric components in the transverse isotropy plane, and $\boldsymbol{M}.$ are unit second order tensors. Based on this decomposition, a minimal integrity basis is constructed and used to formulate a Gibbs free energy for linear elasticity. This yields the following constitutive laws

$$\begin{bmatrix} e_f \\ e_h \end{bmatrix} = \begin{bmatrix} S_F & S_{FH} \\ S_{FH} & S_H \end{bmatrix} \begin{bmatrix} s_f \\ s_h \end{bmatrix}, \qquad \boldsymbol{e}_{fs} = S_{FS} \boldsymbol{s}_{fs}, \qquad \boldsymbol{e}_d = S_D \boldsymbol{s}_d, \tag{2}$$

where the new set of elastic constants $(S_F, S_{FH}, S_H, S_{FS}, S_D)$ can be related to the longitudinal and transverse Young's moduli E_L and E_T, the in plane Poisson's coefficient υ_{LT} and the longitudinal and transverse shear moduli μ_L and μ_T as follows

$$S_F = \frac{1}{E_L}, \qquad S_{FH} = -\frac{\sqrt{2}\upsilon_{LT}}{E_L}, \qquad S_H = \frac{2}{E_T} - \frac{1}{2\mu_T}, \qquad S_{FS} = \frac{1}{2\mu_L}, \qquad S_D = \frac{1}{2\mu_T}. \tag{3}$$

In [3], the terms (S_F, S_{FH}, S_H) are considered to be controlled essentially by the fibres' behaviour, as well as by the matrix's bulk response, thus they are considered elastic, while (S_{FS}, S_D) are considered to be affected by the matrix's deviatoric response, and thus they are considered as viscoelastic. This assumption is obviously an approximation of the real composite response. The quality of the approximation is evaluated through analytical and numerical homogenisation techniques.

3. Analytical homogenisation results

Analytical homogenisation results enabling to relate the constituents' properties and volume fractions to the elastic and viscoelastic response of transversely isotropic composites were derived by Hashin through a cylindrical model [5]. These results enable us to obtain a first evaluation of the pertinent of the assumption introduced in [3].

The results, discussed in more details in [4], show that the new elastic constants defined in [3] can be separated into two groups, depending on their behaviour as the matrix's shear modulus $\mu_m \to 0$:

- $(S_{FS}, S_D) \to \infty$, no stiffness remains;
- (S_F, S_{FH}, S_H) retain a finite value, and thus a finite stiffness remains.

This shows that the two sets of elastic parameters distinguished in [3] have fundamentally different dependence on the matrix shear modulus, and they are thus differently affected by its viscoelastic response.

A more quantitative evaluation can be obtained by computing the values of the different elastic constants as μ_m varies, for typical carbon fibres, polymer matrix composites properties. The results are depicted in Figure 1. Due to the significant stiffness gap (around 2 orders of magnitude) between the fibres and the matrix, the longitudinal response S_F is essentially unaffected by the matrix shear modulus. The terms S_{FH} and S_H, related respectively to the Poisson's effect coupling the fibres to the isotropy plane and to the hydrostatic response in the isotropy plane, are affected to some extent, but they retain 80-90% of their original stiffness when $\mu_m \to 0$. Therefore, neglecting this effect seems to give a reasonable approximation of the transversely isotropic composite response.

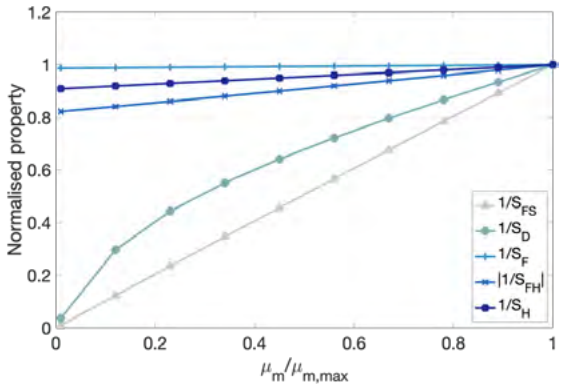

Figure 1. Normalised composite parameters for decreasing normalized matrix shear modulus (initial set of parameters from [6]: $E_f = 248$ GPa, $\upsilon_f = 0.2, E_m = 3.24$ GPa, $\upsilon_m = 0.4$, $\upsilon_f = 0.5$) – from [4]

4. Numerical homogenisation results

Numerical homogenisation can also be used to obtain the composite's properties based on its constituents' properties and microstructure. Here, a periodic homogenisation approach was used, enabling us to impose, for each component, the macroscopic stress Σ_{ij} or strain E_{ij} as a function of time. More specifically, three types of tests were simulated:

- relaxation tests ($E_{ij}(t) = 0.01$, other components = 0) to obtain the full relaxation response of the composite and identify the new composite model parameters;
- uniaxial creep tests at different loading angles ($\boldsymbol{\Sigma}(t) = 100\boldsymbol{e}_x \otimes \boldsymbol{e}_x$ MPa, with $\boldsymbol{e}_x \cdot \boldsymbol{e}_f = cos\theta$) to compare the response of the RVE to the one of the new composite model;
- a constrained creep test, where the stress is imposed in the transverse direction of the composite ($\Sigma_{xx}(t) = 100$ MPa with $\boldsymbol{e}_x \cdot \boldsymbol{e}_f = 0$), but the other normal strain components are blocked ($E_{yy}(t) = E_{zz}(t) = 0$); this last test is designed to test the limits of the proposed model by

highlighting the role of the terms S_{FH} and S_H, which are the ones for which the retained approximation is the least valid.

A periodic RVE extracted from a hexagonal fibres arrangement was used for the simulations. The finite element computations were carried out in Abaqus, using a in-house Python script to couple the corresponding nodes and introduce the additional constraint equations associated to periodic boundary conditions. The elastic properties of the constituents are the same as those used for analytical homogenisation (see caption of Figure 1), while a generalised Maxwell model is used to describe the matrix viscoelastic deviatoric behaviour, with three Maxwell elements having the following values of (τ_i, μ_i): (1 s,$0.1\mu_{inst}$), (10 s,$0.2\mu_{inst}$), (100 s,$0.2\mu_{inst}$). More details can be found in [4].

The results of the relaxation tests are depicted in Figure 2. The initial values of the RVE response are used to identify the elastic parameters for the new composite model. Furthermore, the curves for (S_{FS}, S_D) are used to identify the associated viscoelastic relaxation parameters, supposing also a three elements generalised Maxwell model for the composite. A more general viscoelastic relaxation model could be assumed for the composite, but this was beyond the scope of this work. The list of identified parameters is reported in [4].

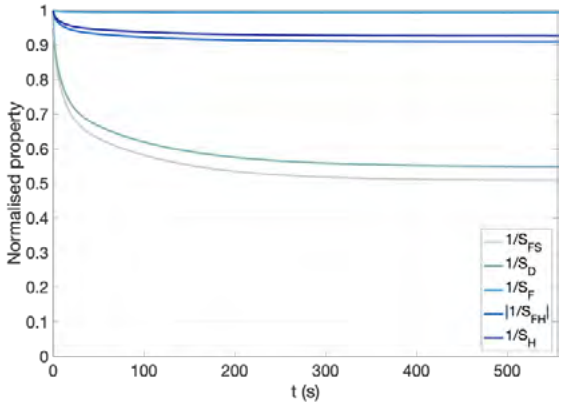

Figure 2. Normalised composite parameters as a function of time, obtained through numerical relaxation tests on the RVE – from [4]

The results of the creep tests are depicted in Figure 3. As it can be seen, the responses of the RVE and of the new composite model are nearly identical, which confirms the pertinence of the model proposed in [3].

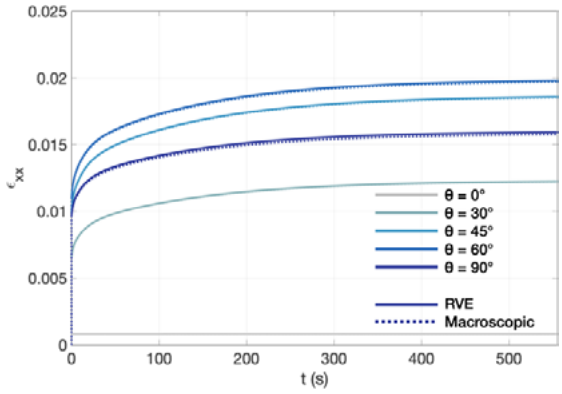

Figure 3. Strain as a function of time in the loading direction, obtained through numerical uniaxial creep tests on the RVE and on the new composite model – from [4]

Finally, the results of the constrained creep test are depicted in Figure 4. A discrepancy is observed between the RVE and the macroscopic model results, since this test is designed to excite particularly the terms S_{FH} and S_H, whose viscoelastic behaviour was neglected. Even in this unfavourable case, the maximum discrepancy between the two models amounts to 6% of the total strain in the loading direction. If this approximation is not acceptable for a given application, the composite model can be enriched by including viscoelastic relaxation for these terms, resulting in a more complex composite model.

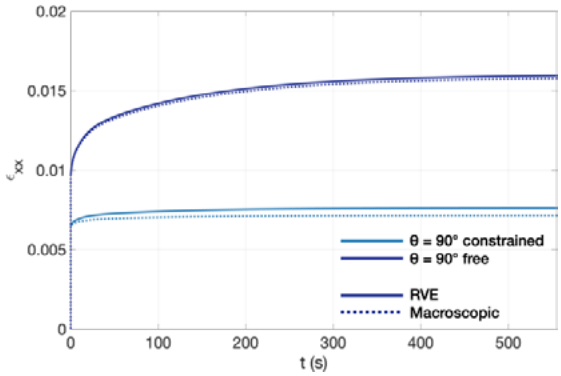

Figure 4. Strain as a function of time in the loading direction, obtained through free and constrained numerical creep tests on the RVE and on the new composite model – from [4]

5. Conclusions and perspectives

This work summarised the results presented in [3,4] on the viscoelastic modelling of transversely isotropic composites based on a Cartan decomposition. The new elastic parameters defined in [3] are easier to relate to the underlying constituents, and supposing a viscoelastic relaxation for only two of them leads to a limited error in the overall composite response, as assessed through analytical and numerical homogenisation approaches in [4]. Perspectives of this work include the implementation of a complete identification procedure for the viscoelastic response of the composite, as well as the exploration of the Cartan decomposition interest for the modelling of other aspects of the transversely isotropic response, as other nonlinear material and geometric behaviours.

Acknowledgments
The authors would like to acknowledge Dr. Marc Olive for his key role in the geometrical formulation of the macroscopic transversely isotropic model. This work was motivated and partly funded by Cetim within the framework of the Laboratoire Commun Comp'Innov.

Keywords: Acoustic emission, Numerical simulation, Carbon fiber/epoxy matrix laminates

Abstract

Transverse cracking induced acoustic emission in carbon fiber/epoxy matrix composite laminates is studied both experimentally and numerically. The influence of the type of sensor, specimen thickness and ply stacking sequence is investigated. The frequency content corresponding to the same damage mechanism differs significantly depending on the sensor and the stacking sequence. However, the frequency centroid does not depend on the ply thickness except for the inner ply crack and a sensor located close enough to the crack. Outer ply cracking exhibits signals with a low-frequency content, not depending much on the ply thickness, contrary to inner ply cracking, for which the frequency content is higher and more dependent on the ply thickness. Frequency peaks and frequency centroids obtained experimentally are well captured by numerical simulations of the transverse cracking induced acoustic emission for different ply thicknesses

1. Introduction

A main challenge in acoustic emission (AE) monitoring of damage in composite materials consists in determining a link between the AE sources (*i.e.*, the damage mechanisms) and the acquired signals. This is essential in order to set-up robust damage mechanism classification approaches [1-3]. Establishing such a correspondence is not straightforward since the AE signals acquired by the sensors are actually the result of the initial source signal that propagated within a medium and that was transformed by a sensor. The AE signals depend not only on the damage source but also on the specimen geometry, the material properties and the type of sensor and acquisition chain [4].

This work focuses on the numerical simulation of the AE due to transverse cracking in laminate composites. The objective of the work is the experimental characterization and numerical simulation of the influence of the ply thickness and stacking sequence on transverse matrix cracking induced acoustic emission. The experimental setup and the numerical models are presented in Section 2. The influence of the ply sequence and thickness on the AE is studied in Section 3.

2. Experiments and simulation setup

Transverse cracking induced acoustic emission in carbon fiber/epoxy matrix composite laminates is studied both experimentally and numerically. Monotonic tensile tests are performed on AS4 carbon fiber (60 vol.%) embedded in epoxy resin [$0_n/90_n/0_n$] or [$90_n/0_n/90_n$] laminates (n=1 or 3, one ply thickness being 0.3 mm). Four AE sensors (two sensors of two different types, namely [micro80, Mistras Group, Princeton, NJ, USA] and [picoHF, Mistras Group,Princeton, NJ, USA are fixed on the specimens to detect signals originating from damage mechanisms occurring within the composites. Each couple of sensors are placed on both sides of the specimen. For each acquired signal, both temporal and frequency descriptors are extracted from the signal and its fast Fourier transform (FFT). Floating amplitude thresholds (0.1% for the beginning and 5% for the end of the signal) are used for the signal time windowing. In addition to the experiments, finite element (FE) simulations of matrix transverse cracking in 90 deg. plies are set-up. Boundary conditions consist of prescribed displacements at the end of the specimen. The symmetry of the studied configuration enables modelling only 1/8 ([$0_n/90_n/0_n$]) or 1/4 ([$90_n/0_n/90_n$]) of the specimen (Figure 1a) and compare the AE signal characteristic to the ones measured experimentally (Figure 1b).

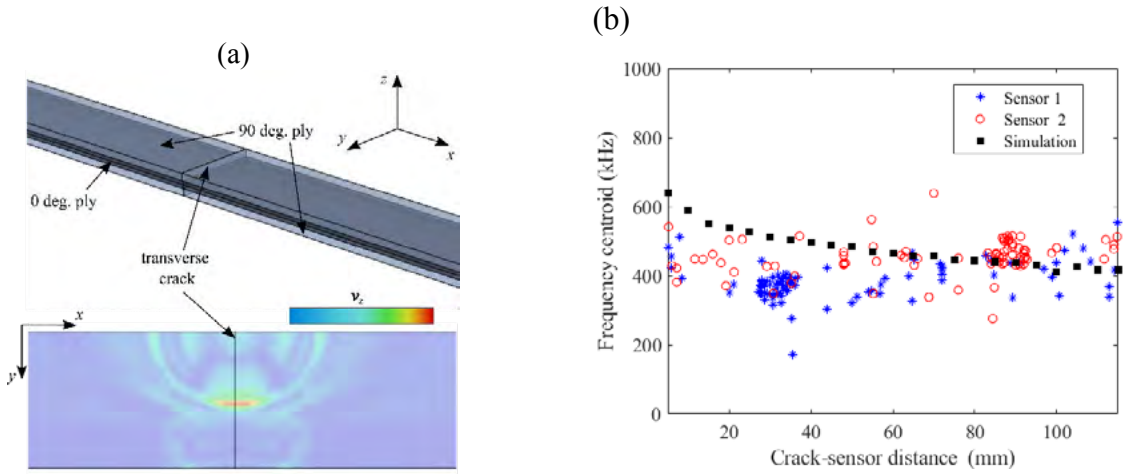

Figure 1. a) FE model of [$90_n/0_n/90_n$] laminates. Example of velocity field on the specimen surface. b) Frequency centroid variation as a function of the distance obtained numerically and experimentally.

A dynamic implicit solution is adopted in order to simulate first, transverse cracking nucleation dynamics and then acoustic wave propagation in the composite due to transverse cracking (Figure 1a). The mesh is refined in the vicinity of the transverse cracking location with at least 10 elements in one ply thickness, resulting in models containing approximately 500,000 degrees of freedom. Transverse cracking is modeled by progressively unbuttoning all the nodes along the crack surface during a given time at a loading level equal to the critical strain at first transverse cracking determined using finite fracture mechanics [5]. The maximum time step during the subsequent wave propagation is set to 10^{-7} s in order to consider a frequency range up to 1 MHz. AE signals are collected on a perfect punctual sensor at several distances from the transverse crack, from which temporal and frequency descriptors are calculated.

3. Results

We now analyze the transverse cracking induced acoustic emission with varying stacking sequence and ply thickness considering a perfect contact sensor. We study the influence of transverse cracking occurring either in inner [0n/90n/0n] (n = 1 or 3) or outer [90n/0n/90n] (n = 1 or 3) ply. Figure 2 shows the signals recorded by the sensor on the specimen surface at the transverse crack epicenter.

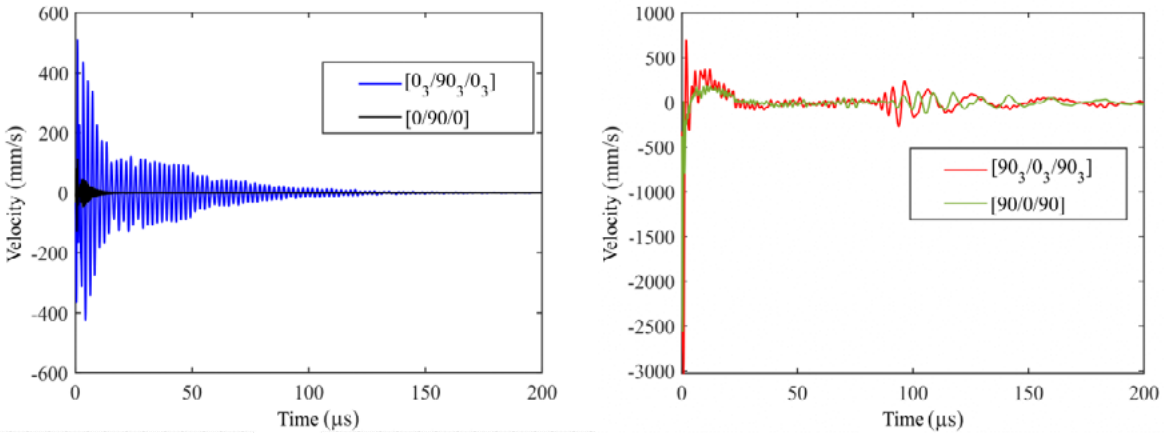

Figure 2. Acoustic emission signal obtained by a point-sensor at the crack epicenter for two ply thicknesses for a) $[0_n/90_n/0_n]$ or b) $[90_n/0_n/90_n]$ laminate.

Noticeable differences are evidenced depending on the ply thickness and transverse cracking location. This is due to the size of the initiated crack and also to the signal attenuation with propagation. Outer ply transverse cracking results in signals with a larger amplitude than inner ply transverse cracking at the crack epicenter. This is evidenced by inner ply cracking induced signals having larger amplitudes for larger plies and outer ply cracking induced signals having larger amplitudes than inner ply cracking signals. Outer ply transverse cracking induces similar signals at the crack epicenter, whatever the ply thickness (Figure 2a), whereas significantly different signals are induced by transverse cracking depending on the inner ply thickness (Figure 2b). This phenomenon may be explained by the difference in the acoustic wave propagation distance in the specimen thickness for inner ply cracking. Therefore, it is expected that the descriptors of the signals near the crack epicenter are close for outer ply cracking and different for inner ply cracking.

The same damage mechanism may result in signals exhibiting different descriptors depending on their location in the composite and on the composite stacking sequence. Frequency centroid of transverse cracking signals for the different stacking sequences and ply thicknesses are analyzed as a function of the distance between the sensor and the crack in Figure 3. Near the crack epicenter, the dependency of the frequency centroid on the ply thickness is marked for inner ply cracking and much less pronounced for outer ply cracking (Figure 3). However, far enough from the crack (distance larger than 60 mm), the same frequency centroid is retrieved whatever the ply thickness for a given stacking sequence. For any distances between the sensor and the crack, the frequency centroid magnitude is significantly different.

3. Conclusions

Experimental characterization of transverse cracking induced acoustic emission in composite laminates highlights the dependency of the AE results to the sensor type and the specimen thickness.

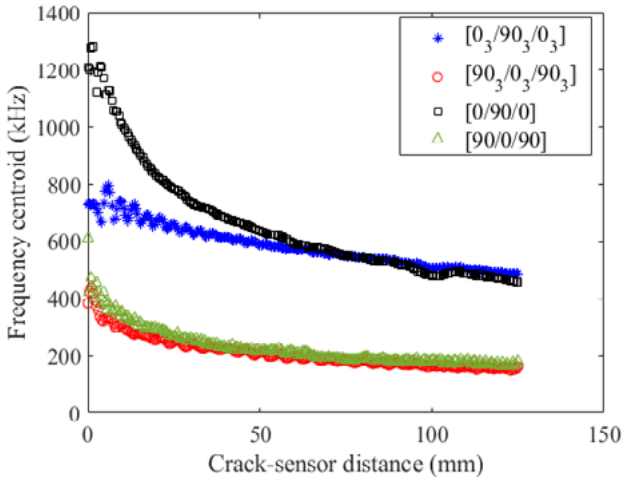

Figure 3. Frequency centroid variation as a function of the crack to sensor distance obtained for two different stacking sequences and two different ply thicknesses.

Frequency peak and frequency centroid obtained experimentally are well captured by numerical simulations of transverse cracking for different ply thicknesses. The influence of the ply thickness on acoustic emission signals recorded at the crack epicenter is significant only for inner ply transverse cracking, whereas similar signals are obtained for outer ply cracking. It thus raises the following question: should inner ply and outer ply transverse cracking should be considered as two different damage mechanisms in a classification approach? The influence of the ply thickness on AE signals (on the frequency centroid, for instance) decreases as the sensor is far from the crack; however, the influence of the stacking sequence remains, regardless of the sensor location. The frequency content of signals induced by outer ply transverse cracking does not depend on the ply thickness.

Keywords: polyamide-6 (PA6), short fibre-reinforced composites (SFRPs), tensile tests, digital image correlation (DIC), thermomechanical coupling

Abstract
This paper studies thermomechanical coupling during room-temperature tensile testing of polyamide-6 (PA6) and short glass fibre/PA6 (50 wt%). The tests were performed for different dominant angles of the short fibres (0°, 45°, 90°), moisture contents (dry, 50%RH), and strain rates (10^{-4}, 10^{-2}, 10^{-1} s^{-1}). Digital image correlation (DIC) was coupled with infrared thermography. The contribution of the local strains, strain rates and temperatures to the global mechanical behaviour was investigated throughout deformation. The initial thermoelastic response was used to estimate the coefficient of thermal expansion. In PA6, neck development caused significant self-heating at high strain rates, differently between dry and 50%RH. In glass/PA6, however, temperature rises were always small (< +3 °C) despite local strain rate peaks in the fracture zone. This was ascribed to limited plastic deformation, as confirmed by post-mortem microscopy. The full-field data can be highly valuable for the development of advanced constitutive models for both pure polymer and short fibre composite.

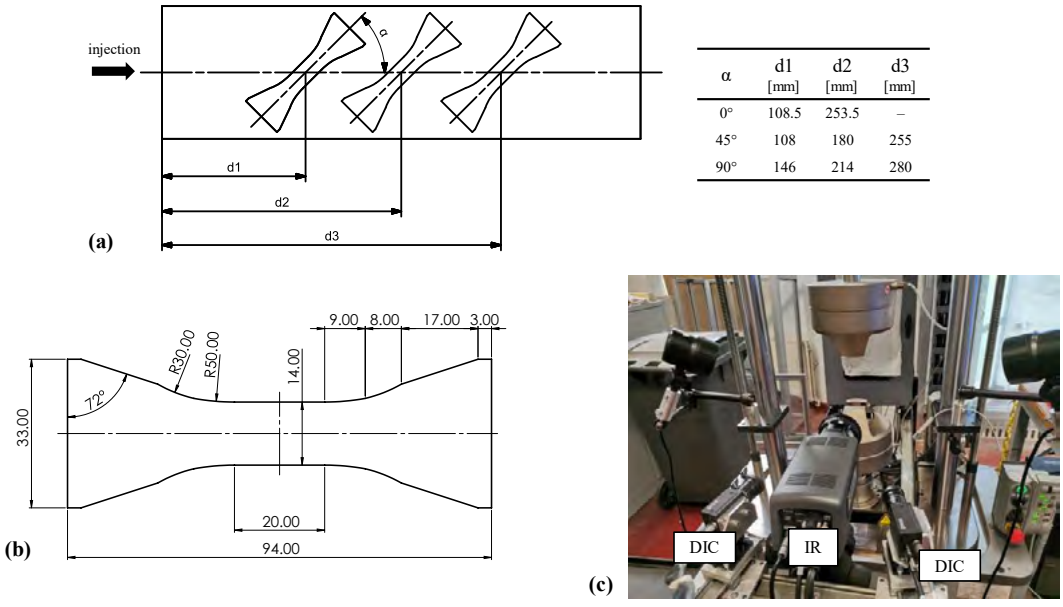
1. Introduction

Short fibre-reinforced thermoplastic composites are increasingly popular in the automotive industry. Lightweight, low cost, easy processing and recyclability make them appealing as replacement for metal and thermoset-based parts. However, higher sensitivity to loading rate and environmental conditions may limit the range of applications. The material response needs to be thoroughly characterised keeping all those effects into account.

Among other thermoplastic composites, injection-moulded glass/polyamide-6 (GPA6) has found many applications in functional and structural car components. Like all polyamides, PA6 is hygroscopic: water molecules from the surroundings enter the material and break the hydrogen bonds between the chains in the amorphous phase, increasing their mobility and thus lowering the glass transition temperature (T_g). PA6 is also sensitive to the strain rate, and the rate sensitivity is temperature-dependent. All these effects are to some extent retained in the composite. The effect of moisture, temperature and strain rate on PA6 and GPA6 has been studied extensively [1–5].

Besides, the strain rate can also be related to self-heating. In polymers, work from plastic deformation is converted to heat. If heat is generated faster than can be evacuated to the surroundings, the material heats up. Due to low thermal conductivity, polymers may experience self-heating even under quasi-static loading [6,7]. In polymer composites, global failure strains are generally low, but the matrix may undergo local plastic deformation while interacting with the fibres, possibly leading to significant local

temperature rises as shown by simulations [8,9]. These effects have never been addressed in monotonic tensile testing of PA6 and GPA6.



The aim of this work is to look into thermomechanical coupling and self-heating during monotonic tensile testing at room temperature of PA6 and GPA6. The influence of fibre orientation and moisture content was investigated at different strain rates. A dedicated setup with digital image correlation (DIC) and infrared (IR) thermography was used for synchronised, full-field measurement of strains and temperatures, to gain insight into thermomechanical coupling on both a local and global level. The results presented in this paper are included in [10].

2. Material and methods

The PA6 and GPA6 in this work were supplied by DOMO Chemicals – PolyTechnyl SAS (France) as injection-moulded plates with size 360 x 100 x 3 mm^3. The GPA6 grade had a high glass fibre content of 50 wt%. Dogbone specimens for tensile tests were machined from the plates, at different angles (0°, 45°, 90°) to the injection direction and at specific locations (Figure 1a). The PA6 specimens were only cut at 90°. The shape and dimensions of the tensile specimens are shown in Figure 1b.

Monotonic tensile tests were performed at room temperature. Prior to testing, the specimens were conditioned either dry (T_g = 70 °C) or 50%RH (T_g = 23 °C). The tests were performed in displacement control at 0.36, 36 and 360 mm/min, roughly corresponding to nominal strain rates of 1×10^{-4}, 1×10^{-2} and 1×10^{-1} s^{-1}. The strain rates were chosen to range from isothermal to adiabatic conditions, as will be clarified in Section 3.2.1.

Strains were measured full-field on the specimen surface via stereo DIC. The temperature field was also mapped with a FLIR A6750sc IR camera, calibrated and synchronised with the DIC cameras. The setup is shown in Figure 1c.

α	d1 [mm]	d2 [mm]	d3 [mm]
0°	108.5	253.5	–
45°	108	180	255
90°	146	214	280

3. Results and discussion

3.1. Mechanical response

Figure 2 shows the true stress-true strain curves. For PA6, after yield the curves at 10^{-2} and 10^{-1} s^{-1} intersect with those at 10^{-4} s^{-1}, suggesting thermal softening as will be discussed in Section 3.2.3.

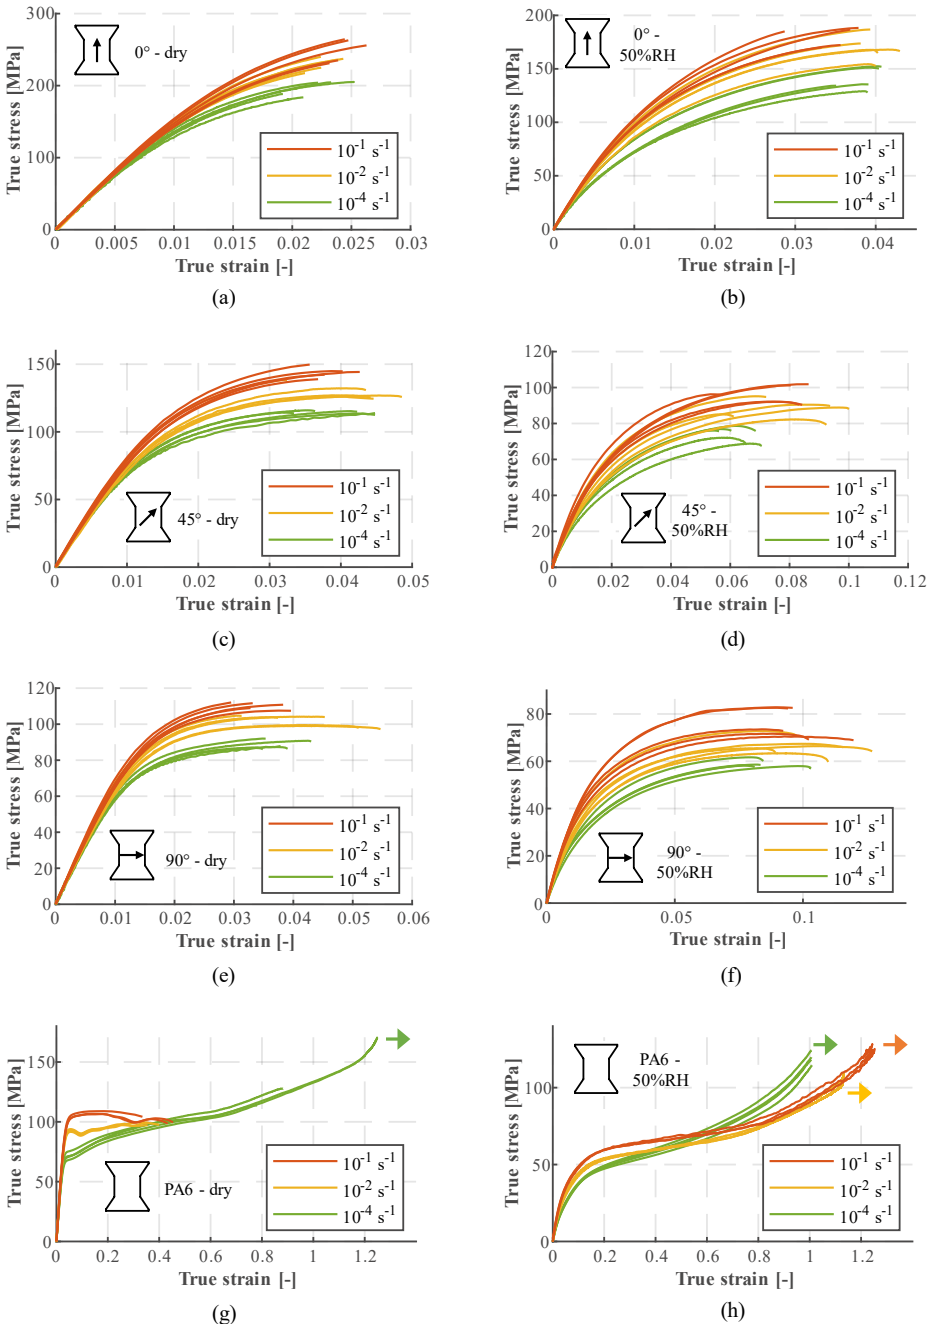

Figure 2. Stress-strain curves of GPA6 and PA6 at different (nominal) strain rates. *Left*: dry; *right*: 50%RH.

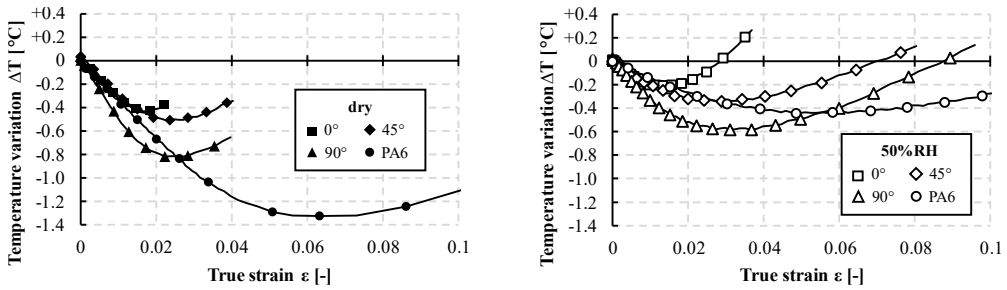
3.2. Thermomechanical coupling

3.2.1. Critical strain rate

As mentioned in the Introduction, plastic deformation in polymers is accompanied by heat generation. If the rate of deformation is higher than a critical value, heat is generated by plastic work faster than it



can be dissipated and the material heats up (adiabatic conditions). An approximate formulation for the critical strain rate $\dot{\varepsilon}_c$ can be derived from the characteristic thermal diffusion time Δt_d of the one-dimensional heat diffusion equation [6,8,11]:

$$\dot{\varepsilon}_c = \frac{1}{\Delta t_d} \approx \frac{(k/\rho c_p)}{L^2} \tag{1}$$

where: k is the thermal conductivity, ρ is the density, c_p is the specific heat capacity, and L is a characteristic length of the specimen. For PA6, this results in $1.62 \times 10^{-2}\ \mathrm{s}^{-1}$. Therefore, the following conditions are realised in this experimental campaign: $10^{-4}\ \mathrm{s}^{-1}$ isothermal; $10^{-2}\ \mathrm{s}^{-1}$ transition; $10^{-1}\ \mathrm{s}^{-1}$ adiabatic.

3.2.2. Thermoelasticity and coefficient of thermal expansion

In adiabatic conditions ($10^{-1}\ \mathrm{s}^{-1}$), the thermal response of the material is purely due to the mechanical deformation, while heat transfer can be neglected. This makes it possible to study thermomechanical coupling. Figure 3 gives the average temperature variation as a function of strain for the adiabatic case. The initial linear part reflects the thermoelastic effect, i.e. cooling associated with stretching. The temperature variations are in the order of fractions of a degree, so the impact on the mechanical response is minimal. Afterwards, the temperature starts increasing due to plastic dissipation, which will be addressed in Section 3.2.3.

(a) (b)

Figure 3. Average temperature variation vs. strain at a nominal strain rate of $10^{-1}\ \mathrm{s}^{-1}$ for PA6 and the different orientations of GPA6: (a) dry, (b) 50%RH. For PA6, the strain range is truncated to 0.1.

For a thermoelastic material under adiabatic deformation, the temperature variation ΔT is related linearly to the applied stress $\Delta\sigma$ by the equation:

$$\Delta T = -\frac{\alpha_T T}{\rho c_p}\Delta\sigma \tag{2}$$

where: α_T is the coefficient of linear thermal expansion, T the absolute temperature, ρ the density, and c_p the specific heat capacity at constant pressure [12,13]. Having access to mechanical and thermal data, it is possible to obtain the coefficient of thermal expansion. This approach was applied to PA6 and GPA6 for the different orientations and moisture contents, using literature values for c_p. Table 1 lists the calculated coefficient of thermal expansion for PA6 and GPA6. The values obtained in this study appear to be excellent estimates when compared to datasheet values for GPA6 [14].

Table 1. Coefficient of linear thermal expansion (α_T) estimated with Eq. (2). When available, literature values are provided within brackets for comparison.

Orientation	α_T dry [10^{-6}/K]	α_T 50%RH [10^{-6}/K]
PA6	80 (50–100)	102, 117
GPA6-0°	16 (13)	15, 16
GPA6-45°	30	39, 40
GPA6-90°	54 (55)	70

3.2.3. Self-heating

Figure 4 compares the temperature field of 50%RH PA6 for the different strain rates, at the same applied displacement of 52.4 mm. The strain rates of 10^{-2} and 10^{-1} s^{-1} show prominent self-heating, as opposed to 10^{-4} s^{-1}, thus confirming the theoretical calculations about the critical strain rate. It can be noted that the hot spots tend to move towards the shoulders of the neck. As can be seen in Figure 5, the strain rate concentrates there, while it is virtually zero in the middle. In fact, heat build-up is dependent on the local plastic work rate, in turn related to the local (true) strain rate. The full-field data allows to capture this interdependency.

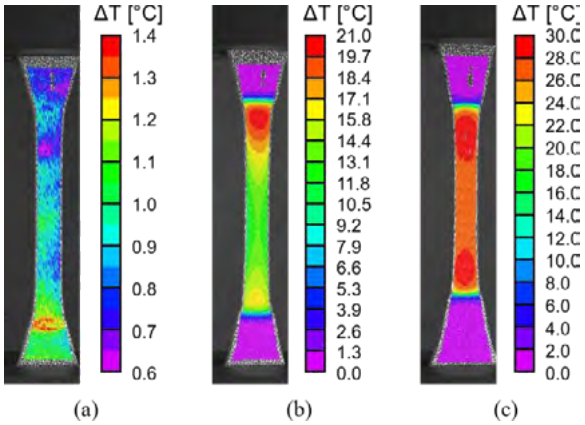


Figure 4. Temperature variation field of 50%RH PA6 for the different (theoretical) strain rates, at the same applied displacement of 52.4 mm: (a) 10^{-4} s^{-1}, (b) 10^{-2} s^{-1}, (c) 10^{-1} s^{-1}.

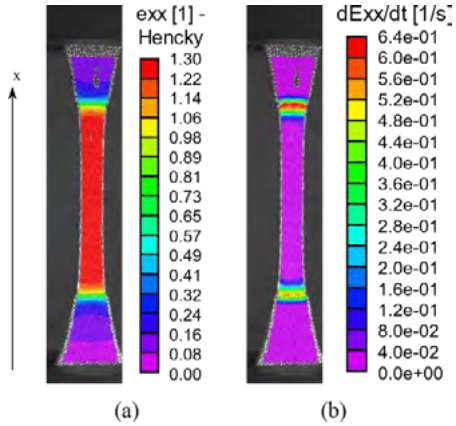

Figure 5. (a) Strain and (b) strain rate fields of 50%RH PA6 at 10^{-1} s^{-1}, at an applied displacement of 52.4 mm.

While the same general observations apply to dry PA6, necking is much more localised, leading to steeper temperature rises compared to 50%RH. In Figure 6, PA6 dry and 50%RH (10^{-1} s^{-1}) are compared at the same average strain of 0.41. Dry PA6 (Figure 6a) has a sharper strain gradient in the neck, such that the applied displacement at this stage is 6.5 mm as compared to 14.6 mm of 50%RH (Figure 6b). It also features a much higher temperature increase. In the next acquired frame, the local temperature increase of dry PA6 in the neck hits almost +70 °C, reaching about 92 °C which is well above the T_g.

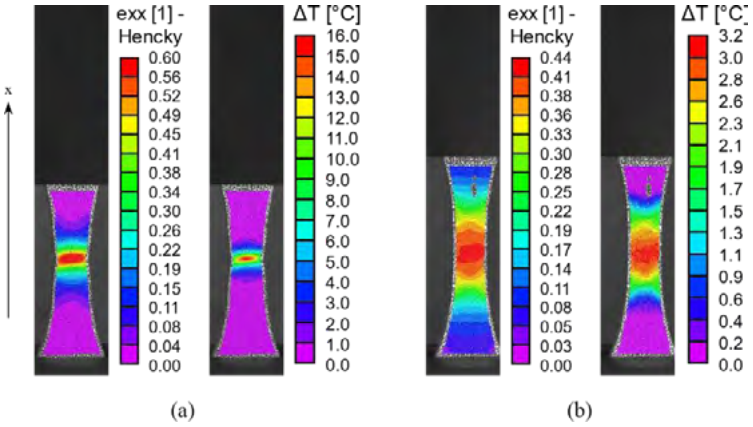

Fig. 6. Strain field and temperature variation field during a test at 10^{-1} s^{-1}, at an average strain level of 0.41: (a) dry PA6 (displacement = 6.5 mm), (b) 50%RH PA6 (displacement = 14.6 mm).

As for GPA6, Figure 7 depicts the strain, strain rate and temperature fields immediately before breakage of the specimen for which the most extreme strain rate concentration was observed (GPA6-90°, 50%RH, 10^{-2} s^{-1}). Even though the strain rate increased 80x in the fracture area compared to the nominal applied rate, the temperature increase was limited to +3 °C. This was the maximum temperature increase recorded among all the specimens. A possible explanation is that failure occurs too early in GPA6, the strain reaching at most 0.2 in 50%RH specimens in a very localised spot, while self-heating becomes prominent in PA6 starting from $0.3 - 0.4$ strain.

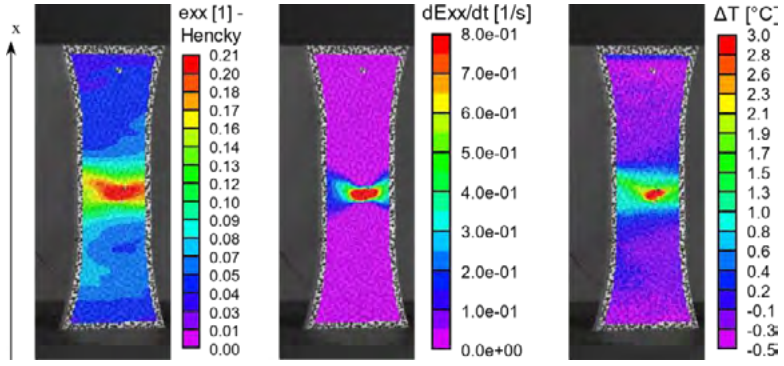

Figure 7. Strain, strain rate and temperature variation fields of 50%RH GPA6-90° at 10^{-2} s^{-1}, last frame before failure. Although the local strain rate peaks at 80x the theoretical nominal strain rate, the temperature rise is quite limited (~3 °C).

4. Conclusions

Thanks to synchronised DIC-IR measurements, full-field strain and temperature data were used to investigate thermomechanical coupling in PA6 and GPA6.

The coefficient of linear thermal expansion could be estimated from the linear thermoelastic response under adiabatic conditions (10^{-1} s^{-1}) for PA6 and GPA6 for all orientations and moisture contents, yielding excellent results.

Significant self-heating was recored in PA6 at 10^{-2} and 10^{-1} s^{-1} after yield. The necking phenomenon was different between dry and 50%RH specimens. In particular, the neck tended to localise in dry PA6 with very sharp gradients (temperatures exceeding the T_g in the neck), while in 50%RH PA6 it spread out more evenly across the gauge length. In both cases, heat accumulation could be linked to the true local strain rate field during plastic deformation measured by DIC. At any given instant, the local strain rate may be order of magnitudes higher or lower than the nominal strain rate estimated from the test speed.

Local surges in strain rate were also observed in GPA6 when approaching failure, yet self-heating was found to be insignificant there (max. local temperature rise +3 °C), likely because of early failure and limited matrix plasticity.

The results of this research can be valuable input for advanced material models for both pure polymers and SFRPs. The full-field data can be used to incorporate thermo-mechanical coupling in the rate-dependent response. The local strain rate information can lead to a more accurate interpretation of the global stress-strain behaviour.

Keywords: Double-Double, Homogenisation, Mechanical Testing, Low-Velocity Impact, Compression After Impact

Abstract
An investigation of the homogenisation, mechanical performance and compression after impact strength of Double-Double (DD) laminates is presented. DD laminates are a new layup design approach composed of repeated sub-laminates, comprising two sets of bi-angled plies, ±Φ° and ±Ψ°. The DD laminate approach simplifies the design of composite structures, reduces manufacturing complexity, and allows for rapid thickness tapering, presenting substantial prospects for reducing structural mass. Updated homogenisation criteria are proposed, aimed at mitigating warpage in DD laminates. These criteria were experimentally validated through laminate manufacture using Carbon Fibre Reinforced Polymer (CFRP) prepreg material. A framework to convert any CFRP laminate to a DD sub-laminate, based on equivalent stiffness, has been developed. Physical testing of both in-plane tensile and flexural specimens, for quad and DD laminates, was carried out to validate the framework. Additionally, low-velocity impact and subsequent compression after impact testing were conducted on quad and DD laminates. Initial findings indicate the potential for a reduced delamination area and increased CAI strength.

1 Introduction

When the orientation of plies in a laminate is limited to a collection of 0°, ±45° and 90° angles, they are considered to be quad laminates or Legacy Quad Laminates (LQL). Designing with conventional quad laminates entails adhering to numerous design rules and guidelines. There are some 39 legacy guidelines for designing composite structures, summarised by Bailie *et al.* [1]. These guidelines have introduced vast complexity into the design process, limiting innovation and causing severe difficulties regarding layup optimisation.

DD laminates are a new layup design approach which seeks to address the limitations of quad laminates. First proposed by Tsai *et al.* in 2017 [2], DD simplifies the design of composite structures and allows for simplistic and rapid thickness tapering with the potential for structural mass reduction and increased manufacturing speeds. DD laminates are typically made up of repeated building blocks or sub-laminates, composed of two sets of bi-angled plies, as shown in Figure 1. LQLs limit the design space by restricting the angle increments to four discrete values. DD eliminates these restrictions, ensuring the presence of each ply angle in the laminate is optimised and justified, while simultaneously simplifying the design process.

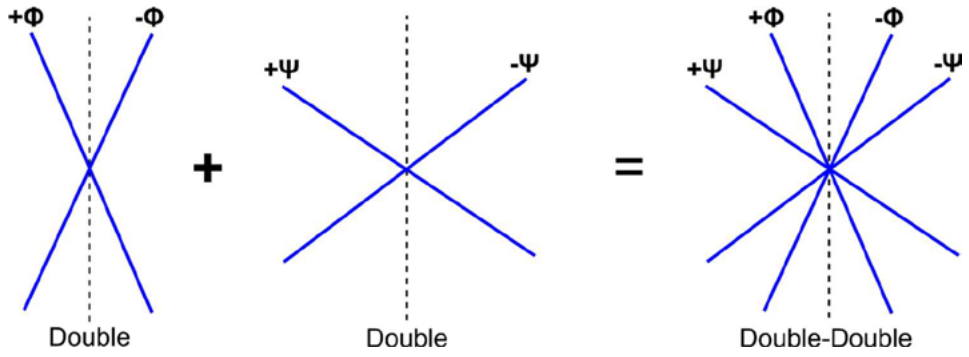

Figure 1 - Sub-laminate building block for DD Laminates.

Through-thickness homogenisation of the laminate is a fundamental characteristic of the DD layup methodology. It is achieved through a minimum number of repetitions of the asymmetric DD sub-laminate, sufficiently suppressing coupling terms in the laminate [ABD] matrix. Asymmetric laminates tend to warp when cooled from an elevated temperature cure cycle, due to unbalanced thermal residual stresses. Sufficient homogenisation ensures the DD laminate will be free from warpage, even when cured at an elevated temperature. Homogenisation criteria have been proposed for this purpose [3], [4, Ch. 4]. However, little experimental validation has been carried out to test and validate these criteria. The first part of this work assesses the existing homogenisation criteria through DD laminate manufacture. Following this, an updated homogenisation criteria was proposed and subsequently validated.

Given a quad or unconventional laminate, it is possible to convert to a DD layup, resulting in a DD laminate of equivalent stiffness. Exact in-plane stiffness matches are possible using the standard 4-ply DD sub-laminate when the quad laminate contains less than 50% 0° or 90° plies. A closed-form solution for converting to a standard DD layup was derived using lamination parameters by Tsai [4, pp. 26–28]. The work presented here builds on the Tsai's theory, establishing a novel framework for converting any laminate to a standard or extended DD sub-laminate. The efficacy of the framework was then validated through tensile and flexural mechanical testing of both quad and equivalent DD laminates.

Low-velocity impact (LVI) and compression after impact (CAI) are standard procedures in assessing the structural integrity of composite materials, particularly in aerospace applications. LVI involves subjecting a structure to a relatively low-energy impact, typically resulting in localised damage such as delamination, fibre breakage, and matrix cracking. Subsequently, CAI refers to the residual strength of the composite laminate, following an impact event, i.e. its ability to withstand further loading conditions. Understanding the mechanical response of a composite laminate to LVI and CAI is fundamental for predicting their damage tolerance and long-term performance, especially for aerospace applications. Little work has been done to assess the LVI and CAI performance of DD laminates [5], [4, Ch. 6]. The final section of this study compares the LVI and CAI performance of quad and in-plane/flexural stiffness equivalent DD laminates.

2 Methodology

Computations for homogenisation in Section 2.1 and stiffness matching framework in Section 2.2 are independent of CFRP material. This was achieved through the use of Master Ply values which represent the average proportions of stiffness in each direction for any CFRP material [6], [7], [8]. The Master Ply values used in this study were calculated by Tsai *et al.* [9] to be $Q_{11}^{*} = 0.8849$, $Q_{22}^{*} = 0.0525$, $Q_{66}^{*} = 0.0313$ and $\nu_{12}^{*} = 0.3$. Terms denoted with the superscript "n*", indicate thickness normalisation and computation using Master Ply values.

In each of the three studies, laminates were manufactured from a 145gsm carbon-epoxy prepreg, IM7 977-2. During layup, plies were tacked together using a heat gun, and the laminate underwent debulking

approximately every five plies to enhance stack consolidation. Subsequently, laminates were cured at 180°C under 6 bar pressure for 3 hours with ramp and cool down rates set to 2°C/min.

2.1 Homogenisation of Double-Double Laminates

2.1.1 Homogenisation Framework

A simplified homogenisation framework is shown in Figure 2. Initially, unique permutations are obtained by eliminating those that are effectively the same in terms of a DD sub-laminate. These unique permutations are then evaluated at specified increments between 0° and 90° to determine the minimum number of sub-laminate repetitions to meet the homogenisation criteria. For each angle combination the $[ABD]^{n*}$ matrix is calculated for both arrangements, or orders, of angles with the sub-laminate i.e. DD angle 1 = Φ, DD angle 2 = Ψ and vice versa. The angle order that that minimises the required repeats or minimises the highest value in the B^{n*} coupling matrix is selected. If both metrics are equal, no preferential order is specified.

Once all permutations for a particular sub-laminate have been evaluated, those requiring the minimum number of repeats to meet the criteria are identified. In the scenario where more than one permutation remains, the permutation that minimises the highest value in the B^{n*} coupling matrix is selected. Subsequently, the resultant grid recommends only one stacking sequence permutation per cell. The following sections will cover the use of this framework and present homogenisation grids for use as a design tool.

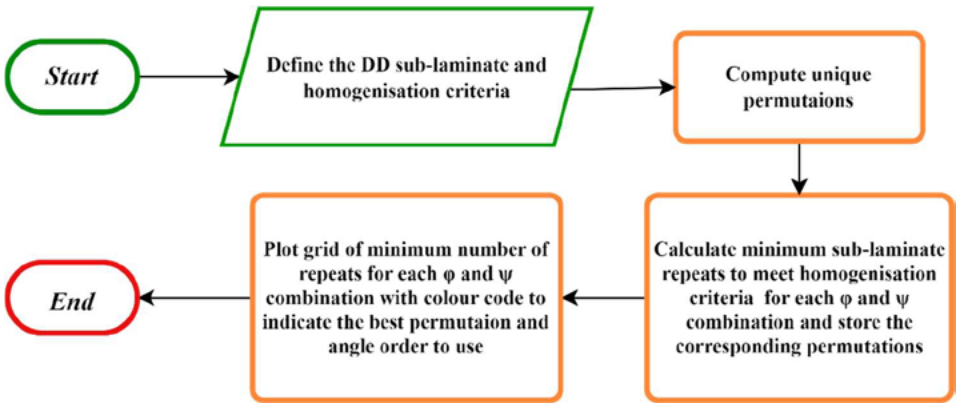

Figure 2 – Simplified illustration of homogenisation workflow.

2.1.2 Assessment of Homogenisation Criteria

The homogenisation criteria proposed previously in literature [4, Ch. 4] are summarised in Equation (1). Based on these criteria, four laminates were manufactured. The stacking sequences for these laminates are given in Table 1. It is noteworthy that not all of these stacking sequences are necessarily optimal for the specified angle combinations to achieve homogenisation. However, all fabricated laminates adhered to the homogenisation criteria outlined in Equation (1).

$$[\mathrm{D}^{n*}] - [\mathrm{A}^{n*}] < 2\% \quad \text{and} \quad [B^{n*}] < 2\% \tag{1}$$

Following the outcomes of the laminate manufacture based on the original homogenisation criteria, shown in Section 3.1.1, updated homogenisation criteria were proposed. These criteria further constrain the $[B^{n*}]$ coupling terms and are shown in Equation (2). Based on these updated criteria and framework outlined in Section 2.1.1, an additional four laminates were manufactured to assess the efficacy of this revised criteria. The stacking sequences are given in Table 1.

$$[\mathrm{D}^{n*}] - [\mathrm{A}^{n*}] < 2\% \quad \text{and} \quad [B^{n*}] < 1\% \tag{2}$$

Table 1 – Stacking sequences for assessment of homogenisation criteria.

Original Criteria	Updated Criteria
$[+22.5/-67.5/-22.5/+67.5]_4$	$[+22.5/-67.5/-22.5/+67.5]_8$
$[+22.5/-67.5/+67.5/-22.5]_5$	$[+17/-64.5/-64.5/-17]_8$
$[+61.5/-9/-61.5/+9]_5$	$[+9/-61.5/+61.5/-9]_5$
$[+47/-9/-47/+9]_5$	$[+9/-47/+47/-9]_5$

2.2 Mechanical Performance of Double-Double Laminates

An automated workflow has been developed to transform any CFRP laminate to a DD sub-laminate of equivalent thickness. Should a solution to the closed-form equations exist, it will be employed. In instances where there is no solution to the closed-form equations, an optimisation procedure will be executed utilising the Particle Swarm Optimisation Algorithm (PSOA) across all DD sub-laminates, with the optimal solution subsequently chosen. Notably, DD laminates with ID DD-An are tailored to match the in-plane properties of the candidate laminate, while the ID DD-Dn corresponds to a match of the out-of-plane flexural properties.

Readers are referred to [10] for a more detailed explanation of the automated conversion workflow, DD sub-laminate stiffness domain and closed-form solutions. The domain for which an exact stiffness match is possible can be expanded through the use of five and six ply DD sub-laminates. The authors previously derived closed-form equations for extended DD sub-laminates [10].

2.2.1 Mechanical Testing for Validation

In order to validate the aforementioned conversion workflow, tensile and flexural tests were performed in accordance with ASTM D3039 and ASTM D7264, respectively. Composite laminates were laid up with 16 or 20 plies of IM7 977-2. Table 2 shows the specimen details used in this study.

Table 2 – Stacking sequences for validation of framework.

Layup ID	Stacking Sequence	Test Type	No. of Specimens
Quad-TF	$[0/45/90/-45]_{2s}$	Tensile / Flexural	5 / 8
DD-An-T	$[22.5/-67.5/-22.5/67.5]_4$	Tensile	5
DD-Dn-F	$[9/-61/61/-9]_5$	Flexural	8

Tests were performed using a Zwick Z100 Proline. 100 kN and 10 kN load cells were used for the tensile and flexural specimens respectively. 350 Ω strain gauges were bonded to each tensile specimen and a System 8000 StrainSmart data acquisition system was used to record synchronised force-strain data.

2.3 LVI and CAI Performance of DD laminates

A quasi-isotropic quad laminate was chosen as the starting laminate for this study. Using the framework outlined in Section 2.2, DD sub-laminates were matched to the in-plane and flexural properties of the quad laminate. Table 3 shows the specimen details used in this study.

Table 3 – Stacking sequences for LVI/CAI Study.

Layup ID	Stacking Sequence	No. of Specimens
Quad-LC	$[0/45/90/-45]_{4s}$	3
DD-An-LC	$[22.5/-67.5/-22.5/67.5]_8$	2*
DD-Dn-LC	$[17/-64.5/64.5/-17]_8$	3

*One specimen emitted from results due to double impact during LVI testing

2.3.1 LVI Setup

LVI of the CFRP specimens was carried out in accordance with ASTM D7136. Based on a nominal laminate thickness of 4.64 mm, an impact energy of 31 J was used. The impact was administered using an ERN 45 Rosand Falling Weight Impact Tester. A steel hemispherical impactor with diameter 16 mm and total weight of 5.63 kg was released from a height of 561.5 mm. Post-impact, the panels were subjected to ultrasonic inspection where C-scan images were produced to assess internal delamination.

2.3.2 CAI Setup

CAI testing was performed in accordance with ASTM D7137. A Zwick-Roell Z100 Proline with 100 kN load cell and an Instron 2580 Series with 150 kN loadcell were used for the compression testing. The side of specimens subjected to the impact was painted white and speckled black. Two synchronised cameras were used to record the test. Digital Image Correlation (DIC) was subsequently performed using VIC3D from Correlated Solutions.

3 Results and Discussion

3.1 Homogenisation of Double-Double Laminates

Homogenisation grids in the subsequent sections were created using the framework set out in section 2.1.1. A 5° resolution between DD angles was chosen for visualisation purposes, with the framework capable of producing grids to any desired resolution.

3.1.1 Laminate Manufacture – Original Homogenisation Criteria

The homogenisation grid depicted in Figure 3 was based on the original homogenisation criteria, Equation (1). Figure 4 shows the resulting manufactured laminates. Significant warpage was observed in all laminates due to unbalanced thermal residual stresses induced during the cure cooldown cycle. This observation suggests that the original homogenisation criteria are insufficient in preventing warpage of DD laminates cured at elevated temperatures.

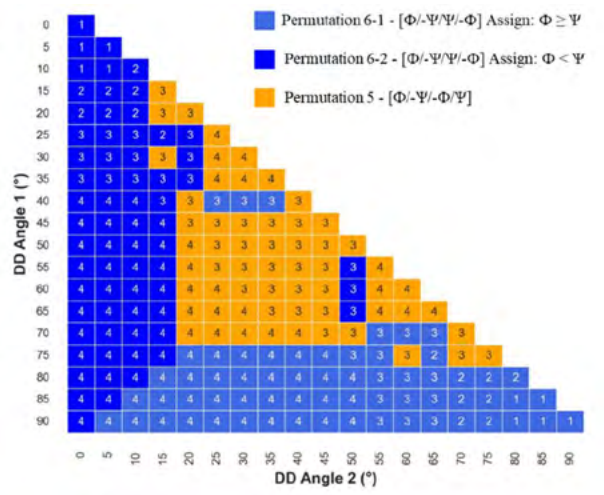

Figure 3 – Homogenisation grid based on original homogenisation criteria.

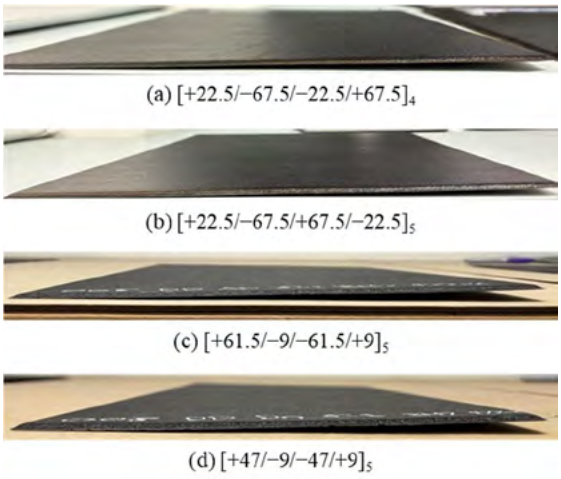

Figure 4 – Laminates manufactured based on original homogenisation criteria.

3.1.2 Laminate Manufacture – Updated Homogenisation Criteria

Figure 5 shows the resulting homogenisation grid based on the updated homogenisation criteria, Equation (2). A range of DD angle combinations were chosen for manufacture as previously set out in Table 1. The resulting laminates are shown in Figure 6. In all cases, zero or insignificant warpage was observed, suggesting the updated homogenisation criteria is sufficient to prevent warpage. Further validation, through laminate manufacture with additional DD angle combinations and material variations, is required.

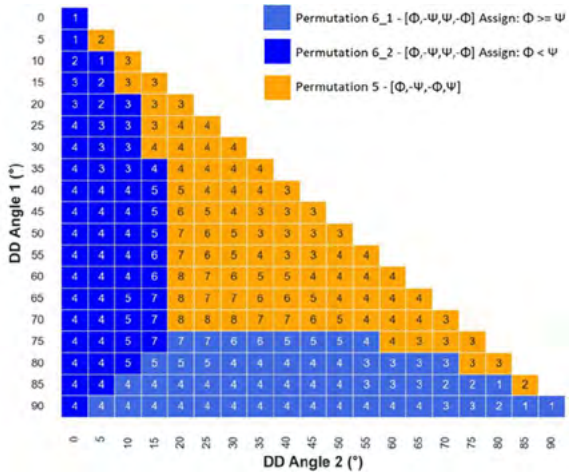

Figure 5 - Homogenisation grid based on updated homogenisation criteria.

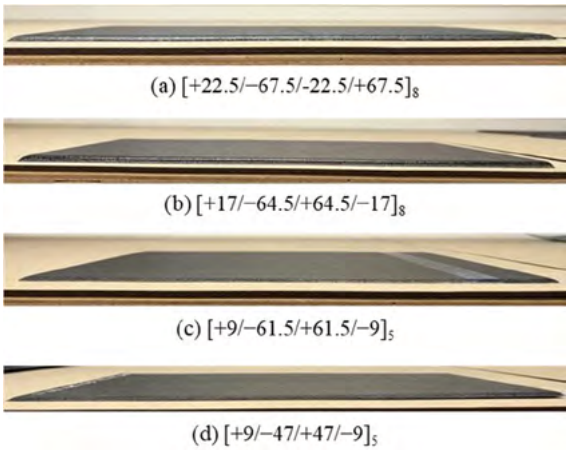

Figure 6 - Laminates manufactured based on original homogenisation criteria.

3.2 Mechanical Performance of Double-Double Laminates

The mechanical properties of quad and corresponding DD laminates are shown in Table 4. Tensile and flexural modulus values between quad and DD laminates correlate closely, with differences of 0.06 % and 2.05 % respectively. These preliminary tests establish a solid foundation in validating the framework in Section 2.1.1, which will be explored further in future studies.

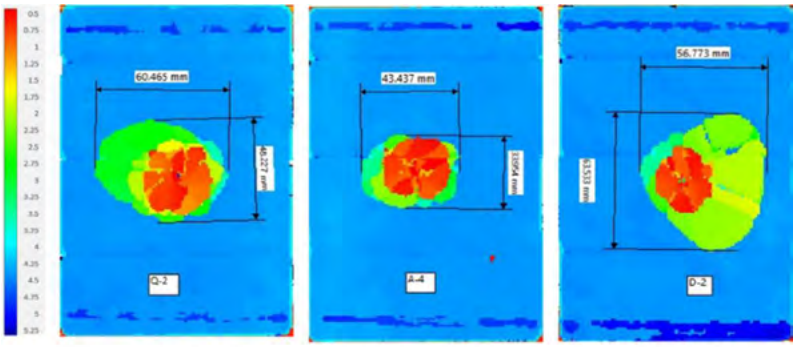

Table 4 –Mechanical properties of quad and DD laminates.

	Tensile Modulus		Flexural Modulus	
Layup ID	Quad-TF	DD-An-T	Quad-TF	DD-Dn-F
Mean (GPa)	52.31	52.28	60.99	62.24
SD (GPa)	0.95	1.98	0.70	1.18
CoV (%)	1.81	3.80	1.15	1.90

3.3 LVI and CAI Performance of DD laminates

3.3.1 Delamination of Specimens Subjected to LVI

C-scan images of one impacted specimen per laminate are shown in Figure 7. The DD-An-LC laminate, matched to the in-plane stiffness of the quad laminate, displayed the smallest delamination area. The largest delamination area was observed in the DD-Dn-LC laminate, matched to the flexural stiffness of the quad laminate. Since only one impacted specimen from each laminate was scanned, no definitive conclusions should be drawn. However, further study is planned with repeated specimens.

(a) Quad-LC (b) DD-An-LC (c) DD-Dn-LC

Figure 7 – C-scan images from ultrasonic inspection of impacted panels.

3.3.2 CAI Strength

The residual compressive strength results are given in Table 5. An increased in residual strength was observed in both DD laminates compared to the equivalent quad laminate. The increase in strength of 3.95 % in DD-An-LC is likely due to the decrease in delamination area compared to Quad-LC. DD-Dn-LC matched the out-of-plane flexural stiffness of Quad-LC. Despite having the largest delamination area, DD-Dn-LC had a 10.38 % higher residual strength compared to Quad-LC. This can be attributed to the 15.65 % higher pristine compressive strength of DD-Dn-LC when compared to Quad-LC. An ANOVA test, comparing DD-An-LC, DD-Dn-LC and Quad-LC, indicated a large effect size (factor = 2.13) but with no statistically significant difference between the means of the datasets at the 5% significance level ($p = 0.2137$). This result warrants further investigation of the CAI performance, with a larger number of specimens.

Table 5 – CAI residual strength of Quad and DD laminates.

Layup ID	Quad-LC	DD-An-LC	DD-Dn-LC
Mean (MPa)	218.26	226.89	240.91
SD (MPa)	12.62	8.50	16.18
CoV (%)	5.78	3.74	6.72

Conclusions

A framework for determining the best DD stacking sequencing and minimum sub-laminate repetitions to satisfy specified homogenisation criteria is presented. Through fabrication of numerous CFRP laminates, it was demonstrated that the previously proposed homogenisation criteria were inadequate in mitigating warpage in DD laminates subjected to elevated temperature curing. An updated homogenisation criteria is proposed and subsequently validated, producing warpage-free laminates. To further build confidence in these criteria, additional laminates in a variety of prepreg materials should be manufactured and examined.

The conversion framework outlined facilitates the transformation of any CFRP laminate into a stiffness equivalent standard or extended DD sub-laminate. An assessment of the tensile and flexural properties of DD laminates in comparison to their stiffness equivalent quad laminate was conducted. These initial tests form a solid foundation for validating the conversion framework.

LVI and CAI testing was conducted on quad and corresponding in-plane and flexural stiffness equivalent DD laminates. C-scan images show DD laminates have the potential to reduce delamination area. Improvements in residual strength were observed for both DD laminates when compared to the original quad laminate. Due to testing on a limited number of laminates and specimens, general conclusions on the performance of quad vs DD laminates for LVI and CAI cannot yet be drawn. Results obtained from this physical testing will be used to validate ongoing numerical simulation of LVI and CAI events for DD laminates.

Keywords: CFRTP, structural health monitoring, thermo-oxidative aging, vibration

Abstract
Reducing vehicle weight through carbon fiber reinforced thermoplastic composites (CFRTP) is critical for improving automotive fuel efficiency and combating climate change impacts. However, these components, for example those used in under-the-hood automotive applications, might degrade under severe thermo-oxidative environments. Therefore, it is important to study aging processes and non-destructively assess the structural integrity. In this study, a sandwich-structured CFRTP with a sheet molding compound skin and carbon fiber paper reinforced thermoplastic core was investigated. Composites were fabricated with varying springback ratios (SBRs) to introduce a controlled porous structure and reduce weight. Thermo-oxidative aging at 90-170 °C for up to 100 hours simulated severe service environments. Aged composites were characterized using mechanical testing, vibration analysis, and microstructural evaluations, and an inverse finite element modeling approach was conducted to quantify residual modulus distribution. The results revealed that higher SBRs and aging temperatures/durations degraded flexural properties and induced fracture mode transitions from brittle failure to delamination. The detailed spatial modulus distribution was inversed by the natural frequencies of the specimen after aging, with a satisfying average absolute error as low as 4-6%. The proposed vibrational method provides with a perspective of non-destructively assessing the structural integrity.

1. Introduction

Climate change is among the most focused issues of global concern. Addressing climate change requires strict restrictions on CO_2 emissions [1][2]. Strict restrictions necessitate a reduction in the body weight of automobiles to improve their fuel efficiency and minimize their environmental impact [3]-[5]. In this regard, carbon-fiber-reinforced thermoplastic (CFRTP) has significant advantages in terms of its short molding time, low processing cost, and excellent recyclability. CFRTP has undergone extensive study for structures requiring low weight and high impact resistance, making it particularly suitable for mass-produced automotive components [6][7].

Polyamide 6 (PA6) with excellent performance and heat resistance has been largely applied in the automotive industry such as semi-structural components and some interior accessories [8]-[10]. Especially, there has recently been a strong demand for the use of molded composites that serve as divided manifolds, front-end modules, and other under-the-hood applications [11][12]. These applications place stringent requirements on CFRTP composites in terms of dimensional stability, mechanical properties, and chemical resistance. Once these composites are exposed to high temperatures for a prolonged period, they become sensitive and vulnerable to factors including radiation, moisture, heat, or light [13][14]. Hence, investigations into the mechanical properties under severe serving

environments and monitoring the structural health condition under temperatures as high as 150 °C, or even 200 °C are significant for long-term service of PA6-based CFRTP composites [15].

The imperative to address climate change and the demand for eco-friendly automotive materials underscore the need for innovative testing methods. The ultrahigh cost of static mechanical tests and the increasing need for real-time monitoring make destructive tests infeasible [16]. In contrast, nondestructive evaluation is an analytical and measurement technique for quantitatively characterizing materials, components, and structures in real-time and without causing any damage to material properties [17]. In particular, for the vibration method, with advantages of relatively simple equipment and low testing costs, it is necessary to apply an external excitation to the specimen and extract the modal parameters, such as natural frequencies (NFs) and vibration mode shapes, which are considered the main parameters for determining the elastic properties of a composite [18]. The vibrational method has shown satisfying accuracy when inversing the modulus distribution matrix [19].

In this study, sandwich structured composites were fabricated utilizing CFRTP sheet moulding compound (SMC) as skin and carbon fiber paper reinforced thermoplastics (CPT) as core and were reheated to achieve the springback phenomenon with different ratios. The specimens were aged under thermos-oxidative environments for various periods to simulate complex aging situations. The mechanical property decline was tested, and the vibrational signals of natural frequencies were conducted to reflect the changes. Finally, the aging mechanism was proposed to help understand the aging process of sandwich-structured CFRTP composites.

2. Experiments

2.1. Fabrication and aging

The sandwich composite was fabricated with 6 pieces of SMC as skin and 12 pieces of CPT as core. Both two kinds of prepregs were cut into the size of 125 * 250 mm and then were fabricated into plate composite under 280 ºC and 5 MPa, and the detailed temperature and pressure curves were shown in Fig. 1a. Then the margin parts (10 mm) of as-fabricated plate were cut off and the remained part was re-heated to specific thickness by two stoppers, as shown in Fig. 1b. The ratio of thickness before and after re-heating was named as springback ratio (SBR).

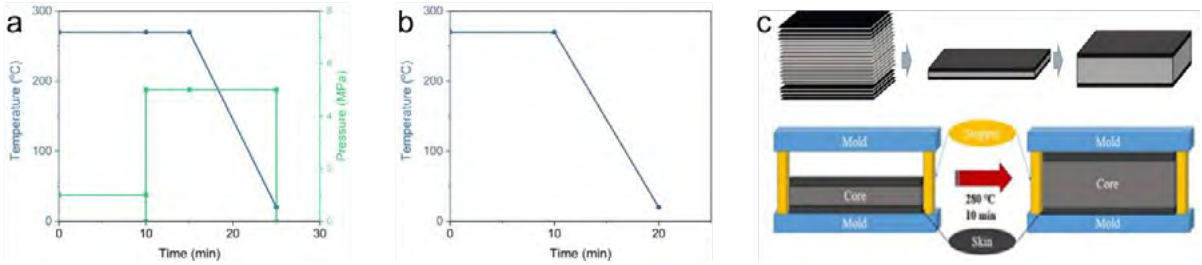

Fig. 1 Temperature and stress data for fabricating (a) sandwich and (b) springbacked plate and (c) scheme diagram of the two-step method for springbacked structure.

The thermo-oxidative aging test was carried out on a box-type electric furnace (Elepot SH, Hata Electric Co., Ltd.) in the air for a total of 100 hours. The test temperatures were chosen as 90 ºC, 130 ºC, and 170 ºC, respectively. Specimens with different SBRs (1.0, 1.2, and 1.6) were aged at a certain temperature for 20 hours and then naturally cooled in the furnace, which is defined as one cycle. The test lasted typically for 5 cycles.

2.2. Mechanical and vibrational properties

The sandwich composites with different SBRs were cut into sticks for a 3-point bending test using a 5 kN universal testing machine (AGS-X, Shimadzu, Japan). The specimens were manufactured to meet the span-thickness ratio standard of 16:1 and an additional 10 mm were maintained on each side and the speed of bending is 1 mm min^{-1}. A high-speed camera (FASTCAM SA-X) was applied to record the

fracture procedure during the flexural test. The micromorphy was observed by the digital microscope (VHX-8000, Keyence) and the X-ray scanning system of TDM1000-II 3D (Yamato Scientific Co., Ltd. Japan) was applied to analyze the inner structures. The natural frequency and mode shapes were tested using modal tests. The electrical signal was converted into visual vibrational data using a signal analyzer (OROS 34, TOYO, Japan). A dynamic mechanical analyzer (DMA, RSA-G2, TA Instruments, USA) was used to perform the tensile test to detect the tensile modulus, where temperature was set at 25 °C.

2.3. Modulus inversing based on NFs

This inverse analysis is based on FE simulation using the genetic algorithm, as shown in Fig. 2. The natural frequencies and modal shapes can be easily and accurately measured by modal tests. With the geometry information of the structure, the natural frequencies of the structure can also be predicted by FE simulation. However, the simulated natural frequencies may not agree with the natural frequencies of the real structure due to inaccurate material parameter settings in the FE model. So the inverse analysis is to update the material parameter setting in the FE simulation by optimization algorithm to make the simulated results agree with real results. The final material parameter setting in the FE model is the identified modulus of the structure, which is the residual modulus after aging.

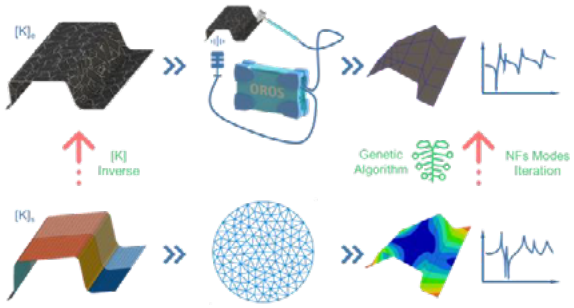

Fig. 2 Schemtic of inversing the residual modulus based on the non-destructive vibrational method.

3. Results and discussions

3.1. Microstructures of sandwich with various SBRs

The micromorphy apparently revealed the sandwich structure, as shown in Fig. 3. The different layers of SMC skin are easily observed. For the SBR1.0 specimen, few pores could be observed and the bond between skin and core is tight. The distribution of fiber and resin is not even, and the resin-rich may serve as failure initiation zones. The fiber in the CPT core shows a random orientation, from the isotropy of mat. After springback, the thickness of the two skins changed, mainly coming from the flowing during the second step of springback, showing the excellent molding property of SMC. And porous structure was generated while the porosity increased with the SBRs. Besides the expansion of the CPT core, the delamination occurred within the skin and was even more severe in the SBR1.6 specimen. Also, the interface gets weak, and more voids appear in the link area, making it easier to fail.

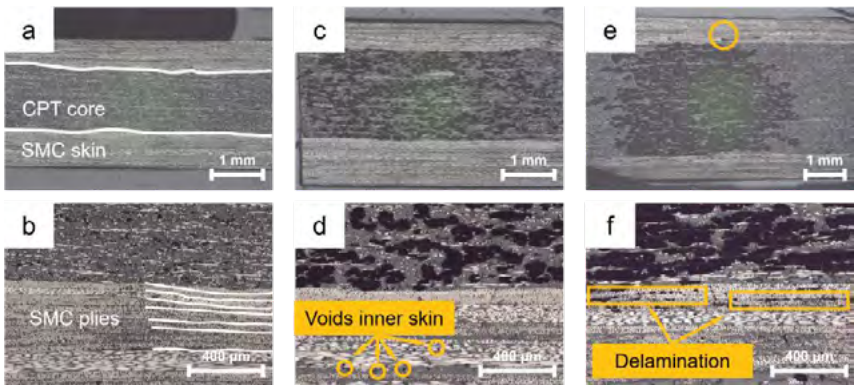

Fig. 3 Microstructure of specimens of (a-b) SBR1.0, (c-d) SBR1.2 and (e-f) SBR1.6.

Fig. 4 prensents the X-ray scanning results. For both the skin and core, the out-plane angle of θ highly concentrated at 90 °, resulting from the lamination of plies. The change of peak values after springback is not large because the SBR is limited. For the φ of SMC skin, the distribution is generally homogeneous, except for the abnormal peak at 90 °, which is similar to CPT. Also, For the core, the apparent peak at 0 ° is the machine direction of the raw CPT plies, showing an aligning performance. After aging at 170 °C for 100 hours, the trend shows good consistency with the specimen without aging. The springback ratio is smaller, resulting in a weak deformation.

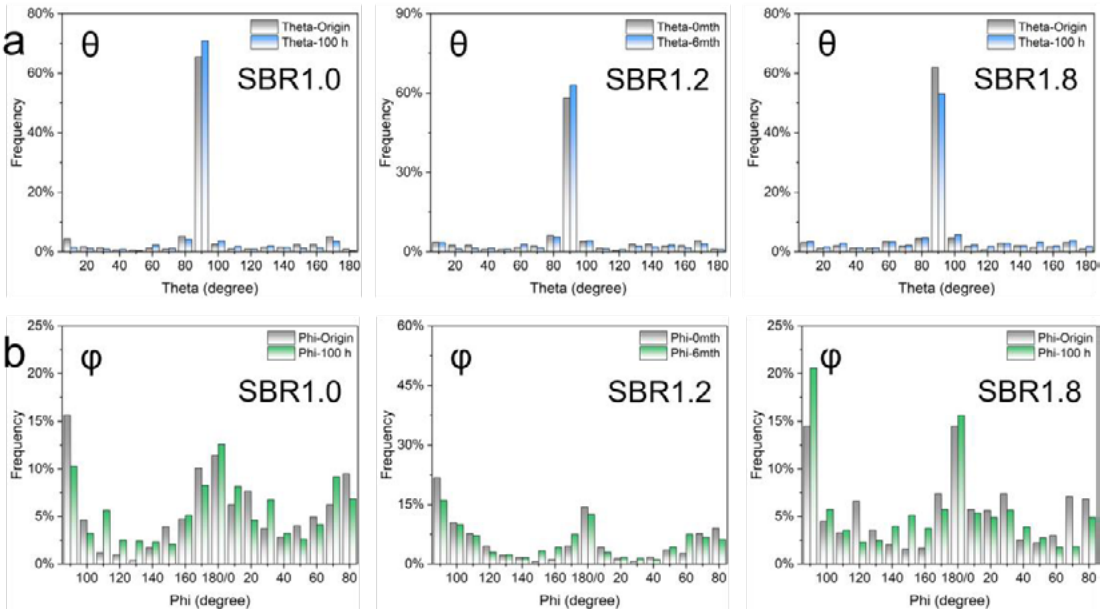

Fig. 4 Fiber orientation distributions of (a) θ and (b) φ of SMC skin.

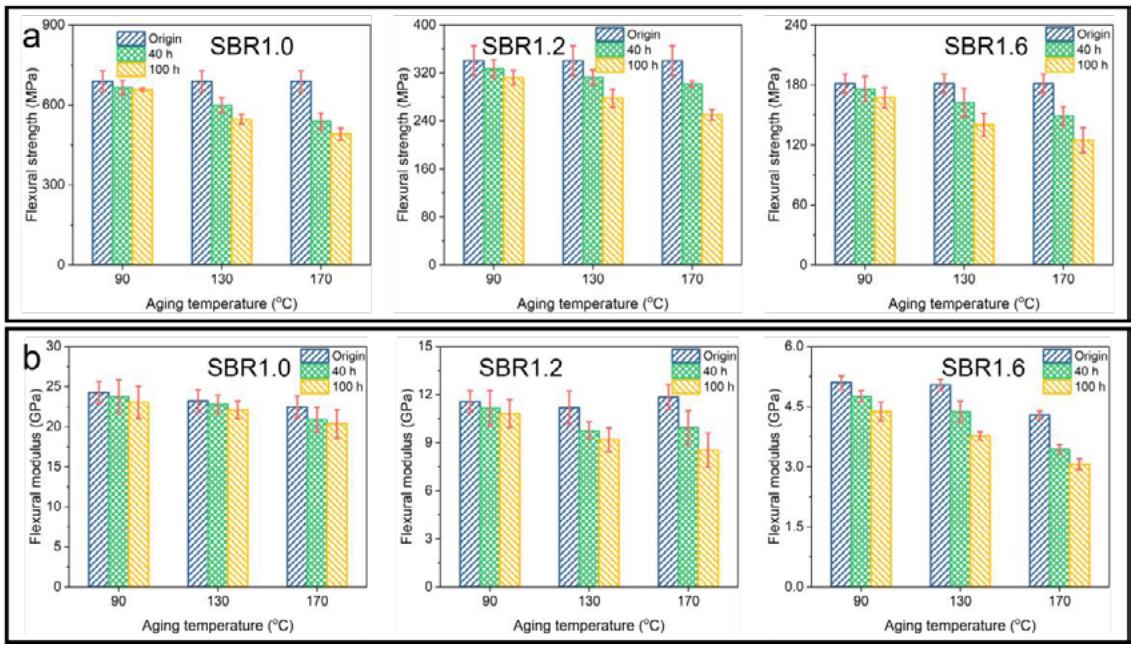

Fig. 5 Reduction of (a) flexural strength and (b) modulus after aging.

3.2. Mechanical properties

Both the flexural strength and modulus decreased with aging duration and SBR increasing, as shown in Fig. 5. The springback caused a giant reduction of the mechanical properties, and the porous structure does not benefit the bearing and easily generates cracks. The error of sandwich with SMC skin is large, mainly comes from the scatter of SMC. The reduction after the first 40 hours is apparent, proving the aging is effective. But the reduction ratio of modulus is relatively low because it is mainly determined by the skin of SMC. The thermo-oxidative aging caused enormous damage to the mechanical properties, so the assessment of structural integrity is necessary for the automobile application.

In Fig. 6a, for the original specimens of SBR1.0, the brittle failure occurred soon but a bearing period can be found for springbacked specimens before the failure. The displacement before fracture increased with SBRs, proved the advantage of energy absorption from the porous structure. But for aged specimens, the bonding between fiber and resin is destroyed and the transfer of stress gets weak. And delamination occurred in the springbacked specimens. And this kind of failure mode change is more obvious when aged at higher temperatures. The bearing force by the bottom skin after the first drop also reduced, from the aging damage to the resin.

The curves are divided into 4 parts for SBR1.0. point A belongs to the elastic period, and cracks were generated on the top surface because of the stress at Point B. For not springbacked specimens, the crack rapidly grows and penetrates through the bottom skin, causing brittle failure. But for aged specimens, the crack slowly propagates inner the core and finally reaches the bottom skin, and then causes the fracture. Partial delamination could be observed in the top skin, driven by the stress concentration during the start period. For SBR1.6 specimens, a gradual failure mode change occurred. The blue curve of the not-aged specimen shows a longer linear period before the first drop, which comes from the fracture on the top skin. Then the core is gradually compressed finally the bottom skin is fractured, leading to complete failure. For the aged specimens, two situations exist. The green curve shows a similar trend, with the first drop of crack on the top skin, but the second drop comes from the delamination at the interface. For the yellow curve, the delamination directly occurred before any crack was generated, showing a more severe aging effect.

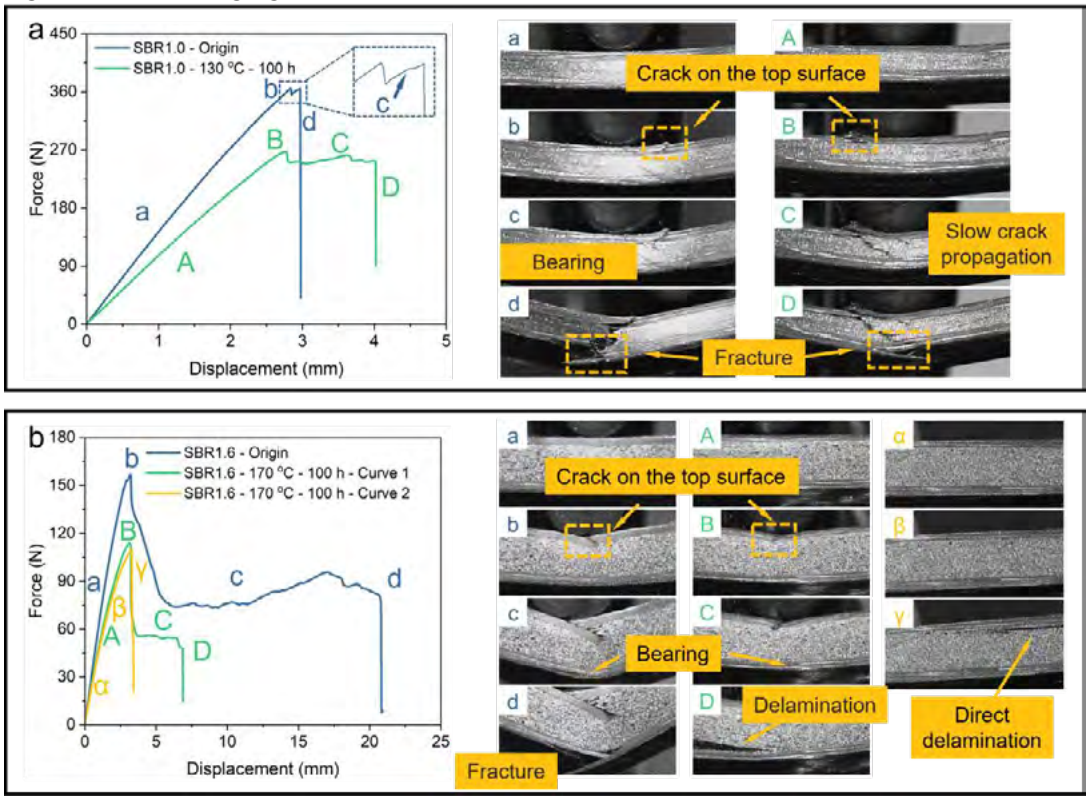

Fig. 6 Reduction of (a) flexural strength and (b) modulus after aging.

Acoustic emission (AE) testing was applied to monitor the fracture process, as shown in Fig. 7. The peak of the AE count is highly consistent with the fracture of the specimen. For the left figure, the fracture of two skin is reflected on the AE, while the middle signal proves the growth of cracks. For the middle figure, the count of delamination is much higher than the first drop of crack emerging, because delamination absorbs more energy by generating new surface. For the right figure, lower peaks of AE signals proved the process that the delamination first generated in the local position and then extended to the whole interface.

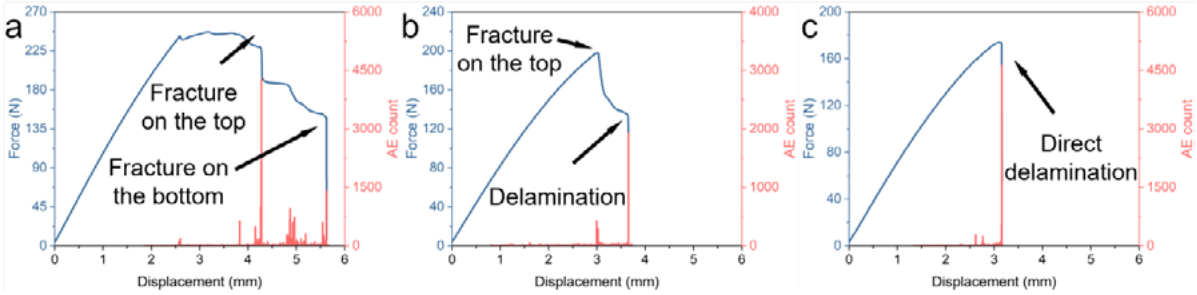

Fig. 7 AE counts of SBR1.2 (a) without aging and aged at 170 °C for (b) 40 hours and (c) 100 hours.

3.3. Structural strength assessing by vibration

It has been verified that the non-destructive vibrational method could be applied to inverse the detailed modulus distribution from easily tested natural frequency singles with satisfying accuracy [19]. In this case, the thermos-oxidative aging inflicted continuous damage on the specimens, and the gradual decrease in modulus is also reflected in the natural frequencies of the aged specimens, as shown in Fig. 8. Natural frequencies refer to the frequencies at which a system tends to oscillate or vibrate naturally, without any external forces acting on it. In a mechanical system with multiple degrees of freedom, there will be multiple natural frequencies, each corresponding to a specific mode of vibration. The order of natural frequencies is typically arranged from the lowest frequency to the highest. The value of the Y axis refers to the change of the first 40 hours and the additional 60 hours. The aging under the temperature of 90 °C is relatively weak, so the aging effect on natural frequencies is not strong. The reduction of all SBRs is small. When the temperature increased, the reduction immediately increased. The springback process brings porous structure to the specimens, so the aging is generally homogeneous occurred inner the core, causing a regular reduction of natural frequencies without abnormal values. Also, longer aging duration caused a larger reduction.

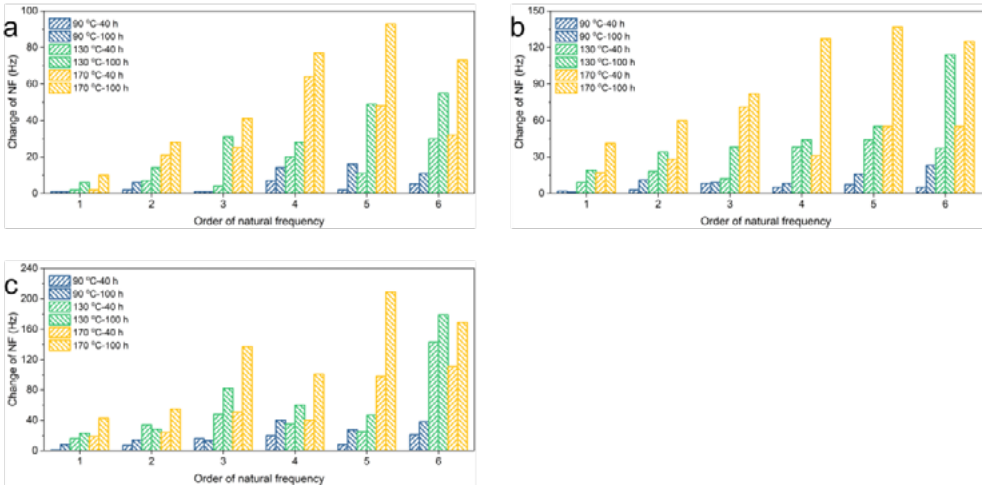

Fig. 8 Reduction of first 6 order NFs of (a) SBR1.0, (b) SBR1.2 and (c) SBR1.6.

The FE model and real sandwich plate after aging in freshwater for 6 months were as shown in Fig. 9(a-b), with geometry size of 100 * 100 mm. Both the virtual and real square plate were divided into 4 parts, and A1 and B1 are for modulus along the X direction, namely E_x, while A2 and B2 are for modulus vertical to the direction, namely E_y. The integration method of linking 3 models presents the best inversing accuracy. Beside the original plate without extra mass blocks, two kinds of mass distributions were achieved with the model shown in Fig. 9(d-e). The mass distribution affected the vibration, although the shapes of the same order are similar, the position relation is apparently different. The thickness was tested. And the inverse process is to calculated the modulus distribution and compare the calculated values with the tested values, which is referred to errors. And the everage absolute error refers to the average of error of all the four parts. For the sandwich and springback, the average absolute errors are around 4% and 6%, respectively. And the terms of P_x means the different plate models with various mass distributions, which is revealed in Fig. 9(d-e). The major factor of reduced accuracy is the thickness of the springbacked specimen is larger compared to the edge of the square, which cannot be regarded as a pure 2D stress state. However this accuracy still could be used to assess the structure integrity after long-time thermo-oxidativel aging.

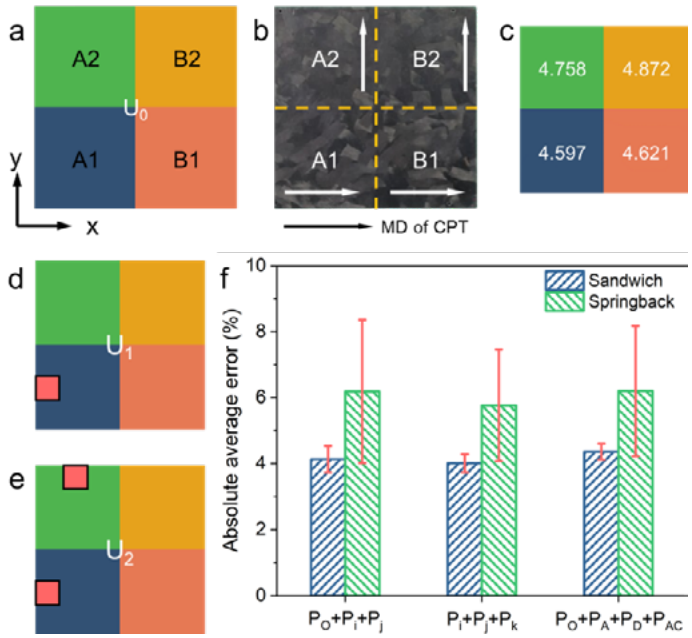

Fig. 9 (a) FE model and (b) real sandwich structures used for inversing residual modulus, (c) thickness distribution, (d-e) mass blocks distribution, and (f) inversed average absolute errors.

4. Conclusions

A sandwich structure with SMC skin and CPT core is prepared for use in automobile components and is lightweight through the springback effect with different SBRs; The springback phenomenon introduced porous structure and low density to the core material, which apparently reduced the mechanical properties. The thermo-oxidative aging simulating the automobile serving environment caused an apparent reduction of flexural strength and modulus, and the fracture mode also shifted to delamination at the interface. The application of the as-proposed inversing method was applied to the sandwich structure with various thicknesses, showing satisfying accuracy. For practical usage, concerning the influence of environmental factors, the effect of humidity and heat on the mechanical properties was investigated. In conclusion, this chapter provides valuable insights into the effects of thermos-oxidative aging on the mechanical properties, microstructure, and failure mechanisms of sandwich CFRTP composites. The non-destructive vibrational method proves to be a promising tool for assessing the structural integrity of aged composites.

WEAR ANALYSIS OF MICROSTRUCTURE IMAGE-BASED 3D MODELS TO HELP DESIGN THE BEST ABRADABLE COATING COMPOSITION

Prakash Jadhav and Anitha Azmeera

Email: Prakash.j@srmap.edu.in

SRM University AP- Andhra Pradesh, India 522240

Keywords: Finite element analysis, Microstructure-image based modeling, Abradability

Abstract: Enhancing abradable or wear-resistant coatings within the high-temperature zones of aero engines is recommended to boost efficiency and power density in gas turbine engines for both military and commercial aircraft. The development of these coatings is driven by the aim of reducing blade failures and enhancing resistance to wear and erosion. Abradable coatings or seals are suggested to achieve these objectives, minimizing the space between the rotor and the shroud with an abradable seal at the blade's tip. Coatings typically consist of multiphase materials applied via thermal spray methods, comprising a metal matrix, oxide particles, and void space. Maintaining an optimal blend of qualities, such as erosion resistance and hardness, during production is crucial. The research objective is to devise a microstructure-based modeling methodology to mimic the coating wear process and aid in designing the composition of abradable coatings. This involves microstructure modeling, meshing, and wear analysis using tools such as Fusion360, Hyper Mesh, and LS-Dyna. An abradable coating model is developed and wear analysis is conducted using simulated rub rig tests. The relationship between percentage composition and morphological variations of metal, oxide, and voids with output parameters such as abradability over time is explored.

Introduction

Indeed, advancements in air transportation necessitate continuous improvements in jet engine performance, particularly in terms of efficiency and power output. Closing the gap between the blade tip and shroud is a critical area of focus to reduce parasitic leakage flows through seals. This is crucial for enhancing engine efficiency, reducing fuel consumption, and ultimately improving overall performance. Engineers and researchers are constantly working on innovative designs and materials to achieve tighter clearances and minimize leakage, thereby maximizing the efficiency and power output of industrial turbines for jet engines [1-3] Abradable seals are indeed a significant advancement in turbine technology, allowing for tighter clearances between the blade tip and shroud. In these systems, the blade tip intentionally incurs into the shroud, minimizing the tip gap. The various types of abradable materials are being developed for this purpose, and they can be manufactured using different methods. Among these methods, thermal spraying stands out as the most popular choice for processing abradable seal materials [4-5]. During the service, abradable materials undergo complex wear mechanisms due to interaction with blade tips. These mechanisms include cutting, smearing, adhesive transfer, crushing, melting, erosion, and oxidation. By employing high-quality abradable seal coatings, gas turbine blades become more reliable, as they are better protected against various types of failures, including high-temperature damage, creep failures, fatigue failures, corrosion failures, and thermal exposure [6-7]. Abradable materials typically comprise composite mixtures of two or three structural components to achieve the desired properties, including a metallic matrix and a second phase acting as a solid lubricant, often with controlled porosity. The testing of abradable coatings involves using a test rig that simulates the conditions experienced by turbine blades in a gas turbine engine. The ratio of volume loss due to shroud wear to blade wear is known as abradability and is a key parameter in assessing the performance of abradable coatings. Rub tests are conducted at various feed and exit speeds to measure the force and wear on the blade tip. Overall, the testing of abradable coatings is crucial for ensuring their effectiveness

©2024 | 3_Jadhav_Prakash_61QOA.pdf

in real-world applications [11-12]. Scanning Electron Microscopy (SEM) is an invaluable tool for studying the microstructures of coatings. Furthermore, Finite Element (FE) models are employed in simulation software to complement experimental observations and provide a deeper understanding of coating behavior. These models simulate the thermal and mechanical responses of coatings under various conditions, allowing researchers to ascertain the Residual Stress Distribution, Fracture Mode of Thermal Barrier Coating (TBC), Fretting Wear in Composite Cermet Coating, Effective Material Properties, Thermo-Mechanical Behavior [13-15]. Bolelli [16] work highlights the importance of incorporating microstructural details into finite element modeling to understand and predict the thermo-mechanical behavior of thermal spray coatings accurately. B.Klusemann [18] developed a comprehensive FE model of the microstructure of abradable coatings using SEM images. By incorporating detailed microstructural features such as porosity, phase distribution, and grain structure into the model, also simulate the mechanical behavior of the coating under various loading conditions. D. Aussavy [21] study likely involved comprehensive characterization of the thermo mechanical properties of various coatings, such as hardness, toughness, thermal conductivity, coefficient of thermal expansion, and elastic modulus. Prakash Jadhav [22] research focuses on utilizing microstructure-based image models of coatings to study abradability through simulations. This approach is highly valuable for gaining insights into the behavior of abradable coatings at the microstructural level and understanding their performance under different conditions. Azmeera.A.k [23] developed microstructure-based modelling methodology which mimics the coating wear process and subsequently help in designing the abradable coating composition. Microstructure modelling, meshing, and wear analysis using many tools such as Fusion360, Hyper Mesh, and LS-Dyna were used to develop an abradable coating model and perform wear analysis using a simulated rub rig test. The relation between percentage composition and morphology variations of metal, oxide, and voids to the output parameters such as hardness, abradability, and other mechanical properties is explored using simulated finite analysis models of real micrographic images of abradable coatings. The primary objective of current study is to establish and further validate a simulation approach aimed at comprehending and forecasting the abradability of coatings through microstructure-based image models. To validate the proposed methodology, experimental data from the paper referenced as [24] were utilized.

2. Methodology

2.1 Critical Design Factors for Turbomachinery Sealing Employing Systems Featuring Abradable Seal Coatings

The Coatings are resistant to attacks from corrosive substances at high temperatures, such as sulphides, chlorides, and silicates (CMAS), to sintering at high temperatures, and to thermal shock or cycle-induced degradation of solid particles. The primary purposes of abradable coatings are their compatibility with labyrinth seals, shrouded versions of turbine, compressor, or fan blades, or their unshrouded counterparts. This is because abrasive wear and/or friction-induced overheating of the dynamic component may be mitigated if the coating of the abradable counterpart is softer than the material of the dynamic rubbing component. Abradable seal systems are utilized on the surface of the stator to facilitate the blade tip's free incursion into the shroud. These coatings can be several millimeters thick and serve as sacrificial layers, minimizing the tip gap. Ideally, abradable coatings should not damage the blade as it incurs into the shroud and must maintain a perfectly smooth surface to achieve this objective. In particular, the coatings are designed to improve the clearance control between the turbine blades and the casing. Overall, the application of coatings like NiCrAl-Bentonite and CoNiCrAlY-BN-Polyester etc. plays a critical role in ensuring the safe and efficient operation of high-temperature turbine stages.

2.2 The Methodology for Rub Rig Event-Modelling

The rub experiments were conducted using the abradable test gear shown in fig, which employs an abradable seal to simulate the wear experienced by gas turbines during operation. In this test setup, a

©2024 | 3_Jadhav_Prakash_61QOA.pdf:2

wheel spins at high speeds, resulting in the removal of the coating and wear on the wheel itself. After each experiment, data is collected on the wear of the coating on coupons and the wear of the blade tip. The performance of the coating is typically evaluated in terms of its abradability, which is a measure of how effectively the coating wears compared to the blade. To assess abradability, simulations are used to replicate the dynamic processes occurring within the coating microstructure as it interacts with the blade. Abradability is quantified as the ratio of coating wear to wheel wear, determined by measuring wear on both the wheel surface and the coating surface. A desirable abradability ratio for a good abradable seal falls within the range of 10 to 20. This indicates that the coating wears at a rate that is 10 to 20 times greater than the wheel, ensuring sufficient clearance control while minimizing wear on the blade. By evaluating the abradability of coatings through rub experiments and simulations, researchers can assess their suitability for use in gas turbine applications. Achieving the optimal abradability ratio ensures effective sealing performance while mitigating wear on critical turbine components.

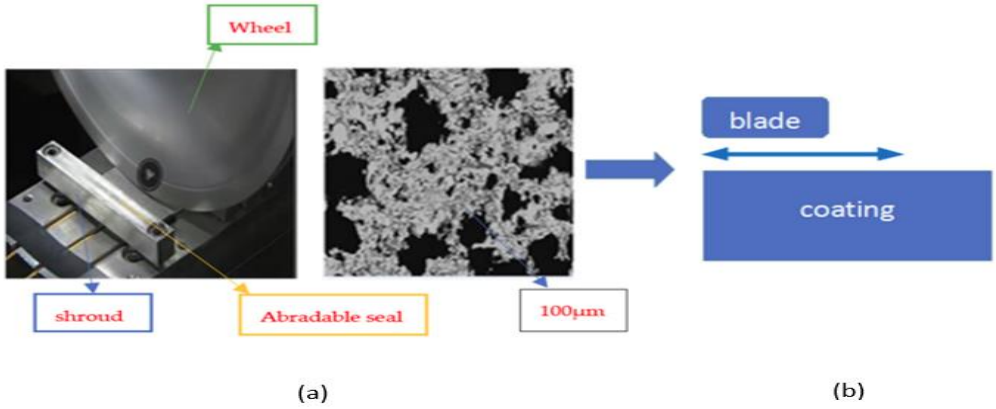

Figure 1 (a) Rub ring test apparatus. (b)Planning set up of rub rig test method

Figure 1 shows the modeling process involves creating 3D finite element analysis (FEA) models of the rub rig setup, incorporating a microstructure-based foundation to accurately represent the coating's behavior. The coating is initially prepared using air plasma spraying (APS) on coupons. The microstructure of the coating is then examined using micrograph to understand its structural characteristics. A proprietary technique is utilized to create the FEA model and mesh based on the microstructure image of the coating. Software tools such as Autodesk Fusion 360 2021 and Hyper Mesh 2021 are employed for this purpose. These tools allow for the creation of detailed and refined mesh structures that accurately represent the coating's microstructure. The generated mesh file is imported into LS-DYNA 13.1 for additional processing and simulation. The LS-DYNA program is used to simulate the behavior of the coating under dynamic wear conditions, replicating the rubbing action experienced in the rub rig test setup. The simulation accounts for the motion of the blade, which moves forward and backward repeatedly to mimic its motion in the actual test setup. After the simulation is complete, the abradability of the coating is evaluated by examining the volume loss of both the blade and the coating microstructure. This assessment allows researchers to determine how effectively the coating wears compared to the blade and assess its suitability for use in the intended application.

2.3 Representation of microstructure and its three-dimensional geometric modeling.

The microstructures of abradable coatings used in this study are derived from [24] in this paper, the focus is on abradable seals classified based on their temperature capabilities, specifically on NiCrAl-Bentonite coating. This coating is a metal matrix-dislocator designed to withstand temperatures up to 850 °C. The coating was applied using the combustion spray process with a Metco 6PII gun. Microstructures of coatings were obtained using Scanning Electron Microscopy (SEM) Phillips XL-30 and a ZEISS DSM 982 Gemini apparatus. After mounting the samples in low viscosity resin, conventional mechanical polishing metallographic techniques were employed. The coating images were

©2024 | 3_Jadhav_Prakash_61QOA.pdf:3

primarily captured under backscattering electron imaging conditions. This methodology allows for detailed examination and characterization of the coating microstructure, essential for understanding its properties and behaviour in high-temperature environments. In this study, NiCrAl-Bentonite -polyester was used as the material of interest to model and simulate the abrasion resistance of thermal barrier coatings. The following methodology was employed: Autodesk Fusion 360 2021 software was utilized for microstructure modeling. This software allows for the creation of detailed representations of microstructures, essential for accurately simulating material behavior. The Image J program was used to create separate DFX file formats for each of the three phases: metal, oxide, and porosity. These files serve as inputs for the modeling process and ensure consistency and accuracy in the representation of the coating microstructure. The DFX files for each phase were used to construct and assemble the three-phase models, incorporating the metal, oxide, and porosity components. Hyper Mesh 2021 software was employed to generate refined meshes with consistent element sizes and densities. Meshing is a crucial step in finite element analysis, as it determines the accuracy and reliability of the simulation results. Mesh style was utilized to create fine meshes, ensuring that the simulation captures detailed features of the microstructure accurately. The generated mesh file was imported into the LS-DYNA program for further processing. It was used to produce a 3D model of the coating and simulate the micrograph model, allowing for the analysis of abrasion resistance. This 3D representation was created using Fusion 360 software, where the porosity level was specified, and the metal and oxide phases were represented by distinct colors. Each phase exhibits unique sizes and shapes, contributing to the overall complexity of the microstructure. Despite the variations in the ingredients' sizes and shapes, the overall dimensions of the micrograph remain consistent, measuring 0.219 mm by 0.16 mm. This detailed visualization allows for a comprehensive understanding of the microstructure's porosity and its impact on the material's properties and behavior.

2.4 3D Mesh Modal for Microstructure

Just the 2D surface depiction is seen in Figure 2a, which displays the microstructures mesh. Different colors are used to identify the metal and oxide phases. A mesh was created for the metal oxide and porosity structure in this situation, using a first-area-phase (porosity) element size of 5. In the blade model, there were 64425 elements on average, compared to 614415 elements in the coating. Hex 8-node solid element with continuous stress was the element formulation applied to the coating and the blade model. Crucially, all of the ingredient’s metal, oxide, and porosity were formulated with the same elements.

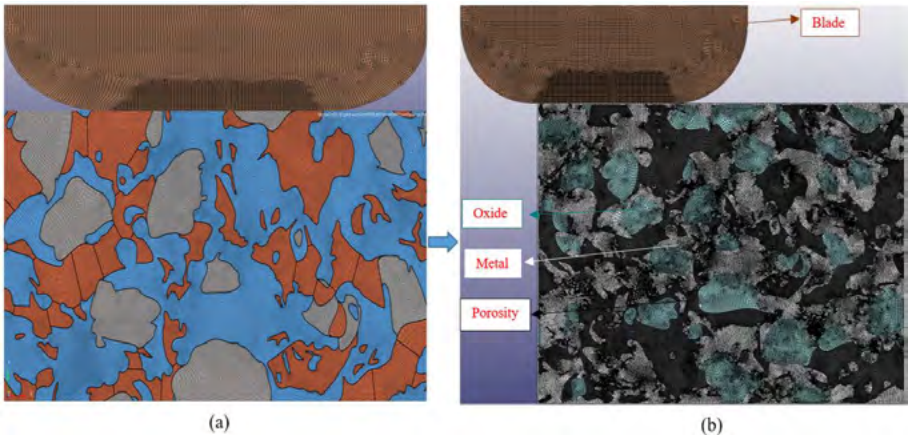

Figure 2 (a) two dimenstional microstructure mesh modal in Hper mesh tool (b) three dimenstional microstructure mesh modal in LS -Dyna tool.

The coating's 3D model in LS Dyna software, which is 0.219 mm by 0.16 mm in the planar direction and only a few elements thick in the thickness direction. Different hues correspond to the coating's metal, oxide, and porosity phases. Porosity is represented as modular components to avoid the model collapsing. The porosity is built as separate entities in the 3D modal and using a semicircular bottom

©2024 | 3_Jadhav_Prakash_61QOA.pdf:4

form and a thickness of a few elements, Figure shows a 0.17 mm × 0.06 mm 3D blade model was created. Importing the coating and blade models into the LS-Dyna 13.1 program completes the simulation setup. During post-processing, the blade moves back and forth to guarantee consistency after initially resting still on the coated material. By taking into account the existence of porosity and how it affects the behavior of the coating under dynamic loading conditions, this method enables the realistic modeling of the interaction between the blade and the coated material.

2.5 Microstructure FEM Modal in LS-DYNA 13.1 Software

The experimental rub rig emulates the challenges faced by blade tips interacting with a high-speed spinning wheel by placing a wheel onto a coupon at a predetermined feed rate. A coupon is coated and affixed to the mount, whereupon the blade tip scrapes the coating upon contact. Following the experiment, data on the coating wear on coupons and the tip wear on blades are collected. Abradability serves as a metric to assess coating performance, comparing coating wear to blade wear. Instead of simply replacing the revolving wheel with a rotating blade, the blade was programmed to move forward and backward repeatedly, replicating the wheel's motion. Furthermore, to closely emulate the rubbing action, the blade's movement matched the tangential speed of the revolving wheel, approximately 400 m/s. To prevent dynamic wave reflections from the bottom surface, appropriate boundary conditions for the coating model involve treating the bottom surface as non-reflective. Constraining the left and bottom sides along their edges aids in containing the coating. In the case of plain strain, longer vertical surfaces are constrained to a perpendicular or out-of-plane orientation. Additionally, the blade was assigned suitable boundary conditions, including forward and backward displacements, alongside velocity. Normal strain limitations also apply to surfaces of blade length. For material representation, the piecewise linear plasticity (Ti64) model was utilized for the blade, while the kinematic plasticity (AP) model was employed to simulate the alloy coating in LS-Dyna. Notably, a relatively small modulus was assigned to the porosity components. Strain-based failure assumptions were applied to all coating components, with estimates of failure strains provided for metal, oxide, and porosity. Through trial simulations, the optimal value of the porosity failure strain was determined to be between 1% and 2%.A piecewise linear plasticity model, accounting for temperature at 600 degrees Celsius, was employed alongside stress–strain data for the blade material. Modulus and Poisson’s ratio were additional inputs for the blade. The MAT ADD EROSION command was employed within the material model to define stress limits for blade failure under load. To mitigate hourglass errors, the hourglass command was universally implemented. Motion of blade represented as two sets of data indicating vertical and horizontal motion along the y-axis and x-axis, respectively. These data are expressed as velocity as distance versus time, divided into 60 intervals. The specified times ensure correct horizontal and vertical positions of the blade. The instruction specifying contact between the blade and the coating materials utilizes a contact eroding surface-to-surface approach. When elements near the failure limits defined in the material models, this contact enables the elements to fail. Similar to the gradual wearing away of particles over time, failed elements are eliminated from the simulation. The simulation calculates the overall volume loss percentage of coating material and blade elements. By comparing the volume of coating (metal and oxide) removed to the volume of the blade, the abradability parameter is determined. Optimal shrouds and coatings exhibit an abradability of 20 or more, indicating their capability to remove a volume of coating at least 20 times greater than that of the blade.

2.6 Material properties for both the coating and blade, as well as input parameters for the blade

The primary focus of this investigation was to assess how variations in the material properties of both the coating and blade components impact abradability. By understanding the influence of each individual parameter, optimal settings can be identified to enhance abradability effectively. As previously stated, a representative microstructure-based finite element analysis (FEA) mesh model is employed across all scenarios examined. Table 1 provides detailed attributes of the blade and shroud materials, emphasizing that all material inputs remain constant throughout the analysis. Notably,

©2024 | 3_Jadhav_Prakash_61QOA.pdf:5

porosity components are assigned a very small modulus value. Strain-based failure assumptions are applied uniformly across all coating components, with estimated failure strain limits provided for metal (1.5%), oxide (1%), and porosity (2%).

Table: 1 Characteristics of metal, porosity, oxide, and blade materials [21].

s.no	Material	Density (kg/mm³)	Young's modulus (Gpa)	Poisson's ratio	Yield strength (Gpa)	Tangent modulus (gpa)	Failure strain
1	Metal(NiCrAl-Bentonite)	2.7e-6	142	0.3	0.4	130	0.015
2	Porosity	1e-6	1	0.33	0.025	0.1	0.02
3	Oxide+Bentonite	3.8e-6	190	0.34	0.375	180	0.01
4	Titanium64	4.4e-6	159	0.342			

Blade material stress strain behavior data was used as input, with consideration given to its behavior at 600°C. Additionally, a value of 0.9 GPa is assumed for blade erosion in the event of stress-based failure.

3. Results

3.1 abradable seal after erosion results

The velocity depicted in Figure 5 dictates the motion of the blade. In Figure 7a, it can be observed that the blade ceases its movement after a predefined duration, with various colors denoting diverse pore sizes and shapes within three phases in microstructures corresponding to distinct metallurgical stages.

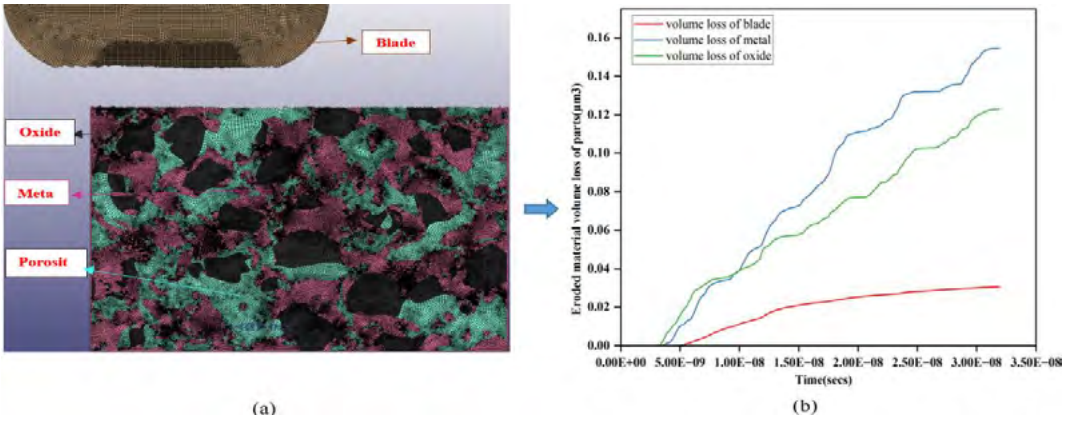

Fig 7: (a) Appearance of NiCrAl-Bentonite-polyester coating post-erosion. (b) Time-dependent erosion of metal and oxides and blade volume loss.

However, during this process, the coated material experiences some loss of its constituents, particularly metal and oxide. While the reduction in blade material is evident, it's crucial to acknowledge that losses in metal and oxide, as well as the blade itself,Occur concurrently. Eventually, a small gap emerges between the blade and the coated material. After completing the simulation, the volume of material loss for metal, oxide, and the blade was calculated using the volume fail command, as depicted in the D3 plot and the time history graph.

Figure 7b illustrates the increase in the rate of metal erosion as the blade penetrates deeper, with the volume loss of metal surpassing that of oxide, albeit marginally. Notably, the volume loss of the blade is observed to be lower than that of both metal and oxide. As the blade delves further into the coated substance, the graph demonstrates a corresponding increase in the volume loss of the blade. Throughout the entire duration, the volume loss of the blade, along with metal and oxide, was monitored. However,

©2024 | 3_Jadhav_Prakash_61QOA.pdf:6

it's worth noting that the abrasion-resistant seal incurred loss of metal and oxide compared to the abradable seal, which was expected to exhibit the highest volume loss at a given porosity and hardness. Consequently, the predicted volume loss of the blade over the entire time span was anticipated to be less than that of the abradable seal.

3.2 Variation of abradability with respect to time

The blade undergoes vertical downward motion from left to right and from right to left, adhering to the prescribed boundary conditions. With each cycle, it systematically removes metal fragments, thereby experiencing material loss. Over the entire sequence, spanning 50 rotations, the blade steadily eliminates material. However, Figure 7b provides an opportunity to compute individual metal volume loss, oxide volume loss, and blade volume loss based on data accumulated over the last 50 rotations.

Subsequently, the abradability is calculated using the following formula:

Abradability = (Volume fraction of coating removed or shroud wear) / (Volume fraction of blade removed).

Table: 2 Erosion properties and abradability evolution of the abradable seal over time.

s.no	Time (secs)	Metal wear (µm3)	Oxide wear (µm3)	Shrude wear (metal+oxide) (µm3)	Blade wear (µm3)	Abradability
1	5.82E-09	1.19E-02	2.11E-02	3.30E-02	1.40E-03	2.36
2	8.72E-09	2.99E-02	3.29E-02	6.28E-02	8.58E-03	7.32
3	1.17E-08	4.85E-02	4.35E-02	9.20E-02	1.40E-02	6.57
4	1.46E-08	6.95E-02	5.64E-02	1.26E-01	2.04E-02	6.17
5	1.74E-08	8.74E-02	6.68E-02	1.54E-01	2.28E-02	6.76
6	2.03E-08	1.11E-01	7.71E-02	1.88E-01	2.55E-02	7.37
7	2.32E-08	1.23E-01	8.95E-02	2.13E-01	2.69E-02	7.90
8	2.61E-08	1.32E-01	1.03E-01	2.35E-01	2.85E-02	8.23
9	2.92E-08	1.42E-01	1.13E-01	2.55E-01	2.97E-02	8.58
10	3.19E-08	1.54E-01	1.23E-01	2.77E-01	3.05E-02	9.08

The formula (1) allows for the determination of abradability, which exhibits a consistent increase from the initial time to the final interval of time, as depicted in Figure 8b. And the increasing and decreasing value of the abradable coating, blade, and abradability number is shown in Table 2. The loss of both the titanium blade and the abradable seal can be illustrated. Here, we can assume that the loss of the blade and the abradable seal increases linearly with time. The only difference is that the titanium blade has a much smaller volume loss than the abradable seal, and the abradable seal's volume loss is calculated as the sum of metal and oxide. The abradability increases gradually from the first interval of time to the last period of time. Until the gap created between the blade and seal, the abradability changes linearly with respect to time.

4. Conclusion

This study presents a microstructure-based modeling methodology designed to replicate the coating wear process and aid in formulating the composition of abradable coatings. Simulation techniques were employed to develop an abradable coating model and simulate wear using rub rig tests. The relationship between percentage composition and morphological variations of metal, oxide, and voids with output parameters such as hardness, abradability, and other mechanical properties was investigated using simulated finite analysis models based on real micrographic images NiCrAl-Bentonite polyester coatings. Based on these images, 3D finite element models of the coatings were constructed, meshed,

©2024 | 3_Jadhav_Prakash_61QOA.pdf:7

and refined by incorporating the blade using various tools. Subsequently, simulated rub rig tests were conducted on the coating models using LS-Dyna. The study concludes that the Abradability number increases as the level of coating wear rises or blade wear decreases over time.

Abstract

Composite materials are increasingly favored for their exceptional mechanical properties and lightweight nature, although their inherent brittleness poses challenges. Metals like aluminum offer ductility but lack lightweight properties. Hybrid materials, combining aluminum's ductility with composite materials' stiffness, offer enhanced energy absorption and performance. Understanding the bending response of these hybrid structures is crucial for optimal performance. Automated Fiber Placement (AFP) technology can wrap thermoplastic composite material around an aluminum tube precisely, as demonstrated in this paper. The four-point bending test conducted on a hybrid tube showed improved strength and stiffness compared to solely an aluminum tube. Additionally, the hybrid tube exhibits secondary resistance after failure. This research underscores the feasibility and advantages of integrating composite materials into aluminum structures, in a form of hybrid aluminum/thermoplastic composite tube, providing insights for enhancing performance in many applications such as energy absorber structures like bumpers and rocker panels in automobiles, or landing gear in helicopters. By combining the properties of both materials, engineers can achieve superior performance while maintaining overall lightweight.

1. Introduction

In engineering applications, lightweight structures offer numerous advantages. Lightweight structures find applications in industries such as aerospace, transportation, and pipelines [1-3]. In transportation, they contribute to improved fuel efficiency, reduced fuel costs, and lowered exhaust gas emissions. Additionally, lightweight structures decrease the quantity of materials needed for manufacturing. In this case, hybrid aluminum/composite structures prove highly beneficial, as both materials are lightweight and, when combined, they can attain the required properties for various engineering applications.

In simpler terms, hybrid aluminum/composite tubes enhance structural performance through their synergistic interaction. For instance, when exposed to transverse impact, these hybrid tubes exhibit superior impact resistance compared to singular composite tubes [4]. Regarding material selection for composite components, both glass and carbon fibers can be viable options depending on factors such as

the application, environment, and required specifications. However, for fatigue resistance, carbon fiber proves more durable than glass due to its superior strength-to-weight ratio and stiffness [5].

In most prior studies, thermoset resin was the prevalent choice for the composite part. However, considering thermoplastic composites could be a superior alternative, especially for applications where energy absorption is crucial. Therefore, manufacturing hybrid tubes using thermoplastic resin for the composite component is a worthwhile approach.

This study investigates the force-displacement characteristics of hybrid Aluminum/Carbon-PEEK tube during bending test and compared it with sole aluminum tube as well as analytical solution.

2. Experiment

2.1. Manufacturing procedure using Automated Fiber Placement (AFP)

To make a hybrid aluminum/composite tube, AFP can be used as it involves applying composite tape onto an aluminum tube, with layers gradually building upon each other over time as illustrated in Figure 1. This technique proves highly advantageous for hybrid tube production. The first reason is that certain applications require complex shapes that may not be easily fabricated using methods like hand lay-up or filament winding. AFP, on the other hand, is capable of generating various geometries across a wide size range rapidly and with minimal human involvement, ensuring greater consistency compared to hand lay-up, which is susceptible to human errors. Additionally, AFP is well-suited for thermoplastic composites, which offer superior performance in mentioned applications where energy absorption is a critical parameter. Unfortunately, previous research often had to resort to thermoset composites due to limitations in their chosen manufacturing techniques.

It's worth noting that using AFP positions the composite layer on the outer surface of the aluminum, making it impossible to have the composite on the inner side using AFP. However, a hybrid tube with aluminum inside the composite for transverse loading scenarios is likely to exhibit enhanced crashworthiness [6].

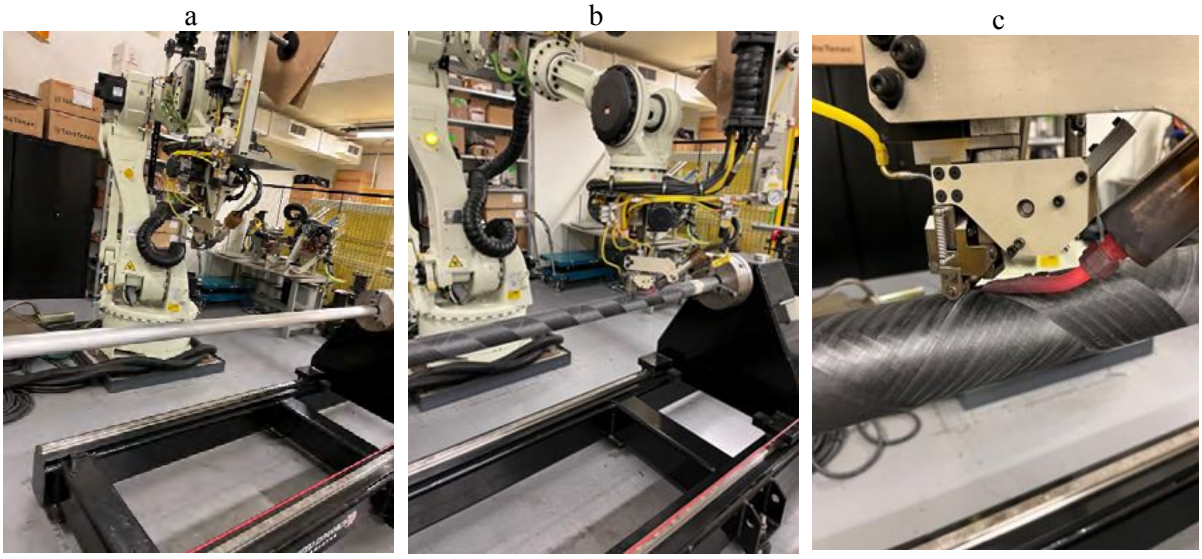

Figure 1. Using AFP for manufacturing of hybrid aluminum/Carbon-PEEK (a) An aluminum tube (b) Hybrid aluminum/Carbon-PEEK during manufacturing process (c) A closer view of the feeding tape on the surface of hybrid tube.

An aluminum mandrel made of T6061-T6 alloy, featuring an outer diameter of 63.5 mm, a thickness of 3.175 mm, and a length of 2438 mm, served as the pivotal component for depositing thermoplastic composites. For the composite layers, thermoplastic composite materials, specifically a carbon/PEEK composite, has been used.

A challenge emerged due to the substantial discrepancy in thermal expansion coefficients between aluminum and the thermoplastic composites. When subjected to the heat from the torch, the aluminum mandrel expanded more than the composite material. This creates good contact between the aluminum mandrel and the first layer of the composite. However, when things cool down, the aluminum mandrel contracts more than the composite, particularly in the initial layers at a 90-degree orientation. This resulted in the undesirable outcome of the aluminum mandrel loosely rotating within the initial layers of the composites.

To address this issue, a modified deposition schedule was employed, characterized by lower temperatures, and reduced compaction forces for the initial layers, as detailed below:

• Layer 1: Orientation - 90 degrees, Temperature (T) - 650°C, Compaction Force (F) - 30 lbs, Nitrogen Flow (N) - 60 Standard Liters per Minute (SLPM)
• Layer 2: Orientation - 90 degrees, Temperature (T) - 800°C, Compaction Force (F) - 30 lbs, Nitrogen Flow (N) - 60 SLPM
• Layer 3: Orientation - 90 degrees, Temperature (T) - 875°C, Compaction Force (F) - 40 lbs, Nitrogen Flow (N) - 60 SLPM
• Layers 4 to 40: Temperature (T) - 875°C, Compaction Force (F) - 60 lbs, Nitrogen Flow (N) - 80 SLPM

These adjustments effectively mitigated the issue of mandrel rotation and ensured the proper deposition of subsequent layers of thermoplastic composites.

During the initial deposition of the first four layers, a strategic cooling method was employed to maintain the mandrel's temperature. Compressed air was directed ahead of the torch, effectively reducing the heat transfer to the mandrel, and thereby minimizing its expansion. This approach was instrumental in ensuring that the initial composite layers adhered securely to the aluminum mandrel.

In this study, hybrid aluminum/carbon-PEEK composite tubes have been tested with a lay-up sequence as [Aluminum/90^{Glass}/90^{Carbon}/$(\pm 20)_5$/90_2/$(\pm 30)_4$/90_2/$(\pm 45)_4$]). It should be notable to mention that we introduced a layer of glass between aluminum and carbon as the first composite layer. This choice was driven by the imperative to avoid galvanic corrosion. Therefore, lay-up sequence comprises a total of 32 layers. The overall thickness was calculated as follows: aluminum (3.175 mm) + glass-PEEK (0.168 mm) + Carbon-PEEK (4.332 mm) = 7.675 mm. Figure 2 provides dimensions of the hybrid tube.

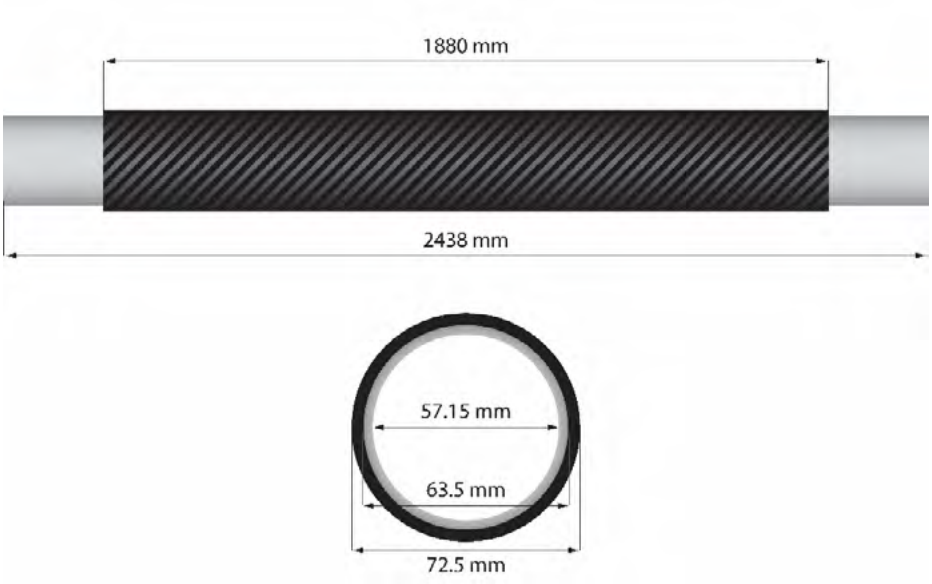

Figure 2. Dimensions of the hybrid tube.

2.2. Four-point bending test

The tube underwent a four-point bending test, where fiber glass/epoxy reinforcing pads were strategically affixed onto the tube's support and loading regions to mitigate stress concentrations. The locations of these supporting pads on the tube are illustrated in Figure 3.

Four-point bending tests were conducted at the Concordia Center for Composites using a specialized four-point bending fixture shown in Figure 4. This fixture utilizes servo hydraulic technology to operate a load cell. The load cell employed in this setup has a capacity of 50 KN.

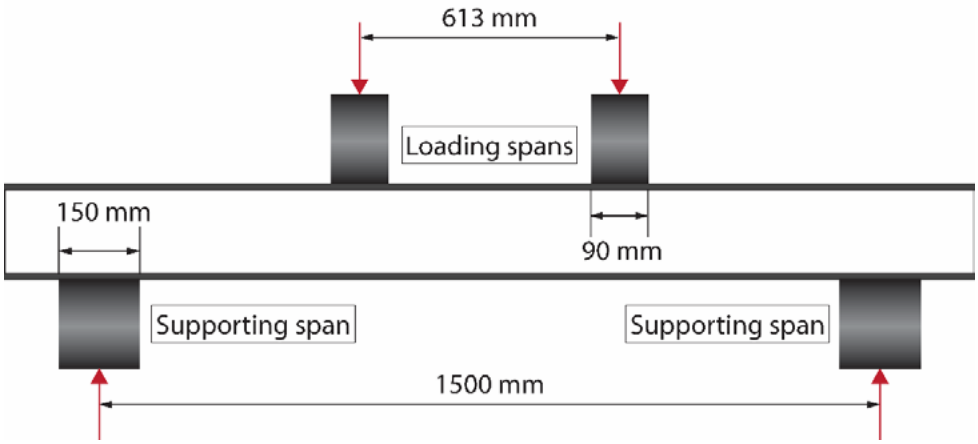

Figure 3. Locations of the reinforcing pads.

Figure 4. A hybrid aluminum/thermoplastic composite tube in the four-point bending test set-up.

3. Analytical solution

From the mechanics of materials, it is viable to calculate the flexural stiffness (or bending stiffness) of both tubes and plot the force-displacement diagram for the linear part. This provides insight into how closely the behavior of tubes in experiments aligns with or deviates from the analytical solution. To accomplish this, we assume there is a beam illustrated in Figure 5. The displacement can be expressed as a function of x [7].

$$\delta = \frac{Pa(3La - 3x^2 - a^2)}{12EI} \tag{1}$$

At the loading point where x=a, equation (1) can be rewritten as:

$$\delta = \frac{Pa^2(3L - 4a)}{12EI} \tag{2}$$

To plot the force-displacement diagram, we can rewrite equation (2) as:

$$\frac{P}{\delta} = \frac{12EI}{a^2(3L - 4a)} \tag{3}$$

In equation (3), EI represents bending stiffness. In order to calculate the bending stiffness, one way is using summation of bending stiffness of individual layers. In other words, we can utilize equation (4) as follows [8]:

$$(EI)_T = \sum_{i=1}^{n} E_i I_i \tag{4}$$

Equation (4) does not account for inter-layer interactions and cannot be useful for a case of composite tube or hybrid tubes. Thereby, we can use simple case of equation (4) for sole aluminum. Another equation, developed by Jolicoeur and Cardou [9], addresses this aspect:

$$(EI)_T = \sum_{n=1}^{N} \frac{\pi}{C_{33},n} \left\{ \begin{array}{c} \sum_{i=1}^{4} K_{i,n} \left(C_{34,n} \times g_{i,n} \times m_{i,n} - C_{13,n} - C_{23,n}(m_{i,n}+1) \right) \times \\ \left(\frac{b_n^{(m_{i,n}+2)} - a_n^{(m_{i,n}+2)}}{(m_{i,n}+2)} \right) + \\ (1 - \mu_{1,n}(C_{13,n} + 3C_{23,n}) + 2\mu_{2,n}C_{34,n}) \times (\frac{b_n^4 - a_n^4}{4}) \end{array} \right\} \quad (5)$$

All parameters in equation (5) are elucidated in [8,9] references. For a hybrid tube, we employ equation (5) to evaluate the difference in bending stiffness compared to experimental results. By computing the total bending stiffness using equations (4) and (5), and incorporating Equation (3), it becomes feasible to generate linear behavior plots for comparison with experimental results.

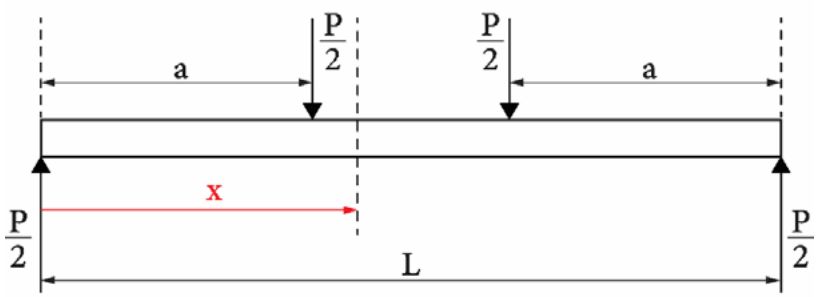

Figure 5. A beam under a four-point bending test with corresponding parameters.

4. Results and discussion

Figure 6 presents experimental data as well as analytical solutions. By studying Figure 6, it becomes evident that in terms of energy absorption, the hybrid tubes surpass those of the sole aluminum tube. The hybrid tube demonstrates notably stiffer and stronger resistance compared to the sole aluminum tube. Specifically, the load steadily increases until reaching 37,600 N at a displacement of 57.5 mm. At this juncture, there is a sudden drop in load to 22,400 N. Following this drop, there is additional resistance of the hybrid tube as the load increases again to 24,200 N and then decreases gradually. This observation holds significance because if failures occur in the hybrid tube, there exists secondary resistance after composite failure.

Secondary resistance helps mitigate sharp drops in force-displacement compared to a structure made solely of composite material. Combining aluminum and composite materials offers advantages over using a solely composite tube, where sharp drops in force-displacement occur after a certain point with no additional resistance. However, compared to using solely aluminum, the drop can be a disadvantage of using a hybrid tube. Therefore, addressing and minimizing this issue is vital to enhancing design quality. It's evident that achieving optimal stiffness and excellent load capacity isn't exclusive to metals such as aluminum; rather, one aspect cannot be achieved without the other.

Regarding the analytical solutions in Figure 6, the results for aluminum exhibit good agreement, as it is a single aluminum layer. For the hybrid tube, equation (5) overestimates the bending stiffness due to the consideration of interaction effects between all layers. In a real hybrid tube, slips may occur between

aluminum and composite parts, and perfect bonding cannot be achieved. Furthermore, defects occurring in the manufacturing process can diminish stiffness. Consequently, this disparity can be attributed to two factors: 1. Potential slippage between layers. 2. Presence of voids and other imperfections within composite layers. While it's inevitable to completely eliminate these issues, mitigating their impact is indeed possible.

In Figure (6), there is also a diagram illustrating the pure composite, which corresponds to the composite layers depicted in Figure (2). The diagram suggests that both the aluminum and composite layers contribute to the overall stiffness, as well as other parameters such as the maximum energy absorption of the hybrid tube.

Overall, it's important to compare important parameters associated with the hybrid tube. These parameters illustrate the advantages of the hybrid tube, including slope, maximum load, the degree of smoothness of the force-displacement diagram, energy absorption (EA), and specific energy absorption (SEA). Table 1 provides these parameters for both tubes. Based on the parameters mentioned in this table, four indicators for the hybrid tube can justify its advantages over the hybrid aluminum/composite tube. For instance, even creating a very thick aluminum tube to achieve the same maximum load and energy absorption results in a significant decrease in specific energy absorption as the total weight of the tube increases too much. Moreover, a purely composite tube can offer excellent maximum load capacity. However, due to the brittleness of the composite material, there is no secondary resistance, resulting in decreased energy absorption.

It stands to reason that optimizing these parameters cannot be achieved by using solely aluminum or solely composite materials. Instead, a hybrid aluminum/composite material can mitigate the limitations of each material and provide better overall performance.

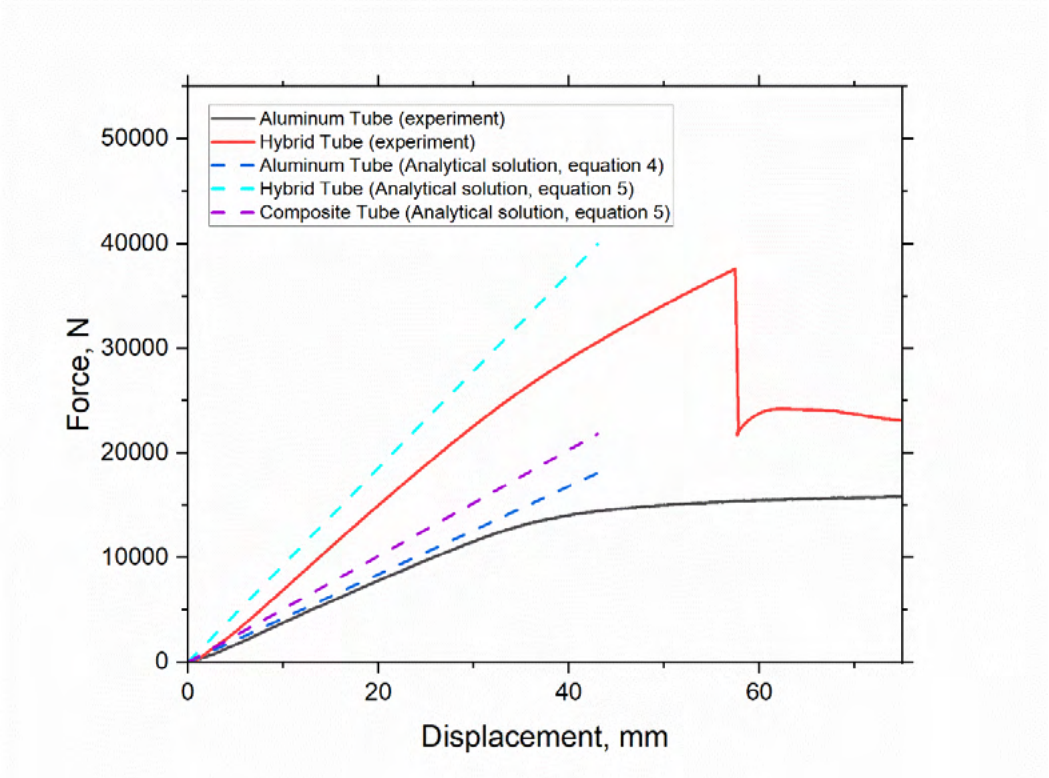

Figure 6. Load-displacement curves for three hybrid aluminum/thermoplastic composite tube tubes and a pure aluminum tube.

Table 1. Comparison of some parameters for both tubes.

Specimen	Slope (N/mm)	Maximum Force (KN)	Smoothness	EA (J)	SEA (j/g)
Aluminum Tube	384.7	15.85	Excellent	836.5	0.07967
Hybrid Tube	755.1	37.60	Moderate	1558.3	0.1113

5. Conclusions

The hybrid aluminum/thermoplastic composite tube presents a desirable characteristic vital for the functionality of bumpers and rocker panels in automobiles, as well as landing gear in helicopters. An examination of the important indicators or parameters reveals that to enhance overall performance, employing a hybrid aluminum/composite material can effectively address the limitations associated with using solely aluminum or composite materials. While achieving a flawless balance between a smooth diagram, excellent stiffness, maximum load capacity, and energy absorption might not be feasible, it's crucial to recognize that these parameters work together. One cannot be achieved without considering the others.

Keywords: T-C fatigue, anti-buckling, ultra-thin plies, cross-ply laminates, microscopical inspection

Abstract
Tension-compression (T-C) cyclic loading is an open research topic nowadays in the composite field. There are different studies dealing with the appearance and growth of damages under T-C fatigue, its understanding at the microscopic level being relevant to insight into the physics of the microscopic damage processes. In this way, the comprehension of these damage mechanisms is studied hereby involving ultra-thin plies.
As the damage appearance is due to the tensile part of the load cycles, the specimen design is the same as the one used in tension-tension fatigue. To prevent buckling in the compressive part of the load cycles, a tailor-made anti-buckling device is used. Carbon/epoxy cross-ply laminates made of conventional (150 g/m^2) and ultra-thin (30 g/m^2) plies are cyclically tested.
A comparison of the damage onset observed in both conventional and ultra-thin 90º ply blocks is carried out. As expected, there is an advance in the appearance of the first transverse damage in the 90º ply block of a cross-ply laminate under T-C cyclic loading compared to the tension-tension case. The onset seems to be more pronounced when ultra-thin plies are used in the 90º ply block of a cross-ply laminate.

1. Introduction

Most composite structural components are subjected to fatigue during their life cycles. For instance, aircraft wing skins are constantly subjected to either tension or compression. Hence, it is a challenging task to broaden the scientific community's horizons about tension-compression (T-C) cyclic loading, which is an open research topic in the composite field. There are different works related to this matter from the late 90s up to nowadays, such as Gamstedt and Sjögren [1] and Carraro et al [2], respectively. Most of these studies use an anti-buckling device to prevent buckling phenomena in the compressive part of the load cycles because tension-like specimens are used as the damage onset is expected at the tensile part of the load cycles. Jeon et al [3] designed their own anti-buckling jig to obtain the S-N curves, thus the Goodman diagrams. Just et al [4] also performed their anti-buckling device, focused on the transverse cracking growth under fatigue, observing them microscopically. Liu et al [5] developed a simpler anti-buckling device comparing rectangular and dog-bone samples to obtain constant life diagrams and observe the fatigue fracture surfaces at the same time. Huang et al [6] designed their own anti-buckling device with openings to be able to use infrared thermography during fatigue, combining it with the use of synchrotron radiation computed tomography to observe damage in the post-mortem specimens.
There is an alternative study, Carraro et al [2], which uses shorter specimens under different stress ratios to observe the appearance and growth of the damage mechanisms, comparing the results with the

numerical predictions based on their damaged-based model for the simulation of fatigue damage in multidirectional laminates.
Although each research group has its study perspective, focusing on fatigue life (or S-N) models, phenomenological models, progressive damage models, or even a mix of them, the comprehension of the damage mechanisms affecting composite materials under T-C cyclic loading is essential to insight into the physics of the microscopic damage processes.
The comprehension of the appearance and growth of the different types of damages associated with the failure of composite materials at the microscopic level under fatigue motivates this study when ultra-thin plies are involved.

2. Experimental Methodology

2.1. Materials

Carbon/epoxy cross-ply laminates are made of TP402/T700S prepreg from North Thin Ply Technology. The stacking sequences selected are the same ones used in Sánchez-Carmona et al [7], which follow the configuration $[0_4/(90_n)/0_4]$, where all 0º plies are made of 150g/m^2 prepreg. Two different laminates are handly-layed-up manufactured, CP-30 means one ply (n=1) of 30g/m^2 prepreg and CP-450 means 3 plies (n=3) of 150g/m^2.
The samples are prepared following recommendations from the tension-tension (T-T) technical standard ASTM D3479 due to the fact that there are no standards for T-C testing. All samples are sanded and polished on their lateral free edges to be able to observe the onset of damages using an optical microscope.
The pattern of damages in the 90º ply under T-T cyclic loading is shown in Sánchez Carmona et al [8], an example being shown in Figure 1. Not all damages are transverse. As can be seen in Figure 1, longitudinal damages are also predominant when an ultra-thin ply is used due to the edge effect phenomenon.

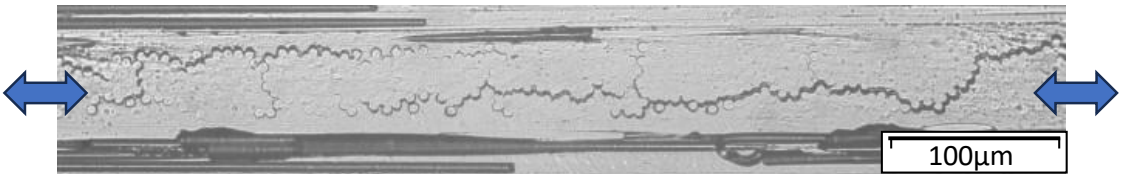

Figure 1. Damage mechanisms that occur in an ultra-thin 90º ply.

The same type of damage is expected to appear under T-C cyclic loading as T-T fatigue, although earlier regarding the number of cycles.

2.2. Experimental set-up

A tailor-made anti-buckling device is designed and manufactured for this experimental programme, Figure 2.(a), similar to the one used in Liu et al.[5]. As can be noticed, the separation between the device and the grips is the minimum possible to prevent local buckling along the free lengths.
To ensure that the set is not buckling two dial gauges are placed, one on each side of the assembly, to measure its lateral displacement, if present. Figure 2.(b) shows that the lateral displacement that the assembly is suffering is 15µm, which is completely negligible compared to the displacement during fatigue loading.
Once the set-up is ready, a cycling test is carried out in an Instron 8802 hydraulic testing machine, controlling the load by means of a sinusoidal function with a stress ratio R (being defined as the minimum applied stress divided by the maximum applied stress) which depends on the cross-ply laminate that is going to be tested. This stress ratio is selected as -0.84 for CP-450 and -0.71 for CP-30 since the biaxial stress state in the 90º ply block is intended to be the same for both laminates.

Figure 2. Anti-buckling device for T-C testing: (a) set-up installation, and (b) corroboration of its usefulness.

3. Results and discussions

The microscopic observation of damages in each 90º ply block along the free edges is carried out using a replica, taken from each sample free edge after stopping the cycling test as can be seen in Figure 3. Once the replica is cured, it can be taken away from the sample to continue cycling up to the next stop defined. The micrograph shown in Figure 1 is performed from a replica taken with this technique.

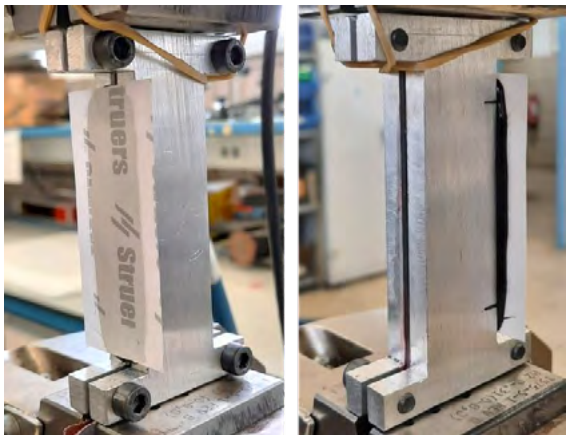

Figure 3. Performance of a replica at each stop defined.

Due to the novelty of these results, only the results for one specimen are shown in this paper. The onset of the first transverse damage that appears for each case is shown in Figure 4. The first transverse crack appears between $2 \cdot 10^4$ and $2{,}5 \cdot 10^4$ cycles for CP-450 whereas the first transverse damage for CP-30 occurs between 500 and 1000 cycles. Although it can be noticed that the first transverse damage appears before in the ultra-thin 90º ply, the overall relevance of the transverse damage is much lower than in the thicker case (CP-450). Whereas the transverse damage is a full transverse crack in CP-450, only a path of debonds that are not completely connected from one 0/90 interface to the other appears in CP-30.

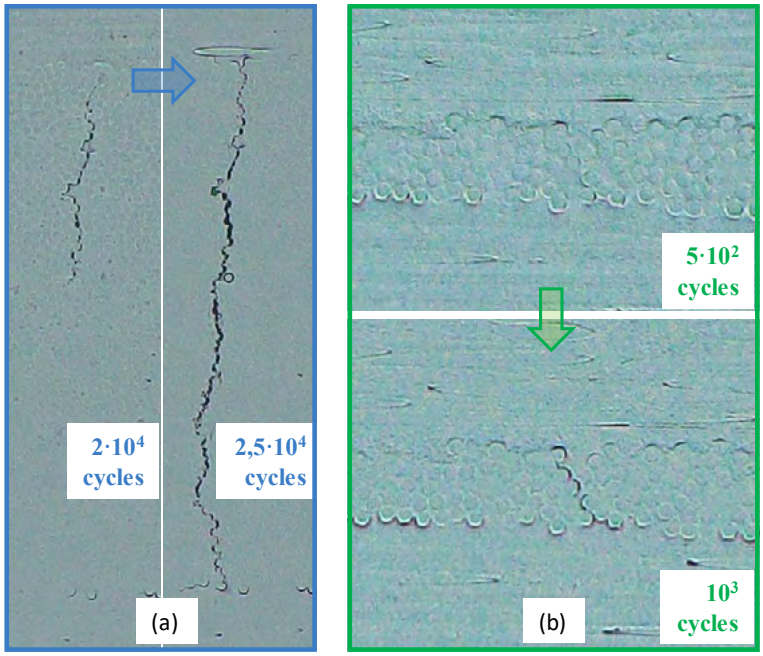

Figure 4. Appearance of the first transverse damage for: (a) CP-450 and (b) CP-30.

Comparing these T-C results to those from the T-T cyclic study of Sánchez-Carmona et al [7], the first transverse damage appears $2{,}5 \cdot 10^4$ cycles before in CP-450 whereas $9{,}9 \cdot 10^4$ cycles before in CP-30. As expected, T-C cyclic loading leads to an advance in the appearance of the first transverse damages in composites, being more accused in the ultra-thin case. Nevertheless, it is worth highlighting that the relevance of the first damage is much more damaging for the thicker case, as shown in Figure 4.

4. Conclusions

The experimental observation of the damage mechanism of ultra-thin plies under cyclic loading has been studied in this work. Two different cross-ply laminates, one made of conventional and another of ultra-thin plies, have been investigated. A preliminary result shows that there is an advance in the onset of transverse damage in the 90º ply block of a cross-ply laminate under T-C cyclic loading compared to the T-T case, being more pronounced when ultra-thin plies are used in the 90º ply block. However, the transverse crack in the thicker 90º ply block is much more damaging than the transverse damage, a path of debonds not completely connected to both 0/90 interfaces, that appears in the ultra-thin 90º ply block. More samples need to be tested to corroborate the advance of the onset of the transverse damages that appears in the 90º ply block of a cross-ply laminate under T-C cyclic loading compared to the T-T case.

Acknowledgments

Keywords: permeability, model, statistical representative volume element, Liquid Composite Molding

Abstract
Permeability quantifies the ability of fluid to flow through a porous media such as composite fiber reinforcment structures. The multiscale structure of textile-based composites must be taken into account for numerical permeability prediction (NPP). Due to limited computing power, multiscale approaches are used for NPP by first calculating the microscale and then considering these results on the mesoscale. This requires models that accurately represent the structure. Also, suitable model size and resolution must be identified. Appropriate models can be described as statistical representative volume elements (SVEs). If several simulations are performed with randomised SVEs, a distribution of the permeability based on structural variations in textiles can be obtained analogous to experimental permeability determination.
The aim of this work is to develop guidelines for the creation of micro and meso-level SVEs for NPP. Experimental and numerical benchmark studies have shown that the results can be subject to a spread of over 20 % [1-3]. Therefore, the target is a maximum deviation of 20 % from experimental reference values. However, the best results in this study, considering randomized fiber and textile structrues with complex roving deformation due to a virtual compation, still show a deviation of 17 to 62 %.

1. Introduction

Textiles in fiber-reinforced polymers (FRP) exhibit multi-scale porosity with microscopic pore spaces within fiber bundles and mesoscopic pore spaces between the fiber bundles. Typical FRP components consist of multiple textile layers, formed into a preform and impregnated using e.g. liquid composite molding (LCM). The robustness and efficiency of the impregnation in LCM processes can be improved by filling simulations. For the filling simulations, a homogenized component model is used, which omits the fiber structure and therefore the physical effects at lower scale levels. The physical properties are directly assigned to the finite elements of the homogenized component model [4]. The permeability is one of these properties and a crucial input parameter for the simulation. It relies strictly on the geometric structure of the material. In order to determine the permeability numerically, multi-scale approaches can be used to maintain computational manageability. For this, seperate simulations are performed on each scale and the results are transferred to the respective upper scale [5-7]. The three scales typically considered for flow in LCM are microscale and mesoscale for the permeability determination and the macroscale for the filling simulation (Figure 1). At the microscale, numerical permeability prediction is based on the creation of structural models that statistically reproduce the fiber structure inside fiber bundles. For each material configuration, several randomized models must be created and calculated for statistical validation [8-10]. At the mesoscale, on the other hand, structural models are generated that are statistically representative for textile stacks as they can be found within the component. In these models, the rovings are created as continuum elements, to which the previously determined anisotropic microscopic permeability is then assigned. With this upscaling, the micro permeability is taken into account on the mesoscale. To perform a numerical simulation, three sets of input parameters have to be

defined: 1) the incompressible fluid viscosity, 2) the experimental process parameters including flow direction, boundary conditions and pressure difference and 3) the structural model [11].

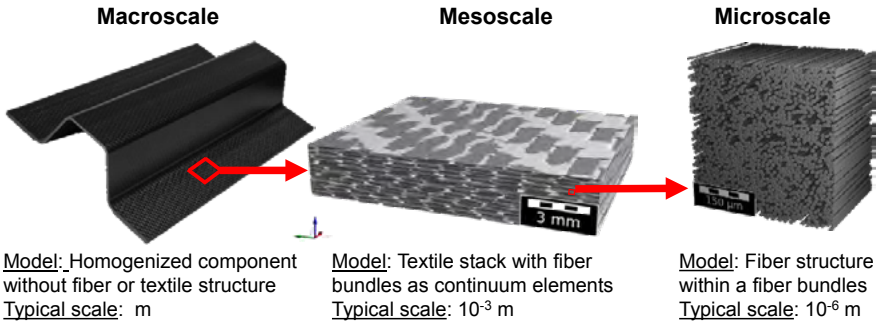

Figure 1: Relevant scales for the simulation of a LCM process

Creating sufficient structural models that take into account all relevant structural details is particularly critical and at the same time costly in terms of computational effort. The structural models can be generated artificially or derived from 3D images of a real structure [1, 6]. The latter requires a lot of effort and is limited to relatively small samples, which means that statistical variance of the structure, as given in real structures, can hardly be reproduced. The artificially created models, on the other hand, allow a systematic investigation of the influence of structural features, such as fiber diameter or fiber volume content (FVC). When considering the state of the art for modeling microscopic and mesoscopic models, one notes a considerable range from regularly distributed 2D cross sections [12] up to 3D models with randomly distributed, undulated fibers or fiber bundles [13]. Representative volume elements (RVEs) should be representative for the whole material with one simulation result as shown in Figure 2 [14]. This means that local variations are not considered and the models must be very large. This can lead to problems in terms of limited computing power. Further developed models show statistically distributed fibers and properties according to given boundary conditions. They are thus referred to as statistically representative volume elements (SVEs) [15-17]. Many studies exist on microscopic and mesoscopic structural models, but most of them do not validate the model size, resolution and number of individual models for statistical validation, as performed e.g. by Rimmel et al. [18] for 2D micro models.

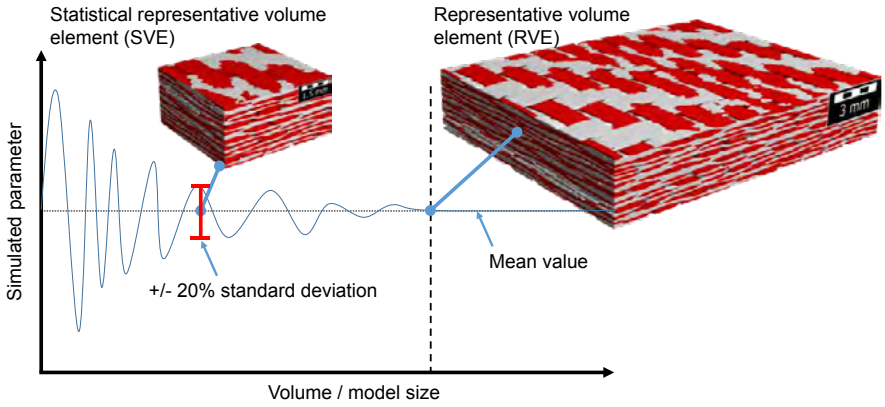

Figure 2: Difference between SVE and RVE adapted from Bear [19]

Based on the statistical representative volume elements (SVEs), the flow fields are solved numerically using the Stokes equation (2) and the permeability is calculated using Darcy's law [20]. Numerical permeability prediction in addition with artificial structure model generation allows for automated parameter studies to be carried out over a wide range. This allows an efficient screening of different model settings to identify suitable SVE settings. The objective for the SVE is to achieve an accuracy of +/- 20 %, as is also achieved in numerical and experimental benchmark studies [1-3].

2. Methods for SVE Development

Target accuracy is the most important factor in SVE development, which then also influences the range of settings to be analysed. The first step is to develop an SVE for the microscale that basically represents a structure as it could be present at a randomly selected position within a fiber bundle. Due to the statistical nature, the permeability of two randomly generated SVEs can strongly differ, just like in a real fiber bundle. For meaningful averaging procedures, the combination of model size and number of models simulated per randomization setting must reach a certain level, which is to be determined via a convergence analysis. Furthermore, a coarse resolution might cause numerical inaccuracies influencing the result but is of course beneficial in terms of computational effort. Therefore, the minimum model size and resolution without negative influence on the results must be identified. The voxel-based structure modeling is performed in GeoDict using FiberGeo [21]. This is a tool for generating fiber structures in which individual fibers are randomly placed in the domain until the defined FVC is reached. FlowDict (GeoDict) can then be used to determine the steady state saturated permeability using Darcy`s law. One flow simulation is performed for each direction along the coordinate axis with each structure model. Periodic boundary conditions (BCs) are defined in the flow direction and in tangential direction. In- and outflow regions of 10 voxels are added to the model, which do not contain any fibers and avoid the possibility of closed flow channels when using periodic BCs. A resin viscosity of 50 mPas is defined and the flow is induced by a differential pressure of 1 Pa from inlet to outlet. These settings are in accordance with the recommendations of the virtual permeability benchmark [1]. The LIR solver with the LIR-Tree-approach is used, that enables grid refinement during the flow simulation [22]. An error bound of 0.03 for in-flow and tangential permeabilities is defined as the stopping criterion [11]. To determine suitable SVEs for the microscale, ten randomized models for three model resolutions (0.4^3, 0.5^3, 0.6^3 µm^3/voxel) and five model sizes (120^3, 220^3, 320^3, 420^3, 520^3 voxels) were evaluated for three FVCs of 56 %, 60 %, 64% and two fiber diameters of 7 µm and 10 µm as shown in Figure 3.

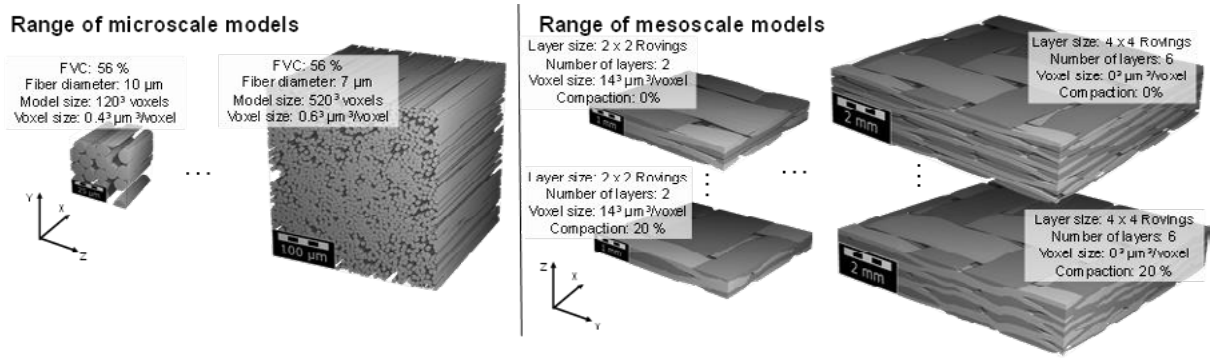

Figure 3: Range of the micro- and mesoscale models for the SVE development

For the SVE development on the mesoscale, the resolution is also considered again, but instead of the model size in voxels as on the microscale, the number of rovings per layer and the number of layers are considered. The number of rovings per layer is specified as 3x3, for example, which means that three weft and three warp rovings per layer are included in the model. The GeoDict modules WeaveGeo, LayerGeo and ProcessGeo are used for modelling. The model is created as follows: 30 individual textile layers are generated and then stacked with a randomised in the plane displacement. This stack is then cut to the appropriate size according to the number of rovings per layer. This is followed by four consecutive compaction steps, where the FVC of the textile stack is increased by 5 % during each step. The flow simulation is then carried out in FlowDict (GeoDict) using the SimpleFFT solver. In contrast to the LIR solver, the SimpleFFT solver enables the assignment of anisotropic micropermeabilities to the rovings. This means that customised anisotropic microscopic permeability values are assigned to all weft and warp rovings before the simulation. All other settings were selected analogue to the microscale. To determine suitable SVE settings, four layer sizes (2x2, 2.5x2.5, 3x3, 4x4 rovings per layer), four numbers of layers (3, 4, 5, 6 layers) and four different resolutions of (8^3, 10^3, 12^3, 14^3 µm^3/voxel) were investigated. The permeability of these setting combinations was determined for each compaction stage.

3. Statistical Representative Volume Element for the Microscale

The results of the SVE study for the microscale are presented in Figure 4, 5 and 6**Fehler! Verweisquelle konnte nicht gefunden werden.**. The standard deviation (SD) of the permeability for 10 randomized models per parameter set is displayed in the form of error bars in the diagrams. Configurations are sought that provide sufficiently accurate permeabilities for all directions and FVCs. It is assumed that large models with many fibers and the highest possible resolution achieve the most accurate results. Models with a higher resolution of 0.4^3 µm³/voxel contain fewer fibers compared to a lower resolution (e.g. 0.6^3 µm³/voxel) with the same number of voxels, but these are resolved over more voxels per diameter. Similarly, models with a higher FVC contain more fibers. The fact that the voxel sizes 0.4^3 and 0.6^3 µm³/voxel cannot exactly map the fiber diameter of 7 µm is solved in such a way that some of the fibers, e.g. at 0.4^3 µm³/voxel resolution, are modelled with 6.8 µm (17 voxels) and 7.2 µm (18 voxels), so that the average fiber diameter is 7.0 µm. The same applies to the combination of 0.6^3 µm³/voxel resolution and 10 µm fiber diameter.

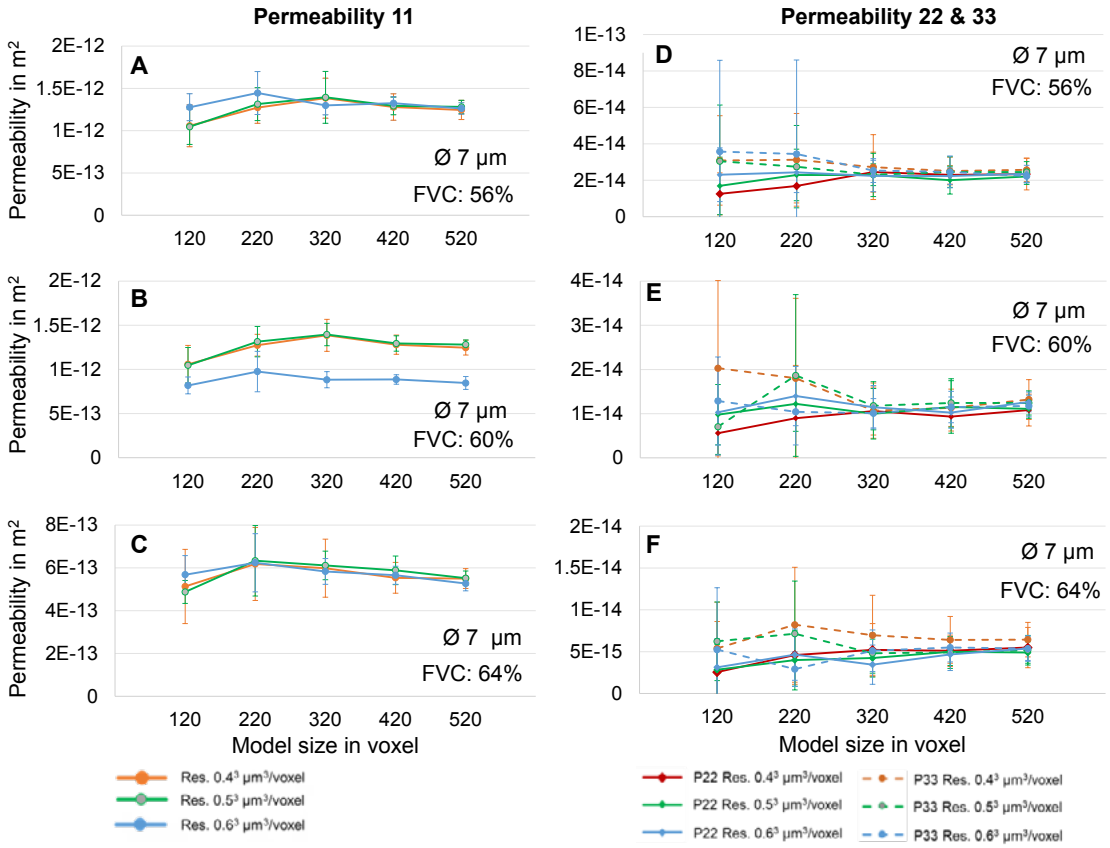

Figure 4: Permeability results of SVE development for models with 7 µm fiber diameter

Diagram B in Figure 4 and 5 show that the resolution of 0.6^3 µm³/voxel differs considerably from the results with a resolution of 0.4^3 and 0.5^3 µm³/voxel. In addition, there is a clear trend in all diagrams that the SD decreases with increasing model size. Diagrams D and E in particular show a significant difference between model sizes 220^3 and 320^3 voxels according to the SD. In Figure 5**Fehler! Verweisquelle konnte nicht gefunden werden.** (diagram D, E, F) the mean values for the models with a resolution of 0.4^3 µm³/voxel and a model size of 320^3 voxels also deviate significantly from the defined reference values. Based on these observations, the voxel size of 0.4^3 and 0.6^3 µm³/voxel and model sizes smaller than 320^3 voxels are excluded. Models with a resolution of 0.5^3 µm³/voxel and model sizes of 320^3, 420^3 and 520^3 voxels achieve comparable results and SD. In view of the strongly increasing computation time in Figure 6, a model size of 320^3 voxels was defined for the following studies as a

compromise between accuracy and computational effort. This corresponds to at least 14 voxels per fiber diameter at 7 µm fiber diameter and thus with a model size of 320^3 voxels about 450 fibers at 60% FVC. This is slightly less than the 785 fibers Rimmel and May [32] defined as minimum. However, they considered 2D models and taking into account that 3D models basically include multiple 2D slices this is a reasonable result. The voxel size of $1/14^{th}$ of a fiber diameter used in this study is significantly smaller compared to Rimmel and May's requirement of $1/10^{th}$ of a fiber diameter for 2D models.

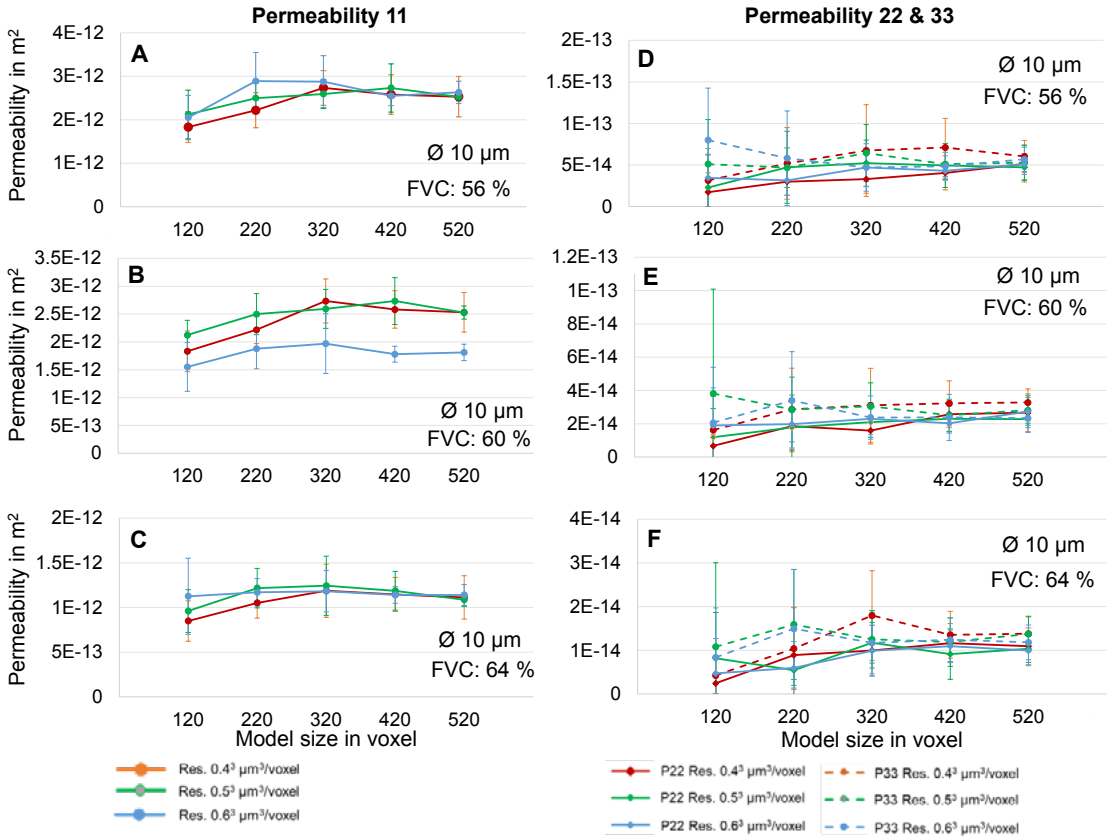

Figure 5: Permeability results of SVE development for models with 10 µm fiber diameter

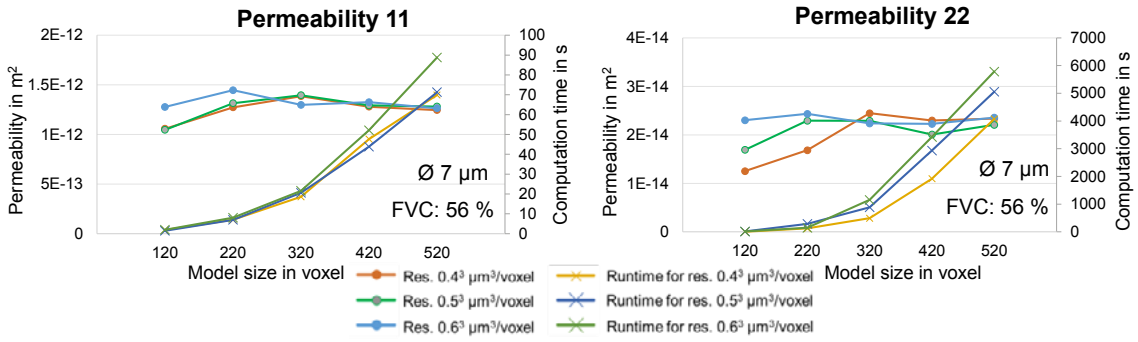

Figure 6: Permeability results and the corresponding computational times on the secondary axis

4. Statistical Representative Volume Element for the Mesoscale

The results of the first parameter screening are shown in Figure 7. Coefficients of variation (CV) of less than 20% were achieved in some cases, but only for low degrees of compaction and for K11 and K22. In all cases, the CV was highest for K33. One reason for this could be the significantly shorter flow paths. In addition, there was a clear trend that with increasing compaction, the results were subject to

greater scatter. Looking at the graphs in Figure 7, there is a clear trend that finer resolution produces better results than the coarser resolutions. The standard deviations are also lower with a number of layers of four or more than with two or three layers. The evaluation of the results for varying layer sizes showed that models with 3x3 rovings per layer had the lowest scatter, even compared to 4x4 rovings per layer. The mean CV for 3x3 rovings per layer and 8^3 µm³/voxel for all compaction levels was 29 % for K11, 15 % for K22 and 38 % for K33. If we only look at the compaction levels 0, 5 % and 10 %, the CV is reduced to 16 %, 12 % and 33 % for K11, K22 and K33.

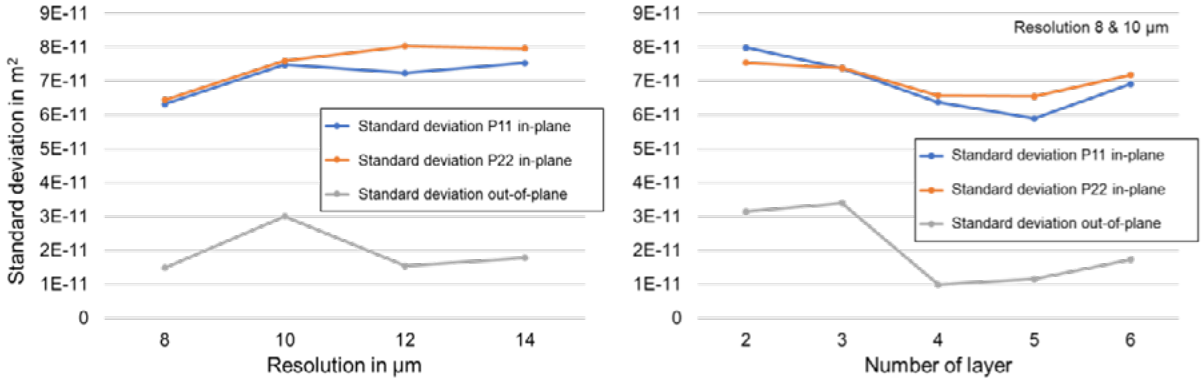

Figure 7: Results of the meoscale SVE development for different resolutions (left) and number of layers (right)

In order to achieve the objective of less than 20 % scattering for all values, additional simulations were carried out. The error bound was reduced from 0.03 to 0.01 in order to achieve more accurate results. Furthermore, a resolution of 8^3 µm³/voxel and 3x3 rovings per textile layer were defined and ten as opposed to five randomized models per parameter set were simulated. The number of textile layers was varied with 4, 5, 6 and 8. Even with these results (see Table 1), the required scatter of less than 20 % could not be achieved for all models. It has been shown here that K33 is still the critical value and that the scatter increases with increasing compaction. Furthermore, it can be seen that a number of layers greater than six does not provide better results. From this it can be interpreted that the resolution of 8^3 µm³/voxel may not be sufficient and higher resolutions of e.g. 6^3 µm³/voxel must be investigated.

Table 1: Results of the additional simulations for the SVE development

Number of layers	Compaction	Mean value in 10^{-12} m²			Standard deviation in 10^{-12} m²			Coefficient of Variation			Mean value of Solid volume percentage

5. Discussions and Guidelines for the Generation of SVE for Microscale and Mesoscale

In this work, the focus is on an often unjustly neglected topic, the creation of suitable models for the numerical determination of characteristic values. In the SVE, not only the suitable structural characteristics, such as the fiber diameter or the FVC, must be correctly modeled, but also suitable modeling parameters, such as resolution, model size and a suitable number of models for statistical validation. The guidelines derived from this work are intended to provide assistance in developing suitable SVEs for the numerical determination of permeability.

The first step is to define a suitable scatter that is to be achieved. In this work, a dispersion of 20 % was defined, which is derived from the benchmark studies mentioned. For the creation of the micro- and mesoscale models, essential structural parameters must be known, such as fiber diameter, relevant FVC range, roving width, textile architecture, etc. This is the only way to generate meaningful models that can be used to develop SVEs. It is important to note that the SVEs are only valid within a limited spectrum. To ensure this, SVE development should ideally be carried out with combinations of characteristic values that cover this range.

For the microscale, a suitable model size and resolution for statistical representative volume elements (SVE) for fiber level permeability prediction was determined. A model size of 320^3 voxels and a voxel size 0.5^3 µm³/voxel were determined, which represents a voxel size of 1/14th of a fiber diameter and corresponds to 200 to 500 fibers per model, depending on fiber diameter and FVC. These values are to be seen as guidelines for comparable material structures, but must be checked for different materials or areas of application.

The target of 20 % could not be fully achieved for the mesoscale. However, these results prove all the more the necessity of SVE model development in order to be able to predict numerically reliable permeability values. In plane, the target values are achieved for lower compactions with a resolution of 8^3 µm³/voxel, 3x3 rovings per layer and 6 textile layers, but not for the entire targeted application area. In future studies, the causes of the increased scattering will be investigated and the guidelines will be successively expanded and specified.

Keywords: Thermoplastic laminates, Kerosene flame, Mechanical testing, X-ray tomography

Abstract
As thermoplastic based composites are increasingly used in aeronautical applications, it is a major concern to understand their mechanical behavior in the critical conditions of an engine fire. The aim of this work is to investigate the tensile behavior of carbon reinforced PEEK laminates exposed to a kerosene flame. An experimental kerosene burner is employed to mimic the fire certification conditions (flame temperature of 1100°C and heat flux of 116kW/m²). The thermal decomposition during the first minute is characterized by calculating the porosity content. X-ray tomography analyses were performed and show that all stages of the porosity formation process occur during the first 15 seconds. The tensile behavior is then studied using two kinds of tests: (i) residual tensile tests at room temperature after fire exposure and cooling and (ii) in situ tensile tests during fire exposure and for different times of exposure. Compared to the virgin specimens, the in situ axial strength (-85% after 900s) decreases more significantly and faster than the residual axial strength (-80% after 900s).

1. Introduction

The current environmental concerns (CO_2 emissions and energy demand) shows that one of the key issues in aeronautics is the design of lightweight structures [1]. Therefore, the integration of polymer matrix composites in structural parts is increasing [2]. However, due to their polymer matrix, their behavior is highly dependent on their thermal working conditions, which can be an issue in the case of an exposure to a flame. In fact, polymers decompose at high temperatures (400-600°C), which results in the formation of cavities filled with pyrolysis gas inside the plies. As the solid matrix is replaced by gas, there is less matrix available to ensure the load transfer. Thus, the mechanical behavior of the composite is altered [3]. For this reason, fire issue is of primary concern for aircraft manufacturers [4]. Understanding the thermomechanical behavior of composites under critical conditions (fire) is therefore essential. The literature on the fire behavior of composites has mainly focused on thermoset (TS) matrix composites [3] and much less on thermoplastic (TP) based composites [5,6].

In a previous work [7], an experimental bench was instrumented to study the thermo-mechanical properties of CG/PEEK laminates with a quasi-isotropic lay-up. A kerosene burner was used to reproduce the conditions of certification fire tests of aeronautical structural parts: flame temperature of 1100°C and heat flux of 116kW/m² [4]. At the same time, a tensile load was applied to the sample. This study [7] has shown the dependence of the residual tensile properties (axial strength and axial stiffness) to the exposure time.

To understand the relationship between the thermal aggression and the mechanical loading, it is important to dissociate the different phenomena that occur within laminates. This study focuses on a

C/PEEK laminates with a QI stacking sequence. Several tests have been carried out. The thermal decomposition process in the first seconds of the fire exposure is first analysed in terms of porosity content; it correlates well with the evolution of the mechanical properties and thereby constitutes a good indicator of damage level. Then, the residual tensile properties at room temperature after exposure to the flame were determined. Finally, the tensile behavior during the exposure was investigated.

2. Materials and experimental set-up

2.1. Materials and specimens

The laminate used in this study consists of a polyetheretherketone (PEEK) thermoplastic matrix reinforced with a 5-harness satin weave carbon faber fabric (Tenax® -E HTA40 3K). The laminate consists of 7 plies following a quasi-isotropic (QI) lay-up [(0/90),(±45),(0/90),(±45),(0/90),(±45),(0/90)]. The fiber volume fraction is 50%. The average thickness of C/PEEK is approximately 2.17mm. The characteristic temperatures for C/PEEK are given in Table 1. Tensile specimens with dog-bone geometry were cut by water jet from 500x500mm² plates. Several thermogravimetric analyses were performed under N_2 at different heating rates to estimate the decomposition onset temperature.

Table 1. Characteristic temperatures of C/PEEK

Glass transition temperature (T_g)	Melting temperature (T_m)	Decomposition onset temperature (T_{onset})
145°C [8]	342°C [8]	600°C

2.2. Kerosene flame exposure

The burner is a domestic device supplied by Cuenod. A kerosene nozzle produces a hollow cone spray with an angle of 80°. The flow rate of 0.3g/s is controlled by a mass flow meter (MINI CORI-FLOW™ – Bronkhorst). Another mass flow meter (EL-FLOW® Prestige – Bronkhorst) controls the air flow. An air/fuel ratio of 0.85 of the stoichiometric value has been chosen to meet the aeronautical fire certification requirements, i.e. a flame temperature of 1100°C and a heat flux of 116kW/m². A protective shield is placed between the 50mm diameter steel tube and the sample. The function of this shield is to limit the area affected by fire to an area of a given size (e.g. 20x20mm² for samples used to determine porosity content and 40x20mm² for tensile specimens) and to ease the comparison between the different testing conditions.

2.3. Porosity content determination

First, the porosity content, i.e. the porosity volume fraction, is evaluated for 25x25mm² samples after a 15s, 30s, 45s and 60s exposure to the flame (20x20mm² area affected by fire). The purpose of these analyses is to understand the process of porosity formation from the first seconds of a fire. Different experimental techniques are used to determine the porosity content: (i) mass loss, (ii) geometry and (iii) X-ray tomography. The mass loss method involves measuring the mass of a sample before and after exposure to fire. The porosity content computed by mass loss is the ratio between the volume corresponding to the mass loss and the volume corresponding to the virgin mass. The geometry method consists in measuring the outer dimensions of a sample with a caliper before and after exposure and in computing the porosity volume from the dimensions changes. The X-ray tomography method is based on tomography analyses using an EasyTom150 device from RX Solutions. After segmentation and 3D reconstruction from the CT scans,the volume of each constituent can be determined. Two different volumes of analysis are considered (Figure 4): (i) a restricted central volume with a section of 3.7x3.7mm² and the specimen thickness and (ii) the whole sample, i.e. a section of 25x25mm². These methods have advantages and drawbacks, as summarized in Table 2.

Table 2. Experimental methods to determine porosity content

Method	Advantages	Disadvantages
Mass loss	Easy and rapid to implement	The mass of carbonaceous residue (char) on the sample after fire exposure could counterbalance the mass loss due to matrix decomposition Does not account for swelling of the material
Geometry	Take account of swelling Easy and rapid to implement	Dependent on where thickness is measured (due to swelling)
X-Ray Tomography	Possibility to analyze porosities (shape, repartition, localization)	Time consuming Dependent on the considered volume

2.4. Mechanical characterization of residual tensile properties

Monotonic mechanical tests allow the residual tensile properties of C/PEEK to be evaluated at room temperature (RT) after a 300s, 600s and 900s exposure to the flame. A 100kN capacity load cell of a MTS servo-hydraulic testing machine is used in displacement-controlled mode (1mm/min) to apply the tension. Axial strains were obtained from a blade extensometer. Three specimens were tested in each configuration and the mechanical properties were determined according to the European Standard EN 6035 [9].

2.5. Combined mechanical-thermal loadings

These tests (Figure 1) consist of two stages:

- A creep loading of 0.5kN during the flame exposure (300s, 600s and 900s) to prevent specimen buckling,
- A force-controlled tensile loading (0.5kN/s) until failure of the specimen.

During the test, mechanical load is measured by a 100kN load cell and the displacement is measured by means of a Linear Variable Differential Transformer sensor. In addition, a 7.5-14µm FLIR A655sc infrared (IR) camera, assuming a 0.9 sample emissivity and a 97% mirror transmission, measures the back surface temperature of the specimen during flame exposure. The average temperature is then calculated within two areas: (i) a centered 18x38mm² rectangle and (ii) a centered 10mm diameter circle (Figure 2). These measurements show a relatively homogeneous temperature field within the exposed area, denoting a relatively low in-plane conductive heat transfer.

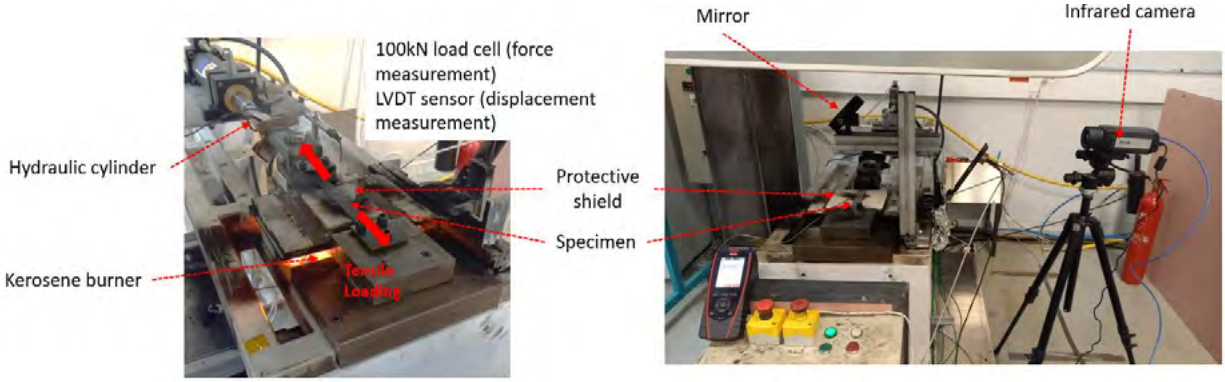

Figure 1. In situ tensile experimental bench: C/PEEK laminates subjected to a kerosene flame during mechanical loading

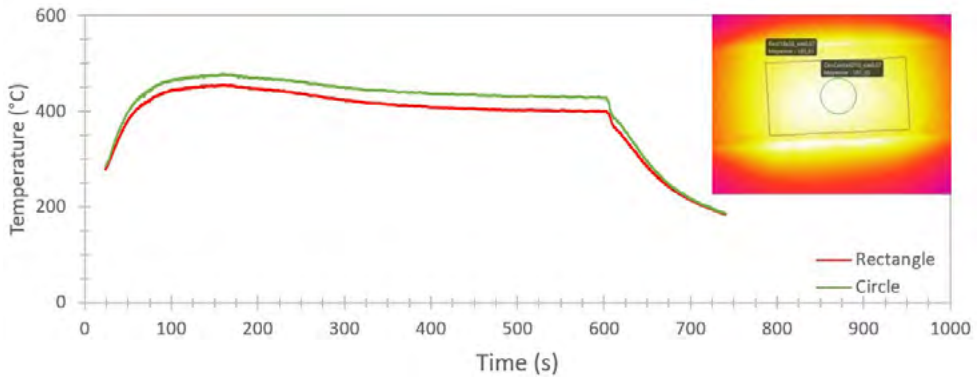

Figure 2. Back surface temperature evolution during 600s exposure on C/PEEK laminates, as measured by IR camera

3. Results and discussion

3.1. Mass loss and porosity content

During fire exposure, the PEEK matrix undergoes a thermal decomposition leading to mass loss and to swelling, resulting from the formation of porosities. Microscopic observations (Figure 4) show that two areas can be identified through the thickness of the sample: (i) a thermally degraded area and (ii) a relatively preserved area [10]. Thermal degradation starts within the first few seconds of exposure. Figure 3 shows the porosity content calculated by the different methods. Not surprisingly, a prolonged exposure results in an increase of the porosity content. However, there are a few differences between these methods. The porosity content obtained from the mass loss is lower than the one obtained from other methods. This can be explained by the fact that the mass loss method does not consider the swelling of the sample. The overall trend for porosity content calculated from geometry changes is similar to the one obtained from X-ray tomography observations on different volumes. The porosity content computed from CT-scans seems to depend on the considered volume. Indeed, for 15 and 30s exposure times, the restricted central volume provides the highest porosity content; at this place damage is more important than along the edges of the sample (Figure 4); and for 45 and 60s of exposure, then the full size sample provides the highest porosity content.

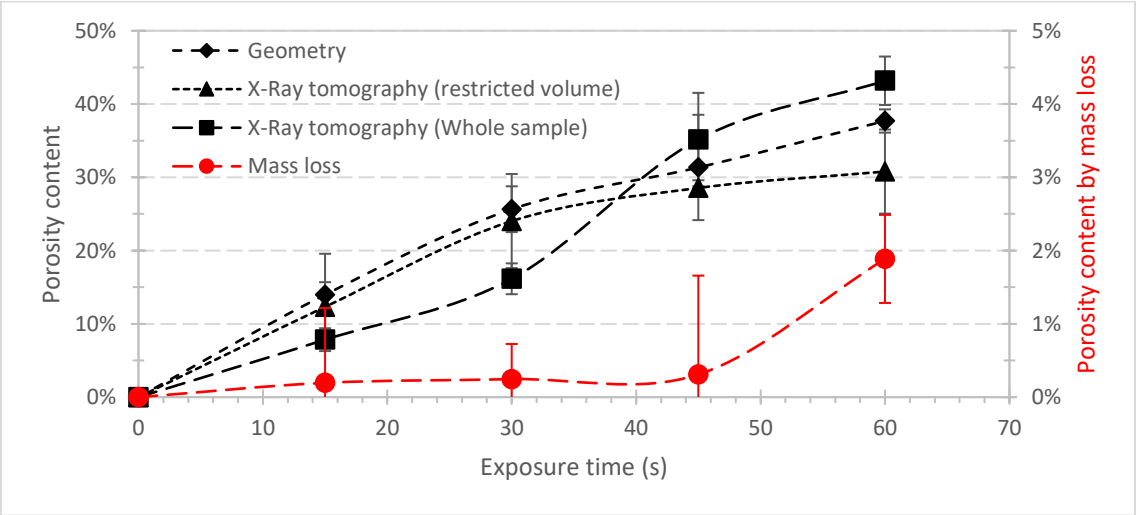

Figure 3. Comparison of porosity content obtained from different methods in C/PEEK laminates exposed to the flame for different lengths of time

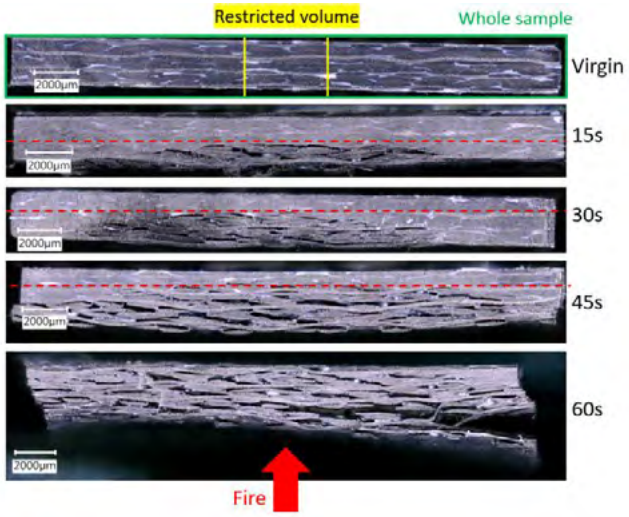

Figure 4. Through-thickness microscopic observations of C/PEEK laminates subjected to the flame for different lengths of time

X-ray tomography allows not only the porosity content to be obtained but also to visualize the porosity network. Different types of cavities, corresponding to different steps in the porosity formation process, can be identified in Figure 5: (i) small spherical cavities that have just nucleated, (ii) larger spherical ones that have grown due to the internal pressure of pyrolysis gases, (iii) those with disturbed shapes resulting from the coalescence of several spherical cavities, (iv) large ones leading to inter-ply delamination and (v) intra-fiber bundle longitudinal cavities along the fiber direction, resulting from the decomposition of the PEEK matrix used to impregnate fibers.

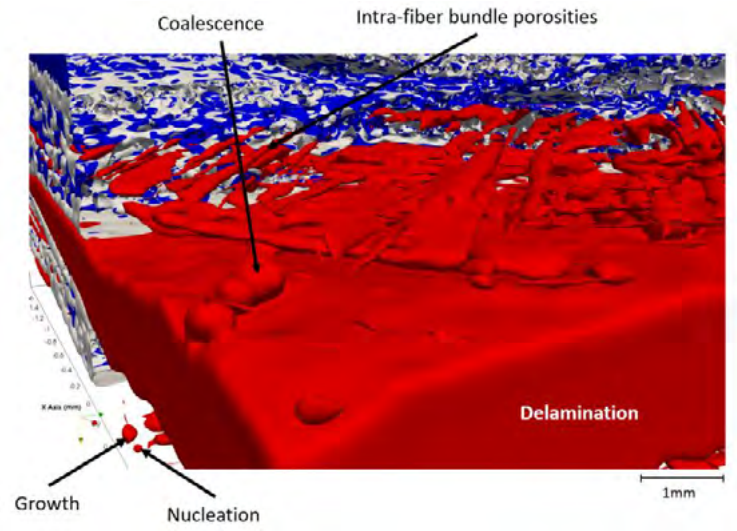

Figure 5. X-Ray tomography observation of C/PEEK after a 15s exposure to the flame

3.2. Residual tensile properties after fire exposure

To quantify the residual tensile properties of C/PEEK after flame exposure, monotonic tensile tests were performed on specimens after cooling. The macroscopic responses (Figure 6 (a)) show that the tensile behavior of both virgin and thermally degraded material is virtually elastic-brittle. The responses of thermally degraded specimens show several drops in the axial stress which could correspond to the failure of a ply. The response of the 600s exposed specimen is similar to that of the 900s specimen.

Figure 6 (b) shows that both axial strength and stiffness decrease with increasing exposure time. This can be correlated to the porosity content which becomes higher as the exposure time increases, also meaning that there is less matrix to ensure the load transfer. After 600s exposure, both axial stiffness and strength seem to reach a plateau at about 20% and 30% of the virgin properties respectively. As shown in Figure 7, the ultimate failure of the specimen is caused by the breakage of 0° fibers, i.e. in the direction of mechanical loading. Under fire conditions, the 0° oriented fibers bearing about 73% of the axial load (according to the classical laminates theory) are the ones contributing most to the axial strength in QI laminates.

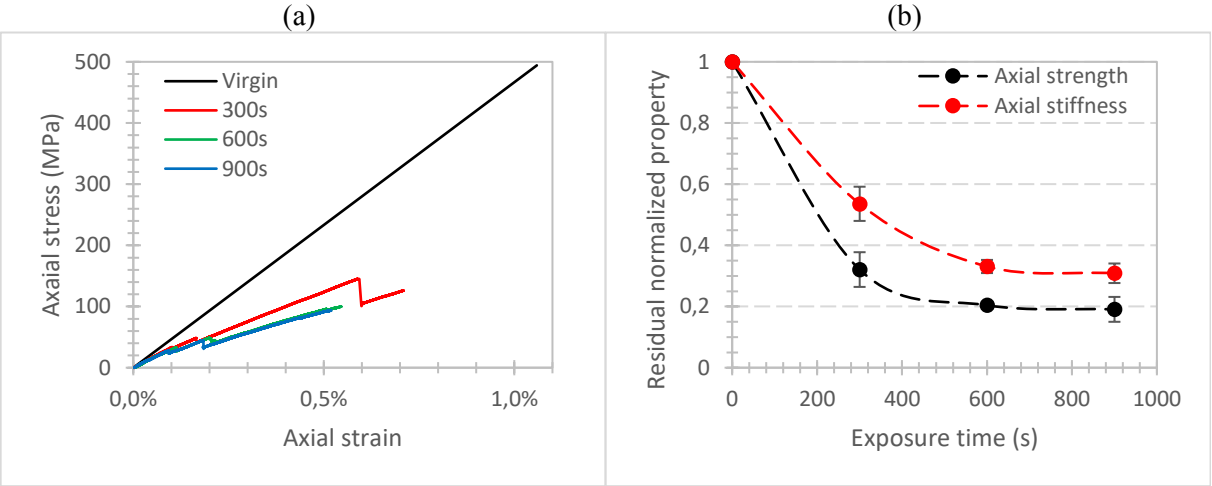

Figure 6. Tensile behavior of C/PEEK laminates subjected to the flame (a) Stress-strain response (b) Changes in tensile properties VS exposure time

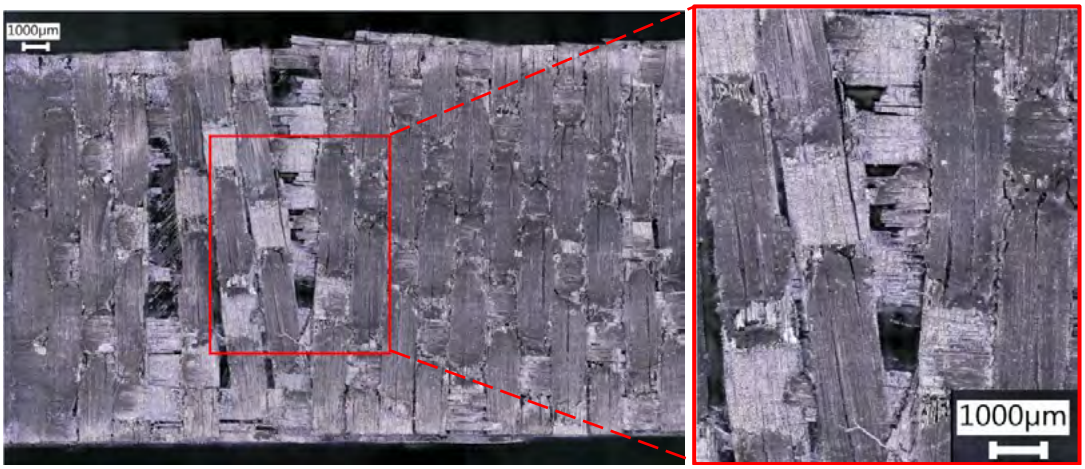

Figure 7. Microscopic observations of the exposed surface of the laminates after a 300s exposure to the flame and a residual tensile test

3.3. In situ tensile properties

The previous section allows the characterization of the tensile properties of QI C/PEEK laminates after a fire event and a cooling at RT. It is now interesting to compare the residual axial strength with the axial strength during fire exposure. Tensile tests under fire were then carried out. First, a specimen is exposed to the kerosene flame for a given time (300s, 600s or 900s) while maintaining a tensile load of 0.5kN to avoid specimen buckling. Then, still under fire exposure, a tensile load is applied in load-

controlled mode (0.5kN/s). At the same time, the back surface temperature is measured with an IR camera. Figure 8 shows that the axial strength remains stable at about 15% after a 300s exposure to fire. The axial strength is lower than the one determined after flame exposure. This difference could be explained by the back surface temperature. It reaches 450°C, which is higher than the melting temperature. Therefore, under the flame, the whole PEEK matrix is at best melted and at worst decomposed. As a result, the matrix does not ensure the load transfer between the fibers. In the case of residual tensile testing at RT, matrix that has not decomposed on the back surface, has resolidified and can therefore ensure the bond between fiber bundles and thus the load transfer. As for the back surface temperature, it increases up to 200s of exposure and then it slightly decreases to remain stable. This decrease could be explained by the delamination of the laminates contributing to form an insulating gas layer. X-ray tomography analyses show significant swelling and failure of the 0° oriented fibers on the exposed surface (Figure 9).

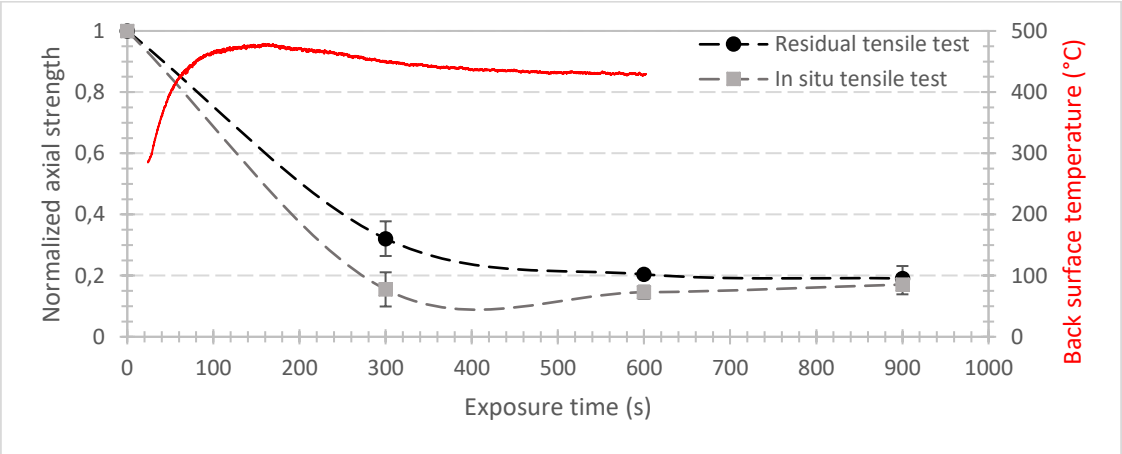

Figure 8. Changes in the axial strength of C/PEEK laminates subjected to a tensile loading after fire exposure (residual) and under (in situ) fire conditions

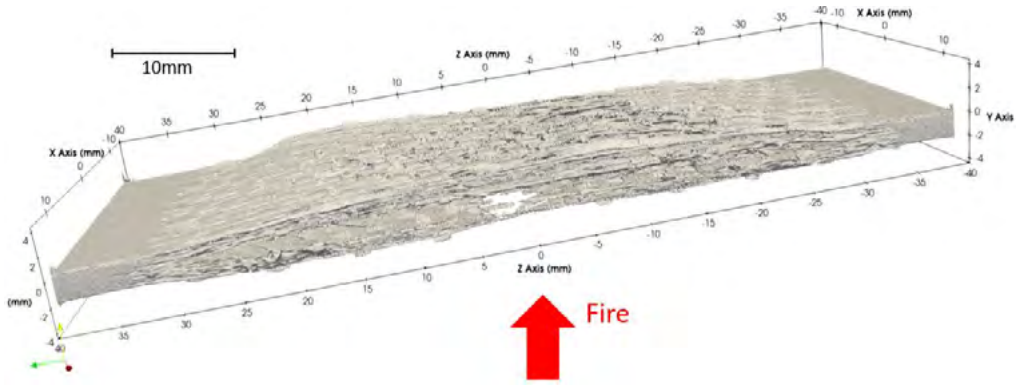

Figure 9. X-ray tomography observations of C/PEEK laminates after a 900s exposure to fire followed by an in situ tensile loading

4. Conclusion

The main objective of this work was to investigate both thermal and mechanical phenomena at play in quasi-isotropic carbon reinforced PEEK laminates. A fire test bench was used to mimic the aeronautical fire certification conditions (a 1100°C kerosene flame and 116kW/m² heat flux). To understand the thermal decomposition during the first minute of fire, the porosity content and morphological distribution were characterised. To study the relationship between thermal aggression and mechanical

loading, two types of tensile tests were carried out: residual tensile test at RT and in situ tensile test under the flame.

From the obtained results, the following conclusions can be drawn: (i) all the stages of the porosity formation process appear in the first few seconds of exposure and the porosity content reaches 40% after one minute of exposure, (ii) the residual axial strength is higher than the in situ axial strength because of the cooling of specimens leading to the resolidification of the PEEK matrix, (iii) the contribution of plies to axial strength depends on the orientation of fibers within each ply, (iv) porosities have a detrimental effect on the tensile properties but may contribute to the reduction of back surface temperature.

The temperature within the laminate needs to be further investigated in order to quantify the degradation of each ply and thus estimate the contribution of each ply to the load carrying capabilities. It is also necessary to develop a numerical model to estimate the temperature in-plane and through the thickness of the laminates.

Acknowledgments
This study has benefited from the financial support of Region Normandie and the European Funds for regional development (FEDER) through the ACERIN project 2023 for the equipment in X-Ray tomography.

Keywords: open-source, layered model, FEM, structural simulation, validation

Abstract
FEA simulations are state-of-the-art today in the industry. Due to the anisotropic properties of fibre-reinforced composites, FEA is a crucial tool when designing such parts and helps to reduce prototype iterations, money, and resources.

However, due to the high prices of commercial FEA software, SMEs are often choosing not to use these tools, despite the potential long-term economic gains. The commercial software available on the market is usually too feature-rich and complex for most applications, especially to validate a few layup ideas. Therefore, open-source software could provide a solution for SMEs.

Based on requirements as stated by SMEs for the basic dimensioning of FRP structures, Salome_Meca was identified as a potential open-source FEA software. In this work, the abilities of the software were validated by comparison to an analytical solution for a three-point-bending test of a carbon fibre-reinforced polymer sample. The comparison shows good agreement and hence validates the use of Salome_Meca for FRP structure dimensioning. Using Python, additional features can be added according to the use case of the SMEs, such as various failure criteria, visualization, and reporting.

1. Introduction

Today, the rough dimensioning of fibre-reinforced polymer (FRP) composite structures is usually performed with the experience of a skilled engineer. Pragmatic analytical formulas and a trial and error approach are common in SMEs to find a proper layup for their parts. FEM software is available and engineers at universities usually are trained on how to use and apply it to calculate different layups or even optimize the layup automatically, improving the material usage and reducing waste. Despite this fact, SMEs often stick to their approach as commercial FEM software exceeds their funds. The high acquisition, training, and operation costs won't lead to a sufficient turnaround.
Finding, evaluating and improving an open-source FEM software for the basic dimensioning of FRP structures for Swiss SMEs is part of an ongoing project. In the scope of the project, Code_Aster [1] was identified as a promising FE solver. The Salome (Simulation numérique par Architecture Logicielle en Open source et à Méthodologie d'Évolution) software package includes a CAD-geometry editor , a mesher and a visualisation tool. It supports industry-standard import formats for 3D files (IGES, STEP, BREP). The variation where the Code_Aster FE solver and FEM study creator are combined is called Salome_Meca .

In this work, the validation of Salome_Meca for use in dimensioning FRP structures is presented for simulations using 2d shell elements. These are valid for monolithic, shell-like FRP structures [2]. A three-point-bending test is implemented in FEA, and the resulting deflection is compared to the analytical solution. Additionally, the results are compared to commercially available FEM-Software.

2. Methods

The principle workflow of calculating the structural response of a 2D FRP part is shown in (Figure 1).

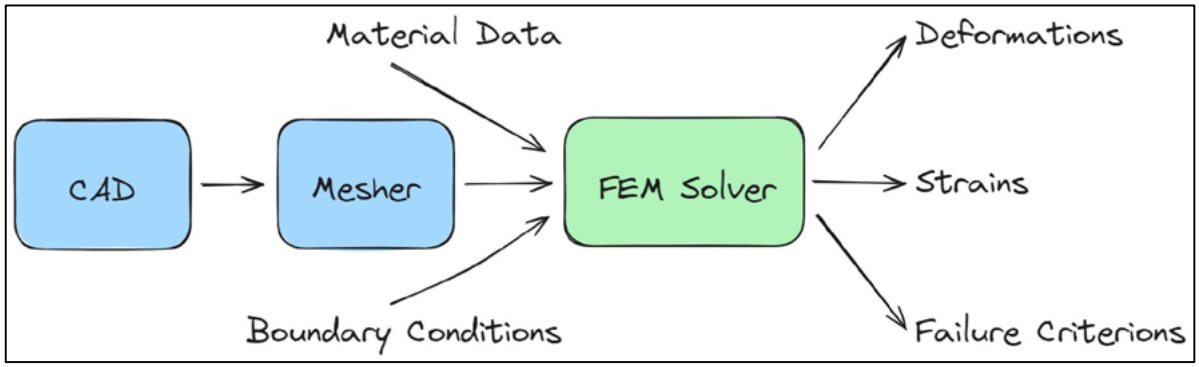

Figure 1. General Workflow for FEM Analysis of a FRP Structure in Salome_Meca

The shell geometry of the structure is either drawn in the geometry module or imported from CAD software. The geometry is subsequently meshed in the mesh module and finally the material properties, composite layup and boundary conditions are defined and the model is solved in the code-aster FE solver. The results can then be visualised using the Paravis [3] module, where deformation, strains and possible failure criteria can be shown.

In the scope of the project, SMEs filled out an extensive survey concerning their research needs and current technologies. The material they use most often is carbon fibre-reinforced composite (CFRP) with an epoxy matrix. The mechanical properties of such laminates with 40% fibre volume content were measured experimentally, using vacuum bagging as the manufacturing method. The measured properties for a unidirectional CFRP ply are summarised in (Table 1).

Table 1. Mechanical Properties of a single layer (CF UD 200g/m2; epoxy matrix, wet laminate, 40% FVC), experimentally measured values

Property	**Abbreviation**	**Unit**	**Value**
E-Module longitudinal (0°)	E_{11}	MPa	92500
E-Module transverse (90°)	E_{22}	MPa	6300
Shear modulus - planar	G_{12}	MPa	5700
Transverse contraction	ν_{12}	-	0.33
Layer thickness	t_i	mm	0.28

The validation of Salome_meca is conducted by considering a three-point bending test according to the ISO 14125 standard. The test is implemented in Salome_Meca and compared to the analytical solution (2.1). The geometry of the test setup is shown in (Figure 2). The test specimen is a plate of rectangular cross-section with a width w of 25 mm and a span length L of 300 mm. The thickness of the specimen is governed by the CFRP layup.

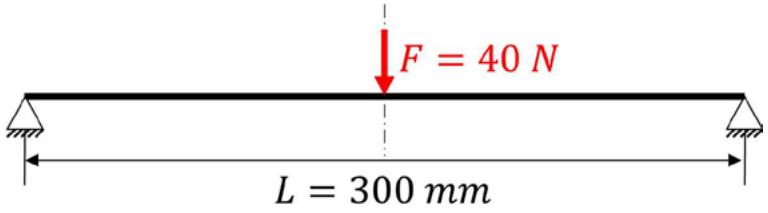

Figure 2. Three point bending experiment according to ISO 14125

As the homogenisation of the FRP layup in Salome_Meca is crucial for FEM analysis, specifically for loading under bending because of the stiffness distribution in the cross-section of the beam, two different layups of equal thickness were implemented. The primary direction, i.e. 0° orientation is along the span axis. In layup L1 the stiff 0° plys are at the exterior of the laminate, while in layup L2, the stiff plys are positioned in the center near the bending neutral plane. The resulting layups are summarized in (Table 2).

Table 2. Two different CFRP layups considered in this work.

Designation	Layup	Layer material	Bending Modulus [MPa]
L1	$[0°,0°,+45°,-45°]_S$	CF UD	83334
L2	$[+45°,-45°,0°,0°]_S$	CF UD	27741

The validation of the FEM model is conducted by comparing the maximal deflection under a known bending force F of 40 N.

2.1. FEM Analysis

For the FEM analysis of the bending test, the symmetry of the setup was exploited. In (Figure 3) the side view of the simulated test is shown including the symmetry plane in the center.

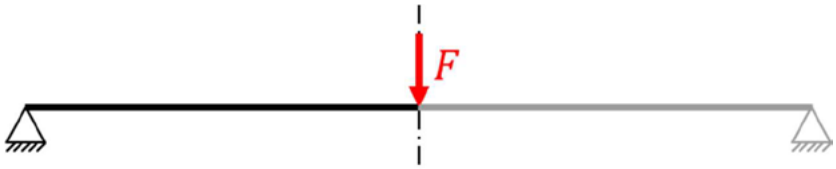

Figure 3. Simulated three-point bending test, including the symmetry plane in the center.

The specimen was modelled as a 2D rectangle of width w and length $L/2$ as seen in (Figure 4). The boundary conditions are also shown.

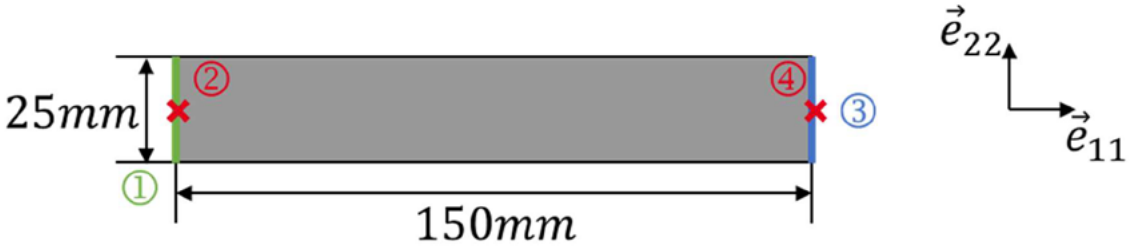

Figure 4. Top view of the simulated speciment with the numbered boundary condition location. The local coordinate system is also shown.

The edge on the fixed support (1) is fixed for rotary and translatory degrees of freedom (DoF) in two directions. The center point (2) is fixed in all 6 Dof. For the symmetry constraint, the edge on the right (3) is partially fixed as well as the point (4), which has to fulfil the symmetry constraint. The load was introduced as half the load F as a line load. Due to the symmetry, only half the load was applied in the simulation. The boundary conditions (2) and (4) are added, to ensure that sufficient DoFs are restricted for the simulation to converge. The load and boundary conditions are summarized in (Table 3).

Table 3. Summary of the boundary conditions applied in the FEM analysis.

Constraint Nr.	Constraint
(1)	$u_{33} = 0$
(2)	$u_{22} = u_{33} = 0$
(3)	$u_{11} = \omega_{11} = \omega_{22} = \omega_{33} = 0$
(4)	$u_{11} = u_{22} = \omega_{11} = \omega_{22} = \omega_{33} = 0$
F	$q_{33} = \frac{-F}{2 \cdot 25mm} = \frac{-40N}{2 \cdot 25mm} = -0.8\,{}^{N}/_{mm}$

2.2. Analytical Analysis

To validate the results the three-point bending specimen was approximated as a Euler-Bernoulli bending beam. This first-order theory is valid, as the length-to-thickness ratio is an order of magnitude over 10. For a three-point bending beam the maximal deflection u is calculated as shown in the following equations (Eq. 1, Eq. 2).

$$u = \frac{FL^3}{48 \cdot E \cdot I} \tag{1}$$

$$I = \frac{w \cdot h^3}{12} \tag{2}$$

As the specimen is made of CFRP, the bending stiffness of the specimen is calculated based on the homogenization of the layup using the Classical Laminate Theory [4]. To homogenize the properties the open-source program ElamX from TU Dresten [5] was used.

The resulting bending stiffness in the longitudinal direction (11-direction) is given for the two layups as in (Table 2)

3. Results and Discussion

The simulated specimen was made of 3900 2D DKT elements with a mean edge length of 1 mm. The undeformed and the two deformed results are shown in (Figure 5).

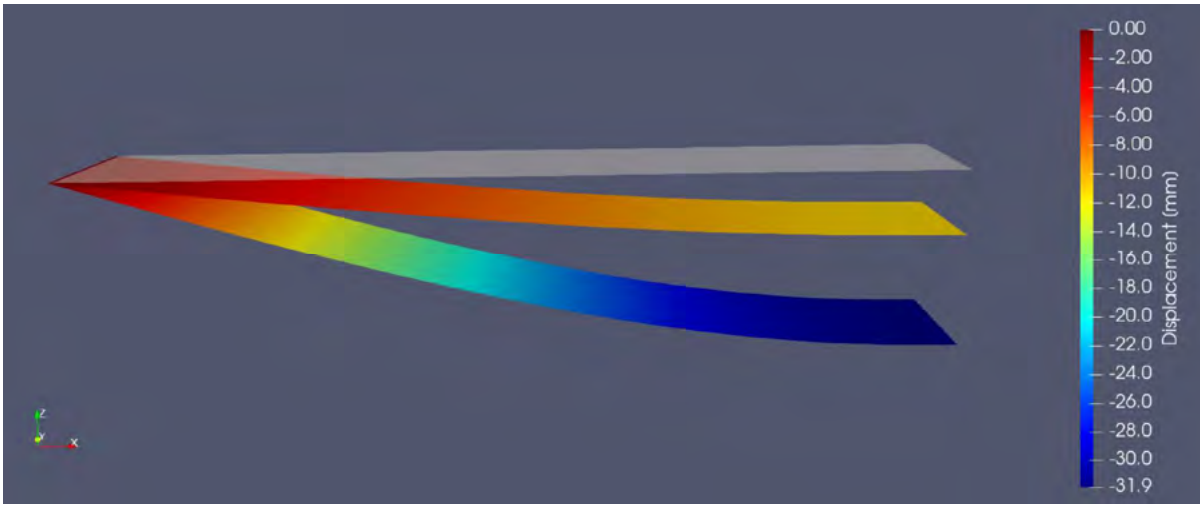

Figure 5. The undeformed and two deformed specimen shapes for the two layups shown in the Paravis module of Salome_Meca.

The displacement of the nodes can be extracted, and the maximal value is used for the validation for either layup. Obviously, the bending stiffness difference between L1 and L2 is visible by the different levels of deformation as seen in the figure above.

The maximal deflextion based on the FEM analysis and analyitical solution are summarised in (Table 4). Additionally, the maximal deflection is compared to a commercially available FEM programme in (Table 5).

Table 4. Summary of resulting maximal deflection of the FEM analysis and Analytical analyis. The difference is shown in percentage.

Result	Salome_Meca	Analytic	Deviation [%]
Bending test L1 [mm]	11.45	11.53	-0.70
Bending test L2 [mm]	31.91	34.64	-7.88

Table 5. Summary of resulting maximal deflection of the FEM (Salome_Meca) and a commercially available FEM software. The difference is shown in percentage

Result	Salome_Meca	Commercial FEA	Deviation [%]
Bending test L1 [mm]	11.45	11.43	0.18
Bending test L2 [mm]	31.91	31.25	2.11

All three results, the FEA by Salome_Meca, the FEM programme and the analytical results agree on the deflection order of magnitude. Furthermore, the increased deflection due to the lower bending stiffness of L2 is also well captured. The difference is below 1% for the stiffer specimen, whereas for L2 the difference is as large as 7.88%. Obviously, the error of the FEM analysis increases with lower bending stiffness. This is a consequence of the boundary conditions used. Idealised in a three-point bending loading scenario, the average tensile strain of the sample is 0. Experimentally this is seen as the sample moves on the simply supported supports. The way the FEM analysis is implemented, the boundary condition (1) does not allow any movement, only rotation. Hence for large deflections, the slipping of the specimen is prohibited, which introduces a tensile loading of the specimen superimposed to the bending load. Hence, the expected deflection is smaller, which is the case as seen in the results. Hence, the FEM analysis is validated.

4. Conclusion

As a validation to see if the model and the strategy used were correct, the three-point bending test was a good approach. Further tests will be done on the specimen to compare with the simulations.

As the next steps, other functions will be implemented, such as damage according to Hashin. A buckling analysis has already been performed but not validated.

To make it suitable for industrial applications, other geometries and load cases need to be implemented and tested to verify the usability for SMEs.

Keywords: Braided composite, Multi-scale simulation, Micromechanics, Stress amplification, Progressive failure model

Abstract

In this study, a simulation model was developed to predict the nonlinear mechanical behavior of braided carbon fiber-reinforced pipes, incorporating multi-scale simulation and progressive failure analysis. The multi-scale modeling was employed by setting Periodic Boundary Conditions (PBC) for Representative Volume Elements (RVE) at the micro- and meso-scale levels. Then, the effective equivalent properties and Stress Amplification Factors (SAF) to predict and damage states at each scale were derived. From these results, the failure criteria of each material were applied to determine the stress states of fibers and matrix. As a result, the mechanical behavior of macro-scale pipe was predicted. To verify the simulation results, compression, bending, and torsion tests were conducted on carbon fiber-reinforced circular pipes with a 45-degree plain braid angle and a 70-degree twill braid angle. In summary, a multi-scale-based simulation model incorporating micro-scale damage mechanics for braided carbon fiber-reinforced composites was developed, showing a high accuracy through experimental validation.

1. Introduction

Owing to superior mechanical properties such as high stiffness and strength with low weight, carbon fiber-reinforced composites have received tremendous attention recently as essential materials for enabling innovative performance improvements in various industries. Particularly, woven carbon fiber-reinforced composites exhibit excellent impact resistance with their enhanced out-of-plane properties, and formability with balanced in-plane properties compared to unidirectional composites, making them widely utilized. Among various weaving techniques, braiding offers advantages in three-dimensional structure fabrication, localized direction and density control, and production automation, leading to increased applications in industries such as aerospace, automotive, and energy [1]. Therefore, there is a growing demand for understanding the properties of braided composites considering different braiding patterns and angles as shown in Figure 1.

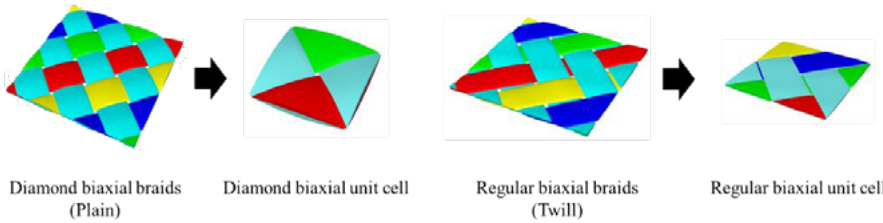

Figure 1. The schematic of braiding type

To simulate real braided composites and predict their mechanical properties, it is necessary to develop reliable models that realize complex braided composite structures. In this study, micro-mechanics based multi-scale modeling and finite element analysis were conducted to predict the non-linear behavior of braided composites [2]. Micro-scale and meso-scale representative volume element (RVE) models were developed, and the meso-scale stress of fiber yarn was transferred to the micro-scale stress of fiber and matrix using a stress amplification factor (SAF) [3]. A progressive damage model based on the multi-scale method was applied to the meso-scale RVE model consisting of fiber yarn and the matrix pocket, from which the non-linear behavior of a braided composite could be predicted [4]. Using the developed damage model, simulations for various braiding types and mechanical tests were conducted. The results of predicted damage model was compared with experimental results, and failure analysis was performed for the meso-scale braided material and macro-scale braided composite pipe.

2. Finite element analysis & Experimental verification

2.1. Multi-scale simulation to derive effective equivalent properties and the stress amplification factor

The multi-scale simulation of braided composites is presented in Figure 2. It was demonstrated that the braided composite damage of the macro-scale homogenous part can be indicated by meso-scale damage to either the fiber yarn or matrix pocket. Failure in the matrix pocket is regarded as damage in the isotropic matrix. Meanwhile, the damage mechanisms within the fiber yarn are represented by failure modes identified for a UD composite. Two micro-scale failure modes (fiber failure and matrix failure) were identified within the yarn. The local stress distributions in the braided composite could be obtained by linking an arbitrary global stress to the local stress.

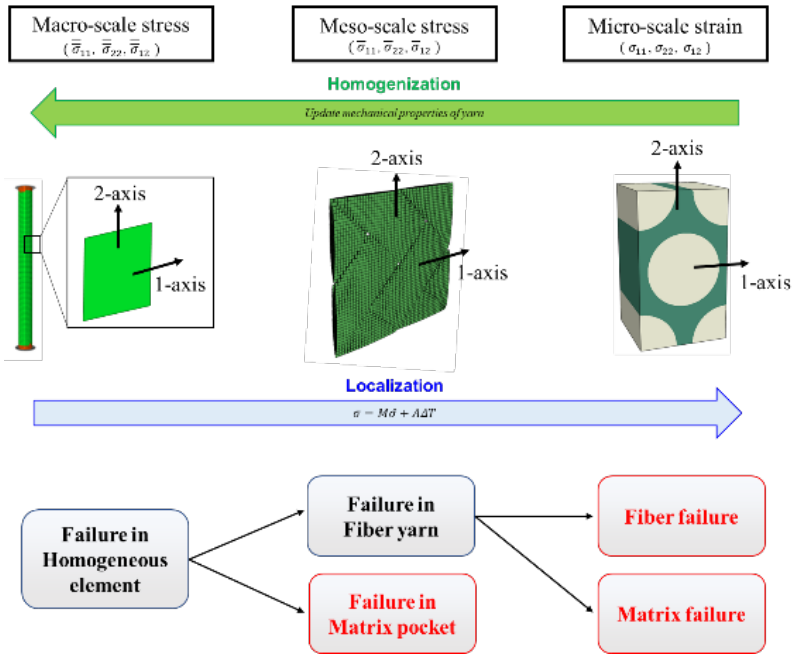

Figure 2. The schematic of multi-scale simulation process

To apply micro-mechanics based multi-scale analysis to yarn composed of fibers and matrix, a process of stress calculation meso-units to micro-units is necessary. A correlation between meso-scale stresses and micro-scale model stresses was established with the stress amplification factor as expressed by the following equation (1): [5]

$$\sigma_i = M_i \bar{\sigma} + A_i \Delta T \tag{1}$$

where σ_i and σ_i are the micro-scale stress and meso-scale stress. M_i is the stress amplification factor to calculate meso-scale stress with micro-scale stress, and A_i indicates the thermal stress amplification factor for the temperature increment. In this work, thermal stress caused by temperature changes was not considered. The SAF was determined through finite element simulation of the micro-scale RVE model with each corresponding periodic boundary condition as shown in Figure 3 (The mechanical properties of fiber and matrix are shown in Table 1) [6]. The relationship between meso-scale stress and micro-scale stress is expressed as follows:

$$\begin{pmatrix}\sigma_1\\ \sigma_2\\ \sigma_3\\ \sigma_4\\ \sigma_5\\ \sigma_6\end{pmatrix} = \begin{bmatrix}M_{11} & M_{12} & M_{13} & M_{14} & 0 & 0\\ M_{21} & M_{22} & M_{23} & M_{24} & 0 & 0\\ M_{31} & M_{32} & M_{33} & M_{34} & 0 & 0\\ M_{41} & M_{42} & M_{43} & M_{44} & 0 & 0\\ 0 & 0 & 0 & 0 & M_{55} & M_{56}\\ 0 & 0 & 0 & 0 & M_{65} & M_{66}\end{bmatrix}\begin{pmatrix}\bar{\sigma}_1\\ \bar{\sigma}_2\\ \bar{\sigma}_3\\ \bar{\sigma}_4\\ \bar{\sigma}_5\\ \bar{\sigma}_6\end{pmatrix} \quad (2)$$

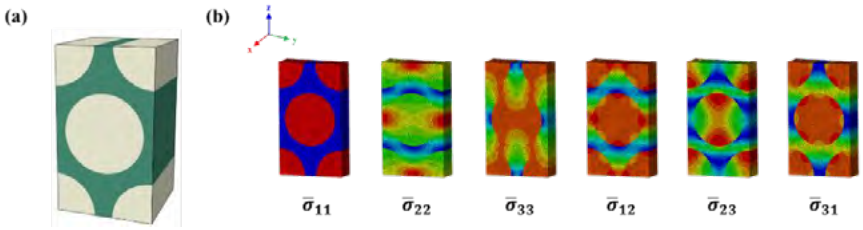

Figure 3. (a) Micro-scale RVE model and (b) stress distribution of micro RVE model according to each stress direction.

Table 1. The mechanical properties of carbon fiber and matrix.

Constituent	Properties	Value
Fiber	E_{f1} [GPa]	230
	E_{f2} [GPa]	15
	G_{f12} [GPa]	27
	G_{f23} [GPa]	7
	ν_{12}	0.2
	ν_{23}	0.2
	T_f [MPa]	4800
Matrix	E_m [GPa]	3.1
	ν_m	0.35
	T_m [MPa]	50
	C_m [MPa]	100
Yarn volume fraction	V_f	0.55

The stress calculation macro-scale to meso-scale was conducted by a similar process. The meso-scale RVE model was modeled using the textile geometric modeling software TexGen with various braiding

conditions. In this analysis, shell elements were used at the macro-scale model. Therefore, the relationship between macro-scale stress and meso-scale stress is expressed as follows:

$$\begin{pmatrix} \bar{\sigma}_{11} \\ \bar{\sigma}_{22} \\ \bar{\sigma}_{12} \end{pmatrix} = \begin{bmatrix} M_{11} & M_{12} & M_{13} \\ M_{21} & M_{22} & M_{23} \\ M_{31} & M_{32} & M_{33} \end{bmatrix} \begin{pmatrix} \bar{\bar{\sigma}}_{11} \\ \bar{\bar{\sigma}}_{22} \\ \bar{\bar{\sigma}}_{12} \end{pmatrix} \tag{3}$$

where $\bar{\bar{\sigma}}$ and $\bar{\sigma}$ are the macro-scale stress and meso-scale stress, respectively, and M is the stress amplification factor.

2.2. Progressive failure analysis

To accurately predict the non-linear behavior of a braided composite with finite element simulation, a distinguished failure criterion for the progressive damage model should be used (see Figure 4).

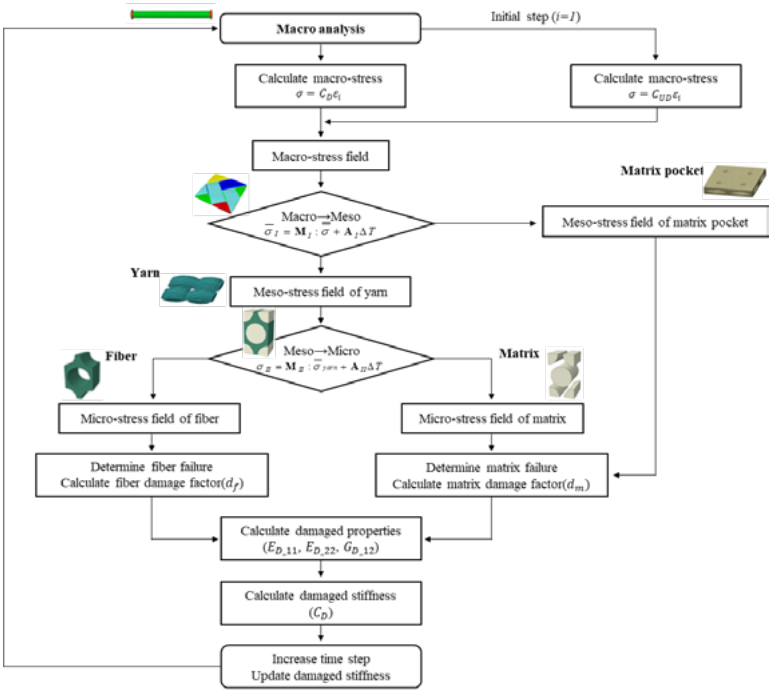

Figure 4. The schematic of multi-scale simulation

In the matrix, von Mises failure criterion was used as follows: [7]

$$\frac{\sigma_{VM}^2}{C_m T_m} + \left(\frac{1}{T_m} - \frac{1}{C_m}\right) I_1 = 1 \tag{4}$$

where C_m and T_m are the compressive and tensile strength of the matrix, and σ_{VM} and I_1 are the von Mises equivalent stress and the first stress invariant [8]. The matrix failure criterion is defined as a function of equivalent stress as follows: [9]

$$\sigma_{ep} = \frac{(\beta - 1) I_1 + \sqrt{(\beta - 1)^2 I_1^2 + 4\beta\sigma_{VM}^2}}{2\beta} \tag{5}$$

where β is defined as the ratio of the matrix compressive strength to the tensile strength. This equivalent stress is also termed Stassi's equivalent stress [10]. From this equation, failure criterion comparable to

the condition of equivalent stress, σ_{ep}, was calculated by the matrix failure index (k_m) according to the following equation:

$$k_m = \frac{\sigma_{eq}}{T_m} \tag{6}$$

where T_m is the tensile strength of the matrix. After matrix failure was generated, damage accumulated, and the stiffness of the matrix progressively decreased. The damage model was used as follows:

$$D_m = \begin{cases} 1 - exp[\gamma(1 - k_m)] & (1 < k_m < \alpha) \\ 0.99 & (\alpha < k_m) \end{cases} \tag{7}$$

where γ is a matrix damage factor. For gamma, the larger the braiding angle, the larger the gamma value used (for braiding angles of 70°, γ = 3 / 45°, γ = 1.5 / 20°, γ = 1). α is set to 1.5 [11]. When σ_{eq} is larger than the strength of the matrix, D_m is set to .99 to give complete fracture of the matrix. In the fiber, a maximum longitudinal stress failure criterion was used as following equation:

$$k_f = \frac{T_f}{\sigma_{f11}} \tag{8}$$

where k_f is the fiber failure index and T_f and σ_{f11} are the tensile strength and micro stress of the fiber in the longitudinal direction, respectively. When k_f was larger than 1, the fiber failed and its stiffness rapidly decreased. This fiber damage factor is expressed as follows:

$$D_f = \begin{cases} 0 & (k_f \leq 1) \\ 0.99 & (1 < k_f) \end{cases} \tag{9}$$

2.3. Mechanical tests of the braided composites

The tests for mechanical properties of the meso-scale braided composite were performed with carbon fiber/epoxy material with two braiding types (plain and twill) at angles of 20-degree, 45-degree, and 70-degree respectively. Meso-scale specimens were fabricated through a vacuum assisted resin transfer molding (VARTM) process, based on the ASTM standard method (see Figure 5(a)). In addition, macro-scale tests were conducted for circular composite pipe of two braiding type(plain 45-degree and twill 70-degree). The braided composite pipes were also fabricated through the VARTM process. In accordance with Figure 5, mechanical properties of meso-scale and macro-scale specimens were evaluated and compared with the results of the progressive failure model based on the multi-scale method.

3. Results and discussion

To verify the micro-meso multi-scale simulation, comparisons between the results of material property tests and simulations were conducted. The multi-scale simulation considered the failures of the matrix pocket and yarn component in meso-scale as well as the failures of fiber and matrix in micro-scale yarn. The micro-scale failures in the yarn were realized by the progressive failure model based on multi-scale simulation. The equivalent material properties of yarn were obtained through micro-scale RVE model simulation (Table 2).

Table 2. The equivalent mechanical material properties of yarn.

Properties	E_1 (GPa)	E_2 (GPa)	E_3 (GPa)	G_{12} (GPa)	G_{23} (GPa)	G_{31} (GPa)	v_{12}	v_{23}	v_{31}
Value	139	7	7	4	2.8	4	0.24	0.33	0.24

Figure 6 shows comparisons between tensile test results and simulation of the braided composite. A stress-strain curve of the meso-scale RVE model was effectively predicted by the progressive failure model based on multi-scale simulation. The elastic modulus and failure strength decreased as the braiding angle increased. The compressive tests results (Figure 7) and shear tests results (Figure 8) were also compared with compressive test simulations and shear test simulations, respectively. Similarly, stress-strain curves of the compressive test and shear test were closely predicted by the progressive failure multi-scale simulation. As a result, the non-linear mechanical behavior and mechanical properties of the braided composites were successfully predicted by the progressive failure model based on multi-scale simulation with high accuracy.

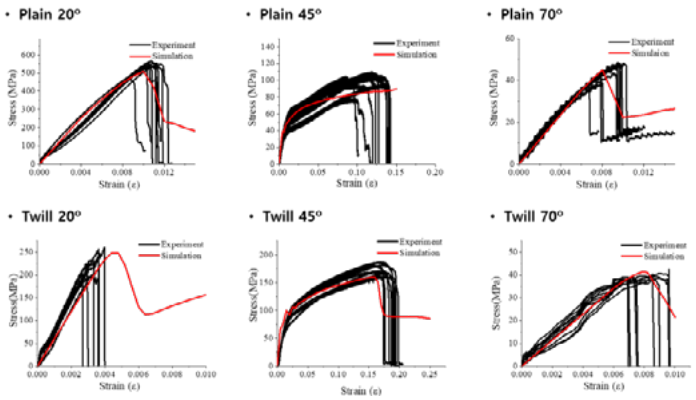

Figure 6. The tensile test results of braided composite with various braiding condition

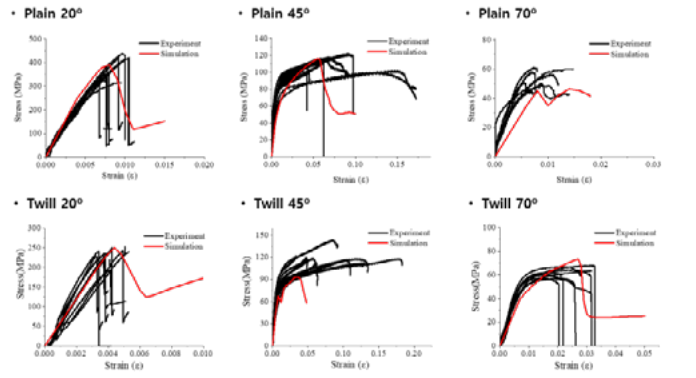

Figure 7. The compressive test results of braided composite with various braiding condition

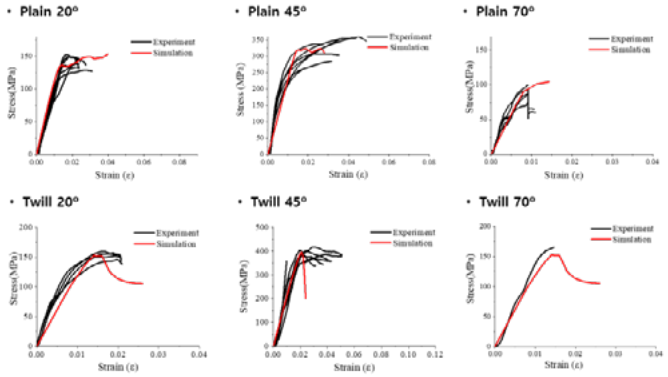

Figure 8. The shear test results of braided composite with various braiding condition

The macro-scale experiments and simulations were conducted using a braided composite pipe. Figure 9 shows comparison results between the experiment and simulations. Results for the compressive test, 3-point bending test, and torsion test confirmed that the mechanical behavior between the experiments and simulations were similar, and the load-displacement curves showed similar values. In addition, it was identified that the progressive failure behavior was realized through a decrease in load after matrix failure. Moreover, the failure pattern from the simulation results was similar to the failure pattern observed in actual experiments, as shown in Figure 10. It was confirmed that the progressive failure model based on multi-scale simulation accurately simulated actual experiments.

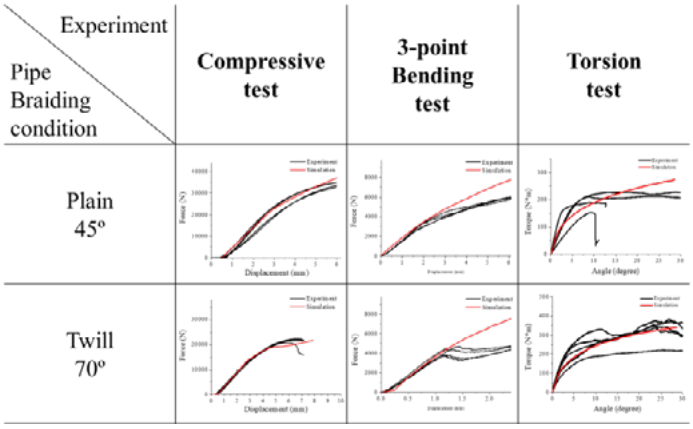

Figure 9. The compressive test, 3-point bending test and torsion test results of braided composite pipe with various braiding condition

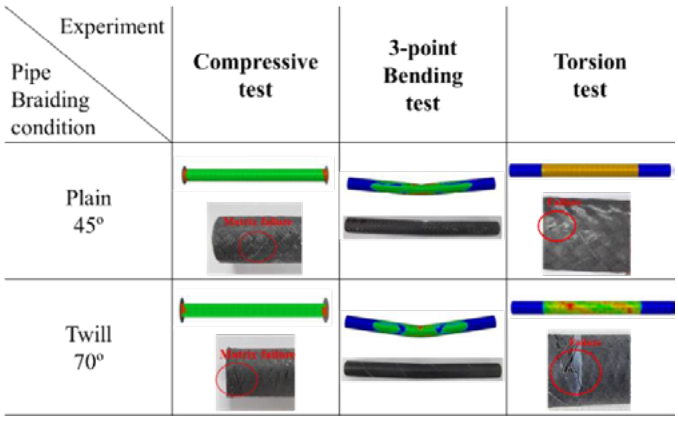

Figure 10. The comparision of failure pattern between experiment and simulation

4. Conclusion

In this study, a multi-scale approach to model the progressive failure in braided composites was proposed. Multi-scale modeling of three different scale units (micro, meso, and macro) was simulated to define the non-linear mechanical behavior of braided composites. The equivalent material properties were obtained from material property homogenizations based on RVE modeling with periodic boundary conditions. On the other hand, the stress amplification factor was employed to calculate local stress from the global stress. Additionally, the progressive failure model based on multi-scale simulation was used to evaluate fiber and matrix failures in micro-mechanical analysis. To verify the proposed progressive failure model based on multi-scale simulation, experiments using braided composite pipes were conducted and compared with simulations. As a result, the proposed model accurately predicted the actual experiments. This simulation model is expected to be utilized for predicting the nonlinear mechanical behavior of various braided composites considering fiber types, fiber dimensions, fiber volume fractions, and weaving patterns.

Keywords: variable stiffness composite laminates, composite damage, thermal buckling, stochastic analysis

Abstract

The present investigation centers on examining the impact of composite uncertainty on the thermal buckling behavior of optimized variable stiffness composite laminates (VSCL) plates that incurred damage. The study involves the analysis of VSCL plates consisting of eight discrete composite materials that are subjected to SSSS boundary conditions. The damages have been observed to occur across two discrete locations (corner and mid), exhibiting three distinct levels of severity ($\Lambda = 3, 4, 5$). The impact of internal defects is evaluated through an improved first-order shear deformation theory (IFSDT) based finite element (FE) model. Further, the influence of uncertain composite properties of optimized VSCL plates on thermal buckling response is evaluated. In order to address the significant computational expenses involved with Monte-Carlo simulations (MCS), an RBFN-based surrogate model has been utilized. Moreover, the application of the RBFN-based surrogate model is expanded to the estimation of failure probability.

Nomenclature

u^*, v^*	=	in-plane displacements of mid-surface in x and y axes, respectively
w^*	=	transverse displacement of mid-surface
Ψ_x, Ψ_y	=	cross-sectional rotations around the y and x axes, respectively
h, χ	=	plate thickness and laoding parameter
$[K], [K_G]$	=	elastic and geometric stiffness matrix, respectively
$\{F\}, \{\delta\}$	=	force and displacement vector, respectively
Φ_1, Φ_2	=	damage parameters along and orthogonal to fiber direction, respectively
Λ	=	damage ratio
$\aleph$	=	approach to estimate uncertain composite properties effect
Θ, ϕ	=	MCS operator and stochasticity level
ω, r	=	weight coefficient and radial basis function
$\|\iota - \iota_p\|$	=	Euclidean distance of the point from the center ι_p
M, t	=	number and observation of uncertain samples

1. Introduction

Modern processing techniques enable the conception and production of complicated composite structures, even if numerous approaches for optimizing conventional constant stiffness composite laminates (CSCL) have been established. Akhavan and Ribeiro [1] studied the natural frequencies and mode shapes of VSCL, consisting of curvilinear fibers with fiber angle variation in the horizontal direction. Ribeiro and Akhavan [2] performed numerical experiments employing non-linearity in a p-version finite element technique to investigate oscillation discrepancies between VSCL and CSCL plates. Uncertain free vibration response of VSCL plates caused by various composite properties randomness is analyzed by Sharma et al. [3]. Punera and Mukherjee [4] presented the utility of VSCL plates towards flexibility in various composite measures such as design, stress distribution, and buckling load capacity. Despite having many benefits, composite materials are prone to internal defects. This can significantly reduce the stiffness of the structures, which in turn affects their various static and dynamic abilities. Valliappan et al. [5] modeled an anisotropic damage-based FE model and performed validation for the developed elastic constitutive relationship influenced by damage. Chandrakar et al. [6–10] have conducted various studies on composite laminates that have incurred internal defects while also considering the presence of uncertainties. Launch and reentry vehicles that operate at high speeds are exposed to extreme conditions, including aerodynamic heating, during routine operations. The structural integrity of supersonic and hypersonic vehicles may be compromised by material degradation at high temperatures and thermal stresses resulting from restrained thermal expansions at elevated temperatures, leading to reduced safety and longevity. Devarajan and Kapania [11] developed an efficient isogeometric analysis utilizing level sets to simulate the thermal buckling of stiffened laminated composite plates with cutouts. The study of Yang and Xie [12] showcases that the thermal buckling potential of Carbon Fiber Reinforced Plastics may be influenced by emulating bio-inspired Bouligand architectures.

Earlier researchers have investigated the enhancement of thermal buckling performance by optimizing VSCL plates composed of diverse composite materials [13]. Composite manufacturing is an intricate task, and this complexity may lead to variability in the composite properties; sometimes, this causes defects in the composite structures. The operating circumstances of composites may also be responsible for defect formation, and this defect potentially leads to the undesired mechanical performance of composite structures. Hence this study undertakes the possibility of damage formation and investigates the effect of uncertain damage composite characteristics in eight optimized VSCL plates. Furthermore, the potential of the IFSDT-based FE formulation has not been investigated for the impact of defects on thermal buckling characteristics, in conjunction with the use of optimized VSCL, for the estimation of buckling strength. The present investigation encompasses damages of varying severity and occurring in two distinct locations. The composite properties are subsequently exposed to variability to examine the impact on buckling performance. The Latin hypercube sampling method is utilized to generate random samples. The surrogate model based on RBFN serves as a substitute for the computationally expensive MCS. Subsequently, the RBFN-based surrogate model is utilized to approximate the likelihood of failure.

2. IFSDT based FE formulations

2.1. VSCL formulation

Single fiber orientation can not adequately characterize the angled fibers used in VSCL plates. Instead, the fiber orientation in VSCL laminates may vary across the plane based on the x and y coordinates. The fiber orientation that is being employed in the current study varies linearly with x, from θ_1 at the center of the plate to the other value, θ_2, at $a/2$ from the origin (Fig. 1). The designation of VSCL is done by $< \theta_1|\theta_2 >$. The fiber orientation (θ) at x units from the fiber's origin is represented as follows:

$$\theta(x) = \left\{ \begin{array}{c} \frac{-2}{a}(\theta_2 - \theta_1)\, x + \theta_1 \;\; for \; \frac{-a}{2} \leq x \leq 0 \\ \frac{2}{a}(\theta_2 - \theta_1)\, x + \theta_1 \;\; for \; 0 \leq x \leq \frac{a}{2} \end{array} \right\} \tag{1}$$

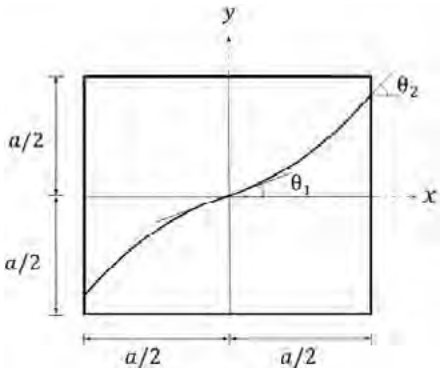

Figure 1. VSCL reference path

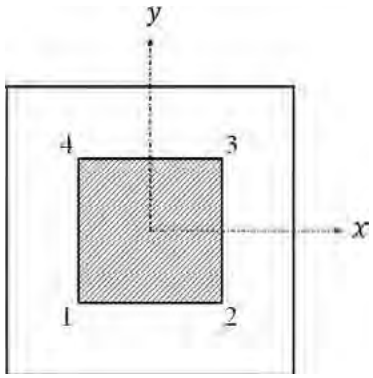

Figure 2. Damage zone location

2.2. Thermal buckling

The displacement field approximation considered in the present work is given as,

$$\left\{ \begin{array}{c} u\left(x,y,z\right) \\ v\left(x,y,z\right) \\ w\left(x,y,z\right) \end{array} \right\} = \left\{ \begin{array}{c} u^{*}\left(x,y\right) \\ v^{*}\left(x,y\right) \\ w^{*}\left(x,y\right) \end{array} \right\} - z \left\{ \begin{array}{c} \Psi_{x}\left(x,y\right) \\ \Psi_{y}\left(x,y\right) \\ 0 \end{array} \right\} \tag{2}$$

The shear stress estimation in FSDT does not follow the physical requirement, as it produces uniform shear stress throughout the thickness, thus to provide the actual parabolic shear stress variation the IFSDT incorporated in the present work. The IFSDT utilizes improved shear correction factor ($\kappa\left(z\right) = 5/4 - 5z^{2}/h^{2}$) to distribute shear stress accordingly [14]. The equation for the state of minimum potential energy equation provided by the equilibrium requirement is given below [15],

$$\Pi = \{\delta\}^{T}\left\{\left[\left[K\right] - \left[K_{G}\right]\right]\{\delta\} - \{F\}\right\} \tag{3}$$

The first derivative of the above equation leads to the estimation of $\{F\}$, which is further utilized to solve the generalized eigenvalue problem formed by the second minimization of energy functional, given as,

$$\left|\left[K\right] + \chi\left[K_{G}\right]\right| = 0 \tag{4}$$

The estimation of critical buckling temperature is then followed as,

$$T_{cr} = \chi \Delta T \tag{5}$$

2.3. Continuum damage modeling

The anisotropic damage modeled in the present work is considered to be non-progressive with the applied load as suggested by Valliappan et al. [5]. This formulation is based on the concept of stiffness change. The damage parameters are given by the equation,

$$\left.\Phi_{q} = 1 - \frac{A_{q}^{dam}}{A_{q}}\right\} q = 1,2 \qquad \Lambda = \Phi_{1}/\Phi_{2} \tag{6}$$

2.4. RBFN-based surrogate modeling

The undesired randomness in various composite properties is responsible for the structural uncertainties. Thus, the sources of randomness in the present study are given as,

$$\aleph\left(\phi\right) = \Theta\left\{ \begin{array}{l} E_{11}\left(\phi\right), E_{22}\left(\phi\right), G_{12}\left(\phi\right), G_{23}\left(\phi\right), G_{13}\left(\phi\right), \upsilon_{12}\left(\phi\right), \\ \alpha_{11}\left(\phi\right), \alpha_{22}\left(\phi\right), \theta_{1}\left(\phi\right), \theta_{2}\left(\phi\right), \Lambda\left(\phi\right) \end{array} \right\} \tag{7}$$

The RBFN model employed in the current work is one of the surrogate models used by modern engineering tools to find optimal solutions faster. The RBFN-built model is,

$$R(\iota) = \sum_{p=1}^{m} \omega_p r\left(\left\|\iota - \iota_p\right\|\right) \tag{8}$$

The algorithm produces a surrogate model and forecasts the results based on several predetermined radial basis functions [3]. The equation estimates the likelihood of failure as,

$$P_f = \frac{1}{M} \sum_{s=1}^{M} f\left(g\left(t^s\right) < 0\right) \tag{9}$$

3. Results and Discussion

3.1. Thermal buckling analysis

The current study employed IFSDT-based FE MATLAB code to investigate the buckling performance of eight optimized VSCL plates (Figure 1) constrained to SSSS boundary conditions. The plates considered are the square ones with a uniform rise in temperature ($\Delta T = 1$). Three stages of damage severity are considered in the VSCL plates at the two most affected damage locations (corner and mid). The accuracy of the developed IFSDT-based FE model is established with ref.[13] (Table 1). The damage location is depicted in Table 2, and Figure 2. The suitable mesh size is found to be 12x12.

The buckling performance of VSCL plates is subject to variation due to damage, as it may impact the load-bearing capacity of the structure. Figure 3 displays the percentage decrease in critical buckling temperature resulting from the presence of damages located at the corner and mid of VSCL plates. The

(a) Corner damage **(b)** Mid damage

Figure 3. Critical buckling temperature drop (%) of damaged VSCL plates concerning healthy VSCL plates with multiple damage levels and damage locations

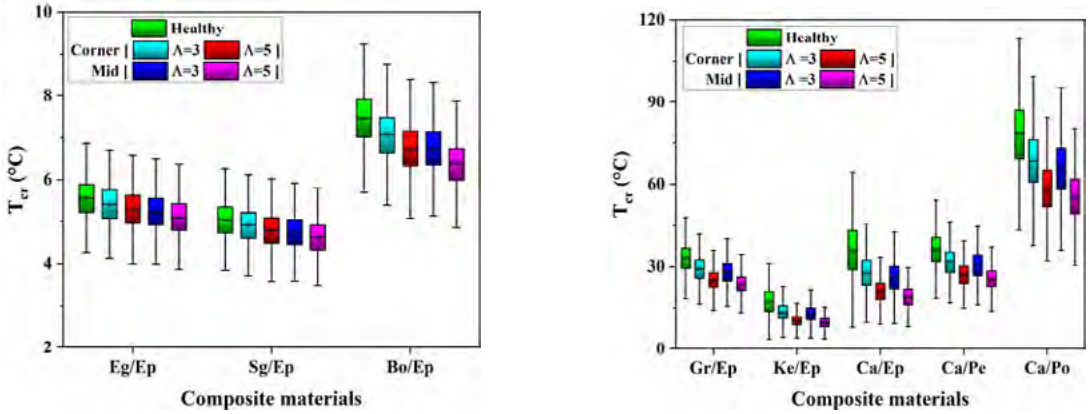

Figure 4. Composite properies randomness effect over multiple composite materials of VSCL plates

initial discernible finding suggests that the decline in performance is more conspicuous in the VSCL plates with mid damage. Nevertheless, the trajectory of the decrease adhered to similar trends for both the damage locations. The escalation in the severity of damage results in premature failure of the VCSL plates, regardless of the location of the damage. The present study pertains to the investigation of the impact of damage on the buckling strength reduction of eight distinct composite materials. The findings reveal that Ca/Ep exhibits the highest degree of sensitivity towards internal defects. However, the Eg/Ep and Sg/Ep plates exhibit superior resistance to composite damage.

3.2. Stochastic study

Further, the variability ($\phi = \pm 10\%$) in the various composite properties is introduced to observe the effect on the buckling behavior of various damaged (with minimum and maximum severity considered, i.e. $\Lambda = 3, 5$) composite materials (Figure 4). There is a very minimal difference in the scattering range of healthy and damaged Eg/Ep, Sg/Ep, and Bo/Ep VSCL plates; however, the incorporated damage proves its existence, as it reduces the mean critical buckling temperature. The highest-performing VSCL plate (Ca/Po) showcased the maximum dispersion of critical buckling temperature with the same input variability.

The composite material Ca/Po exhibited the highest critical buckling temperature. However, it is noteworthy that the maximum reduction in performance resulting from damage was observed in the case of Ca/Ep. The Ca/Po recorded maximized dispersion of output response. Nonetheless, the aforementioned

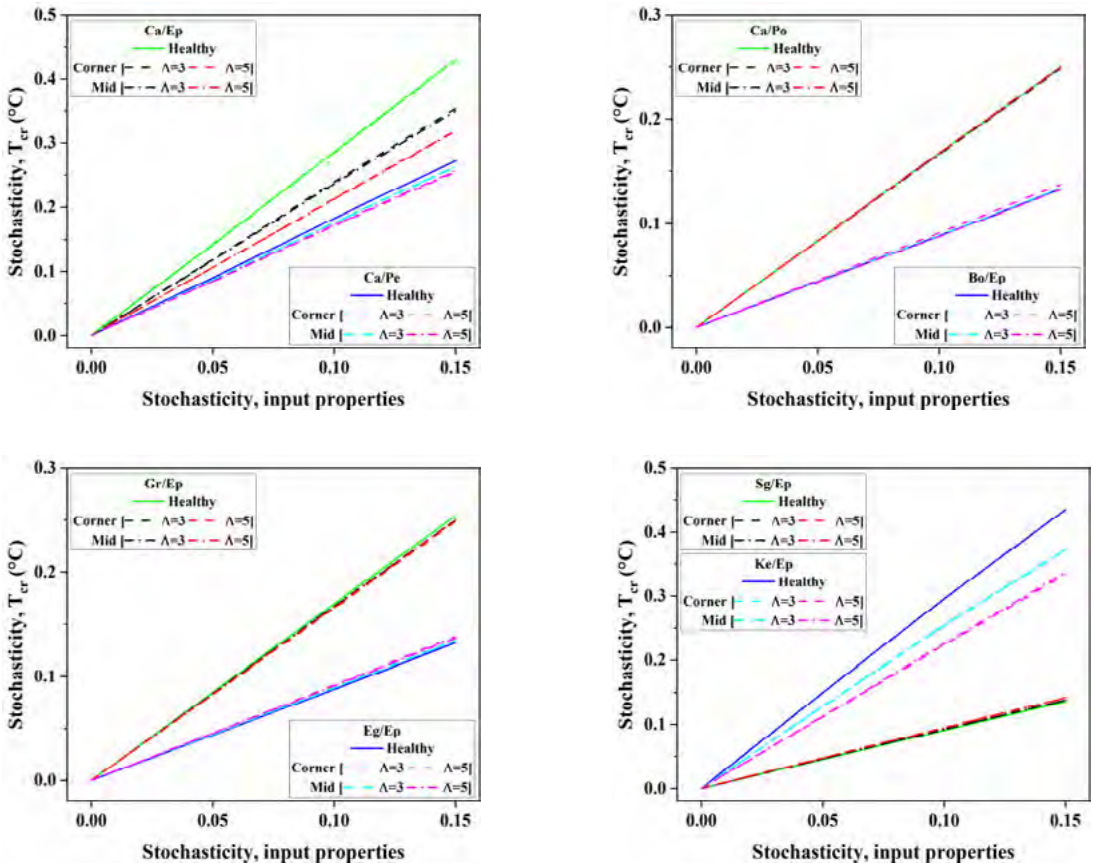

Figure 5. Output Stochasticity with respect to composite properties randomness

performance criteria are inadequate in offering a comprehensive understanding of output randomness. Figure 5 illustrates input-to-output stochasticity relation, with the response exhibiting a linear trajectory. The variability in the composite properties produced the highest critical buckling temperature randomness with Ca/Ep and Ke/Ep VSCL plates, indicating that the sensitivity of input randomness is maximum with Ca/Ep and Ke/Ep VSCL plates. Additionally, it has been observed that the Eg/Ep and Bo/Ep VSCL plates exhibit the lowest level of output stochasticity; this finding suggests that despite the introduction of equivalent levels of randomness in composite properties, the influence of input variability on buckling strength is notably reduced. Although the damage in the VSCL plates degraded the buckling strength, the output variability is also reduced with damage in the case of Ca/Ep, Ca/Pe, and Ke/Ep composite materials; this facilitates the fact that the correlation between input variability and buckling strength exhibits a considerably lower degree of dependence with damage. The reduction in percentage is notably substantial for plates that have sustained mid damage, although the stochastic response remains comparable across various damage locations. As the level of damage severity increases, a decrease in the degree of variance in buckling strength is noted. Furthermore, similar variations in response are observed between healthy and damaged (i.e., corner and mid) plates for the remaining composite materials.

The construction of a cumulative distribution function plot is a crucial aspect of stochastic analysis, particularly in the context of failure prediction (Figure 6). The initial instance of failure has been documented concerning Ca/Ep VSCL plates, whereas the Ca/Po VSCL plates have demonstrated the highest degree of resistance to such failure. The Bo/Ep composite material exhibits the lowest range of failure probability, implying that the Bo/Ep VSCL plates experience failure in significantly shorter durations than other composite materials. For all the studied composite materials, the damage may cause premature failure of VSCL plates. Nevertheless, empirical evidence suggests that the mid position of the

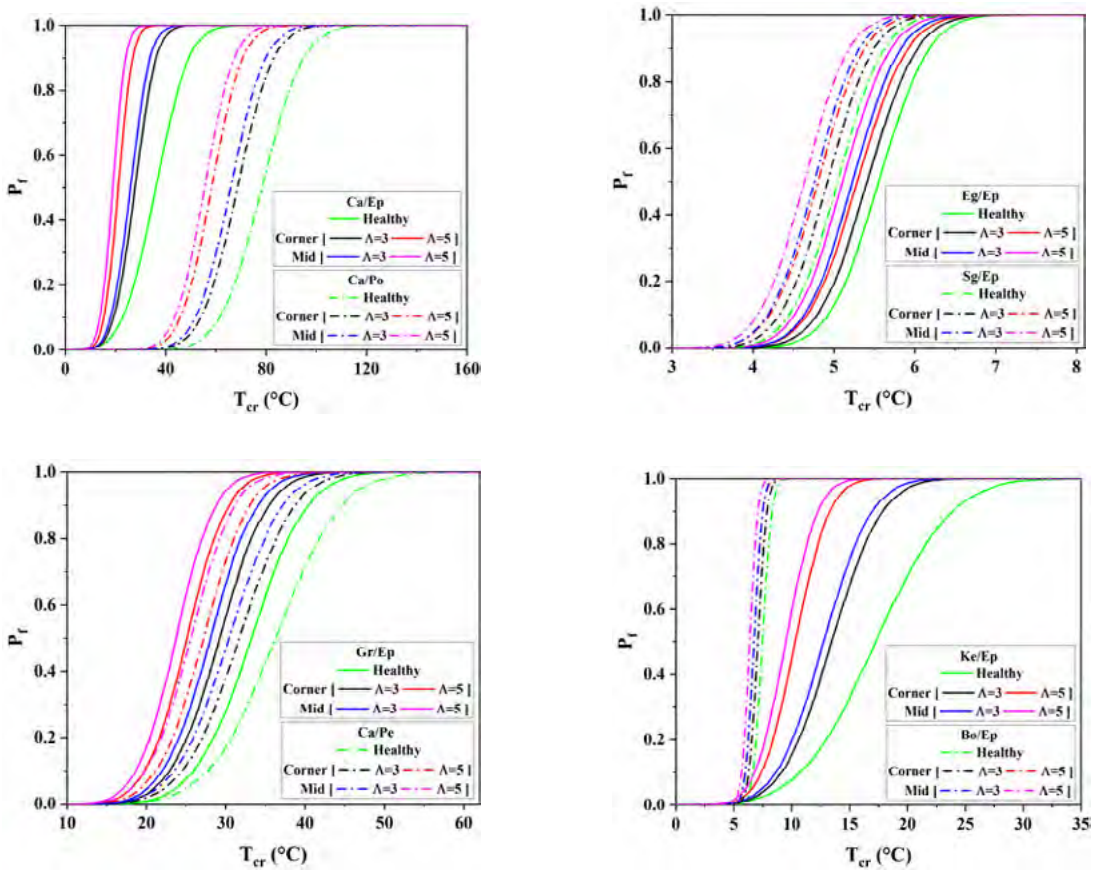

Figure 6. Failure probability estimation

damage is more prone to inducing the collapse of all VSCL plates.

4. Conclusions

The present research examines the impact of stochasticity ($\phi = \pm 10\%$) on the optimized VSCL comprising eight distinct composite materials under the influence of internal defects. The plates are subject to three degrees of damages ($\Lambda = 3, 4, 5$) at the corner and mid locations constrained to SSSS boundary conditions along their edges. The study reveals that the severity of damage is more pronounced in the mid location. Additionally, the Ca/Ep VSCL plates demonstrated heightened sensitivity to damage, while Eg/Ep and Sg/Ep VSCL exhibited superior resistance to composite damages. The introduction of variability in diverse composite materials results in the manifestation of linear input-to-output stochasticity. The study found that the Ca/Ep and Ke/Ep VSCL plates exhibited the greatest sensitivity to randomness in composite properties. Furthermore, the observation implies that despite the incorporation of comparable degrees of randomness in composite characteristics, the impact of input variability on buckling strength is significantly mitigated with Eg/Ep and Bo/Ep composite materials. The buckling strength of all damaged VSCL exhibits similar levels of randomness concerning damage location, suggesting that the location of the damage does not contribute much to variability response. The Ca/Ep VSCL plates have been observed to demonstrate the first occurrence of failure. In contrast, the Ca/Po VSCL plates have exhibited the most significant resilience against such failure. The Bo/Ep composite material exemplifies a comparatively lower probability of failure range, indicating that the Bo/Ep VSCL plates have a shorter duration of failure in comparison to other composite materials.

A STRIP METHOD TO PREDICT SKIN-STIFFENER DEBONDING IN POST-BUCKLED PANELS

Richard Butler[1] and Thomas Maierhofer[1]

[1]Centre for Integrated Materials, Processes and Structures, University of Bath, Bath , UK
R.Butler@bath.ac.uk, http://www.bath.ac.uk/mech-eng/people/butler

Keywords: Strip method, Post-buckling, Debonding, Delamination, Thermoplastic, Welding

Abstract
A new semi-analytical method which calculates the strain energy released as a skin buckle relaxes during damage propagation by delamination or debonding of a stiffened panel is presented. Propagation can either occur in the bond or within the attached stiffener foot. An existing Strip method calculates skin buckling loads, and finite differences provide the sensitivity of these loads to perturbation of delamination or debonding variables. These are combined with post-buckled panel stiffness to obtain the strain energy release rate which, when equated to the critical strain energy release rate of the respective damage surface, determines the damage initiation load.

Strip results for stiffener debonding of an idealised panel are within 1% of converged FE results for a thermoplastic weld but differ by 9% for a co-cured thermoset joint. Depending on the relative toughness of the bulk and joint materials, damage may occur in the bond or in the stiffener. The new Strip based method creates opportunities for the design and analysis of bonded composite structures, with results that are (i) obtained in seconds of CPU, compared with hours using cohesive zone methods, and (ii) independent of mesh refinement and additional interface properties required by other commonly used FE methods.

1. Introduction

Bonding of composite parts is significantly more structurally efficient than the traditional use of mechanical fasteners, provided concerns about repeatable and certifiable strength can be overcome via testing and analysis [1]. Analysis of bond-line delamination using cohesive zone model (CZM) methods requires computationally expensive FE models which may be prohibitive for design and certification. Added to this, there is a need to consider the uncertainty of such joints, both in production and in service.

Analytical strain energy release rate has previously been calculated using the localised stress-strain distributions in the vicinity of delaminations [2-4]. This requires a detailed analysis of specific features or numerical FEA with sufficiently small elements to accurately capture the local energy.

Here we formulate the axial strain energy in terms of the applied load versus strain relationship with linear stiffness both before and after stable post buckling. We evaluate the Strain Energy Release Rate (SERR) in terms of the sensitivity of buckling load to perturbations in the damage variable, expressed as the width of a strip with thickness defined by the delamination interface. This new non-local approach does not require a detailed mesh, provided that the buckling mode is stable and can be modelled as periodic. We use a very efficient Strip method [5] to calculate the buckling load and the buckling sensitivity. Results are obtained for a post-buckled panel and compared with FEA results using a cohesive zone modelling approach.

2. Analytical Strip model

In the case of a stiffened panel with linear post-buckled stiffness, we can expand the strain energy release rate G, defined as the derivative of strain energy with respect to delamination area A_d, using

$$G = \frac{\partial U}{\partial A_d} = \left(\frac{\partial U}{\partial \varepsilon^C}\right)\left(\frac{\partial \varepsilon^C}{f(x)\,\partial b}\right)\left(\frac{f(x)\,\partial b}{\partial A_d}\right) = \left(\frac{\partial U}{\partial \varepsilon^C}\right)\left(\frac{\partial \varepsilon^C}{\partial b}\right)\left(\frac{\partial b}{\partial A_d}\right) \tag{1}$$

where ε^C is the buckling strain of the panel and ∂b is a perturbation of a strip width representing delamination. Note that $f(x)$, an unknown function in the axial x direction defining the shape of propagation, cancels enabling us to simplify the growth of delamination using a prismatic strip of width b.

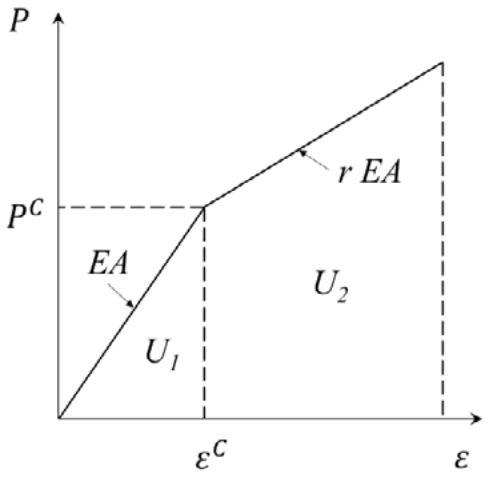

Figure 1. Axial load-strain plot for post-buckled panel. P^C and ε^C define the axial load and strain for panel buckling buckling, EA and $r\,EA$ are the pre-buckled and post-buckled axial stiffnesses of the panel, respectively.

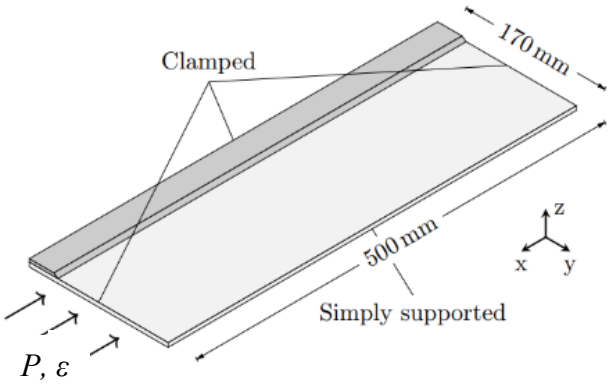

Figure 2. Schematic of the simplified stiffened panel with assumed boundary conditions.

From Fig. 1, the axial strain energy of the skin panel over one full buckling wavelength (2λ) at some strain ε above buckling is

$$U = U_1 + U_2 = \int_0^{2\lambda} EA\left[\left(\frac{\varepsilon^C}{2}\right)^2 + \varepsilon^C(\varepsilon - \varepsilon^C) + \frac{r}{2}(\varepsilon - \varepsilon^C)^2\right] dx$$

$$= 2EA\lambda\left[\left(\frac{\varepsilon^C}{2}\right)^2 + \varepsilon^C(\varepsilon - \varepsilon^C) + \frac{r}{2}(\varepsilon - \varepsilon^C)^2\right] \tag{2}$$

And therefore,

$$\frac{\partial U}{\partial \varepsilon^C} = 2EA\lambda(1-r)(\varepsilon - \varepsilon^C) \tag{3}$$

Assuming that delamination only occurs over the half wavelength causing opening, the area of delamination or debonding is given by

$$\partial A_d = \lambda \, \partial b$$

Hence

$$\frac{\partial b}{\partial A_d} = \frac{1}{\lambda} \tag{4}$$

Substituting Eqs. (3) and (4) into Eq. (1)

$$G = 2EA\,(1-r)(\varepsilon - \varepsilon^C)\frac{\partial \varepsilon^C}{\partial b} \tag{5}$$

Or, in terms of applied loading, noting that

$$\frac{\partial \varepsilon^C}{\partial b} = \frac{1}{EA}\frac{\partial P^C}{\partial b}$$

$$G = \frac{2}{EA}\,(1-r)(P - P^C)\frac{\partial P^C}{\partial b} \tag{6}$$

Since this strain energy release rate is (i) non-local because it is derived in terms of propagating a strip of width b and (ii) derived in terms of axial strain energy which is orthogonal to the direction of propagation (i.e. there is no crack driving force) we assume it gives a lower bound value, initiating as Mode I fracture. Hence, we can rearrange Eq. (6) to give the load at which delamination or debonding initiates

$$P_{init} = P^c + \frac{G_{1C}EA}{2(1-r)\frac{\partial P^C}{\partial b}} \tag{7}$$

Here we use the Strip software VICONOPT [5] to calculate both P^C the buckling load and $\partial P^C / \partial b$ the sensitivity of this load to perturbation of any strip width b. For the results that follow, the value for post buckling stiffness reduction r is determined using nonlinear FEA.

3. Results for an idealized skin-stiffened panel

Damage propagation of a fusion bonded joint between two thermoset composite components [6] is studied using the proposed new analytical Strip method and results are compared with FEA. Furthermore, the likelihood of damage propagation within the thermoset laminate of the adherend is studied and the potential mechanical performance gain between a fusion bonded joint and a co-cured thermoset joint is demonstrated.

To illustrate the new method, it is assumed that a bonded skin-stiffener joint within a stiffened panel can be represented by modelling a single skin-stiffener bay, as shown in Fig. 2 and by applying idealised boundary conditions. Thus, only the stiffener flange and the unsupported skin section are modelled. To account for the respective boundary conditions, the transverse ends (y-axis direction) are clamped. Along one longitudinal edge of the panel, where the stiffener flange is attached to the skin, it is assumed that the stiffener effectively prevents bending and torsion, which is simulated by a clamped boundary. The opposite longitudinal edge of the panel is assumed to be simply supported.

To account for the thermoplastic surface layer required to make the thermoset composite components weldable, a 250 µm thick polyetherimide (PEI) film is modelled on the respective weld interfaces of both the skin and the stiffener flange. The skin and stiffener laminates are HexPly® IM7/8552 (CF/epoxy), with a ply thickness of 0.125 mm. The ply properties are E_{11} = 150.0 GPa, E_{22} = 9.08 GPa, $G_{12} = G_{13}$ = 5.29 GPa, $\nu_{12} = \nu_{13}$ = 0.32, ν_{23} = 0.52, G_{IC} = 277 J/m^2 and G_{IIC} = 788 J/m^2. The properties of the PEI are E = 32 GPa, ν = 0.36, G_{IC} = 1,083 J/m^2 and G_{IIC} = 3,327 J/m^2. The skin has stacking sequence $[\pm 45/0/90/0_3/\pm 45/0_2/\overline{90}]_S$ and the stacking sequence of the stiffener flange is $[\pm 45/0/90/0_3/\pm 45/0_2/\overline{90}]_S$.

3.1 Finite Element results

FE results are obtained using the ABAQUS Explicit solver [7] with 8-node continuum shell (SC8R) elements for skin and stiffener, and zero-thickness surface-based cohesive zone model (CZM) interactions at the delamination interfaces. A ply-by-ply modelling approach with CZM surface interactions between individual plies is considered to study the likely location of damage initiation. Three separate delamination cases are considered: (i) along the welded joint between the skin and the stiffener; (ii) at the interface of the first and second plies in the stiffener flange and (iii) along the 8552-resin interface between a co-cured skin and stiffener. To study the crack growth behaviour of a weld at the joint interface, interlaminar CZM surface interactions within the flange were disabled and replaced with tie-constraints. The cohesive properties for a fusion bonded joint are s_{33} = 56.0 MPa, s_{13} = 107.0 MPa and η_{BK} = 2.90 and for a co-cured joint s_{33} = 62.3 MPa, s_{13} = 92.3 MPa and η_{BK} = 1.634 for 8552-resin. A penalty stiffness $K = 10^6$ N/mm^3 is used for all cohesive zone interfaces. For accuracy, multiple elements are required within the length of the cohesive zone. Using Hillerborg's approach [8], the length of the cohesive zone for PEI and 8552 is approximately 2.64 and 0.65 mm, respectively. Since the latter is prohibitively small, requiring element sizes of less than 0.3mm, the interface strengths are reduced, based on a method proposed by Turon et al. [9], to s_{33} = 29.8 MPa and s_{13} = 50.3 MPa, allowing for a mesh size of 0.5 mm in the region of delamination, see Fig. 3.

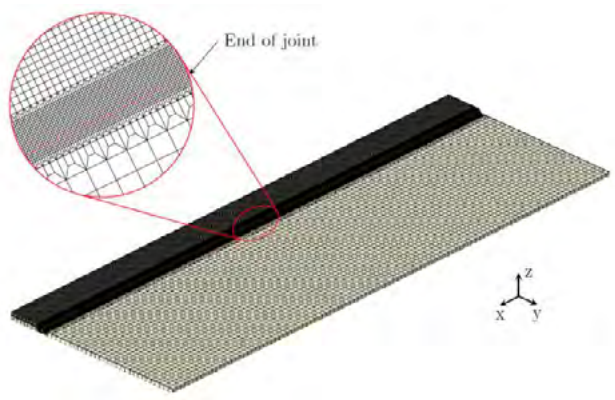

Fig. 3 FEA mesh of panel showing refinimenet near edge of skin-flange joint.

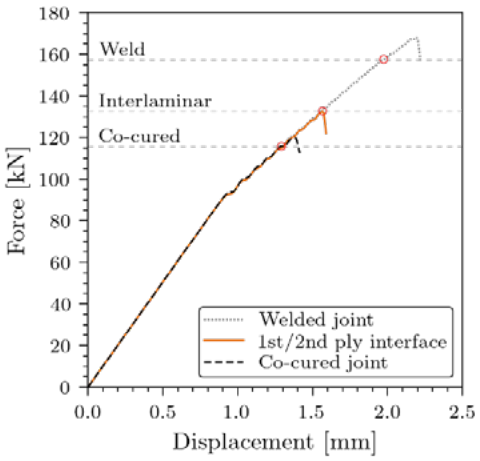

Fig. 4 FE results for delamination of welded and co-cured skin-flange joints. Circles indicate damage initiation.

Load-end shortening plots for delamination at the interfaces (i), (ii) and (iii) described above are given in Fig. 4 and the numerical values of loads at which buckling and delamination first occur are in Table 1. Note that the panel with a fusion bonded joint is predicted to delaminate between the first two plies in the flange before joint failure, since this occurs at lower load. The critical buckling mode is shown in Fig. 5.

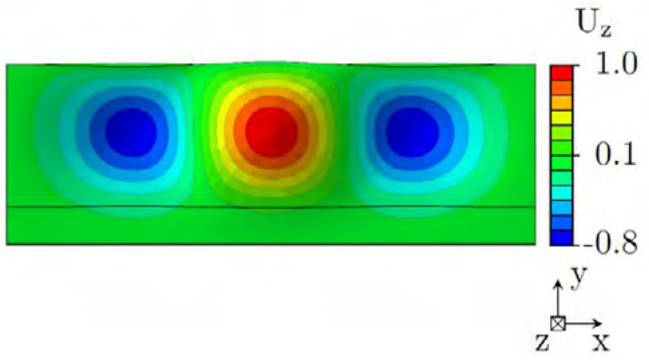

Fig. 5 FEA buckling mode for panel of Fig. 2

3.2 Strip results

The panel of Fig. 2 is also modelled using three strips, one each for the skin, stiffener flange and the skin beneath the flange. The sensitivity of buckling load to strip width $\partial P^C/\partial b$ is obtained for (i) a skin strip with a thickness representative of delamination along the bondline (PEI or 8552) interface; (ii) a flange strip of thickness representing delamination between the first and second flange plies nearest the weld. It is noted that buckling sensitivity along the bondline is independent of bonding material. The Strip analysis is executed for a range of buckling modes with half-wavelengths $\lambda = 500/n$ with n = 2, 3, …, 10, in order to capture the critical (lowest) buckling load. The post-buckling stiffness reduction r = 0.654, which is obtained from the FEA and the axial stiffness of the panel EA = 49,620 kN. Table 1 shows that the critical buckling mode has a half-wavelength λ = 125 mm and presents the buckling load, buckling sensitivities and delamination initiation loads for delamination in the fusion bonded and co-cured joint, and within the bulk material of the stiffener flange

Table 1. Comparison of axial loads for skin buckling and initiation of delamination using Strip and FEA models. Strip buckling sensitivities are also given. The critical buckling mode for the Strip results has half-wavelength λ = 125 mm.

P^C (kN)		Delamination Interface	$\partial P^C/\partial b$ (kN/mm)	P_{init} (kN)	
Strip	FEA		Strip	Strip	FEA
88.03	86.7 (+1.5%)	PEI weld	1.130	156.8	157.6 (+0.5%)
		Flange – above 1st ply	0.438	133.3	132.7 (-0.5%)
		Co-cured skin/flange	1.130	105.6	115.8 (+8.8%)

4. Discussion

Table 1 shows that the buckling loads produced by the Strip and FE models are within 2%. The Strip model assumes a periodic buckling mode, indicating that the mode shape evident in Fig. 5 can be represented by a sinusoidal mode with four half-waves over the panel length.

Table 1 also shows that the new Strip method to predict debonding and delamination is within 1% of FEA results for both (i) debonding of the fusion bonded joint and (ii) delamination at the first ply interface within the stiffener. The FEA prediction of the debonding load in the co-cured case is 9% above the Strip initiation load. It appears unlikely that the inaccuracy of this case is in the Strip result since the buckling load and sensitivity values are the same for debonding of both types of joint and the different delamination loads arise entirely from the difference in G_{IC} of the thermoplastic and thermoset materials present at the bondline. However, there will be a greater stress concentration in the FEA at the bondline than at the first ply interface within the flange. The mesh size and required alteration of the interface properties, may not be fully representative of the true localised stresses at the joint interface for 8552 matrix properties. Thus the initiation and propagation for the low toughness thermoset material may not be accurately captured.

In terms of structural performance, as suggested by the authors previous work [6], fusion bonding of thermoset composites improves the mechanical joint performance. It is observed that on a structural level, the tougher thermoplastic joint interface shifts the site of damage initiation from the bondline into the bulk material of the stiffener. Experimental testing would be required to confirm this behaviour, and to validate the accuracy of the Strip method. Nevertheless, the shift of damage away from the bondline is potentially an extremely attractive feature for the certification of fusion bonded joints for primary aerospace structural applications.

The proposed novel Strip method requires at least five orders of magnitude fewer elements than FEA using the traditional CZM approach showing significantly better computational efficiency, eliminating the need for small element sizes, being mesh-independent. This makes the method suitable for use in statistical analysis to explore uncertainty in material properties and as-manufactured geometry, as well as providing a fast toolset to assess joint performance during the design phase. However, it is important to note that (i) the post-buckled stiffness *rEA* requires nonlinear FEA, albeit with a coarse mesh, and (ii) such FEA needs to ensure that transition to another potentially unstable mode of buckling does not occur before debonding or delamination.

5. Conclusions

The new Strip method evaluates the Strain Energy Release Rate (SERR) in terms of the sensitivity of buckling load to perturbations in the damage variable, expressed as the width of a strip with thickness defined by the location of the delamination interface. This non-local approach does not require a detailed mesh, provided that the buckling mode is stable and can be modelled as periodic. Results are obtained for a post-buckled panel and compared with FEA using a cohesive zone modelling approach to predict bondline failure.

The new method predicts debonding or delamination to within 1% of FEA results for both (i) debonding of a fusion bonded joint and (ii) delamination at the first ply interface within the bulk material of the stiffener. The FEA prediction of the debonding load in the co-bonded case is 9% above the equivalent load predicted by the Strip model. The new method is solely based upon the strain energy released unlike FEA, which requires accurate resolution of localised stresses using a very fine mesh, rendering the analysis of larger structures impractical. This further raises a question about the reliability and applicability of the CZM approach for larger structures.

Results show that a tough thermoplastic joint interface as a result of fusion bonding of two thermoset components shifts the site of damage initiation from the bondline to interlaminar failure within the component. The shift of damage away from the bondline is potentially an extremely attractive feature for the certification of fusion bonded joints in primary structures. Experimental testing would be required to confirm this behaviour, and to validate the accuracy of the Strip method. Furthermore, a study on different joint geometries and the applicability of the Strip method to other structures needs to be investigated. Nevertheless, it is demonstrated that the new method may offer a vastly more efficient approach to analyse the onset of interlaminar damage propagation and disbonds.

Keywords: cellulose nanofiber, thermoplastic polymer composite filaments, nonlinear properties, multiscale homogenization analysis

Abstract
This study investigated the reinforcing effect of cellulose nanofibers through multiscale nonlinear finite element analysis, aiming to enhance the mechanical properties of composite materials for improved stability and reliability in industrial applications. The research focused on characterizing the interfacial interactions between the fiber and the polymer, and further analyzed the impact of fiber morphology on material performance. The results show that the elastic modulus and maximum stress value in the longitudinal direction of the fiber in the model are both greater than those in the transverse direction. The randomization leads to an increase in the elastic modulus of the material and an increase in the maximum tensile stress compared to a uniform fiber arrangement. This study aimed to provide new guidelines for designing more efficient composite materials.

1. Introduction

Cellulose fiber-reinforced thermoplastic composites are renowned for their high stiffness, strength, moldability, and corrosion resistance. These properties position them as promising candidates for diverse applications in sectors such as transportation, information technology, healthcare, electronics, and architecture [1-3]. To achieve this potential, there is a surge in research and development activities focused on these composites, encompassing aspects from surface treatment of cellulose fibers to modifications in base polymers, interface interactions between fibers and polymer materials, blending of fibers with the polymer, as well as molding and recycling processes [4-6].

There are many factors influencing the performance of materials, and here, we will focus on fiber distribution. Based on the spatial dimensions of fiber arrangement, fiber distribution can be categorized into 1D, 2D, and 3D distributions. 1D distribution includes dry spinning [7], wet spinning [8], and 3D printing [9], among others, which have already been widely developed. 2D distributed materials are often sheets or films prepared by extrusion or hot pressing [10]. A classic example of 3D distribution is the random distribution of fibers during the injection molding process. This paper will focus on the performance changes and mechanism studies of materials under the fiber arrangements. In practical applications, the distribution of fibers directly affects the mechanical properties of composite materials. However, when it comes to analyzing the mechanism, it is difficult to design it at an experimental level. In this case, a common approach among researchers is to introduce simulation analysis methods. For example, finite element analysis (FEA) can help researchers better understand the impact of fiber

distribution on material properties. In addition, these simulation methods enable the optimization of fiber arrangement designs to achieve optimal performance in actual production.

In this study, we focused on fiber distribution to analyze mechanical properties. Employing multiscale nonlinear finite element analysis based on homogenization theory [11], we elucidated the mechanical behavior of cellulose composites under ideal conditions, considering one-dimensional orientation as the limit for performance improvement through controlled fiber orientation in fused filament fabrication and other applications. The impact of the fiber-polymer interface on the composite material's performance was assessed through a two-step homogenization process. This study aimed to provide new guidelines for designing more efficient composite materials.

2. Multiscale simulation

In our microstructural modeling, a representative volume element (RVE) model is utilized, where cellulose discontinuous fibers are oriented in one direction and randomly dispersed within the polymer. The generation of the fiber dispersed RVE model employs the Random Sequential Adsorption (RSA) algorithm. In the RSA process, fibers are added individually to the RVE domain until a predetermined fiber volume fraction is achieved. Interferences, where a newly added fiber intersects with previously inserted fibers, are resolved by either removing interfering fibers or reconfiguring and repositioning the newly added fiber. This methodology has been applied to various short fiber-reinforced composites, including glass, carbon, and cellulose fibers, and even Carbon Nanotubes [12], demonstrating its practicality.

Figure 1 presented the multiscale modeling of CNC-dispersed composite materials, considering the interface phase. In the microstructure, a cubic region is defined where CNC with the interface phase is adjacent. For the meso-structure, we assumed a dispersed state of fiber composites, reflecting the uniform characteristics derived from the microstructure. The nonlinear response to external loads in the macrostructure was analyzed. Treating high-stiffness, high-strength cellulose fibers as elastic materials, we incorporated the experimentally obtained nonlinear stress-strain relationship into the polymer for the nonlinear analysis of the composite. Material damage was not considered, with a focus on mechanical properties prior to damage occurrence. A multi-scale, scale-coupling analysis based on homogenization theory was employed. Simulations were conducted using Sim, and ANSYS was utilized as the FEM solver.

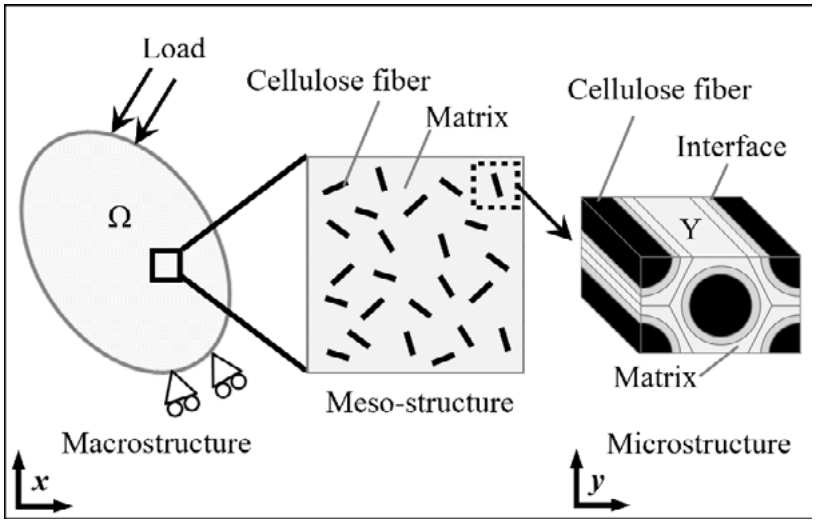

Figure 1. Multiscale modelling of cellulose nanofiber-reinforced polymer composite filaments

3. Results and discussion

To streamline the analysis, all fibers were aligned in a single direction. We then introduced two distinct fiber distribution models, depicted in Figure 2. These models consist of a random short fiber arrangement and a uniform short fiber arrangement. To thoroughly examine the impact of fiber distribution on performance, we maintained consistent fiber volume fractions across both models.

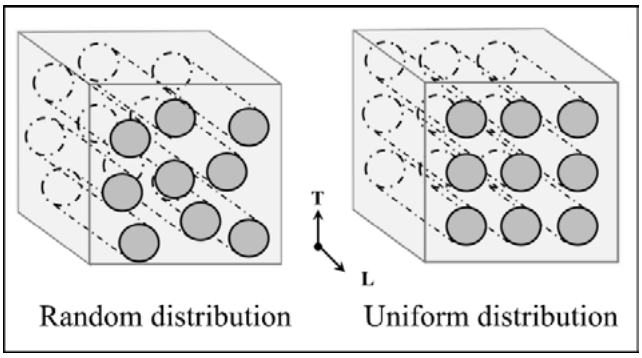

Figure 2. The models of random distribution and uniform distribution

Comparative analyses were carried out with the fiber length direction denoted as the "L direction" and the fiber diameter direction as the "T direction." The analysis of stress-strain results for the two models is illustrated in Figure 3. Based on the stress-strain curves, we analyzed the performance in both the L direction and the T direction for each model. Starting with the elastic modulus, the elastic modulus for both the L direction and the T direction are discussed. In both models, the elastic modulus in the L direction exceeds that in the T direction. It is well-established that fibers are inherently anisotropic materials, exhibiting optimal performance along the fiber's length direction and suboptimal performance along the fiber's diameter direction. In this simulation, since the fibers are oriented in a single direction, the elastic modulus in the L direction surpasses that in the T direction.

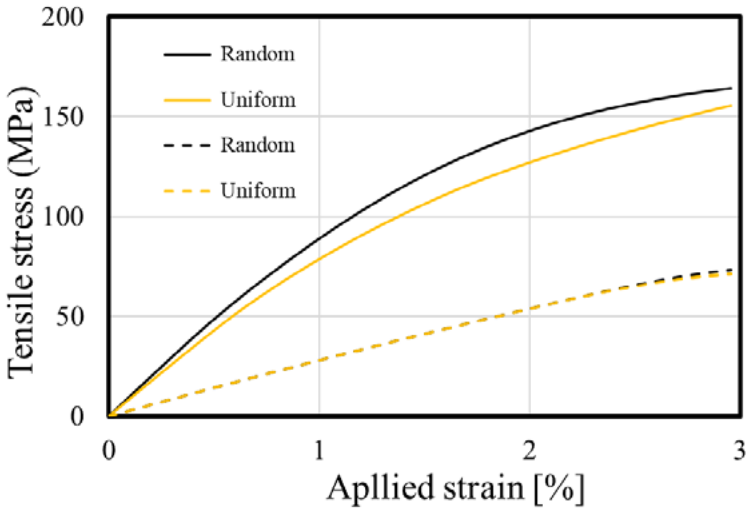

Figure 3. The stress-strain results of random distribution and uniform distribution

In the L direction, the random model exhibits the highest modulus. In the T direction, the modulus for both models are approximately similar. For the uniform model, its uniform arrangement results in more concentrated areas of the resin matrix, leading to a lower elastic modulus under external forces compared to the random arrangement model. Subsequently, we compared the maximum stress values, as shown in Figures 3, for both the L direction and the T direction. Similar to the elastic modulus, the maximum stress values in the L direction are higher than those in the T direction across all models. In the L

direction, the random model demonstrates the highest maximum stress value. In the T direction, the maximum stress values are approximately similar across all models.

4. Results and discussion

In this research, we utilized a multiscale nonlinear analytical method grounded in homogenization theory to examine the influencing elements and mechanisms on uni-directionally aligned nanocellulose composites under optimal conditions.

From the perspective of fiber distribution, compared to a uniform arrangement, the randomization of fiber alignment in short fiber-reinforced composite materials increases the elastic modulus in the L-direction by 11% and the maximum tensile stress by 5.5%. Additionally, the mechanical properties in the L-direction of composite long filaments are significantly greater than those in the T-direction. The insights gained from these results hold significant implications for the development and practical deployment of nanocellulose composites, offering crucial guidance for future exploration and advancements in this field.

MODELLING FATIGUE DAMAGE GROWTH OF T700/M21 COMPOSITES UNDER HIGH FREQUENCY TESTING

M. Lasen, J.Schönthaler and D. Di Maio

Abstract

Experimental laws used to characterise fatigue in composites materials, such as Paris-Erdogan Laws or S-N curves, require time consuming testing campaigns because of their low excitation frequencies [1]. To reduce this long-lasting testing time and to improve the tracking of damage by a more sensitive characteristic physical parameter, a High Frequency Fatigue Testing (HFFT) approach [2] is proposed as an alternative. HFFT can be used at excitation frequencies which can easily be two orders of magnitude higher than low frequency testing. Low frequency fatigue testing has been the benchmark in academia and industry and its extensive use has evolved to the level of a standardised method [3]. These standards allow to obtain experimental laws and hence easily derive, for example, Energy Release Rate (ERR) and crack progression during fatigue testing. However, to build a Paris-Erdogan Law with HFFT a hybrid approach is required to estimate the ERR as the crack progresses.

A Finite Element (FE) simulation routine, written in Python and Abaqus, is designed to reproduce the experimental conditions of the HFFT as accurately as possible. This work presents the first steps to the hybrid simulation-experiment fatigue laws, by introducing the framework of the Python-Abaqus routine.

Keywords: High Frequency Fatigue Testing, Abaqus, Python, Crack growth.

1. Introduction

HFFT is a testing approach to study fatigue at high frequencies by tracking the frequency response phase of the samples measured at constant excitation frequency [2,5,6]. Its main characteristics are that the samples are run at constant excitation frequency (near the resonance), constant amplitude severity and have time-dependent varying properties. Commercially available FE fatigue software are limited in this sense, not allowing to continuously modify these properties.

To overcome these limitations, a Python routine has been designed to iteratively adapt the input conditions to the simulations, such that at every single step of crack progression the excitation resonant frequency and time-dependent damping are modified, while maintaining the FE model samples at a constant severity level.

2. The FE model.

The Abaqus FE model, in Fig. 1 has a dimension of 270x25x2.5 mm. The model is clamped in the 3 middle columns of nodes at the nodal line of the first bending vibration mode. Fig. 1 shows the Concentrated Force Loading Nodes, attached with a Kinematic Constraint. At these Loading Nodes, the forces are applied to reach the desired displacement severity level, which is measured at the indicated Measuring Reference Point, 35 mm from the Clamped Nodes at the mid-width of the sample. Three parts are defined in the model which facilitate the definition of the interfacial properties between them. The continuous orthotropic material properties used in the FE-model are summarised in 1 [4].

The elements used in the model mesh are continuum solid shell elements (CSS8, Abaqus). The thickness of the model consists of 10 plies, with a single element per layer. Each layer has a thickness of 0.25 mm. The different plies that make up the laminate are unidirectional and are stacked with the following layup: $[90_{cut}/0_{cut}/90_{cut}/0/90/90/0/90/0/90]$, where 'cut' indicates the pre-crack separating the Top Part into Left and Right. The cut-ply is offset 10 mm from the clamped centre of the

sample, represented by the Transverse Crack Nodes in Fig. 1. From there, the horizontal crack is expected to grow, horizontally between the 3rd and 4th layers, to the left and right sides of the cut-ply.

The horizontal crack progression uses a VCCT fracture model, which allows to obtain the ERR at the left and right side of the transverse crack. In the Abaqus-Python routine the fracture criterion of the VCCT formulation does not determine to which side the crack is opened, the criterion is imposed after the VCCT simulation, by determining the highest ERR between the left and right sides.

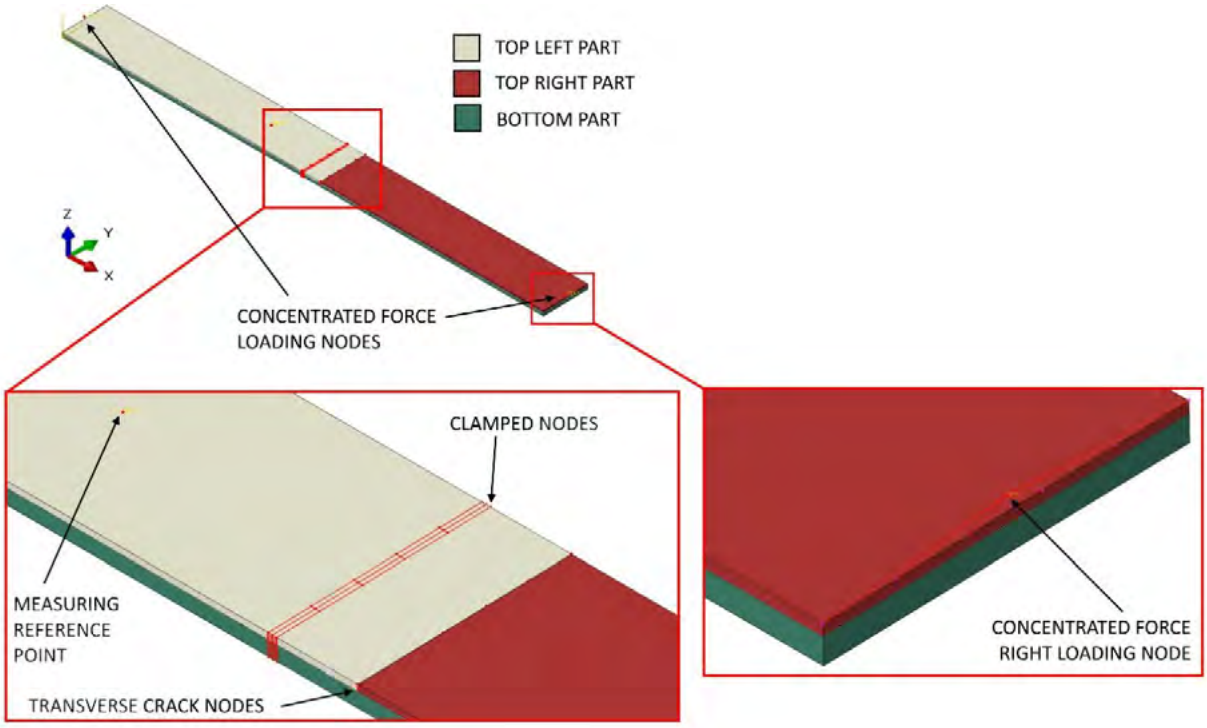

Figure 1 FE model overview and key node sets.

Table 1. T700/M21 material properties in the FE-model.

Properties	*Value*	*Unit*
Longitudinal Young's modulus E_1	124,250	MPa
Transverse Young's modulus E_2	7,660	MPa

3. The Python and Abaqus routine.

An overview of the Python-Abaqus is depicted in Fig. 2. The framework has 3 steps: '0: Base Case', '1: Steady State Dynamics' and '2: Static - VCCT', each of them is described in terms of the specific FE model used in each framework step, the corresponding Abaqus steps of each simulation and their key outputs.

The following subsections describe each framework step, the reasons behind them and the crack opening criterion used for the iteration of the routine.

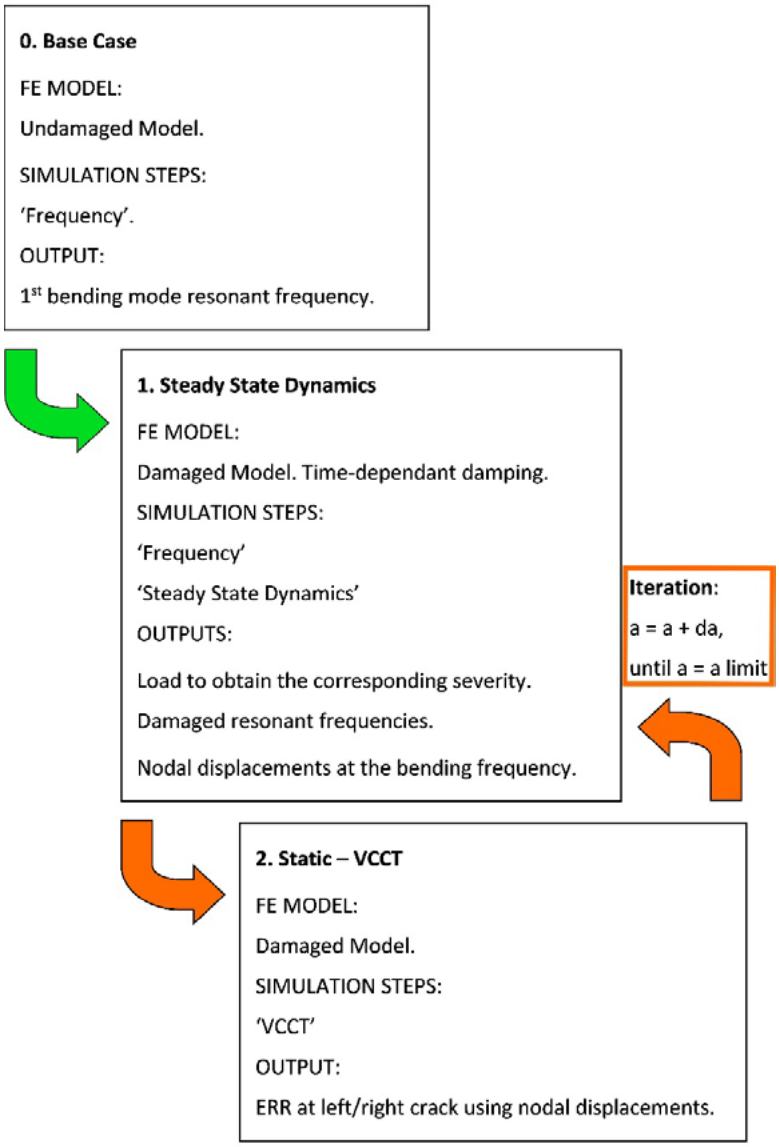

Figure 2 Python-Abaqus framework.

3.1 Framework Step 0: 'Base Case'

In Framework Step 0 (FW-step 0) an undamaged version of the FE model described in Section 1 is used, without cracks. This FW-step allows to obtain a base case of the 1st bending resonant frequency, which is used in the next FW-step.

3.2 Framework Step 1: 'Steady State Dynamics'

FW-step 1 makes use of the FE model described in Section 1. The first time the routine invokes FW-step 1, the crack opening consists of simply one element, 0.1 mm, to each side of the transverse crack. As the crack grows, the crack edge is opened uniformly across the width of the model such that the crack front is always a straight line.

To determine the right input load to match the desired severity level, the damaged FE model is run three times. The first two are run at arbitrary loading forces and the displacement severity is measured at the measuring point displayed in Fig. 1. From these two auxiliary simulations an interpolation is run to find the best representation of the loading conditions for the Steady State Dynamics, in the third simulation.

The damage accumulation needs to be reflected not only in the crack growth but also in the decay of the material properties, i.e. damping. Damping is hard to monitor during a real fatigue experiment, however, it can be studied before and after the fatigue test is done. The damping level used at each crack opening is simply an interpolation between the damping measured before and after a representative fatigue experiment.

The simulations have two Abaqus steps. (i) A 'Frequency' step is used within an arbitrary range with an upper frequency limit set by the undamaged resonant frequency from FW-step 0, from there the frequency only drops. (ii) A Steady State Dynamics (SSD) step is used to obtain the dynamic response of the damaged cases analysing two critical frequencies, the first is the current resonant frequency, obtained in (i) and the second is the previous damaged resonant frequency, at the previous crack opening.

The most important outputs of FW-Step 1 are twofold, (a) the nodal displacement at the damaged resonant frequency and (b) the dynamic response phase, phase lag between the input Concentrated Loading Force and the response of the system at the Measuring Reference Point. Studying the response allows to compare how the phase decays when damage accumulates as the crack and damping grow.

3.3 Framework Step 2: 'Static - VCCT'

FW-step 2 uses the same damaged FE model from FW-step 1. The purpose of this step is to quantify the ERR in a representative simplified loading cycle. The simplification is necessary because running iteratively a VCCT simulation to account for the ERR evolution with number of cycles, at each adjusted excitation frequency, is computationally too expensive.

To capture the behaviour of a simplified loading cycle, two Abaqus simulation are run within this step. (i) A positive bending static simulation, where the specimen is bent in a U-shape (upwards in the z-axis), and (ii) a negative bending static simulation, where the specimen is bent in an inverted U-shape. The load paths for both simulations (i, ii), are linear ('Ramp' Amplitude in Abaqus). This means that the load starts from a resting position until the prescribed nodal displacements, found in FW-step 1, are reached.

The boundary conditions holding the prescribed nodal displacements, extracted from the SSD simulations in FW-step 1 are applied sufficiently afar from the crack, otherwise it can affect the results of the total ERR. A safe window of 10.2 mm in the X-axis is used. This is considered a safe window volume since the total maximum crack length, imposed in the iteration of the Python-Abaqus routine is 5.1 mm and both left and right cracks develop sufficiently far from any of the edge's planes of this window volume. Several convergence simulations were tried against the crack opening tendency (which crack opens more left or right) to determine a safe window that does not affect this tendency.

The outputs of this step are the following, for each simulation positive and negative: the ERR of the individual modes (crack opening Mode -I, -II and III) and total ERR at each crack front, left and right. These outputs are key to determine in which direction the crack is opened in the next iteration.

3.4 Crack opening criterion in the Python-Abaqus framework.

After the last Abaqus simulation is finished, the total ERR from both positive and negative bending simulations are added at each crack front, in Python. Then the added total ERR (positive and negative) is compared between the left and right cracks, and the crack with the higher ERR is opened in the next iteration. The next iteration opens the crack front by da = 0.1 mm, either at the left or right crack, and the Python routine comes back to FW-step 1, with a modified FE model (larger crack, new damping level). The routine is iterated until an arbitrary total limit of 5 mm is reached, adding both left and right cracks.

4. Results

4.1 Crack progression

Fig. 3 shows the progression of the crack length to the left (blue) and right (red) of the transverse crack. The progression starts at the base of the vertical axis with the initial crack of 0.1mm at each side of the transverse crack, it then grows to the left towards the clamped nodes until it reaches a length of 2.4 mm without any growth to the right, only at this point the crack starts growing to the right.

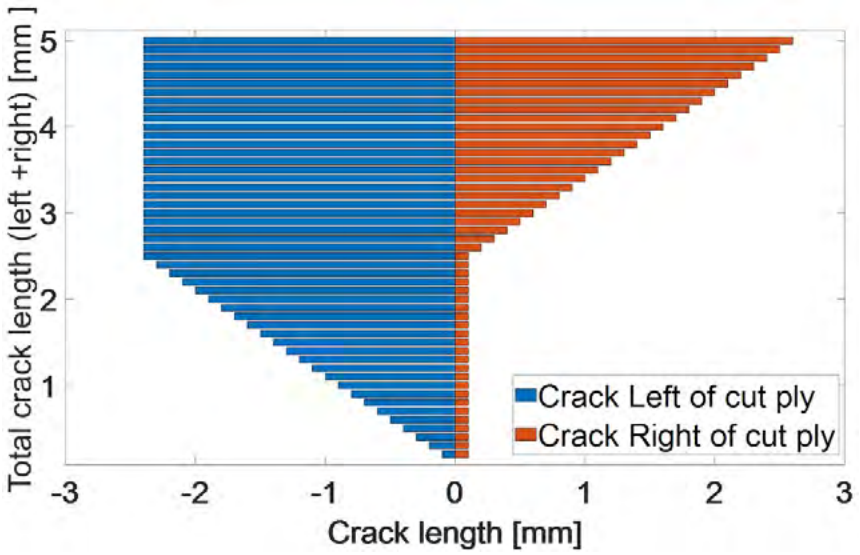

Figure 3 Simulation crack opening up to 5mm.

4.2 Phase decay

The concept of phase decay reflects on the fact that the structural strength of a component deteriorates with fatigue, this deterioration is captured in the dynamic phase response. It has previously been shown that the phase response which is the lag between the input-output (Measuring Point-Loading Point) grows as the material fatigues [5,6].

The Steady State Dynamics analysis, in FW-step 1, is performed at two key frequencies for each crack length, one is the frequency at the current damaged state, 'f_i', and the second is the frequency of the previous damaged state, 'f_{i-1}', see Fig. 4. This allows to determine the Instantaneous Phase decay, ϕ_I, which is the phase decay between the response vibration phase of, ϕ, at one damage case, c_I, at its resonance, f_i, and the resonance of the previous damaged case, f_{i-1}. Fig. 4 describes this concept by using simulated FRFs from the same damaged models (crack opening and evolving damping) used in the Python-Abaqus routine, it is worth noting that the Python-Abaqus routine only performs the SSD at $f_i$and f_{i-1} and that the FRFs shown here, with a frequency range between 116 - 122 Hz, are only used as a tool to explain the concept of phase decay. It can be seen in the close up view on the initial few damage cases

In reality, a good measurement system would compute the phase decay continuously, hence the Instantaneous Phase Decay need to be accumulated and gathered in a single curve to represent a total phase decay, as the crack grows. Fig. 5 displays the instantaneous phase decay at each crack length for a strategy considering a constant damping level equal to the initial damping state and a second strategy where the damping is continuously increased, as explained in Section 3.1.

The initial crack opening is 0.2 mm and the next opened case is 0.3 mm, therefore the first instantaneous phase decay is evaluated at c_I = 0.3 mm, as it is a differential with respect to the previous case. The total phase decay, $\Delta\Phi(c_I)$, is simply the sum of the instantaneous phase decay jumps from the initial case up to the current level of damage, that is, $\Delta\Phi(c_I) = -1 * [\phi_{I_i}(c_I) + \phi_{I_{i-1}}(c_I - 0.1mm) + \phi_{I_{i-2}}(c_I - 0.2mm) + \cdots + \phi_I(c = 0.3mm)]$. In other words, the total phase decay is the cumulative sum of previous phase jumps. Since $\Delta\Phi$ is an arbitrary function it has been adjusted to start from 0, such that $\Delta\Phi(c = c_I)$ is the total Phase decay jump for any c_I, its sign is negative to denote the loss of strength. Fig. 5(b) shows the total Phase decay with the definition explained above.

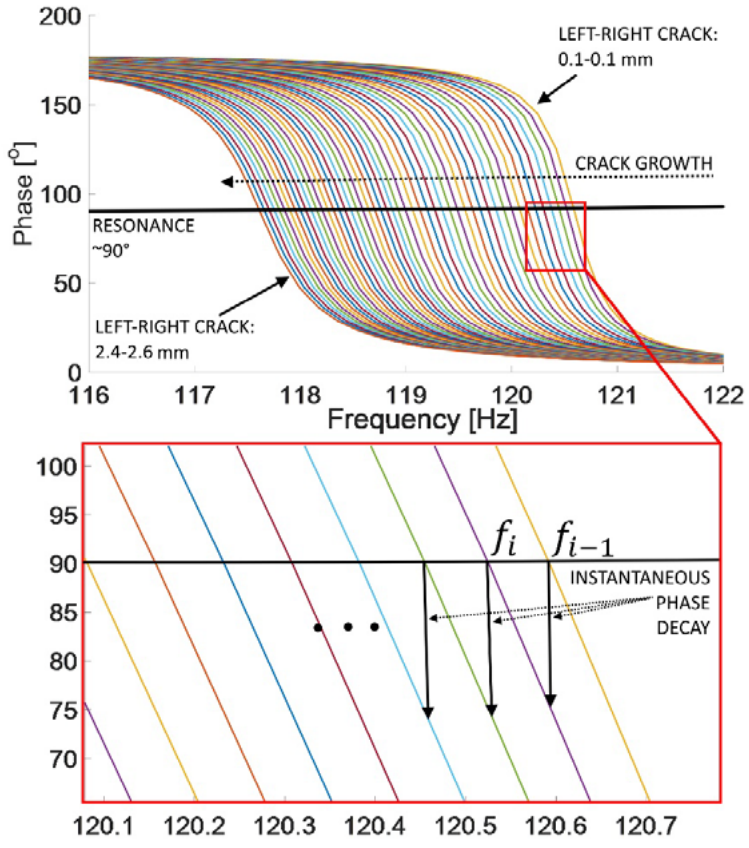

Figure 4 Concept of Phase decay explained with auxiliary FE model FRFs

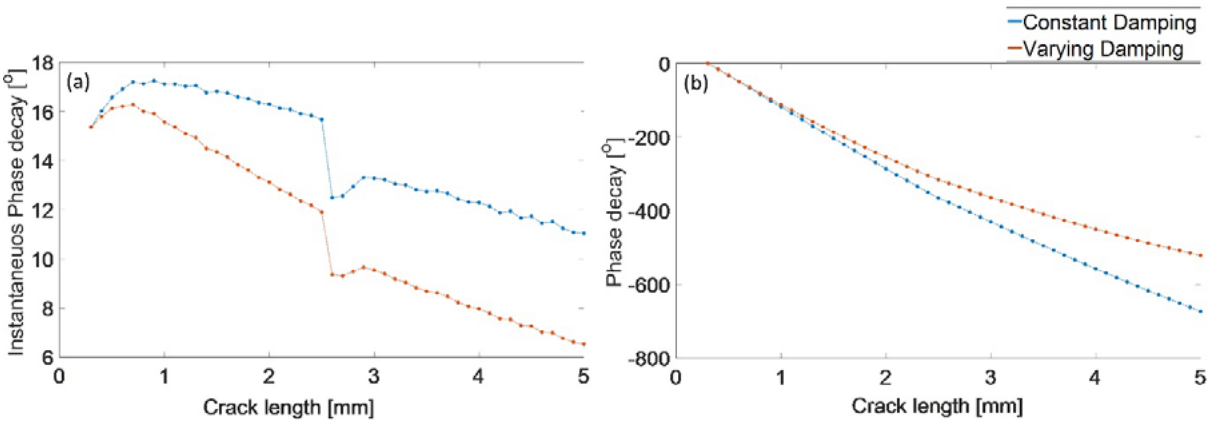

Figure 5 FE model Phase Decay. (a) Instantaneous. (b) Cumulative Total.

5. Discussion

It can be seen from Fig. 5(a) that at 2.5 mm crack length there is a sudden instantaneous phase jump. This is due to the start of the development of the right-side crack, as it can be seen from Fig 3. After that, the instantaneous phase decay of the right-side crack is the same as for the left side crack, a small increment, probably due to small or no sliding frictional behaviour at that interface, followed by a steady decrease.

In Fig. 5(b) the total accumulated Phase decay shows the effect of progressively decreasing magnitude of instantaneous phase jumps, by displaying a slight curvature.

The results in Fig. 5(a), also show the effect of a linear increasing varying damping, where the instantaneous jumps are smaller than the constant damping curve. The larger jumps in phase in the constant damping curve are reflected in the accumulated total phase decay, in Fig. 5(b), by displaying a steeper curve. The reason for this is that larger damping provides a softer response, which can be seen in Fig. 4, where the initial crack phase response is steeper around resonance than the last case of a total crack length of 5 mm.

6. Conclusions

This work shows the overview of a Python-Abaqus framework capable of representing the crack opening condition of a real HFFT experiment. Its main modelling capabilities are: (i) frequency variation due to damage, (ii) varying damping from material fatigue and (iii) constant severity level displacement throughout the entire routine.

These features provides insight into: (a) understanding of the crack growth at small scales, starting from 0.1 mm to arbitrary limits values, as well as (b) providing estimations of the ERR magnitudes for mixed modes and for two cracks, left and right, type of defects, and finally (c) a prediction of the total Phase Decay, which is an experimental signature characterising the material loss of strength from the HFFT experiments.

Keywords: Mechanical metamaterials, Architected interfaces, Thick bond lines, Failure, DCB test

Abstract
Mechanical metamaterials are known for superior material properties such as high strength-to-weight and stiffness-to-weight ratios. Introducing those mechanical metamaterials as an interface in thick bond lines allows for case-specific bond line design also referred to as architected interfaces. The wide range of geometries used for the cellular structures on the meso scale level requires a good modelling approach to understand the material and failure properties of those architected interfaces. This work presents a numerical model that considers a double cantilever beam configuration with a lattice interface material. Due to the loading configuration, the interface material is locally subjected to tensile and compression loading. The interface is described by beam elements allowing for a discontinuous representation of the highly-porous lattice structure. Failure of the individual struts is modelled by a complete softening of the base material taking the fracture toughness of the local structural element into account. Examples of different interface geometries are presented showing some of the advantages of using architected interfaces e.g. tunable material properties and toughening effect. The proposed method contributes to a better understanding of the behaviour and damage of architected interfaces.

1. Introduction

The geometrical cellular structure on the mesoscale level of mechanical metamaterials enables the possibility of achieving superior material properties such as high strength-to-weight and stiffness-to-weight ratios [1,2], high energy absorption [3], improved fracture toughness [4,5] etc. With the rapid development of additive manufacturing, we can today produce many of those complex structures from different base materials ranging from the nano to meter-scale [6,7].

Focusing the topic of mechanical metamaterials on lattice structures the materials can in general be divided into two groups, stretching and bending-dominated depending on their node connectivity [8]. Considering first the stretching-dominated structures, here the individual struts are loaded in tension whereas in the bending-dominated structures, the individual struts are bending loaded. This has a direct effect on the mechanical behaviour which is reflected in the material properties. Take as an example the Young's modulus for low strut thickness-to-length ratios (t/l) in the linear elastic regime, the dependence of the Young's modulus on this ratio can described by a power-law [8]:

$$E \propto \left(\frac{t}{l}\right)^n E_s \tag{1}$$

where E_s is the modulus of the base material and n is a scaling factor depending on the behaviour (stretching or bending dominated). For high thickness-to-length ratios, Zhong et al. [9] have proposed a model taking shear effects into account. The failure strength and fracture toughness are also directly related to the topology of the metamaterial [10]. Besides material failure of the base material, buckling failure must also be considered for stretching dominated structures [11]. Over the reason years multiple

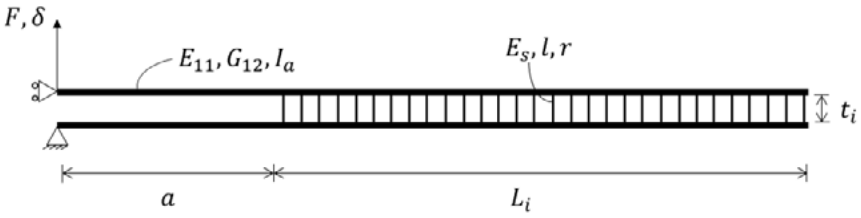

Figure 1. DCB with a pillar interface.

studies have been performed to improve the method to describe the failure mechanisms and fracture toughness of mechanical metamaterials [1,10,11,12].

Athanasiadis et al. [13] have proposed the use of mechanical metamaterials as a replacement for adhesives in thick bond lines utilising their significant material properties and the possibility of toughening mechanisms [14]. Today mechanical metamaterials are typically studied under the assumption of an infinity length scale neglecting boundary effects. To replace adhesives in thick bond lines or use mechanical metamaterials in other confined settings a better understanding of the behaviour and failure of confined metamaterials is needed. In this paper, we present a numerical model to study confined lattice materials. Failure is implemented by a complete softening of the base material allowing for the failure of individual struts without remeshing.

2. Modeling

We consider a double cantilever beam (DCB) with a thick interface of a stretching dominated lattice material loaded in mode I. An example is shown in Figure 1 where a simple pillar interface is represented. A CFRP UD laminate is considered for the adherend of the DCB with the modulus of $E_{11} = 150$ GPa and a shear modulus $G_{12} = 6$ GPa [15]. The thickness and width of the adherend $t_a = w = 5$ mm resulting in a second moment of area of $I_a = 1/12\, w t_a^3$. The initial crack length $a = 10 t_a$. The interface thickness $t_i = 10$ mm and the interface length L_i is varied from 400-800 mm so the full tension and compression zone occurring under loading is captured. The length of a single strut is denoted by l and it has a circular cross-section with a radius r. The interface is modelled using the elastic-brittle trimethylolpropane triacrylate (TMPTA) with the Youngs modulus $E_s = 430$ MPa, failure strength $\sigma_f = 11$ MPa, Poisons ratio $\nu = 0.3$ and fracture toughness $\mathcal{G}_0 = 840$ J/m^2 [11]. In the setup with the pillar interface the strut length $l = t_i$ and the pillars are placed at a distance of $s = t_i/2$. Comsol multiphysics is used for a finite element simulation using Timoshenko beam elements. The simulation is made displacement controlled by δ applied on the left end of the adherend as shown in Figure 1, and the resulting force is denoted F.

2.1. Material model for interface material

The material of the interface is assumed to be linear elastic up to failure occuring when the critical strain $\epsilon_f = \sigma_f / E_s$ is reached. The damage process is modelled based on the traction-separation law:

$$\sigma = \sigma_f \left(1 - \frac{u_f \sigma_f}{2\mathcal{G}_0}\right) \tag{2}$$

During the damage process, the modulus of the damaged lattice element is given by [16]:

$$E_D = -\frac{\sigma_f^2 l_{\text{elm}}}{2\mathcal{G}_0} \tag{3}$$

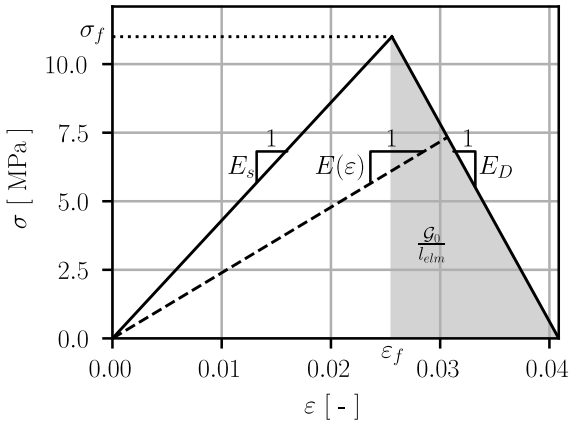

Figure 2. Representation of the material model for the base material of the interface.

where l_{elm} is the element length. The area under the stress-strain curve of the material model is shown in Figure 2 where $\mathcal{G}_0/l$ represents the area under the curve of the damage process [10]. The Young's modulus of the interface material implemented in the finite element model is given by:

$$E(\varepsilon) = \begin{cases} E_s & if\ \varepsilon < \varepsilon_f \\ \frac{\sigma_f - \varepsilon_f E_D}{\varepsilon} + E_D & if\ \varepsilon_f < \varepsilon < \varepsilon_u \\ \frac{E_s}{k} \approx 0 & if\ \varepsilon > \varepsilon_{max} \end{cases} \quad (4)$$

where E_s/k represents a minimum modulus of the interface material to ensure the modulus is strictly positive avoiding the need for remeshing [14]. In this study a value of $k = 10^9$ is used. Due to the brittle behaviour of the material, the modulus is evaluated from the maximum tensile strain over the cross-section thereby taking both tension loading and bending into account [4]. This will result in a reduction of the released energy from the fracture process since bending stresses lead to a variating stress level over the cross-section. Considering the assumption of a stretching-dominated interface only limited bending will be introduced, e.g. the strut in the pillar interface will experience small rotations at the boundaries from the bending of the adherends, thereby it can be assumed this reduction of the released energy will be small. Additionally, the assumption of limited bending allows the representation of a strut by a single element [17]. Representing a strut by only one element ensures that the strut can only fracture once along the length, which is expected in reality. Considering the slender structure of the struts loaded in compression loading failure can occur due to buckling. This is taken into account by comparing the axial strain of the centre line to the buckling strain determined from the Euler buckling load of a column with fixed boundaries. If this buckling load is exceeded the modulus is set to a very low value of E_s/k.

3. Results and discussion

3.1. Failure of confined lattice interface

The force-displacement of a pillar interface for a strut radius of 1 mm and 0.15 mm are depicted in Figure 3. For both strut radiuses, the force is first increased linearly where a tensile zone (area with red struts) and compression zone (area with blue struts) are introduced in the interface (A). As the strut radius decreases the interface modulus decreases (see eq. 1) so the size of the tension and compression zone increases. Considering the interface with a radius of 1 mm, when damage is introduced a softening of the materials occurs in the area next to the crack front, and the struts will fail one by one starting from the crack front (B). The force-displacement doing the crack growth follows the power-law relation of $F \propto \delta^{-0.5}$ also seen in homogenous interfaces [18]. For the interface radius of 0.15 mm failure is occurring in the compression zone due to buckling (C). Here, we see a sudden failure of a large area of the interface. It is important to note that no contact is incorporated in the model, so the model becomes invalid after the failure in such a large area of the interface in compression since it can not capture the

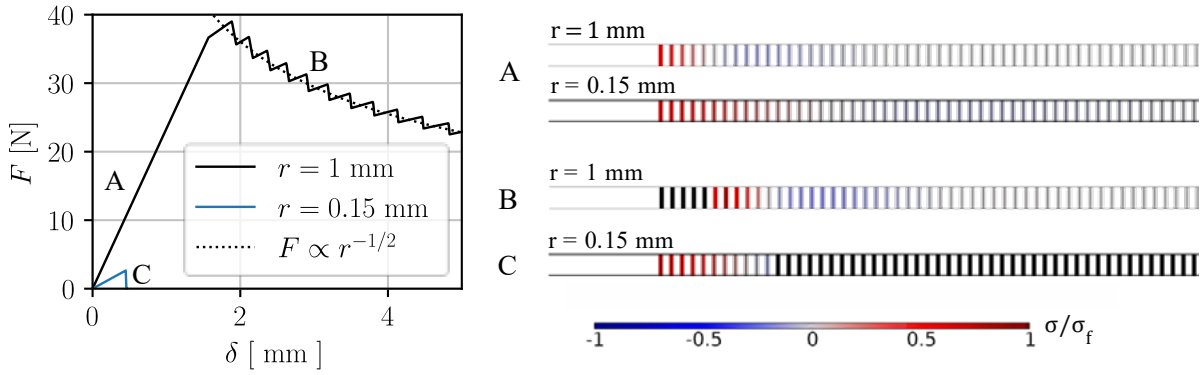

Figure 3. Force displacement plot a DCB with pillar interface. The failed interface is marked in black. For both interface radiuses, the interface length is longer than shown here so the entire tension and compression zone are fully captured at all times.

touching of the two adherends and the interface material in between. Similar results for both the tension and compression failure were reported by Hedvard et al. [14]. As mentioned in section 2 the material model is based on the assumption of the interface being stretching-dominated with only limited bending introduced. Considering the strain in the interface with a strut radius of 1 mm just before the first damage, the tensile strain contributes with 94% of the total maximum axial strain over the cross section so the assumption that the interface being stretching dominated holds.

The force can be normalized using [13]:

$$\tilde{F} = \frac{F\lambda^3}{E_{11} I_a h_i} \tag{5}$$

where λ is the characteristic wavelength given by $\lambda = \left(\frac{2h_i E_a I_a}{E_i w}\right)^{\frac{1}{4}}$. Here E_i is the homogenized modulus of the interface there for a pillar interface is given by $E_i = \pi(r/s)^2 E_s$. The maximal normalized force over the slenderness ratio (r/l) for different strut radiuses are plotted in Figure 4. The failure types can be separated in two: tension (material failure) and compression (buckling) related to the slenderness ratio. For each failure type regression is used to determine a power law [13]. The power law relation follows the maximal force well and can be used to determine the critical force and failure mechanism for a specific value of the slenderness ratio of the interface.

3.2. Toghening effects of lattice structures

An interface is created by four rows of equilateral triangles. The interface height is kept constant which results in a strut length of $l = 2.9$ mm. The slenderness ratio is set to $r/l = 0.1$. To break the symmetry of the setup and thereby avoid the unrealistic case of two symmetric cracks growing in the interface the strut radius of the first triangle in the top two rows is increased by 1%. The force-displacement plot for the triangular interface is shown in Figure 5. First (A) a linear relationship shown into damage of the interface is introduced. As for the pillar interface, a tension and compression zone of the interface is detected, however, horizontal struts in the tension zone experience compression due to the interface topology. After the damage onset, a toughening zone is detected (B) where the force is increased further. Here only a part of the struts are failing creating a bridging-like behaviour. The partly fractured material seen in the bridging zone is also detected in triangular mechanical materials by Hedvad et al. [14] or Gu et al. [19]. After the maximum force is reached a sudden large decrease of the force is detected and the crack starts to grow (C). As shown here by a simple change of the interface topology, the interface's failure process is changed significantly. Thereby with a good understanding of different interfaces, we can design case-specific interfaces controlling the damage process where toughening zones can be used for safe design.

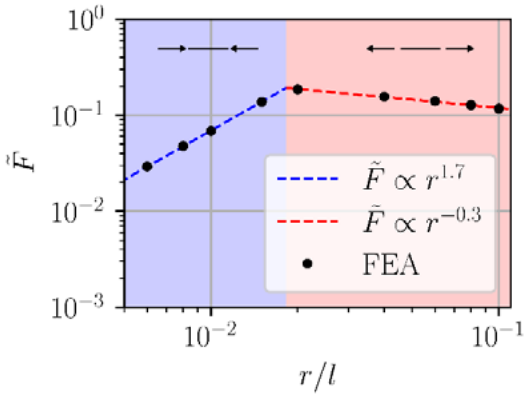

Figure 4. Failure map of DCB with pillar interface. The compression failure is marked in blue, while tension failure is marked in red.

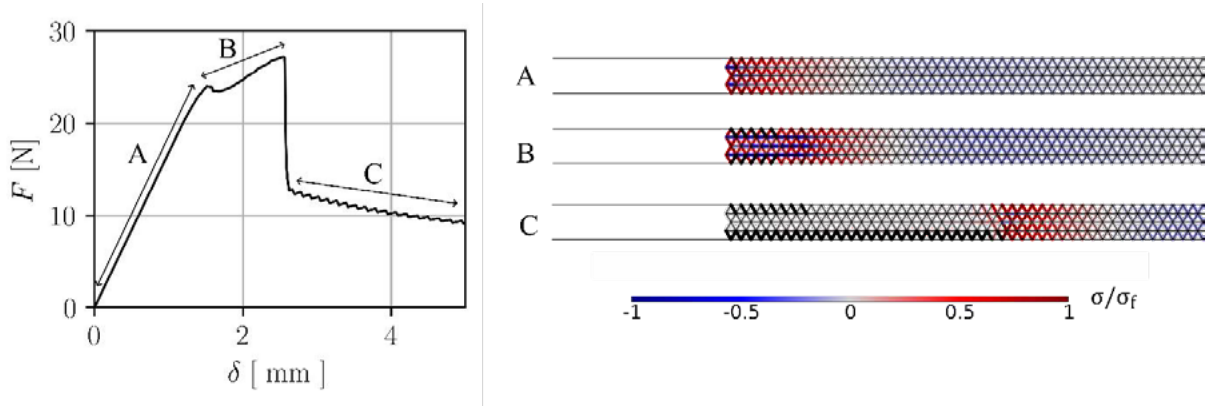

Figure 5. Force displacement plot a DCB with a triangular interface for $r/l = 0.1$. The failed interface is marked in black. For both interface radiuses, the interface length is longer than shown here so the entire tension and compression zone are fully captured at all times.

4. Conclusion

A numerical model has been implemented for investigating confined metamaterials in a double cantilever beam setup. The model allows for both material failure where the fracture toughness is taken into account and buckling failure. A failure map has been created for a simple pillar showing a power law relation for each of the two failure types. Additionally, a triangular interface is studied showing toughening effects under failure. Considering different topologies and slenderness ratios of the interface material, we can alter material properties and failure behaviour. This indicates the potential for the use of mechanical metamaterial as interface materials allowing us to create architected interfaces tuning the material and failure properties wanted for the specific design case.

Keywords: viscoelasticity, thermal expansion, chemical shrinkage, injection pressure, residual stress

Abstract
A multi-scale modeling strategy for the simulation of the stress evolution in a composite material during the curing process is presented. It consists of a coupled thermo-kinetic simulation of the evolution of temperature and degree of cure taking into account heat transfer and the exothermal reaction enthalpy, and a thermo-mechanical simulation taking into account the thermal expansion of the material, the volume loss of the resin due to chemical shrinkage and the resin added during the curing process to maintain the consolidation pressure. The temperature and cure dependent viscoelastic properties and expansion coefficients are obtained from the constituent properties by homogenization. Due to the viscoelastic behavior of the resin, the resulting expansion coefficients are time-dependent. The effect of the resin injection is modeled by an additional parametric strain accounting for the volume change of the resin in the same way as the volume loss due to chemical shrinkage. The added resin quantity is an additional degree of freedom that evolves with the aim of reaching equilibrium between the injection pressure and the pressure in the mold. With increasing resin viscosity, the change of resin quantity is slowed down, leading to a pressure drop when the resin passes the gel point.

1. Introduction

The generation of residual stresses in polymer matrix composites is a complex multi-physics and multi-scale process. The polymerization kinetics of the resin during the curing process can, in general, phenomenologically well be described by an autocatalytic model [1] for the evolution of the degree of cure, which depends on temperature and the current state of cure. The polymerization reaction is exothermal, thus influencing the temperature evolution in the composite part. Residual stresses are generated due to a volume loss of the resin during the polymerization (chemical shrinkage) and the different coefficients of thermal expansion (CTE) of the fibers and the matrix. The amount of residual stresses and their impact on the part shape and damage onset and evolution is influenced by the mechanical behavior of the constituent materials, which in the case of the resin strongly depends on temperature and degree of cure [2]-[4]. Residual stresses are present at each characteristic scale of the composite, starting from the micro-scale due to the mismatch between the expansion coefficients of the fibers and the matrix, over the meso-scale where the architecture of the fibrous reinforcement is defined, up to the macro-scale of the structure where residual stresses have an impact on the final shape of the composite part.

Numerical simulation of the generation of residual stresses thus requires constitutive models that take into account the different physics involved and appropriate scale change methods. In this contribution,

we present a multi-scale modeling strategy that consists of a thermo-kinetic simulation of the evolution of temperature and degree of cure and a thermo-mechanical simulation of the evolution of the internal stresses. The thermo-kinetic simulation takes into account the exothermal reaction enthalpy of the polymerization and the heat transfer within the composite and between the composite and the mold. The evolutions of temperature and cure in time at each integration point are taken as locally varying input parameters to the thermo-mechanical simulation. They drive the chemical shrinkage and the thermal expansion and influence the mechanical behavior of the material. The influence of the resin injection pressure is modeled phenomenologically by means of an additional parametric strain that accounts for the increase of the resin volume in the composite during the curing cycle, which compensates partially the volume loss due to chemical shrinkage. If the consolidation pressure decreases significantly before the degree of cure of the resin reaches a critical value, gas bubbles may nucleate leading to porosity in the composite part [5]-[6]. With the proposed approach, the pressure drop caused by the chemical shrinkage of the resin can be estimated and the risk of porosity formation can be evaluated.

For the mechanical behavior of the composite, a viscoelastic constitutive behavior with time-dependent expansion coefficients is used [8], which is obtained by homogenization [7]-[8] from the behavior of its constituents [4]. The formulation of the model and the homogenization method are briefly described in section 2. In section 3, the thermo-kinetic simulation of the curing process is presented. The thermo-mechanical simulation with the approach to take into account the influence of the resin injection pressure is described in section 4. Some results of the stress evolution in a composite plate obtained with the presented modeling strategy are shown in section 5.

2. Viscoelastic homogenization with time-dependent expansion coefficients

2.1. Viscoelastic behavior

The viscoelastic behavior of the resin and the composite is modeled by a 3D anisotropic version of a generalized Maxwell model [7]. The stress evolution is given by

$$\underline{\sigma}(\xi) = \left(\underline{\underline{E}}_\infty + \sum_{k=1}^{N} \underline{\underline{E}}_k\right) : \underline{\varepsilon}^{ve}(\xi) - \sum_{k=1}^{N} \underline{\underline{E}}_k : \underline{\varepsilon}_k^{ve}(\xi) \tag{1}$$

where $\underline{\underline{E}}_\infty$ is the asymptotic relaxed stiffness tensor of the material and $\underline{\underline{E}}_k$ are the coefficients of the Prony series expansion of the relaxation master curves. $\underline{\varepsilon}^{ve}$ is the viscoelastic part of strain (see section 2.2) and $\underline{\varepsilon}_k^{ve}$ are internal variables accounting for the strain history. Their evolution is given by

$$\frac{d\underline{\varepsilon}_k^{ve}(\xi)}{d\xi} = \frac{1}{\tau_k}\left(\underline{\varepsilon}^{ve}(\xi) - \underline{\varepsilon}_k^{ve}(\xi)\right) \tag{2}$$

ξ is a reduced time that describes the horizontal shifts of the relaxation curves along the logarithmic time scale upon change of temperature and degree of cure under the assumption of time-cure-temperature superposition [9]:

$$\xi(t) = \int_{-\infty}^{t} \frac{1}{a_T(t')} dt' \tag{3}$$

For the polymer matrix, the tensors $\underline{\underline{E}}_k$ and $\underline{\underline{E}}_\infty$ take an isotropic form. Creep is supposed to be isovolumetric, hence the $\underline{\underline{E}}_k$ are purely deviatoric. The experimentally observed shear relaxation master

curves are well reproduced by Prony series whose coefficients follow a continuous function of the form [4]

$$G(\tau) = A \exp\left(-\left(\frac{\log_{10}\tau - \log_{10}\tau_{peak}}{l_{peak}}\right)^2\right) + \frac{B}{2}\left(1 - \mathrm{erf}\left(\frac{\log_{10}\tau - \log_{10}\tau_{peak}}{l_{peak}}\right)\right) \tag{4}$$

Taking one relaxation time per decade provides a sufficiently smooth relaxation curve in good agreement with the experimental data [4]. For the viscoelastic behavior of the consolidated tows at the meso-scale and for the average behavior of the composite over a representative volume element (RVE), the tensors $\underline{\underline{E}}_k$ and $\underline{\underline{E}}_\infty$ are anisotropic and obtained from the homogenization procedure described in section 2.3. Besides the anisotropy of these tensors, the formulation of the model is the same.

2.2. Time-dependent expansion coefficients

In a small-strain framework, we use an additive decomposition of the strain tensor into a mechanical (viscoelastic) part $\underline{\varepsilon}^{ve}$ that is used in the constitutive behavior presented before, a thermal part $\underline{\varepsilon}^{th}$ that is caused by a temperature change, and a chemical part $\underline{\varepsilon}^{ch}$ that is caused by the volume loss of the resin during polymerization.

$$\underline{\varepsilon} = \underline{\varepsilon}^{ve} + \underline{\varepsilon}^{th} + \underline{\varepsilon}^{ch} \tag{5}$$

The mismatch in the CTE between the fibers and the matrix causes internal stresses in the composite if the temperature changes. Due to viscoelastic phenomena, such as creep and relaxation, these stresses evolve in time after a temperature change even if the temperature is kept constant. As a result, the average strain of the composite also evolves in time after a temperature change. This effect is modeled following a formulation proposed in [10] with a time-dependent CTE, which if written in terms of a Prony series, leads to a formulation similar to the generalized Maxwell model described in the previous section. The evolution of the thermal strain as a function of the reduced time (Eq. 3) is then given by [8]

$$\frac{d\underline{\varepsilon}^{th}(\xi)}{d\xi} = \left(\underline{\alpha}_\infty^{th}\big(T(\xi), c(\xi)\big) - \sum_{k=1}^{N} \underline{\alpha}_k^{th}\big(T(\xi), c(\xi)\big)\right)\frac{dT(\xi)}{d\xi} - \sum_{k=1}^{N} \frac{1}{\tau_k}\underline{\varepsilon}_k^{th}(\xi) \tag{6}$$

with internal variables $\underline{\varepsilon}_k^{th}$ accounting for the history of temperature and the CTE. Their evolution is given by

$$\frac{d\underline{\varepsilon}_k^{th}(\xi)}{d\xi} = \underline{\alpha}_k^{th}\big(T(\xi), c(\xi)\big)\frac{dT(\xi)}{d\xi} - \frac{1}{\tau_k}\underline{\varepsilon}_k^{th}(\xi) \tag{7}$$

The tensorial coefficients $\underline{\alpha}_\infty^{th}$ and $\underline{\alpha}_k^{th}$ of the Prony series expansion may depend on temperature and degree of cure, hence the slightly different formulation compared to the viscoelastic model presented in section 2.1. An exactly equivalent formulation can be used for the coefficients of chemical shrinkage (CCS), setting the CCS of the fibers to zero.

2.3. Homogenization

As shown in various works ([11] cited here only as an example), the generalized Maxwell model is obtained from the integral form of viscoelasticity if the time-dependent relaxation function is written in

terms of a Prony series. If the Laplace-Carson (LC) transform is applied to the integral form of a linear viscoelastic behavior, a relation equivalent to a linear elastic behavior is obtained, with a stiffness tensor that depends on the LC transform parameter. This well-known formalism was extended in [8] to time-dependent CTE written in the formulation of [10], leading to a thermo-elastic relation in the LC space. If Prony series are used for the relaxation function and the time-dependent CTE, the LC-transform can be written by a system of equations [7] for the relaxation function

$$\hat{\underline{\underline{E}}}(p_i) = \underline{\underline{E}}_\infty + \sum_{k=1}^{N} \mathcal{L}_{ik} \underline{\underline{E}}_k \tag{8}$$

where $\hat{\underline{\underline{E}}}(p_i)$ is the LC transform of the relaxation function evaluated at a LC-transform parameter p_i and $\mathcal{L}_{ik}$ are given by

$$\mathcal{L}_{ik} = \frac{p_i}{p_i + \frac{1}{\tau_k}} \tag{9}$$

The LC transform of the time-dependent CTE for a given temperature T and degree of cure c is given by

$$\hat{\underline{\alpha}}^{th}(p_i, T, c) = \underline{\alpha}_\infty^{th}(T, c) - \sum_{k=1}^{N} \mathcal{L}_{ik} \underline{\alpha}_k^{th}(T, c) \tag{10}$$

The same formulation is used for the CCS.

The LC transform of the relaxation function and the time-dependent expansion coefficients is then obtained with classical thermo-elastic homogenization methods. If we assume that the relaxation function and the expansion coefficients of the homogenized material can also be well fitted by a Prony series with weights that follow continuous functions if plotted against the logarithm of the relaxation times, we can choose the same relaxation times as for the matrix behavior to discretize these continuous spectra. Then, if we determine the LC transform of the homogenized behavior for at least $M \geq N$ different p_i, the homogenized behavior in the time-domain is obtained by solving the least squares problems given in Eqs. (8) and (10) to obtain the coefficients $\underline{\underline{E}}_k$ and $\underline{\alpha}_k^{th}$ of the homogenized material. Since this problem is often ill-conditioned, the proper choice of the p_i is important [7] and sometimes a Tikhonov regularization may be necessary [8]. In the case of a composite with a woven reinforcement, two homogenization steps are needed: the first one to determine the homogenized behavior of the consolidated tows from the constituent (fiber and matrix) behaviors, and the second one to determine the homogenized behavior of the composite.

3. Thermo-kinetic simulation of the curing process

The curing process of a flat plate of composite with a 3D woven reinforcement as the one used in [7]-[8] is simulated. The dimensions of the plate and the curing cycle correspond to those used in [13]-[14]. In the first step of the curing process simulation, the heat transfer equation is solved using the Finite Element (EF) software Z-set [12]. The heat generated by the exothermal polymerization reactions is taken into account by a heat source term that is added to the heat transfer equation:

$$\vec{\nabla} \cdot \left(\underline{\kappa} \cdot \vec{\nabla} T \right) = -\rho C_p \dot{T} + \rho H_R \dot{c} \tag{10}$$

where $\underline{\kappa}$ is the anisotropic 2nd order tensor of thermal conductivity of the composite, ρ is its mass density, C_p the heat capacity per unit mass and H_R the reaction enthalpy per unit mass. The evolution of the degree of cure c is simulated using the autocatalytic model proposed in [1]

$$\dot{c} = (k_1(T) + k_2(T)c^m)(1-c)^n \tag{10}$$

with reaction velocity coefficients $k_{1,2}$ that follow a classical Arrhenius dependence on temperature. The heat source term accounts for the overheating that may occur in thick composite parts. However, as the simulated plate is relatively thin (6.7mm), the temperature remains quite homogeneous during the curing process (not more than 0.5°C between the surfaces and the center of the plates). Therefore, the curing temperature is applied directly to the surfaces of the plate. Heat transfer boundary conditions can alternatively be applied, but this does not influence the result if the overheating due to the exothermal reaction is insignificant. The evolution of temperature and degree of cure are shown in Figure 1.

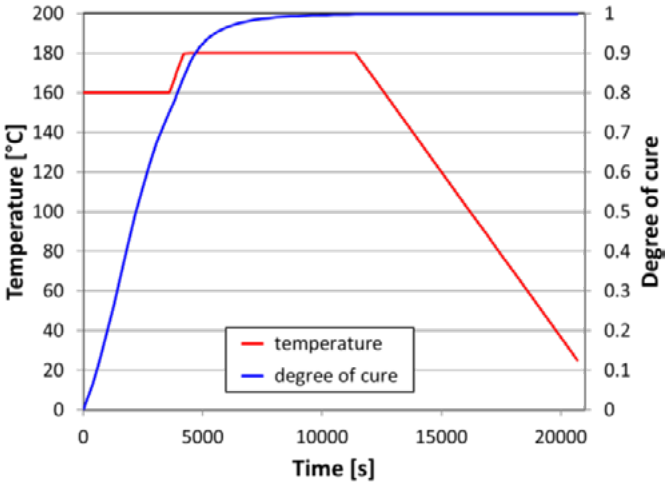

Figure 1. Evolution of temperature and degree of cure during the simulated curing cycle.

4. Thermo-mechanical simulation of the curing process

4.1. Boundary conditions and input parameters

Temperature and degree of cure obtained with the thermo-kinetic simulation are taken as input parameters to the thermo-mechanical simulation. They drive thermal expansion and chemical shrinkage and influence the viscoelastic behavior as described in section 2. The same FE mesh is used as in the thermo-kinetic simulation, so the data is directly transferred at each integration point. The presence of the mold is simulated by a frictionless contact at the top and bottom surface that allows the plate to contract through the thickness but not to expand with respect to its initial state. On the lateral surfaces of the plate, no contact conditions are applied, as there is a small space between the composite and the mold frame. During the curing process, this space is filled with resin at the injection pressure. Therefore, this pressure is applied to the sides of the plate.

4.2. Modeling the influence of the resin injection pressure

During the curing phase, the resin injection continues at a high pressure in order to compensate a part of the volume loss due to chemical shrinkage and maintain the consolidation pressure in the mold to ensure desorption of gas bubbles until the resin is sufficiently polymerized. The effect of this ongoing injection is modeled in the same way as the chemical shrinkage, as it leads to an increase of the resin

volume in the composite, while chemical shrinkage leads to a volume loss. An additional strain $\underline{\varepsilon}^{pr}$ is therefore added to Eq. (5) accounting for this volume increase. It follows the evolution given in Eq. (6) and (7) but is driven by the injected resin quantity instead of temperature for $\underline{\varepsilon}^{th}$ or degree of cure for $\underline{\varepsilon}^{ch}$. The expansion coefficient that translates its effect on the composite level is obtained by homogenization in the same way as the CCS of the composite, taking zero expansion for the fibers and the relative volume change for the resin.

The injected resin quantity is unknown and driven by the injection pressure. Therefore, this quantity is added as an additional degree of freedom to the FE problem. The associated residual for the global Newton-Raphson algorithm is the difference between the internal pressure in the mold (the volume average of the trace of the stress tensor) and the applied injection pressure. If the resin is liquid with negligible viscosity, it can flow everywhere in the composite and the equilibrium between pressure in the mold and injection pressure is reached immediately. However, the viscosity of the resin increases with degree of cure, which after the gel point becomes a viscoelastic solid. This transition is taken into account in the viscoelastic model by a Maxwell element with a relaxation τ_{gel} that increases exponentially with the degree of cure:

$$\tau_{gel} = t_{load} \exp(a + bc) \tag{10}$$

This leads to an apparent relaxed shear modulus that increases with the degree of cure as shown in Figure 2. This evolution is close to the one observed experimentally by [2] on a different epoxy resin. t_{load} corresponds to the loading time at which the apparent relaxed shear modulus is measured.

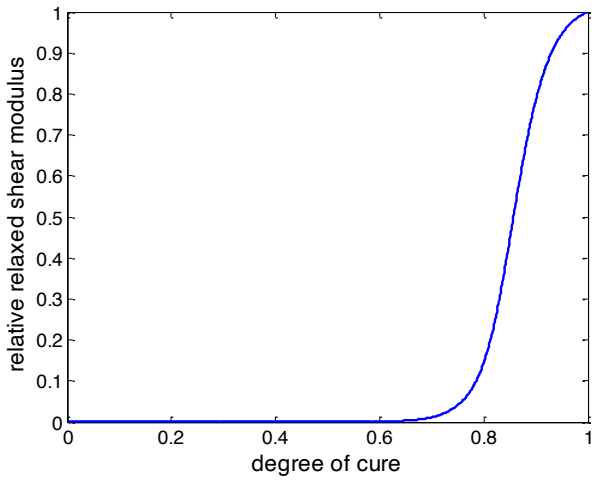

Figure 2. Evolution of the ratio between the relaxed shear modulus as a function of cure and its value for the fully cured resin.

The influence of the resin viscosity on the injection pressure transmission is taken into account by a residual that ensures that relative volume change of the resin in the mold is given by

$$\frac{\dot{V}}{V} = \frac{1}{\eta}\left(P^{ext} - P^{int}\right) \tag{10}$$

where η is the viscosity of the resin, P^{ext} the applied resin injection pressure and P^{int} the pressure in the mold. The resin viscosity is taken from the viscoelastic model, using for each Maxwell element the product of its shear modulus with the temperature and cure dependent relaxation time.

5. Results

The evolution of the out-of-plane stress in the composite plate throughout the curing process obtained with the presented simulation strategy is shown in Figure 3a. In Figure 3b, the out-of-plane stress is plotted against the degree of cure. Comparison with the temperature cycle presented in Figure 1 shows that during the first dwell at 160°C when the resin viscosity is still very low, the out-of-plane stress corresponds to the imposed injection pressure. Towards the end of the 160°C dwell, when the degree of cure exceeds about 60%, the relaxed stiffness of the resin starts to increase (see Figure 2) and thus the chemical shrinkage is no longer immediately compensated. This leads to a small decrease in pressure towards the end of the first dwell (between 60% and 70% of cure, see Figure 3b). During the heating phase up to 180°C, the out-of-plane stress increases due to the thermal expansion of the resin. When the 2nd dwell temperature is reached, the pressure starts to decrease immediately, as at this point the resin viscosity is already significant (about 84%, see Figure 3b), and the chemical shrinkage can no longer be compensated by the resin injection. With the present model for the resin viscosity, the out-of-plane stress drops to zero at a degree of cure of about 91%.

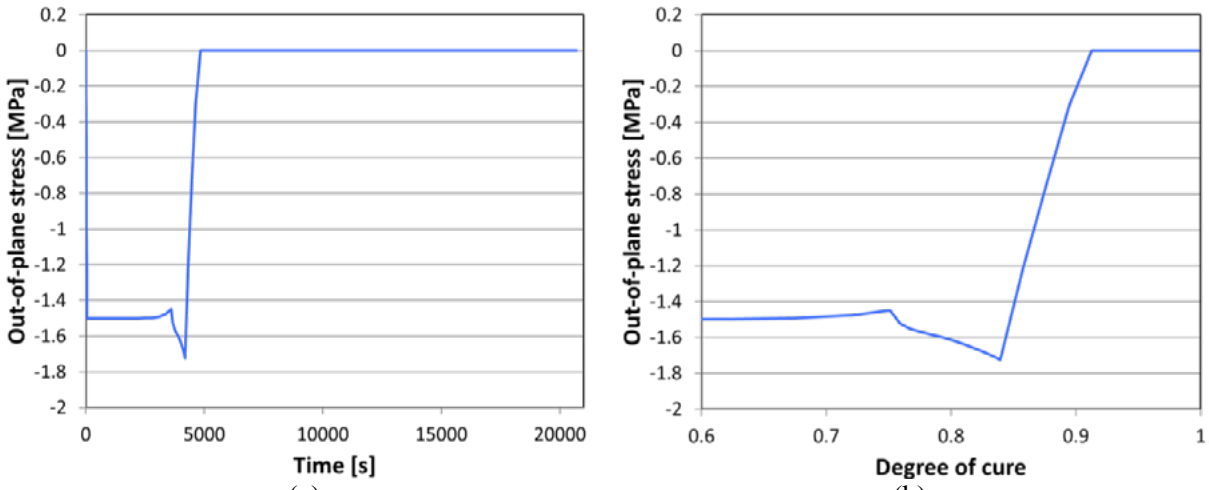

Figure 3. Evolution of the out of plane stress during the curing process of a composite plate as a function of time (a) and plotted against the degree of cure (b).

6. Conclusions

The presented multi-scale modeling strategy takes into account the couplings between the different physical phenomena involved in the generation of residual stresses in polymer matrix composites. With the presented homogenization strategies, the temperature- and cure-dependent material properties can be determined from the constituent behaviors. Due to the viscoelastic nature of the matrix, time-dependent expansion coefficients have to be used for the homogenized behavior of the composite. The ongoing resin injection during the curing phase that compensates part of the chemical shrinkage in order to avoid an early pressure drop is modeled by an expansion coefficient in the same way as the volume loss due to chemical shrinkage, but with an opposite sign. In the present model, this method supposes that the injected resin is distributed homogeneously through the whole composite. Especially in bigger parts, this assumption is in general not true. In these cases, the resin flow during injection has to be modeled beforehand, taking into account the increasing viscosity during the curing process and the permeability of the fibrous reinforcement. The resulting distribution of resin in the reinforcement can be used as heterogeneous input parameter with the presented model in the same way as the temperature and degree of cure obtained with the thermo-kinetic simulation are used for the thermal expansion and the chemical shrinkage in the thermo-mechanical simulation.

The presented test case of a thin flat plate is very simple and avoids most of the heterogeneities. Future work will consist in application of the presented modeling chain to more complex structures, with heterogeneous temperatures (either due to an inhomogeneous heating or overheating caused by the exothermal polymerization), heterogeneous material properties (various reinforcement architectures in one part) and more realistic boundary conditions. In particular, the thermal and mechanical deformation of the mold and the friction and adhesion between part and mold must be taken into account. Furthermore, the small space between the reinforcement and the mold frame is filled with resin and thus more realistically modeled by a thin resin layer around the composite. If these different aspects are correctly taken into account, the proposed modeling chain is able to predict both the evolution of the pressure in the composite during the curing process and the generation of residual stresses and their impact on the final part shape.

Keywords: Composite sandwich, impact damage, double impact position, damage mechanism

Abstract
Composite structure sandwich are widely used in the aerospace industry due to their excellent in-plane mechanical properties. However, its face sheet exhibit poor delamination resistance subjected to impact, due to the lack of reinforcement in the through thickness. Besides, composite sandwich structure are often subjected to multiple impacts, and such impacts generally occur at certain distance from each other. Therefore, the impact behavior and CAI strength of composite sandwich structure considering different impact positions were investigated and studied. After each impact, non-destruction inspection (NDI) C-scans and scanning electron microscope (SEM) were performed to assess damage status and internal defects. The comparisons between repeated impact events in terms of impact history, absorbed energy history, contact duration and the delamination damage projected area (DDPA) were studied. The results show that there existed a obvious interference relationship between the first and second impact events. Moreover, the impact energy and bending stiffness at different impact position will also affect impact performance

1. Introduction

Composite sandwich structure attracted an increasing attention in automotive industry, aeronautics and astronautics due to excellent mechanical properties [1][2], such as lightweight, high specific stiffness and strength. However, its composite face sheet exhibited weak transverse load-bearing capacity, which was sensitive to low velocity impact [3]. The impact damage might cause internal damage without visible sign, resulting in the reduction of mechanical properties. Therefore, the dynamic mechanical responses of composite sandwich structure were wisely studied and discussed [4]. It was deserved to be noted that the composite structures usually experienced complex loading conditions such as being subjected to various impact events [5][6]. Some evidences exhibited that there was an overlapping state in damage regions on the double impact positions [7]. Moreover, the accumulation of repeated impact event with low impact energy might erode the mechanical properties, but a single impact did not [8]. Therefore, assessing the dynamic responses of composite laminate with double impact positions was very important and meaningful.

In recent years, some research had been conducted for composite laminate after being subjected to different impact events [9][10]. For instance, Atas et al. [11] conducted an experimental study the effect of various thickness on the repeated impact response of woven E-glass/epoxy composites. Kashani et al. [12] compared the impact responses of fiber metal laminates under the single impact and two divided impacts. It indicated that different impact energy and impact sequence have great influence on impact response. Li et al. [13] revealed the dynamic behavior of aluminium and composite layers as well as their interfaces considering four different impact angles. In fact, multi-impacts always occurred at the different position and had a certain distance from each other. Zhou et al. [14] investigated the mechanical responses of composite at double position subjected to low velocity impact. The results shown that the critical separation distance between the two impacts had different characteristic under different impact energy levels. Besides, Liao et al. [15] discussed the effect of Z-pinning technology on the impact

behaviors of composite laminates under double impact positions. It indicated that such technology could suppress the internal defects and delamination damage by weakening the damage interference at high impact energy. However, those studies on double-position impact behavior [16], but the effect of multiple impact damage on the compression after impact (CAI) strength was still lack of studies. Besides, the mechanism of influence between the multiple-impact is not clear.

Therefore, the impact responses and damage mechanism of the composite sandwich structure considering different impact positions were investigated. Besides, the delamination damage projected area (DDPA) and failure modes were measured and observed after each impact. Typical mechanical characteristic such as maximum impact force and displacement was compared to reveal the interference level between multiple impacts.

2. Material and preparation

Composite sandwich structure considering corrugated core and polymethacryimide (PMI) foam core were considered, and the schematic diagram was shown in Figure 1. The composite face sheet and corrugated core were fabricated using T700/9A16 unidirectional prepreg, and the face sheet and core were assembled using an adhesive film GXA120.

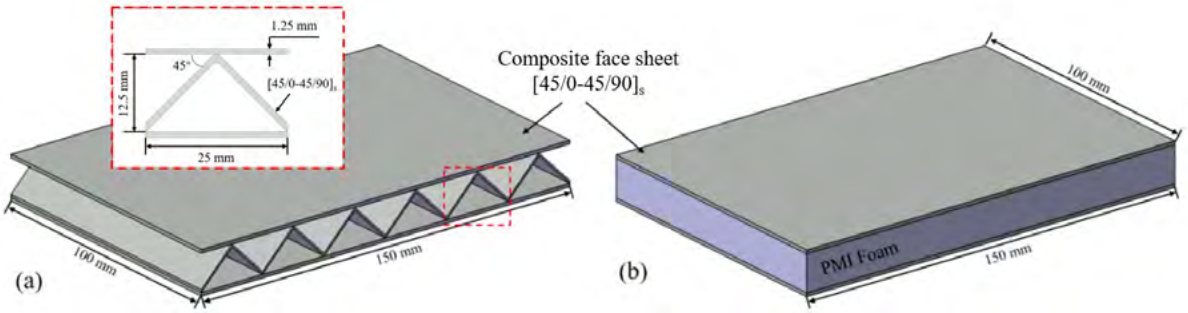

Figure 1. The schematic diagram of specimens. (a) Composite corrugated sandwich structure; (b) Composite PMI foam sandwich structure.

The double impact test of composite sandwich structure was conducted according to ASTM D7136 using Instron Dynatup 9350 HV Impact Testing Machine. The double impact test strategy for specimens was shown in Figure 2. The drop-point of impactor in machine is fixed, a modified fixture was designed as shown in Figure 3(a). Besides, after double impact, the CAI tests were carried out te assess the residual compressive properties of composite sandwich structure based on ASTM D7137, as shown in Figure 3(b). The impact test matrix was summarized in Table 1.

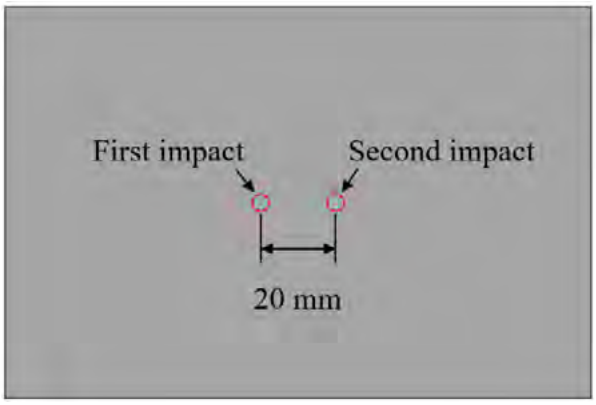

Figure 2. The double impact test strategy for specimens.

Specimen ID	Core material	Impact sequcen	Impact energy (J)
C-5J	Corrugated core	First	5
CS-5J	Corrugated core	Second	5
F-5J	Foam core	First	5
FS-5J	Foam core	Second	5
C-5J	Corrugated core	First	10
CS-5J	Corrugated core	Second	10
F-5J	Foam core	First	10
FS-5J	Foam core	Second	10

3. Results and discussion

3.1. Impact response

Figure 4 illustrated the impact responses of the composite corregated sandwich structure and composite foam sandwich structure at impact energies of 5 J and 10 J. It can be found that the impact responses of the first and second impact events for composite foam sandwich structure are in good agreement when impact energy is 5 J. For high impact energy case (10 J), then there is a slight deviation, but the maximum impact load, maximum impact displacement and absorbed energy are basically the same. Therefore, it can be considered as two separate impact event, and the first impact event has basically no influence on the second impact event.

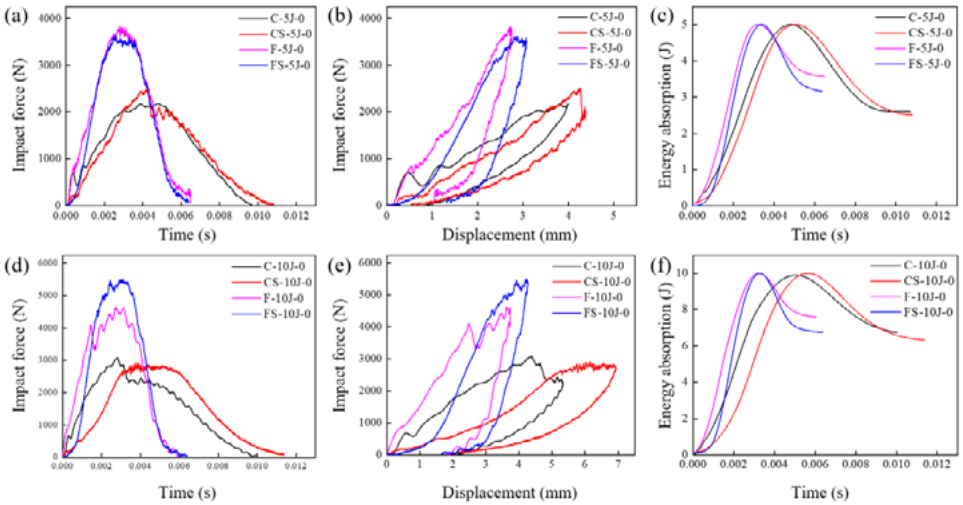

Figure 4. impact responses of the composite corregated sandwich structure and composite foam sandwich structure.

For composite corrugated sandwich structure, the impact response curve of second impact event starts smooth, and its maximum displacement is larger than that of the first impact event. The reason is that impact of the first impact event influenced the second impact event due to the reduction of bending stiffness. Besidesm the impact response curve of the first impact event at 5 J and 10 J did not decrease at the beginning of the curve, i.e., there is no fiber breakage. For second impact event at 10 J, the moment of impact load drop is slightly later than the first impact point. In a word, the first impact event could influence the impact response of the second impact event for composite sandwich structure when distance between impact position is 20 mm, and similar conclusion is not suitable for composite foam sandwich structure.

DDPA was normally regarded as an influential factor for evaluating resistance to impact damage, as shown in Figure 5. It could be observed that larger DDPA appeared for higher impact energy. The delaminate area of C-10J was 298.72 mm^2, and the two impact damage regions of CS-5J were still separate (i.e., non-interfering state). Then, for higher impact energy case, the two impact damage regions of CS-10J increased and overlapped (i.e., interfering state). Figure 6 illustrated the scanning electron microscope (SEM) results of C-10J and CS-10J at the impact point. It can be seen that fiber breakage and matrix cracking existed around the impact point.

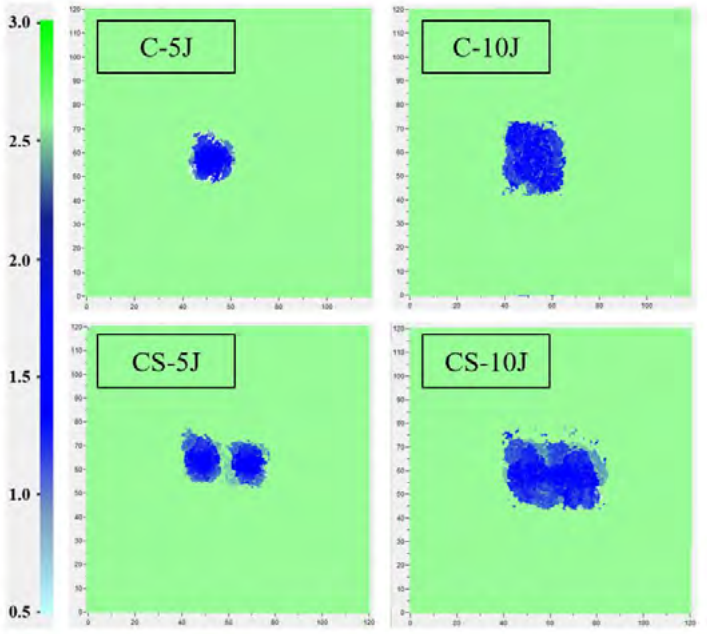

Figure 5. Ultrasonic C-scan damage of damaged laminates.

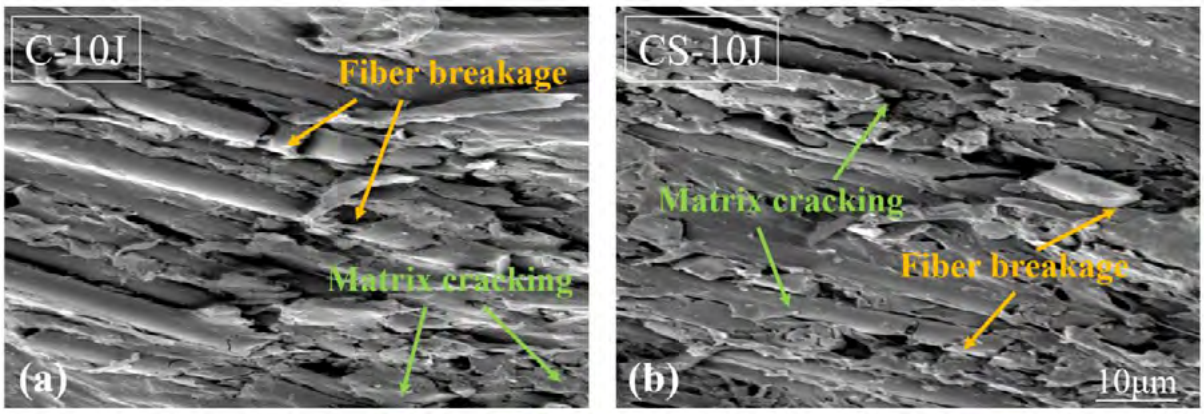

Figure 6. Scanning electron microscope (SEM) results of C-10J and CS-10J at the impact point.

3.2. Discussion of CAI strength

The CAI strength of composite corrugated sandwich structure and composite foam sandwich structure was shown in Figure 7. It can be seen that higher impact energy result in lower CAI strength, and the CAI strength of composite foam sandwich structure was larger than that of composite corrugated sandwich structure. The reason was that foam core provided stronger interface properties.

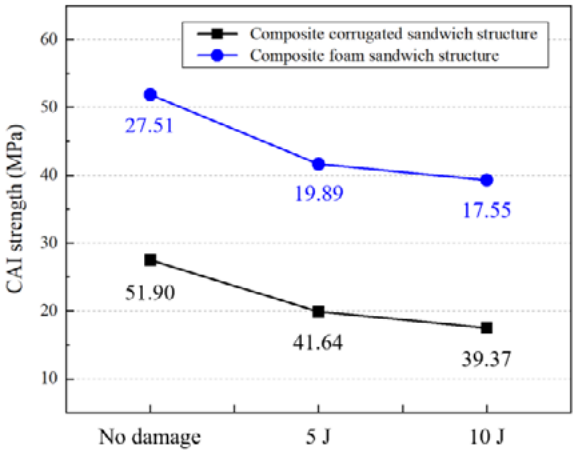

Figure 7. The CAI strength of composite corrugated sandwich structure and composite foam sandwich structure.

4. Conclusions

In this paper, the impact responses and damage mechanism of the composite sandwich structure considering different impact positions were investigated. The conclusions are shown as follows:

(1) For composite foam sandwich structure, it can be considered as two separate impact event, and the first impact event has basically no influence on the second impact event for all impact energy cases.

(2) Two impact damage regions composite corrugated sandwich structure of at 10 J impact energy increased and overlapped (i.e., interfering state), compared with 5 J impact case.

(3) The higher impact energy result in lower CAI strength, and the CAI strength of composite foam sandwich structure was larger than that of composite corrugated sandwich structure. The reason was that foam core provided stronger interface properties.

Keywords: Deployable folding structures, X-ray micro computed tomography (XCT), real representative volume element (RVE), FE modeling, flexure.

Abstract
In this work, X-ray micro computed tomography (XCT) based 3D model of the flexible region is developed which is composed of a single-layer plain-weave glass fiber reinforced elastomer. A representative unit cell called as representative volume element (RVE) of the flexible region was modelled by supervised segmentation of the XCT image stacks into 3D voxels associated to fibers having anisotropy and local orientation and isotropic matrix i.e. elastomer. Owing to the fact that there exist fibers' undulating patterns and also the material properties of both the fibers and the matrix are substantially different, therefore, it is expected that the bending response utilizing the real RVE will provide a more reliable bending-curvature response. The bending stiffness of the real RVE was determined and compared with the bending response of homogenized elastomer laminate using ABAQUS®. Quasi-static bending analysis for small strains was conducted in ABAQUS®, utilizing the linear elastic properties of constituent materials. It is concluded that a significant contrast was found in the bending stiffness obtained with the two approaches using real RVE and homogenized RVE during bending of the flexible region in the deployable folding structure.

1. Introduction

Foldable structures are increasingly utilized across industries such as space exploration, civil architecture, robotics, biomedical engineering, and biomimetic engineering [1–3]. Traditional metallic joints in foldable structures are susceptible to plastic deformation, prompting the exploration of jointless folding structures using rigid parts and elastic hinges. Fiber-reinforced polymer composites (FRPCs) offer a promising alternative, with several proposed composite folding structures showcasing novel materials, architectures, and fabrication techniques [4,5].

Designing these structures requires optimization in the design phase, which is challenging due to the difficulty in experimentally determining structural-level elastic constants. Morever, for thin laminates made of single layer of woven fabric, due to the complex undulating patterns of the fibers and substantial differences in material properties between the fibers and the matrix, the real micro-model of the laminate is expected to provide a more accurate bending-curvature response. Non-destructive techniques such as micro-CT (μCT) offer detailed examination capabilities for a wide range of engineering materials,

facilitating the development of voxel-based models for mesh generation and material property assignment since mechanical characterization and determination of elastic constants are time-consuming and challenging. A real 3D voxel based model of thin FRPCs laminates can be used to compute the bending stiffness for the finite element (FE) modeling. Recently, a generic XCT-driven virtual characterization framework was proposed by Ahmed et al. [6] capable to perform homogenization and predict the elastic properties of all the multi-material regions of a FRPC laminate to define the complete stiffness matrix required for the structure-level linear elastic FE modeling.

In this study, a 3D model of the flexible region is developed using X-ray micro computed tomography (XCT). This region comprises a single-layer plain-weave glass fiber reinforced elastomer laminate. The XCT image stacks are segmented into 3D voxels to distinguish fibers, which exhibit anisotropy and local orientation, from the isotropic matrix, which is the elastomer. This segmentation process facilitates the creation of a representative unit cell, known as the representative volume element (RVE). The Voxel model RVE for the elastomer laminate is developed using VoxTex®. The bending stiffness of the real RVE is determined by applying a moment on one side while imposing periodic boundary conditions (PBCs) and symmetry boundary conditions (BCs) on the remaining three sides of the 3D RVE model in the finite element (FE) software ABAQUS®. For comparison, RVE models of homogenized elastomer laminate, meshed with 3D solid FE element C3D8R in ABAQUS®, are also subjected to bending under the same curvature values. A quasi-static bending analysis for small strains is conducted in ABAQUS®, utilizing the linear elastic properties of the constituent materials.

2. Fabrication and Micro-CT

2.1. Fabrication of flexure member and its constituent laminates

To fabricate the elastomer laminate (flexible region), a dry woven glass fabric (GURIT® RE210D) has been infused with a silicone-based elastomer (Smooth SIL™ 936). Smooth SIL™ 936 is a two-part elastomer so appropriate quantitites (10A:1B) as recommended by the manufacturere of both the parts were mixed and poured into the mold followed by degassing for 10 min to remove any trapped bubbles (see **Figure 1**). For manufacturing of the stiff region made-up of the hybrid laminate, a 2×2 balanced twill weave glass/epoxy prepreg known as Hexply® M26 patches was stacked on the dry fabric and cured in hot press as illustrated in **Figure 1.** During the compression molding, a pressure of 2 bar was applied for a duration of 1.5 h at 124ºC . The elastomer mixture was poured on the dry fabric and then left to cure at room temperature for 24 h. The samples were cut in sizes of 200 mm × 20 mm, and 30 mm × 20 mm for µCT imaging. For the fold member, a large sized fabric is taken where the prepregs are placed with a gap which is filled with the elastomer achieving uniform thickness of 0.4 mm following the same technique as for the constituent laminates resulting in a complete flexure member ready for testing (**Figure 1)**.

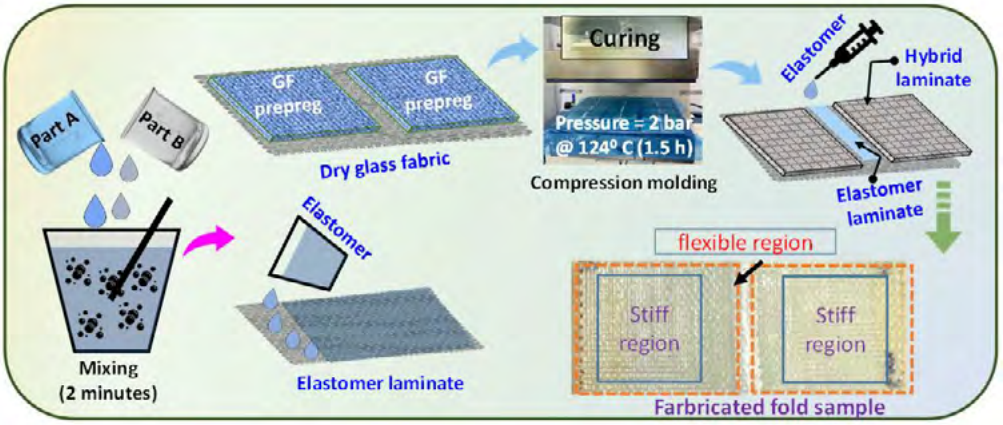

Figure 1 Preperation of elastomer, elastomer laminate and hybrid laminate for XCT and folding experiment.

2.2. Micro-CT assisted virtual characterization

A General Electric (GE) Phoenix Nantom® M X-ray computed tomography (XCT) machine (high-power nano-focus tube with a tungsten target, max capacity 180kV/15W) was used to scan the fabricated thin laminated samples. All the radiographic projections of the two different materials systems were performed with a tube voltage of 120 kV and current of 230 µA. A rotation angle step of $0.36^0/step$ was also provided as a user input to the XCT equipment which was used for the complete 360º radiographic projections of the samples mounted on the rotating platform. For glass fiber reinforced polymers (GFRPs), the recommended resolution is 4 µm [7] which was used to scan all of the samples.

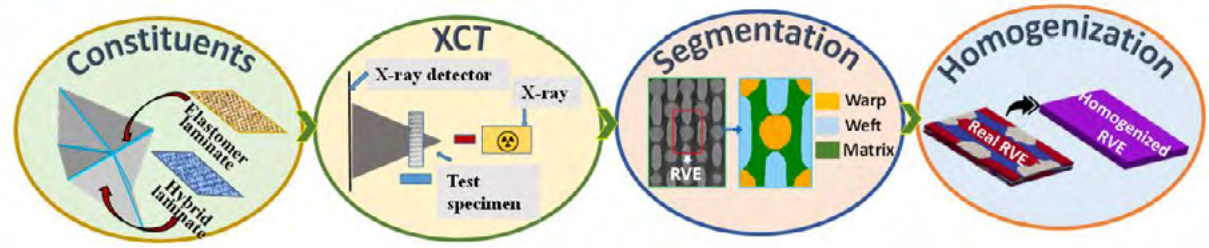

Figure 2 Micro-CT driven virtual characterization for computing homogenized properties of thin laminates

The 3D model and scanned images acquired from the XCT machines provide a digital representation of the actual geometry of the laminate. VoxTex is used for segmentation where a supervised learning technique (a class of machine learning technique) is employed to segment the FRPC laminate into the warp, weft and matrix. It starts with a manual selection of 3D sub-domains from the images provided serving as training sets for the matrix, warp, and weft. The voxel size was set to 16 µm or 4 pixels of 4 µm each as recommended. Segmentation of RVE into different constituents was performed based on a feature vector denoted by f (AGV, β, Phi), where AGV represents average gray value (or density), β signifies anisotropy, and Phi denotes fiber orientation angle. Anisotropy (β) is computed from the eigenvalues of the structure tensor (S), calculated from gradients of the image intensity in a 3D space.

The tensor $\boldsymbol{S}$ is computed from the gradients of the image intensity i.e. $\partial I/\partial x_i$ in a 3D image, $I = (x_1, x_2, x_3)$[7].

$$S_{ij} = \int_W \frac{\partial I}{\partial x_i}\frac{\partial I}{\partial x_j} dv \tag{1}$$

Where (W) is the window size of integration in a 3-dimensional (3D) space. The anisotropy (β) is calculated from the eigenvalues $\lambda_1 \leq \lambda_2 \leq \lambda_3$ of the tensor $\boldsymbol{S}$ and represented as:

$$\beta = \begin{cases} 1 - \dfrac{\lambda_1}{\lambda_3}, \lambda_3 > 0 \\ 0, \lambda_3 = 0 \end{cases} \tag{2}$$

The effective stiffness tensor $[C_{eff}]$ is calculated as:

$$C_{eff} = \sum_{i=1}^{N} w_i [T_i]^T [C_i][T_i] \tag{3}$$

Where w_i is the volume fraction of the i^{th} voxel in the RVE, N is the total number of voxels whereas C_i stands for the stiffness matrix of i^{th} voxel. $[T_i]$ is the transformation matrix used for transforming the local material coordinate system to the global RVE coordinate system. **Figure 2** shows the process of virtual characterization staring from X-ray scanning of constituent laminates to obtain the real and

homogenized RVE. The real RVE model can be imported in any commercial FEA software for futher analysis. In addition, Voxtex® also provides the homogenized elastic constants obtained through orientational averaging of properties of all the voxels in the model. The Chamis model is used for finding the elastic constants of each voxel pertaining to the yarns for which the elastic constants of each constituents are needed. The elastic constants of the glass fiber, epoxy and elastomer used to compute the homogenized elastic constants are given in **Table 1.**

Table 1 Material properties for the constituent materials

Material	**Young's modulus *(E)***	**Poisson's ratio (ν)**
E-glass fiber	72.45 (GPa)	0.22
Epoxy	3.50 (GPa)	0.35
Smooth SIL936	0.80 (MPa)	0.49

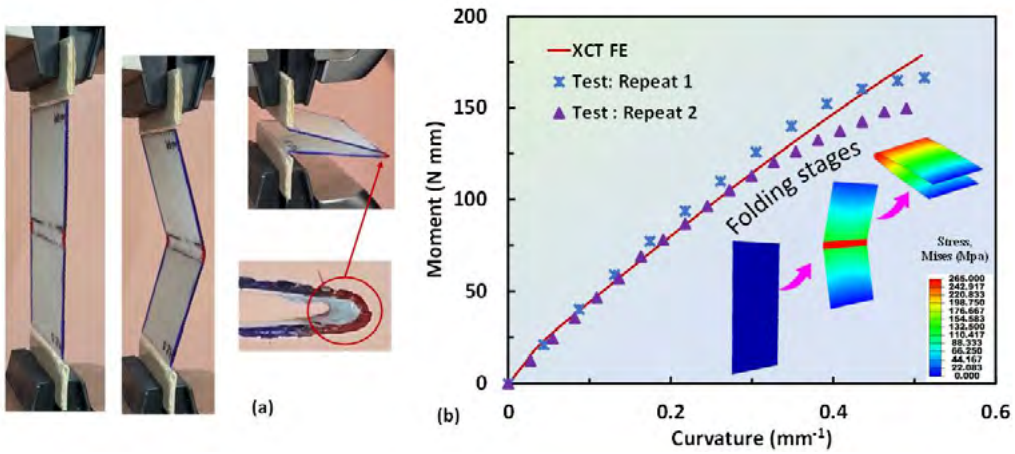

Figure 3 (a) Experimental setup and testing of a fold, (b) Comparsion of test and simulation results for moment vs. curvature of the fold

The bending stiffness matrices computed using the homogenized properties [6] and laminate thickness of the hybrid laminate (stiff laminate) and the elastomer laminate (flexible region) based on the classical laminate theory (CLT) are as follows:

$$D^{hy} = \begin{bmatrix} 129.721 & 20.211 & 0 \\ 20.211 & 155.469 & 0 \\ 0 & 0 & 27.306 \end{bmatrix} \text{N mm and } D^{el} = \begin{bmatrix} 8.689 & 1.273 & 0 \\ 1.273 & 9.786 & 0 \\ 0 & 0 & 0.131 \end{bmatrix} \text{N mm}$$

Where D_{ij}^{hy} is the the bending stiffness of the hybrid laminate and D_{ij}^{el} is the bending stiffness of the elastomer laminte in the flexible region. The bending test and a FE simulation has been perfomed for the fold using the the homogenized elastic constans of the contituents laminates as inputs and the moment vs. curvature results are compared as shown in **Figure 3 (b)** [8]. It can be seen that the FE results obtained using the homogenized properties of the thin laminates are in good agreement with the experimental results.

3. Real RVE

In the previous section, we demonstrated how XCT can be used to develop a voxel based real RVE of any FRPC laminate and to compute the homogenized elastic constants. The bending stiffness of the thin elastomer laminate presented in the previous section is computed from the homogenized inplane elastic constants which may be different from the real bending response due to the intricate undulating patterns of the fibers and the significant material property variations within both the fibers and the matrix. In this section, the real RVE model is used for computing the bending stiffness of the present single-layer

elastomer laminate. To compare bending stiffness obtained through different approaches, RVE models, i.e. homogenized elastomer laminate (HEL) and real RVE-based elastomer laminate (REL) were modeled in ABAQUS and subjected to bending up to the same curvature, achieved by applying an appropriate moment.

Periodic boundary conditions (PBCs) and symmetry BCs were applied to the three sides of the model, while a moment was applied to the fourth side [9] . The FE models displayed in **Figure 4**, measuring 2.128 mm × 1.6 mm × 0.4 mm, were meshed with C3D8R solid elements, with each side measuring 0.016 mm for REL and 0.32 mm for ELP models. Quasi-static bending analysis for small strains was conducted in ABAQUS®, utilizing the linear elastic properties of constituent materials.

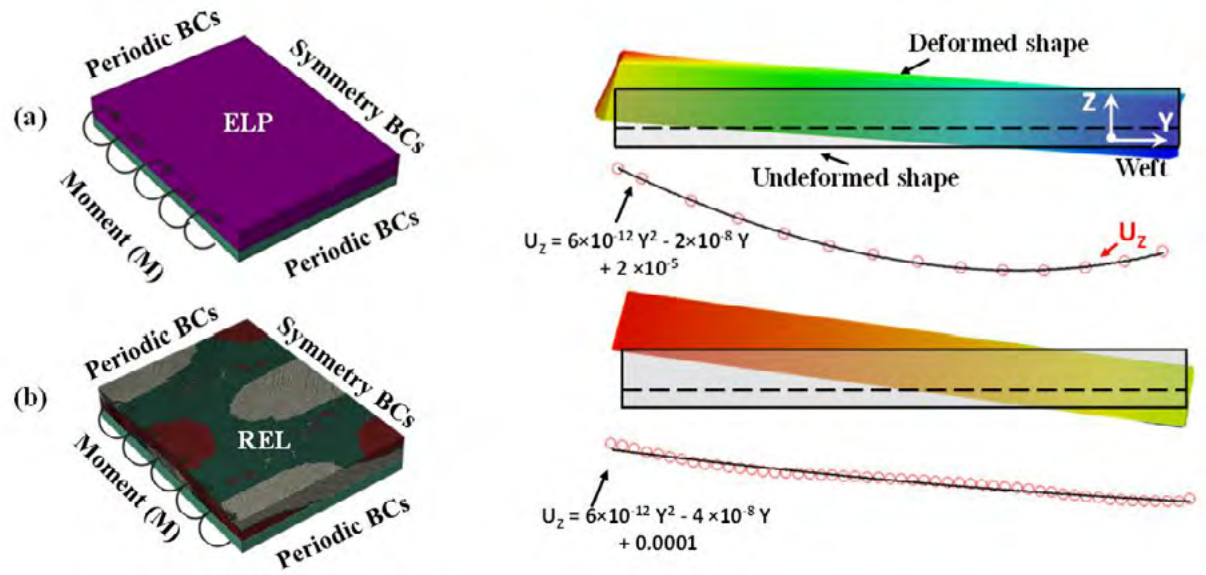

Figure 4: RVE models and the curvatures, (a) homogenized elastomer laminate plus elastomer (HEL) and (b) real RVE based elastomer laminate (REL).

Notably, when HEL is used within the flexible region, the viscoelastic effects from the pure elastomer layer become inconsequential due to the overwhelming dominance of the fabric laminate layer and therefore not discussed here in detail.

Table 2 compares the bending stiffness computed based on the three approaches. It was anticipated that the real RVE model would offer more accurate bending stiffness compared to the other two FE models. However, due to non-uniform curvature associated with local fiber undulation in the plain-weave fabric, the curvature was found to be non-uniform, leading to a highly underestimated bending stiffness. As a result, employing homogenized properties of the elastomer laminate provides a better option for modeling woven fabric thin laminates established through previous studies on XCT-assisted virtual characterization and FE modeling of thin laminates [6,8].

Table 2 Calculation of bending stifness of elastomer lamiante using various methods.

Bending stiffness (N mm)	CLT	Homogenous FE Model	Real RVE FE Model
D_{11}	8.689	8.621	0.392

4. Conclusions

An XCT driven FE model of a real RVE of an elastomer laminate is developed and analysed for its flexural response. The FE model incorporates the material properties of each constituent to be used for obtaining the effective bending stiffness of the thin laminate which is thought to be more accurate than obtained through homogenized elastic constants. However, when moment is applied on the real RVE model a non-uniform curvature is observed owing to the local fiber undulation in the plain-weave fabric leading to a vastly different bending stiffness than that obtained through homogenized RVE model. The strain energies were also found to be in great contrast amomg each other when FE models of pure elastomer , homogenized elastomer laminate plus elastomer (ELP) and real RVE based elastomer laminate (REL) were analysed. The study concludes that there is a significant difference in bending stiffness obtained with the two approaches i.e. using the real RVE and the homogenized RVE for the flexible region. In conclusion, it can be summarized that using the homogenized elastic constants is a better option for modeling woven fabric thin laminates.

Keywords: Variable loading fatigue, Viscoelastic media, Entropy, Numerical simulation, Durability

Abstract
This study numerically predicts fatigue failures in viscoelastic materials caused by variable loadings, employing an entropy damage criterion for analysis. Understanding the durability of polymer matrix resin is crucial for ensuring the long-term reliability of composite materials, as it is a primary factor influencing their overall durability. This dependency on matrix resin, which is time-sensitive, is a critical aspect of our research.
Initially, a general S-N curve is derived from numerical simulations with constant amplitude fatigue loadings. The simulations use a single finite element, incorporating a constitutive relationship based on the entropy failure criterion. The load frequency in this study is a constant 2Hz, with a stress ratio consistently at zero. The material's viscoelastic characteristics are considered, and the dissipated energy related to viscosity work is linked to material damage through entropy value.
In authors' previous work, the authors integrated a constitutive relationship comprising 15 Maxwell models involving entropy damage into the commercial finite element method software ABAQUS, using the user subroutine UMAT. According to the linear cumulative damage (LCD) law, famously known as Miner's law, we determine a random variable loading set for fatigue failure based on the numerically obtained S-N curve. We vary the load sequence of this variable set and predict fatigue failures.
When the load sequence begins with the lowest amplitude, increases in order, and concludes with the highest amplitude, the total lifetime is as long as predicted by LCD, marking this as the longest case for fatigue failures due to variable loadings. Conversely, with a random sequence, the total lifetime is significantly shorter than that predicted by LCD. This shortening is even more pronounced in intermittent fatigue scenarios. In real-world fatigue conditions, such intermittent and random sequence loadings are common, suggesting that actual fatigue lifetimes may be considerably shorter than those predicted by conventional S-N curves and Miner's law. This discrepancy highlights the potential risk in conventional durability evaluation methods.
Furthermore, the study extends to explore the implications of these findings for the evaluation of composite material durability. The research underscores the necessity for more comprehensive and realistic testing methods to accurately predict the lifespan of composite materials in variable loading conditions. Our findings prompt a re-evaluation of standard durability assessment practices, advocating for a more cautious and nuanced approach to ensure safety and reliability in practical applications.

1. Introduction

The durability of Carbon fiber reinforced plastics (CFRPs) is still very important. There are several issues in the study of CFRP fatigue, including underdeveloped numerical simulation techniques, unclear dependence on stress ratio and frequency, unknown residual strength during fatigue, reliance on Miner's rule when the load level changes mid-cycle, unclear temperature dependence, and difficulty in conducting accelerated testing. To address these problems, the Koyanagi Laboratory is focusing its efforts on the study of CFRP fatigue, primarily through numerical simulations, even if this field may seem less prominent now.

When researchers want to quickly assess the durability of a material, they might increase the frequency of cyclic loading, which speeds up the testing process. However, this approach can cause problems when dealing with polymer materials or FRP. Since the durability of FRP is significantly influenced by the plastic matrix, we will consider only the durability of polymer materials. Polymers, being viscoelastic, are highly dependent on frequency. Specifically, different frequencies result in different numbers of cycles to failure. At low frequencies, the material is more affected by the viscous characteristics of viscoelasticity, leading to greater damage accumulation per cycle and a reduced number of cycles to failure. Conversely, at high frequencies, the heat generated due to viscoelasticity surpasses the heat dissipation from the material's surface, causing the temperature of the specimen to rise. As the temperature increases, the rate of heat dissipation from the surface also increases, eventually stabilizing at a temperature where heat generation and dissipation are balanced. Regardless, as the temperature rises, the time-dependent behavior is significantly accelerated according to the time-temperature superposition principle, resulting in greater damage accumulation per cycle and a reduced number of cycles to failure. Consequently, when plotting frequency on the horizontal axis and the number of cycles to failure on the vertical axis, the curve is convex, indicating different results depending on the frequency. The issue is that the peak of this convex curve, where temperature does not rise and the influence of viscosity is minimal, often corresponds to the cyclic loading conditions typically set by researchers aiming to evaluate durability. This means that the durability assessment in fatigue tests tends to overestimate the actual durability of the material.

Next, I would like to discuss cases where the load level fluctuates during cyclic loading. It is important to note that research on this topic is extremely challenging. Even when creating a simple S-N diagram for fatigue, the number of cycles to failure exhibits significant variability. Typically, the horizontal axis is logarithmic, so the order of variability is not in percentage terms but can be several times higher or lower, resulting in considerable spread when considering the actual experimental time. For instance, conducting fatigue tests with only two stress levels, changing from high to low and vice versa, and determining which condition results in a shorter fatigue life is highly complex. Previous results from the Koyanagi Laboratory have shown through numerical simulations that stress variation from high to low results in a shorter lifespan compared to low to high stress variation. When considering the initial loading condition, it was found that a zero-high-low sequence results in a shorter lifespan than a zero-low-high sequence, suggesting that significant stress variations shorten the fatigue life. Moreover, based on Miner's rule, the fatigue life under variable loading is consistently lower compared to constant stress fatigue life. Thus, considering that cyclic loads in real environments are not constant, fatigue tests under constant loads tend to overestimate the material's durability.

To address these challenges, the Koyanagi Laboratory has developed a viscoelastic/elastoplastic entropy damage model to summarize fatigue research encompassing the complex phenomena mentioned above. Additionally, they have developed a mesoscale model based on entropy to simulate strength degradation[1-13]. This work has enabled the creation of a numerical simulation environment for assessing the durability of polymer materials and FRP in general, facilitating a wide range of analyses. In the present study, we focus on durability of viscoelastic media subjected to variable loading fatigue because that of CFRP is dominated by the durability of viscoelastic media itself.

2. Numerical

2.1. Viscoelastic constitutive equation

In this study, parallel maxwell models shown in Fig. 1 is used.

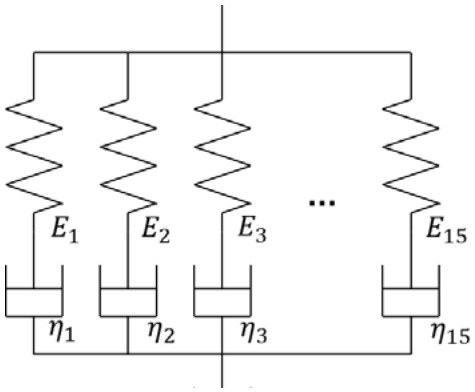

Fig.1 Maxwell model

Creep tests were conducted on epoxy resin over the temperature range of 40°C to 80°C, in 10°C increments, and at stress levels ranging from 10 MPa to 40 MPa, in 10 MPa increments. The obtained results were shifted using the time-temperature superposition principle, and the constants for C(t) were determined by comparing the results with the strain function (Eq.1).

$$\varepsilon(t) = C(t) \times \sigma \qquad Eq.1$$

$$C(t) = \frac{1 + \left(\frac{t}{T_c}\right)^n}{E_0} \qquad Eq.2$$

The inverse of C(t), denoted as the relaxation modulus E(t), was determined with the following parameters: E0 = 3300 MPa, Tc = 1000000, and n = 0.2. This E(t) was considered as the master curve for determining the material constants. While the standard transformation would require a Laplace transform, numerical calculations in this study showed close agreement, and thus, it was considered equivalent. Using the created master curve, the elastic modulus and viscosity coefficients for 15 Maxwell elements were determined. The determined material constants are presented in Table 1.

Table 1 Elastic Modulus and Viscosity Coefficient

No.	Elastic Modulus /MPa	No.	Viscosity Coefficient /MPa・s
E_1	220	η_1	7.94×10
E_2	220	η_2	5.01×10^{3}
E_3	220	η_3	1.00×10^{5}
E_4	220	η_4	6.31×10^{5}
E_5	220	η_5	2.51×10^{6}
E_6	220	η_6	2.00×10^{7}
E_7	220	η_7	3.98×10^{7}
E_8	220	η_8	2.51×10^{8}
E_9	220	η_9	5.01×10^{8}
E_{10}	220	η_{10}	3.16×10^{9}
E_{11}	220	η_{11}	1.58×10^{10}
E_{12}	220	η_{12}	3.98×10^{10}
E_{13}	220	η_{13}	5.01×10^{11}
E_{14}	220	η_{14}	6.31×10^{12}
E_{15}	220	η_{15}	1.00×10^{16}

Also, damage is related to dissipated energy and entropy. The detailed description is shown in some of authors previous works[10, 11].

2.2. S-N curve for constant amplitude fatigue failure and load set for variable loading fatigue

The numerical results for constant amplitude fatigue failure simulations are shown in Fig.2. Based on this result, we determine variable loading set as shown in Table 2, which is based on well-known Miner's law. The simulation is done by one element with commercial finite element analysis software ABAQUS. The entropy damage criterion is implemented using UMAT subroutine in ABAQUS.

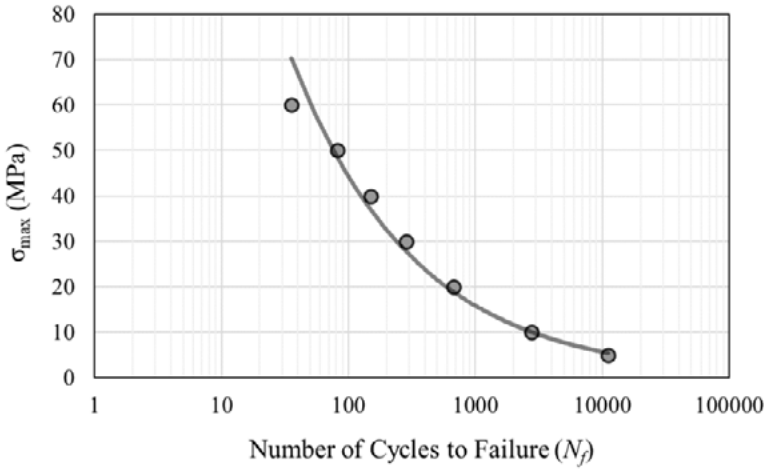

Fig. 2 Numerical results fatigue lifetime for constant amplitude

Table 2 Loading sequence from low to high based on the Miner's law

σ_{max} (MPa)	Number of cycles
5 MPa	371
10 MPa	189
20 MPa	98
30 MPa	56
40 MPa	28
50 MPa	14
60MPa	7

2.3. Results and conclusion

We simulate various patterns using the load set shown in Table 2 in which orders of variable loadings are varied. The results are not what we expected. Almost all cases result in the lifetime subjected to variable loading fatigue are shorter than that estimated by Miner's law. The important thing is that there is an interesting report of experimental work in which the lifetime of a FRP subjected to variable loading fatigue is much shorter than that estimated by Miner's law [14]. In other words, the result in this article is consistent with the numerical result presented in this study.

Abstract
In this paper, we developed an artificial neural network-based viscoplastic model to predict the properties of polymer matrix and combined fiber composite materials. The viscoplastic constitutive model chosen for the neural network features a 3-dimensional J2 yield function and isotropic hardening with power law. The ANN was used to calculate the corrected stress using the trial stress as input in the return mapping algorithm. The flow stress was also considered as an input to account for hardening, and the viscoplastic function was included to address strain rate effects. The training data for the neural network model was numerically generated using conventional return mapping . To optimize data collection and network training , dimensionality reduction techniques were implemented in the data space, including principal stress, deviatoric stress. During training , physics -based constraints were enforced using physics in the return mapping to prevent physically inconsistent predictions . We integrated our trained neural network into an ABAQUS user material subroutine originally designed for simulating the mechanical behavior of short-fiber reinforced plastics. The test involved single- element tests for tensile, shear, and biaxial tensile properties followed by multi-element tests at the part level. Our neural network -based model simulation results closely match those predicted by the return mapping constitutive model.

1. Introduction

Modeling the complex viscoplastic behavior of polymers is essential for accurately predicting the performance of polymers, either independently or as component of fiber composite materials. Numerous constitutive equations have been developed using return mapping based on Newton-Raphson iterations to simulate these viscoplastic properties. [1]

While these methods achieve satisfactory accuracy, their reliance on Newton-Raphson iterations results in significant computational costs and time limitations for practical applications such as pseudo-grain modeling of short fiber-reinforced plastics. Each pseudo-grain represents a set of aligned short fibers embedded within the plastic matrix, and its mechanical behavior can be simulated using Newton-Raphson iterations for every pseudo-grain calculation. [2] This substantial computational burden can be alleviated by employing a data-driven approach in viscoplasticity modeling.

The field of artificial neural networks has been rapidly growing recently, and there is a growing trend to apply artificial neural networks to describe the mechanical behavior of materials. Several studies have shown attempts at using ANN-based constitutive models, with examples seen in applications under plane stress conditions, elastoplasticity or hyperelasticity. [3,4,5] In applying artificial neural networks, it is essential to consider the appropriate reduction of noise for ensuring accuracy and interpretational stability, as well as obtaining an adequate dataset which greatly impacts the final performance.

In this study, we propose a viscoplastic model based on physics-informed artificial neural network that can replace Newton-Raphson iterations. To enhance data collection efficiency and improve overall performance by reducing output noise, we reduced the data space using deviatoric stress and principal stress transformation. We also incorporated physics related to return mapping into the training loss function to reduce noise of output. After the completion of training, the ANN model was implemented to ABAQUS User Subroutine (UMAT) and verified its performance. Single and multi-element simulations were conducted under typical loading paths such as uniaxial tension.

2. An artificial neural network-based constitutive model

2.1 Systems that introduce artificial neural network

With time-discrete stress integration scheme, the target system that introduce artificial neural network follows a J2 effective stress and power law-based isotropic hardening law as,

$$\varepsilon_{ij} = \varepsilon_{ij}^{e} + \varepsilon_{ij}^{vp} \rightarrow \Delta\varepsilon_{ij} = \Delta\varepsilon_{ij}^{e} + \Delta\varepsilon_{ij}^{vp} \tag{1}$$

$$\bar{\sigma} = \sqrt{J_2}, \quad J_2 = \frac{3}{2}(s : s) \tag{2}$$

$$\sigma_y^0 + \kappa(\varepsilon_e^{vP}) = \sigma_y^0 + C(\varepsilon_e^{VP})^B \tag{3}$$

where s is deviatoric stress and $\boldsymbol{\varepsilon_e^{VP}}$ is effective viscoplastic strain. The viscoplastic flow rule representing plasticity uses the Norton's power law as,

$$\dot{\varepsilon}^p = g_v(f)\frac{\partial f}{\partial \sigma}, \quad g_v(f) = \frac{\sigma_y}{\eta}\left(\frac{f}{\boldsymbol{\sigma_y^0}}\right)^m \tag{4}$$

where $\boldsymbol{g_v(f)}$ is viscoplastic function. Accordingly, the yield function f can be expressed as follows:

$$f = |\bar{\sigma}| - \sigma_y^0 - \kappa(\varepsilon_e^{vp}) \tag{5}$$

In the artificial neural network approach, the plastic corrector step in return mapping algorithm is replaced with ANN, while the elastic prediction step remains consistent with the conventional approach. After elastic prediction, consistency condition checks if given loading path induces plastic deformation using trial stress $\left(\boldsymbol{\sigma^{TR}}\right)$ and viscoplastic effective strain with following equation:

$$R = \bar{\sigma}(\sigma^{TR}) - \kappa(\varepsilon_e^{vp}) \tag{6}$$

If the computed value by the equation (6) is less than or equal to 0, it indicates elastic loading; updated stress equals trial stress and there is no accumulation of plastic strain. However, if it is above 0 then a plastic correction is necessary which occurs through return mapping. In a conventional return mapping scheme for viscoplasticity, iterative calculations are carried out based on Newton-Raphson algorithm applied to two equations iteratively.

$$k_\sigma\left(\varepsilon_e^{vp}, \bar{\sigma}\right) \equiv |\bar{\sigma}| + 3\mu_e \Delta\varepsilon_e^{vp} - |\bar{\sigma}|^{trial} = 0 \tag{7}$$

$$k_p\left(\varepsilon_e^{vp}, \bar{\sigma}\right) \equiv \Delta\varepsilon_e^{vp} - g_v(f)\Delta t = 0 \tag{8}$$

Meanwhile when a proposed ANN-assisted method is used, corrected stress can be directly determined without iterative return mapping process.

2.2 Selection of neural network inputs and outputs

To replace plastic correction using ANN, the trial stress obtained from elastic prediction is used as input to obtain corrected stress as output. In general, a 3D stress undergoing return mapping consists of six components, including 3 normal and 3 shear elements. Therefore, to set up stress as input and output, six components need to be added for both input and output, which is very inefficient for ANN construction. On the other hand, when stress is transformed into principal stresses through the principle of stress transformation, the stress can be represented in three principal components without any shear component.

Then, the transformed three-dimensional principal stresses can be decomposed into hydrostatic and deviatoric stresses. Hydrostatic stress does not affect plastic deformation and its value remains unchanged even after plastic correction. Plastic deformation is only affected by deviatoric stress, specifically for the J2 effective stress, stress changes on a 2D plane called deviatoric plane during plastic correction. When transforming the stress to a cylindrical coordinate system with the z-axis perpendicular to the deviatoric plane, only two components are needed because of the zero value for z axis. Since the plastic correction occurs perpendicular to the yield surface, the direction of correction for J2 effective stress always points towards the hydrostatic axis. As a result, when expressing coordinates in terms of radius and azimuthal angle on the deviatoric plane, there is no change in azimuthal angle during correction processes. Ultimately, stress changes due to plastic correction can be represented solely by the radial value ($\mathbf{S_R}$) on the deviatoric plane.

Therefore, the input and output stress of the artificial neural network are represented using $\boldsymbol{S_R}$ on deviatoric plane. Prior to applying the artificial neural network, a transformation of principal stresses, extraction of deviatoric stress, and coordinate system conversion take place. Following application of the artificial neural network, an inverse transformation process is carried out for the calculated output values. After converting output stress to deviatoric stress in the global coordinate system, add the saved hydrostatic component, then transform it to global stress using the stored eigen vector for principal stress calculation. In addition to stress, the flow stress from the previous step is used as an input to reflect the yield function affected by hardening. Lastly, the viscoplastic function value is used as input to account for the influence of strain rate in viscoplasticity. In the case of output, $\mathbf{S_R^{n+1}}$ is used to calculate the corrected stress and flow stress is used to determine the effective viscoplastic strain increment.

$$ANN : \left\{ \begin{array}{l} \mathrm{S}_R^{TR} \\ \rho(\bar{\varepsilon}^{p,n}) \\ g_v(f)\Delta t \end{array} \right\} \rightarrow \left\{ \begin{array}{l} \mathrm{S}_R^{n+1} \\ \rho(\bar{\varepsilon}^{p,n+1}) \end{array} \right\}$$

Figure 1. Proposed artificial neural network

3. Training the ANN model

3.1 construct database for ANN

The training data were generated numerically using a conventional return mapping scheme from an ABAQUS single-element simulation. As explained in the previous section, there are three main values

used as input and output in the artificial neural network: deviatoric stress, flow stress, and viscoplastic function. These three values were extracted by modifying the simulation conditions at each step of the simulation. The modified simulation conditions included final strain for 1 element simulation, time increment size, and strain rate and the established dataspace is shown in fig. 2. Due to significant scale differences between deviatoric stress, flow stress, and viscoplastic function, a regularization process was required.

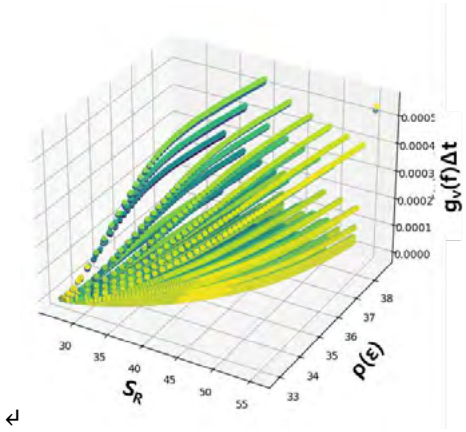

Figure 2. constructed dataspace

3.2 Physics-induced neural network (PINN)

When using an artificial neural network trained only on data, there could be some cases where physically impossible predictions are produced. For example, it is physically impossible for the effective plastic strain to decrease after a plastic correction. However, due to noise in the artificial neural network, such physically unrealistic predictions can be produced and it can lead to instability in finite element analysis when applied. To prevent these physically implausible predictions beforehand, it is possible to incorporate physics into the training of artificial neural networks and construct a Physics-induced Neural Network (PINN). By introducing physics, it is possible to more effectively learn patterns present in the data and aid in building a more stable network. Physics is incorporated into the loss during artificial neural network training by calculating physics loss based on the patterns found between input and output values; this physics loss is then added to the data-driven loss for use in training Two conditions have been added based on incorporated physics used during learning of constructed artificial neural networks: corrected deviatoric stress must be smaller than trial deviatoric stress and flow stress must increase after correction.

3.3 Selecting a neural network structure

To train a neural network, the database was divided into three parts: 90% for training, 9% for testing the final artificial neural network, and 1% for preventing overfitting during training by using it as a validation set. The data split was further refined by employing 5-fold cross-validation to ensure that all data points were utilized at least once for model training and validation. In order to build an artificial neural network that effectively captures the patterns in the data, it is crucial to appropriately configure the number of neurons and hidden layers in the neural network as these parameters directly impact the performance of neural network. In order to find the appropriate combination of neurons and hidden layers, we chose the grid search method. After training each structure for more than 10 epochs, we selected the simplest structure where overfitting did not occur based on the loss from the validation set. The final chosen structure consists of three hidden layers with 24 neurons in each hidden layer. Additionally, for nodes other than the output node, Rectified Linear Unit was used as the activation function.

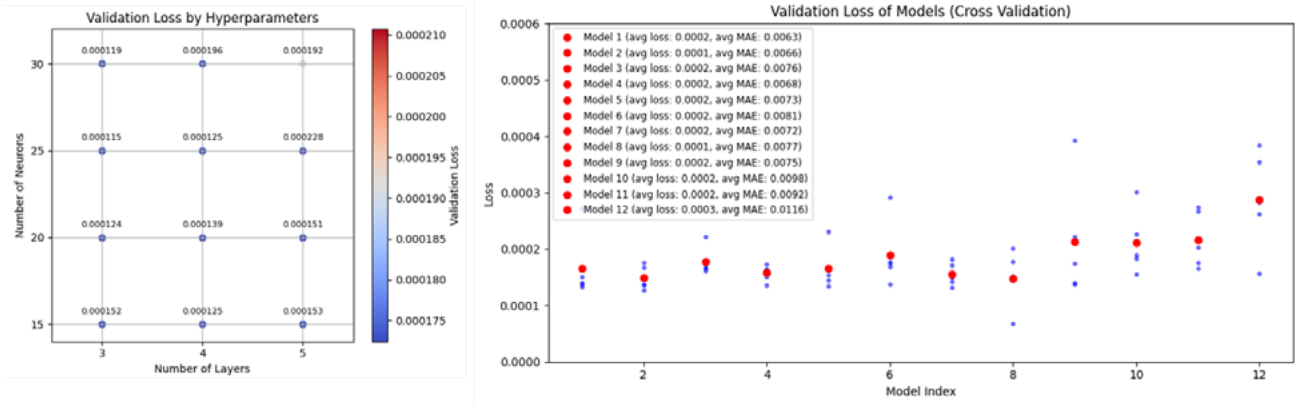

Figure 3. Grid search method and cross validation results

4. Neural network training results and UMAT application results

After completing the training, the artificial neural network was evaluated using test sets. When plotted for both predicted and actual values of two output variables, it showed remarkably high accuracy with an R-squared value of over 0.9999 in both cases as shown in fig. 4. The weights and biases of the trained artificial neural network were extracted and combined with ABAQUS UMAT for short fiber reinforced plastic with viscoplastic matrix homogenized with elastic fibers. Initially, tests were conducted on uniaxial tensile, biaxial tensile with ratio of 3:10, and shear cases for one element each; as shown in fig. 5, all three results closely matched those obtained from conventional return mapping analysis methods. To evaluate analysis stability and computation time, analyses were performed for 1000 elements under tensile and shear loading conditions. In both cases, the analyses completed stably without any aborts occurring and fig. 6 shows that its accuracy is moderate. The time taken for these analyses decreased by approximately 3%, demonstrating improved computational efficiency. When dealing with highly nonlinear paths during analysis, greater reductions in computation time can be expected.

Keywords: Split-Hopkinson pressure bar, Passenger airbag, Strain rate effect, Thermoplastic olefin, polypropylene

Abstract
Airbag covers made of thermoplastic olefin (TPO) material should be deployed quickly without debris under various environments. To accurately predict airbag deployment during a collision, the mechanical properties of polymer materials at high strain rates according to temperature should be considered. In this study, the mechanical properties of TPO and polypropylene were measured at high strain rates via split-Hopkinson pressure bar tests under various environmental temperatures ranging from -35 to 85 °C. Through this, tensile strength and failure strain were derived for each strain rate. As the polymer phase moves toward the high strain rate region, the β-transition becomes dominant, resulting in a non-linear increase in tensile strength in the Eyring plot. Additionally, an airbag module impact simulation was conducted to verify the effects of strain rate on airbag deployment using the LS-DYNA software. It was found that the TPO and polypropylene airbag deployment could be accurately predicted using the strain-rate-dependent mechanical behavior rather than quasi-static properties alone.

1. Introduction

Airbags serve as crucial components within vehicles, offering vital protection to occupants during collisions. According to the US National Highway Traffic Safety Administration (NHTSA), between 1987 and 2010, approximately 32,500 individuals were saved by frontal airbags. These airbags notably diminish driver fatalities by 29% in frontal crashes and reduce fatalities among front-seat passengers aged 13 and above by 32% [1]. Given their pivotal role in safeguarding human life within automobiles, it is imperative that airbags function effectively in the event of an accident.

Under normal circumstances, the airbag cover must withstand impact forces to accommodate the airbag cushion. In the event of a collision, the airbag cover should swiftly open to trigger the airbag module, facilitating the rapid deployment of the airbag cushion within milliseconds. Furthermore, it is crucial that airbags deploy securely, devoid of any fragments that could potentially harm occupants. Airbag covers must endure a range of temperature conditions and demonstrate appropriate opening behavior even under extreme temperatures.

Typically, during deployment in low-temperature environments (e.g., -35 °C), the airbag module should open within a designated cover area without fragmentation. Similarly, in high-temperature conditions (e.g., 85 °C), the cover should not deform or peel upon deployment.

To meet these criteria, thermoplastic olefin (TPO) materials have gained widespread use for airbag covers due to their combination of rubber-like hyperelasticity and the high modulus and strength of plastic. Achieving enhanced reliability in airbag components requires accurate prediction of airbag deployment in car crash simulations. Consequently, it is crucial to thoroughly investigate the effects of strain rates on the mechanical behavior of TPO, given the significant strain rates (ranging from 100 to over 1000 /s) induced during automobile crash events.

During airbag deployment, the airbag chute experiences extremely high strain rates, typically occurring within milliseconds. This underscores the importance for airbag manufacturers to meticulously design their systems, taking into account the strain-rate-dependent material properties.

This study involved measuring the mechanical properties of TPO and polypropylene (PP) at high strain rates using a split-Hopkinson pressure bar (SHPB), a widely employed apparatus for characterizing dynamic mechanical behavior at strain rates ranging from 100 to 10,000 s^{-1} [2,3]. Dynamic stress-strain curves of TPO and PP were recorded at various temperatures and strain rates. Subsequently, an airbag deployment simulation was conducted for passenger airbag (PAB) modules made of TPO and PP materials, incorporating strain-rate-dependent mechanical behavior, utilizing LS-DYNA, an impact finite element analysis (FEA) software. Additionally, a PAB deployment simulation was performed using only static properties of TPO and PP for comparison with results obtained considering strain-rate-dependent mechanical properties.

2. Experimental procedure and simulations

2.1. High strain rate test

Dynamic tensile tests were conducted using a modified tensile Split-Hopkinson Pressure Bar (SHPB), as illustrated in Fig. 1. In the SHPB setup, it is imperative that both the incident and transmission bars remain elastic to adhere to the one-dimensional elastic wave propagation theory [4]. Moreover, the length-to-diameter ratio of the bars must exceed 20 to ensure that the incident and reflected waves, measured by the strain gauge of the incident bar, do not overlap, thus maintaining the principles of one-dimensional elastic wave propagation [5].

For this experiment, the SHPB equipment consisted of two aluminum bars, each with a diameter of 20 mm and a length of 2 m (as specified in Table 1). Strain gauges were affixed to both bars, allowing for real-time measurement of incident, reflected, and transmitted wave signals, as depicted in Fig. 3. Strain gauges with a resistance of 350 ohms (manufactured by TML, Japan) were employed, featuring a gage length of 3 mm and a gauge factor of 2.11 ± 1.0%. To prevent overlap between the reflected and incident waves, strain gauges were symmetrically positioned 420 mm from the ends of the bars, ensuring a distance longer than one wavelength from the specimen.

The strain gauge signals were amplified using an ST-AM1000 amplifier (manufactured by SENSTECH, Korea), providing a 500-fold amplification of the output voltage. The amplified signals were then recorded using a data acquisition system consisting of a PXIe-1082 chassis equipped with a PXIe-5105 digitizer card, manufactured by National Instruments (USA).

Dynamic tensile tests were conducted at strain rates of 1000, 1500, and 2000 s^{-1} by adjusting the pneumatic pressure within the SHPB setup.

Bar diameter	mm	20

2.2. Quasi-static and medium strain rate tests

TPO and PP were evaluated as potential materials for airbag covers. Tensile test specimens were prepared in accordance with the ASTM D3039 standard. In designing the specimen shape, it was essential to ensure that the gauge length was sufficiently short to allow stress equilibrium during dynamic tests and to achieve high strain rates. Thus, a dog bone specimen shape was selected, as depicted in Fig. 4, with dimensions tailored accordingly. The width of the specimen was carefully chosen to minimize stress concentration at its ends, achieved by incorporating a smooth radius of curvature in the transition region. Aluminum grips were utilized to clamp the specimen securely, which were affixed to a cylindrical jig connecting each bar and fastened in place using screws.

2.3. Materials and specimen preparation

TPO and PP were evaluated as potential materials for airbag covers. Tensile test specimens were prepared in accordance with the ASTM D3039 standard. In designing the specimen shape, it was essential to ensure that the gauge length was sufficiently short to allow stress equilibrium during dynamic tests and to achieve high strain rates. Thus, a dog bone specimen shape was selected with dimensions tailored accordingly. The width of the specimen was carefully chosen to minimize stress concentration at its ends, achieved by incorporating a smooth radius of curvature in the transition region. Aluminum grips were utilized to clamp the specimen securely, which were affixed to a cylindrical jig connecting each bar and fastened in place using screws.

2.4. Airbag deployment simulations

Airbag deployment simulations were performed to verify the mechanical properties by considering the strain-rate effect. The simulations were conducted using the commercial FEA software LS-DYNA (Livermore, USA), which is often used for collision analysis. Fig. 2 (a) shows a FEA model of the cockpit of a DN8 vehicle (Hyundai Motors, Korea), while Fig. 2 (b) shows the PAB and airbag deployment. As shown in Fig. 2(c), the PAB deployment system consists of a crash pad, a PAB chute, and airbag housing. A crash pad is fabricated by injecting a PP material, and its function is to protect the driver and passengers by absorbing shock during a collision. The PAB chute, made from Thermoplastic Olefin (TPO) material, is integrated with the crash pad. During an accident, the PAB chute door opens, initiating the deployment of the airbag towards the passenger. The airbag housing, constructed from steel, contains the folded airbags. Upon collision, the inflator explosively deploys the airbag at high speed (refer to Fig. 2(b)).

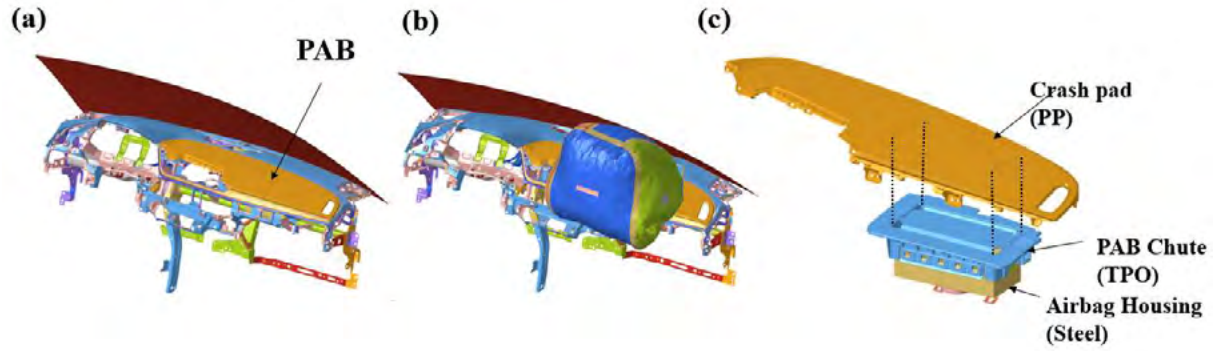

Figure 2. Passenger Airbag module (PAB) deploy FEM simulation ; a)before deploy (b)after deploy c) structure of PAB module

3. Results and discussion

Fig. 3 illustrates the tensile strength of TPO and PP at various temperatures as a function of strain rate, presented in an Eyring plot. Both TPO and PP exhibit significant dependence on tensile strength with respect to strain rate. At quasi-static rates, the Eyring plot shows a relatively gentle slope, indicating a minor increase in tensile strength with rising strain rate. However, at strain rates surpassing 1000 s^{-1}, both TPO and PP demonstrate a notable augmentation in tensile strength, with the rate of increase surpassing that observed at quasi-static rates.

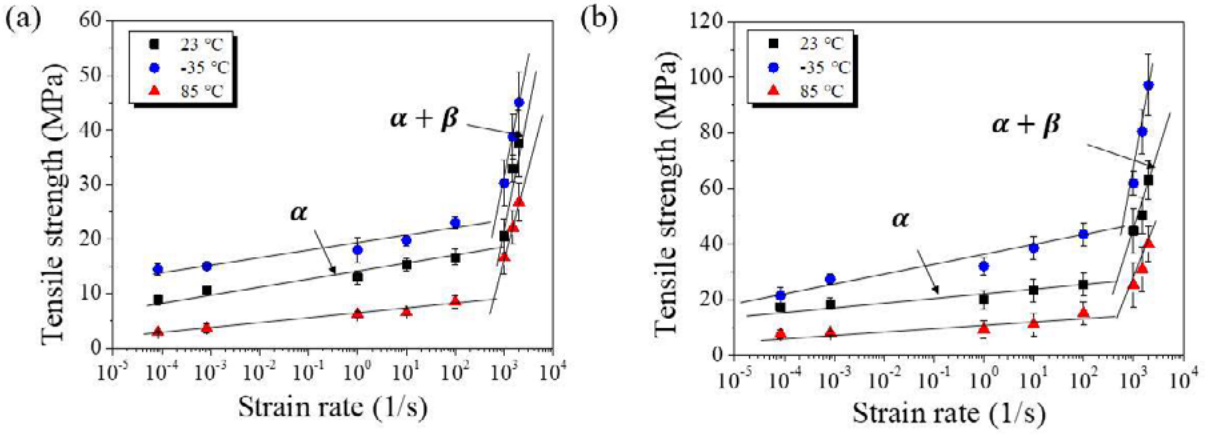

Figure 3. Passenger Airbag module (PAB) deploy FEM simulation ; a)before deploy (b)after deploy c) structure of PAB module

The slope of the Eyring plots for TPO and PP is determined through linear fitting, expressed by Equation (1):

$$\sigma_y = m * \left(\log \frac{d\sigma}{dt}\right) + c \quad (1)$$

The slope was calculated by dividing the tensile strength at each strain rate under each temperature condition into data of less than 100 s^{-1} and data of more than 1000 s^{-1}, and the results are summarized in Table 2. The relationship between tensile strength and strain rate in TPO and PP materials displays a bilinear dependency on strain rate. PP, being a semi-crystalline polymer, exists in two distinct crystalline forms known as the α- and β-phases. The transition between these phases is influenced by both temperature and strain rate.

Table 2. Linear fitting parameters in static and dynamic strain rates of TPO and PP

	Temperature	~100 s^{-1} (α)		1000~2000 s^{-1} ($\alpha + \beta$)	
		m	*c*	*m*	*c*
TPO	- 35 ℃	1.27	19.14	49.11	-117.08
	23 ℃	1.15	13.83	42.62	-102.73
	85 ℃	0.85	6.31	33.58	-84.22
PP	- 35 ℃	2.89	35.32	117.05	-289.82
	23 ℃	1.21	21.97	58.85	-133.22
	85 ℃	1.02	11.09	48.01	-119.58

At low strain rates, PP predominantly undergoes deformation governed by the α-transition, also known as segmental relaxation. This phase transition entails a high activation energy for deformation, resulting in a limited sensitivity of tensile strength to changes in strain rate. However, as the strain rate escalates, the polymer shifts towards the less stable β-phase. In this phase, deformation requires a lower activation energy, leading to a sharp increase in tensile strength with rising strain rate. This transition is known as the β-transition.

At high strain rates, both α- and β-transitions contribute to an elevated slope in the Eyring plot, thereby causing a more pronounced increase in tensile strength with increasing strain rate [6,7,8]. This phenomenon may be attributed to the glass transition moving towards room temperature under high strain rates [9].

The effect of the strain-rate-dependent mechanical properties on the door deployment angle in the PAB module deployment was analyzed and compared with the experimentally obtained deployment angle. As shown in Fig. 4(a), the deployment angle was measured at the center of the airbag door. The angle was measured by tracking three nodes on the crash pad, namely, the door opening point, the rotation center point, and a point on the pad. The angle was measured at two positions: the front door on the passenger side and the back door on the windshield side (see Fig. 4(a)). When the strain-rate-dependent material properties were used in the FEA model, the door angle changed faster than when only quasi-static mechanical properties were used in the FEA model. It is noteworthy that the strain-rate-dependent

behavior could make the FEA results more accurate, similar to the actual experimental results (see Figs. 4b–d).

This observation underscores the significance of strain-rate-dependent mechanical properties in enhancing the accuracy of FEA predictions. When solely quasi-static mechanical properties are utilized, the FEA model tends to reflect relatively low tensile modulus, tensile strength, and larger failure strains. Conversely, accounting for strain-rate-dependent mechanical properties leads to rapid airbag deployment, driven by the tendency for higher strain rates to correlate with increased tensile strength and reduced failure strains.

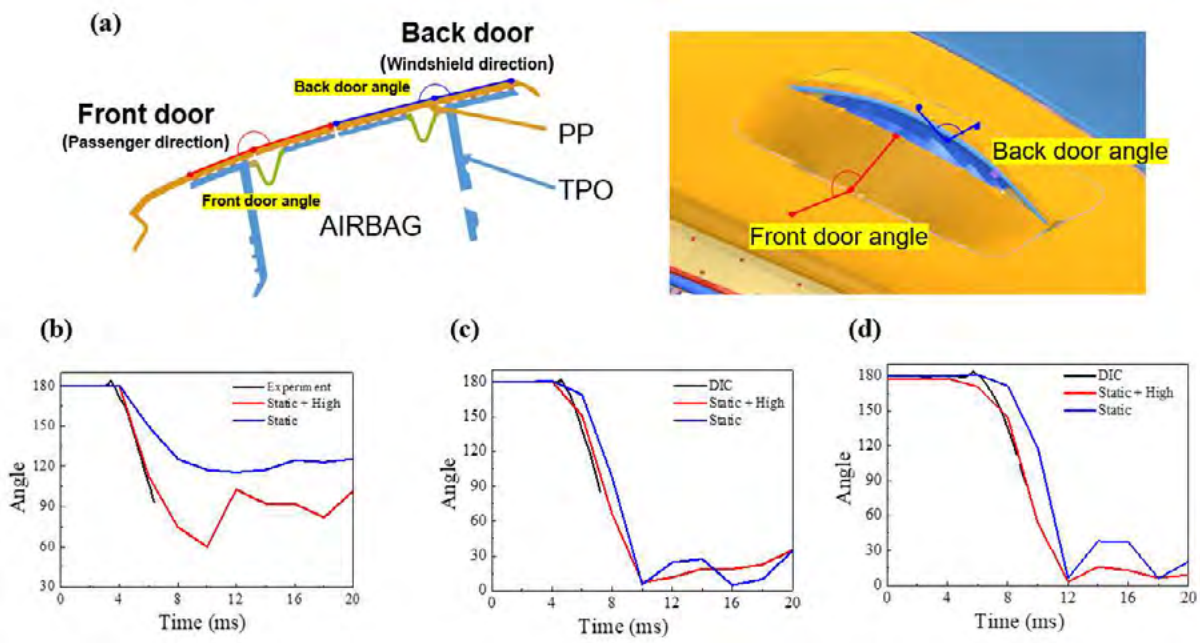

Figure 4. Passenger Airbag module (PAB) deploy FEM simulation ; a)before deploy (b)after deploy c) structure of PAB module

4. Conclusions

In this study, the strain-rate-dependent mechanical behavior of thermoplastic olefin (TPO) and polypropylene (PP) was measured under high strain rates and various temperature conditions using split-Hopkinson pressure bar equipment. The measurements were verified via high-speed camera imaging and digital image correlation analysis. Using the strain-rate-dependent properties of TPO and PP, an FEA simulation of passenger airbag (PAB) deployment was carried out and compared with the airbag deployment experimental results. It was found that the deployment angle and PAB deployment behavior could be accurately predicted using the strain-rate-dependent mechanical properties. Based on the results and findings of this study, it is suggested that the strain-rate-dependent mechanical properties should be measured and used in PAB chute simulation and design, because plastic materials show a much stiffer modulus and higher strength as the strain rate increases.

Keywords: failure prediction, z-beam, composite, aeroelastic tailoring, machine learning

Abstract
Aeroelastic tailoring is a promising passive aeroelastic control method that can benefit the aerodynamic and structural performance of aircraft. To achieve the maximum performance of aircraft, original wing concepts need to be optimized in early design stages. For this purpose, it is necessary to enable fast prediction of the properties and performances for the wing box. Using an original Z-beam wing box concept as an application example, a two-level multi-scale machine learning model is proposed for the preliminary design of high aspect ratio wings with Z-beam structures applied in the wing tip region. The proposed model consists of two parts: 1) at the level of global Z-beam wings, a model is trained to predict the weight, homogenized stiffness, and potential failure hotspots of a Z-beam unit cell; 2) in the level of local hotspots, a model is trained to predict the failure indices from LaRC05 failure model. Unit cells of wing box with different geometric parameters and composite layups are sampled and simulated to build a database for training. Results show that the proposed model achieves high prediction accuracy for the novel wing structure.

1. Introduction

Europe's aviation industry has announced its initiative, Destination 2050, towards the net zero European aviation [1]. Increasing the wing aspect ratio to reduce induced drag is one of the main approaches [2]. For example, Boeing's 777-X utilizes a folding wingtip to increase its wingspan [3]. Airbus' zero emission (ZEROe) program [4], University of Bristol's Ultra-Green wing (BUG)[5], among others, are exploring the benefits and challenges of high aspect ratio wings in all aspects [2]. One of the major challenges is that the high aspect ratio significantly contributes to the wing structural weight [6].

Aeroelastic tailoring is a promising passive approach to affect the aerodynamic and structural performance in a beneficial way [7]. Stodieck and Airbus proposed a Z-beam structural concept to achieve more efficient aeroelastic tailoring, especially to reduce the manoeuvring and gust loads [8][9]. This can serve as an enabler to address the aeroelastic challenges of HARW, as shown in Figure 1. The black lines represent the spar and rib of the wing box, the grey lines represent the stringers, the red lines represent the Z-beam.

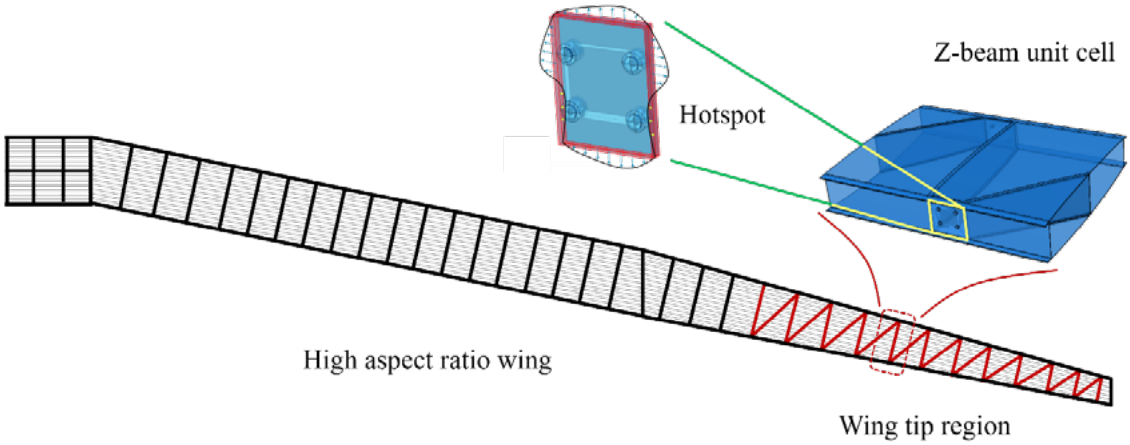

Figure 1. Z-beam structures in the wing tip region, and the hotspot for failure

In this paper, a two-level multi-scale machine learning model is proposed for the fast prediction of novel wing structures. The Z-beam structure is selected as an example. The behaviour of the Z-beam wing box of wing tip is represented by segmenting the Z-beam into several unit cells, as shown in Figure 1. The unit cell model is simulated under periodic boundary conditions including tension, bending and torsion. After identifying the hotspot of composite failure in the unit cell model, a refined local model for the hotspot is built for failure analysis.

2. Parametric Modelling and Computational Methods

2.1. Parameters of the Z-beam Unit Cell

The Z-beam unit cell consists of the upper and lower cover skins, the front and rear C-shape spars, the zigzag I-shape beam, and bolts. The bolts are made from Ti-6Al-4V aerospace grade titanium, the material for other parts is IM7/8551-7 carbon/epoxy. For simplicity, only three independent geometric parameters are chosen, as shown in Figure 2. Their meaning and range are listed in Table 1. It should be noted that the span-wise length (L_z, mm) is dependent on α_{beam}. The laminate layup is the same when the thickness is the same, and it is not changed during sampling or machine learning.

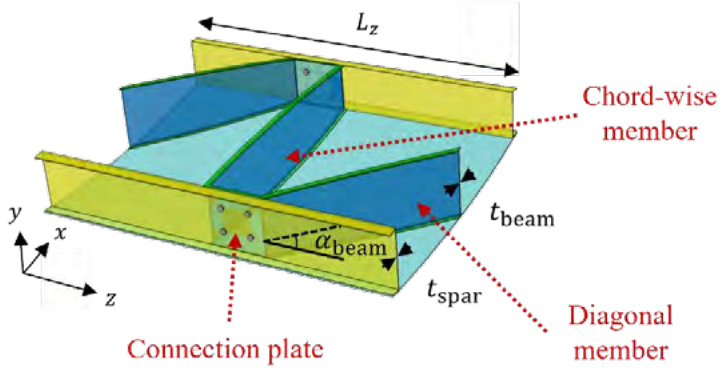

Figure 2. Geometric parameters of the Z-beam unit cell model

Table 1 Independent geometric parameters

Variable	Meaning	Range
t_{spar} (mm)	thickness of spar	[5, 25]
t_{beam} (mm)	thickness of beam	[10, 22]
α_{beam} (°)	angle between diagonal member of the beam and the spar	[20, 60]

2.2. Periodic Boundary Conditions

The behaviour of the complete zigzag beam in the wing tip region of BUG wing, as shown in Figure 1, is approximated by Z-beam unit cells arranged in a one-dimensional series. The aeroelastic deformation of the full wing box can be simulated by reduced order models [10], which only requires the homogenized stiffness matrix of each unit cell (Eq. 1).

$$\begin{bmatrix} F_z \\ M_z \\ M_x \\ M_y \end{bmatrix} = \begin{bmatrix} C_{11} & C_{12} & C_{11} & C_{14} \\ C_{21} & C_{22} & C_{23} & C_{24} \\ C_{31} & C_{32} & C_{33} & C_{34} \\ C_{41} & C_{42} & C_{43} & C_{44} \end{bmatrix} \begin{bmatrix} \epsilon_z \\ \kappa_z \\ \kappa_x \\ \kappa_y \end{bmatrix} \tag{1}$$

The loads applied on the unit cell model include the axial strain in z-axis (ϵ_z), twist rate about z-axis (κ_z, rad/mm), and the curvature about x/y-axis (κ_x, κ_y, 1/mm). The loads are employed using periodic boundary conditions (PBCs).

2.3. Finite Element Models

Abaqus is used as the numerical solver in this work. The failure criterion is the LaRC05 failure criteria [12]. A global-local modelling approach is employed to use a more refined mesh for the hotspot, so that more accurate failure predictions can be obtained. The details can be found in [13] and are therefore not repeated here.

3. Machine Learning for Z-beam wing boxes

3.1. Database

The database is built by evenly spaced sampling in the range listed in Table 1. There are 470 valid unit cell samples in the database. The homogenized stiffness matrix [C] and mass matrix ([M]) are extracted. Figure 3 shows the relationship between the stiffness components with geometry parameters. It shows that t_{spar} dominates C_{11}, C_{33}, C_{13}; t_{beam} dominates C_{23}; t_{spar} and t_{beam} have same level of influence on C_{22}.

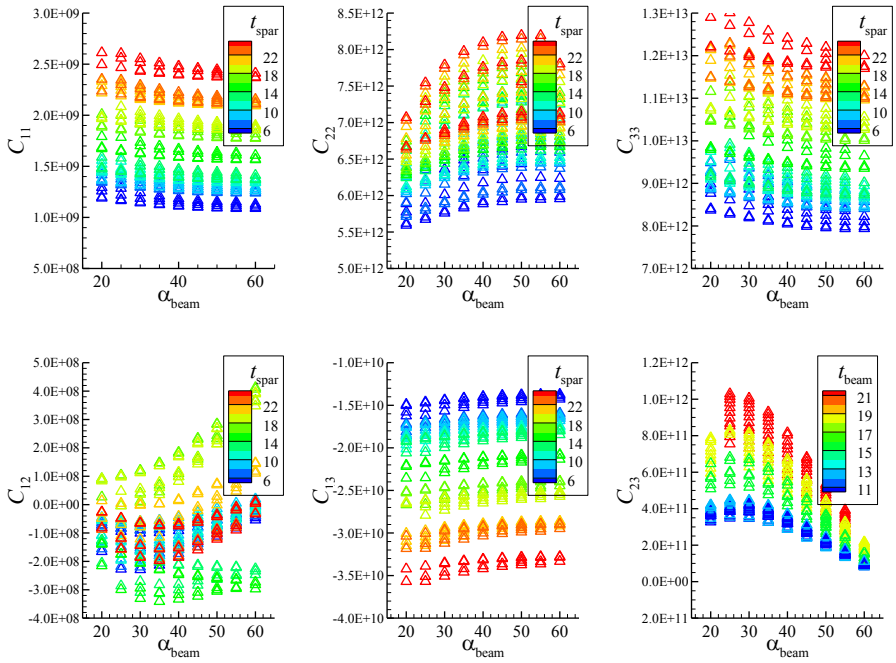

Figure 3. Distribution of stiffness components in the database

3.2. A Machine Learning Model for Z-beam Unit Cell's properties

A machine learning model is used to predict the properties of Z-beam unit cell that are independent of the loads, i.e., the weight and homogenized stiffness matrix. The model input is the geometric parameters,

the output is the weight (w) and components of the stiffness matrix, as shown in Figure 4. Denote the geometry parameters as $\boldsymbol{\theta} = [t_{\text{spar}}, t_{\text{beam}}, \alpha_{\text{beam}}]^T$. A simple artificial neural network (ANN) is employed, which contains three hidden layers with 512 neurons. The loss function is the mean square error (MSE) between the predicted values and the real values. The initial learning rate is 0.001 for 500 epochs. Adam optimizer[14] is used for training. 20 samples are randomly selected for testing. Figure 5 shows the prediction error on the training set and testing set during training. It shows that the model can achieve a good prediction accuracy.

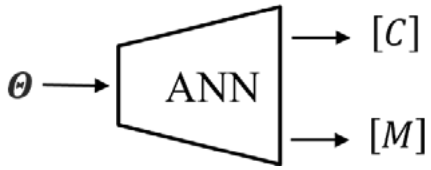

Figure 4. ANN for the prediction of weight and stiffness

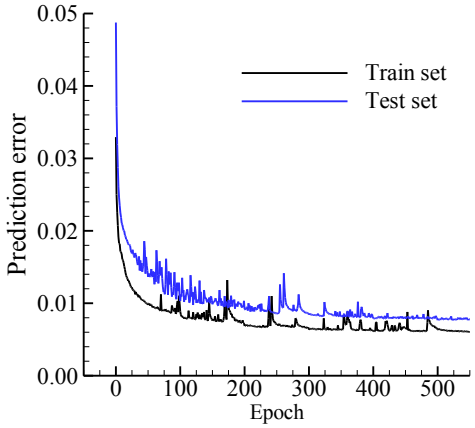

Figure 5. Prediction error on the training set and testing set during training.

3.3. A Two-level Machine Learning Model for Failure Prediction

As the results in [13] showed, the failure always happens around bolt holes. Since the geometry of the hotspot model is the same for unit cells with different beam angles, splitting the failure prediction into two levels can reduce the need for training samples. Figure 6 shows the architecture of the two-level machine learning model. The unit cell level model predicts the displacement boundary of the hotspot ($\boldsymbol{u}$) under specific geometry ($\boldsymbol{\theta}$) and loads $\boldsymbol{\Delta} = [\epsilon_z, \kappa_z, \kappa_x, \kappa_y]^T$. The hotspot level model predicts the stress field around bolt holes based on the geometry ($\boldsymbol{\theta} = [t_{\text{spar}}, t_{\text{beam}}]^T$) and boundary condition ($\boldsymbol{u}$). Then, the failure index field is calculated with the LaRC05 model, the maximum failure index is extracted, and the failure mode is determined. The two models, one of each level, are trained separately with their corresponding database. The loss function is the mean square error (MSE) between the predicted values and the real values. The initial learning rate is 0.001 for 2,000 epochs. Adam optimizer is again used for training. The database of the hotspot model is still in progress. The results will be presented in the conference.

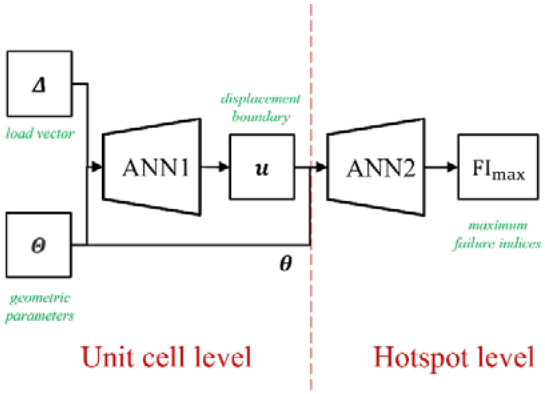

Figure 6. Two-level model for the failure prediction

4. Conclusions

The Z-beam structure can provide custom bending-torsion couplings by changing its geometry. A simple neural network is trained to predict the homogenized stiffness of the Z-beam unit cell, which provides fast and accurate predictions for preliminary design of high aspect ratio wings. A two-level machine learning model is proposed and trained for its failure prediction. The model takes advantage of the linear characteristics of the physical nature in its failure behaviour. Therefore, the proposed machine learning model achieves good prediction accuracy and generalization ability with fewer training samples. This approach is therefore shown to be usable for early-stage design of generic original composite concepts.

Keywords: multiscale, composites, wing, machine learning, failure prediction

Abstract
A multiscale modelling approach is introduced to accurately predict the failure mode of a non-conventional wingbox structure with increased bend-twist coupling. The proposed methodology consists in employing both global-local analysis and machine learning to estimate the failure indexes of a bolted joint in a new structural concept. Applying strain based global loads, the failure indices of the local model are calculated and used to train a machine learning model, currently being trained. The expected outcome is a fast failure prediction tool for the analysis of novel structural features.

1. Introduction

As the aeronautical industry aims to reduce its impact on the environment, different designs and solutions have been proposed such as the change from metal to composite airframes. Another promising solution is the use of High Aspect Ratio Wings (HARW), which are able to offer higher aerodynamic efficiency and therefore less fuel consumption. However, some challenges arise due to their increased span, such as higher root bending moments and non-linear aeroelastics. A new concept, the Z-beam concept (Figure 1), was introduced by Stodieck [1] as a potential structural concept able to provide custom tailored bend-twist coupling of wings. This can serve as an enabler to address the aeroelastic challenges of HARW [2].

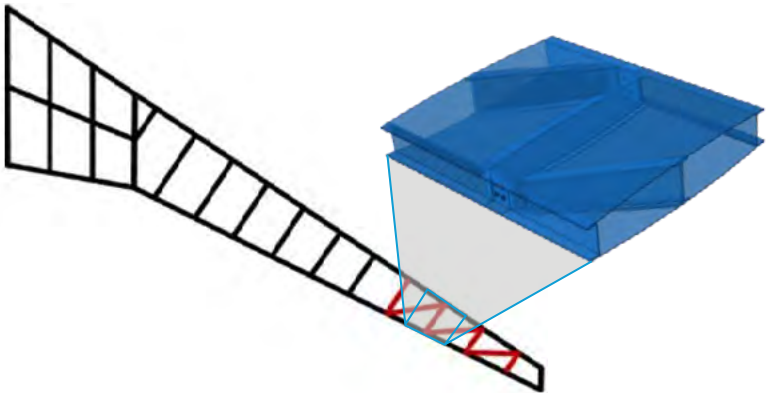

Figure 1. Z-beam concept.

However, moving away from conventional design brings significant challenges in the structural analyses of such novel configurations. Therefore, detailed analysis and simulations are required to evaluate these new concepts to ensure the structure satisfies the strength requirements (or a multitude of potential failure modes). Still, detailed numerical analysis of such components can also be time consuming, specially when large models are involved and sufficient accurate stress states need to be captured. This prevents its usage in the design stage, when multiple rapid iterations are required. In this work, a multiscale modelling strategy, including composite failure and machine learning, is introduced as a way of reducing costs and time in the design of novel components.

2. Methodology

The proposed methodology consists in a two-level multiscale analysis strategy, at the global and local levels, followed by machine-learning models. The workflow (Figure 2) starts by determining the strain-based loads which are to be applied on the global structure. This is a representative structural element of the wing, assumed to be subject to Periodic Boundary Conditions (PBCs). The analysis yields the displacement field, which is used to extract the boundary conditions of the local model. This is a more detailed model of a structural feature, in this case, the bolted joints of the spars, which can be used for failure indices estimation. The global-local analyses can be performed for a multitude of structural dimensions and applied loads. Generating sufficient data, it is then possible to train a machine learning model, which aim is to predict both the local model boundary displacements and maximum failure index based on the applied strains.

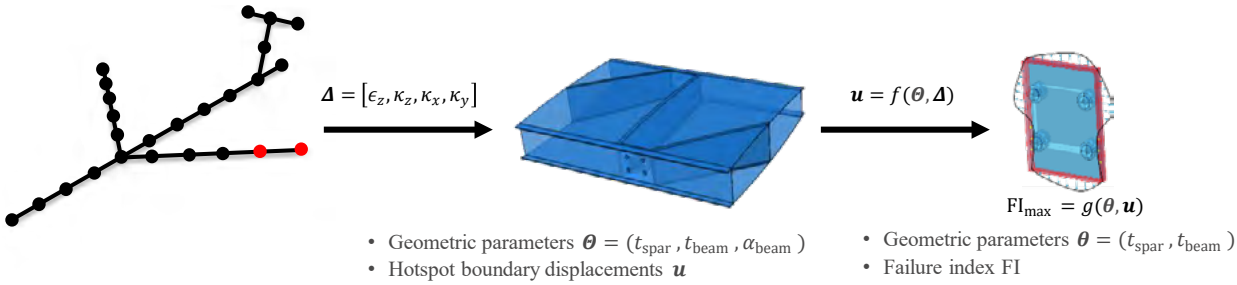

Figure 2. Multiscale model strategy workflow.

2.1. Global-Local

The global-local simulation strategy is a useful approach to be followed when a higher level of detail is needed to analyse a specific region, in this case, the bolted joints (Figure 3) of a larger parent structure [3]. There are different ways of employing this strategy. The one used in this work is referred to as series method [3]. In this method, after the displacement field of the global model is known, the values of the relevant nodes at the boundary of the zone of interest are used as interpolation points for the local model boundary displacement reconstruction.

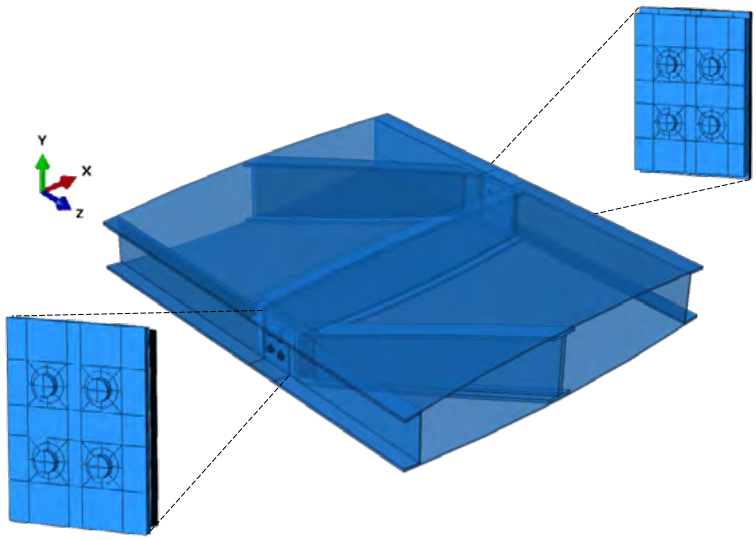

Figure 3. Global and local finite element models.

2.2. Machine learning

A physics guided artificial neural network model is proposed, the details of which can be seen in Ref. [4].

3. Finite element models

3.1. Geometry

The geometry of the Z-beam wing box was generated so it is fully parametrised, having 30 different parameters such as the angle of the diagonal members, airfoil shape and component thicknesses. The local model mimics the geometry of the bolt connection of the global counterpart.

3.2. Materials

The materials used for the composite parts are IM7/8551-7 carbon/epoxy and Ti-6Al-4V for the bolts. A model [5,6] evolved from LaRC05 [7] failure criteria was employed using an UVARM sub-routine to determine the failure indexes for different failure modes.

3.3. Mesh

Continuum shell elements with reduced integration (SC8R) were used to model the laminates of the global model, meaning 1 element per laminate with an attributed composite section. 8-noded linear brick elements (C3D8R) with enhanced hourglass control were employed in the local model and in the bolts of both models, having a 1 element per ply strategy been followed. The size of the mesh was sufficiently refined so that the convergence was attained. The final element ratio is approximately 15, i.e., the smallest element edge length in the radial direction in the local model is 15 times smaller than in the global one. Both meshes are displayed in Figure 4.

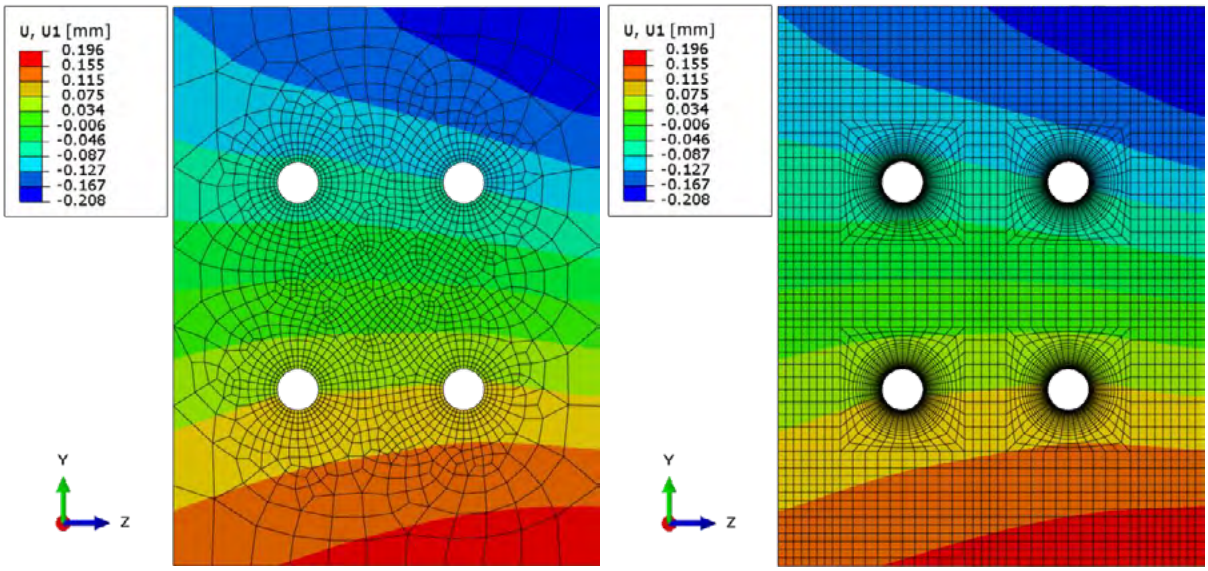

Figure 4. Global (left) and local (right) meshes and comparison of the U_1 displacement field.

3.4. Loads

Four different loading scenarios: tensile, bending due to drag and lift forces, and torsion, are applied using periodic boundary conditions which ultimately allows to determine the homogenised stiffness matrix of the Z-beam representative structural element.

4. Results

Regarding the local model, results have shown that its implementation is necessary once the registered strains to failure suffer a significant reduction for every load case (50-60%). This is due to the use of a more refined mesh, which is able to better capture the high stress gradients that arise near the hole boundaries, as seen in Figure 5.

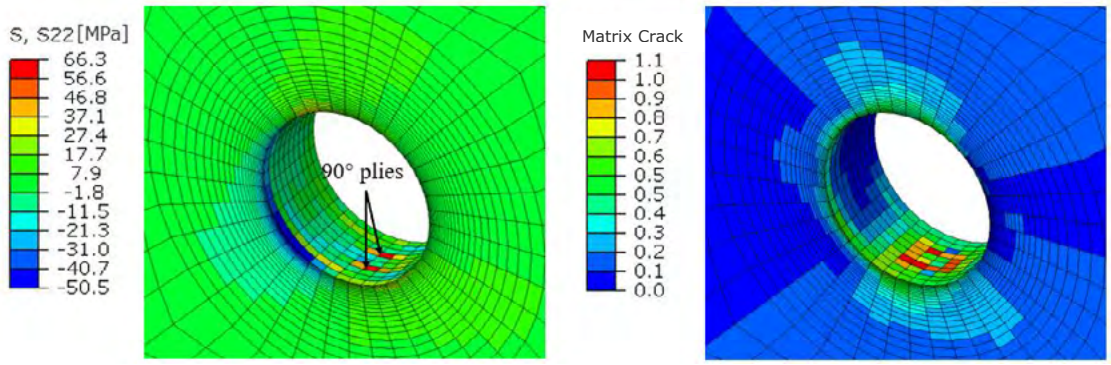

Figure 5. In-plane transverse stress (left) and matrix cracking failure index (right) fields at a spar bolt hole.

Relatively to the critical spots and failure mechanisms it was observed that the critical bolt holes were tendentially the same, having the failure mechanism transitioned from compressive nature failure modes to tensile ones, due to the high stress concentrations. The physics based neural network is currently under training, and the respective results will be shown at the conference.

5. Conclusions

A multiscale strategy is introduced as a fast and accurate composite failure prediction model, which is applied to a non-conventional wing box structure. For a strain based load applied to a representative structural element model of the new concept, the displacements are retrieved and enforced in a bolted joint local model, after which, the failure indices are calculated using LaRC05 failure criteria. A machine learning model is being trained with the available data generated for different cases. This methodology is promising for the design of novel components and features, reducing computational costs while maintaining a suitable degree of accuracy.

Keywords: Vacuum-Assisted Resin Infusion (VARI), Composite Sandwich Panels, Computational Fluid Dynamics (CFD), Experimental Validation, Infusion Time, Flow Front

Abstract
The manufacturing of wind turbine blades predominantly features composite sandwich panels made through the Vacuum-Assisted Resin Infusion (VARI) process. These sandwich regions involve multiple components, which include a lightweight balsa or foam core with grooves and channels encased in non-crimp glass-fibre fabric skins. Understanding resin flow behaviour and infusion time through these materials is difficult as there are a large number of parameters to consider. Therefore, this study focuses on developing a Computational Fluid Dynamics (CFD) model to provide a more accurate prediction of resin flow for the investigation of a wide range of parametric changes. The CFD model is initially developed to simulate resin flow through the lower reinforcement layers and shallow grooves of composite sandwich panels. The simulated flow front has been compared with the experimental ones captured at the top and bottom of the fabric at different infusion times. The experimental and simulated results agree relatively well; providing a new venue for investigating resin infusion performance through complex features of the layup. Furthermore, the model has been exploited to investigate the influence of groove spacing on the flow front, resin-filled volume, and infusion time.

1. Introduction

Vacuum-Assisted Resin Infusion (VARI) is an essential process in the modern composite manufacturing industry, particularly in wind turbine blade manufacturing, which requires large-scale production of lightweight and efficient components. Understanding resin flow plays a crucial role in this process [1]. Significant areas of wind turbine blades comprise composite sandwich panels, which provide the twofold benefit of high strength and lightweight regions. The representative layup of these panels consists of two configurations of glass NCF, including unidirectional and biaxial layers, serving as composite skins [2]. These layers are positioned on both sides of a lightweight foam core with specific grooves and channels to improve formability and resin flow. Additional layers of resin distribution media, perforated release films, and peel plies are also used underneath the vacuum bags to support resin flow and demoulding during manufacture. Understanding the resin flow and filling of these sandwich regions is critical as it directly relates to the performance and quality of the wind turbine blade.

Computational Fluid Dynamics (CFD) models have shown considerable success in predicting resin flow for different infusion techniques, including VARI, resin injection pultrusion, resin film infusion, resin transfer moulding, etc. [3–8]. The majority of the CFD models employed for the modelling of resin transport in porous media rely on Darcy's Law, linking fluid velocity to pressure drop within the

medium, resulting in a single differential equation [9–11]. A detailed summary of the simulation studies within the scope of the VARI process has been outlined by Pierce [2]. Such modelling approaches are sufficiently helpful in predicting the resin flow and approximate infusion time within the porous media; however, they neglect some considerable features [12]. For example, the interplay of the groove channel flow with the fabric-reinforced layers or the through-thickness flow behavior is commonly overlooked.

In this study, a CFD model has been developed to simulate resin flow through shallow grooves and the lower reinforcement layer of non-crimp glass-fiber fabric skin. The simulated results are compared with experiments to analyze the flow fronts at the bottom and top of the reinforcement layer. Furthermore, the effect of the cut-to-cut distances of shallow grooves on the flow fronts, resin-filled volume, and infusion time has been investigated. Section 2 outlines the methodology of the study, providing details of the experiments conducted and the CFD model. Section 3 presents the results of the study. Finally, the conclusions drawn from the results are summarized in Section 4.

2. Methodologies

2.1. Single channel flow experiments

In order to validate the CFD models, a series of single channel flow experiments were conducted. Four layers of 250×900 mm^2 biaxial glass fabric were sandwiched between an acrylic plate with a single machined channel and a tempered glass mold. The average thickness of the fiber preform was 2.2 mm. Permeability values for the fabric in three principal directions were determined from an independent set of experiments consistent with previous studies [13,14]: K_1 = 1.89e-10 m^2; K_2 = 6.14e-11 m^2; K_3 = 1.093e-11 m^2; with a K_1 orientation of 45.19 ± 1.38° relative to the roll direction. The 900×250×14.7 mm^3 transparent polymethyl methacrylate (PMMA) plate was used instead of real core material for two reasons: firstly, to simplify the validation case for modelling (avoiding resin absorption into the core) and secondly, to allow for video observation from both sides of the experiments.

The machined channel was produced with dimensions 1×3 mm^2 and a pressure sensor was placed as close to the channel inlet as possible as shown in Figure 1-a, to help establish the inlet pressure boundary conditions over time for modelling. The whole configuration was covered by a vacuum bag, representative of a typical VARI process, and a 200 mm peel-ply breaking zone was used to arrest the flow between the end of the channel and the vacuum outlet.

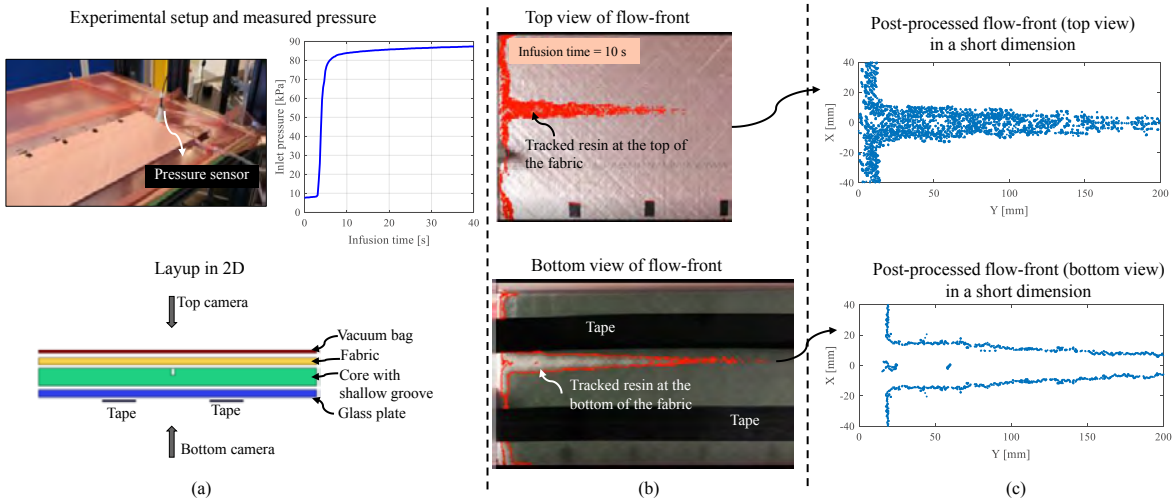

Figure 1. In-plane experiments and data post-processing. (a) Experimental setup, layup details, and the measured pressure profile over time; (b) Flow-front captured by the top and bottom camera after the tracking of the resin at the top and bottom of the fabric, respectively; (c) Post-processed flow-front in a short dimension to compare with the simulation results.

An 85% glycerol-water solution with density 1222 kgm^{-3} was used as the test fluid, with a viscosity of 0.0963 Pa.s at 20 °C, which is representative of a typical low-viscosity resin for infusion. The pressure difference between the fluid reservoir at the inlet (open to ambient conditions) and the vacuum outlet (set with a constant 7500 Pa pressure) was used to drive the flow in the experiments. Videos recorded from both the top and bottom of the experiments were processed with a Python image-processing script based on the OpenCV library in order to track and visualize the flow front position over time as seen in Figure 1-b. The flow front propagation has been investigated for a reduced area of interest (80×200 mm^2), cf. Figure 1-c, in order to assist the CFD analysis described in the later section.

2.2. CFD model

The CFD model has been developed in FLOW-3D® [15] to simulate resin flow through the lower reinforcement layers and shallow grooves of composite sandwich panels. The model comprises a non-porous shallow groove in the core material and a porous channel at the top replicating the lower reinforcement layers of non-crimp glass fiber fabric skins, cf. Figure 2-a. The figure 2-a also shows the computational domain and implemented boundary conditions. The porous channel and the shallow grove are assigned pressure inlet boundary conditions at one end and pressure outlet at the other end. Time-dependent pressure boundary conditions have been implemented at the inlet according to the measured values in the experiment (cf. previous subsection) to better replicate experimental conditions. A constant pressure of 7500 Pa is applied at the outlet to mimic the vacuum outlet pressure during experiments. The top plane of the domain is a stationary wall representative of a rigid mold surface. The bottom plane (i.e., bottom of the porous channel and shallow groove) is also assigned to wall boundary conditions, reflective of the PMMA experiments. Although it should be acknowledged that this configuration neglects any fluid absorbance into the real core material. The rest of the planes are assigned to continuative boundary conditions having a zero velocity gradient while exiting the boundary.

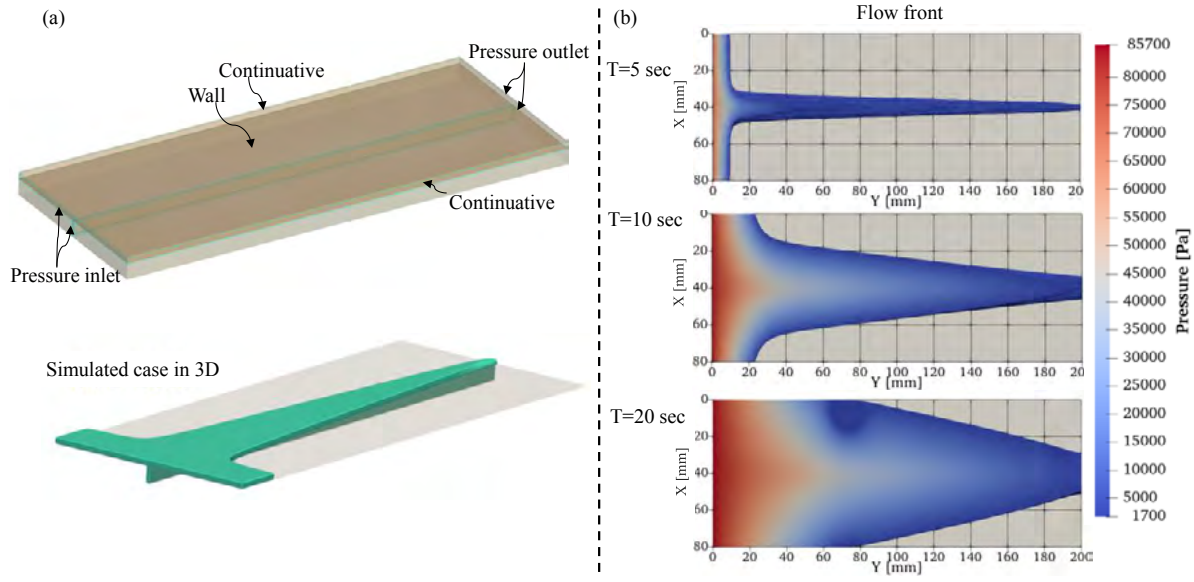

Figure 2. (a) CFD model geometry and the boundary conditions (top) and simulated sample in 3-dimension (bottom); (b) Flow front and pressure profile of the simulated cases at different infusion times.

The fluid flow is assumed to be transient, isothermal, and incompressible with a constant density ρ. The flow within the porous medium is solved based on the Darcian saturated drag model that adds a drag term to the momentum equations. Therefore, the flow dynamics are governed by the following mass and momentum conservation equations:

$$\nabla . \boldsymbol{u} = 0 \qquad (1)$$

$$\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u}.\nabla \boldsymbol{u} = -\frac{1}{\rho}\nabla p + \boldsymbol{g} + \frac{\mu}{\rho}\nabla^2 \boldsymbol{u} - \boldsymbol{F} \quad (2)$$

where $\boldsymbol{u}$ is the velocity vector, p is the pressure, t is the time, $\boldsymbol{g}$ is the gravitational acceleration vector with components $(0,0,-g)$; $g = 9.81$ ms^{-2} is the gravitational acceleration, and $\boldsymbol{F}$ is the resistance to flow in the porous medium, i.e., the drag term, and is given as follows:

$$\boldsymbol{F} = \boldsymbol{F_d}\boldsymbol{u} \quad (3)$$

where $\boldsymbol{F_d}$ is the drag coefficient vector of the porous media and is given as follows:

$$\boldsymbol{F_d} = \frac{\boldsymbol{\epsilon}\mu}{\rho K} \quad (4)$$

where $\boldsymbol{\epsilon} = (\epsilon_x,\ \epsilon_y,\ \epsilon_z)$ is the porosity vector equivalent to the volume fraction of the porous media, and K is the permeability of the porous media.

The permeability values found in experiments are different in x, y, and z directions (three principal directions) with a constant porosity (0.506 = volume fraction) in all directions, and they are implemented in the CFD model as directional porosity found by the equation of the drag coefficient, i.e., by Equation 4, where the permeability K is constant. Initially, the drag coefficient is calculated by $F_d = \epsilon\mu/\ \rho K$; where $\epsilon = 0.506$, and $K = 1.25$e-10 (derived from the sinusoidal transformation of the permeability along the principal direction, i.e., averaging K_1 and K_2, as the angle of orientation is 45°). Finally, three porosity values are obtained by $\epsilon_i = F_d \rho K_i/\mu;$ using the calculated F_d and the princpal permeabilities (K_1, K_2, K_3). The porosity values corresponding to the permeability in principal directions are summarized in Table 1, which also includes specific details regarding the shallow cut and fabric dimensions.

The developed one fluid and void model uses the Volume of the Fluid method to track the free surface of the fluid through the low-pressure void domain, and the Finite Volume Method is used to discretize and solve the continuity and momentum equations. Figure 1-b showcases the simulated flow front for different infusion times, where the color represents the fluid pressure profile that changes over time.

3. Results and discussions

The flow fronts and the fluid filling between grooves over infusion time are investigated for two different configurations of the shallow grooves, i.e., single and double grooves, and are presented in Figures 3 to 7. Figures 3 to 5 present the flow fronts at different infusion times, specifically 5, 10, and 20 seconds, representing distinct stages of inlet pressure: sudden pressure buildup, the end of the buildup, and stabilized pressure, respectively. Figure 3 showcases experimental and simulated flow fronts at the bottom and top of the fabric at the infusion time of 5 seconds. The experiment shows that the flow fronts at the bottom and top of the fabric have significant differences, as expected, attributed to the more prominent flow along the groove and the slower flow along the z-direction within the fabric due to its lower permeability, cf. Figure 3-a. The simulated flow fronts at the bottom and top of the fabric

presented in Figure 3-b effectively capture the above phenomena. Figure 3-c provides the qualitative comparison between the experimental and simulated flow fronts. While simulations exhibit relatively good agreement, small discrepancies are observed. Specifically, the simulation slightly under-predicts the flow front length and width in both views; nevertheless, the resin flow within the fabric is more accurately predicted in the top view compared to the bottom view.

Figure 4 presents the flow fronts at the bottom and top of the fabric obtained from both experiment and simulation at an infusion time of 10 seconds, corresponding to the phase when the inlet pressure begins to stabilize. The experimental and simulated results, as illustrated in Figures 4-a and 4-b, respectively, exhibit similar patterns as observed in Figures 3-a and 3-b, apart from the fact that the flow front is more developed at this stage due to longer infusion time and the inlet pressure buildup. The qualitative comparison between the experimental and simulated flow fronts is presented in Figure 4-c. It is seen that the simulations tend to over-predict the flow compared to the experimental observations, regardless of the viewing perspective (i.e., top or bottom views).

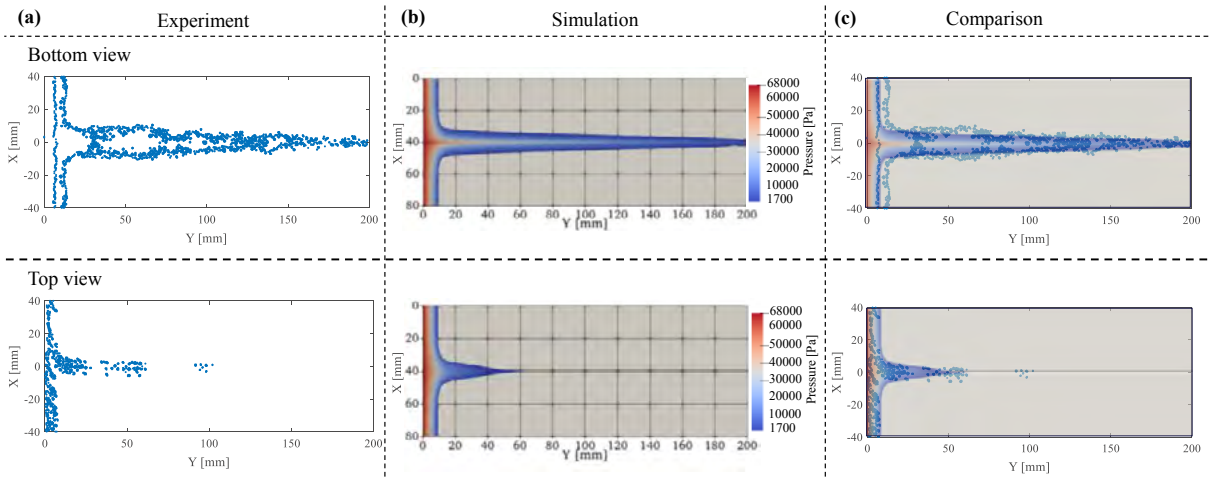

Figure 3. Flow fronts at the bottom and top of the fabric at an infusion time of 5 seconds. (a) Flow front captured during the experiment; (b) simulated flow fronts; and (c) qualitative comparison between experimental and simulated flow front.

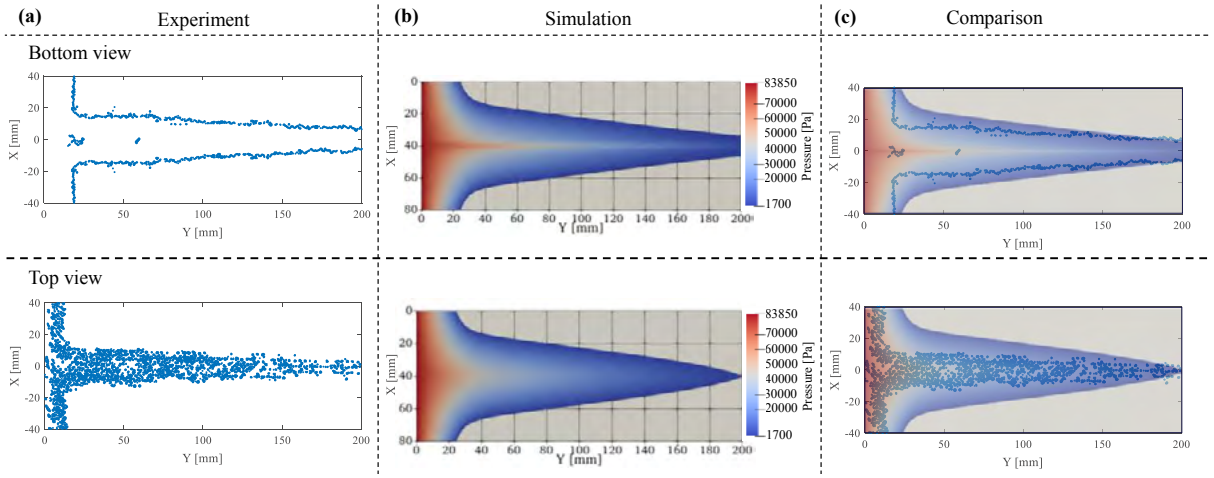

Figure 4. Flow fronts at the bottom and top of the fabric at an infusion time of 10 seconds. (a) Flow front captured during the experiment; (b) simulated flow fronts; and (c) qualitative comparison between experimental and simulated flow front.

Furthermore, the flow fronts are investigated at an infusion time of 20 seconds, corresponding to stable inlet pressure, and presented in Figure 5. Unlike previous observations, both experimental and simulated flow fronts at the bottom and top of the fabric are nearly identical, cf. Figures 5-a and 5-b. This similarity primarily arises from the dominance of flow through the fabric by high inlet- and groove-pressure, especially when looking into a smaller dimension. However, this phenomenon is required to be investigated to better understand this behaviour for different thicknesses, permeability of the fabric, and inlet pressure. The qualitative comparison between the experimental and simulated flow fronts in Figure 5-c gives similar information as seen in Figure 4-c that simulation tends to over-predict the flow in the fabric.

Overall, the simulations well predicted the nature of the flow fronts and their differences at both the top and bottom of the fabric. The simulations show the flow fronts and the resin flow in the fabric give the closest experiments when the infusion time is shorter. For larger times, the discrepancies become strong due to the dominating nature of the flow in the fabric from the channel in the investigated cases. These discrepancies can partially be due to issues of variability in permeability characterization and the difficulty in non-destructively assessing experimental fibre volume fractions. The predicted details are, however, sufficiently in agreement with the experiments, so the CFD model is used to investigate the flow fronts and filling between two grooves for different cut-to-cut (CtC) spacing of shallow grooves and are presented in Figures 6 and 7.

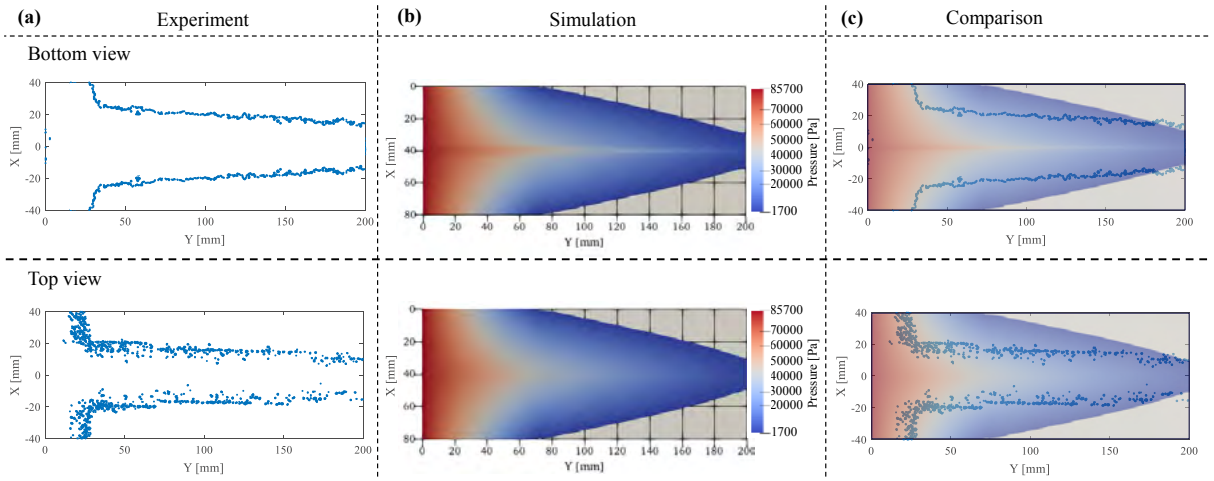

Figure 5. Flow fronts at the bottom and top of the fabric at an infusion time of 20 seconds. (a) Flow front captured during the experiment; (b) simulated flow fronts; and (c) qualitative comparison between experimental and simulated flow front.

Figure 6 illustrates the flow fronts at various infusion times for two grooves with different cut-to-cut (CtC) spacings: 10 mm, 20 mm, and 40 mm. The computational domain remains constant, as in the previous simulated case, at 80×200×2.22 mm³, with the number of grooves limited to two. Realistically, a repeated pattern of grooves would be used in the true core materials. Therefore, while keeping computational complexity down, the presented results focus only on the filling between channels. Figure 6 shows that increasing CtC spacing increases the filling time between the channels, as expected. It can also be noticed that the minimum flow distance between channels (FD_{min}) changes for different CtC spacing, cf. Figure 6. Figure 7 quantifies the FD_{min} and presents it as a function of infusion time for both the top and bottom fabric surfaces. The FD_{min} reaches the length of the domain (200 mm) faster when the CtC is smaller, while it takes longer for the larger CtC spacing. Furthermore, it can seen that the FD_{min} at the top and bottom of the fabric varies. For CtC 10 mm, the largest differences between the top and bottom FD_{min} are observed (blue curves), while the differences reduce when CtC spacing increases. For the largest investigated CtC 40 mm, the FD_{min} is identical at the top and bottom of the fabric throughout the filling (purple curves).

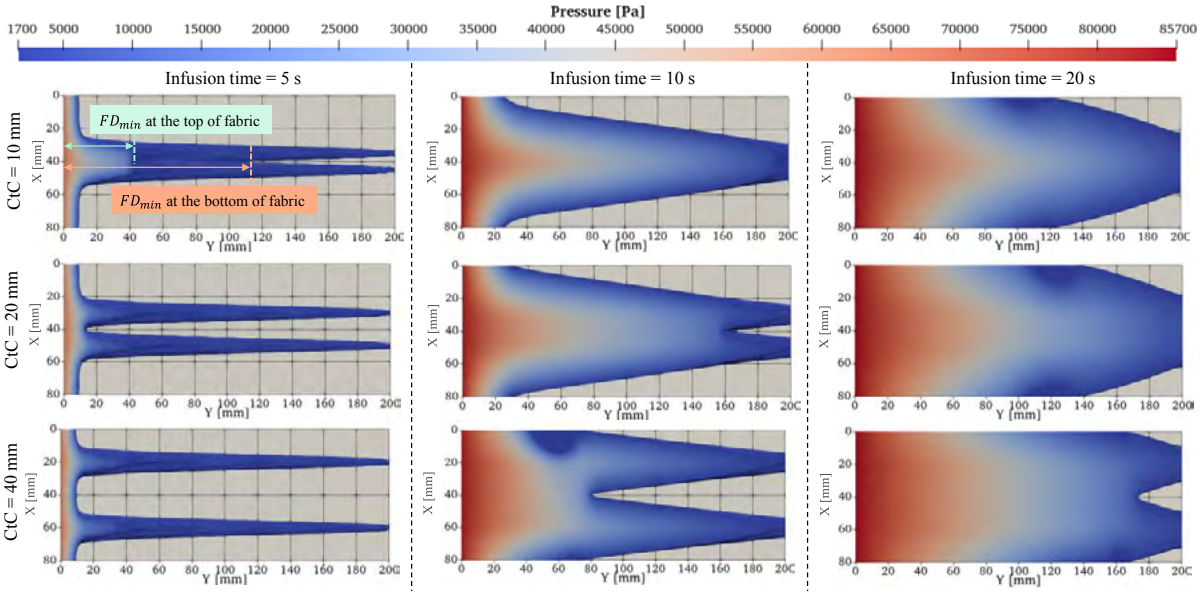

Figure 6. Flow fronts for different cut-to-cut (CtC) spacing of 10, 20, and 40 mm at different infusion times of 5, 10, and 20 seconds.

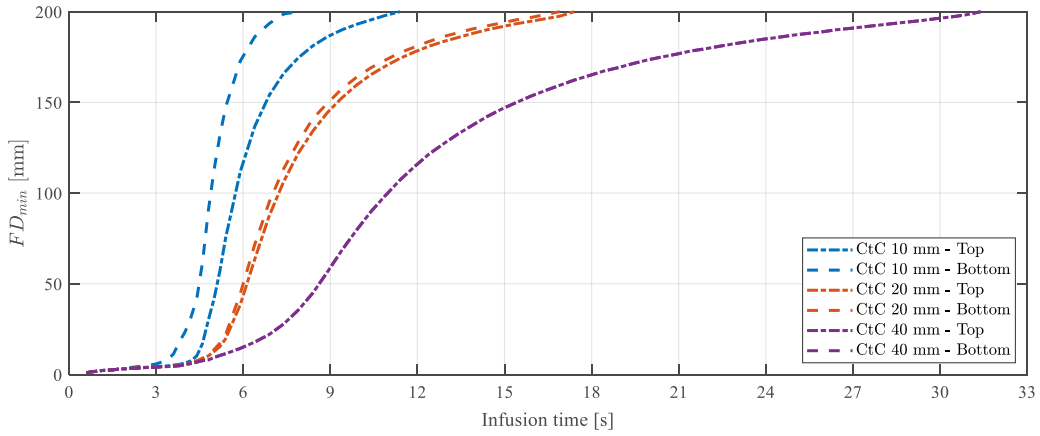

Figure 7. Minimum flow distance between channels (FD_{min}) at the top and bottom of the fabric as a function of infusion time for different cut-to-cut (CtC) spacing.

3. Conclusions

This paper investigates the Vacuum-Assisted Resin Infusion (VARI) process for manufacturing composite sandwich panels using experiments and simulations. The study focuses on the lower reinforcement layers and shallow grooves of the composite sandwich panels to analyze flow front profiles and infusion time. The simulated results accurately capture flow front profiles and patterns at both the bottom and top of the fabric, showing reasonable agreement with experimental data. Discrepancies are observed primarily for larger infusion times. Both experiments and simulations demonstrate that flow fronts at the bottom of the fabric are more pronounced than those at the top for smaller infusion times. However, as infusion time increases, flow fronts become more identical due to the dominance of flow through the fabric driven by high inlet and groove pressure. Furthermore, the model is utilized to simulate infusion with the presence of two shallow cuts, and the filling of fluid between two grooves is investigated for different cut-to-cut (CtC) spacings. As expected, the filling of fluid between two grooves takes less time for smaller CtC spacing. Additionally, it is noted that the minimum flow distance between the grooves varies at the top and bottom of the fabric. The differences are more pronounced when the CtC spacing is smaller, and they decrease when the CtC spacing is increased.

In future work, the simulated results can be compared with experiments involving various configurations of the channel, through-thickness experiments, and different fabric properties. This comparative analysis will provide deeper insights into the accuracy and applicability of the simulation model across diverse scenarios. Subsequently, a parametric study can be performed to better understand the process.

Abstract
A new technology of composite wrapped joints emerges as a promising solution for improving the long-term performance of connections between circular hollow sections (CHS). The use of composite materials is shown to improve the fatigue life of structures. However, a major challenge to the implementation of this technology is to ensure the long-term performance of the composite materials subjected to the operational conditions. This work aims to evaluate the effects of temperature changes on the fatigue delamination of a glass fiber reinforced polymer (GFRP) for application in offshore structures. Specimens were manufactured by hand lay-up and series of experiments are performed to access delamination fatigue crack growth behavior in a range of operational temperatures: -10, 21 and 70 °C. Displacement controlled end-notched flexure (ENF) tests were applied to measure the fatigue behavior together with a digital image correlation (DIC) system to monitor the displacements during the tests. Results show that the delamination fatigue performance of the composite material is not significantly affected by the range of tested temperatures. The fracture behavior also remained unchanged. Standard ENF test method has limited range of crack growth to evaluate the fatigue behavior of composite laminates.

1. Introduction

Composite materials, e.g. fiber-reinforced polymers (FRPs), are increasingly popular in structural applications due to their high strength-to-weight ratio, design flexibility, and fatigue resistance. In the construction sector, an innovative joining technique for steel hollow sections has been introduced using wrapped composite joints instead of traditional welded joints [1]. The loadings in jacket structures are transmitted through a wrapped glass fibre reinforced polymer (GFRP) with a large bonded area. The stress concentration can be significantly relieved, improving fatigue resistance. The elastic stiffness, static resistance, and fatigue behaviour are equivalent to or larger than those of their welded alternative for the properly designed composite wrap. However, the mechanical behavior of the composite material under operational conditions still needs to be clarified for the implementation of the technology.

The performance of composite structures is significantly influenced by environmental factors [2]. Short-term changes of temperature can have a significant impact on the mechanical properties of the material. In particular, the mode II delamination crack growth is the most relevant for the design of composite wrapped joints. Understanding the effects of temperature on the mode II delamination fracture and fatigue of the material is crucial for the design and structural integrity of the joints during operational life.

©2024 | 3_MOREIRA AROUCHE_Marcio_14XKZ.pdf

In this work, the effects of temperature changes on the fatigue delamination of a glass fiber reinforced polymer (GFRP) is investigated. Specimens were manufactured by hand lay-up and series of experiments are performed to access delamination fatigue crack growth behavior in a range of operational temperatures. The reference temperature of 21 °C, a low temperature of -10 °C and a high temperature condition of 70 °C are tested.

2. Materials and Manufacturing

Glass fiber reinforced polymer (GFRP) plates were manufactured. A vinyl ester resin was applied to the hand lay-up lamination of glass fiber bi-directional woven interleaved to layers of glass fiber chopped strand mat (CSM), as shown in Figure 1. A non-adhesive insert of 32 µm thickness was placed at the mid-plane to create an artificial pre-crack. The laminated plate cured in air conditions of 18±1 °C and 50±5% humidity. Then, the composite plate was cut to 0/90 coupon specimens using water jet. Finally, part of the specimens was post cured in an oven at 120 °C for 7 h. The testing specimens have a nominal length of 230 mm, and an average width (w) and thickness (2h) of 19.68±0.14 mm and 7.68±0.21 mm, respectively, measured from the average of 3 different sections using a digital caliper.

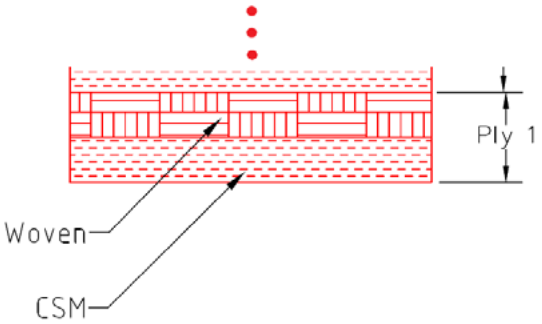

Figure 1. Scheme of the composite lay-up.

3. Experimental procedures

3.1. Test Set Up

A thin layer of white matt paint was coated and a random black speckle pattern was applied to the measurement surface of the specimen. A high resolution camera (50.6 MPx) and a blue LED light source were positioned to the measurement surface to acquire the full field displacements by DIC. Photos were taken every 200 cycles at the minimum and maximum displacements, synchronized with load measurements from the testing machine. For the image processing, surface points were recognized by a small neighborhood of a square with a side length of 19 pixels and a step size of 11 pixels set in the DIC software.

Displacement controlled fatigue ENF tests were performed. Table 1 shows the test matrix. The first test (01-RT) was used to verify the most appropriate displacement level. Then, the maximum displacement, δ_{max}, was set to have an initial force of 70% of the critical force obtained from quasi-static tests. The minimum displacement, δ_{min}, was set to have $\delta_{max}/\delta_{min}$ equals 0.1. Table 1 also includes the mode II critical SERR, G_{IIc}, and the flexural modulus of the material, E_f, obtained from static tests of specimens cut from the same plate and tested in different temperatures.

Specimens were tested at the room temperature (RT) of 21±1 °C, and a climate chamber was used with the test set up for conditioning specimens in the low temperature (LT) of -10±1 °C and the high temperature (HT) of 70±1 °C. Two air mixing fans improved stability of air conditions over time and

the specimens were maintained in a constant condition for 7 hours prior to the tests to ensure a homogeneous temperature field in the material. Series of 3 specimens were tested in each configuration.

Table 1. Test matrix.

Specimen	Temperature (°C)	Maximum Displacement (mm)	G_{IIc} (N/mm²)	E_f (GPa)

09-LT	-10	3.01		

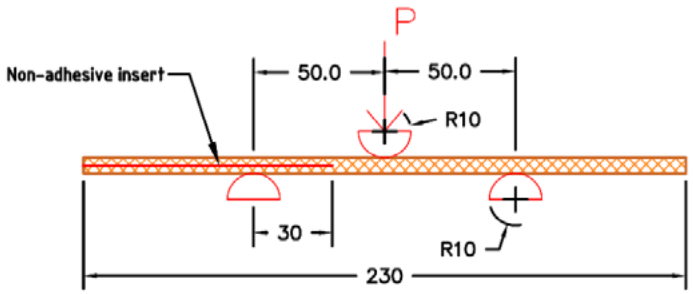

Figure 2. ENF test set up.

3.2. Calculation of the strain energy release rate

The delamination fracture toughness is described by the Resistance curves, or R-curves, that relates the strain energy release rate (SERR) with the crack length. The SERR, or *G*, from the crack growth of a tested specimen can be analytically derived from Irwin-Kies Equation (1):

$$G = \frac{P^2}{2B}\frac{dC}{da} \tag{1}$$

where *P* is the applied load, *B* is the specimen width, *C* is the specimen compliance, or the ratio of the load point displacement to the applied load ($C = \delta/P$), and a is the crack length. The compliance based beam method (CBBM) [3] relates Timoshenko beam theory and the specimen compliance to obtain the fracture energy.

For a ENF test set up, the specimen compliance becomes Equation (2):

$$C = \frac{3a^3 + 2L^3}{8E_f Bh^3} + \frac{3L}{10G_{13}Bh} \tag{2}$$

where L is the half span of the ENF test. Combining Equations (1) and (2), the mode II fracture toughness, G_{II}, can be obtained:

$$G_{II} = \frac{9P^2a^2}{16B^2h^3E_f} \tag{3}$$

The flexural modulus, E_f, can be estimated experimentally, for each ENF test specimen, using the initial compliance C_0 and the initial crack length a_0, as shown in Equations (4) and (5):

$$E_{f(ENF)} = \frac{3a_0^3 + 2L^3}{8Bh^3C_{0\text{corr}}} \tag{4}$$

Where:

$$C_{0\text{corr}} = C_0 - \frac{3L}{10G_{13}Bh} \tag{5}$$

Finally, the CBBM suggests that the crack length, a, can be estimated from the specimen compliance as an equivalent crack length, a_e, obtained directly from Equation (6):

$$a_e = \left[\frac{1}{3}\left(\left(C - \frac{3L}{10G_{13}Bh}\right)8E_fBh^3 - 2L^3\right)\right]^{1/3} \tag{6}$$

This method allows accounting for the variation in the bending modulus of the material of each specimen and due to the effect of temperature.

4. Results and Discussion

The mode II SERR was calculated by the CBBM using Equation (4). In the case of the fatigue ENF tests performed in this work, the displacements were measured with DIC as the difference between the vertical displacement of the load point and the average vertical displacement of the support points. The initial compliance was the measured minimum compliance in the points of maximum displacement. A nominal value of 3.5 GPa was used for G_{13}.

The variation of the SERR with the mode II fatigue cycles is presented in Figure 3 for the different temperautres. The range of SERR in fatigue over the critical SERR ($\Delta G_{II}/G_{IIc}$) remained below 0.4, which is typical of the ENF test set up [4]. Tests in room and low temperatures showed similar results, such as in the G_{IIc} from static tests (see Table 1). A more significant decrease of ΔG_{II} is noticed in high temperatures.

Figure 4 shows the Paris curves of ENF tests in different temperatures. It is observed that high temperature conditions resulted in a slightly better performance of the mode II interlaminar fracture under cyclic loadings. This can be measured by the slope of the Paris curves, represented by the m-parameter in Table 2 where results of high temperature shows relatively smaller m parameter than others.

The experimental flexural modulus (E_f) was obtained from the fatigue tests using the initial compliance at the maximum force. Differently from the results of static tests (see Table 1), the fatigue tests was not able to measure a clear change of the E_f with temperature.

Representative fracture surfaces are shown in Figure 5. All tests resulted in the same failure mode. The crack growth occurred between the woven, on the upper side, and the chopped strand mat, on the lower side of the specimens.

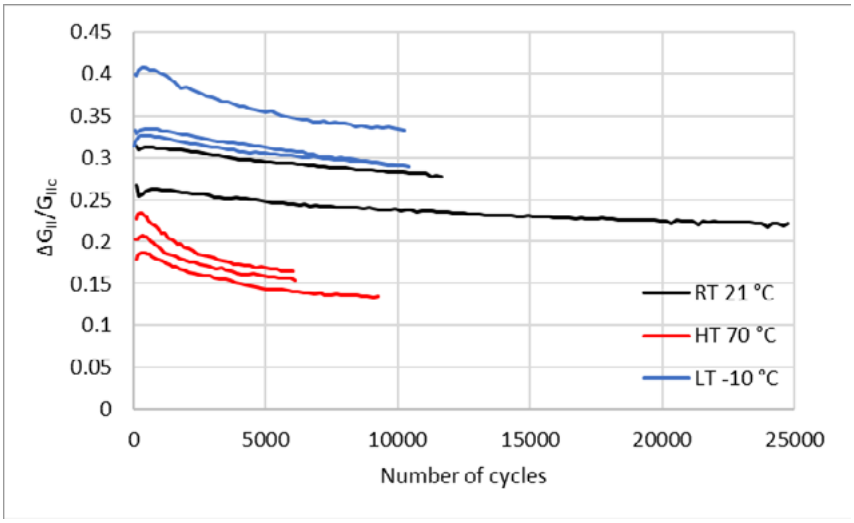

Figure 3. Variation of the SERR with the mode II fatigue cycles in different temperatures.

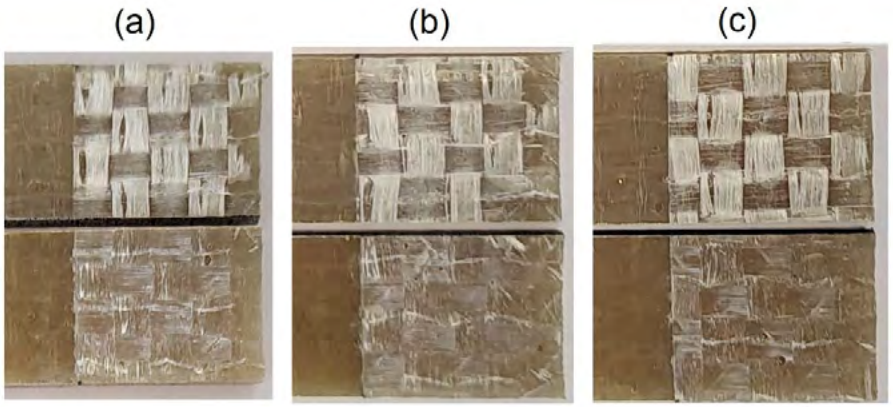

Figure 5. representative fracture surfaces of specimens tested in different temperatures.

5. Conclusions

The effects of temperature changes on the fatigue delamination of a GFRP was investigated. Displacement controlled ENF tests were applied to measure the fatigue performance in room conditions (21 °C), and using a chamber at -10 and 70 °C. A DIC system to monitor the displacements during the tests.

Changes of temperature did not significantly affect the delamination fatigue performance of the composite material. In addition, no change in the fracture surfaces was observed with temperature.

The standard ENF test method has limited range of crack growth to evaluate the fatigue behavior of composite laminates.

Abstract
This study explores the use of bicomponent core-sheath filaments, featuring a hard core and a soft sheath, as a potential solution to common issues such as poor adhesion, voids, and rough surfaces, which are often encountered with conventional monofilaments. Through co-extrusion and overcoating techniques, various filaments were produced and evaluated. The tensile properties of 3D-printed parts from bicomponent filaments, at different raster angles (0° and 45°), were compared to those of standard monofilaments. Results indicated that while bicomponent filaments made of polylactic acid (PLA) performed comparably to monofilaments, those with polyamide (PA) cores showed significant improvements, particularly at the 45° raster angle. Notably, filaments with a carbon fiber reinforced PA core and a PA sheath enhanced both processability and structural integrity. Additionally, two overcoated filaments, featuring polyethylene terephthalate (PET) and polyphenylene sulfide (PPS) monofilament cores with a copolyester (CoPES) sheath, were developed for 3D printing. Parts printed from PET/CoPES overcoated filaments exhibited good consolidation when printed at temperatures above the melting point of PET.

1. Introduction

In the field of additive manufacturing (AM), material extrusion (MEX), commonly known as fused deposition modeling (FDM) or fused filament fabrication (FFF), is notable for its simplicity, cost-effectiveness, and versatility in materials. However, the layering structure often results in limited adhesion and the formation of voids between layers, which adversely affects the mechanical properties of the printed parts, leading to reduced strength and durability [1, 2]. Additionally, the rough surfaces produced by the FDM process and abrasive surface materials, such as short fiber-reinforced composites, can pose challenges for post-processing tasks such as painting, chrome-plating, or milling. To address these challenges, employing a bicomponent core-sheath approach offers a promising solution [3, 4]. This technique uses a high-viscosity polymer core for structural integrity, paired with a low-viscosity sheath material, ideally compensating for irregularities resulting from the layered production.

Bicomponent melt-spinning technology, dating back to the 1960s, combines two polymers to enhance functionality [5, 6]. However, incorporating different polymers in products complicates recycling due to sorting and separation challenges. Identifying and separating polymers becomes costly and complex, diminishing recycling feasibility. Therefore, careful polymer selection in product design is crucial, ensuring products composed of different polymers are designed for recyclability to promote sustainable recycling practices.

In this work, we prioritized recycling strategies. Using co-extrusion melt-spinning technology [5] or overcoating extrusion [7], we produced various bicomponent feedstock filaments compatible with filament forming techniques. To ensure miscibility, recyclability, and polymer-polymer adhesion through chain interdiffusion, we selected the same generic polymers as core and sheath materials for specific co-extruded filaments. We chose two different polylactic acid (PLA) grades with varying melt flow indexes (MFI): PDLLA (a mixture of both L-lactic acid and D-lactic acid) specifically formulated for materials extrusion 3D printing, and a low-viscosity PDLA homopolymer. Polyamides (PA), another commonly used polymer group in 3D printing, offer a large choice of miscible materials with various properties such as melt temperature, viscosity, softness, and short fiber reinforcement. To tackle the challenge of 3D printing soft materials, we pursued two approaches: (i) utilizing bicomponent melt-spinning with a soft co-polyamide (CoPA) in the core of a PA filament, and (ii) employing overcoating of a tensile polyester monofilament with a soft co-polyester (CoPES) hot melt adhesive. An added advantage of the overcoating technique is the ability to co-extrude two materials with significant differences in melting temperatures, allowing for a sheath material with high melt flowability (high MFI) compared to the core. This high flowability of the adhesive, combined with the solidification and stabilization of the base polymer during 3D printing, enhances adhesion by maximizing contact area between the two materials.

Our objective was to assess the printability of bicomponent filaments and compare the properties of resulting 3D-printed parts to those made from monocomponent filaments. The study involved analyzing the effect of different filament types on the printability of infilled 3D structures with two raster angles (0° and 45°), and evaluating the corresponding mechanical properties of the printed parts.

2. Materials and methods

2.1. Materials processing and sample preparation

For the co-extrusion process, various polymer combinations were utilized. Two grades of PLA were employed: PDLA LUMINY® D120 from TotalEnergies Corbion (Gorinchem, The Netherlands), and PLA Ingeo 3D850 from Natureworks LLC (Minnesota, USA), serving as the reference material. EMS-Chemie AG (Domat/Ems, Switzerland) supplied four grades of PA: PA6 Grilon A26, Grilon F34 (a PA6 variant), Grilon CF6S (a low viscosity Co-PA), and PA12 Grilamid L16. Spectrum PA6 CF15S, a filament reinforced with 15% carbon fiber (CF), was provided by Spectrum Group Sp. z o.o (Warsaw, Poland), pelletized for extrusion in this study. Griltex® D 1619E, a CoPES hotmelt adhesive, was also supplied by EMS-Chemie AG. Two types of monofilaments were used for overcoating: polyethylene terephthalate (PET) monofilament Rhodia Y114 from Nexis Fibres a.s. (Humenné, Slovakia), and polyphenylene sulfide (PPS) monofilament 50–46 E from Monosuisse AG (Emmenbrücke, Switzerland).

Co-extruded bicomponent filaments were fabricated using an extrusion line comprising two extruders, a spin pack, and a filament take-up unit, as depicted. The extrusion unit, custom-manufactured by Collin Lab & Pilot Solutions GmbH (Maitenbeth, Germany), consisted of a 16 mm and a 20 mm, 30 L/D single-screw extruder, each equipped with a gear pump (Mahr Metering Systems GmbH, Göttingen, Germany) respectively. These gear pumps were controlled to regulate the polymer output rates, ensuring consistent filament diameter and core/sheath volume ratio. The core and sheath polymers were joined in the spin pack using a specially designed "single" die [5] with a 3.5 mm diameter die capillary and a 3.0 mm diameter core capillary, developed by our laboratory. Extrusion temperatures were adjusted to equalize the viscosities of both polymer melts within the die, guaranteeing steady melt flow during filament production.

For the overcoated filaments, a custom pilot line was employed, featuring a 16 mm, 30 L/D single-screw extruder (Collin Lab & Pilot Solutions GmbH, Maitenbeth, Germany) equipped with a 1.2 cm³ gear pump (Mahr Metering Systems GmbH, Göttingen, Germany). The overcoating of the monofilaments (or yarns) with pressurized molten polymer was performed within a custom-made wire coating spin pack, as depicted in reference [7]. To accommodate the lack of rigidity in PET and PPS monofilaments,

a metallic capillary tube was used as a guide within the coating die, which had a diameter of 3.5 mm. CoPES, dried and fed into the extruder, was melted and pressurized to 40 bar, then conveyed by the melt pump to the overcoating die operating at 150°C.

All extruded filaments were then cooled in water and collected using a customized take-up unit, maintaining a controlled speed of 10-11 m/min to achieve the desired filament diameter, measured by the X/Y laser controller Zumbach ODAC 18XY (Zumbach Electronic AG, Orpund, Switzerland). Each filament, with a diameter of 1.75 ± 0.04 mm, was wound onto a standard spool for 3D printing. **Table 1** summarizes all received filaments and co-extruded and overcoated bicomponent filaments, along with the materials employed for the core and sheath, including their respective volume ratios.

Table 1. List of as-received filaments and co-extruded and overcoated bicomponent filaments with calculated and measured core diameter and sheath thickness.

Reference and co-extruded filaments	Core material	Sheath material	Core diameter (mm)	Sheath thickness (mm)
PLA*	PLA 3D850		NA	NA
PLA/PDLA	PLA 3D850	PDLA D120	1.43[a]	0.16[a]
PDLA/PLA	PDLA D120	PLA 3D850	1.01[a]	0.37[a]
PA6	PA6 A26		NA	NA
CoPA/PA6	CoPA CF6S	PA6 A26	(1.04 ± 0.01)[b]/1.01[a]	(0.40 ± 0.03)[b]/0.37[a]
PA12/PA6	PA12 L16	PA6 A26	(1.04 ± 0.03)[b]/1.01[a]	(0.38 ± 0.02)[b]/0.37[a]
PA6/PA12	PA6 A26	PA12 L16	(1.47 ± 0.01)[b]/1.43[a]	(0.16 ± 0.01)[b]/0.16[a]

3D-printed samples were manufactured using the Flashforge Guider IIS 3D-printer (Flashforge, Zhejiang Province, China) in high-temperature processing mode, fed with monofilaments and co-extruded or overcoated bicomponent filaments. 3D-printed specimens from monofilaments PLA, PA6 and PACF served as reference samples. For tensile testing, dumbbell-shaped specimens of ISO 527 type 1BA (width 5 mm, thickness 2 mm) [8] were printed using monofilaments and co-extruded bicomponent filaments. For each filament type, several specimens were printed with raster angles, [0°/0°] and [+45°/−45°], respectively. Other dumbbell-shaped specimens of different size (width 12 mm, thickness 2 mm, Figure 3b) were printed using overcoated filaments, because a larger diameter of nozzle was used, resulting in larger deposited strands.

2.2. Characterzations

Dumbbell-shaped specimens underwent uniaxial tensile tests at 23°C and 50% relative humidity by using a Zwick Z100 testing machine (Zwick-Roell AG, Ulm, Germany), equipped with a 5 kN load cell. Strain was recorded using videoXtens. The elastic modulus of 3D-printed dumbbell-shaped specimens, following ISO 527 type 1BA standards, was determined employing a crosshead speed of 1 mm/min and

a gauge length of 30 mm. As per ISO 527, the elastic modulus was calculated as the average secant values between strain levels of 0.05% and 0.25%. Fracture properties were assessed for dumbbell-shaped specimens of ISO 527 type 1BA from co-extruded filaments at a crosshead speed of 10 mm/min.

3. Results and discussion

The tensile properties of dumbbell-shaped samples made from co-extruded bicomponent filaments were evaluated and compared with those of reference samples produced from monofilaments. The samples were divided into three groups: PLA, PA, and PA reinforced with carbon fibers, as depicted in **Figure 1**. The PLA, PDLA/PLA, and PLA/PDLA samples demonstrated similar elastic moduli, approximately 3.3 GPa, peak maximum tensile stress around 54 MPa, and strains at break about 2%. This analysis reveals that the mechanical properties of the bicomponent and monofilament samples are similar, due to the similar material characteristics of PLA and PDLA, which did not significantly enhance the tensile properties of 3D-printed components using a bicomponent approach.

PA-based specimens fabricated with a 0° raster angle showed average elastic moduli between 1.0 and 1.5 GPa, with maximum tensile stresses ranging from 32.5 to 40.5 MPa, which are typical for conditioned polyamide [9]. The elastic moduli of PA6 and HD-PA/PA6 specimens are comparable due to the similar properties of these materials. However, specimens combining PA6 with PA12 (PA6/PA12 and PA12/PA6) exhibited superior performance. This enhanced performance is attributed to two factors: (i) water acts as a plasticizer in PA, diminishing its strength and stiffness, and (ii) PA12 has a lower equilibrium moisture content than PA6, which contributes to higher tensile strength and stiffness. Technical datasheets from manufacturers confirm that conditioned PA12 is superior to PA6. Additionally, the thermal properties, such as viscosity and melting points, of PA12 differ significantly from those of PA6. Despite this, the effectiveness of the reinforcement might be compromised in the PA6/PA12 configuration due to the thinness of the PA6/PA12 filament sheath, which measures only 0.16 mm, compared to a thicker 1.0 mm core in the PA12/PA6 configuration, (see **Table 1**).

When assessing the mechanical properties of 3D-printed specimens with a 45° raster angle against those with a 0° raster angle, notable differences emerge. For PA6 and HD-PA/PA6 materials, both the elastic modulus and maximum stress increase at a 45° raster angle, likely due to enhanced contact between the extruded non-oriented microfilaments and a reduced presence of voids at this angle. On the other hand, samples made from PA12 and PA6, co-extruded into bicomponent filaments and printed at the 45° raster angle, showed decreased maximum stress compared to those without PA12, shown **Figure 1b**. The lower performance in PA6/PA12 and PA12/PA6 at the raster angle 45° samples is most likely due to fractures at the PA6-PA12 interface, caused by insufficient adhesion between the two polymers. This type of failure was not observed in samples with a 0° raster angle, where the PA6-PA12 interfaces align parallel to the stress direction. Additionally, the CoPA/PA6_45° samples performed well, likely because CoPA is specifically designed as an adhesive polymer that effectively bonds to PA6.

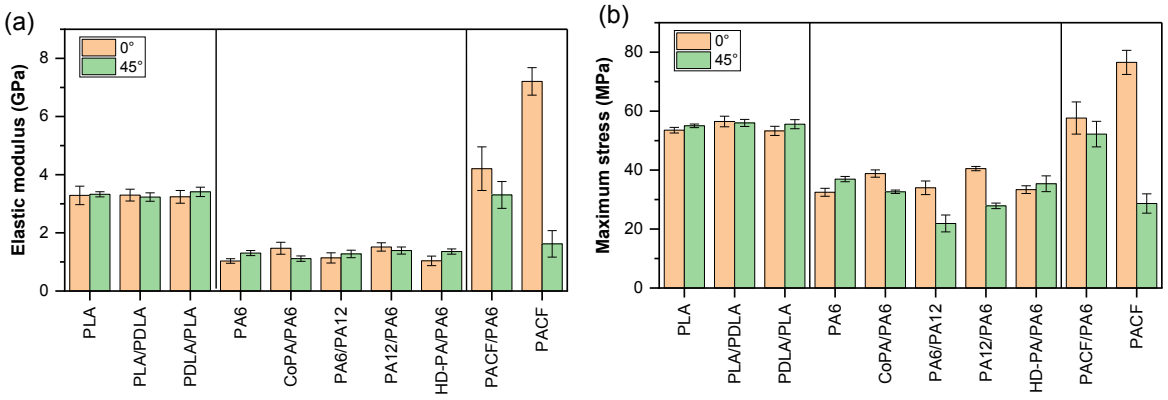

Figure 1. Tensile properties of PLA and PA specimens 3D-printed with a 0° and 45° raster angle: Elastic modulus (a) and maximum stress (b).

The third set of specimens included those reinforced with carbon fiber in a PA matrix. 3D-printed specimens composed of PACF/PA6 and PACF alone, with a 0° raster angle, showed superior elastic moduli and tensile strengths relative to PA6 alone. This enhancement is attributed to the reinforcing effects of the carbon fibers, which are highly oriented within the strands. Notably, **Figure 1** illustrates that due to a lower carbon fiber content of about 9.9 wt% in the PACF/PA6 filament, both the elastic modulus and tensile strength of the bicomponent PACF/PA6_0° are less than those of the PACF 0° alone. The PACF/PA6_45° sample displayed improved mechanical performance compared to the pure PACF_45° specimens.

To overcome the challenges associated with 3D printing soft materials, we implemented a method by overcoating two commercially available PET and PPS yarns and producing 3D prints from them. We utilized a CoPES sheath as an adhesive layer to effectively minimize voids in the 3D-printed objects. Additionally, the yarn within the filament acted as a structural support, enhancing the printability of these materials. This combination of yarn with a CoPES sheath could be a promising technique for optimizing quality and performance of 3D-printed parts.

Figure 2 shows the actual 3D-printed specimens at a 45° raster angle and cryo-fracture cross-sections of these printed specimens. Initially, it was intended to print below the melting point of the core yarn, however, nozzle clogging issues prohibited a successful printing using this approach. To maintain a steady flow of the yarn core between layers, it was necessary to increase the working temperature above the core material's melting point. For instance, PET/CoPES was successfully printed at 280°C, achieving a smooth surface finish as shown in **Figure 2**. On the other hand, PPS/CoPES required a higher temperature of 300°C and utilized a larger 0.8mm nozzle. Attempts to print with nozzles sized 0.4mm and 0.6mm were unsuccessful due to clogging. Using the 0.8mm nozzle resulted in a rough and irregular surface on the specimens, as evidenced in **Figure 2**, likely due to irregular flow.

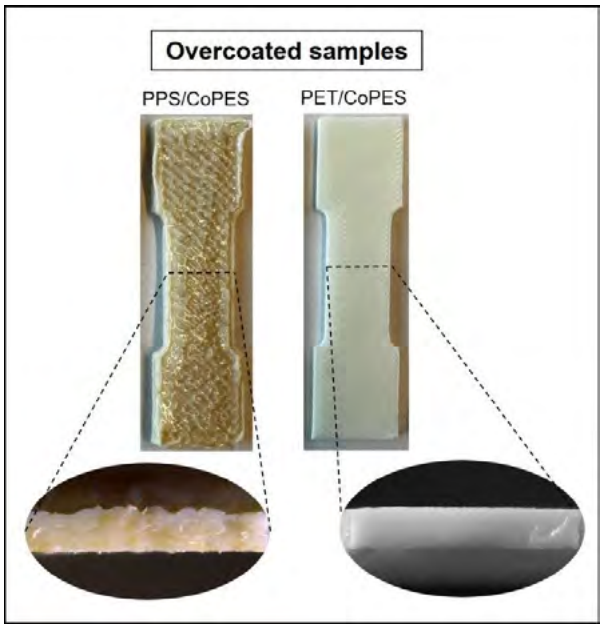

Figure 2. Specimens 3D-printed from overcoated filaments with 45° raster angles.

4. Conclusions

This study explores the impact of bicomponent feedstock filaments, produced through co-extrusion melt-spinning and overcoating extrusion technology, on both the 3D printing process and the tensile

properties of resulting printed parts. These filaments with a core-sheath structure, comprising two polymers of the same generic type but with distinct viscosities, promoting miscibility to enhance polymer-polymer adhesion and recycling strategies. This enhances the utility of these bicomponent filaments compared to traditional monocomponent ones.

When utilizing PLA-based bicomponent filaments for 3D printing, no significant differences were noted compared to monocomponent filaments, owing to their similar properties. PA-based bicomponent filaments showcased notable improvements. In particular, when printing infilled structures at a 45° angle, the combination of different PA types distinctly influenced the properties of 3D-printed parts, unlike printing at a 0° angle, where no significant differences were observed. The bicomponent PACF/PA6 filament particularly demonstrated enhanced processability and increased stiffness and tensile strength of infilled structures printed at a 45° angle.

Two overcoated filaments, consisting of PET and PPS monofilaments coated with a CoPES sheath, were assessed for their 3D printability. PET/CoPES exhibited good consolidation and satisfactory results when printed at a 45° angle above the melting point of the PET monofilament, whereas the filament with the PPS core did not show improvement.

Abstract
With an increasing demand for lightweight solutions, there is a growing focus on delving deeper into the energy absorption characteristics of thin-walled structures. This study employs a combined approach of numerical simulation and experimentation to investigate the size effect of energy absorption properties in carbon fiber resin matrix composite tubes. Four sets of proportionally sized 3D-scaled composite tubes were designed, and quasi-static axial crushing tests were conducted, concurrently establishing finite element models. Normalized analysis of the experimental results reveals that the load-displacement curves for the three different-sized composite tubes almost overlap, but the load for the 1/4 scale is slightly higher than the other sizes. Analyzing the failure modes of composite tubes of different sizes also shows highly similar post-crushing damage morphologies for size ratios of 1/2, 3/4, and 1, all exhibiting a 'flower-like' failure pattern, while the 1/4 size ratio displays a 'water ripple' pattern formed by the fracture of 90° fibers. Additionally, the finite element results exhibit high consistency with the experimental results, effectively replicating the experimental failure processes.

1. Introduction

The composite material has excellent mechanical properties, corrosion resistance, light weight and high strength. In recent years, composite materials have been widely used in various fields, especially in the design and manufacture of thin-walled structures [1-3]. With an increasing demand for lightweight solutions, there is a growing focus on delving deeper into the energy absorption characteristics of thin-walled structures. The energy absorption properties of composite materials are influenced by numerous factors, encompassing ply stacking sequence [4, 5], geometry, and trigger shape [6, 7]. The design of the ply stacking sequence structure can modulate the strength, toughness, and energy absorption capacity of the composite material, while geometry directly impacts the efficiency and mode of energy absorption. Trigger shape plays a pivotal role in the initiation and regulation of the process. Additionally, considering the size effect of composite material properties holds significant implications for broadening its engineering applications and minimizing testing costs.

The size effect, characterized by a change in strength with specimen dimensions, is a recognized phenomenon in composites [8]. Numerous scholars have extensively investigated this size effect. For instance, Swanson et al. [8] explored the scaling laws associated with impact damage in composite materials and structural size. Through fracture mechanics predictions, they observed that the phenomenon of stratification is contingent on the absolute specimen size. Carrillo et al. [9, 10] conducted a study on the size effects of fibra-metal laminate using a scale model. They analyzed the geometric impacts on stiffness, strength, failure strain, and stress/strain response under three scaling methods (1D: scaling thickness dimensions, 2D: scaling plane dimensions, and 3D: scaling all dimensions). In a separate study, Farley et al. [11] investigated the effect of the internal diameter/wall thickness (D/t) ratio on the energy absorption characteristics of graphite and Kevlar reinforced epoxy resin tubes. The results indicated a nonlinear increase in energy absorption capacity with a decrease in the D/t ratio. Green et al. [12] examined the impact of size on the tensile strength of notched composites, maintaining a constant ratio of the hole diameter to the specimen's width and length. Their findings revealed that as the sample size increases, the tensile strength decreases, with a maximum reduction of 64%. In a separate study, Wisnom [13] et al. explored the size effect on the tensile strength of unidirectional and quasi-isotropic epoxy carbon fiber composites. They found that the tensile strength of unidirectional specimens decreases as the size of the specimen increases, with a linear size change coefficient exceeding 14% of 8. Meanwhile, the strength of quasi-isotropic specimens increases with the growth in thickness - a strength increment of 10% was observed when moving from a single layer to four layers. However, the trend reversed when the thickness was further increased by altering the thickness of the blocks, with strength decreasing by 62% when moving from one to eight layers. In all scenarios, none of the laminates achieved the equivalent strength of a unidirectional material. This suggests that in all cases, lateral cracking and edge delamination were the primary causes of early failure.

With the rapid advancement of computing power, numerical calculation methods prove effective in analyzing the impact on the performance of energy-absorbing structures. Utilizing advanced analytical or numerical models for predicting the mechanical behavior of composite structures can serve as a substitute for some mechanical tests, significantly reducing the cost of composite design while providing engineers with essential information for optimized designs. For instance, Luo et al. [14], considering the anisotropic constitutive relationship of composite materials, established a stiffness degradation model based on the extended Hashin failure criterion and the damage evolution law of continuous damage mechanics. They analyzed the progressive failure of G803/5224 composite pipes. Compared with experimental results, the relative error between specific energy absorption and average load was less than 6%. This method demonstrated its utility in estimating the energy absorption characteristics of composite tubes. Sokolinsky et al. [15] proposed a physics-based finite element model for quasi-static crushing of corrugated carbon-epoxy fabric composite plates, considering both intralayer (in-plane) and interlayer (layered) failure mechanisms. The in-plane response of the fabric layer was modeled using a constitutive model implemented in the commercial finite element software Abaqus/Explicit. The layered response of composite plates was simulated using the cohesive surface capability in Abaqus software. Results from Abaqus/Explicit simulation aligned well with experimental data both quantitatively and qualitatively, indicating the applicability of the proposed method and tool for simulating the real extrusion of composite structures. Building on this foundation, Qi et al. [16] and Zhao et al. [17] applied this method to study the energy absorption characteristics of bionic polycysts and tubes with different sections, respectively. Zhang et al. [18] utilized commercial finite element software LS-DYNA to establish a finite element model for the axial crushing energy absorption of composite tubes. Tan et al.'s work leveraged improvements made by Falzon et al. [19-22] to the composite damage model, including enhanced nonlinear shear response and a unified matrix-led damage initiation and mixed model inner damage progression, to simulate post-impact effects and compression.

In this study, the size effect of energy absorption in a carbon fiber resin matrix composite tube is investigated through a combination of numerical simulation and experimentation. The paper analyzes the impact of the layering structure on the size effect of energy absorption, as well as the influence of the diameter-to-thickness ratio of the composite tube on this size effect. These findings offer valuable insights for guiding the design of large-scale energy absorption structures in engineering.

2. Experimental procedures

To investigate the size effect on the energy absorption properties of composite structures, four types of proportionally sized composite tubes were designed and fabricated. Figure 1 illustrates the composite energy absorption tube samples used in this study, while Table 1 provides additional details regarding their sizes. To minimize the impact of irrelevant variables on the size effect of energy absorption properties, the stacking sequence of the composite tube was designed as $[0/90]_{2n}$. By calculating the stiffness of the stacking sequence for different sizes, the stacking sequence structural matrices were set to be proportionally related. Table 2 provides the ABD stiffness matrices for composite tubes at different proportions.

Table 1. The geometric parameters of scaled samples

n	Diameter (mm)	Height (mm)	Thickness (mm)	Lay up
1/4	20	20	0.6	$[0/90]_2$
2/4	40	40	1.2	$[0/90]_4$
3/4	60	60	1.8	$[0/90]_6$
4/4	80	80	2.4	$[0/90]_8$

This study employed unidirectional T300/BR909 carbon/epoxy prepregs with a cured ply thickness of 0.15 mm, supplied by Shanghai Hanhe Ltd. Quasi-static axial crushing tests were performed using a standard testing machine with a maximum load capacity of 200 kN. The tests were conducted at a loading rate of $2\times n$ mm/min, and the final crushing displacement was set at 70% of the sample's total length.

To assess the energy absorption characteristics of the composite energy absorption tube, the following criteria were employed for evaluation: total energy absorption (EA) and specific energy absorption (SEA). The formulas are expressed as follows:
Fp represents the maximum force observed during the crushing process. In most cases, the peak force occurs at the outset of the crushing process, signifying failure initiation following an elastic stage [5].
The EA can be obtained by integrating the force-displacement curve shown in Eq. (1):

$$EA = \int_0^l F(x)dx \tag{1}$$

where 'l' represents the effective crushing distance and F(x) is the reactive load recorded by the drop-weight impact system.
The SEA is used to evaluate the energy absorbing efficiency, accounting for the lightweight requirement for the design of a good energy absorber. This can be calculated by dividing EA by the mass of the damaged part (m) according to Eqs. (2) and (3):

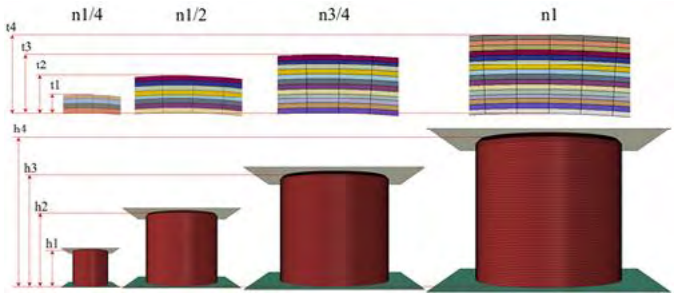
$$SEA = \frac{\int_0^l F(x)dx}{m} \tag{2}$$

$$m = M \times \frac{l}{H} \tag{3}$$

where 'M' and 'H', as indicated before, correspond to the total mass and height of each specimen before impact, respectively.

3. Numerical simulation

A 3D finite element model was created using ABAQUS/Explicit to simulate the crushing behavior of scaled tubes. Figure 2 illustrates the applied boundary conditions, loading direction, and discretized model for the scaled tubes. To represent the load and base platens, discrete rigid elements (R3D4) were utilized. The modeling of the scaled tubes employed 8-noded continuum shell elements (SC8R) with reduced integration and hourglass control.



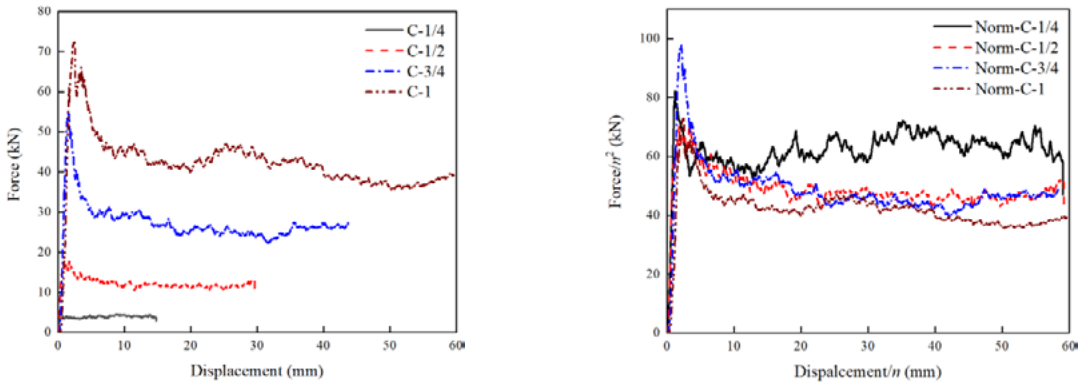


Figure 2. The finite element (FE) model for scaled samples.

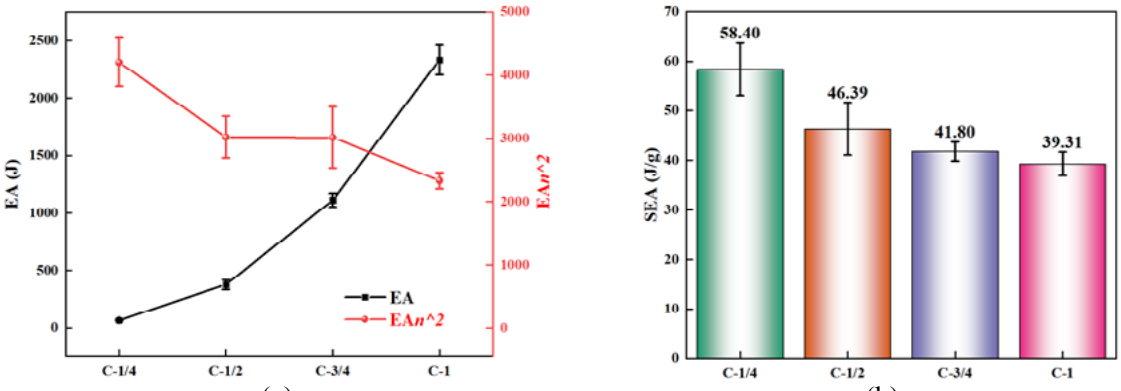
4. Results and discussion

4.1. Experimental results



The displacement and load curves of composite tubes with different sizes were obtained using a testing machine, as depicted in Figure 3(a). The energy absorption tubes of various sizes exhibited distinct four-level in their displacement and load curves. Figure 3(b) illustrates the resulting normalized force-displacement curves for the previously mentioned scaled samples in Figure 3(a). It can be observed that all the normalized curves share a striking resemblance, converging into a single trace. This suggests that the axial energy absorption characteristics of composite tubes follow a simple scaling law.

(a) (b)

Figure 3. The comparison of scaled samples: (a) the absorbed energy(EA) for and (b) the specific energy absorbing (SEA).

Figure 4 compares the total absorbed energy and specific absorbed energy of energy absorbers with different scales. It is observed that the total absorbed energy exhibits a nonlinear increase as the scale proportion increases. Furthermore, after normalization, it is evident that smaller sizes tend to absorb more energy, which is also reflected in the specific absorbed energy (Figure 4(b)).

(a) (b)

Figure 4. (a) Crushing force vs. displacement traces for scaled samples and (b) normalized crushing force vs. displacement traces.

Comparison of final failure modes of composite tubes with different scales is shown in Figure 5. It can be observed that the final failure modes of composite tubes with scales N=1/2, 3/4, and 1 are characterized as 'flower-like' failure pattern, whereas the failure mode of composite tubes with scale N=1/4 exhibits a 'water ripple' failure pattern. This may be attributed to the thinner wall thickness of the N=1/4 composite tubes, resulting in this specific failure mode which leads to greater material damage. Consequently, the normalized specific energy absorption is higher in this case.

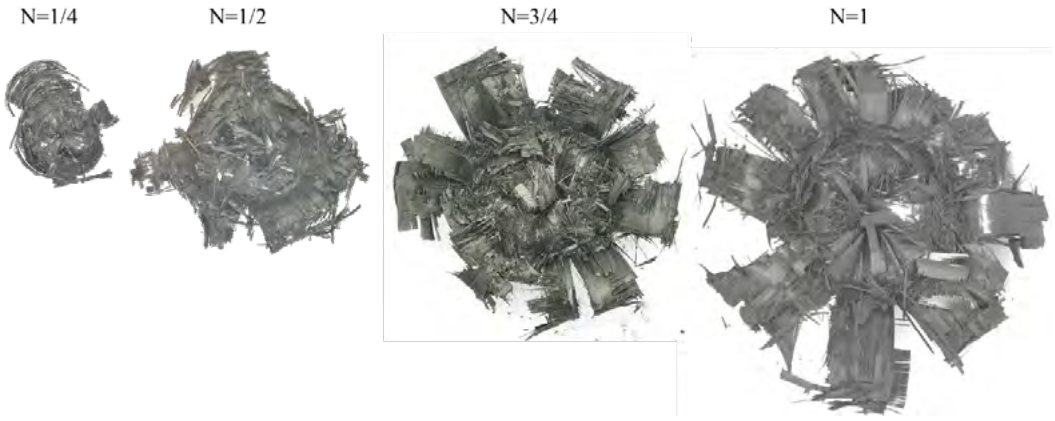


Figure 5. The failure mode of different scales.

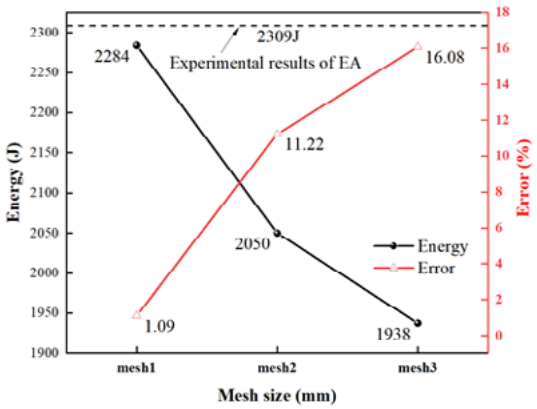
4.2. Simulation results

To improve the accuracy of the finite element model, the influence of the verification mesh size on the computational accuracy of the finite element model was examined. Figure 6 presents the comparison of the calculated energy absorption results of the C-1 composite tube finite element model at three mesh sizes with experimental results, along with the corresponding error magnitudes. It can be observed from the figure that as the mesh size becomes finer, the computational accuracy continuously improves. When the mesh size is 1mm × 1mm × 0.15mm, the calculation error is only 1.09%. Therefore, the final mesh size for the C-1 composite tube was set to 1 × 1 × 0.15mm. To ensure consistency of irrelevant variables, the mesh sizes of finite element models for composite tubes of different proportional sizes were set proportionally. The mesh size for the C-3/4 composite tube was set to 0.75 × 0.75 × 0.15mm, the C-1/2 composite tube to 0.5 × 0.5 × 0.15mm, and the C-1/4 composite tube to 0.25 × 0.25 × 0.15mm.



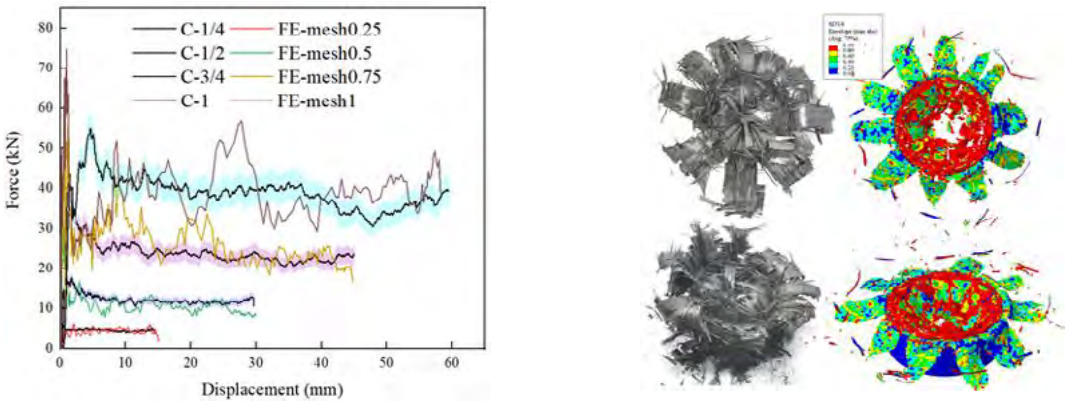


Figure 6. Grid sensitivity verification of finite element model.

Fig. 7 depicts the comparison between the force-displacement curve and the final crushing mode of sample C-1 obtained from the numerical model and the experimental results. The finite element simulation results effectively predict the displacement-load curve and the final failure mode observed in the experimental data.

(a) (b)

Figure 7. Comparison between the numerical and experimental results of C-1 sample: (a) Force-displacement curves; (b) Final crushed mode.

3. Conclusions

This paper investigates the scale effects on the axial energy absorption characteristics of composite tubes. The findings reveal that these characteristics can be accurately predicted using a simple scaling law and a finite element model for composite tubes of various sizes. The study's results provide evidence supporting the use of scaling laws to predict the crashworthiness of composite tubes. This has the potential to reduce costs associated with manufacturing and testing full-scale components.

Keywords: Basalt fibers, impact behavior, impact mass, temperature, electro spun veils

Abstract
The 2000/53/EC regulation promulgated by the European Union was specifically addressed to the transportation sector imposing greener policies and the identification of bio-based alteratives to traditional materials. Basalt fibers were selected as excellent substitute to glass ones in the manufacturing of polymer composites and many studies validated their feasibility both from the quasi-static and dynamic perspective. Despite this, none of them assessed the effect of impactor mass in equienergetic impacts and for this reason the present work focused on this aspect evaluating potential variation in laminates response also as a function of temperature, i.e., 80 °C, and as a consequence of the introduction of electro spun nanoveils as toughening elements. Impactor mass proved to significantly affect basalt/epoxy composites' impact response and damage mode especially at higher impact energies with a progressive decrease in peak force and a progressive increase in maximum displacement for increasing impactor masses, which also resulted in a higher concentration of the damage. The increase in impact temperature made the strain rate effect more visible even at lower impact energies due to the more compliant behavior of the structure while the introduction of electro spun nano veils did not seem to modify significantly the impact response of the laminate.

1. Introduction

The massive production of glass fibers started in 1893 [1] and encountered a steep growth during World War II when structures lightening was of primary importance and their integration with unsaturated polyester resin led to the progressive development of polymer composite materials [2,3]. Since that moment, glass fibers dominated the market of fibrous reinforcements accounting for more than 95 % of the global reinforcements used at an industrial scale [4] especially in the autmotive sector, where their lower cost compared to carbon fibers made them the preferred choice to reduce vehicles weight and the related fuel consumption while keeping low the cost of the final product.

Despite their dominance in the industrial landscape, the environmental decay observed in the last decades encouraged most countries to undertake greener and more restrictive policies in the field of environmental pollution. In particular, the 2008/1/EC directive in the field of Integrated Pollution Prevention and Control (IPPC) issued by the European Union aimed to foster the use of eco-friendlier materials from renewable resources. In this framework, many efforts were made to identify a suitable alternative to the widespread glass fibers and a compelling solution was found in basalt fibers.

Basalt is a bio-based material extracted from volcanic rocks [5] characterized by tensile properties higher than E-glass fibers [6] and by a greener manufacturing process. In particular, basalt fibers manufacturing process is similar to glass fibers one thus ensuring a good adaptability of the industrial plants already available with low investment costs and it is characterized by a lower energy consumption and no need of chemicals and additives addition during the manufacturing process [5,7,8].

Many studies already validated the feasibility of basalt fibers composites from a mechanical perspective [5] and many of them also focused on their impact behavior assessing the effect of different polymeric matrices [9,10], providing comparison with other fiber reinforcements, such as glass and carbon fibers [11–13], and disclosing the effect of low operating temperatures [14], but none of them focused on the effect of impactor mass being equal the impact energy, i.e., strain rate effect.

In light of this and considering that this aspect was deeply analyzed for carbon fiber reinforced composites [15–17], the present work aims to bridge this gap of knowledge providing a thorough characterization of the impact behavior of basalt/ epoxy composites and the related damage assessing the effect of impactor mass for equienergetic impact events using three different impact energies and three different impactor masses. Moreover, the effect of operating temperature was investigated performing the same experimental campaign not only at room temperature, but also at 80 °C. Furthermore, the effect of electrospun nano veils interleaving as toughening elements in basalt/epoxy composites was investigated in the same dynamic conditions.

2. Materials and methods

2.1. Materials and composite production

The basalt/epoxy composite laminates were manufacture by vacuum bagging and autoclave using a prepreg obtained from the plain woven fabric BAS 220 P by Basaltex impregnated with the toughened epoxy resin HEMT-3 by the Fibertechgroup. The laminates were produced by stacking 24 prepreg layers and were cured at 130 °C for 90 minutes applying a 70 mbar vacuum in the bag and a 5 bar in the autoclave for the whole curing according to the optimized procedure provided by the manufacturing company.

Moreover, the Xantu.Layr® electro spun nanoveils provided by Revolution fibers were interleaved in the basalt composite laminates to assess their effect on the overall impact response. This non-woven interlaminar reinforcement is obtained through electrospinning of tough thermoplastic nanofibers and thanks to its high porosity is able to ensure a good penetration of the thermosetting matrix and to ensure an increase in laminates resistance to delamination. Four electro spun nano veils with an areal density of 4.5 g/m^2 were interleaved in the laminate according to the stacking sequence shown in Figure 1.

2.2. Impact tests

The main goal of the present study is to investigate the effect of different strain rates on the impact behavior of basalt composites being equal the impact energy. To this aim, three different impactor masses of 5.055, 10.055 and 15.055 kg were selected and their effect on both reference and interleaved laminate configurations at three different impact energies, i.e., 15, 30 and 45 J, was evaluated. Impact tests were carried out in an Instron/ CEAST 9340 instrumented drop weight tower using a 12.7 mm diameter hemispherical impactor and a circular sample holder with a 40 mm unsupported area according to ATSM D3763 and ISO 6603.Moreover, the combined effect of temperature and impactor mass was also investigated performing the tests on reference basalt composites also at 80 °C. Specimens were pre-

©2024 | 3_SERGI_Claudia_5K3XU.pdf:2

conditioned for 1 hour at the desired temperature to ensure a uniform temperature profile throughout the whole thickness of the laminate.

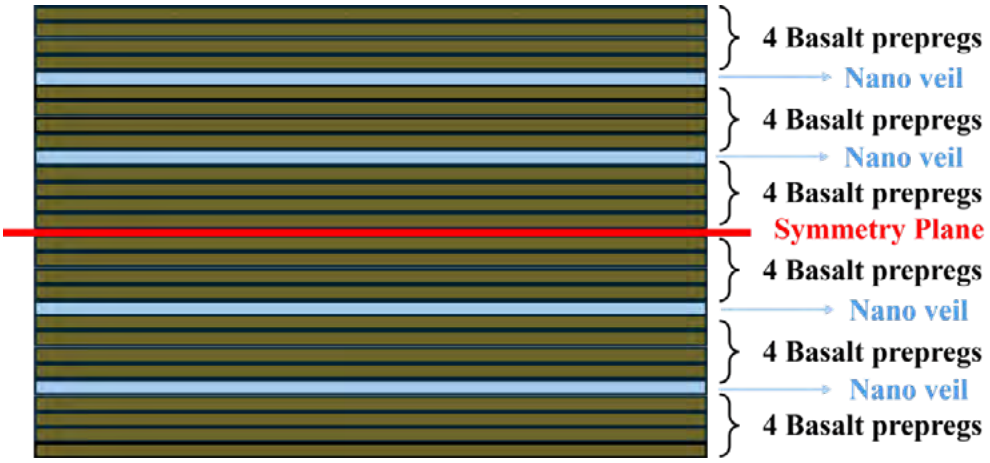

Figure 1. Stacking sequence of the basalt composites interleaved with the electro spun nanoveils

2.3. Post-impact damage analysis

A post-impact analysis through non-destructive techniques, i.e., C-scan and profilometry, was performed on the impacted samples to evaluate the damage extent, i.e., delaminated area and permanent indentation, respectively. The OmniScan MX2 ultrasonic system was used to perform the C-scan analysis using a phased array probe of 3.5 MHz, 64 elements, a 64 mm active aperture, a pitch of 1 mm, an elevation of 7 mm and a water immersion with 25 mm water wedge. The laser profilometer Talyscan 150 by Taylor-Hobson was used to carry out the profilometric analysis using a scanning speed of 8500 µm/s which allowed to obtain a 3D reconstruction of the permanent indentation of the impacted area.

3. Results and discussion

3.1. Impactor mass effect

The effect of impactor mass on basalt/epoxy laminates impact response at equienergetic impacts was investigated at 15, 30 and 45 J and the resulting force versus time and displacement versus time curves are reported in Figure 2.

For all impact energies, it appears evident that a decrease in impactor mass, i.e., an increase in impact velocity, being equal the impact energy, induces a faster response of the laminate with a shifting towards lower values of times of both peak force and maximum displacement. The effect of an increasing strain rate resulting from the decrease in impactor mass is particularly evident at 45 J, where a progressive increase in peak force and a progressive decrease in maximum displacement can be observed for decreasing impactor masses. This highlights a stiffer response of the laminate as also confirmed by the higher slope of the force and displacement versus times curves in the first linear elastic region.

This stiffer response is confirmed also at 30 J and 15 J where a difference in curves slope can be still recognized, but due to the progressive reduction in the impact velocity difference the effect on peak force and maximum displacement becomes progressively less evident. In particular, at 30 J the increase in peak force and the decrease in maximum displacement can be observed only moving from the 15 kg configuration to the 10 kg configuration, but no significant variations were observed with a further reduction of the mass at 5 kg. The effect appears even less pronounced at 15 J where no significant variations in peak force can be observed among the different configurations and just an increase in maximum displacement can be observed for the 10 and 15 kg impacted specimens compared to the 5kg.

No significant variations were observed in laminates damage degree, i.e., ratio between the absorbed and the impact energy, but some variations in composites damage mode were detected. In particular, for the 45 J impacted specimens, a higher localization of the damage resulting in a higher permanent indentation was observed for the 15 and 10 kg impacted specimens while the more impulsive stress resulting from the 5 kg impact induced mainly a diffused delamination in a higher number of plies. This effect is still detectable at 30 J where 5 kg impacted specimens still display a slightly higher delaminated area while no significant differences in the damage mode where observed for the 15 J impact.

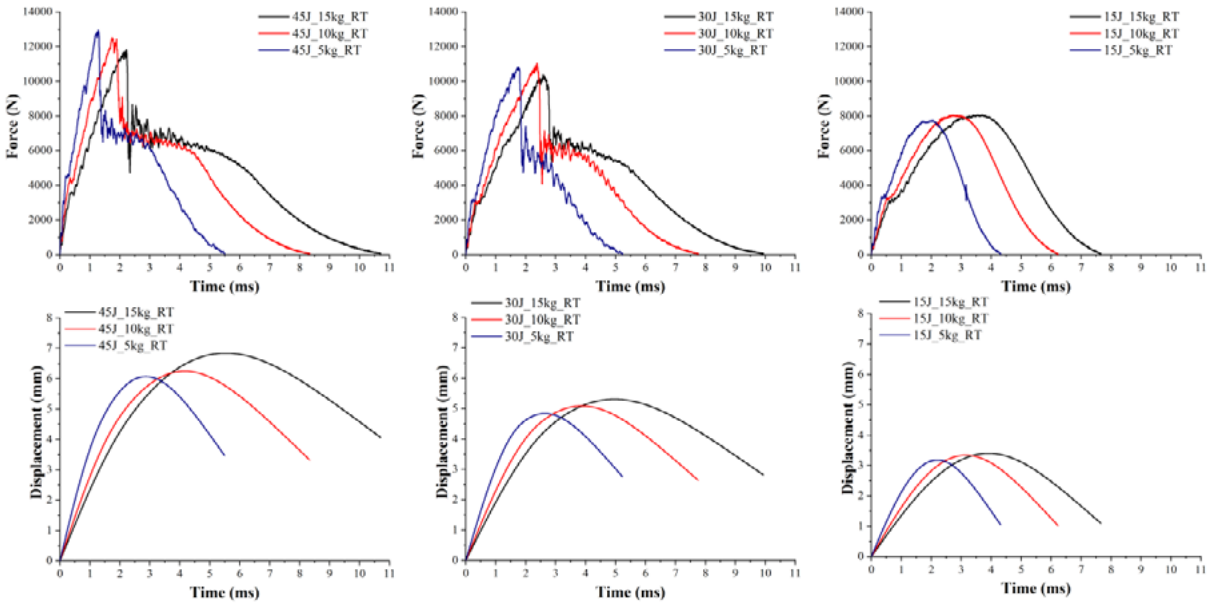

Figure 2. Force vs. time and displacement vs. time curves of basalt/epoxy composites impacted at 45, 30 and 15 J with the three different impactor masses

3.2. Temperature and electrospun nanoveils effects

Concerning the effect of temperature, the increase from room temperature to 80 °C determined a progressive decrease in laminate stiffness thus making it more compliant towards the impact with a decrease in peak force and an increase in maximum displacement. The trend observed as a function of impactor mass in peak force and maximum displacement at room temperature for the 45 J is confirmed also at 80 °C and it can be extended also to the 30 J impact events. Indeed, the reduced stiffness and brittleness of the laminate make the effect of lower strain rates differences more easily detectable. Concerning the 15 J impacts at 80 °C, a trend similar to the one observed at room temperature for the 30 J impact was detected with a progressive decrease in maximum displacement for decreasing impactor masses.

Even in this case no significant variations in the damage degree among the different configuration impacted with different masses were observed, but again a higher localization of the damage with a higher permanent indentation was observed at 45 and 30 J for the specimens impacted with a 15 kg and 10 kg impactor.

The introduction of the electrospun nanoveils does not modify significantly the overall impact response of basalt/epoxy laminates highlighting the same trend observed for the reference composites at 30 and 15 J impacts.

4. Conclusions

Basalt fibers were identified as suitable bio-based alternative to glass fibers for the production of structural epoxy composites applicable in different industrial fields such as the transportation one where the more restrictive regulations promulgated by the European Union impose ecofriendlier policies.

Many studies validated the feasibility of basalt fibers as structural reinforcement in composite laminates investigating both their quasi-static and dynamic performance, but none of them focused on the effect of impactor mass being equal the impact energy. In light of this, the present study aimed to bridge this gap of knowledge providing a characterization of the impact behavior of basalt/ epoxy composites and the related damage investigating the effect of impactor mass for equienergetic impact events evaluating also the effect of operating temperature and investigating the effect of potential toughening mechanisms such as electrospun nano veils interleaving.

The effect of impactor mass proved to be progressively more relevant for increasing impact energies determining a stiffer response of the laminate with an increase in peak force and a decrease in maximum displacement for decreasing impactor masses. This also resulted in a lower localization of the damage with a lower permanent indentation and a more widespread delamination.

The increase of impact temperature at 80 °C made laminate response more compliant toward the impact better highlighting the differences in peak force and maximum displacement also at lower impact energies while the introduction of electrospun nano veils does not modify significantly the overall impact response of the laminate with respect to the reference one.

BUCKLING OF A $[\mp 45]_S$ LAMINATE IN A COMPRESSION-COMPRESSION BIAXIAL TEST WITH A CRUCIFORM SPECIMEN

MC Serna Moreno and S Horta Muñoz

Universidad de Castilla-La Mancha, Escuela de Ingeniería Industrial y Aeroespacial de Toledo, Instituto de Investigación Aplicada a la Industria Aeronáutica, Av. Carlos III, Real Fábrica de Armas, 45004 Toledo, Spain

Keywords: carbon fibres, geometrical instability, laminate mechanics, biaxial testing, DIC

Abstract
Traditionally, the study of the biaxial stress states with cruciform specimens has been focused on positive load ratios. However, more recently there has been a shift towards their application in load cases involving at least one compressed direction. This work proposes the compression-compression test with cruciform specimens (CC test) as a reasonable option to analyse the geometrical instability of a carbon fibre-reinforced polymer. The region of interest (ROI) is tested under equal applied stresses, and is composed of a $[\mp 45]_S$ laminate that exhibits significant flexural-torsional coupling. The ROI possesses a shape and boundary conditions akin to a clamped square plate. Full-field displacements and strains are registered by Digital Image Correlation, determining the bifurcation onset by comparing the strain evolution in both sides of the ROI with the help of strain gages. The bifurcation stress is found to be close to the critical stress obtained according to actual regulations for metallic structures. However, due to the complex response of laminated composites, further work is needed to estimate the relation of the global instability with apparent material non-linearities. In addition, this research explores whether the experimental deflection surface can provide valuable information for quantifying the bending and twist moments at the onset of bifurcation.

1. Introduction

The use of carbon fibre-reinforced polymer-matrix (CFRP) laminates in the primary structure of light vehicles is increasing. These laminates usually have small thickness compared to their other two dimensions. Then, under workloads the problem can be addressed assuming that the stress components outside the plane that defines the laminate are negligible compared to those contained in the plane (plane stress state). There are cases in which the predominant components are normal stresses, as in the pressure hull of submarines that can withstand in-plane bidirectional compression that could lead to geometrical instabilities. While analytical closed-form solutions exist for laminates free of couplings [1-2], most of the results proposed in the literature rely on semi-analytical or semi-numerical approaches [3-5]. A particularly intricate scenario arises when analyzing buckling behavior in ±45º symmetric laminates with a limited number of alternating layers, which exhibit significant flexural-torsional coupling. However, the high sensitivity of compressive tests to boundary conditions and initial geometrical defects presents challenges when comparing the experimental data with the results of theoretical models. This issue becomes more noticeable at the coupon scale with small sizes of the tested region. Consequently, this research investigates the capacity of biaxially loaded cruciform specimens (at the coupon scale) to assess the stability of bi-compressed laminates, even in the presence of pronounced coupling effects.

Cruciform specimens, developed over the past few decades, serve as valuable tools for monitoring material behavior when subjected to biaxial loading. Traditionally, these caharacterizations have

focused on positive load ratios. However, more recently, researchers have proposed their use for analyzing scenarios where at least one direction experiences compression. The literature has primarily explored the tension-compression behavior [6-9], but the experimental works of Horta Muñoz and Serna Moreno [7,9,10] and Zumaquero [8] stand out for the use of cruciform specimens in compression-compression tests (CC tests). Zumaquero investigated the transverse biaxial response of a unidirectional CFRP, revealing that global buckling can significantly impact the cruciform specimen's performance. Meanwhile, Horta Muñoz and Serna Moreno [7,10] specifically examined an equally bi-compressed $[\mp 45]_S$ CFRP laminate using a fixture to mitigate the risk of buckling in the arms of the sample.

The present work is of scientific interest because it introduces the CC test with cruciform specimens as a suitable technique for providing fundamental insights into the bifurcation phenomenon. In particular, the proposal is to evaluate experimentally the geometrical instability of a $[\mp 45]_S$ CFRP laminate, with shape and boundary conditions close to a clamped square plate submitted to equal bi-compression [10]. The test is performed on carbon-fiber/epoxy ∓45º symmetric laminates which exhibit a significant flexural-torsional coupling, adding complexity to the buckling analysis. The use of the Digital Image Correlation (DIC) technique allows to observe the experimental deflection surface, which validates the numerical predictions with the finite element method [11]. This experimental outcome is utilized for analytically estimating the relation between the bending and torsional moments at the instability onset, which could provide valuable information about the post-buckling behavior of the laminate. As well, the method of the strength reduction, usual in the current European regulations for evaluating the buckling capacity of metallic members, is here adapted to estimate the critical stress of a bi-compressed laminate. Considering apparent elastic properties of the laminate in the loading directions, the proposed estimation is found to be close to the experimental bifurcation stress.

2. Materials and methods

2.1. Material, specimen and equipment

A symmetrical ∓45º angle-ply laminate made of pre-impregnated CFRP (M21E/34%/UD268/IMA-12K) [12] is analyzed. Each cured layer has 0.25 mm thickness and consists of an epoxy matrix reinforced with unidirectional carbon fibers (UD). Elastic moduli E_1 and E_2, Poisson ratios ν_1 and ν_2, and failure strengths σ_1^u and σ_2^u were estimated from uniaxial tests on UD specimens [7]. In-plane shear modulus G_{12} was obtained from tension-compression biaxial tests with cruciform specimens following UNE 0074:2023 recommendations [7,9,13]. Meanwhile, the apparent elastic response (elastic modulus E_a and Poisson ratio ν_a) of the proposed symmetrical ∓45º angle-ply configuration under uniaxial compression is defined in Table 2 [14]. Please notice that the non-conventional response of laminates is reflected in an apparent Poisson coefficient higher than 0.5.

Table 1. Average elastic properties and strengths in the in-plane principal material directions [7,9].

E_1 (GPa)	E_2 (GPa)	ν_{12}	ν_{21}	G_{12} (GPa)	σ_1^u (MPa)	σ_2^u (MPa)

E_a (GPa)	ν_a
18.20	0.74

The hand lay-up technique is used to create 300 mm x 300 mm square plates with a $[\mp 45]_{4S}$ stacking sequence. These plates undergo a curing cycle of 7 bars at 180 ºC for 120 minutes using a hydraulic heated platen press LabEcon 300 from Fontijne Grotnes Group. The final geometry and dimensions of

the specimen are achieved through computer numerical control milling (Fig. 1). The cruciform specimen comprises $[\mp 45]_{4S}$ laminate arms, of width l = 30 mm and a thickness H = 4 mm (Fig. 1), uniaxially loaded. Then, a stepped thickness reduction up to h = 1 mm is performed in the biaxially loaded region, transitioning to a $[\mp 45]_S$ stacking sequence. The central region is assumed to be a nearly squared plate clamped at all edges. The CC test is conducted using an electromechanical multiaxial machine from the company Microtest. This installation features four closed-loop synchronized actuators driven by an electric motor, precisely controlled via encoders. Additionally, four force transducers with a capacity of 50 kN are employed using a force control. To enhance stability and minimize issues from sample imperfections, a biaxial anti-buckling fixture is employed [15]. Both the DIC technique and a strain rosette are employed simultaneously on both sides of the central region biaxially loaded. A speckle pattern is applied on the frontal surface for obtaining the full-field displacements and strains by a LaVision Strain-Master stereo-DIC system with two cameras. Meanwhile, in the rear surface a strain rosette, connected to a Kyowa PCD-300B sensor interface, measures the ε_{xx} and ε_{yy} strains in the horizontal and vertical load directions. Each strain gage has a range of acquisition up to 20 millistrains and averages the deformation over a 5 mm length.

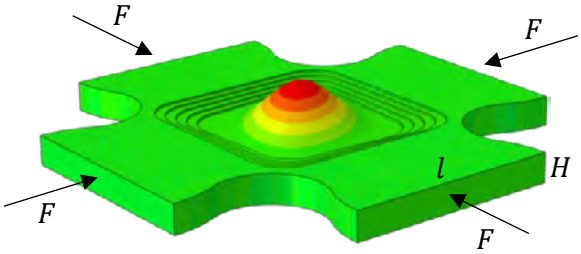

Figure 1. Representation of the buckled cruciform specimen numerically estimated [7,11], indicating the equal bi-compression and the dimensions of the arms' cross-section.

2.2. Analytical approaches

A multiaxial machine applies equal compressive forces F to the arms of the cruciform specimen (Fig. 1). During the linear response of an ideal CC test, the normal stress components of the central region in both load directions are assumed to be equal and denoted as σ. In parallel, longitudinal strains in both load directions are expected to be similar due to the analogous apparent material's behavior. Then, the response of the central region is analyzed using the global biaxial stress (σ) and averaged strain (ε), even when non-linearities occur in the stress-strain relationship after trespassing the critical stress σ_c.

$$\sigma = f\frac{|F|}{lH} \tag{1}$$

$$\varepsilon = \frac{\varepsilon_{xx} + \varepsilon_{yy}}{2} \tag{2}$$

The central stress (Eq. 1) is calculated from the applied force F and the averaged dimensions of the width l and thickness H of the arms' cross-section (Fig. 1). As well, a numerically estimated conversion factor f = 1.496, equal in both loading directions, is taken into consideration. This is obtained from a linear simulation with the finite element method using the software Abaqus/Standard 2021, evaluating the amount of the applied load that is transferred to a central squared zone of 5 mm x 5 mm [7]. An engineering approach is considered, referring the conversion factor to the undeformed geometry.

During the linear stage, the apparent elastic modulus is estimated in both loading directions using Classical Laminate Plate Theory (CLPT) for ∓45º symmetric configurations. The studied $[\mp 45]_S$

laminate exhibits no coupling between in-plane axial terms and in-plane shear, and the membrane-moment coupling components are negligible. Consequently, the apparent biaxial stiffness in the x- and y-directions can be calculated. This serves as a reference for evaluating experimental observations obtained from the CC test with cruciform specimens.

$$E_{\mp 45^\circ}^{CC} = \frac{E_1(1 + 2\nu_{21} + \nu_{21}/\nu_{12})}{2(1 - \nu_{12}\nu_{21})} \tag{3}$$

The buckling stress σ_c accounts for material limitations (finite stress capacity σ^u) and non-ideal conditions (initial imperfections and loading asymmetry). If the strength reduction method is used, a reduction factor $\chi = \sigma_c/\sigma^u$ is typically proposed to estimate the buckling capacity for different modified slimness values $\bar{\lambda}$. Considering a square plate with a side l and a thickness h, clamped in all its edges, that presents a linear elastic material behavior with similar responses in both loading directions and is subjected to equal biaxial compression, the modified slimness that is taken into account is given in Eq. 4 [16,17].

$$\bar{\lambda} = \frac{l}{h}\sqrt{\frac{\sigma^u(1 - \nu_a^2)}{4.4E_a}} \tag{4}$$

Following the recommendation in Annex B of EN 1993-1-5 [18], the real buckling curve could be approximated following an Ayrton-Perry type function which is represented in Fig. 2, assuming that at modified slimness $\bar{\lambda} < 0.7$ the material fails before the plate would buckle.

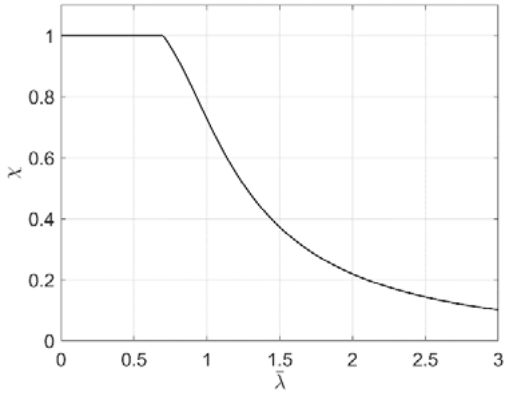

Figure 2. Estimation of the real buckling capacity [18].

3. Results and discussion

In a cruciform specimen subjected to a CC test, the stress-strain evolution of the biaxially loaded region is analysed. Fig. 3 (centre) illustrates this response using the global stress σ (Eq. 1) versus the global strain ε (Eq. 2) and the strain components in each loading direction (ε_{xx} and ε_{yy}) measured by the strain rosette. Fig. 3 (centre) reveals distinct strain states at the ply level because the presence of local shear strains introduces discrepancies between the ε_{xx} and ε_{yy} strains. However, the local shear effects are expected to be mitigated by neighbouring plies. This should result in a null global shear strain ε_{xy} and, therefore, at the global level no significant deviations from the average strain value ε (Eq. 2) are assumed. Therefore, the apparent σ-ε evolution is compared to the CLPT linear estimation (dashed red line). By substituting the compressive properties from Table 1, the biaxial elastic modulus is estimated to be $E_{\mp 45^\circ}^{CC} = 72.98$ GPa (Eq. 3), which agrees with the experimental σ-ε slope at the linear stage. The

onset of instability is assumed to occur when apparent biaxial strain ε deviates from the linear evolution, which is here produced nearby $\sigma_c = 120$ MPa. Prior to this threshold, a biaxial-driven response is assumed, transitioning to a moment-driven response afterwards.

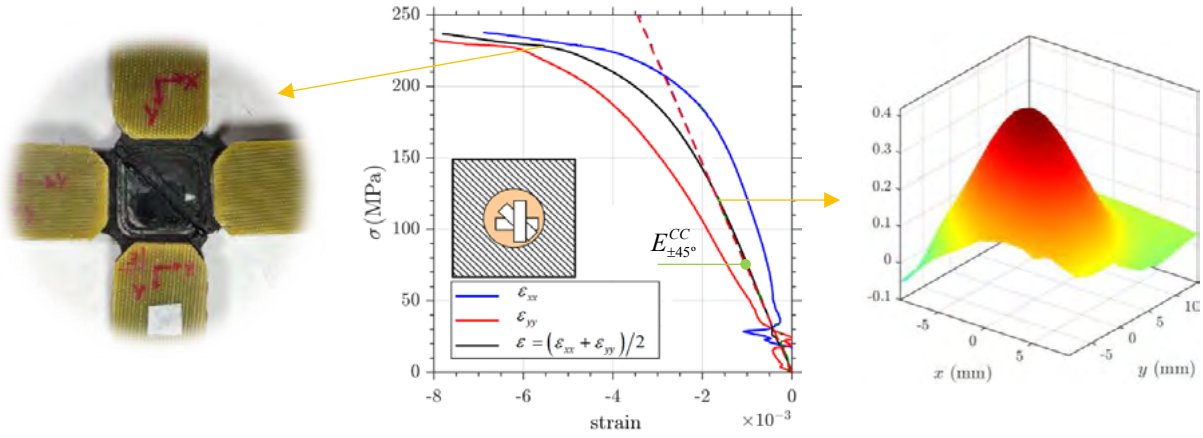

Figure 3. Stress-strain evolutions σ-ε_{xx}, σ-ε_{yy} and σ-ε, detailing: the slope at linear stage including the dashed linear tendency (centre), the out-of-plane displacement at the onset of buckling (right) and the final failure pattern (left).

Despite the visual limitations posed by the opening of the anti-buckling fixture, Fig. 3 (right) displays the deflection surface captured by the 3D DIC system at the point of bifurcation onset. The experimental deflection surface presents strong evidence in the elliptical plane projections of the flexural-torsional coupling, what agrees with the numerical predictions [11]. The final failure of a representative specimen given in Fig. 3 (left) is in concordance with the observed buckling mode, presenting matrix cracking in parallel to the outer fibres and typical kink bands.

As a verification tool of the experimental outcome, it is checked if the experimental bifurcation stress is in concordance with the approximation represented in Fig. 2. The reduction factor is estimated taking into account that its value relies heavily on limit stress determination. As a conservative assumption, the limit value is considered to be equal to the matrix strength under uniaxial compression, i.e. $\sigma^u = \sigma_2^u$ (Table 1). Then, the experimental reduction factor is calculated as $\chi = 0.7$, while the modified slimness factor is $\bar{\lambda} = 0.94$. Please, note that these values are in concordance with the approximation of the real buckling curve given in Fig. 2.

4. Conclusions

In the context of CC tests using cruciform specimens, the buckling features of a clamped square plate made of a $[\mp 45]_S$ CFRP laminate are reviewed. To prevent instability in the specimen's arms, an anti-buckling fixture is employed. Analysing the multiaxial response in an anisotropic material presents complexities, difficulties that are increased by strain variations at the ply level. Considering the global biaxial stress-strain behaviour, prior to strain bifurcation the stiffness agrees with the CLPT prediction. As well, the bifurcation stress is aligned with the critical stress predicted using an adaptation of the reduced strength method. Nevertheless, given the intricate nature of laminated composites, further investigation is needed to understand the relationship between global instability and apparent material non-linearities. After the bifurcation onset, the influence of high flexural-torsional coupling becomes evident in the buckling mode captured by DIC technique, observing an experimental deflection surface which agrees with the numerical predictions. These findings could imply that employing the CC test with cruciform specimens, along with an anti-buckling fixture, offers a suitable approach for observing the buckling modes in bi-compressed laminates. Finally, the variation in the relationship between central thickness and the arms' thickness could provide an opportunity to analyse the instability of the biaxially tested region considering diverse boundary conditions.

Abstract

In a context of massive investments in cryogenic propellant storage, full composite tanks consitute a technological challenge. Their mass-to-performance ratio justifies their potential in aerospace industry, but their permeability is a limiting factor. Indeed, the pressurization of the tank and cryogenic temperatures generate matrix damages that coalesce and generate leakage paths. In order to master the permeability of the structure, composites tubes undamaged and damaged are studied. A methodology is proposed to measure the permeability using mass spectrometry. Tubular specimens are pressurized using helium gas and leak rates are measured. The bench test is then extended to low temperature. Finally, the evolution of the number of leak points is studied since they significantly rise the permeability of the structure.

1. Introduction

The application of CFRP laminates to the structures of cryogenic propellant tanks has been widely attempted in order to drastically reduce the weight of space launch vehicles. However, recent studies suggest that the conventional thermoset composites used in these tanks are prone to matrix cracking when exposed to extreme thermomechanical loads [1], [2]. These damage mechanisms are critical regarding the permeability since this can lead to propellant leakage. These leaks can be tolerated if mastered, therefore it is necessary to evaluate the accumulation of leak points and the leakage rate of the composite as a function of the internal pressure and the temperature.

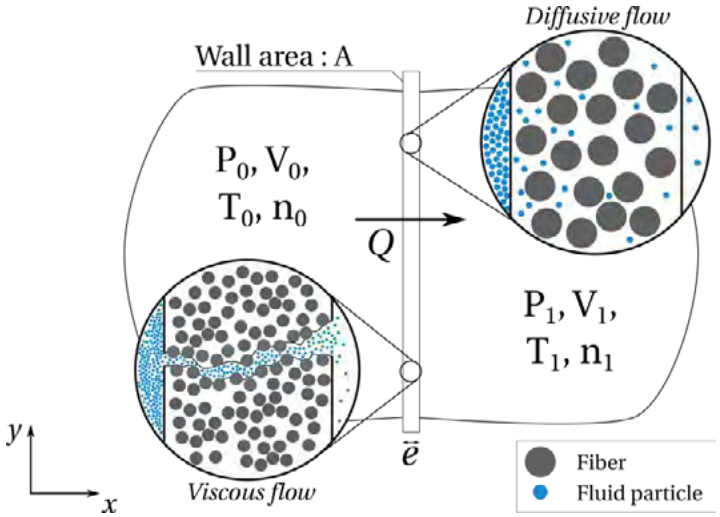

Figure 1. Two types of flow through a wall

Two principle types of flow can go through a composite wall : diffusive flow and viscous flow. The phenomena which govern them are substantially different and imply a definition of the coefficient of permeability which is peculiar to them and which we will try to define on the basis of the case study presented in Figure 1. On the latter, the index 0 and 1 parameters refer respectively to the physical quantities on either side of the wall. We will consider that the test conditions favour a flow from state 0 to state 1.
Diffuse flow can be a dimensioning criterion during long-term storage. These operating conditions involve relatively low flow rates, but can become critical beyond a certain time as for hydrogen storage. In this case, the permeability coefficient is, by definition, the product of the solubility coefficient by that of diffusion [3, 4], it is proportional to the flow rate Q_n through the wall.

$$Pe = \frac{Q_n e}{\Delta P A} \tag{1}$$

With :

- Q_n : the flow rate in $mol.s^{-1}$
- A : the observed area in m^2
- e : the wall thickness in m

When the wall reaches a certain damage level, leak points start accumulating. The opening of the cracks is such that the flow through them is viscous and called Darcy's flow. In the case of the laminar flow of a perfect gas incompressible in steady state, Darcy's law expresses the proportionality between the passing flow and the pressure gradient [5]:

$$k = Q_n \frac{RT\mu e}{\Delta P A P_1} \tag{2}$$

With :

- R : the perfect gas constant in $J.mol^{-1}.K^{-1}$
- μ : the dynamic viscosity in $Pa.s$
- k : the composite permeability in m^2

This expression can be generalized in the case of a compressible fluid. Assuming that the temperature is constant in the system, the permeability k of the wall is written [6]:

$$k = Q_n \frac{2RT\mu e}{\Delta P (P_0 + P_1) A} \tag{3}$$

Permeabilities k or Pe are independent from the test environment (fluid property, pressure, wall thickness…). The physical meaning attributed to the permeability of a material thus depends on the type of flow that passes through it. In the following, we shall distinguish the coefficient Pe from the permeability k according to the type of flow considered. These two parameters are however calculated from the same experimentally measured quantity: the material flow rate Q_n. In practice, the measured quantity is the leakage rate Q expressed in $Pa.m^3.s^{-1}$.

2. Experimental setup

2.1. Specimen design and manufacturing

In order to measure the leakage rate, tubular specimens are manufactured in automated fiber placement (AFP). This type of specimen allows a biaxial loading that is far more representative of the industrial application than place specimen. Il can also reduce significantly the edge effects and it can be pressurized. The stratification is [-50/15/35_2/-35_2/-15/50] with 140 µm plies. It has been developed in order to master the damage scenario. Indeed, the $\pm 35°$ plies damage at first and interact with the adjacent $\pm 15°$ plies, then the $\pm 50°$ ply, that have a slightly higher crack threshold, damage independently from the other plies and drive the accumulation of leak points. To generate a biaxial load, the tube are closed with two INVAR machined flanges. The INVAR is a stainless steel alloy with a very low coefficient of thermal expansion which allows to limit the clearance between the tube and the flanges during tests at low temperatures. The assembly is sealed with PTFE lip seal. In order to transmit the axial loading to the tube, [7] proposes to use a pinned joint as shown in Figure 2.

We chose to integrate the heels directly into the composite tube by drapeing extra prepreg composite. The heel are made of 8 plies with the stacking sequence $[(0/90)/\pm 45]_4$ giving 25% reinforcement at 0°, 90°, 45° and -45°. Their thickness gradually decreases at an angle of around 15° to prevent brutal variation of stiffness. They are also used to reduce the circumferential deformation at the ends, in order to maintain the tightness of the assembly, and to reduce the edge effects by deflecting the flow of forces.

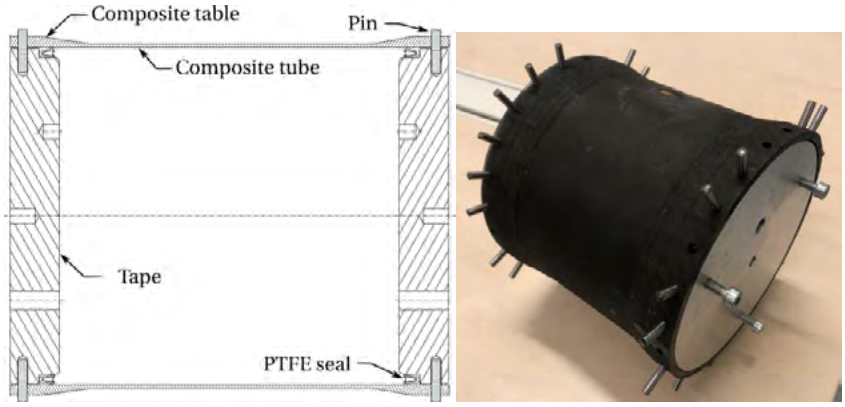

Figure 2. Biaxial loading device on tubular specimen

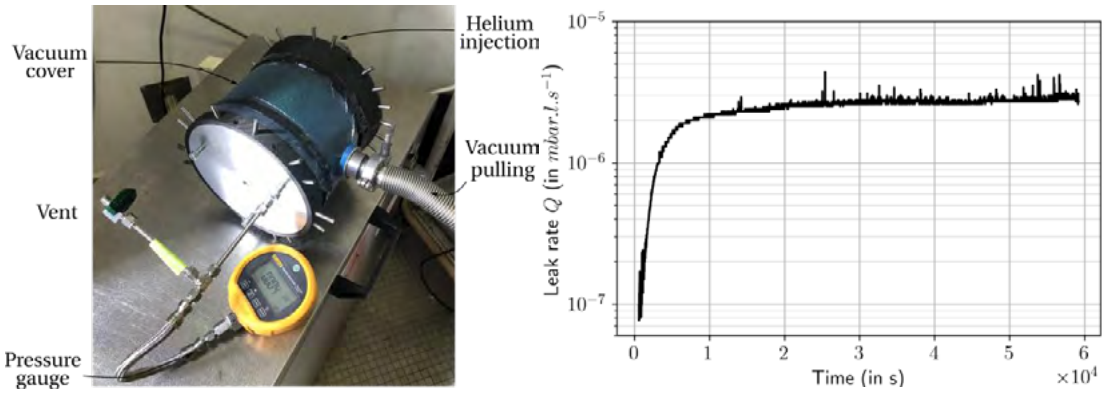
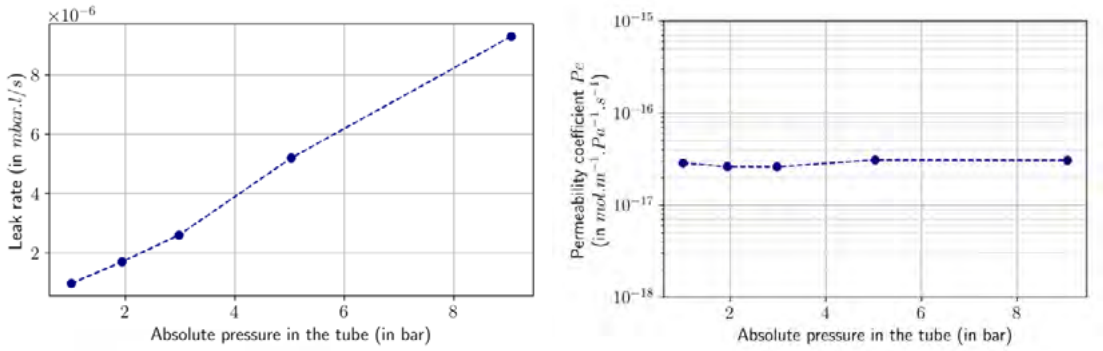


2.2. Permeability measurement on undamaged composite

2.2.1. Permeability at room temperature

The permeability measurement is performed with the vacuum detection method as in [8] work. The useful surface of the tube is covered with a vacuum bag, the sealing of which is provided by a pre-formed butyl mastic as shown in Figure 3a. The vacuum bag is directly connected to the Pfeiffer Vacuum ASM 340 mass spectrometer by means of a steel vacuum socket. The vacuum is pulled to a pressure of less than $5 \times 10^{-3}\ mbar$ between the bag and the composite. The tube is then pressurized with helium and the leakage rate is measured. Figure 3b shows the evolution of the leakage rate Q over time on an undamaged tube for a pressure difference of 3 bars (2 bar of relative pressure in the tube and the vacuum in the bag). It first passes through a transient regime during which the helium concentration gradually increases in the wall before reaching a plateau value. The established regime reflects the constant flow of helium through the wall.

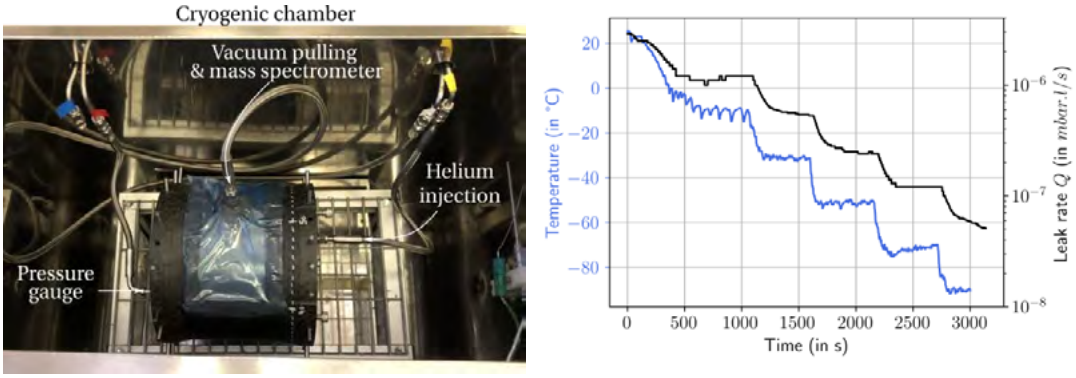


Several leakage rate measurements were made by pressurizing the tube to 1, 2, 3, 5 and 9 bar. At these pressures, no cracks are created *a priori*. The results are plotted in Figure 4a and show the linear relationship between the internal pressure of the tube and the leakage rate measured, which

reflects a diffusive flow. The permeability coefficient Pe of the composite tube is thus independent of the test conditions and $Pe = 2.1 \times 10^{-17}\ mol.m^{-1}.Pa^{-1}.s^{-1}$.

(a) (b)

Figure 3. Leak rate measurement device (a) and leak rate evolution for a pressure difference of 3 bar (b)



(a) (b)

Figure 4. Leak rate (a) and permeability coefficient $\boldsymbol{Pe}$ (b) measured against the pressure

2.2.2. Permeability under cryogenic conditions

In cryogenic storage, the temperature of the wall strongly influences its permeability by reducing the molecular agitation. In order to assess the temperature dependency, a leak rate measurement is first performed at the room temperature and then, once the plateau value is reached, the tube is placed in the cryogenic chamber as shown in Figure 5a. Pressurization at room temperature allows the helium wall to be saturated to reduce the duration of the test. The temperature is then gradually reduced in 30°C increments as shown in Figure 5b. The transition to the next temperature step is made when the leakage rate reaches a plateau value. The measurement was stopped at -90°C, the temperature at which the butyl seal no longer seals the vacuum bag.

(a) (b)

Figure 5. Bench test for the leak measurement at low temperature (a) and evolution of leakage rate and temperature during the test (b)

The permeability coefficients Pe measured at different temperatures are plotted in Figure 6. The Arrhenius law (Eq. 4) was identified from these results with an activation energy $E_p = 14.61\ kJ.mol^{-1}$, which is consistent with the results of [8] and [9], respectively of 25 $kJ.mol^{-1}$ and between 14,6 $kJ.mol^{-1}$ and 19.7 $kJ.mol^{-1}$.

$$Pe(T) = Pe_0 \exp\left(-\frac{Ep}{RT}\right) \tag{4}$$

The quality of the interpolation makes it possible to extrapolate the permeability coefficient of the undamaged material to very low temperatures. Besides, the quality of the results on undamaged material, and thus low permeability, allows to apply the measurement procedure on damaged material with confidence.

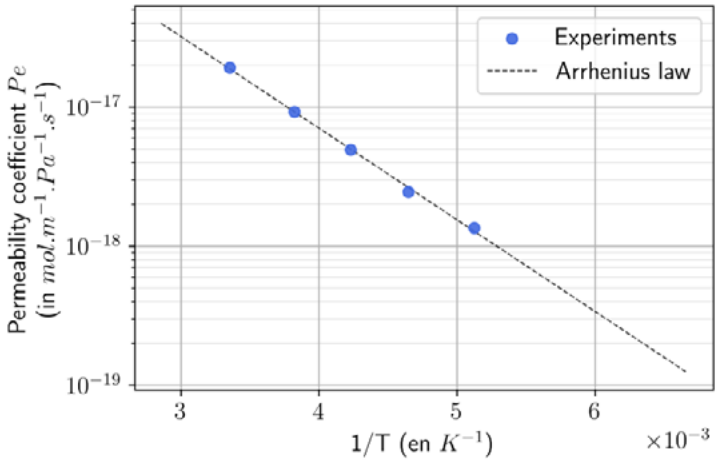


Figure 6. Identification of Arrhenius law from permeability coefficients measured at low temperatures for a pressure difference of 3 bar

3. Permeability of damaged composite

3.1. Leak kinetics measurement

During loading, the accumulation of transverse cracks in the various plies can generate leakage points. In this section we study the evolution of permeability and the number of leakage points during loading. The test bench is shown in Figure 7. Axial and circumferential strains as well as temperature are

measured, and six sensors for Acoustics Emission (AE) monitoring are distributed over the surface of interest.

After each loading step, the leakage rate is measured with a pressure difference of 3 bar. The tube gradually damages, and beyond a loading threshold, it generates leakage points and the flow becomes viscous. This involves studying permeability k rather than permeability coefficients Pe. Figure 8 shows the evolution of permeability k measured at room temperature between each pressure level as well as the cumulative energy of acoustic events. The measured permeability k does not change up to 25 bar, then beyond 27.5 bar, it goes from $1.3 \times 10^{-23}\ m^2$ to $5.1 \times 10^{-23}\ m^2$. Sound activity intensifies at this loading level, which shows that the damage threshold estimated by acoustic emission is the same as the permeability threshold. At 32.5 bar, 120 leakage points were counted manually using a gas revealing spray.

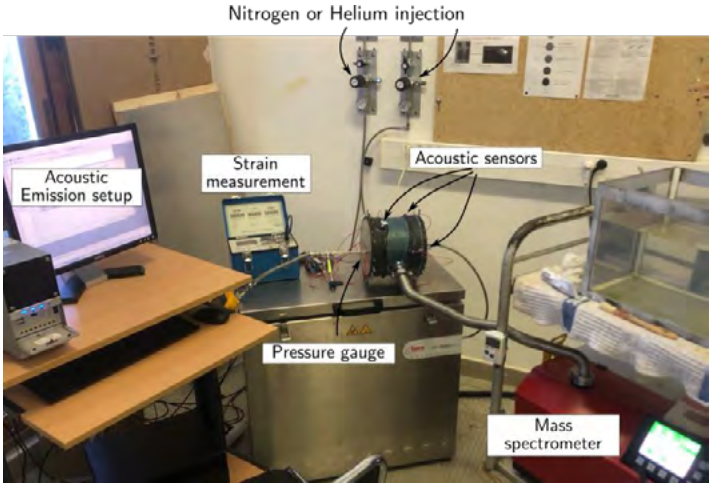

Figure 7. Test bench for the study of tubes subjected to biaxial loading

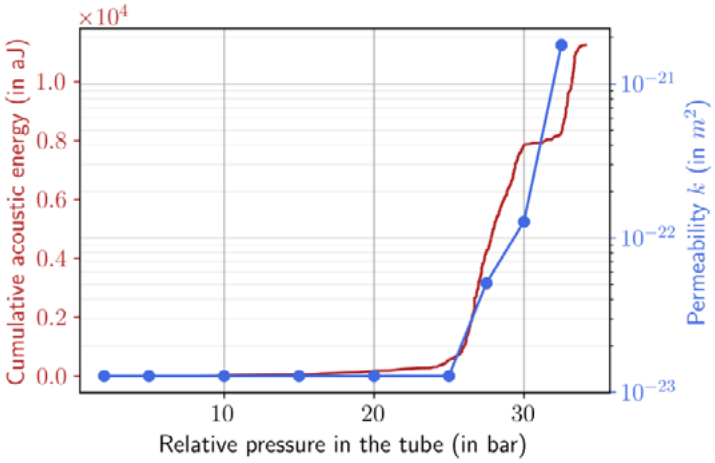

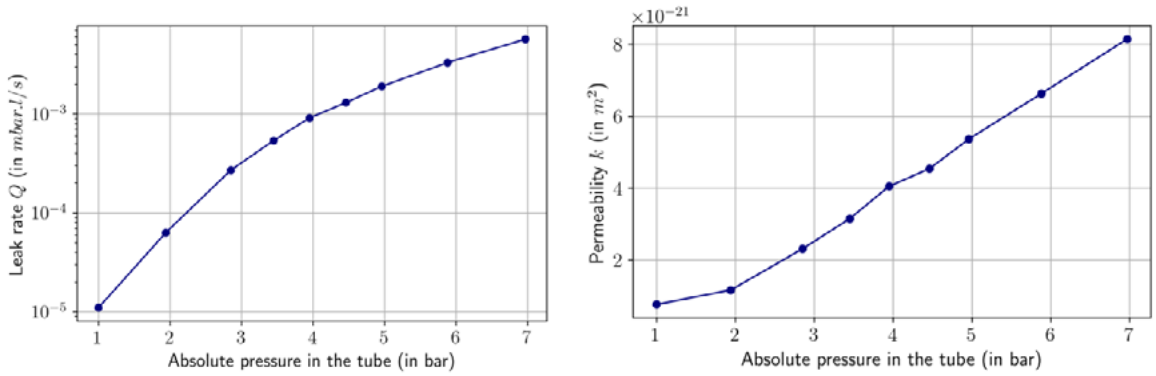

Figure 8. Evolution of permeability and acoustic activity as a function of internal tube pressure at room temperature

3.2. Leak rate evolution

The overall leakage rate Q was measured at different pressure levels below the maximal pressure applied to the tube to determine the influence of pressure on permeability k for a given damage state. These values are plotted on Figure 9 as a function of absolute pressure, since the vacuum is drawn into the bag, this pressure also corresponds to the pressure difference across the wall. As expected, the leakage rate increases with pressure, but the Darcy permeability also increases. This behaviour reflects the effect of

pressure on the opening of cracks in the leakage network, this opening being directly related to the crossing section and therefore to the overall flow rate. This observation has already be made by [10, 11].

(a) **(b)**

Figure 9. Evolution of the overall leakage rate and permeability as a function of the internal pressure after a maximal pressurization of 32.5 bar

3.3. Leak rate under cryogenic conditions

We chose to measure the flow rate of a leakage point using a smaller vacuum bag to identify the influence of the temperature on the leak rate of each leak point. The pressure difference taken is 3 bar. The leakage rate as a function of temperature is plotted in Figure 10. It is noted that, unlike the permeability measurement on a healthy wall, the temperature drop is accompanied by an increase in flow rate from the leakage point. In fact, the increase in cold thermal induced stresses tends to open the cracks, which increases the cross-section and thus the flow rate.

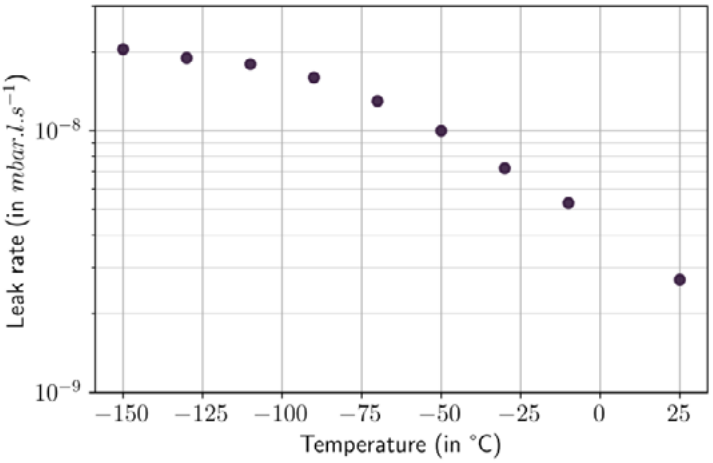

Figure 10. Local leakage rate as a function of temperature

Thermomechanical loading was applied to a second tube. Figure 11 shows the change in the number of leak points counted at -150°C compared to the results at 20°C. At -150°C, the first 77 leak points are observed at 26.5 bar. At this pressure level, the circumferential strain $\epsilon_{\theta\theta}$ is 0.87% against 1.01% at room temperature. Despite the lower strain state of the composite at -150°C, leak points are observed at a lower pressure level than at room temperature. The leakage kinetics is then faster and at 32 bar, 541 leakage points are observed.

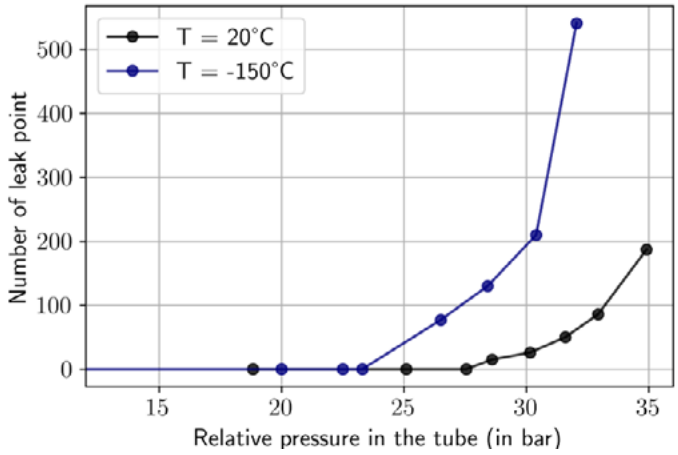

Figure 11. Evolution of the number of leak points as a function of pressure at 20°C and -150°C

4. Conclusion

In this paper, we proposed experimental methods to measure the permeability of a composite laminate using mass spectrometry. Tubular specimens allow applying biaxial stress state representative of a propellant tank. The two types of flow imply the use of two different permeability parameters, able to characterize the permeable behavior of the wall independently from the test conditions. These parameters have been measured on undamaged and damaged composite walls at room temperature and at low temperature. The permeability of the healthy material decreases with temperature but leak points appears at a lower pressure level.

Keywords: *CFRTP-SMC, Peridynamics, Multiscale modeling, Stiffness, Strength*

Abstract
The mechanical properties of carbon fiber reinforced thermoplastic sheet molding compounds (CFRTP-SMC) are closely related to the fiber orientation distribution and its microstructure. A dual scale model has been established to reconstruct the microstructure of SMC material based on probability distribution function and Voronoi diagram. Based on the micropolar peridynamics (MPPD) model considering Timoshenko beam theory, the PD formula was extended to SMC material with three kinds of bond describing the intralayer and interlayer deformation, and the dual-scale model was utilized as the input data for PD model. This model was employed to predict the tensile behavior of SMC material. The predicted tensile stiffness and strength values were found to increase with increasing tape length, which agrees well with literature data, and thus demonstrates the reliability of the proposed modelling framework.

1. Introduction

Mechanical properties of carbon fiber reinforced thermoplastic sheet molding compounds (CFRTP-SMC) are strongly influenced by the complex material flow patterns during the compression molding process [1], besides the randomly oriented strands in SMC induce a multi-scale structure and high heterogeneity [2] which results in the high scatter of its mechanical properties. A lot of research work has been done in establishing multiscale modeling methods for random fiber reinforced composite material [3][4][5]. The common approach is to use information from microscale to homogenize local properties and then the homogenized properties are used as input for subsequent macroscale finite element analyses (FEA) to predict macroscale elastic properties. However, the multiscale structure and high heterogeneity leads to difficulties in mechanical analysis of SMC with FEA. The micro cracks, that is, discontinuous areas in SMC are in natural conflict with the continuity assumption in Classical continuum mechanics (CCM) [6]. Silling [7] proposed a non-local theory of continuum mechanics called the bond-based peridynamic (PD) theory which attracts huge attention for its great advantages in dealing with discontinuous problems. The governing formulas of PD are in integral forms without spatial derivatives so cracks can spontaneously initialize, propagate, converge, and penetrate without prior knowledge of fracture criteria, making PD suitable for analyzing discontinuous problems and being widely utilized in damage and fracture prediction. Gerstle et al. [8] introduced a micropolar PD model (MPPD) by considering pairwise moments as well as forces in the bond-based PD model.

To accurately predict the tensile stiffness and strength of SMC, a dual-scale model has been proposed to reconstruct the mesoscopic structure of SMC. Based on the Timoshenko beam-based micropolar peridynamic method [9][10], the peridynamic model was extended to SMC materials, and the dual-scale model is utilized as the input data of the MPPD model to predict the stiffness and strength of SMC.

2. Dual-scale CFRTP-SMC Model

The SMC microstructure is featured by the random distribution of fiber bundles, not isolated fibers. Figure 1 (a) shows typical SMC microstructure viewed from the thickness direction. Two important features of SMC were observed: 1) The microstructure consists of randomly-oriented fiber tows; 2) Each fiber tow consists of aligned fibers. All fibers have the same orientation inside each fiber tow. Instead of tracing the orientation angle of each fiber, the fiber orientation distribution of the composite is represented by the statistical distribution of fiber tow orientations weighted by the fiber tow area.

Therefore, in this dual-scale CFRTP-SMC model, the probability distribution function (PDF) was recovered of fiber orientation from the fiber orientation tensor in micro-scale. And the Voronoi diagram-based reconstruction algorithm is proposed for constructing the substructure features in SMC composites in meso-scale.

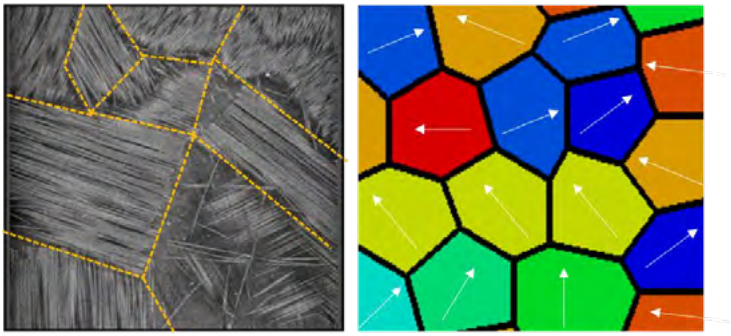

Figure 1. Microstructure image of SMC sample (a), representation of the fiber tows using Voronoi diagram (b)

2.1 Micro-scale

In the microscopic scale, fiber orientation tensor is utilized to reconstruct the probability density function (PDF) of fibers. Notating the fiber orientation tensor matrix by $\boldsymbol{A}$, the second order and fourth order fiber orientation tensors are defined as:

$$\boldsymbol{A}_{ij} = \oint_i^p p_j \psi(\mathbf{p}) \mathrm{d}\mathbf{p}, \tag{1}$$

$$\boldsymbol{A}_{ijkl} = \oint_i^p p_j p_k p_l \psi(\mathbf{p}) \mathrm{d}\mathbf{p}. \tag{2}$$

Where p_i are the components of the unit vector $\psi(\mathbf{p})$ describing the direction of a single fiber and $\psi(\mathbf{p})$ is the fiber orientation PDF. The PDF can be recovered once the fiber orientation tensors are written as:

$$\psi(\mathbf{P}) = \frac{1}{4\pi} + \frac{15}{8\pi} b_{ij} f_{ij}(\mathbf{p}) + \frac{315}{32\pi} b_{ijkl} f_{ijkl}(\mathbf{p}) + \cdots. \tag{3}$$

Where b_{ij} and b_{ijkl} are the deviatoric versions of the orientation tensors, and $f_{ij}(\mathbf{p})$, $f_{ijkl}(\mathbf{p})$ are tensor basis functions of $\mathbf{p}$.

2.2 Meso-scale

In the meso-scale, a random fiber tape reconstruction algorithm is developed to generate a mesostructured model with relative high fiber volume fraction. The number of fiber tapes representing each layer is estimated based on the information of the tape sizes and SMC laminate sizes. Total number of fiber tapes are represented by N_L and N_T respectively, which can be estimated as:

$$N_L = \left\lceil \frac{W_L \cdot L_L}{W_T \cdot L_T} \right\rceil, \tag{4}$$

$$N_T = N_L \cdot n_P. \tag{5}$$

Where W_L and L_L is the width and length of SMC laminate, and W_T and L_T is the width and length of tape respectively. All the parameters beforementioned are the input data of SMC reconstruction based on Voronoi diagram, which is showed in Figure 1 (b). Each Voronoi cell represent a fiber tow, which means that the fibers within each cell are oriented alone the same orientation, as shown by the white arrows.

Figure 2 shows the example of the SMC reconstruction. The fiber orientation tensor $\mathbf{A} = \begin{pmatrix} 0.5 & 0 \\ 0 & 0.5 \end{pmatrix}$, and tape size is 5mm*6mm, 5mm*18mm, 5mm*30mm.

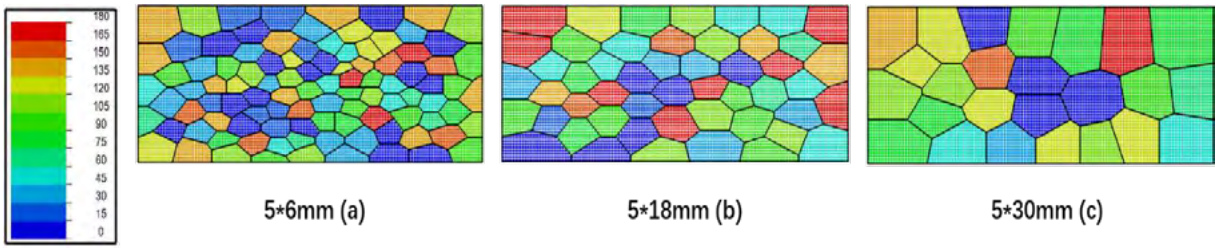

Figure 2. SMC microstructure reconstruction of different tape length

3. Briefly review of MP-PD model for orthotropic materials

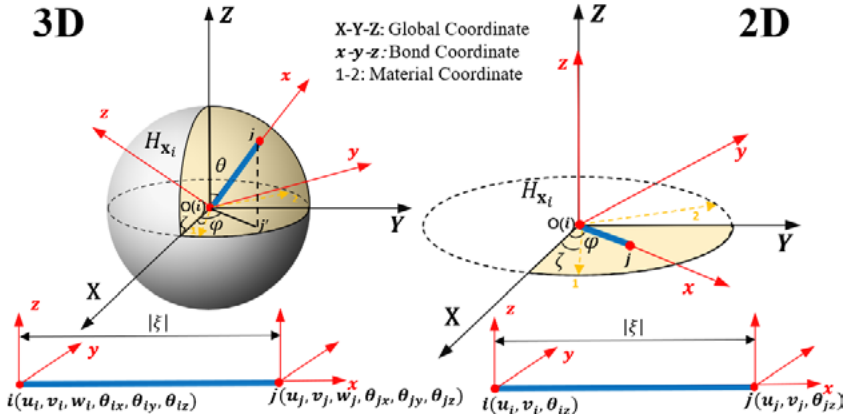

Figure 3. Displacement components in MP-PD model

In MP-PD model, the interaction of material points i and j can be regarded as a beam, which means it can both subject the axial and transverse forces. For 2D orthotropic materials, the displacement vector consisting of the bond endpoint ij, defining as $\mathbf{u}'_{ij}$, which possess six components can be written as:

$$\boldsymbol{u}'^{\mathrm{T}}_{ij} = \{u'_i\ v'_i\ \theta'_{iz}\ u'_j\ v'_j\ \theta'_{jz}\}. \tag{6}$$

The micropotential energy of bond ij, defining as ω_{ij} (J/m^6) includes bending micropotential energy and shear micropotential energy. The micropotential energy of bond ij can be obtained as [9]:

$$\omega_{ij} = \frac{1}{2}\int_{x'_i}^{x'_j} \frac{1}{2}\left(\mathbf{u}'_{ij}(\chi)\right)^{\mathrm{T}} \mathbf{D}\mathbf{u}'_{ij}(\chi)\mathrm{d}x. \tag{7}$$

ω_{ij} can also be rewritten as:

$$\omega_{ij} = \frac{1}{2}\mathbf{u}'^{\mathrm{T}}_{ij}\mathbf{K}^{local}_{ij}\mathbf{u}'_{ij}, \tag{8}$$

where $\mathbf{D}$ is the off-axis micromodule matrix and $\mathbf{K}^{local}_{ij}$ is the local micro stiffness matrix, and can be written as:

$$\mathbf{D} = \begin{bmatrix} C_{xx} & C_{xy} \\ C_{xy} & C_{yy} \end{bmatrix}. \tag{9}$$

$$\mathbf{K}^{local}_{ij} = C_{xx}\begin{bmatrix} 1/\xi & 0 & 0 & -1/\xi & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & I/(A\xi) & 0 & 0 & -I/(A\xi) \\ -1/\xi & 0 & 0 & 1/\xi & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -I/(A\xi) & 0 & 0 & I/(A\xi) \end{bmatrix}$$
$$+C_{yy}\begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1/\xi & 1/2 & 0 & -1/\xi & 1/2 \\ 0 & 1/2 & \xi/4 & 0 & -1/2 & \xi/4 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1/\xi & -1/2 & 0 & 1/\xi & -1/2 \\ 0 & 1/2 & \xi/4 & 0 & -1/2 & \xi/4 \end{bmatrix} + C_{xy}\begin{bmatrix} 0 & 1/\xi & 1/2 & 0 & -1/\xi & 1/2 \\ 1/\xi & 0 & 0 & -1/\xi & 0 & 0 \\ 1/2 & 0 & 0 & -1/2 & 0 & 0 \\ 0 & -1/\xi & -1/2 & 0 & 1/\xi & -1/2 \\ -1/\xi & 0 & 0 & 1/\xi & 0 & 0 \\ 1/2 & 0 & 0 & -1/2 & 0 & 0 \end{bmatrix}. \tag{10}$$

For orthotropic material, critical micropotential energy ω_c need to change continuously with the direction of bond. In order to fully address this anisotropic properties, spherical harmonic expansion was employed to approximate critical micropotentical energy function. The expression of ω_c can be written as:

$$\omega_c(\zeta - \varphi) = A_{00} + A_{20}P_2^0\big(cos(\zeta - \varphi)\big) + A_{40}P_4^0\big(cos(\zeta - \varphi)\big). \tag{11}$$

Where

$$\begin{aligned} P_2^0(cos(\zeta - \varphi)) &= \frac{1}{2}(3\cos^2(\zeta - \varphi) - 1), \\ P_4^0(cos(\zeta - \varphi)) &= \frac{1}{8}(35\cos^4(\zeta - \varphi) - 30\cos^2(\zeta - \varphi) + 3). \end{aligned} \tag{12}$$

For the 1 and 2 axes, assuming that $\omega_c(0°) = \omega_{c1}$ and $\omega_c(90°) = \omega_{c2}$. In order to achieve a smooth transition of $\omega_c(\zeta - \varphi)$ between 0° and 90°, in this study, it is assumed that $\omega_c(45°) = \frac{\omega_{c1}+7\omega_{c2}}{8}$. Substituting these three conditions ($\omega_c(0°) = \omega_{c1}, \omega_c(90°) = \omega_{c2}, \omega_c(45°) = \frac{\omega_{c1}+7\omega_{c2}}{8}$) into eq (11) and eq (12) respectively, and solve the system of four linear equations. The coefficients A_{n0} can be expressed as a linear combination of ω_{c1} and ω_{c2}:

$$\begin{aligned} A_{00} &= 0.1333\omega_{c1} + 0.8667\omega_{c2}, \\ A_{20} &= 0.5238(\omega_{c1} - \omega_{c2}), \\ A_{40} &= 0.3429(\omega_{c1} - \omega_{c2}). \end{aligned} \tag{13}$$

For brittle materials, the energy required for a crack to split a body into two halves equals the sum of the rupture energy of the bonds that initially crossed the crack surface [11]. The critical strain energy release rate is this energy divided by the area of the crack surface. Therefore, the strain energy release rate normal to 1 and 2 of material coordinate systems can be written as:

$$G_{\zeta=0} = 2t\int_0^{\delta}\int_z^{\delta}\int_0^{\cos^{-1}\left(\frac{z}{\xi}\right)} \omega_c(\varphi)\xi \mathrm{d}\varphi \mathrm{d}\xi \mathrm{d}z, \tag{14}$$

$$G_{\zeta=\frac{\pi}{2}} = 2t\int_0^{\delta}\int_z^{\delta}\int_{\cos^{-1}\left(\frac{z}{\xi}\right)}^{\frac{\pi}{2}} \omega_c(\varphi)\xi \mathrm{d}\varphi \mathrm{d}\xi \mathrm{d}z. \tag{15}$$

Therefore, by solving this linear equation group, ω_{c1} and ω_{c2} can be obtained:

$$\begin{aligned} \omega_{c1} &= \left(2.1207G_{\zeta=0} - 0.6205G_{\zeta=\frac{\pi}{2}}\right)\Big/_{t\delta^3} \\ \omega_{c2} &= \left(0.1471G_{\zeta=0} + 1.3528G_{\zeta=\frac{\pi}{2}}\right)\Big/_{t\delta^3} \end{aligned}. \tag{16}$$

Where t is the thickness of model and δ is the radius of PD horizon.

4. MP-PD model for SMC materials

The PD bond in SMC model is consists with three kinds of bond: intra-cell bond which is used to describe deformations within Voronoi cell and inter-cell bond, using to describe inter-cell deformations. Inter layer bond is employed to show the interlayer deformation.

4.1 Intra-cell bond

Each Voronoi cell can be considered as an orthotropic lamina since fibers have the same orientation, and it has independent elastic constants. If two material points are in the same Voronoi cell like bond ij in Figure 4 (a), they are connected by intra-cell bond. The MPPD model for orthotropic materials proposed in section 3 can be directly applied in this case.

4.2 Inter-cell bond

If the material points are in the same ply but belong to different Voronoi cells, like bond ik in Figure 4 (a), it can be considered as inter-cell bond. The peridynamic parameters of such kind bond are determined by averaging the peridynamic parameters of two material points connected. Therefore, MPPD model proposed in section 3 is also available.

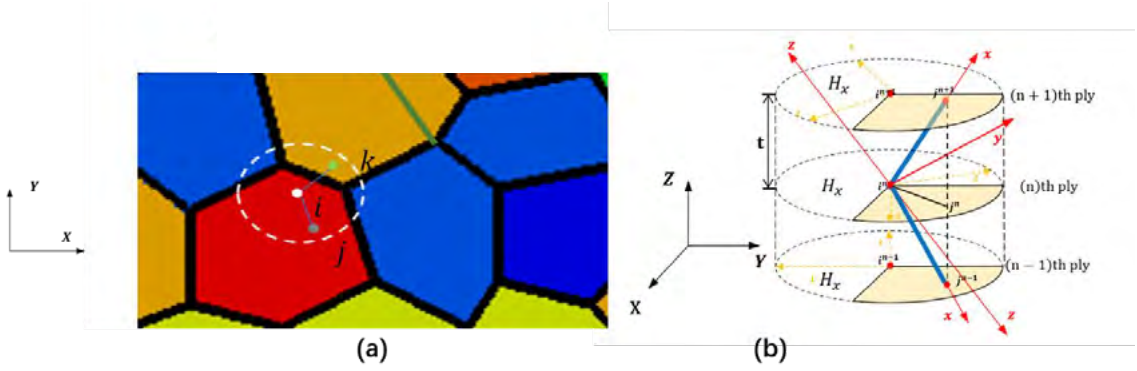

Figure 4. Intra-cell bond, inter-cell bond (a) and inter layer bond (b)

4.3 Interlayer bond

If the material points are in the different ply, it can be considered as interlayer inter-cell bond, which is showed in Figure 4 (b). PD theory assumes that when the stretch index, s_{kj}, exceeds its critical value, s_c, the onset of damage occurs. Damage is reflected by removing the force density vectors between the material points in an irreversible manner. The values of s_c was determined by the type one and type two critical energy release of matrix:

$$S_{\text{Normal}} = \sqrt{\frac{2G_{\text{IC}}}{tE_m}} S_{\text{Shear}} = \sqrt{\frac{G_{\text{IIC}}}{tG_m}}. \quad (11)$$

Where G_{IC} and G_{IIC} are the interface toughness of resin.

5 Numerical simulation and verification

In this section MPPD model was employed to predict the stiffness and strength of SMC within different tape length.

5.1 Determination of appropriate number of layers

The thickness of the tape is 44 μm, while the thickness of the SMC laminate after compression molding is about 2mm-3mm, meaning that there are about 40-50 layers of tape along the thickness direction, which is too much considering computation efficiency in numerical simulation.

Therefore, the tensile modulus of SMC laminate was calculated with layer numbers ranging from 5 to 25 layers, with a total of 6 models per layer, and the microstructure of each model was randomly generated. The results are showed in Figure 5 (a). As the number of layers increases, the fluctuations of calculated tensile modulus begin to decrease. It is determined to have 20 layers in the MPPD model in order to achieve a balance between the prediction accuracy and the computational costs. The mechanical properties of SMC can be referenced in [2][12].

The numerical results of stiffness and strength are compared with experiment results which shows in Figure 5 (b) and Figure 6. A total of six SMC microstructures of 20 layers were randomly generated for each tape length, and the average stiffness and strength of the six models were calculated, as shown in Figure 6. Figure 7 shows the predicted failure path. The microstructure shown in the Figure 7 is the microstructure of the first layer.

It can be seen that the stiffnesses of the six models in the same tape length within 20 layers are relatively close. As the tape length increases, the stiffness increases, which is consistent with the results obtained from the SMC tensile experiment [12]. In terms of strength, the strength of models with different microstructures under the same tape length fluctuated. Figure 5 (b) illustrates the average strength of the six models in each tape length and compared with the experimental results. The standard deviation of the SMC strength obtained from simulation and experiment is very large**,** which is related to the high heterogeneity of this material.

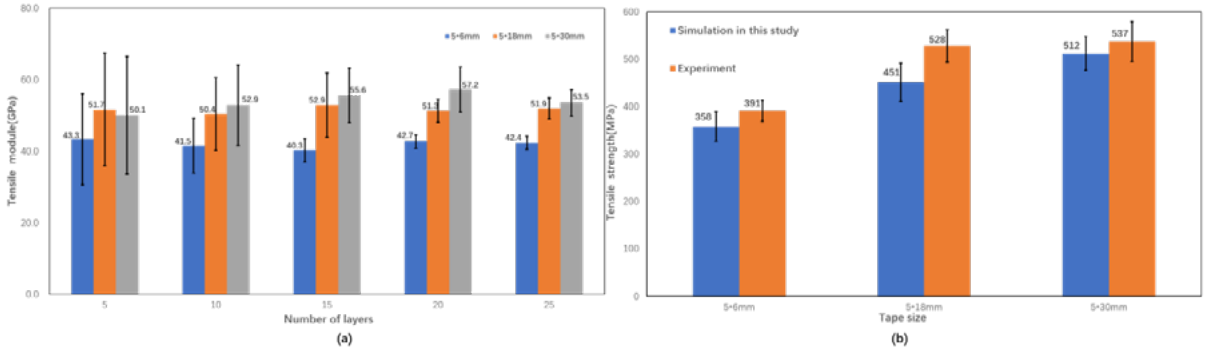

Figure 5 . Tensile module of different layer numbers (a), tensile strength of different tape length (b)

5. Conclusion

A dual-scale numerical model is propped in this study for the mechanical analysis of CFRTP-SMC. This model provides a new numerical modeling method for heterogeneous materials with randomly oriented reinforcements. The model is innovative in its approach, comprising two distinct components.

Firstly, it introduced a microstructure reconstruction method for SMC, leveraging fiber probability density functions and Voronoi diagram. This enables a detailed representation of the material's internal structure, crucial for accurate mechanical analysis. In the second part, the model incorporates a heterogeneous framework based on the MP-PD theory, and three types of PD bonds that characterize both intralayer and interlayer deformation in SMC. By applying this model to simulate tensile tests on SMC, the study quantitatively assesses the impact of tape length on stiffness, strength, and failure strain. Furthermore, the model is able to predict the failure path of SMC, enhancing its utility for predictive analysis and structural design. The actual toughness of SMC from experiments was employed in the damage analysis, making the failure and damage simulation closer to the real situations.

This study's dual-scale numerical model represents an innovative numerical model of CFRTP-SMC, offering a novel approach to understanding and optimizing the mechanical properties of heterogeneous materials, with wide-ranging implications for various engineering applications.

Keywords: CFRP, FEM, Reliability analysis, Monte Carlo method

Abstract
The increasing application of Carbon Fiber Reinforced Plastics (CFRP) across various industries has led to a shift from deterministic to stochastic methods in evaluating their inherent variability. This approach fully leverages the properties of composite materials, particularly in reliability-based design. Carbon Fiber Paper Reinforced Thermoplastics (CPT), a type of potential recycled CFRP, is recognized for its robust mechanical properties and cost-effectiveness, making it suitable for industries such as wind energy and automotive manufacturing. This study utilizes Monte Carlo (MC) methods to explore uncertainties in CPT, particularly focusing on the effects of spatial variability from mesoscopic to macroscopic scales. At the mesoscopic scale, the stochastic distribution of carbon fiber orientation is analyzed using X-ray CT techniques, and the Cox model is employed to calculate the tensile modulus distribution in the principal directions of the sample plane. The study addresses spatial inhomogeneity by generating specimens with varying moduli distributions using an MC approach, significantly impacting the ultimate failure path of CPT laminates. A three-point bending test case study further investigates this aspect, with finite element simulations calibrated against experimental data to ensure accuracy. This analysis examines the ultimate displacement and maximum load in relation to moduli distributions and evaluates the reliability and failure probability of the samples. The error of global strain's mean value is 4.0% while for the stress's is 1.7%, which demonstrate the good consistency between the simulation methods and experimental results.

1. Introduction

The recycling of carbon fibers (CFs) from carbon fiber-reinforced plastic (CFRP) waste is gaining significant attention due to environmental and economic considerations. Various studies have highlighted the importance of efficiently recycling carbon fibers (rCFs) from CFRP waste to be reused in high-value applications [1]. The circular economy approach, coupled with the ability to recover carbon fibers with properties similar to virgin fibers at a lower cost and energy consumption, has motivated research in CFRP recycling [2]. However, the heterogeneous properties of recycled CFRP play a significant role in various manufacturing processes and material applications. The heterogeneity of CFRP, characterized by differences in fiber orientation, distribution, and mechanical properties between the phases of the composite, poses challenges in machining, drilling, and other fabrication processes [3]. Understanding the influence of inhomogeneity in recycled CFRP is essential for optimizing recycling methods and ensuring the quality and performance of the recycled material. Studies on the micromechanical properties and reinforcement architecture of recycled composites have highlighted the impact of inhomogeneities on mechanical responses and failure initiation [4]. Moreover,

the inhomogeneity of recycled CFRP may differ from that of virgin CFRP, necessitating further research to assess differences in machinability and material behavior [5].

In the realm of methodology, the application of Monte Carlo(MC) and k-means methods has been explored in the context of composite materials. The application of the k-means method in composite materials, particularly in the context of inclusions, offers a valuable approach to understanding and analyzing the distribution and clustering of different components within the composite structure. Composite materials, which consist of a matrix and reinforcing inclusions, often exhibit complex microstructures that influence their overall properties and behavior. By applying the k-means method, researchers can effectively segment and classify inclusions based on their characteristics, such as size, shape, and distribution, enabling a deeper insight into the composite's structural organization [6]. On the other hand, the Monte Carlo method provides a powerful tool for considering the randomness and uncertainty inherent in composite materials. By utilizing random sampling techniques, Monte Carlo simulations can model the stochastic nature of material properties, manufacturing variations, and environmental factors that impact composite performance. In the context of composite materials, Monte Carlo simulations can be employed to analyze the probabilistic distribution of mechanical properties, predict failure modes under uncertain conditions, and optimize material design considering variability in constituent properties.

In our previous research, the properties of recycled CFRP composed of short fiber materials were investigated and a property prediction method based on the Monte Carlo method was developed [7]. To further quantify carbon fiber reinforced thermoplastics s uncertainty, this study developed a stochastic model through experimental and numerical methods. The process for constructing this stochastic model is depicted in Figure 1. The study investigates the stochastic distribution of carbon fiber orientation at the mesoscopic scale using X-ray techniques, which enables the fitting of probability distribution functions. Employing the Cox model [8], the distribution of local tensile modulus in the two principal directions of the sample's plane is calculated. Additionally, the experiments facilitate the collection of data on the local modulus distribution. To capture features of inhomogeneity, the k-means clustering method is utilized, allowing for the development of a global model that incorporates spatial inhomogeneity. A deterministic FEM model is formulated based on the experimental data. Integrated with Monte Carlo simulation, this approach allows for the collection of the sample responses' distribution, which is then validated and implemented in structural analysis.

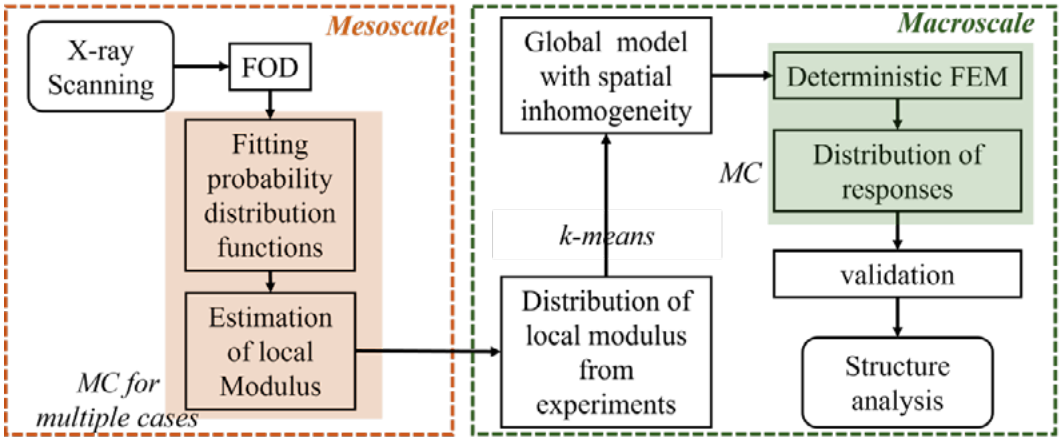

Figure 1. Construction of the stochastic model.

2. Material and method

2.1 Manufacturing of the materials

The material used in this study is manufactured using the wet laid nonwovens process, as shown in Figure 2. Initially, CFs and polyamide 6 (PA6) fibers are mixed in a water-based suspension to form a slurry. This slurry contains CFs and typically includes water or a combination of water and a binding agent, aiding in fiber cohesion during processing. The slurry is then poured onto a moving mesh conveyor or a forming machine, commonly known as a "Fourdrinier machine." As the slurry advances through the conveyor or machine, water drains through the mesh, causing the fibers to interlace and form a fibrous mat. The freshly formed wet mat undergoes pressing and rolling to remove excess water, promoting fiber consolidation and mat compaction. After partial dewatering, the mat is subjected to a drying process to eliminate any remaining moisture. Once dry and with any binding materials removed, the mat is ready for further processing or finishing as needed.

The control of fiber orientation in wet-laid nonwoven mats is influenced by various manufacturing parameters, including line speed, uptake angle, and headbox geometry. Consequently, the resultant wet-laid nonwoven mats typically do not exhibit uniform isotropic characteristics. Instead, the properties of composites depend on the specific orientation of the cut preform. In this study, the composite properties along the machine flow direction (MD) and cross direction (CD) within the manufacturing line are explored, as depicted in Figure 2(b). The MD and CD prepreg sheets were randomly distributed and stacked to produce cross-plied CF/PA6 composites. The stacking sequence of the cross-plied composites is shown in Figure 2(d). For CPT samples oriented in the CD and MD, the elastic modulus in the tensile direction and perpendicular to the tensile direction are significantly different. This variation complicates clustering because the DIC method can only measure the modulus distribution along the tensile direction. In contrast, for cross-plied specimens, the difference in elastic modulus between the two directions is smaller and displays more random characteristics. Consequently, this study will utilize the modulus distribution from cross-plied specimens as the reference for clustering.

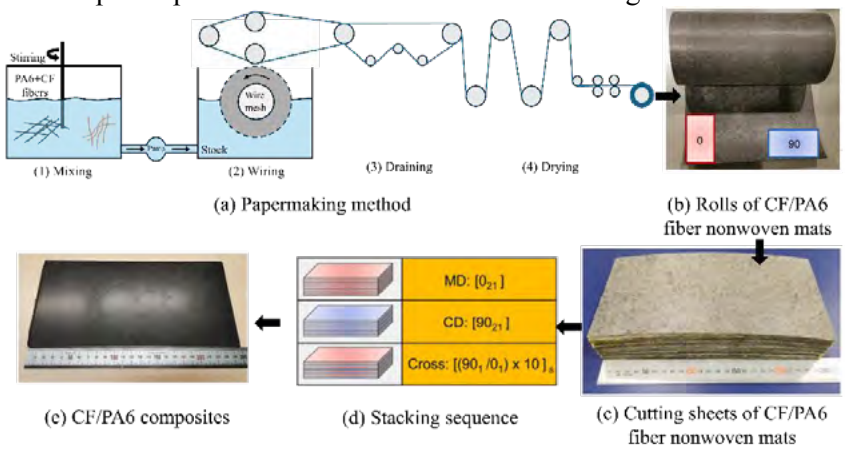

Figure 2. Schematic for the manufacturing of CPTs.

2.2 Detecting of mesoscale features

The internal structural details of the CPTs were captured using the TDM1000-II 3D X-ray scanning system provided by Yamato Scientific Co., Ltd, Japan. During the observation, specimens were secured on a rotating platform. To ensure clear resolution of embedded fibers, the distance between the rotation axis and the radiation source was maintained at 10 mm. The scanning process yielded a raw volume shaped as a right circular cylinder, measuring 0.88 mm in radius and 1.76 mm in height, due to the continuous rotation of the stage. The 3D micro-CT images were reconstructed with a uniform pixel size of 3.4 μm, comprising 512 stacked images in the out-of-plane direction. To enhance image resolution and contrast, air portions within the scanned raw images were excluded during CT acquisition. The CT procedures adhered to the Cartesian coordinate system, necessitating a cubic volume for scanning. Accordingly, the sample was strategically positioned within the scanner's field of view, constrained to a physical volume of 1×1×1 mm, air excluded. For this study, five samples (10 × 2 × 2 mm) were selected from various positions on each panel. Each sample was tested at four different heights. The X-

ray tube's voltage and current were consistently set at 40 kV and 100 μA for all specimens. X-ray projection images were acquired with a rotation step of 0.24 degrees over a total rotation time of 25 minutes. The 3D image reconstruction utilized the image processing unit of the X-ray system, stacking 325 images along the out-of-plane direction for subsequent image processing and CT analysis. A diagram of the scanning process is illustrated in Figure 3(a).

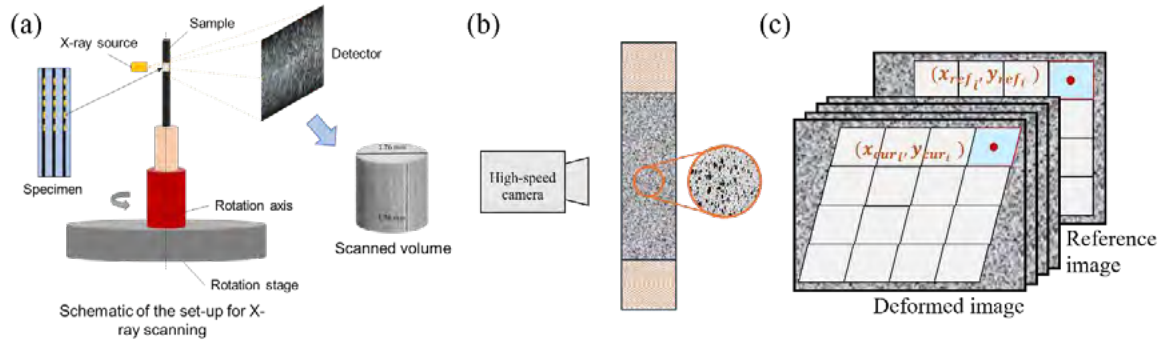

Figure 3. Schematic for (a) X-ray scanning system, (b) DIC method, (c) DIC post-processing

2.3 Calculation of the local modulus

The netting analysis was used to predict the tensile stiffness in this study. This method is useful for quick estimation and gives a simple result by ignoring the presence of the matrix and considering only the loading of the fibers. It assumes that a singe fiber can only transfer tension loading of fiber ends. It assumes that a single fiber can only transfer tension loading and neglects flexural stiffness. When a planar mat of fibers is subjected to tensile strains in two directions and a shear strain ($\varepsilon_x, \varepsilon_y, \gamma_{xy}$), the strain of the fiber at an angle ϕ can be expressed as $\varepsilon_\phi = \varepsilon_x \sin^2\phi + \varepsilon_y \cos^2\phi + \gamma_{xy} \sin\phi \cos\phi$.
The distribution function $f(\phi)$ represents the number of fibers at an angle ϕ and can be written as $\int_0^\pi f(\phi)d\phi = 1$. The elastic moduli along the longitudinal direction (E_L) can be calculated using Eq. 1 combined with the ROM:

$$E_L = E_f V_f \left(c_{11} - \frac{c_{22}^2}{c_{12}}\right) + E_m(1 - V_f) \tag{1}$$

where,

$$c_{11} = \int_0^\pi \cos^4\phi f(\phi)\phi, \quad c_{22} = \int_0^\pi \sin^4\phi f(\phi)\phi, \tag{2}$$

2.4 DIC technology

The local modulus of the CPTs will be investigated using Digital Image Correlation (DIC) technology. The layout and schematic of the DIC setup are illustrated in Figures 3(b) and 3(c). In this study, an open-source two-dimensional digital image correlation (2D-DIC) software package, Ncorr, will be utilized to process the DIC data. The distortions in the x, y, and xy directions will be calculated and visualized separately. Prior to testing, the sample surfaces were prepared by uniformly spraying white paint with an airbrush and then randomly applying black speckles to create contrast, as depicted in Figure 3(b). The mechanical testing was conducted using a set of six groups of axial tensile tests according to JIS K 7073 standards, employing a universal testing machine (AUTOGRAPH AGS-X plus 100KN, Shimadzu Co., Ltd., Japan). During the tests, a high-speed camera captured the deformation of the samples. The resulting images will be processed as shown in Figure 3(c), enabling the collection of detailed strain fields and displacement fields.

2.5 Deterministic FE model

A 2D shell element was constructed using the P11 sandwich property in Altair Radioss to simulate the properties of CPT laminates, as depicted in Figure 6(a). For the CPT sample layers, the material model LAW25 was applied, supplemented by /FAIL/HASHIN for failure analysis. In the bending test, both the cylindrical loading bar and support bars were assigned rigid body properties. The loading bar moved at a constant speed of Vz=120 mm/min vertically to measure the reactive force induced by the sample's deformation. The support bars remained stationary, and surface-to-surface contacts were established between the cylindrical bars and the sample. Element sizes in the contact areas were minimized to enhance the accuracy of stress distribution, while larger elements were used in other regions to reduce computational time. The material properties and failure parameters for this FE model are detailed in Table 1.

Table 1. Mechanical properties for FE model

Parameter			
	Elastic Modulus (GPa)	E_1	32.00
		E_2	11.00
		E_3	11.00
	Shear Modulus (GPa)	G_{12}	2.10
		G_{13}	1.08
		G_{23}	1.08
Strength	Tensile strength (MPa)	X_T,Y_T	360.00
	Tensile fracture strain (%)	ε_T	1.00
	Compressive strength (MPa)	X_C,Y_C	240.00
	Compressive fracture strain (%)	ε_C	0.80
	Shear strength (MPa)	X_S	170.00
	Shear fracture strain (%)	ε_S	1.31

3. Results and discussions

3.1 Modulus distribution of CPTs

An example of the tensile modulus E_{yy} distribution for cross-ply samples, calculated using the DIC method, is shown in Figure 4. The data obtained through DIC reveal a non-uniform distribution of strain across the surface, suggesting a non-uniform internal distribution within the CPTs. The modulus values derived from the DIC method were calculated based on the strain fields output, while the stress values were global and calculated based on the real-time loads. The approximate condition is generally considered acceptable, and the obtained modulus distribution results are viewed as reliable. The distribution of the sample modulus can serve as a reference for assessing the inhomogeneity of the material geometry.

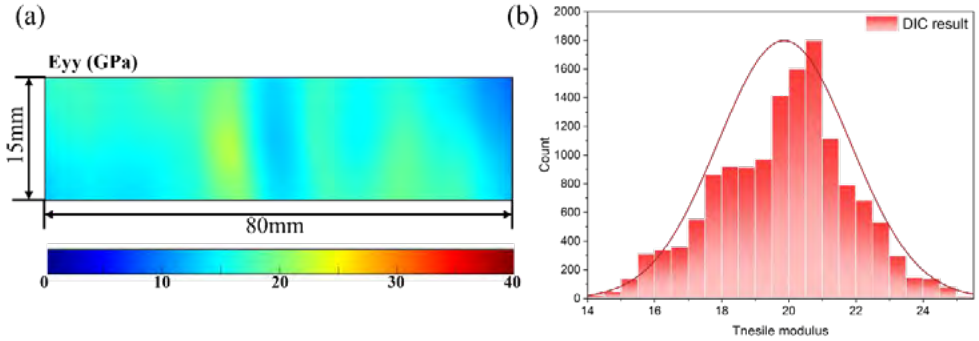

Figure 4. Elastic modulus distribution in Cross-Ply CPT (a) Contour, (b) Counts

3.2 Clustering results

In this study, the modulus data collected from the DIC method is a 3D array including x y coordinates and the modulus value. K-means clustering algorithm can process these data into K clusters which contains the information of modulus inhomogeneity for the samples, as shown in Figure 5 (a). Physically, the uneven modulus distribution in the sample stems from the non-uniform fiber orientation. Applying a clustering algorithm can discretize this continuous non-uniform distribution of fibers, which aids in developing models that incorporate uncertainty. However, determining the optimal number of clusters is a crucial aspect of the k-means clustering method. In this study, both the silhouette method and the elbow method were employed to determine the optimal cluster number. A higher average silhouette score indicates better-defined clusters, and the number of clusters corresponding to the peak silhouette score is considered optimal. On the other hand, the elbow method evaluates the variance within clusters relative to the number of clusters. This method involves plotting the variance explained as a function of the number of clusters and identifying the "elbow" point, which signifies where the addition of more clusters does not yield a significant improvement in the variance explained. The number of clusters at this elbow point is considered optimal for the dataset. By integrating the results from both methods, the optimal cluster number was determined to be 10 for each sample.

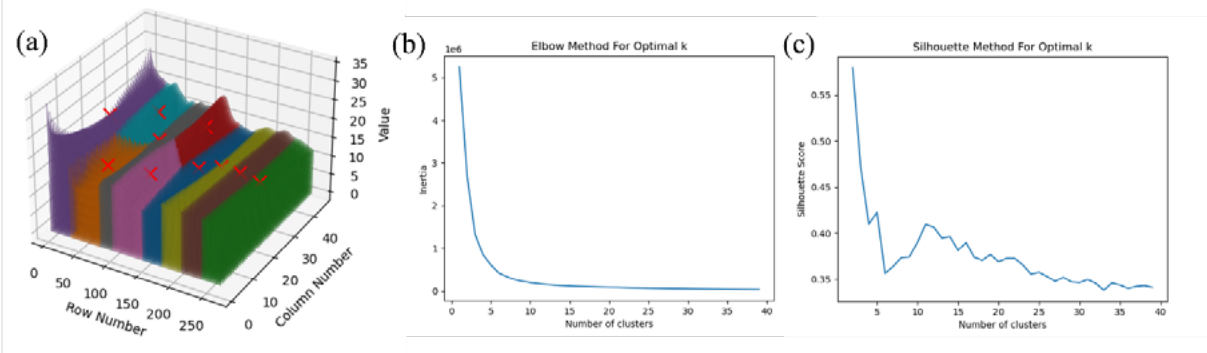

Figure 5. (a) Clustering result for DIC modulus distribution with 10 centroids, (b) Elbow result for a sample, (c) Silhouette result for a sample

3.3 Calibration of FE model

To validate the FE model, a set of 30 samples underwent a 3-point bending test. The results of both the experiment and the simulation are displayed in Figure 6 (b). To enhance the calculation efficiency in the FE solver, the loading speed was set higher than in the actual experiment. Concurrently, the update of the unit stiffness matrix occurred slower than the actual process. Additionally, due to computational time limitations, the element size was set larger. These adjustments resulted in some fluctuations in the calculated displacement-load curve of the simulation; however, these fluctuations did not impact the accuracy of the final maximum load and displacement results. The deterministic simulation results closely matched the experimental outcomes. The failure of the sample, as depicted in Figure 6 (c),

occurred due to tension at the bottom of the sample. In the simulation, elements meeting the failure criteria were dynamically removed after a specified time. Both the experiment and the FE results demonstrated the same failure pattern, characterized by a brittle tensile failure at the bottom of the sample.

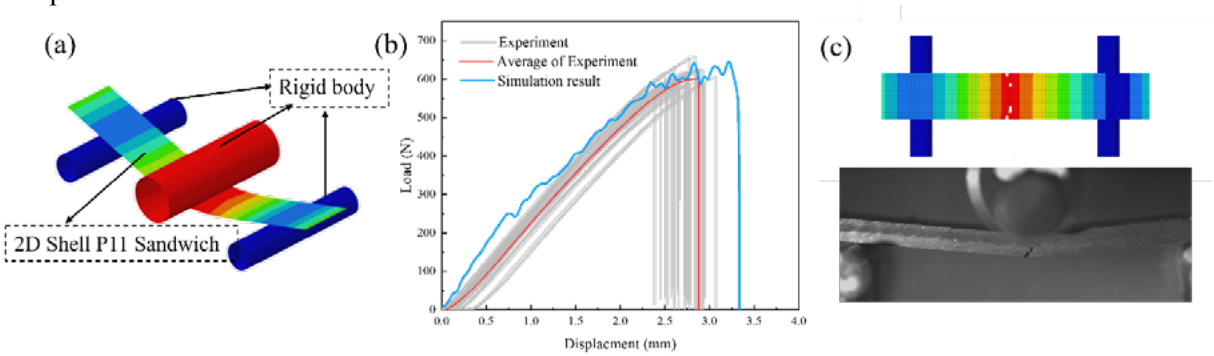

Figure 6. (a) FE model setting (b) Comparison of experiment and simulation results (c) failure status for FE and experiment

3.4 Stochastic results

Stochastic FE models were developed using the clustering results. Voronoi meshes were generated, with the location of centroids predefined. To maintain consistency across the models, the geometry of each model was kept constant, while the elastic moduli E_{11}, E_{22} and G_{12} were varied randomly based on values calculated through the previous netting analysis method. A total of 100 times FE models were computed, providing outputs for contact loads and displacements. Given the variability in specimen sizes, the global stress and strain from both simulations and experiments were quantified and compared.

The simulation and experimental results were analyzed using a Gaussian distribution, where μ is the mean or expectation of the distribution, and σ is the standard deviation. The 95% percentile intervals were also established. Despite the limited number of experimental trials, which contributed to discrepancies between the simulated and experimental strain results, the simulation displacements were also noted to be smaller than the experimental averages. Nevertheless, the 95% percentile intervals derived from the distribution correlated well with the experimental results, affirming the reliability of the stochastic models in capturing key trends and behaviors. The error of global strain's mean value is 4.0% while for the stress's is 1.7%. Standard error for the stress is 5.6%, but for the strain's error, standard error, the error reaches 37%. The main reason for it is that the strain data is relatively small than stress result, and the experimental results are few, which leads to a certain error between the fitting distribution function.

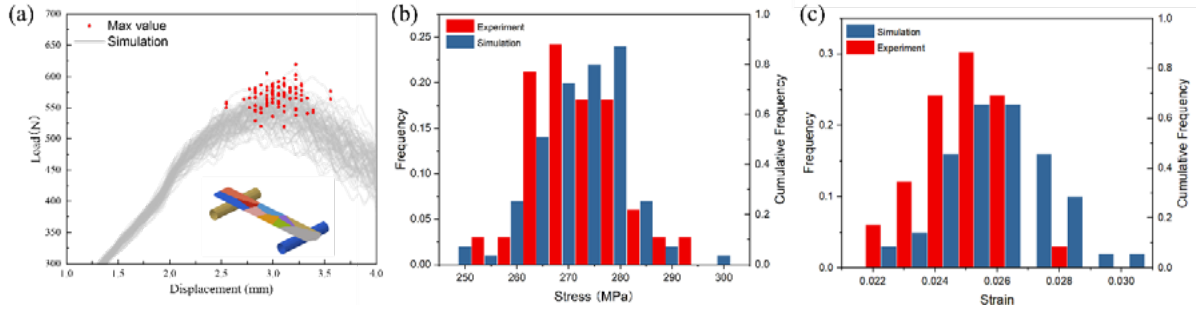

Figure 7. (a) Result of FE models, (b) distribution of global flexural stress, (c) distribution of global flexural strain

Table 2. Statistical results distribution

	Strain (Experiment)	Stress (Experiment)	Strain (Simulation)	Stress (Simulation)
95% percentile interval	[0.0196, 0.0290]	[239, 301]	[0.0195, 0.0325]	[242, 307]
$\boldsymbol{\mu}$ (MPa)	0.025	269.42	0.026	274.10
$\boldsymbol{\sigma}$	0.00236	15.43	0.00325	16.30

4. Conclusions

In the present study, the following conclusions have been drawn:

1. The primary source of inhomogeneity in CPT samples is the uneven fiber orientation, which were assessed using the X-ray scanning method in mesoscale.
2. The size and shape of the inhomogeneity in the CPT samples were evaluated using k-means clustering, and Voronoi meshes were effectively utilized to reconstruct the inhomogeneity geometry.
3. The MC method were applied for local elastic modulus prediction, allowing the mechanical performance distribution of the samples to be calculated based on FE models combined with Voronoi inhomogeneity geometry models.
4. Experiments were conducted to validate the performance distribution of CPT samples, demonstrating good consistency between the simulation and experimental results. The error of global strain's mean value is 4.0% while for the stress's is 1.7%.

However, the inhomogeneity of CPTs may also be influenced by other factors such as the manufacturing process and fiber length, which were not considered in this study. Additionally, only the modulus in a single direction was considered to ensure the consistency of the clustering results. Future researches will include and thoroughly investigate these factors.

Keywords: Residual strength, Oxidation, Acoustic emission, Electrical resistance, Ceramic matrix composites

Abstract
SiC/SiC mini-composites, the primary load-bearing unit of braided composites, are frequently utilized in studies of damage and failure mechanisms due to their straightforward structure. This paper commences with a theoretical and experimental investigation into the oxidation kinetics of the SiC matrix under stress-free environmental conditions. Subsequently, research was conducted on the stress-free oxidation and tensile residual strength testing of SiC/SiC mini-composites, leading to the establishment of a stress-free oxidation model for SiC/SiC mini-composites based on electrical resistance response. Ultimately, post-oxidation residual strength tests and model calculations were performed on the SiC/SiC mini-composites, achieving the prediction of residual strength after stress-free oxidation based on electrical resistance response for SiC/SiC mini-composites.

1. Introduction

Ceramic Matrix Composites (CMCs) have excellent properties such as low density, high strength, high temperature resistance, oxidation resistance, abrasion resistance, corrosion resistance, and small coefficient of thermal expansion. This is not available in many metal materials, polymer materials, and composite materials[1]. In addition, the reinforcement phase enables CMCs to overcome the high brittleness and defect sensitivity of ceramic materials, improving the reliability of CMCs. Therefore, CMCs have become the preferred material for hot end components of aero-engines[2]. Since the 1980s, CMCs have been used in hot-end components such as adjustment sheet, combustion chamber flame cartridges, and turbine blades, which have greatly improved engine efficiency and thrust-to-weight ratios [3].

CMCs structures are not only subjected to fatigue and impact loads during service, but also to high temperatures, water and oxygen, etc., which can easily result in changes in structural performance or damage. Therefore, timely detection of damage and destruction of CMCs structures is of great significance to avoid causing sudden damage to the structures. To ensure the safety and reliability of aero engine structures, traditional methods rely on regular maintenance to reduce the failure rate. This is not only inefficient, but also results in high costs[4]. Structural Health Monitoring (SHM) is the process of identifying and characterizing structural damage. It involves putting sensors into structural components to gather data and information about the health of the structure. This allows for monitoring and tracking of the extent and progression of damage within the structure, enabling prediction of structural damage and estimation of the remaining strength and life of the structure. The application of SHM technology to engine structures results in enhanced efficiency and a reduction in maintenance costs[5].

To achieve real-time "sensing" of damage, the monitoring technology for CMCs structural damage state requires a high level of automation and in-situ detection capability. Commonly used detection techniques of CMCs damage include ultrasound, Infrared Thermography (IRT), and X-ray Computed

Tomography (XCT)[6]. The ultrasonic method can detect materials very well, but it is difficult to detect thinner materials and small defects. It also requires a high level of expertise from the operator[7]. IRT is very effective. However, it can be affected by high temperatures and requires a certain distance from the object being inspected[8]. XCT can detect microscopic defects inside structures, but the equipment is complex and unsuitable for on-site inspections. It also has low detection efficiency and high costs[9].

In this paper, the damage self-sensing capability of ceramic matrix composites is used, combining electrical properties with acoustic emission. By analyzing electrical and AE signals, the relationship between these signals and mechanical properties of the composites is acquired. A residual strength prediction model based on acoustic emission and electrical impedance signals for SiC/SiC mini-composites is established. The prediction results are consistent with experiment.

2. Material and Experimental

2.1. Material and Specimen

In this paper, the material chosen is a SiC/SiC mini-composites with a BN interface, prepared using the PIP process. As shown in Figure 1(a), the graphite mould frames with grooves on the top and bottom sides were prepared, and as shown in Figure 1(b), the SiC fibers were wound onto the graphite mould. This was followed by the deposition of a BN interface on the fiber tows. Finally, the polycarbosilane solution was impregnated into the SiC fiber preform, dried and cured, and then cracked at high temperature under inert gas protection. The preparation of SiC/SiC mini-composites was completed after obtaining SiC matrix with high densities after several cycles of the above operations.

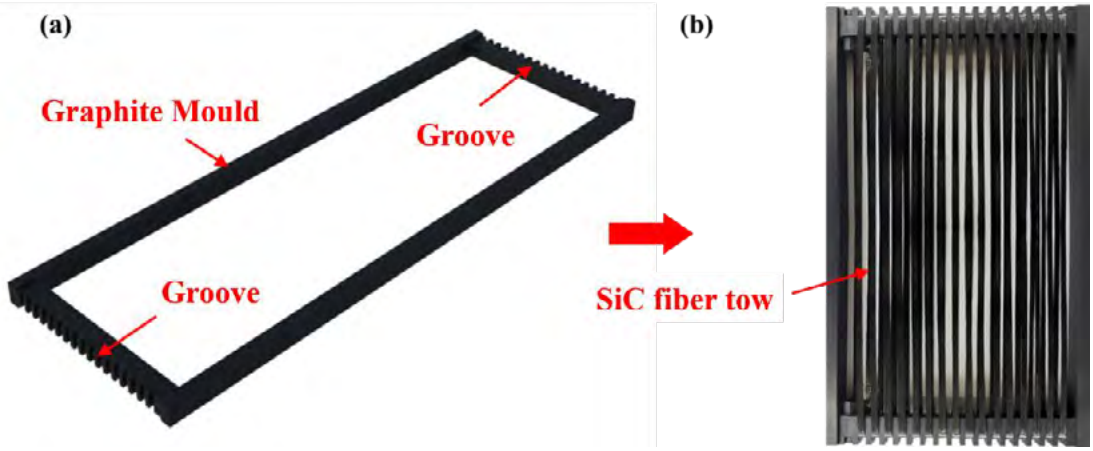

Figure 1. Graphite moulds prepared from SiC/SiC mini-composites

The SiC/SiC mini-composites used is shown in Figure 2, with an overall elongated cylindrical shape. A representative cross-section of the specimen is shown in Figure 2. It can be observed that there are several small pores within the specimen, which are attributed to the escape of numerous small molecules during the decomposition process of the SiC matrix precursor in the densification stage. This results in a large number of holes inside the specimen and causes the overall high porosity of the specimen. There are more microcracks between the matrix blocks and differences in crack sizes. This is due to the fact that the precursor undergoes several cycles of crystallisation and shrinkage during multiple cleavage cycles, resulting in a huge volume contraction of the matrix and hence many of microcracks[10].

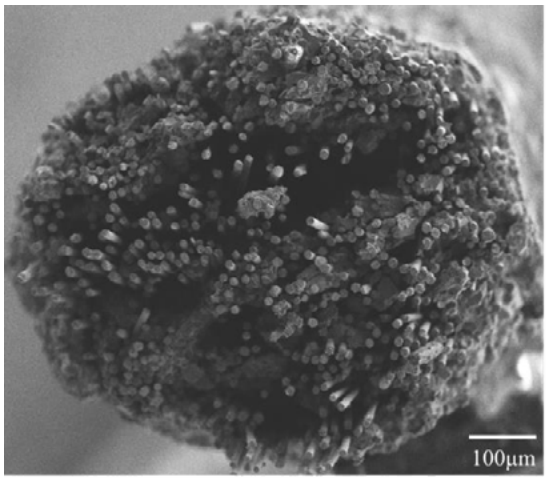

Figure 2. SiC/SiC mini-composites specimen

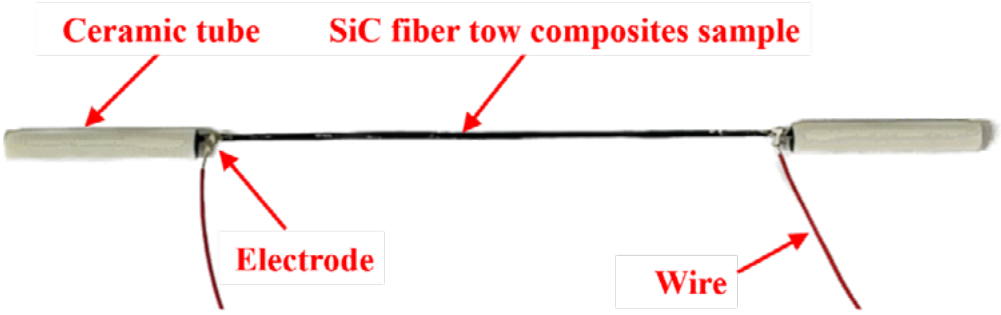
2.2. Experimental setup and Method

Initially, the electrical resistance of the SiC/SiC mini-composites is measured before and after oxidation. The some areas of specimens were oxidised in a homemade high-temperature furnace to avoid as much as possible the disturbance caused by the high-temperature oxidation process. Before oxidation, electrodes and wires were attached at both ends of the specimen, followed by attaching high temperature resistant ceramic tubes to both ends of the specimen. Figure 3 shows the SiC/SiC mini-composites specimen after preparation.



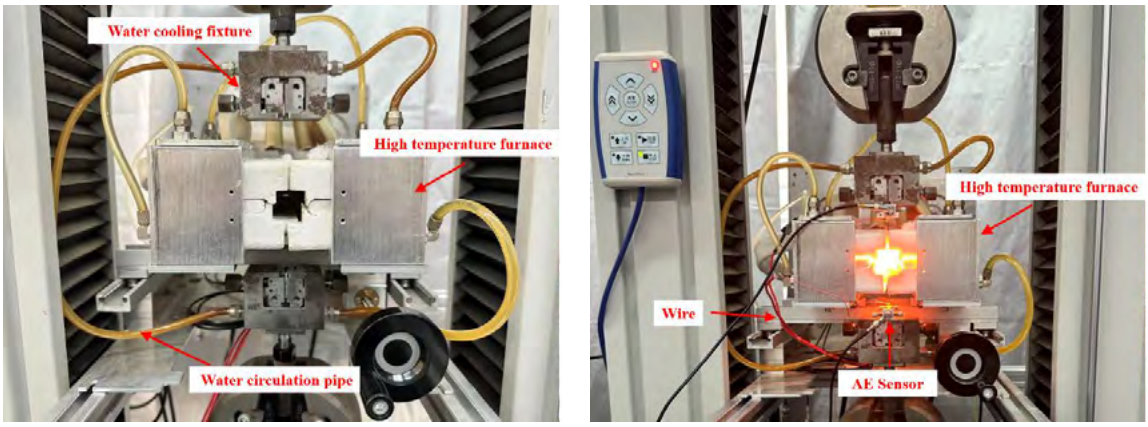


Figure 3. SiC/SiC mini-composites specimen with electrode

Figure 4(a) shows the high-temperature oxidation test system built on an electronic tensile testing machine. The whole device consists of a high-temperature furnace, a water-cooled fixture, a temperature control system and a water circulation cooling system. The high-temperature furnace is used with the temperature control system to create the entire high-temperature test environment. The high-temperature furnace is of the left-right folio type, with a silicon molybdenum rod serving as the heating element on the left and right sides. The water-cooled fixture has a water-circulation connection at the top of both sides of the fixture and two bolts at the bottom to control the displacement of the inner collet for specimen clamping. The water circulation cooling system keeps the high-temperature furnace and fixture cool by circulating water around them. This keeps the system stable for a long time. The system can achieve room temperature ~ 1400 ℃ oxidation environment under static tensile and creep loading.

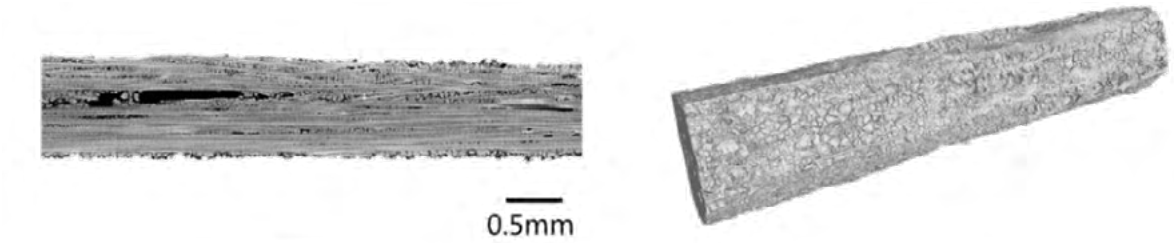
（a）High temperature furnace （b）high temperature oxidation process

Figure 4. SiC/SiC mini-composites high temperature oxidation test

3. Post-oxidation residual strength model under stress-free conditions

3.1. Assumptions of the model

Figure 5 shows the microstructure of the SiC/SiC mini-composites after XCT scanning. The specimen approximates an elongated cylindrical structure with a small number of internal pores. The matrix enveloping the interior fiber surfaces demonstrates a relatively regular blocky configuration, featuring discernible intervals between each matrix block. In contrast, the matrix adjacent the specimen's surface and surrounding the internal pore surfaces varies in shape and size, showing significant differences in the inter-block gaps.



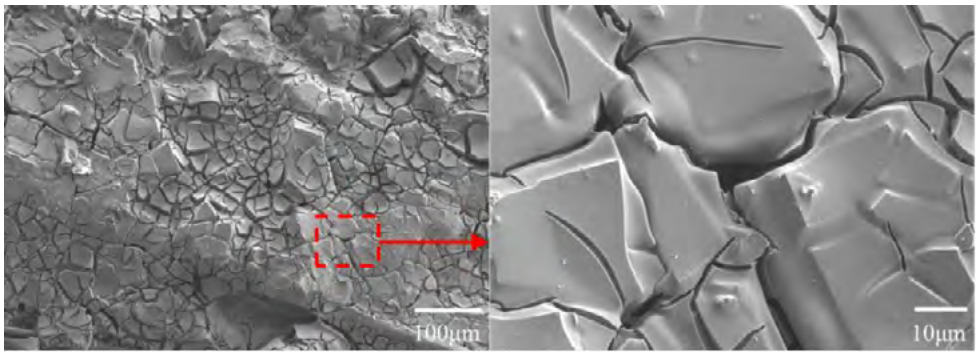


Figure 5. the microstructure of the SiC/SiC mini-composites

Unlike the microcracks formed in CVI processes due to the mismatch of thermal expansion coefficients between SiC fibers and the SiC matrix, the SiC/SiC mini-composites produced by PIP process have a significant volumetric shrinkage of the matrix due to multiple impregnations and pyrolysis during densification, resulting in a block-like distribution of the matrix and a vast number of matrix cracks. Therefore, for materials prepared by the PIP process, matrix cracks serve as the primary pathway for O_2 to penetrate into the material's interior during stress-free oxidation.

Figure 6 revealed that during the oxidation process, it is challenging for the oxidation products to completely block the oxygen diffusion pathway and prevent further oxidation in the PIP process materials due to the matrix crack opening distance.

（a）Surface after oxidation at 1100℃ for 0.5h （b）Local enlargement

Figure 6. Surface morphology of SiC/SiC mini-composites after oxidation at 1100°C

3.2. Establishment of model

Based on the tensile stress-strain curves of SiC/SiC mini-composites after stress-free oxidation and tensile fracture results[12]. The mechanical properties of SiC/SiC mini-composites fabricated through the PIP process are primarily dominated by the SiC fibers. The presence of numerous microcracks significantly diminishes the mechanical of the SiC matrix. The tensile fracture of the oxidized specimens exhibit distinct characteristics of brittle fracture. The morphology and failure characteristics of the materials mentioned above indicate that the oxidized SiC/SiC mini-composites are carried by fibers. The failure of SiC fibers occurs at the crack surface of the matrix, without interface slip or fiber pulling out.

It is thought that the initial cracks in the specimen have reached saturation, so no new cracks will form under stress. The cracks are evenly spaced and parallel to each other, as shown in Figure . The total length of the entire specimen is l_c, the width of the initial matrix crack is e_0, and the initial crack spacing is l_{r0}. The strength of SiC fibers obeys a Weibull distribution. The fracture of the fiber only needs to consider the probability of fracture at the crack surface. The tensile failure process can be simplified as a single-crack failure mode.

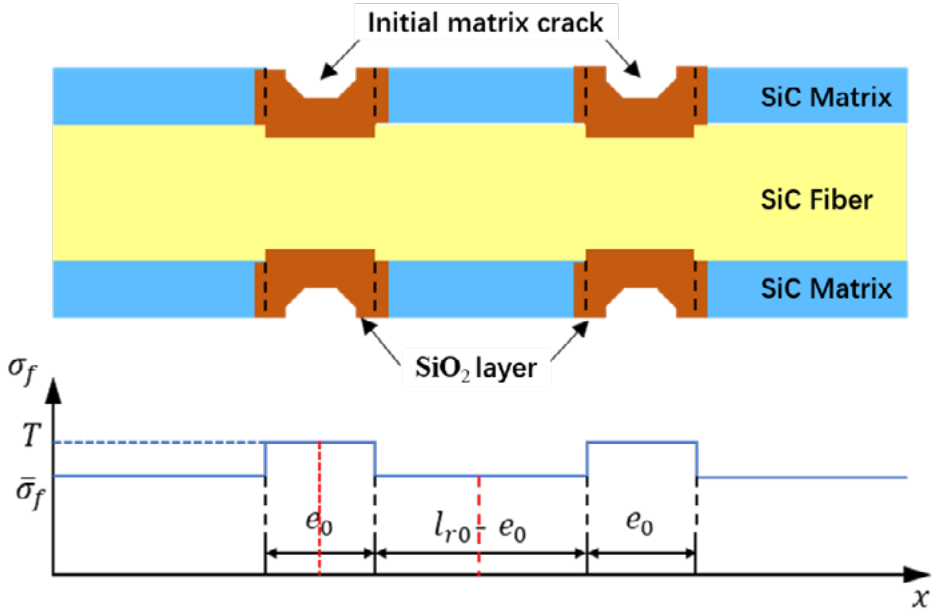

Figure 7. Oxide morphology and stress distribution of SiC fibers after stress-free oxidation

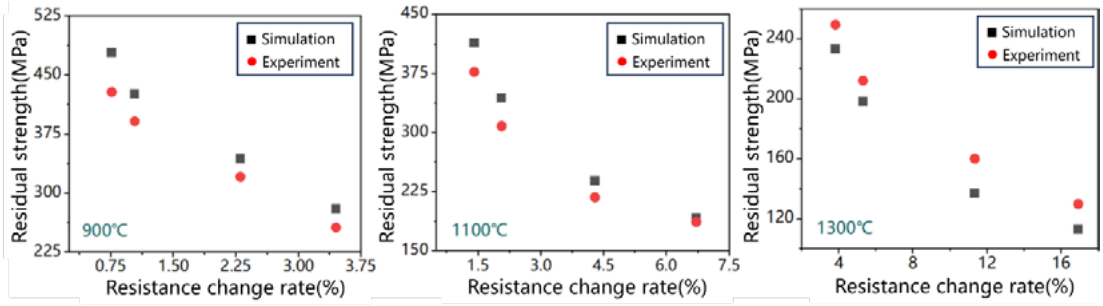

At this point, the stress distribution $\sigma_f(x)$ in the fiber can be express as:

$$\sigma_f(x) = \begin{cases} T & \left(0 \le x \le \frac{e_0}{2}\right) \\ \bar{\sigma}_f & (e_0/2 < x \le l_{r0}/2) \end{cases} \quad (1)$$

Where x is the direction of fiber length, T is the fiber stress on the cracked surface, and $\bar{\sigma}_f$ is the fiber stress on the unoxidised surface.

3.3. Experimental Verification

The residual strength of SiC/SiC mini-composites with different electrical resistance responses after oxidation at different temperatures was calculated using the above stress-free oxidation residual strength prediction model and compared with the experimental values. As illustrated in Figure 8, the discrepancy between the residual strength values calculated based on the resistance response and the test values following the oxidation of the specimens at 900°C, 1100°C and 1300°C is less than 11.60%, 10.28% and 14.48%, respectively. This verifies the reliability of the residual strength values calculated by the aforementioned model and also demonstrates the accuracy and validity of the oxidation morphology dimensions of the specimens calculated by the stress-free oxidation model based on the resistance response.

（a）900℃ （b）1100℃ （c）1300℃

Figure 8. Comparison of residual strength between calculated and tested results of SiC/SiC mini-composites after stress-free oxidation

4. Conclusions

This paper presents a stress-free oxidation residual strength prediction model for SiC/SiC mini-composites. The model is based on the microstructure characteristics of SiC/SiC fiber composites by PIP process, with brittle fracture after stress-free oxidation.The model makes a prediction of the residual strength of the specimen based on the thickness of the internal fiber SiO_2 layer obtained from the stress-free oxidation model. Results indicates that the calculated results agree well with the experimental results, with an error of the model not exceeding 14.48%.

Abstract
Adding nanoparticles to composite materials may enhance their material properties. Specific attention has been devoted to the mechanical properties. However, considering their complex mechanical response under impact loading, the effect of nanofillers is still unclear. Therefore, impact resistance of plain-weave aramid/epoxy composites with nanoparticles is investigated by means of experimental approaches. Carbon nanotubes and graphene nanoplatelets were simultaneously dispersed in epoxy prior to manufacturing the composite. Material tests of composites, including tensile, compressive and shear tests, were conducted to identify the mechanical properties, and improved modulus and strength were found with nanofillers. Similar results for composites with and without nanoparticles were obtained from low-velocity impact tests. However, thermography revealed a smaller delamination area for the specimens with nanoparticles compared to those without, indicating that investigations on nanofillers for high-performance composites should focus on the interface, where delamination can be regarded as focus for nanofiller-reinforced composites.

Keywords: low velocity impact; polyaramid; delamination; thermography

1. Introduction

Nanoparticles are regarded as an efficient solution for the improvement in mechanical properties of composite materials regarding fracture toughness [1,2] as well as impact resistance [3], considering their size effect and unique set of properties. However, as more works on composites with nanofillers are reported, the improvement on the strength and modulus reinforced by nanofillers is limited, especially compared to continuous fibers, which has motivated new focuses regarding their use in composites.

Low-velocity impacts are regarded as a critical threat which can produce invisible impact damage and significantly affect the mechanical performance of composites [4,5].The effect of hybrid nanofillers on the impact resistance of composites has been discussed under low velocity impact [6], where improved impact resistance was barely obtained with the random distribution of nanofillers. Furthermore, the defects introduced with the nanofillers are also an issue. As indicated in [2,7], voids and poor distribution were observed to have a significant effect on the impact and fracture resistance of composites. However, the interface fracture toughness was improved around 60% with nanofillers under both static and dynamic conditions [8], indicating that nanofillers may reinforce the interface, which may provide new insights into nanofiller-reinforced composites.

* Corresponding author

In this work, a comprehensive experimental investigation was conducted including both material characterization and low velocity impact tests for composites with hybrid nanofillers, and interface damage was monitored with thermography to support the findings.

2. Manufacture and specimen preparation

Plain-weave composites, with and without nanofillers, were produced. Kevlar™-29 plain-weave fabric (from Dupont) 0.5 mm thick was used along with Ampreg 26 (from Barracuda Composites), a DGEBA epoxy resin, and a hardener. Multi-walled carbon nanotubes (MWCNT, diameter: 10–30 nm, length: ~30 μm and 85% purity) and graphene nanoplatelets (GNP, thickness: 6-8 nm, width: 25 μm) were used in the current work as a hybrid nano-reinforcements.

The hybrid nanofillers were firstly dispersed in a solution of 60% acetone and 40% ethanol with the VibraCell VCX750 (frequency: 20 kHz) ultrasonic mixer at an amplitude of 250 W for 45 min, repeatedly vibrating for 25 s followed by a 10-s pause. The hybrid ratio for the two nanofillers was set to 1:1 (in weight). A mixture containing hybrid nanofillers was brushed onto both sides of the dried fabric to guarantee a random and homogeneous spread. Five layers of fabric were stacked and sealed for the vacuum infusion process. After infusion, the resin was left to cure for 24 h at room temperature and post-cured for 6 h at 80 °C as suggested by the resin manufacturer. The overall weight fraction of hybrid nanofillers was 1.0 wt.%. Specimens without nanofillers were also manufactured as reference. Specimens were then cut from the laminate using a waterjet cutter, and the edges of each panel were discarded.

3. Experiments

3.1 Material characterization

Composite characterization was performed to obtain their fundamental mechanical properties, with and without nanofillers. Tensile tests were carried out according to ASTM D3039 with a loading rate of 2 mm/min with deformation of the specimens monitored. Compression tests were conducted based on ASTM D6641 with a loading rate of 1.3 mm/min with a strain gauge in the middle of the gauge length. And V-notched-rail shear tests according to ASTM D7078 were carried out with a loading speed of 2 mm/min for in-plane shear properties.

3.2 Low velocity impact

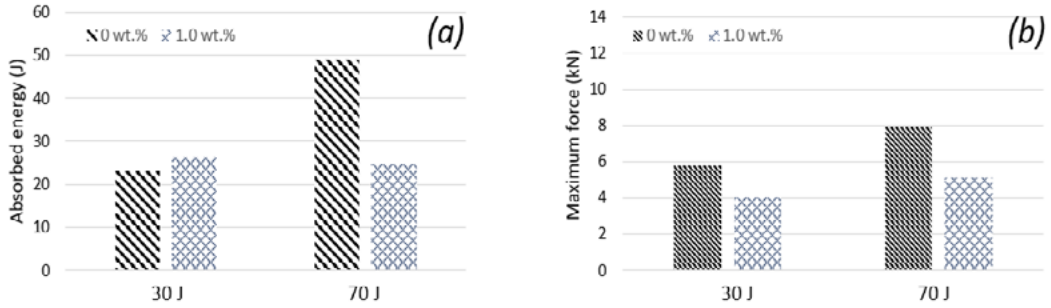
Low-velocity impact tests using a drop tower were performed to assess the effect of nanofillers. The tests followed the standard ASTM D7136 with fully fixed gripping for specimens considering the fully fixed boundary conditions [9]. A hemispherical impactor with diameter of 16 mm was applied. Two different energy levels were considered in the current work, 30 J and 70 J. In the tests, the reaction of the impactor was recorded with an optical sensor for the velocity as well as displacement of the impactor, while the load cell was used to monitor the force between the impactor and the specimen. A pneumatic arm prevented multiple hits to the objectives.

3.3 Delamination detection for impacted specimens

In the current work, infrared thermography is applied for delamination characterization using a continuous heating source from a 1kW halogen lamp. The thermal transient is documented by the infrared camera FLIR Titanium to identify the damaged area. For accurate results on damage morphology, thermal imaging at a 30 Hz frame rate was captured for 40 s. All thermal images are then post-processed with a procedure to obtain the invisible damage morphology for composites with and without nanofillers. The normalized temperature $\hat{T}$ is calculated to enhance the thermal contrast and cancel reflections and non-uniform heat sources, following the equation [10]:

$$\hat{T}(t) = \frac{T(t) - T(t=0)}{T(t=2) - T(t=0)}$$

where $T(t{=}0)$ is the temperature at the beginning of the test, $T(t{=}2)$ is the temperature of the image acquired after 2 s, and $T(t)$ is the temperature of the processed pixel at the general time t. The result will focus on $\hat{T}$ at 10 s, when the thermal contrast is the most suitable to identify the impact damage.



4. RESULTS AND DISCUSSIONS

The results of the composite material characterization with and without nanofillers are shown in Table 1. Some mechanical properties of the composite with nanofillers improved compared to that without nanofillers. The increase in modulus and strength is approximately 20% and 10%, respectively. However, properties such as shear and compressive strength remained constant. Those properties are more related to the matrix where the distribution of nanofillers may not be sufficiently concentrated. Additionally, the matrix includes both nanofillers and defects such as voids during curing, reducing the reinforcement of nanofillers [11]. Even so, the increase in both tensile strength and modulus may improve the impact resistance.

Table 1 Material properties for composite materials with and without nanofillers.

Parameter		Neat composite	Composite with 1.0 wt.% nanofillers
E_X	Elastic modulus along X direction (MPa)	19630 ± 720	20061 ± 1286
E_Y	Elastic modulus along Y direction (MPa)	15220 ± 1120	19240 ± 804
G_{XY}	In-plane shear modulus (MPa)	2123 ± 134	1651 ± 62
S_X^T	Tensile strength along X direction (MPa)	496.7 ± 5.9	513.7 ± 9.9
S_X^C	Compressive strength along X direction (MPa)	94.4 ± 4.2	106.1 ± 5.4
S_Y^T	Tensile strength along Y direction (MPa)	380.6 ± 14.1	486.8 ± 17.3
S_Y^C	Compressive strength along Y direction (MPa)	112.7 ± 5.5	116.1 ± 2.9
S_{XY}	In-plane shear strength (MPa)	38.8 ± 1.2	32.5 ± 1.9

However, the impact performance is not as expected based on Figure 1. Similar results of stiffness and absorbed energy were found at an impact energy of 30 J for composites with and without nanofillers. The composite with nanofillers has even lower performance regarding absorbed energy, being penetrated during impact, while the specimen without nanofillers rebounded the impactor. Considering the main impact, loading may be absorbed by the continuous fibers of the plain-weave composites and the effect of nanofillers can be limited in this case [11]. The difference between material tests and low velocity impact is perhaps due to the effect of defects. For material tests, the dimension of the specimen is limited while the impact specimens are larger and more dependent on the characteristics of the impact zone [7,12], which can amplify the effect of defects.

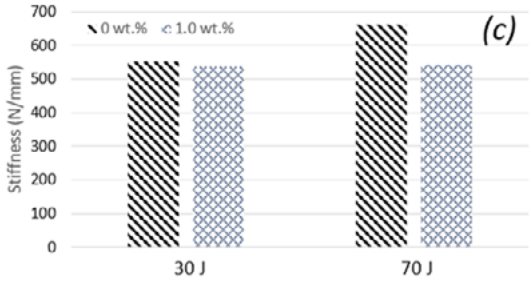


Figure 1 Results of absorbed energy (a), maximum force (b) and stiffness (c) of the composites.

For another perspective, the impact-induced damage was analyzed with thermography (see Figure 2). Thermal images present the rear face of the panels, where the damage is the most critical. The nanofilled composite warmed up much more than the unfilled one, reaching a temperature of about 50°C after the 40 s warming with respect to the unfilled that reached about 35°C. Besides, the thermal transient is different for the two cases; indeed, the nanofilled composite has a steeper warming. For this reason, the normalization procedure resulting in the thermal images of Figure 2 gives $\hat{T}$ values for the nanofilled lower than the unfilled. This is due to the nanofillers that change the thermal conductivity of the composite. However, focusing on the impact application, this is not a limitation, because the procedure allows identifying clearly the damaged region.
With the increase in impact energy, the damage area was larger for both composites (with and without nanofillers), as expected from general investigations [13]. However, the damage area was clearly reduced in the presence of nanofillers, indicating the increase in fracture toughness of the interface. Compared to the uncertain impact resistance of composites with nanofillers, the reinforced interface properties are more interesting.

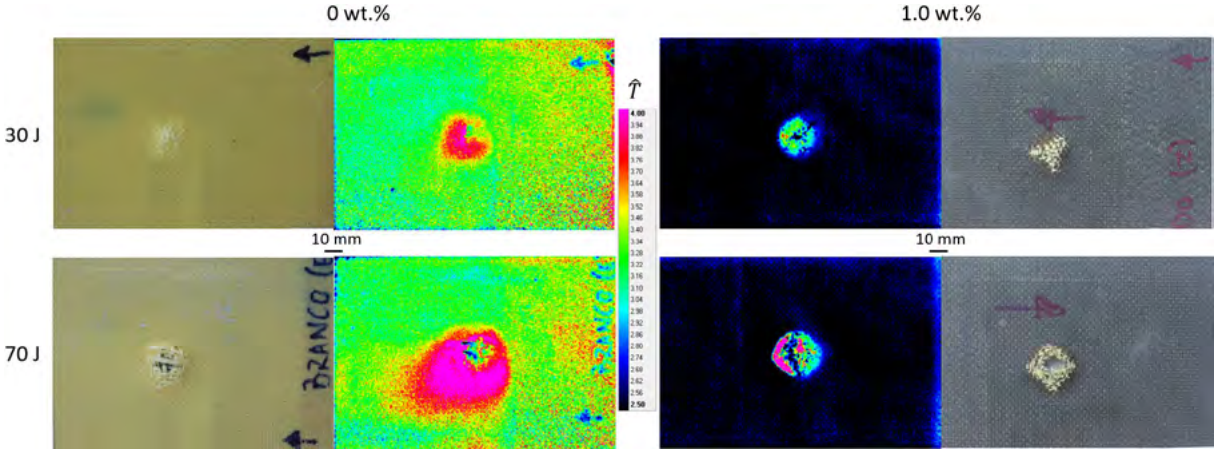

Figure 2 Thermographic results for the damaged composites at the rear face.

5. Conclusions

In this work, a comprehensive experimental activity was performed considering both material characterization and low velocity impact tests, and thermography was used for damage indication. Important material properties were improved, but the results from low velocity impacts were varied and showed limited reinforcement from the nanofillers attributed to the existence of defects. However, the delamination area was significantly reduced by the addition of nanofillers, indicating reinforcement of the interface fracture toughness under impact loading. Therefore, nanofillers were able to reinforce composites if the focus is on interface fracture toughness, which can benefit overall damage resistance and impact resistance, especially if the introduction of defects is limited.

Keywords: Ceramic Matrix Composites; damage model; creep; viscoelasticity; viscoplasticity;

Abstract
Oxide/oxide composites are ceramic matrix composites (CMC) designed for thermomechanical applications. When used at high temperatures, the progressive appearance of creep has been observed. Damage models are therefore no longer sufficient for dimensioning parts. In this paper, the creep of the material is studied experimentally in order to propose a stationary creep law, and then a viscous constitutive equation to take into account variations in loading. This creep modelling is introduced in an elastic-damaging constitutive equation.

1. Introduction

Ceramic matrix composites are one of the most promising solutions for improving aero-engine performance. Compared with the metallic materials used today, they offer superior operating temperatures and lower densities. The development of these materials has accelerated in the last years. Recent examples include CFM's new LEAP engine, which uses SiC/SiC CMC shrouds [1] or an alumina oxide fibre reinforced alumina oxide mixer nozzle developped by GE Aviation in its Passport gas-turbine [2]. Despite these achievements, the demands for incorporating these materials into crucial applications like aerospace gas-turbine engines necessitate extensive testing for design, certification and sustainment. It is therefore necessary to work on design methods that take into account the complex non-linear behavior of these materials.

In the aeronautic industry oxide/oxide composites materials are candidates for exhaust parts, subjected to moderate mechanical loads and temperature of around 700 to 800 °C, for next generation engines. These materials generally consist of alumina fibres embedded in a porous alumina matrix. 3M, the leading manufacturer of oxide fibres, is marketing new products: fabrics to reduce material production costs [3], and tow-pregs for AFP processes [4]. However, the majority of manufacturing processes reported in the literature involve impregnating 2D fabrics and then stacking the plies, pressing them and sintering the whole stack for a short time [5–8]. These brief high-temperature treatments enable the matrix to retain a high porosity level (Figure 1). By introducing such a high porosity rate into the material, the gap between the stiffness of the fibres and that of the matrix is sufficiently large for cracking energy to dissipate within the matrix without breaking the fibres. In a way, this brings it somewhat comparable to polymer matrix composites. In the field of CMC, this is the concept of a weak matrix, as opposed to the principle of composites with a weak interphase [9].

Because of their intrinsically fragile matrix and the dependence on fibres to bear the main load, matrix damage typically initiates at relatively low load levels. Then, damage evolves through processes such as fibre-matrix debonding, fibre sliding, and ultimately delamination and fibre breaking at higher loads. The stress-strain response generally remains almost linear when the load is applied parallel to the fibre reinforcement direction [6,10–12]. Non-linear behaviour is more pronounced for loading off

the direction of the fibres [13,14]. At room temperature, damage mechanisms are the main source of non-linearity.

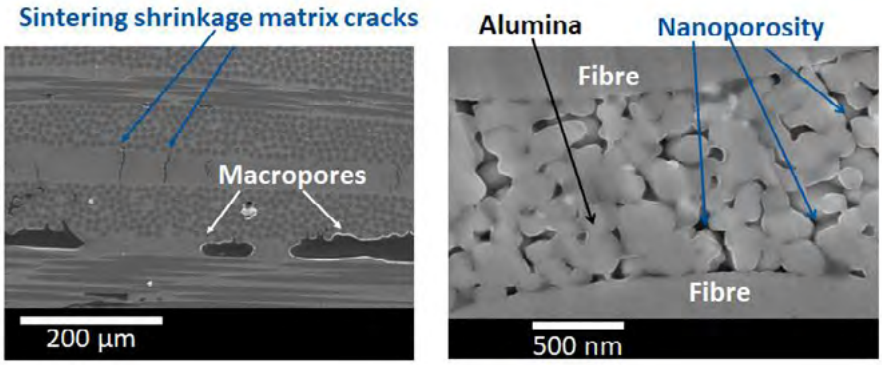

Figure 1. Oxide/Oxide composite microstructure

Fewer studies have been devoted to the oxide/oxide behaviour at high temperatures. Most of these have dealt with the behaviour of fibres or composites at temperatures above 1000°C. This highlighted the loss of stability of oxide fibres, which suffer from granular coarsening and creep. Our previous work focused on intermediate temperatures between 700 and 1000°C, which enabled us to demonstrate the progressive onset of creep [15]. A damage model dealing with in-plane behaviour has also been proposed for loading at temperatures where creep remains negligible [16]. One of the limitations of the work is the underestimation of the strain when the temperature becomes too high.

In this work, we propose a modification of the constitutive equation incorporating viscous behavior so that viscous deformation can be taken into account in part design. It focusses the behavior in tension in the fibre direction. Therefore, a simplified version of the damage law is first presented together with the associated identification. The second part is devoted to creep. First, stationary creep is identified on experimental data. Then, a viscous constitutive equation combining the stationary creep law and a viscoelastic term is proposed and identified in order to be applied to tests with load variations.

2. Damage modelling

A uniaxial version of the law developed in [16] is proposed. The constitutive equation is derived from the Helmholtz free energy (Ψ) as follows:

$$\sigma = \rho\frac{\partial\Psi}{\partial\varepsilon} = E^{eff}.\left(\varepsilon - \varepsilon^{th}\right) - E^{0}.\varepsilon^{r} \tag{1}$$

where ε, ε^{th} and ε^{r} are the total, thermal and residual strains, E^0 and E^{eff} are the intial and effective stifnesses and ρ is the material density.

The driving force for damage (y) is defined using the positive elastic strain (equal to the total strain in this simplified case) $< \varepsilon^{*} >_{+}$ and the initial stiffness E^0. It is written as:

$$y = \frac{1}{2}E^{0} < \varepsilon^{*} >_{+} < \varepsilon^{*} >_{+} \tag{2}$$

In line with ODM models dedicated to microstructure-driven damage [17–22], the driving force is defined in a non-standard thermodynamic framework, i.e. it no longer derives from the thermodynamic potential. However, this model is thermodynamically admissible because it is very easy to demonstrate the Clausius-Duhem's inequality. The use of positive strain alone only allows damage growth in tension.

The damage variable (d) is written as:

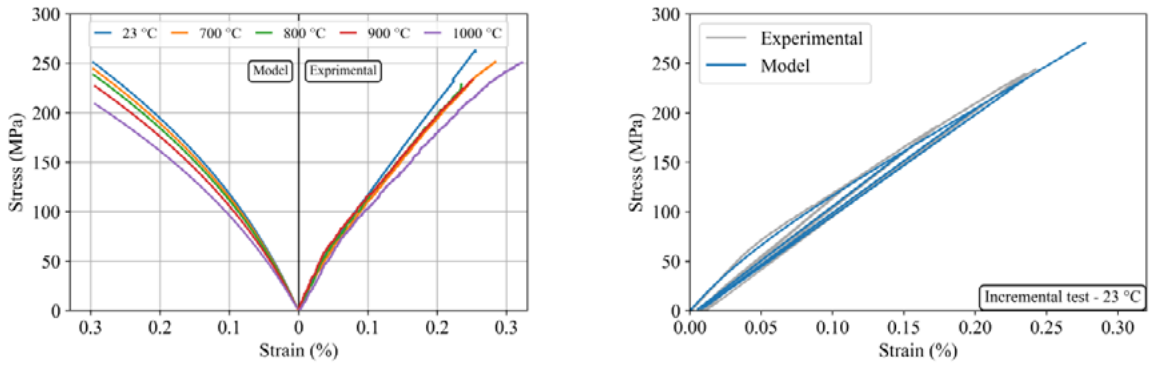
$$d = d_c(1 - \exp(-g(y_{max})^{p_c})) \quad \text{with} \quad g(y) = < \frac{\sqrt{y} - \sqrt{y_0}}{\sqrt{y_c}} >_+ \tag{3}$$

where y_c, p_c and d_c are three model parameters, y_0 the driving force at the damage threshold and y_{max} the maximum driving force y observed during loading. The form chosen for the damage variable allows the definition of a threshold below which the material's behavior remains elastic. One of the particularities of the damage variable defined in ODM models is that it can vary between 0 and $+\infty$, unlike most models for which the damage variable cannot exceed 1.
The damage activation index (η) is introduced to take account of whether cracks are open or closed, and is then worth 0 or 1 respectively. More details on its calculation are given in [16].

The effective compliance (S^{eff}) is expressed as:

$$S^{eff} = \frac{1}{E^{eff}} = S^0(1 + d\eta) \tag{4}$$

Finally the derivative of the residual strain with respect to time is expressed as:



$$\dot{\varepsilon_r} = S^0 \chi \dot{d}. E^{eff}. \eta S^0. E^{eff}. (\varepsilon - \varepsilon^{th}) \tag{5}$$

where χ is a model parameter for adjusting the amplitude of residual strain.

The effect of temperature on the damage behaviour is introduced by the dependence of the initial stiffness (E^0) and the damage threshold (ε^{se}) on temperature using Eq (6).

$$\begin{cases} E^0(T) = E^0.\left(1 + \exp\left(\dfrac{T - T^{se}}{a}\right)\right)^{-1} \\ \varepsilon^{se}(T) = \varepsilon_0^{se}.\left(1 + \exp\left(\dfrac{T - T^{se}}{a}\right)\right) \end{cases} \tag{6}$$

The stiffness and damage threshold as a function of temperature are identified from tensile tests. The other four parameters (d_c, y_c, p_c and χ) are obtained from monotonic and incremental tests, i.e. cyclic tests with charges and discharges while increasing the maximum stress at each cycle. Figure 2 (a) illustrates the comparison between the experimental and the simulated response from monotonic tests.

(a) (b)

Figure 2. Monotonic tensile behaviour from room temperature up to 1000 °C: comparison between experimental data and model (a) and incremental tensile tests at room temperature (b)

With regard to the experimental dispersion, the identification carried out is considered satisfactory. Figure 2 (b) demonstrates how residual strain is taken into account after unloading once the damage threshold has been exceeded. At room temperature, the amplitude is well reproduced. However strain is underestimated beyond 900 °C. This can be explained by the gradual onset of creep. Tests at two loading rates (0.5 mm.min^{-1} and 5 µm.min^{-1}) have shown that creep becomes non-negligible over a period of around one hour before 900°C [15].

3. Introduction of creep in the constitutive equation

3.1. Experimental study of stationary creep

Creep tests were carried out in tension in the fibre direction at temperatures between 850 °C, where measurable creep deformations were observed, and 1050 °C with a fixed duration of 72 hours. Stresses of between 26 and 182 MPa were applied, i.e. 10 to 70% of the average stress at failure of the material at room temperature. Low creep rates are observed at temperatures below 900 °C, even for high stresses. Above 1000 °C, strains of several percent that can lead to failure can be obtained for relatively short periods of time. With the exception of the test carried out at 850 °C, for which the measured strain is very small, the primary creep stage is relatively short and only accounts for a small proportion of the total strain. Behaviour is therefore mainly governed by stationary creep, with strain increasing linearly with time.

It therefore seemed appropriate to use a classical creep law to model the effect of temperature and stress on creep rate. A simple Norton law, in which the creep rate is related to the stress via a stress exponent (n) is combined with an Arrhenius term for the effect of temperature (Eq. (7)).

$$\dot{\varepsilon}^{vp} = A\sigma^n \exp\left(-\frac{Q}{RT}\right) \tag{7}$$

An identification process was implemented by scanning the values of n and Q and calculating the value of $log(A)$ minimising the mean square error between the experimental and simulated values. The numerical values of the three coefficients of the law are then identified: n = 3.5, Q = 632 kJ.mol^{-1} and A = 36.10^{10}. It is then possible to compare the rates calculated by this law with the experimental data from which they are derived (Figure 3). The proposed law, one of the simplest in the literature [23], is an accurate representation of the stationary creep of the studied material.

In order to analyse these results, they were compared with results obtained on fibres alone [24]. Using the previous identification method, the following coefficient values were calculated: n = 3, Q = 632 kJ.mol^{-1} and A = 89.10^{10}. The stress exponent and activation energy are very close to those determined for the composite. Creep therefore appears to be essentially driven by the fibres.

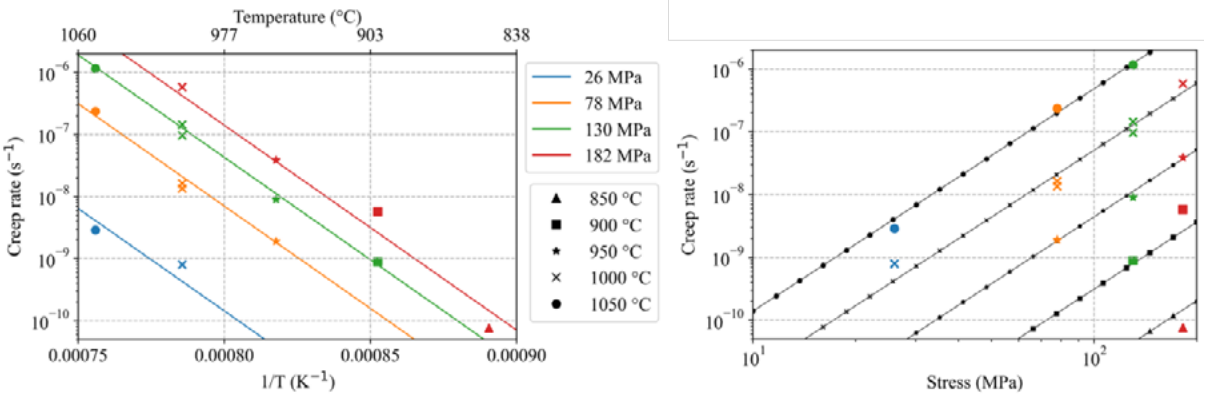


Figure 3. Creep rates as a function of applied stress and test temperature

3.2. Creep modelling

Once again, the formulation is based on the Helmholtz free energy to derive a thermodynamically consistent relationship for the material behaviour:

$$\Psi = \frac{1}{2\rho}\left[\left(\varepsilon - \varepsilon^{th} - \varepsilon^{v}\right).E^{eff}.\left(\varepsilon - \varepsilon^{th} - \varepsilon^{v}\right) - \varepsilon^{r}.E^{0}(T).\varepsilon^{r} + \xi.E^{R}.\xi\right] \tag{8}$$

where ρ is the density, ε, ε^{th} and ε^{r} are the total, thermal and residual strain, ε^{v} and ξ the internal variables representing the viscous strain and the strain-hardening mechanism respectively, E^{0} and E^{eff} are the initial and effective stiffness's and E^{R} the viscous modulus. The definition of the two stiffness's E^{0} and E^{R} makes it possible to define a different evolution of the elastic and viscous mechanisms. In particular, no temperature dependence of E^{R} is considered. In order to keep the model simple, viscoelasticity is assumed to be linear. The internal variables can therefore be written as follows:

$$\begin{aligned} \dot{\varepsilon}^{v} &= \dot{\xi} + a(T).(\xi.E^{R}.\xi)^{p_2}.S^{R}.\sigma \\ \dot{\xi} &= \frac{1}{\tau}(S^{R}.\sigma - \xi) \end{aligned} \tag{9}$$

where τ is the characteristic time of the viscous mechanism ξ and $S^{R} = 1/E^{R}$.

Noting that, in the linear viscoelastic steady-state case, ξ tends to $S^{R}.\sigma$, the viscous strain rate is expressed as:

$$\dot{\varepsilon}^{v} = a(T).(\sigma.S^{R}.\sigma)^{p_2}.S^{R}.\sigma \tag{10}$$

Finally, in order to preserve the stationary creep law identified above, the following conditions are also imposed:

$$p_2 = \frac{n-1}{2} \quad ; \quad a(T) = A\ E^{R\,p_2+1}\exp\left(-\frac{Q}{RT}\right) \tag{11}$$

The viscous strain rate ($\dot{\varepsilon}_v$) comes from two contributions. The first is linked to a viscoelastic phenomenon whose formalism was introduced by Maire [25] and Schieffer [26] to describe the viscous behaviour of PMC laminates or Marcin [20] in ODM models. The form adopted for this viscous term allows a deformation plateau to be reached for a time approximately equal to three times the characteristic time τ. The second term is the result of viscoplastic phenomena and, in our conditions, under uniaxial loading and steady state conditions, allows a strain at a constant rate equal to that predicted by Norton's law.

The law was identified using all the creep tests. Two validation tests called dip-tests were carried out. This involves letting the material creep and then suddenly reducing the applied load. In a first test carried out at 950 °C, a stress of 182 MPa was applied for 45 hours, and then quickly reduced to 72 MPa. Both creep rates measured in the stationary domains are in agreement with the previously identified law. The stiffness measured during discharge is also in agreement with that predicted by the damage model. The second dip-test (Figure 4) was carried out at 1000 °C at a stress of 130 MPa, which was suddenly reduced to 26 MPa. On the close-ups taken during loading and unloading, the stationary creep is well represented by the Norton model (in orange). In addition, the introduction of the viscoelasticity term (in green) helps to better capture the smoothing of the curves during load variations.

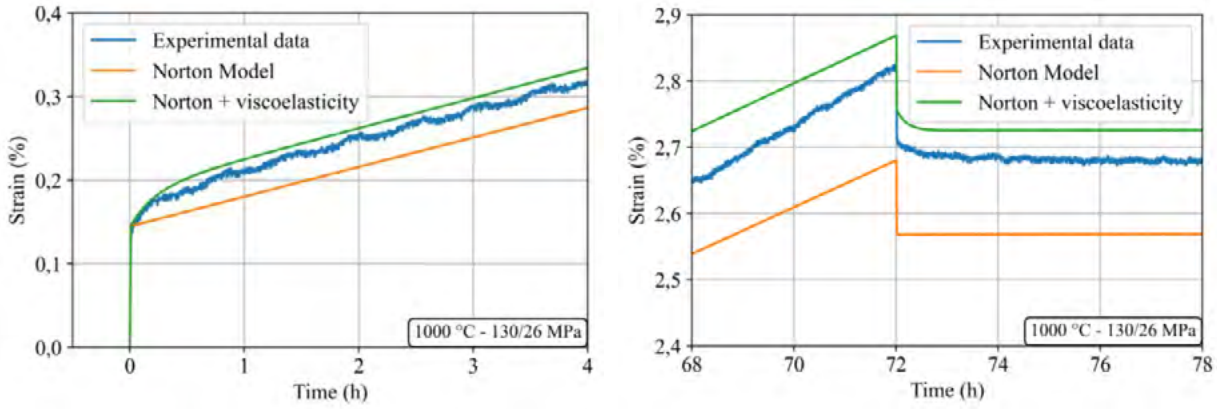

Figure 4. Comparison between a dip-test at 1000 °C (130 then 26 MPa) and simulation with and without viscoelasticity term

The model combining damage and viscous behaviour can then be used to simulate incremental tests, which suffered from underestimated strain during discharges. For this purpose, data on the force applied by the machine as a function of time is used as loading conditions for the model. This represents a test at 0.5 mm.min^{-1} with discharges at each maximum stress increment of 27 MPa. Figure 5 illustrates the simulation of the test with the damage model alone (left) and with the addition of creep (right). Adding the creep term allows the amplitude of the strains to be reproduced when the load returns to zero. Compared to the calculation with damage only, there is also a shift in strain when the load returns to the maximum of the previous increment. This is also observed experimentally and is explained by the material continuing to creep during discharges.

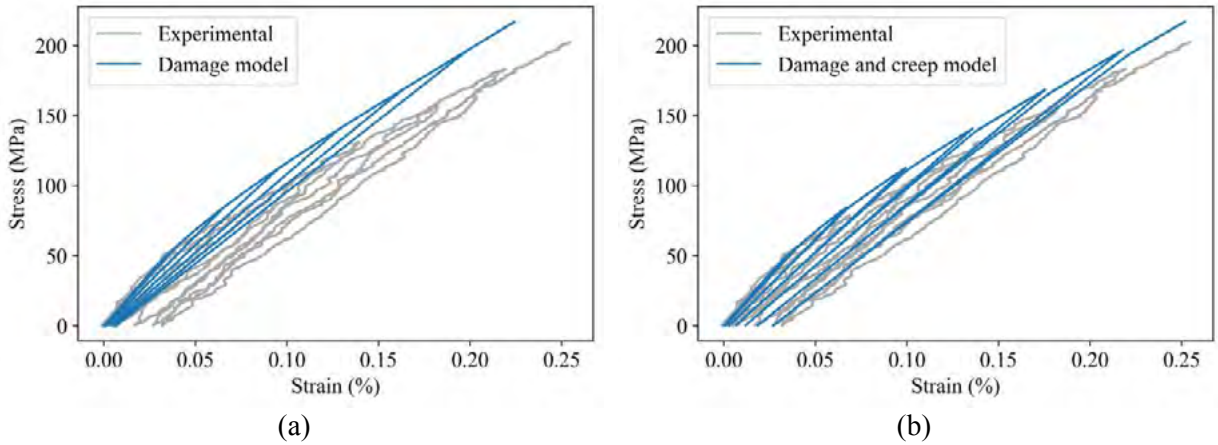

Figure 5. Comparison of the simulated stress-strain behavior during an incremental test at 1000 °C to the experimental data without (a) and with (b) taking creep into account

Finally, this model is intended to be used in a structural calculation code, in particular to help with design of parts. To optimise the use of this material, it seems appropriate to tolerate a certain amount of creep strain. In addition to stress and temperature, the time of use is also a factor to take into account. Figure 6 shows a possible use of the law, indicating the maximum time to reach 0.1% viscous strain as a function of load conditions. At low temperatures, the boundary between yellow and green corresponds to the time taken for viscoelasticity to set in. This graph should of course be combined with a design that takes into account the effect of temperature on stiffness and material damage.

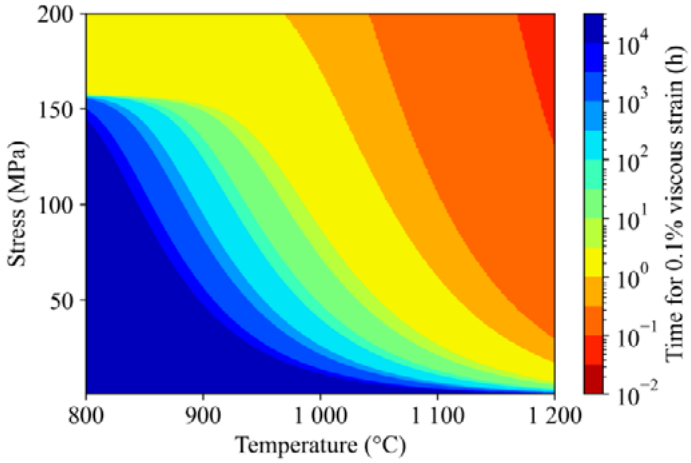

Figure 6. Stress-Temperature-Time diagram for a maximum of 0.1% viscous strain

4. Conclusions

Oxide/oxide composites are being considered for structural temperature applications. While damage does not appear to be affected by temperature, stiffness decreases significantly above 800°C. It is therefore important to have calculation codes that take into account the effect of temperature and material damage. However, creep is also gradually appearing. To use the full potential of these materials, it is therefore necessary to address creep and integrate it into the constitutive equation. In this paper, a creep model based on a Norton's law for the stationary part and a linear viscoelasticity term to better capture load variations was introduced in a damage model. The viscous law was identified on simple creep tests and validated on dip-tests. The value of this law was then demonstrated on an incremental tensile test at 1000 °C. To take this a step further, it is necessary to study creep outside the fibres direction to fully identify the in-plane behavior and thus complete the multiaxial damage model already identified. It also seems important to study the material's behaviour during fatigue tests with holding times that are more representative of aeronautical operating cycles.

Acknowledgments

The authors would like to thank Guillaume Pujol and Grégory Lacoste for conducting the mechanical tests presented in this work.

Keywords: Fiber-matrix, interface, debonding, characterization

Abstract
Fiber-matrix interface debonding is characterized experimentally using single transverse glass fiber within an epoxy matrix specimen tested under uniaxial tension. A dual-vision system, consisting of two synchronized cameras, is used to monitor the initiation and propagation of the fiber-matrix debonding as a function of the applied remote loading. Debonding was found to initiate at the free surface to tunnel at the fiber pole. Debonding topologies are characterized in terms of maximum opening and through thickness length and angle. The debonding angles are challenging to determine experimentally, so that a numerical model is established, which validated the accuracy of the experimental measurements.

1. Introduction

Fiber-matrix interface in composite materials is known to play a major role in the damage and associated ultimate properties. Indeed, stress concentration resulting from elastic mismatch, proximity to adjacent fibers, and low fracture properties can rapidly induce damage at the interface. Therefore, it is crucial to accurately characterize their fracture properties.

Fiber-matrix interface fracture characterization can be achieved using single-fiber tests such as, *e.g.*, multi-fragmentation or pull-out tests [1]. Fiber-matrix interface primarily undergoes shear loading using above-mentioned methods. However, tensile properties are as important and require other characterization methods to be used. Single-fiber sample loaded transversely can be used to assess opening fracture properties. Koyanagi *et al*. [2] used the debonding length and cohesive zone model to identified fracture properties. Authors reported the difficulty in identifying the debonding shape due to compression loading on the fiber equators. Debonding monitoring may thus require more in-depth characterization method to enable accurate inverse identification.

Livingston and Koohbor [3] performed experimental observations of macro-scale debonding. Single-fiber composite specimens were tested under uniaxial tension and full-field measurements at the fiber vicinity was performed to observe debonding stages. For this purpose, DIC was used to extract local strain fields and debonding angle at the free surfaces as a function of the applied loading [4]. However, debonding observations are limited to the front surface which provides limited information on the complete debonding process.

The present work thus improves the above-discussed experimental investigation of fiber-matrix interface by using a dual-vision approach to enable the simultaneous characterization of in-plane and through-thickness debonding process in single macro fiber model composites. Section 2 details the experimental set-up along with samples preparation. Results obtained from the debonding characterization are presented and confronted to numerical simulations to be further discussed in Section 3. Finally, conclusions on the proposed approach are drawn.

2. Experiments

2.1. Materials and sample preparation

Single fiber samples are made by embedding a 1 mm diameter quartz glass fiber in a translucid, room-curable epoxy. The epoxy resin (SD2505/SR1500, Sicomin, France) is cured at room temperature for one month to ensure that the resin is fully cured. Isotropic elastic properties of the fiber and the matrix are given in Table 1. Elastic properties of the epoxy matrix are determined in-house, using 5 tensile fiber-free samples prepared under the same curing conditions. The final sample, whose geometry is shown in Figure 1, has a 5 mm wide and 5 mm thick cross-section.

Table 1. Elastic properties of the matrix and fiber.

Property	Epoxy	Glass fiber
Young's modulus [GPa]	2.7 ± 0.2	72
Poisson's ratio	0.41 ± 0.04	0.3

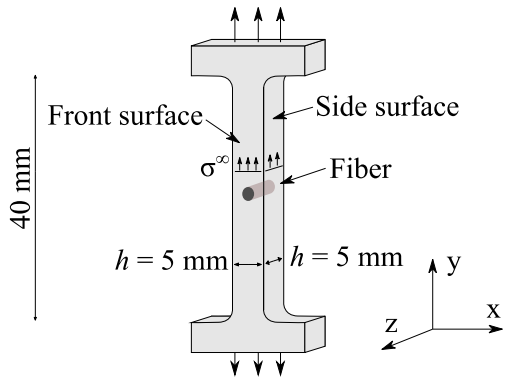

Figure 1. Single fiber specimen geometry and dimensions.

The single fiber is held in place using a 3D-printed jig. The surface of the fiber is cleaned with isopropanol to remove any unwanted substances from the surface. The matrix is poured into a silicone mold, where the latter is drilled at the location of the fiber to allow it to protrude from the final sample. This eliminates the need to polish the end of the fiber itself. The front surface of the sample is slightly polished with fine sandpaper with a grain size of approximately 8 µm. The side surfaces are also polished, first using similar fine sandpaper, then using a rotating cotton disc coupled with a polishing solution to obtain a perfectly transparent, flat side surface. The front surface is then spray painted for DIC. Samples are tested under tension at room temperature at a constant displacement rate of 0.18 mm/min. A dual-vision system consisting of two perpendicularly positioned cameras (FLIR Grasshopper GS3-U3-41C6M-C) is installed. This allows simultaneous observation of the front and side surfaces of the sample.

2.2 Mechanical test and image-based measurements

Figure 2 shows the parameters describing debonding geometry. Since straight-faced samples are used, debonding is likely to initiate at the free surface [5]. Debonding can be described by the debonding angle θ_{d} at the free face, measured by the angle between the two debonding tips. The quantity δ_{nn} corresponds to the maximum normal debonding opening. It is worth noting that considering the samples geometry and loading condition, maximum opening will occur at the pole of the fiber. The debonding opening actually reflects the distance separating the two lips of the crack. The length of debonding through the thickness is described by l_{d}, which corresponds to the length of debonding in the z-direction at the pole of the fiber.

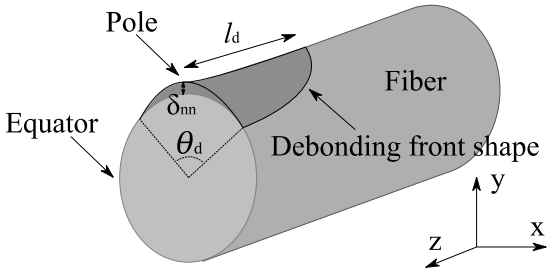

Figure 2. Fiber-matrix debonding geometrical parameters.

The debonding length determination consists in observing and monitoring the debonding propagation through the thickness of the sample, *i.e.*, in the z-direction. Since the debonding is likely to initiate and propagate at the fiber pole with respect to the loading direction due to the maximum stress attained at this location, the latter also corresponds to the maximum possible debonding length l_d. The method used to determine the debonding length makes use of the image processing free software, ImageJ. The side images are first imported into the software, then aligned to eliminate any motion induced by the tensile test, with the images shifted to match the previous one. In this way, the location of the fibers remains constant for several remote stresses, which facilitates identification of the debonding. The image preceding the onset of debonding is then selected, from which the gray level difference for each pixel is calculated with the subsequent images. As a result, the debonding area results in a large gray level difference compared to the initial image, while the other areas result in a difference close to 0. A threshold of 17% in gray level intensity is then applied to the difference between the two images and superimposed on the real image. The threshold value is set so that the results coincide with the visual observation of a large debonding surface. The new images highlight the debonded area, which length is determined as the maximum distance within the threshold area.

Maximum debonding opening is determined using the displacement fields deduced from DIC measurement. In details, a camera is positioned parallel to the sample front surface. The approach involves the use of Ufreckles software [6], from which displacement fields can be derived. A virtual gauge aligned with the loading direction and passing through the fiber and the matrix at the top pole is positioned. The U_y displacement is determined along the gauge as a function of the applied remote load within both the fiber and matrix. From a certain loading level, displacement discontinuously develops at the fiber-matrix interface, which can be associated with debonding initiation. From this loading level, the displacement remains almost constant within either the matrix or the fiber, allowing the debonding opening δ_{nn} to be assessed by computing the displacement jump.

The debonding angle remains difficult to observe because it is characterized by sub-pixel mechanisms that cannot be captured either by optical observation or by the DIC residuals. As a consequence, inverse calculation based on elastic calculations performed on a 3D numerical is used to determine the debonding angle.

3. Results and discussion

The following results are presented for one sample to illustrate the characterization approach. Since debonding is likely to initiate from the free surfaces of the sample at the pole of the fiber relative to the loading direction, 4 preferred initiation sites can be defined. For the sake of simplicity, only the first debonding site is considered in what follows.

Figure 3a shows multiple side images illustrating the debonding process, with both raw and thresholded images, left and right images, respectively, for different loading level σ^∞. The location of the crack tip is highlighted by a red triangle marker, enabling the debonding length to be determined as the distance

to the free surface. Notably, the fiber from the studied sample is slightly tilted, approximately 4 deg. relative to the loading direction, potentially influencing the debonding shape topology.

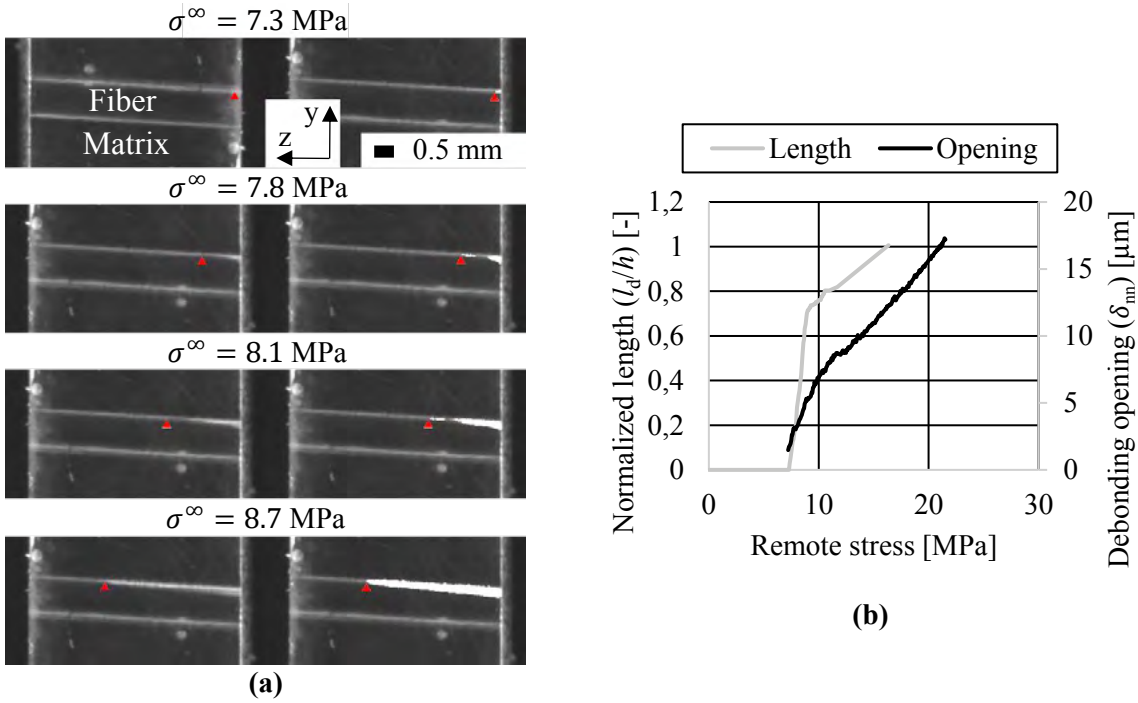

Figure 3. (a) Debonding propagation observed using the raw image, left column and using a threshold, right column. **(b)** Variation of both debonding length and opening as a function of the remote stress.

Figure 3b shows the variation in debonding opening and normalized length as a function of remote stress at the same debonding initiation site. The debonding length is normalized by the sample thickness h. Debonding initiation occurs at a remote stress of 7.2 MPa with both opening and length predictions being consistent. The maximum debonding opening at initiation are given in Table 2. Since debonding initiation occurs between two images, upper and lower bounds for debonding initiation opening can be determined.

Table 2. Debonding opening at initiation.

δ_{nn} [µm] lower bound	δ_{nn} [µm] upper bound
1.5 ± 1.0	1.7 ± 1.0

Difficulties in determining debonding angles are encountered experimentally. The pixel size obtained with the front camera varies between 10 and 12 µm, whereas the DIC provides debonding initiation opening with a sub-pixel size of 1 to 3 µm. Consequently, the resolution of the camera is not sufficient to capture the early stages of debonding at the free surface. Nevertheless, coupled experimental-numerical approach is established to retrieve the debonding angle and shape that best match the experimentally measured opening and debonding length. The approach consists of numerically comparing various debonding geometries approximated using a power-law of exponent 4. The appropriate geometry thus gives the debonding angle at the free surface and the shape of the debonding front. Identification can be performed at several debonding stages, providing debonding angles as a function of remote loading.

Debonding angles obtained from the coupled numerical-experimental approach are shown in Figure 4 by the white markers. The debonding angle can also be assessed using the side observation, using results from Figure 3a, shown by the solide line in Figure 4. The side observation method provides precise debonding angles for small angles only. For angles larger than 70 degrees, the difference in reflective index brought by the debonded zone is not sufficient to capture the actual debonding area. The mixed shear-compression loading causes the debonding area to be partially captured. Despite those differences, the proposed method offers an accurate description of the debonding angle for early stages of debonding.

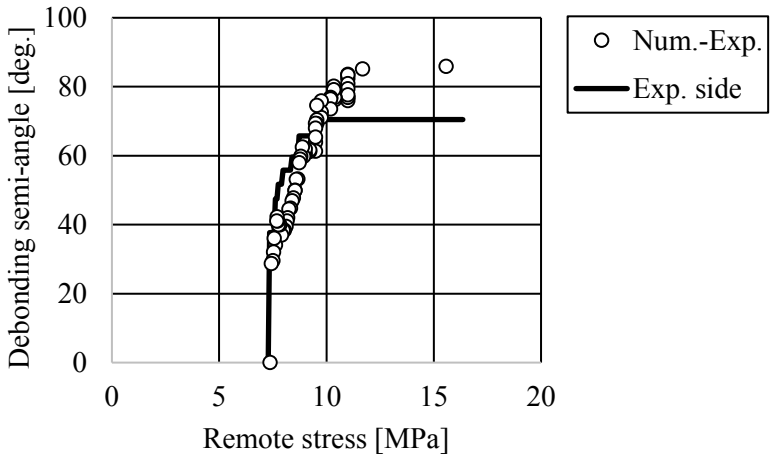

Figure 4. Variation of the debonding semi-angle as a function of the remote stress.

4. Conclusion

The proposed method enables the thorough description of the debonding process using different geometrical parameters. The extracted quantities provide key information such as the debonding initiation remote loading. Additionally, the debonding propagation can be monitored as a function of the remote stress. Experimental-numerical approach that couples experimental debonding opening and length to numerical results enables determining the debonding angle as a function of the remote loading. Debonding angle determined using the side observation is confirmed to be accurate except when the interface undergoes mixed shear-compression. Such experimental debonding observation can be used to calibrate an inverse identification approach that requires the debonding topology to be computed. Such inverse identification may enable the determination of the fiber-matrix interface fracture properties.

Keywords: Crack propagation, Fracture criteria, Mode I, II, and mixed mode I/II fracture toughness, Pultruded plates, CFRP

Abstract

Driven by the energy transition and the reduction of carbon emissions, pultruded CFRP plates have emerged as an affordable high performance material for designing wind turbines with larger rotors. To enable the creation of thicker laminates, pre-cured plates are bonded together using an epoxy resin. The present study focuses on characterizing the fracture behaviours of these laminated bonded plates under different modes, and to generate fracture criteria for numerical simulations establishing design allowables and service life. Double cantilever beam tests, end-loaded split tests, and mixed-mode bending tests were conducted under quasi static loading for such plates. Mode I crack propagation showed brittle failure while mode II fracture tests on the other hand, presented a more stable crack growth. Finally, power law and Benzeggagh-Kenane law criteria were established to numerically describe the fracture behaviours. Overall, the results show that the available standards for fracture toughness testing are also suitable for these laminated-pultruded composite plate structures, enabling the material characterization needed for design.

1. Introduction

Larger and larger rotors have been designed for wind turbine blades to enable more energy capture, resulting in ever increasing structural loading. Carbon fibre reinforced polymer (CFRP) composites, due to their outstanding mechanical performance, have been utilized in spar caps of wind turbine rotors to carry and transfer increased loads in the flap direction. Among them, pultruded CFRP plates have emerged as an affordable high performance material for wind turbine design [1, 2]. To enable the creation of thicker laminates, pre-cured plates are bonded together using an epoxy resin. Considering the dominant role of such CFRP composites in load-bearing structures of wind turbine blades, it is necessary to characterize the fracture behaviours of these novel laminates under different modes, and to further generate fracture criteria for numerical simulations establishing design allowables and service life.

One question which may rise first is should these laminated pultruded plates be treated as composite laminates or adhesive joints? Considering the standardized tests are mainly proposed for composite laminates with a thickness of 2 mm to 5 mm, it is not clear whether the characterization of fracture

behaviours of such bonded pultruded plates can follow these existing test standards or not. So far, some researches have been conducted to consider the modification of standard specimen dimensions for pultruded composites. Burda et al. [3] recommended that the length of double cantilever beam specimens should be at least 250 mm to characterise the pure mode I fracture behaviour of pultruded glass fibre-reinforced epoxy rods and to provide a suitable R-curve. Yan et al. [4] found that mode II crack propagation using the end-notched flexure test configuration becomes more stable when increasing pre-crack length for pultruded carbon fibre-epoxy composites. Zhang et al. [5] increased the length of specimens for end-loaded split tests to investigate the mode-II fracture properties for an adhesive layer of 2 mm thickness. However, a systematic inversitiagtion into the applicability of different test standards on the laminated pultruded composite plates is needed, covering different loading modes (i.e. mixed mode ratio). Besides, it will also be interesting to understand how the the development of the fracture pattern is affected by different loading modes for such plates, which is rarely reported in literature.

Therefore, the present study aims at provide a comprehensive insight on quasi-static behaviours of laminated pultruded composite plates under four types of loading modes. Both the applicability of the existing test standards and effect of loading modes on the fracture pattern of such plates will be explored further.

2. Experimental setups

2.1. Materials and specimens

Zoltek™ PX35 pultruded plate bonded with SWANCOR 2511-1AL/BL epoxy resin was studied in the present work, and the overall thickness of such laminated pultruded plates is about 6.1 mm. At the interfaces between the top and the bottom pultruded plate, a glass fibre veil (M524-ECR30A) with an areal weight of 30 g/m^2 was placed during the resin infusion process, to improve the fracture toughness. The curing process consists of 24-hour curing at room temperature, followed by 3-hour curing at 65°C and 4-hour curing at 80°C. According to ASTM D5528, ISO 15114 and ASTM D6671 [6,7,8], specimens were cut in different dimensions for each type of loading mode, as summarized in Table 1. The initial crack length is measured from the loading line to the crack front. Aluminum loading blocks were bonded on the specimens using LOCTITE EA 3430 and cured at room temperature for at least 24 hours.

Table 1. Geometry dimensions of different types of specimens.

Specimen Type	Loading mode	Length (mm)	Width (mm)	Initial crack length (mm)
DCB	Mode I	200	25	80
ELS	Mode II	180	20	66
MMB	Mixed mode I/II	170	25	32

2.2. Experimental procedures

For most of specimens, mode-I pre-cracking with a length of 2 mm to 10 mm was created. Afterwards, double cantilever beam tests (DCB), end-loaded split tests (ELS), and mixed-mode bending (MMB) tests were conducted under quasi static loading at a rate of 0.5 mm/min or 1 mm/min, as shown in Figure 1. For ELS specimens, the free delamination length is 110 mm and the clamping region is 60 mm. For MMB specimens, the distance from the loading line to the mid supporter is 70 mm. Eventually, four mixed-mode ratios (MMRs), calculated as the ratio of mode II strain energy release rate to the total strain energy release rate, were covered in the present study, i.e. 0, 0.33, 0.67, 1. During the tests, the crack propagation was monitored by an OPTOMOTIVE camera with a resolution of 2048 × 2048 pixels, and image acquisition was performed every 1-5 second(s). For DCB tests, the test was stopped when the crack propagated along the entire interface. For ELS tests, the test was

stopped when the crack propagated close to the clamping region where the force start to increase. For MMB tests, the test was stopped at either the crack propagating to the middle support or unstable crack propagation along with a sudden drop of force. Three to four tests were repeated for each mixed mode ratio. Regarding the data reduction methods for determining mode I and mode II crack intiation toughness, the Compliance Calibration method [6] and the Corrected Beam Theory using Effective crack length [7] were used for mode I and mode II, respectively.

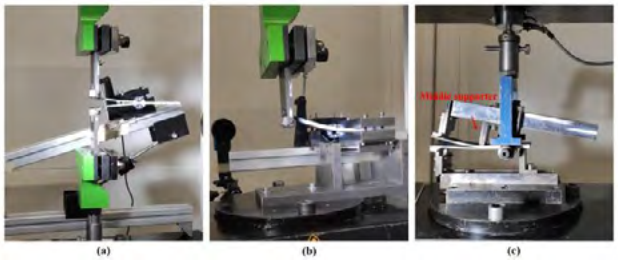

Figure 1. Test setups: (a) DCB tests, (b) ELS tests, (c) MMB tests.

3. Results and discussions

FigureFigure ***2*** shows the force-displacement curves and the crack length history under different loading modes. Overall, a sudden drop of force occurred more frequently for mode I dominant fracture tests (i.e. MMR = 0 and 0.33) accompanying unstable or fast crack propagation, while the post-peak section of force-displacement curves were smoother along with stable and slow crack propagation for mode II dominant fracture tests (i.e. MMR = 0.67 and 1). For the mode I dominant fracture tests, adhesive and substrate failure accompanied cohesive failure. In contrast, mode II dominated fracture tests only showed cohesive failure of the epoxy resin at the interfaces.

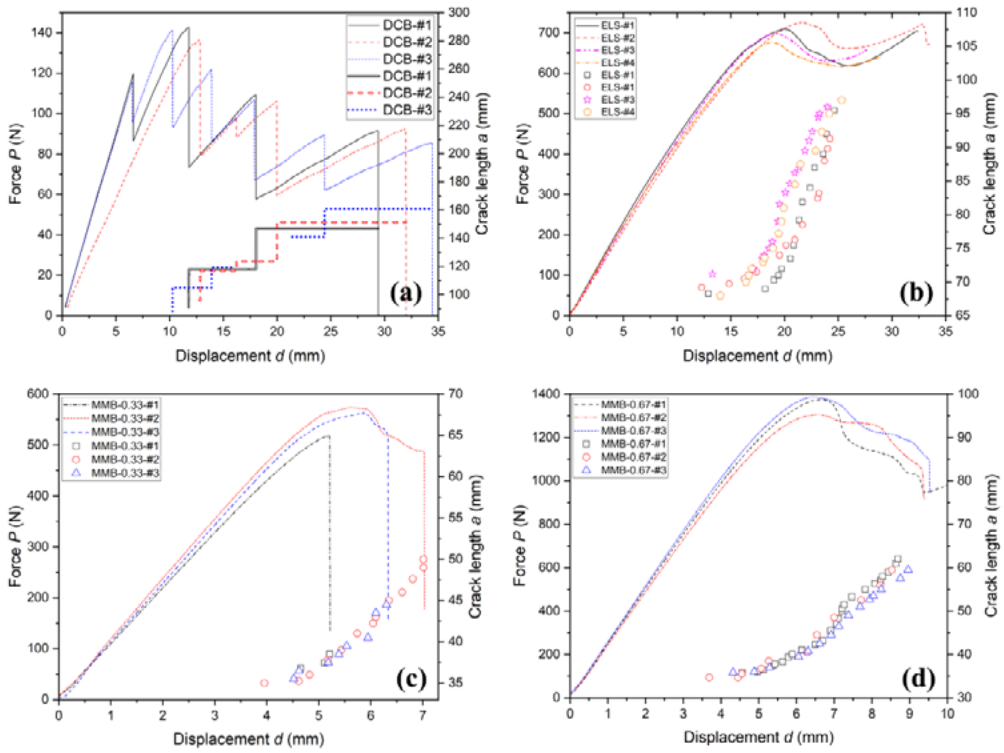

Figure 2. Force-displacement curves and crack length-displacement curves obtained from DCB tests (a), ELS tests (b), MMB tests at a mix-mode ratio of 0.33 (c) and MMB tests at a mix-mode ratio of 0.67 (d).

A plateau of the SERR-crack length curves was not clearly presented for all loading modes, as shown in FigureFigure ***3***. This phenomenon indicates either the crack propagation of such laminated-pultruded plates is relatively less stable in general or suggests a redesign of specimen dimensions to allow sufficient crack growth.

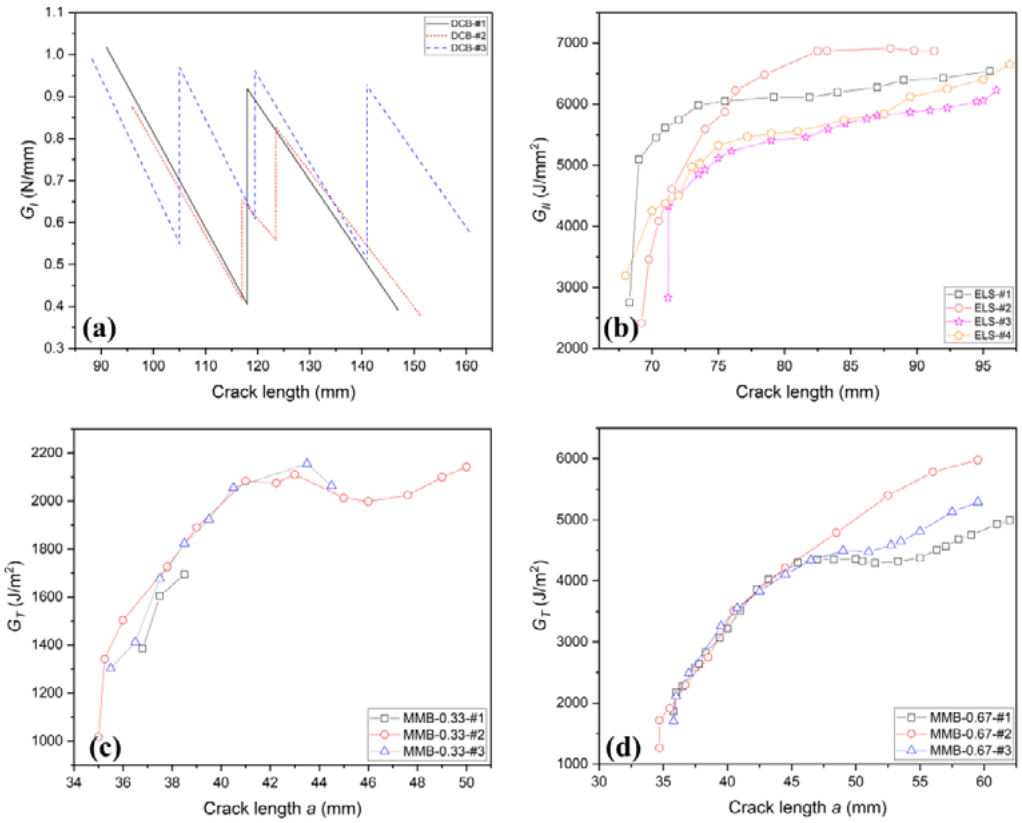

Figure 3. R-curves obtained from DCB tests (a), ELS tests (b), MMB tests at a mix-mode ratio of 0.33 (c) and MMB tests at a mix-mode ratio of 0.67 (d).

To establish the mixed mode I/II failure envelope, both power law and Benzeggagh-Kenane (B-K) law were selected. In the present study, the crack initiation toughness was considered for fitting the failure envelope while the crack propagation toughness could not be determined as no clear plateau of the SERR - crack length curves can be recognized from the DCB, ELS and MMB tests. The crack initiation was identified visually, rather than using the criteria based on the change of compliance of force-displacement curves which could produce over-conservative measurements. Although the determination of crack initiation using the visual observation is highly affected by the image resolution and may create manual deviations, it is less conservative. As shown in Figure Figure ***4***, a high coefficient of determination (R^2) is presented whether using the power law or B-K law. Among the three different fits by applying the power law, the one with fitting parameters equal to 1.0 (Fitted 3 in Figure Figure ***4*** (a)) indicates the possibility of a linear relation between the mixed mode I/II fracture toughness components.

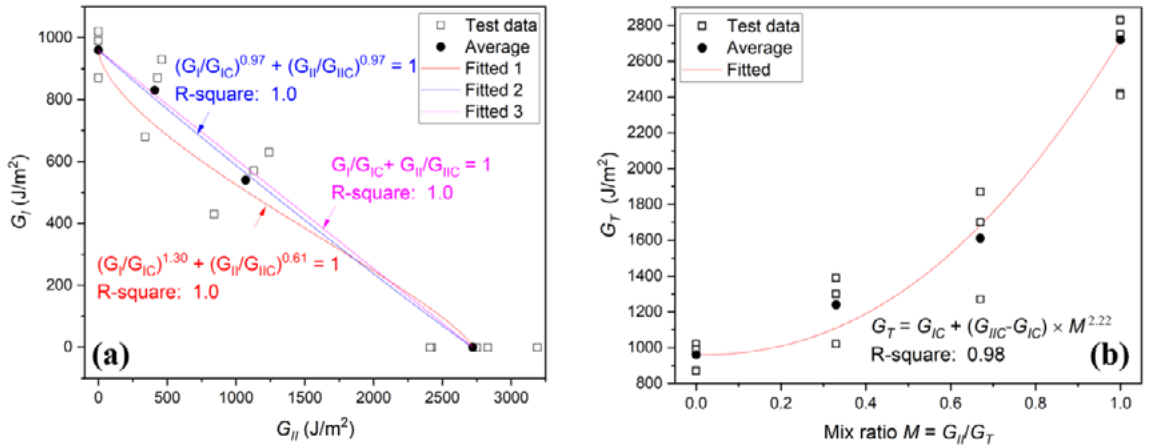

Figure 4. Mixed mode I/II failure envelope based on power law (a) and B-K law (b).

By following specimen design and test configurations introduced in the test standards [6,7,8] , the pure mode I mode I, pure mode II and mixed mode I/II interlaminar fracture behaviour of laminated pultruded composite plates can be obtained properly. However, considering the specimen thickness in the present work is close to the recommend values, whether these test standards are applicable for very thick laminated pultruded composite plates should be investigated further.

4. Conclusions

The interlaminar fracture behaviours of laminated pultruded CFRP plates was characterized at four mode mix ratios by conducting DCB, ELS and MMB tests. Then both power and B-K laws were selected to create the mixed mode I/II failure envelope. The main conclusions are listed hereafter:

1) Mode I dominant fracture tests presented frequent sudden drop of force accompanying unstable or fast crack propagation. As for mode II dominant fracture tests, the post-peak section of force-displacement curves were smoother along with stable and slow crack propagation.
2) Both the power law and B-K law are capable to describe the mixed mode I/II failure envelope. A linear relation between the mode I SERR component and the mode II SERR component may exist for such plates according to the fits using the power law.
3) The existing test standards are applicable for such laminated pultruded CFRP plates with a thickness slightly over the recommend limit. However, more investigations should be continued to verify their capabilities for very thick laminated pultruded composite plates.

Acknowledgments

The authors would like to acknowledge Dr. Jaykarna Bhangale for help in manufacturing the specimens. The research was funded by the European Union under GA No. 101091409 (D-STANDART). Abstract
The present work aims at studying the influence of different thermal stress conditions on the fracture behavior of PolyEther Ether Ketone-reinforced carbon/glass fiber hybrid laminates (CG/PEEK), as a function of heating temperature and fire exposure time. Compact Tensile (CT) specimens are exposed to isothermal (from 350°C to 550°C in a high temperature furnace) and kerosene flame (characterized by a heat flux of 116 kW/m^2 and a temperature of 1150°C) exposure conditions. Tensile tests are then conducted to assess the mode I translaminar fracture toughness at room temperature. Crack propagation is measured during mechanical loading using a Digital Image Correlation (DIC) device combined with a binarization algorithm. Then, the G-R curves have been obtained from the compliance method. In the isothermal case, the residual mechanical properties degrade with increasing temperature, particularly once thermal decomposition is about to start, due to the formation of porosities and extensive delamination. Under the flame exposure, the microscopic and tomographic observations reveal thermally and mechanically induced damages with a heterogeneous distribution due to temperature gradients. Depending on the pyrolysis degree of each ply, the structural capacities of the plies gradually deteriorate from the exposed to the opposed side, resulting in a lower strain energy release rate and larger secondary cracks.

1. Introduction

Along with the development of manufacturing techniques and certification issues, there has been a growing demand to use high performance thermoplastic-based (TP) composites in aeronautics field over the last fifteen years [1]. However, regarding the flammability of composites and stringent fire safety regulations, the wide use of most TPs is limited by their mechanical properties under severe heat exposure with different environmental conditions [2]. After exposure to elevated temperatures up to the polymer matrix decomposition, it is a critical safety issue to determine the residual mechanical properties since the loss in creep resistance could cause the ultimately failure of composite structures [3]. Compared to isothermal conditions, the presence of high temperature gradients (resulting from a fire event) through the thickness could induce different physical and chemical transformations [4].

Compact Tension (CT) specimens are typically used to estimate the translaminar fracture toughness of laminates, which plays a fundamental role in the damage tolerance of composite structures [5]. To date, most of the studies dealing with translaminar mode I failure are based on unidirectional-ply (UD)

thermosetting (TS) matrix laminates. However, there are far less studies dealing with the fracture toughness of TP-based composites under critical service conditions met in aeronautics [5]. The question is still open when it comes to the assessment of the residual fracture behavior of severely thermally degraded woven-ply composites [8]. Indeed, it is therefore essential to understand the thermomechanical response and design properties of TP-based woven-ply composite subjected to severe temperature environments (for temperatures higher than melting and pyrolysis temperatures).

Thus, the present work was aimed at investigating the thermal decomposition and the residual translaminar fracture behavior of CG/PEEK laminates under different temperature conditions, including isothermal (from matrix melting temperature 350°C to pyrolysis temperature 550°C) and kerosene flame exposure (116 kW/m^2 and 1150°C) conditions. This involves the experimental measurement of the critical energy release rate at initiation and the fracture energy during propagation using CT specimens. The post-mortem examination by means of microscopic observations and micro-CT analyses makes it possible to understand the influence of severe thermal aggression on both the thermal degradation mechanisms and the translaminar fracture of TP based laminates.

2. Materials and experimental set-up

2.1. Materials and specimens

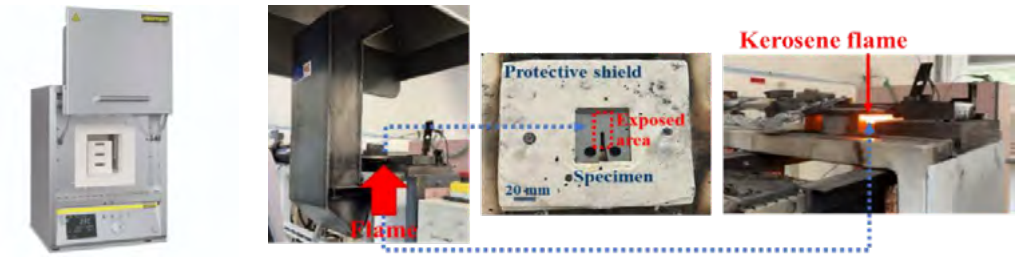
The laminates used in this study is CG/PEEK, which consist of a PolyEther Ether Ketone (PEEK) thermoplastic matrix reinforced with a continuous carbon fiber fabric, and the two outer plies of glass fabric are used to provide corrosion and electrical protection. The Compact Tension (CT) specimens (in accordance with ASTM test standard E399-12 [9]) have 16 plies (average thickness is about 4.5 mm) with a quasi-isotropic layup $[(0/90)_G,(0/90),(\pm45),(0/90),(\pm45),(0/90),(\pm45),(0/90)]_S$. The characteristic temperatures of PEEK matrix are given in Table 1.

Table 1. Characteristic temperatures of CG/PEEK laminates [2].

$T_{\text{glass transition}}$ (°C)	T_{melting} (°C)	$T_{\text{decomposition}}$ (°C)
143	350	583

2.2. Isothermal and fire exposure conditions

In this study, a high temperature furnace and kerosene burner bench [4] are used to provide isothermal and fire exposure, respectively, to reach temperature levels resulting in the phase transitions of the PEEK matrix (Figure 1). The specimens were placed on a grid platform in the furnace. Considering the characteristic temperature, the tests were carried out for 900 s at 350-450-500-550°C. In the case $T > T_d$, as the high temperature furnace has a relatively enclosed heating environment, it may lead to the ignition of the pyrolysis gases and damage the furnace. In agreement with certification requirements, a maximum 900 s exposure to a 1150°C flame was chosen to comply with fire exposure conditions. A protective shield is used to limit the thermal decomposition area of the specimen (Figure 1.b). Three CT specimens have been tested in each configuration: after a 300-600-900 s kerosene flame exposure.



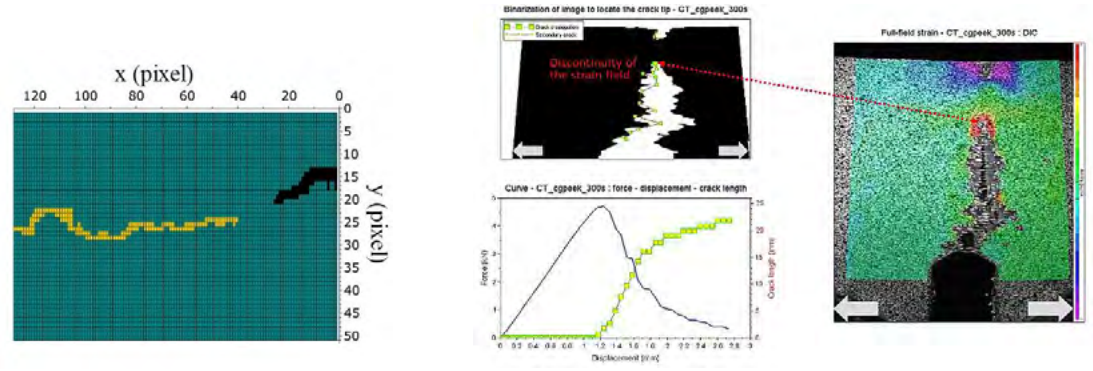


Figure 1. Experimental heating set-up: (a) High temperature furnace – (b) Kerosene burner bench [3].

2.3. Mechanical characterization of residual properties and fractographic analysis

After thermal degradation under isothermal and fire exposure conditions, mechanical tests were further performed in displacement-controlled mode (1 mm/min) at Room Temperature (RT) by means of a MTS 810 uniaxial servo-hydraulic tensile machine consisting of a 100 kN capacity load cell. The specimens are held in position by a standardized device in accordance with ASTM-399 [9], which is maintained by the hydraulic grips of the machine and transfers the mechanical load via pins inserted in the holes of the specimens [7]. Fractographic analyses have been carried out by means of microscopic (numerical optical microscope Keyence VHX-5000) and tomographic (RX Solutions EasyTOM-150) observations to visualize, classify and quantify the thermally and mechanically damaged areas.

2.4. Crack growth measurement and data reduction method

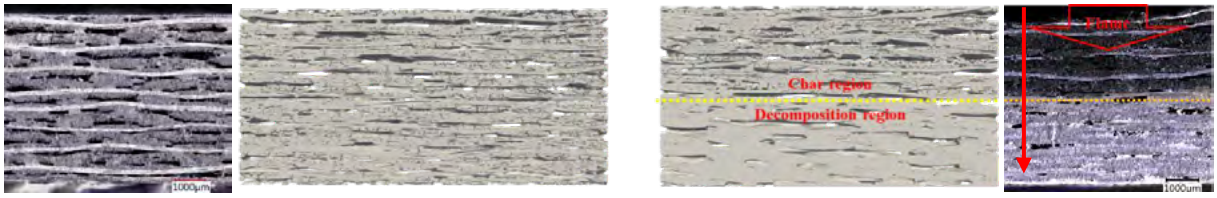
A DIC non-periodic pattern is painted on each CT specimen back surface, and VIC-Snap software is used to process the images correlation. Using an algorithm implemented in the Scilab code [8], the crack tip is located via the discontinuity of the strain field resulting from the crack propagation (Figure 2.a). The evolution of crack length when the load gradually decreases during propagation is then determined from the crack tip position in each pattern, as shown in Figure 2.b. The spatial resolution of the crack length is defined by the size of the subsets used in the DIC method [7].

(a) **(b)**

Figure 2. Binarization algorithm to locate the crack tip during mechanical loading [8]: (a) Algorithm illustration – (b) Example of specimen after 300 s flame exposure.

The compliance method is used to calculate the evolution of the strain energy release rate from the force-displacement curve at the initiation and propagation of the crack, and then to determine the evolution of compliance $C = \delta/P$, where δ is the displacement, P the force and e the thickness of CT specimen:

$$G_{\mathrm{I_c}} = \frac{P_c^2}{2e}\left(\frac{\mathrm{d}C}{\mathrm{d}a}\right) \tag{1}$$

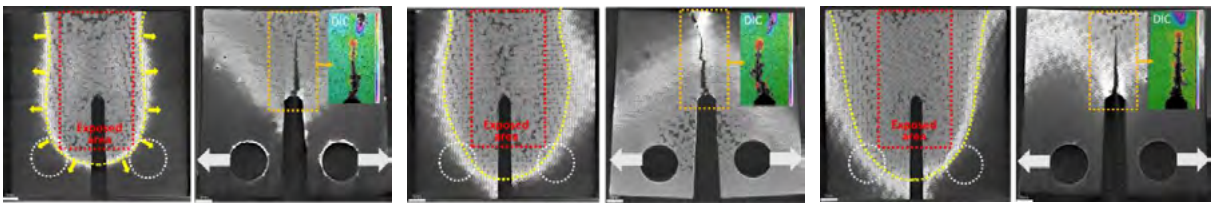


Classically a cubic function of the compliance versus the crack length has been fitted on the whole test for each experiment [10], then an analytical derivative was used to compute the fracture toughness value.

3. Results and discussion

3.1. Thermally induced degradation and fire behavior

As temperature increases, the PEEK matrix is gradually degraded and undergoes a gradual transformation from matrix melting, cracking and eventually into pyrolysis gases. The degradation of matrix caused by the increasing temperature results in the fibers becoming visible and further leads to the production of heat, smoke, and volatiles. When the temperature reaches T_d, the heat flux causes

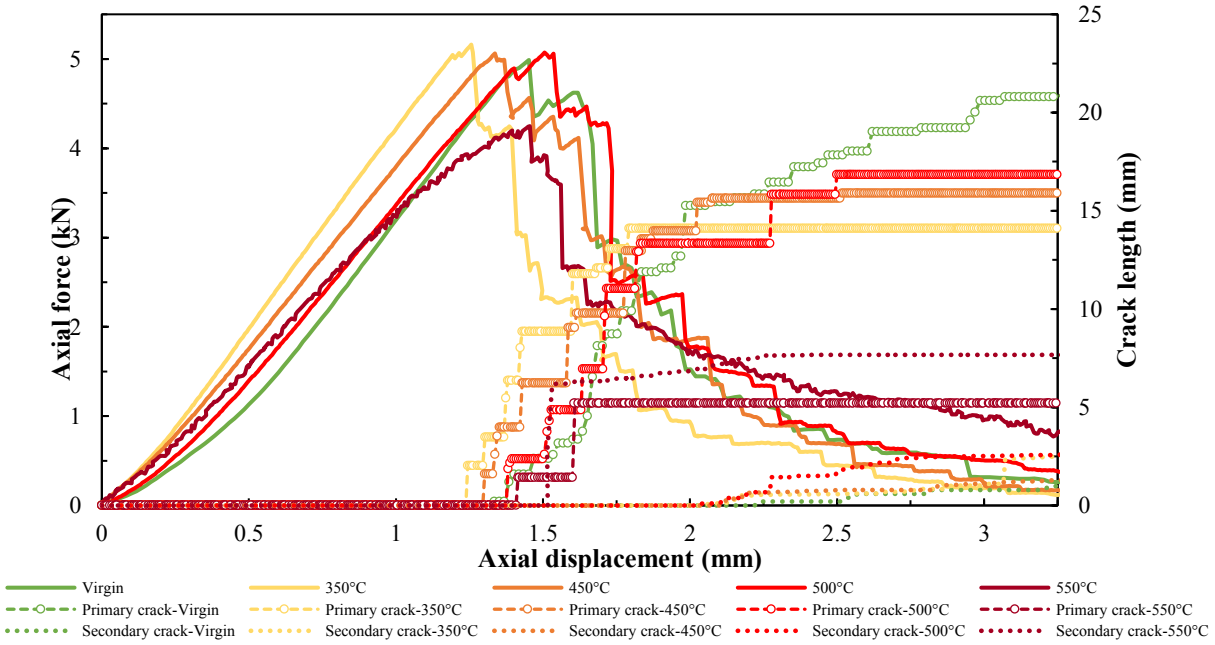


chemical bonds to break, which results in the thermal decomposition, leading to the formation of porosities and delamination, as shown in Figure 3.a. Compared to the isothermal conditions, the through-thickness and in-plane temperature gradients cause heterogeneous damages modes. Following the through-thickness direction, the laminates after flame exposure could be divided into two well-defined areas: the thermal degraded area and the relatively preserved area, as shown in Figure 3.b. In the first region of char, which is a carbon residue [1], the polymer content is negligible since the matrix has decomposed, then the matrix in the second region is partially decomposed (char and pyrolysis gases). Below it, the laminates observations show delamination cracks between the plies and small matrix cracks within the plies because of the combination of pressure build-up and matrix softening.

(a) (b)

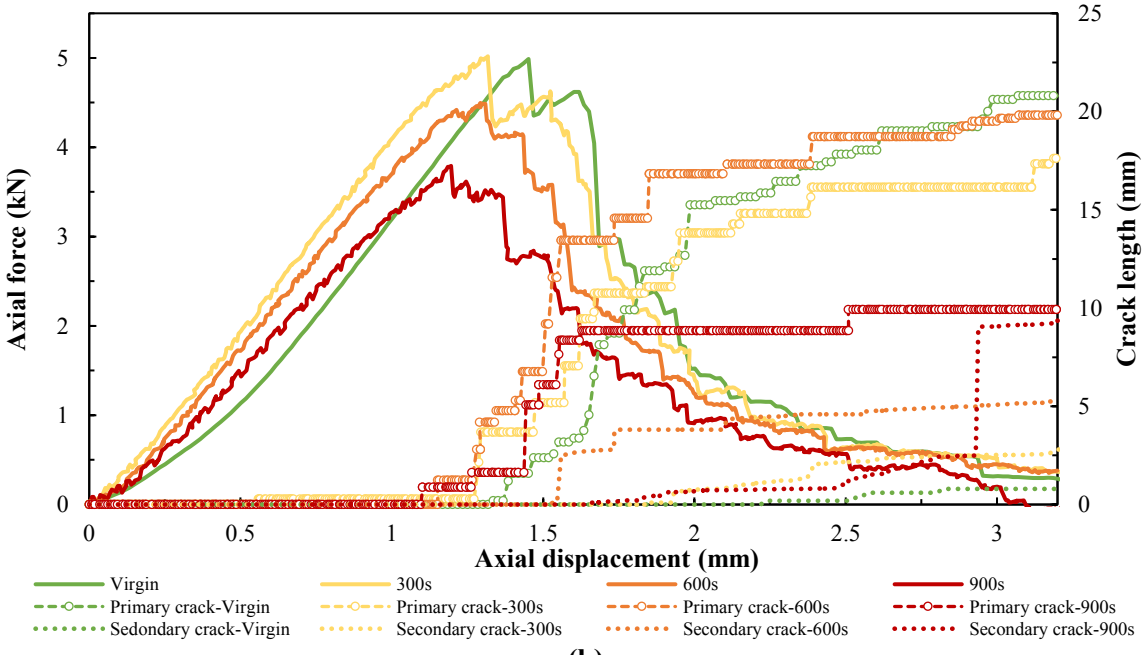
Figure 3. Microscopic and tomographic observations of CG/PEEK laminates subjected to different conditions: (a) Isothermal heating for 900 s at 550°C – (b) Kerosene flame exposure for 500 s.

In addition, micro-CT observations of post exposure specimens (before and after tensile test) allow the thermal aggression and the crack propagation to be visualized in each ply. As shown in Figure 4, the exposed surface of laminates reveals that the magnitude of temperature and thermally-induced degradation gradients significantly depends on the flame exposure time. As expected, the degraded area becomes larger as the exposure times increases. Under one-sided kerosene flame exposure up to 900s, the carbonaceous char formed along with the matrix melting and pyrolysis on the exposed surface, whereas the back-surface experiences little matrix melting. The decomposition of PEEK matrix further results in both extensive delamination and ablation of Glass/PEEK outer ply after flame exposure. These thermal degradation within the laminates are expected to have a further influence on their post-fire mechanical performance.



(a) (b) (c)

Figure 4. Tomographic observations of post fire CT specimens: (a) 300 s – (b) 600 s – (c) 900 s.



3.2. Residual fracture behavior

The propagation of the macroscopic crack is identified from the jumps observed on the force-displacement curves [8]. From the curves shown in Figure 5, it is observed that CG/PEEK quasi-isotropic laminates have similar macroscopic responses with a quasi-linear force-displacement curve before crack propagation. In the isothermal case, when the heating temperature below T_d, the overall response is similar to the one of as received specimens (referred to as virgin specimens unexposed to thermal aggression) with almost the same level of load before the first fiber breakage. At the end of the CT test, the primary crack (tensile crack) length increases as the environment temperature increases. Compared to virgin specimens, the final secondary crack length (compressive crack) grows larger, as the result of PEEK matrix melting and re-solidification.

Once the temperature reaches $T_{d,}$ the decomposition process of PEEK matrix has a major influence on the structural capabilities and contributes to a significant decrease in the residual properties of laminates compared to previous cases. The macroscopic observations of damaged areas suggest that an extensive delamination occurs during CT testing as well. The mechanical loading causes a significant increase in the secondary crack length, since the load bearing capabilities of the laminate is significantly affected, with a volume porosity ratio (defined by the percentage of porosities of matrix over the whole specimen) around 34% (estimated from tomographic analyses).

(a)

(b)

Figure 5. Mechanical responses and changes in the crack length for different testing conditions: (a) Isothermal conditions (different temperatures) – (b) Fire conditions (different exposure time).

When subjected to a one-sided kerosene flame exposure, longer fire exposure times lead to (i) lower initiation loads at failure and (ii) larger cracks with respect to the ones observed in as received specimens (Figure 5). The microstructure of charred layers (Figure 3.b) is characterized by a high void content and a small amount of solid char. Consequently, the mechanical properties of the charred layers are rather low for different loading conditions due to degraded load transfer capabilities. In the case of a 300 s exposure, the influence of thermal aggression remains moderate, despite the early appearance of fracture. After a 600 s fire exposure, the initiation of compressive failure by plastic buckling (Figure 6.b) on the edge opposite the notch was observed, which is mainly attributed to the decomposition of the matrix and the formation of porosities within the laminates. With a prolonged exposure time up to 900 s, the secondary crack tends to play a more important role than the one under isothermal conditions.

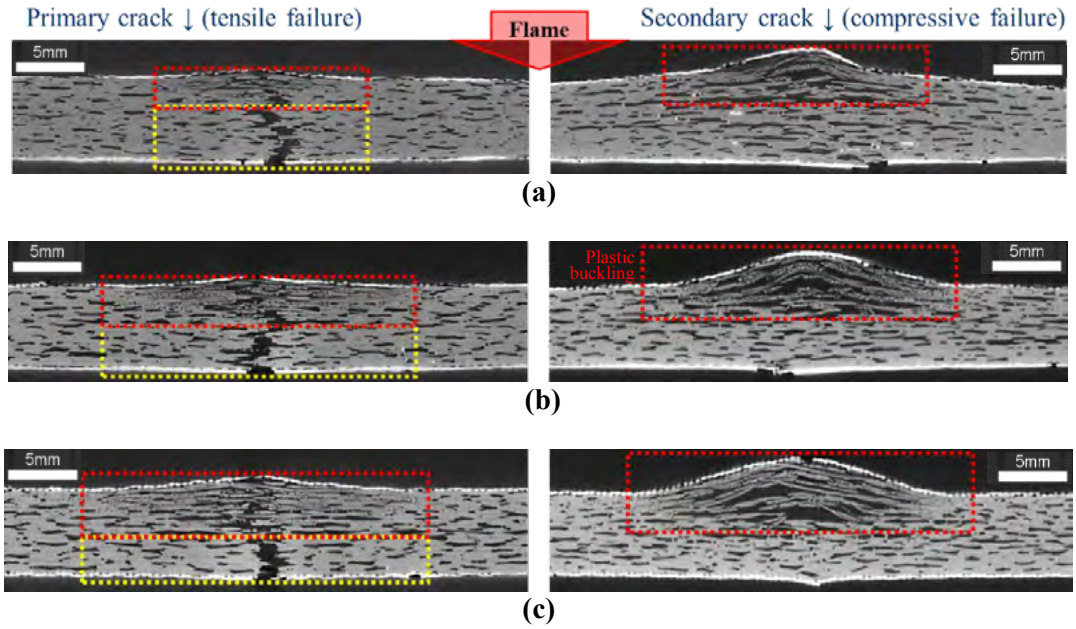


Figure 6. Tomographic observations of post-fire CT specimens' failure mechanisms as a function of flame exposure time: (a) 300 s – (b) 600 s – (c) 900 s.

Post-mortem damages are also analyzed by means of micro-CT observations (Figure 6). The mode I failure of quasi-isotropic laminates primarily results from the translaminar failure of the fibers in tension. The cross sections of primary and secondary crack clearly reveal that the two regions (char and decomposition region) with different thermally-induced damages do not contribute the same way to take up the tensile loading from mechanical behavior standpoint. Depending on the thermal decomposition of each ply (function of the exposure time), the bearing capabilities of the plies is gradually degraded along with delamination growth in the char region due to compressive failure. Thus, it is expected that the residual mechanical properties may reflect on the thermal degradation degree within different regions of the laminates, previously exposed to a kerosene flame for different exposure times.

3.3. Estimation of the strain energy release rate

Within the framework of Linear Elastic Fracture Mechanic (LEFM), the determination of R-curves is the key point to quantify fracture in terms of energy required to grow a crack in quasi-isotropic laminates [7]. The resistance of a laminate to translaminar crack initiation and propagation are characterized by a resistance curve, called the R-curve. The first point of the curve can be defined as the critical strain energy release rate related to crack initiation (G_{Ic}). Here, the compliance method is used to estimate the critical strain energy release rate (by Eq. 1) during the crack propagation [10], as shown in Figure 7.

Under isothermal conditions, when the temperature is lower than T_d (350°C), PEEK matrix melting and re-solidification seem to foster the intrinsic toughness [7] at the crack tip, whereas a decreasing evolution of the fracture energy is observed during crack propagation, with lower values compared to the virgin case. For higher temperatures (450°C and 500°C), the overall evolution of R-curves is similar: the initial value decreases with the increasing environment temperature, and tends to slightly increase during the crack propagation. Once temperature reaches T_d, the formation of porosities and delamination (Figure 3.a) induced by PEEK matrix pyrolysis has a major influence on the structural integrity of laminates, resulting in different R-curves compared with the previous cases. Secondary cracks appearing almost at the same time as the primary ones, the strain energy release rate at the crack initiation is more significant in this case. The curve tends to decrease dramatically once these two cracks propagate in the opposite direction, with much shorter primary cracks induced by the severe delamination.

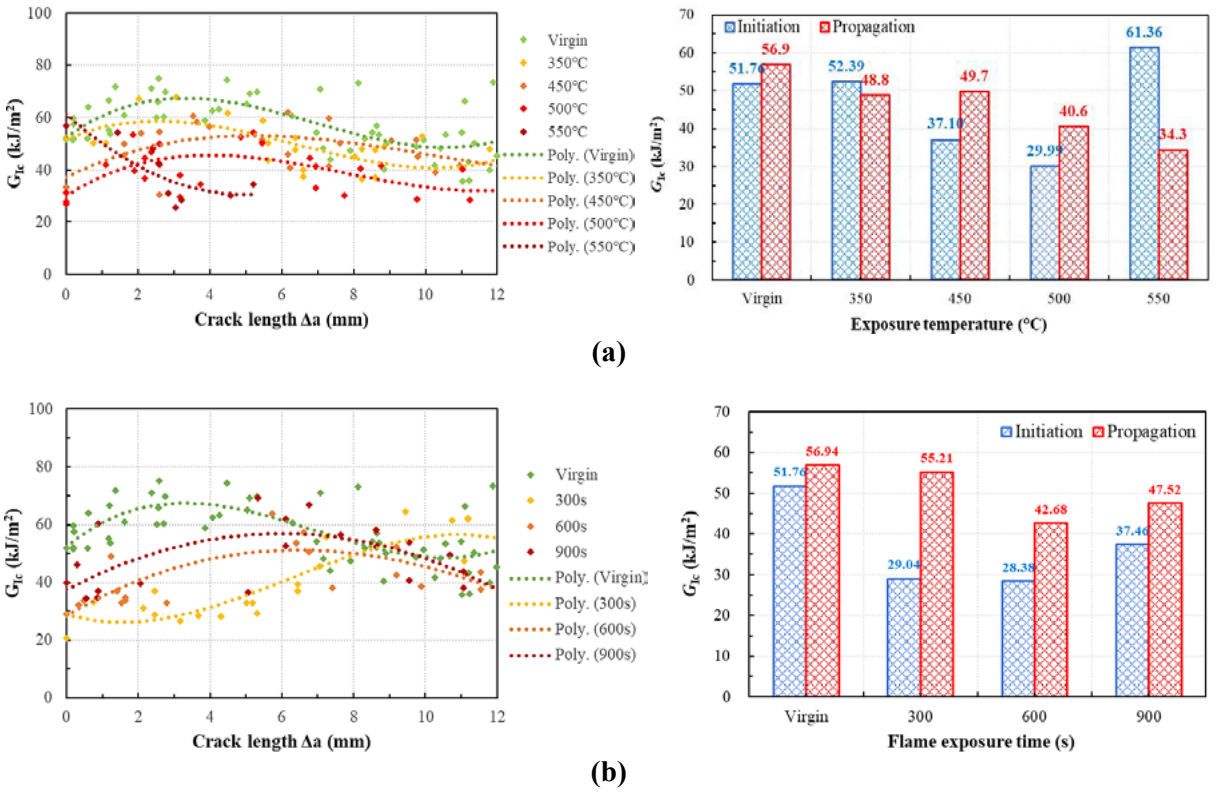

Figure 7. R-curves obtained with the compliance method from CT specimen tests: (a) Isothermal conditions (different exposure temperature) – (b) Fire conditions (different exposure time).

Regarding the influence of different flame exposure times, the structural capacities decrease as flame exposure time increases. In the 300 s and 600 s exposure cases, the same level of initial value is observed with respect to the case of 500°C, as the decomposition region has a porosity ratio close to the isothermal environment. During crack propagation, the R-curves tend to increase and then decrease slightly, which could be explained by the early appearance of secondary fracture induced by the char region. After a 900 s exposure, the char region representing almost 2/3 of the laminates thickness, the compressive failure plays a more important role (Figure 6.c), ultimately resulting in higher strain energy release rates compared to the 600 s case. Indeed, secondary cracks contribute to the dissipation of mechanical energy during fracture, which prevents an accurate assessment of the strain energy release rate from an overall computation using force-displacement curves.

4. Conclusions

The influence of different critical temperature conditions (isothermal and kerosene flame exposure) on the thermal degradation and the residual translaminar fracture behavior of CG/PEEK laminates was studied by means of CT specimens. The evolution of the strain energy release rate associated with mode I tensile failure from force-displacement curves during crack propagation is monitored using the compliance method combined with a digital image analysis technique.

From the obtained results, the following conclusions can be drawn: (i) the thermo-mechanical behavior clearly depends on the temperature conditions, the presence of a temperature gradient (fire exposure case) causes heterogeneous degradation mechanisms, compared to the isothermal case; (ii) under isothermal conditions, with the increasing temperature, the secondary crack becomes more important due to PEEK matrix melting and cracking, and the structural integrity of the laminate is significantly affected by the decomposition of PEEK matrix once temperature reaches T_d; (iii) under kerosene flame exposure, the bearing capabilities of the plies are gradually degraded as a function of the exposure time, and the two regions (char and decomposition region) characterized by different thermally-induced damages do not take up the mechanical loading the same way; (iv) regarding the critical strain energy release rate, the initial value decreases with more severe temperature conditions. The translaminar fracture toughness tends to slightly increase during crack propagation, whereas the structural capabilities of CG/PEEK laminates decrease with the increasing flame exposure time, as secondary cracks within the char region may prevent the compliance method to be applied.

Ultimately, the correlation between post-fire residual mechanical properties and thermally degraded regions needs to be further investigated. In a forthcoming work, an analytical model based on the porosity content ratio of each region will be implemented to better account for the coupling between thermomechanical behavior and different critical service conditions.

Keywords: Conductive nanocomposite, strain sensor, metasurface, spray deposition

Abstract
Chipless, passive and wireless sensors are one of the most important expected developments in wireless sensor technology for Structural Health Monitoring (SHM) because of their compactness and the absence of a battery or chip for the sensor operation. Strain sensitive resonant antenna reflectors based on the strain sensing metasurfaces (i.e. frequency-selective surfaces) are employed for this application. The variation of the spectral response of the metasurface with external perturbation results in an intrinsically effective sensing mechanism. Highly electrically conductive nanocomposites are required for this application. In this work, nanocomposites at high graphite nanoplatelets content (70 wt%) are fabricated by a spray deposition process on a polyetherimide (PEI) support. Experimental tests have been conducted to investigate the electromagnetic response of the material in the X band (8-12 GHz), showing an electrical conductivity of about 2.0 x 10^4 S/m. The design of the metasurface geometry and numerical simulations have been introduced that account for the electromagnetic properties of the material in the non-naturally frequency selectivity response under the mechanical strain in the X band.

1. Introduction

Chipless passive wireless sensors (CLPWs) are among the most important developments in wireless sensor technology. Their compactness combined with the unnecessity of battery or chip for their operation, make these sensors interesting in various fields, medical diagnostics, security, predictive maintenance, and environmental safety [1]–[3]. The recent progress in the materials field goes towards this development. Specifically, metamaterials and metasurfaces are very well-suited for telemetric sensing applications. They are collections of far-subwavelength resonating structures, typically aligned in a regular crystal lattice designed to interact with the free-space propagating electromagnetic waves. These resonators are designed to interact with the free-space propagating electromagnetic waves, rather than being excited directly by a waveguide or transmission line. Due to external perturbations, the spectral resonances can change, resulting in an intrinsic effective sensing mechanism.
Because the metamaterial properties typically depend on the shape, size, orientation, and proximity of the conducting elements, techniques that alter the geometry of the conducting elements can provide an excellent means for tuning or switching the metamaterial response [4]. Owing to their versatility, metasurfaces are currently proposed for several applications. In the recent literature, sensors for strain detection are found [5]–[8]. They are mostly based on shifting of frequency selective surfaces and are characterized by varied sizes and sensitivity. However, reversibility over cycling deformation is not

fully addressed in these preliminary works. For real applications strain sensing sensors based on metasurfaces would require elevated levels of stretchability other than high stretchability and should retain functionality even when being mechanically deformed.
The fabrication of metasurfaces can be complex especially when the periodic structure is not a simple pin or patch. Methods like drilling and milling are limited to simple structures [9]. Additive Manufacturing (AM) is a promising candidate to implement metasurfaces. The design flexibility combined with the possibility of employing a wide variety of materials makes this technique suitable for the rapid prototyping of strain sensors. 3D printed nanocomposite with metal nanofillers, such as silver nanowires (AgNWs) and nanoplatelets (AgNPs) are reported to exhibit the highest electrical conductivity of 10^5 S/m [10], [11], followed by carbon nanotubes (CNTs) (10^4 S/m) [12], [13] and graphene nanoplatelets (GNPs) (10^3-10^4 S/m) [14], [15]. However, this technique limits the electrical conductivity of nanocomposites due to the low content of conductive nanoparticles that can be added to the insulating polymer and produce samples with fraction-of-a-millimeter thicknesses. In this work, a spray deposition printing process is employed to produce thin GNPs/Epoxy nanocomposite coating with high electrical conductivity to be employed in the modelling and fabrication of strain-sensing metasurfaces.

2. Modeling sensor

The physical principle of the sensing mechanism is given by the shift of resonance frequencies due to strain. Design-level simulation provides metasurface geometries optimized for the specific mechanical strain detection, at the frequencies of interest, 10 GHz (X band). The proposed metasurface geometry can decouple surface strain components. Full-wave electromagnetic modelling is employed for optimization.

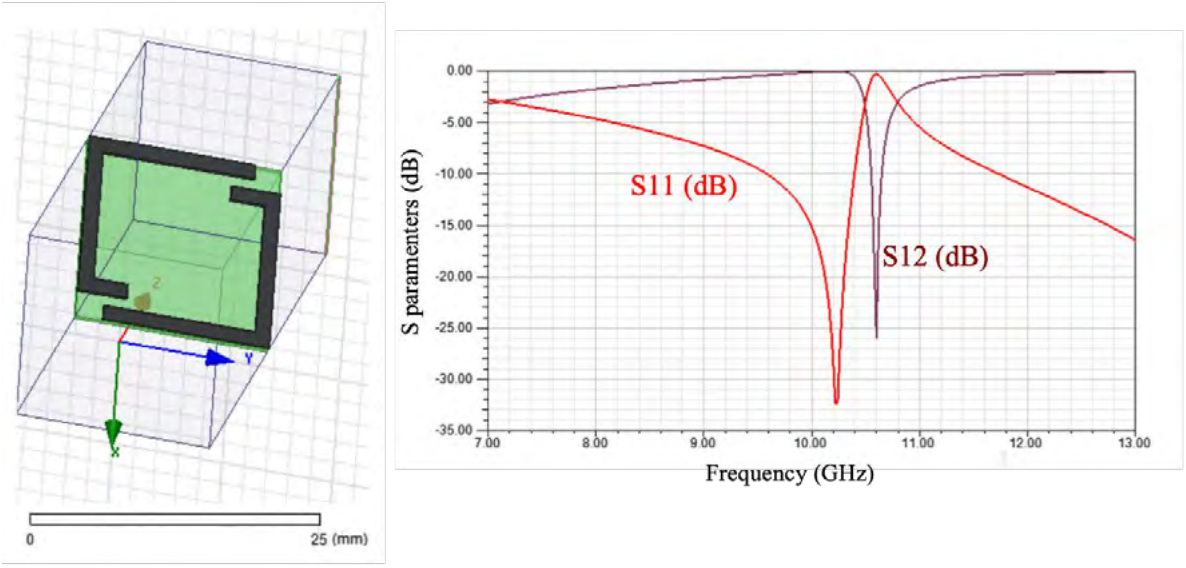

Figure 1. One quarter of metacell for the X band

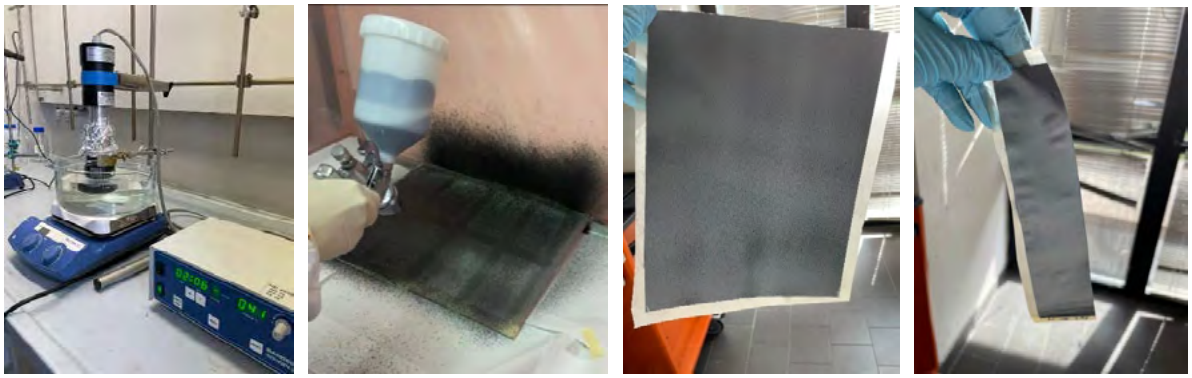
The size of the unit cell, which is spatially repeated to form a metasurface, directly impacts the final size of the device. Figure 1shows an example of unit cell (only one quarter of metacell is shown for symmetry: metal and substrate are respectively 0.4 mm and 0.5 mm thick and have respectively conductivity 4*10^5 and permittivity 2.5) for the operation of the X band.
It is possible to verify, but it is not reported here for brevity, that a strain along x and y directions produces frequency shift of opposite signs. The above considerations assume metallic behavior of the nano-composite material used to define the resonant rings. It is noted that such assumption is well verified, at the considered frequency, for material conductivity exceeding 10^5 S/m. For a strain-detection able to simultaneously disentangle the x- and y-directed strain, the same principle physical mechanism as above can be used. A proper unit cell design allows adjusting their size to let them resonate at the desired frequency band and vice versa. Increasing the size of the unit cell design allows more than one



resonance to come into play, and places more than one zero and/or pole of the transfer function (reflection or transmission) close to each other, to achieve a specific frequency selectivity.

3. Materials production

Graphite nanoplatelets (GNP)/epoxy nanocomposite films have been fabricated with a top-down approach based on a spray deposition process. The GNPs used in this work have a large aspect ratio of 2143 with a lateral size of 30 μm and thickness of 14 nm (supplied by NANESA S.r.l). A three-component resin made of Bisphenol A diglycidyl ether (DGEBA) epoxy resin (ARALDITE® LY 3508), tetrahydro-methyl phthalic anhydride (THMPA) curing agent (ARADUR® 917-1) and 2,4,6-tris (dimethyl aminomethyl) phenol as the catalyst (Accelerator 960-1) was employed in this study, provided by Huntsman corporation. An epoxy mixture with a stoichiometric ratio between epoxy and acyls equal to 0.6 was employed. The substrate used is a polyetherimide film of 100 μm thickness (PEI, Toray Cetex TC1000).

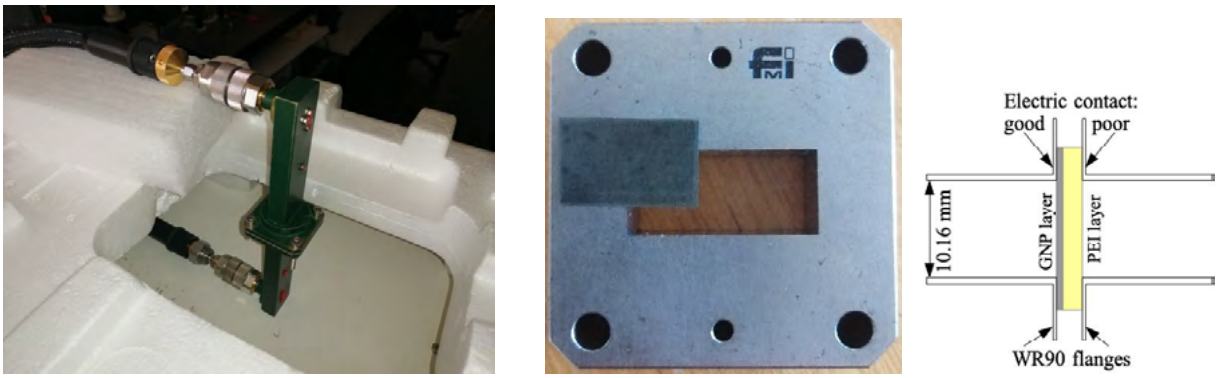
The GNPs/Epoxy nanocomposite coating was deposited on the PEI support using a spray deposition process. Firstly, a dilute dispersion of GNPs in a volatile solvent (acetone) is prepared using a mass volume ratio of 1.4%. The nanoplatelets dispersion is performed using a high-power tip sonicator. Once the dispersion is homogeneous, the epoxy resin is added and further sonicated (Figure 2a). The obtained solution is deposited on the PEI film utilizing an airbrush mounted (Figure 2b). The deposited material is dried all night at room temperature to let the solvent evaporate (Figure 2c). Subsequently, the material is compacted with a calender to promote particle orientation and compactness, obtaining a coating with a metal finish (Figure 2d). Finally, the sample is cured according to the resin polymerization process for 1h30min at 120°C and post-cured for 1h at 140°C.

The thickness (t) of the samples is measured using a digital micrometer by subtracting the PEI substrate thickness of 100 μm. An average value of 13±3 μm is calculated based on several measure points over the area of the sample is considered.

(a) (b) (c) (d)

Figure 2 Steps of the fabrication process of GNPs/Epoxy nanocomposite supported on PEI support. (a) Dispersion of nanoplatelets by ultrasonication. (b) Spray deposition process by using an airbrush. Deposition on PEI substrate (c) prior calendering and (d) post calendering

The sheet resistance (R_{sheet}, Ω/sq) of the coating has been evaluated with a 4-probe system (Napson, Resistest-8A). An average value was obtained considering 5 measure points. The static electrical resistivity (ρ, Ωm) and conductivity (σ, S/m) are computed considering the thickness (t) of the sample, as follows:

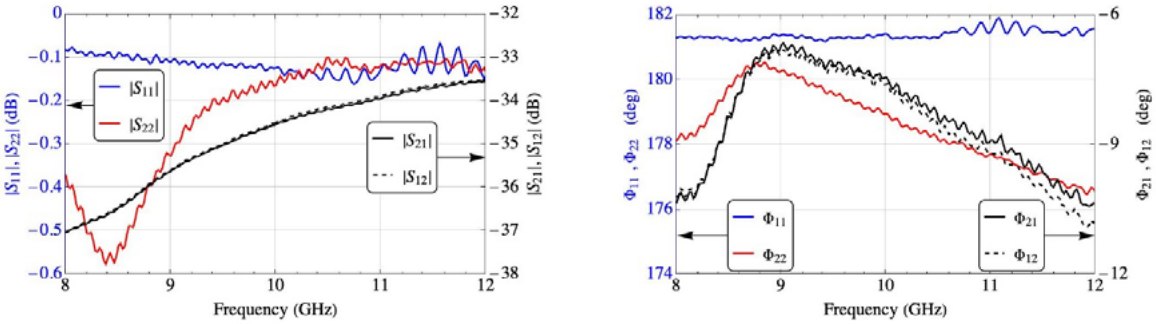


$$\rho = R_{sheet} \cdot t$$
$$\sigma = \frac{1}{\rho} \quad (1)$$

The conductivity (σ, S/m) as estimated by sheet resistance measurements is 2.05 x 10^4 S/m.

4. Electromagnetic Testing

The electromagnetic characterization of the GNPs/Epoxy nanocomposite in the X band (8-12 GHz) has been performed by putting a thin rectangular sample of the material in the cross section of a WR90 rectangular waveguide (22.86x10.16 mm^2) as shown in Figure 3. A Vector Network Analyzer (VNA) has been used to measure the scattering parameters of the sample. TLR calibration technique has been applied to define the reference planes for the scattering parameters at the connecting flanges in the center of Figure 3.



Hence, the scattering parameters S_{ij} shown in Figure 4 are exactly those measured to the left (port 1 of VNA) and to the right of the sample (port 2 of the VNA), in the empty waveguide.

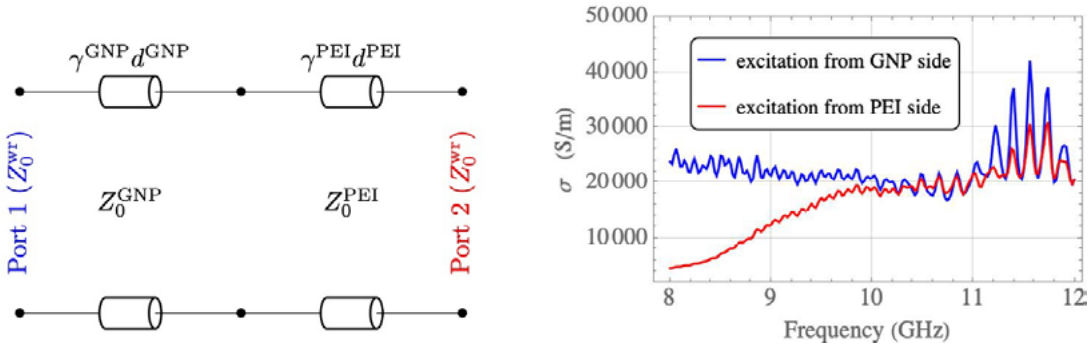
(a) (b) (c)

Figure 3 (a) WR90 rectangular waveguides with the rectangular sample filling the cross section between the connecting flanges in the center of the image. (b) detail of the inner of the WR90 waveguide and a reduced piece of GNPs/Epoxy nanocomposite filling the cross section. (c) detail of the contact between the sample and the waveguide flanges (not in scale).

Amplitudes $|S_{11}|$ and $|S_{22}|$ and phases Φ_{11} Φ_{22} of the reflection coefficients at the two ports are slightly different because the sample is made by two different lossy material layers (the GNPs/Epoxy nanocomposite, d^{GNP}=13 µm thick, and the PEI support, d^{PEI}=100 µm thick) and the effect of the excitation from the two ports of the sample produce different reflections seen at the two ports. The measured amplitudes $|S_{12}|$, $|S_{21}|$ and phases Φ_{12}, Φ_{21} ensure a particularly good reciprocity of the composite medium both amplitude and phase. As a preliminary analysis, the amplitudes of the reflection coefficients are very close to 0 dB (less than –0.2 dB for $|S_{11}|$ and –0.6 dB for $|S_{22}|$) and their phases are close to 180° and these values imply that the composite material has high reflection property, similarly to an ideal conductor that is characterized by total reflection (0 dB amplitude and 180° phase). The differences between S_{11} and S_{22} in the lower part of the band are related to the fact that the wave impinging from the PEI port can flow also in the upper part of the metallic flange of the WR90 waveguide. In fact, the sample placed between the flanges is slightly larger than the cross section to ensure a flat placement between them when they are brought together and screwed. Unfortunately, this kind of placement and overlapping with the flange in the PEI port does not produce perfect electric contact between the PEI part of the sample (dielectric) and port that can cause the difference between S_{11} and S_{22}. On the contrary, electric contact between port 1 and sample is better because the GNP part of the sample is conductive.

(a) (b)

Figure 4 (a) Amplitude and (b) phase of the scattering parameters of the rectangular sample of the GNPs/Epoxy nanocomposite supported on PEI support**.**



4.1. Electromagnetic properties estimation

The estimation of the conductivity of the GNPs/Epoxy nanocomposite can be obtained by the equivalent circuit shown in Figure 5(a). In fact, the two materials (GNPs/Epoxy nanocomposite and PEI) can be seen as two transmission lines characterized their modal impedance based on their conductivity σ and dielectric permittivity $\varepsilon=\varepsilon_0\varepsilon_r$ where ε_0 is the vacuum permittivity and ε_r the relative permittivity:

$$Z_0 = \frac{j\omega\mu}{\gamma} \tag{2}$$

$$\gamma = \sqrt{j\omega\mu_0(\sigma + j\omega\varepsilon_0\varepsilon_r) + \left(\frac{\pi}{a}\right)^2} \tag{3}$$

For the GNPs/Epoxy nanocomposite we can assume the hypothesis of good conductor which implies $\sigma \gg j\omega\varepsilon_0\varepsilon_r$. In Figure 4(a), $Z_0^{PEI}, Z_0^{GNP}, \gamma^{PEI}, \gamma^{GNP}$ refer to the modal impedance and propagation constant in the PEI or in the GNPs/Epoxy nanocomposite. Finally, Z_0^{wr} refers to the modal impedance of the empty WR90 waveguide, where the scattering parameters are measured and normalized. By the transmission line theory, we can calculate the theoretical value of the reflection coefficient seen at the two sides and by equating them to the experimental values we can extract an estimation of the conductivity of the GNPs/Epoxy nanocomposite, assuming ε_r=3.15 and $\frac{\sigma}{\omega\varepsilon_0\varepsilon_r} = 0.0013$ at 1 MHz for the PEI. The estimated values are shown in Figure 5(b) in the hypothesis of excitation from the GNP side (port 1, blue line) or the PEI side (port 2, red line).

(a) (b)

Figure 5 (a) Equivalent circuit of the GNPs/Epoxy nanocomposite supported on PEI. (b) Estimation of the conductivity of the GNPs/Epoxy nanocomposite.

The results in Figure 5(b), about the estimated conductivity of the GNPs/Epoxy nanocomposite, show a good agreement between the measurements made at the two ports of the sample. The differences in the lower part of the frequency band are related to the differences between S_{11} and S_{22}, as previously discussed.

4. Conclusions

This research serves as a significant starting step in the development of nanocomposite-based metasurfaces for structural health monitoring. The initial design of strain-sensitive resonant antenna reflectors has yielded important insights into the potential of this emerging technology to detect strain within the X-band frequency range (8-12 GHz) using chipless, passive, and wireless sensors. The modeling highlighted the importance of high conductivity for the successful operation of such metasurfaces as strain sensors.

A high electrical conductivity (approximately 20,000 S/m) was achieved using graphite nanoplatelets supported by a polyetherimide (PEI) dielectric film. The application of a spray deposition process to manufacture these nanocomposite layers proved to be an effective method for applying thin, uniformly conductive layers onto non-conductive substrates. This manufacturing technique is not only innovative but also scalable, making it suitable for widespread commercial use.

Keywords: biocomposites, phosphorous-based flame retardant, flax fiber, basalt fiber, fiber coatings

Abstract
This study presents a sustainable approach to enhance the fire resistance of natural fiber-reinforced poly(lactic acid) (PLA) composites. A bioinspired approach to functionalize the surface of flax (FF) and basalt (BF) fibers with an innovative organic-inorganic hybrid flame retardant (FR) is proposed. The fibers underwent a three-step coating method: first, ozone (O_3) pretreatment enhanced their surface reactivity by forming oxygen-containing functional groups that, in turn, enable the covalent immobilization of gallic acid (GA) units. Ultimately, inspired by the bacterial iron acquisition mechanism, iron phenylphosphonate was complexed with the phenolic groups of gallic acid units, resulting in FR-coated fibers. The coated flax and basalt fibers were used to produce PLA-based composite materials, named PLA/FF-FeP and PLA/BF-FeP, respectively. Thermogravimetric analysis (TGA) results revealed that, despite the low loading (0.1 wt% as assessed by Microwave Plasma Atomic Emission Spectroscopy - MP-AES) of the coating on the fiber surface, both composites exhibited improved thermal stability. The cone calorimetry test (CCT) highlighted an extended time to ignition (TTI), a reduced time to flame out, an 8% decrease in the peak of heat release rate (pHRR) and a 15% decrease in Fire Propagating Index (FPI) for PLA/BF-FeP. Further, the PLA/FF-FeP turned out to be smoke suppressant, showing a decrease in both total smoke release (TSR) and specific extinction area (SEA) of about 87 and, 68%, respectively.

1. Introduction

In recent years, increased awareness of environmental issues has prompted the implementation of various regulations, both locally and globally, aimed at directing industries toward reducing their environmental footprint and promoting the use of renewable materials [1,2]. In response, both industries and academic research are increasingly focusing on the development of high-performance

materials from renewable origin. In this context, natural fiber-reinforced biopolymers have emerged as a compelling sustainable alternative to traditional synthetic fiber reinforced polymer (FRP) composites [3]. Among the polymer matrices derived from renewable feedstock, poly(lactic acid) (PLA), a biodegradable aliphatic thermoplastic polyester, has received considerable attention [4]. Due to its unique characteristics such as high stiffness and transparency [5], PLA has found applications in various fields, from packaging to fiber production and composite manufacturing [6]. Numerous studies have focused on reinforcing PLA with plant fibers to obtain composites with a favorable combination of physical and mechanical properties [7]. The growing interest in these composites arises from their valuable properties, cost-effective production, and eco-friendly nature. Consequently, there is a growing demand for PLA composites reinforced with natural fibers in various industrial sectors such as construction and automotive. However, despite their merits, significant concern with biocomposite materials regards their limited fire resistance. Indeed, such biopolymers as PLA inherently exhibit high flammability, which intensifies fire propagation, notably through the generation of extended dripping [8]. Compared to synthetic reinforcing fibers, the incorporation of natural fibers significantly exacerbates their already poor fire resistance [9]. This shortcoming is an obstacle to the widespread commercial use of biocomposites, especially in the transportation sector, where fire safety regulations are stringent [10]. Therefore, the use of flame retardants (FRs) is essential to improve the flammability resistance of biocomposites. The predominant approach involves the direct incorporation of FRs into the polymer matrix [11,12]. However, this method frequently leads to compromised mechanical properties and leaching of the FR due to the inherent low compatibility between the two components [13]. An alternative strategy involves the direct grafting of the FR onto the surface of the reinforcing fiber. This approach avoids FR leaching and mitigates the "candlewick effect" induced by the higher thermal conductivity of the fibers as compared to the polymer matrix [14]. This method finds primary application in composites reinforced with plant fibers, exploiting their functional groups to facilitate the bonding of appropriate FRs [15].
The proposed study introduces a bioinspired protocol for the surface modification of flax fiber (FF) and basalt fiber (BF) with a halogen-free phosphorus-based hybrid FR specifically tailored for flame retardant applications in PLA-based biocomposites. FF and BF fibers were selectively chosen considering their different surface reactivity properties. Ozone (O_3) was selected as a safe oxidizing agent for fiber pretreatment to enhance surface chemical reactivity by forming hydroxyl and carboxyl groups for BF and FF, respectively. The new surface functional groups were exploited for the covalent immobilization of renewable gallic acid (GA) units. Subsequently, taking inspiration from the bacterial enterobactin-mediated iron acquisition mechanism [16], iron phenylphosphonate was complexed to the GA phenolic groups. The modified fibers were thoroughly characterized using Fourier transform infrared spectroscopy (FT-IR), thermogravimetric analysis (TGA), scanning electron microscopy coupled with energy-dispersive X-ray spectroscopy (SEM-EDS) and microwave plasma atomic emission spectroscopy (MP-AES). The FR-coated fibers were used as reinforcement in PLA-based composites, with fire resistance assessed through cone calorimetry tests (CCT); further, the mechanical properties were preliminarily evaluated.

2. Materials and Methods

2.1 Fiber coating

A Salinovo ozone generator, air-fed with a maximum diffusion rate of 0.5/h, was employed for fibers ozonization. 20g of fibers were placed in a 500 cm^3 ozonation chamber. The treatment lasted for a maximum of 7 hours. Gallic acid (GA) (34 g, 0.2 mol) and thionyl chloride (100 mL, 0.9 mol) were introduced into a dried single-necked flask. The reaction mixture was heated to 80 °C for 3 hours. After the reaction time, excess $SOCl_2$ was removed under vacuum. Crude galloyl chloride (36.9 g) obtained was dissolved in tert-Amyl methyl ether (TAME) (270.6 g, 2.6 mol) to yield a 12% (w/w) mixture. 30g of fibers were immersed in the mixture and stirred for 2 hours. The resulting sample was washed with H_2O and dried. 36 g of GA-functionalized fibers were mixed with 520 mL of deionized water in a beaker. 130 mL of $FeCl_3 \cdot 6H_2O$ (0.82 g, 3 mmol) aqueous solution was added. After stirring, PPA (0.96 g, 6 mmol), previously dissolved in 130 mL of H_2O, was added dropwise over 6 hours. The

reaction proceeded at room temperature for 12 hours. The resulting iron phosphonate-coated fibers were washed with H_2O and dried [17].

2.2 Composite Manufacturing

The composites were fabricated using Brabender-like equipment (Rheocord EC, Haake Inc.) and a lab hydraulic press (Collin model P400E) to create 100 mm × 100 mm × 4 mm plates. The fibers were mixed with PLA using a micro compounder set at 60 rpm and 180 °C for 5 minutes. Subsequently, the PLA composites were compression-molded at 180 °C with a pressure profile of 2 min at 0 bar, 1 min at 5 bar, 1 min at 10 bar, and 1 min at 20 bar. The cooling down to room temperature was performed while maintaining the material at the maximum pressure of 20 bar. The fiber content was set at 20 wt%. The composite specimens suitable for tensile tests were prepared via injection molding (Haake MiniJet II Pro, Thermo Fisher Scientific) with the loading cylinder at 190 °C and the temperature mold set at 45 °C.

2.3 Characterization techniques

Fourier Transform Infrared spectra were acquired with a Bruker VERTEX 70 spectrometer equipped with an attenuated total reflectance diamond (ATR) cell. The spectra were recorded in the mid-infrared region (400-4000 cm^{-1}) collecting 128 scans, with a resolution of 4 cm^{-1}. The morphology of the fiber surface was examined with a Field Emission Scanning Electron Microscope (FE-SEM) coupled with Energy Dispersive Spectroscopy (EDAX). Micrographs were acquired on a Tescan Mira3 system at 10 kV after having sputtered the samples with chromium. Thermogravimetric analysis was performed with an SDT-Q600 thermoanalyzer (TA Instruments) in a nitrogen atmosphere (100 mL/min) with a heating rate of 10 °C/min from room temperature to 800 °C. Differential scanning calorimetry (DSC) analysis was conducted using a DSC 250 calorimeter (TA Instruments) with high-purity nitrogen flowing at 40 mL/min and heating and cooling rates of 10 °C/min. Detection of iron content on FR-coated fibers was carried out with an MP-AES 4210 instrument. Tensile tests were carried out on a Zwick/Roell Z010 universal testing machine in accordance with ISO 527-2.
The fire behavior was evaluated utilizing an oxygen consumption cone calorimeter (CCT) (Fire Testing Technology Limited FFT Cone Calorimeter model and Noselab instrument (Nova Milanese, Italy) following the ISO 5660 standard.

3. Results

3.1 FR-coated fibers characterization

The effectiveness of O_3 pretreatment in the surface functionalization of flax fibers (FF) with carboxylic groups and basalt fibers (BF) with -OH groups was checked through FT-IR analysis. Pretreated FF showed a new signal at 1731 cm^{-1} associated to carboxylic C=O stretching [18], while BF exhibited new absorptions at 3365 cm^{-1} and 1637 cm^{-1}, attributed to adsorbed water and Si-OH stretching, respectively [19]. TGA analysis of the ozonated FF indicated a marginal decrease in the lignin degradation temperature, attributed to O_3 improved reactivity toward phenols and polyphenols [20]. Pretreated BF exhibited increased weight loss between 200 and 300 °C, likely due to the depletion of surface hydroxyl groups [21]. FT-IR analysis of the fibers, following functionalization with GA units, revealed signals corresponding to O-H stretching of the phenolic ring, C-C stretching of the aromatic ring, C-O stretching, and O-H bending. These signals confirm the presence of GA units bound to the surface of both fibers [22]. The successful functionalization is further corroborated by a noticeable morphological change observed on the fiber surface, as depicted in SEM micrographs (Figure 1). In Figures 1b and 1e, the previously clean and smooth surface of the untreated fibers (Figure 1a and 1d) is replaced by a new rough layer, attributed to the immobilization of GA units. The phenolic groups of GA units were then exploited for iron phenylphosphonate complexation. SEM analysis of the resulting coated fibers (Figures 1c and 1f) revealed the occurrence of a distinct globular coating on the fiber surface. EDS analysis confirmed the presence of phosphorus (P) and iron (Fe), validating that the material adhered to the fiber was indeed iron phenylphosphonate. MP-AES analysis revealed an iron loading of 0.1 wt% on both coated fibers, indicating a reduced amount but significant complexation of Fe^{III}-gallic acid units on their surfaces. TGA analysis of FR-coated BF showed two

distinct stages of weight loss occurring in temperature ranges of 170-270 °C and 270-400 °C, respectively. The 1.8 wt% decrease in the lower range is attributed to the decomposition of gallic acid units [23] and phenyl moiety of FR complex, while the 5.4 wt% reduction at higher temperatures is ascribed to the breakdown of C-C, C-H, and C-P bonds present in the structure of the phenylphosphonic units [24]. FR-coated FF exhibited a maximum decomposition rate temperature (T_{max}) of 309 °C, which is lower than that of untreated FF (354 °C), and a second degradation step in the temperature range from 400 °C to 520 °C. This can be attributed to the presence of the FR complex; the shift to lower T_{max} temperatures is ascribed to the degradation of gallic acid and phosphonate phenyl moieties, which degrade at about 250-260 °C. Subsequently, the iron phenylphosphonate undergoes a secondary stage of thermal degradation at temperatures above 420 °C, associated with the decomposition of the organic constituents of the coordination complex and/or dehydration of the H_2PO_4 and HPO_4 groups formed during the thermal degradation process [25].

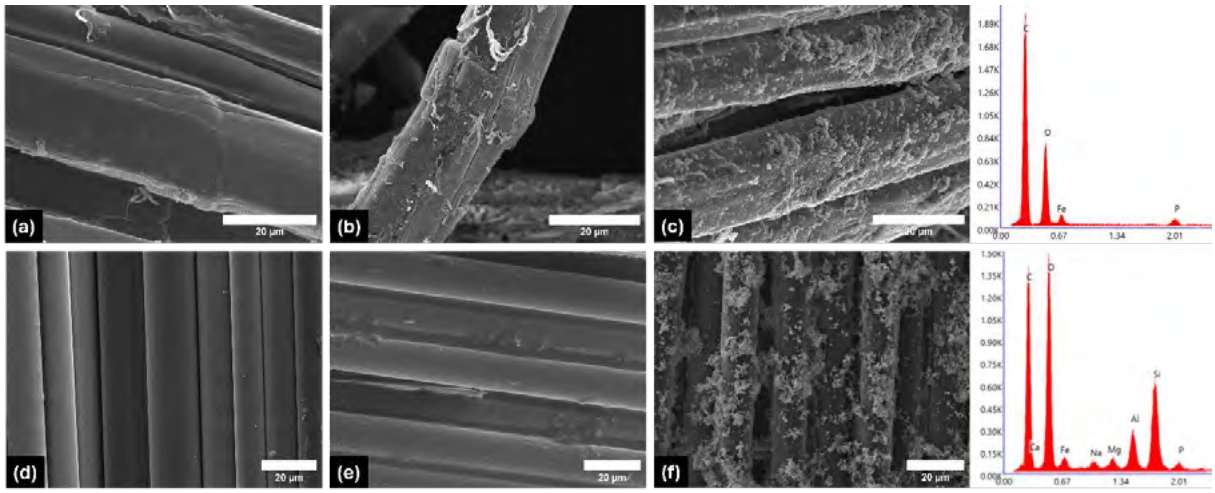

Figure 1. SEM-EDS analysis of (a) neat FF, (b) GA unit-functionalized FF, (c) FR-coated FF, (d) neat BF, (e) GA unit-functionalized BF and (f) FR-coated BF

3.2 PLA-based composites characterization

Fibers coated with the developed flame retardant (FR) complex were employed as reinforcement for fabricating PLA-based composites. Both composites reinforced with coated fibers (PLA/FF-FeP and PLA/BF-FeP) and those reinforced with uncoated fibers (PLA/FF and PLA/BF) were subjected to thermal characterization. The PLA/BF composite exhibited a temperature corresponding to 5% weight loss ($T_{5\%}$) at about 328.5 °C, a temperature for 10% weight loss ($T_{10\%}$) at approximately 338.7 °C, and a maximum decomposition temperature (T_{max}) of roughly 358.1 °C. Conversely, PLA/BF-FeP demonstrated slightly higher temperatures, with values of about 337.8 °C, 345.1 °C, and 365.6 °C for $T_{5\%}$, $T_{10\%}$, and T_{max}, respectively. A marginal increase in temperature was also observed for PLA/FF-FeP compared to PLA/FF. Specifically, PLA/FF recorded $T_{5\%}$, $T_{10\%}$, and T_{max} values at roughly 308.4 °C, 319.4 °C, and 350.9 °C, while PLA/FF-FeP showed slightly higher readings at approximately 318.8 °C, 331.3 °C, and 359.1 °C, respectively. Therefore, despite the low load on the fiber surface, the developed coating appears to be promising for improving the thermal stability of PLA composites.
DSC analysis revealed a peak of cold crystallization temperature (T_{cc}) at about 118.8 C for PLA/FF-FeP and approximately 119.8 °C for PLA/FF. Conversely, no significant differences were observed between PLA/BF and PLA/BF-FeP. To gain deeper insights into the impact of the flame retardant on the thermal properties of the composite, DSC analyses were performed by incorporating the as-synthesized iron phenylphosphonate into neat PLA at a concentration of 1 wt.% (PLA-FeP). The results revealed a reduction in T_{cc} for PLA-FeP (about 111.0 °C) compared to neat PLA (about 115.2 °C), as well as a

significant 65% increase in the degree of crystallinity. This suggests that the FR complex promotes the nucleation phase of the PLA crystallization process.

Cone calorimetry tests were conducted on the composites to evaluate the flame-retardant properties of the developed FR coating complex. PLA/FF-FeP compared to PLA/FF exhibited a slight increase in time to ignition (TTI), a 7% reduction in the peak heat release rate (pHRR), and, most significantly, a remarkable reduction in both specific extinction area (by about 68%) and total smoke released (87%), hence highlighting the high smoke suppressant activity exerted by the treated fiber. In addition, a reduction of 15% in the Fire Propagating Index (FPI = pHRR/TTI ratio) was recorded. When comparing PLA/BF-FeP to PLA/BF, a slight increase in TTI was observed, along with reductions of 13%, 8%, and 14% in the time to flame out, pHRR, and FPI, respectively. Despite its minimal presence on the fiber surface, the designed FR coatings acted as high efficient flame retardants. Finally, some preliminary tensile tests were conducted to assess the impact of FR coating on the mechanical properties of the composites. PLA/FF-FeP and PLA/BF-FeP exhibited a 5% and 17% reduction in tensile strength, respectively, compared to PLA reinforced with the corresponding untreated fibers. This decrease may be attributed to the presence of the organic-inorganic hybrid coating, potentially acting as a stress concentrator [26]. Furthermore, the non-uniform distribution of the coating on the fiber surface might have exacerbated this effect. Conversely, PLA/FF-FeP and PLA/BF-FeP exhibited an increase in stiffness by 15% and 8%, respectively. This finding is likely to be due to the enhancement of fiber stiffness resulting from the presence of the hybrid coating, thereby leading to an increased Young's modulus for the composite. Further characterizations are needed to validate these hypotheses.

4. Conclusion

A sustainable method of coating basalt and flax fibers with an organic-inorganic hybrid flame retardant has been successfully devised. This bioinspired coating process facilitates the immobilization of iron phenylphosphonate on the fiber surface, utilizing moderate reaction temperatures and eco-friendly solvents such as TAME and H_2O. Comprehensive characterization analyses including SEM-EDS, FT-IR, TGA, and MP-AES attest to the efficacy of the coating process, confirming the successful grafting f the flame retardant onto the fiber surface.

The incorporation of these coated fibers into PLA-based composites resulted in improvements in thermal stability and flame retardancy, despite the low loading of the FR coating on the fiber surface. Cone calorimetry tests revealed such improvements as a slight increase in Time to Ignition (TTI), a 5% reduction in Peak Heat Release Rate (pHRR), and substantial decreases of 87% in Total Heat Release (THR) and 68% in Smoke Evolution Area (SEA) for PLA/FF-FEP. Similarly, PLA/BF-FeP exhibited an extended TTI, reduced flame out time, an 8% decrease in pHRR, and a 15% decrease in Fire Propagation Index (FPI) compared with neat fiber-reinforced composite.

However, PLA reinforced with FR-coated fibers showed a decrease in tensile strength compared to the counterparts reinforced with unmodified fibers, likely due to the effect of the hybrid complex that could act as a stress concentrator. Nonetheless, an increase in Young's modulus suggests a potential influence of FR coating on fiber stiffness.

Keywords: Crashworthiness, Triaxial braided composites, Energy absorption, Dynamic crush testing, CFRC tubes

Abstract
The following article presents an experimental investigation into the crashworthiness performance of an innovative tri-axial braided carbon fiber reinforced composite (CFRC) cylinder under dynamic crush loading. Two different test methods were employed, a drop tower test and a very high-speed (VHS) machine test, using both flat and conical impactors. The specimens were manufactured via a novel resin infusion process directly onto the mandrel utilized for the braided process, avoiding any damages to the dry fibers. For each test configuration, the Specific Energy Absorption (SEA), peak load, steady-state crushing load, and Crushing Efficiency (CE) were evaluated and compared against literature data. The flat impactor resulted in higher energy absorption due to fiber fragmentation but lower CE from a high initial peak load. Conversely, the conical impactor exhibited higher CE from smoother load initiation but lower energy absorption dominated by friction and delamination mechanisms. Braided architecture has demonstrated SEA values consistent with the literature while providing higher CE than comparable unidirectional laminates, suggesting the suitability of this architecture for crashworthy applications. However, the contrasting impactor results highlight the need to carefully consider prioritizing either high energy absorption or low peak acceleration for the specific design scenario.

1. Introduction

Industrial interest in carbon fiber reinforced composites (CFRP) for energy-absorbing crashworthy structures is increasing rapidly [1]. Their excellent specific strength, and specific stiffness, among other mechanical properties, are essential for offsetting the structural weight of primary aircraft structures.
Design specifications and standards impose specific limits on the maximum allowable accelerations experienced by vehicle occupants during a crash [2][3]. The use of composite materials allows the designers to have a greater ability to tailor the specific reinforcement direction to control the high initial peak force, thus accelerations experienced during impact, and allow the structure to get into a steady-state crushing phase, through energy absorption [4].

The complex failure modes of composite materials during crushing allow for a much higher energy absorption; while plastic deformation is the main energy absorption mechanism in metallic specimens, multiple failure modes contribute significantly in composites, including transverse shearing (fiber kinking), lamina bending, local buckling, friction between plies, and delamination. Generally, the first two dominate during brittle fracture behaviors [4][5][6].

Crushing is defined as the material characteristic of continuously absorbing energy through fragmentation and destruction [7]. A series of parameters need to be introduced to evaluate the crushing performances of these structures. These include the Specific Energy Absorption (SEA), the Peak Force, the Steady-State Force, and the Crushing Efficiency (CE) just to name but a few.

This work utilizes a tubular specimen produced with a tri-axial braided architecture via Resin Infusion (RI) to assess the crushing behavior and capabilities of the selected geometry and novel fiber architecture.
It has been proven that closed-section geometries have beneficial effects on crushing performance, hence the specific specimen geometry chosen is in this fashion.
This is thanks to the stacking sequence of the hoop fibers that constrain the axial fibers preventing them from splaying, suppressing the propagation of the crush front, and increasing the energy absorption capabilities [8].

The choice of braided fiber architecture is due to its ascending interest inside the aerospace sector to realize primary structural components such as wing flaps, horizontal stabilizer, and fuselage [9]. This architecture resembles a combination of filament winding and weaving that shows a mechanical interlock between fiber yarns, suggesting higher energy absorption capabilities [9]. The ascent of this textile is mainly driven by the possible reduction in production costs due to the possibility of process automation in textile weaving and placing. The architecture is composed of two sets of yarns placed at +60° and -60° degrees and an axial fiber bundle placed at 0°. A specific repetitive unit cell (UC) is obtained [10]; the UC has to follow specific rules of ratios and dimensions, which will be presented later on.
Two different types of test scenarios have been considered. The first scenario simulates a crush with a drop tower where the initial velocity is known, energy is absorbed during the crush, and the drop weight decelerates until the mass reverses its motion. The second scenario analyzed aims to simulate the absence of inertia, maintaining a constant velocity throughout the crushing. The crushing stroke is fixed and given as an input parameter. Moreover, for each of the two testing machines, two different impactors are employed, the first being a flat plate and the second being a conical plug impactor.

For each test performed, a total of 4 samples have been evaluated, so that any variance in experimental data could be analyzed. To maintain statistical consistency, each sample has been produced following the same methodology and under the same environmental conditions. A set of control tests was implemented to strictly follow the manufacturing process, such as infusion time, amount of resin utilized, environmental temperature during infusion, vacuum bag drop tests before infusion, etc. Finally, all the samples were tested using a non-destructive, X-ray CT scan to ensure porosity control and avoid manufacturing defects.

2. Speciment design and manufacturing

The test specimen is a cylinder; its dimensions have been chosen to avoid buckling failure modes, namely, the inner diameter is 50 mm, and the height is 120 mm. The layup consisted of 3 braiding layers with an equivalent stratification of a weaved $[+60°/0°/-60°]_3$, resulting in an average wall thickness of 2.5 mm. An inner 45° chamfer has been machined and used as triggering geometry on one end of the samples. The material system utilized was a Grafil 34-700 12k and 24k carbon fiber tow and a KineTix R118-H103 epoxy resin system.

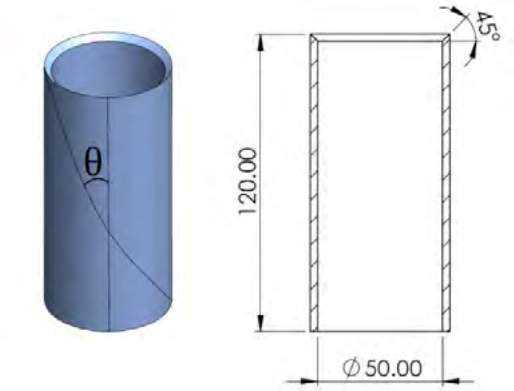

Figure 1. CAD model of the specimen design (dimensions in [mm])

A Herzog RF 1/48-100 radial machine and a Kuka 6-axis robotic arm were used to weave the specified material geometry. The machine has 48 radial bobbins, split into two groups, that spin in opposite directions while interweaving each other. A total of 24 axial bobbins are installed radially on the outer diameter of the specified machine. The radial bobbins are loaded with the 12k carbon fiber tow, while the axial ones with the 24k tow. During the braiding process, two main parameters were controlled: axial speed and rotational speed. The first one is the velocity at which the robotic arm pushes the mandrel into the machine; the second one is the rotational speed of the radial bobbins around the inner diameter of the Herzog. These parameters are strongly related to the diameter of the mandrel and lead to different wrapping angles of the angled tows, resulting in different levels of fiber compaction. In this specific case, the angle and the diameter were set as requirements, and different pairs of speeds were tested. The final speed parameters chosen were 0.0115 m/s for the axial speed and 100 rpm for the rotational speed.

Figure 2. Herzog RF 1/48-100

These two parameters enabled the definition of a repetitive unit cell (UC) [11] comparable to what can be found in the work of Littell et al [10], with similar proportion on both the height-to-width of the cell and the angle of +60° and -60° of the radial fibers.

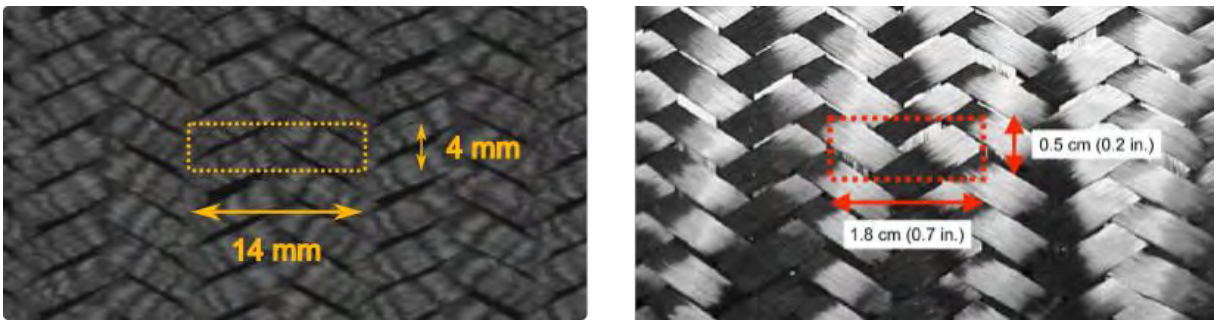

Figure 3. Comparison between the obtained UC (left) and Littell UC (right)

The braiding process described is commonly done by interwinding yarns onto a mandrel.
However, in the case of this study, the mandrel acted also as the mould to allow for a direct resin infusion of the dry fiber architecture. This innovative approach ensured superior mechanical characteristics because it avoided the need to move or cut the fibers from the mandrel to prepare the preform. Figure 4 shows the mould design realized for this scope. It is composed of 4 segments, called sectors, that create the circumferential shape of the cylinder. These segments are held in place by two rims, placed at each end of the mould.

Figure 4. Mould design - Exploded view

This design was then mounted onto the robotic arm and was pushed through the braiding machine. Since the braiding textile design has the 24k tows running in the axial direction, overlapping each braid on top of the other would create a nervature deposition of the fibers (as seen in Figure 5, on the left). To mitigate this phenomenology, every braid layer was deposed onto the previous one with a rotational offset to allow an even deposition of the 24k tows (in Figure 5, right picture).

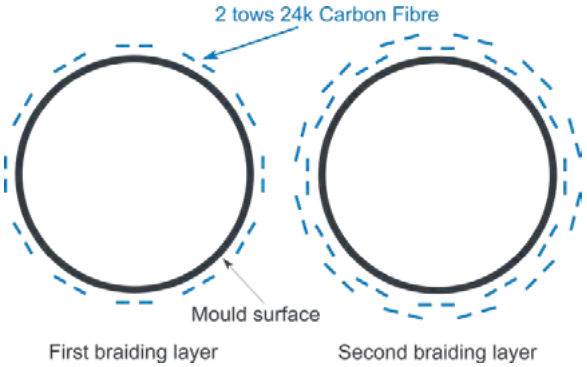

Figure 5. 24k tow deposition onto the mould

Once the preform was laid onto the mould, the consumables needed for the resin infusion process were applied and the component infused.
The resin infusion process employed is a modified SCRIMP. For this specific application, a self-adhesive PTFE-coated fabric sheet was applied onto the mould before braiding, to prevent excessive resin from filtering through the different mould sectors and to give a uniform finish on the inner diameter of the cylinders. The PTFE layer was also needed for an easier demoulding of the final component. After the deposition of the braid layers, peel-ply was added, and then the flow media was specifically cut to reduce resin front flow speed and allow for an even and slow infusion. The vacuum bag design was an envelope bag: one vacuum bag runs on the inner side of the mould and the second one runs on the outer part. The two bags are then sealed at each end with tacky tape. The cylinder was infused vertically, with the resin inlet on the bottom and the venting port on the top. The infusion process was about 40 minutes long, including a 10-minute stop after the tap opening. This allowed for the air contained in the inlet tube to be evacuated correctly, restoring the initial vacuum integrity. Before infusion, the vacuum bag

was inspected with a vacuum drop test for 1 hour; requirements prescribe a pressure drop lower than 0.05 bar to consider the test passed.
To have more vacuum integrity and control over the process, the component once ready to be infused was placed into an oven at 40° C to allow for air expansion and easier evacuation by the vacuum pump. This reduces even more the possibility of having porosity inside the final sample.

Figure 6. Vacuum bag setup

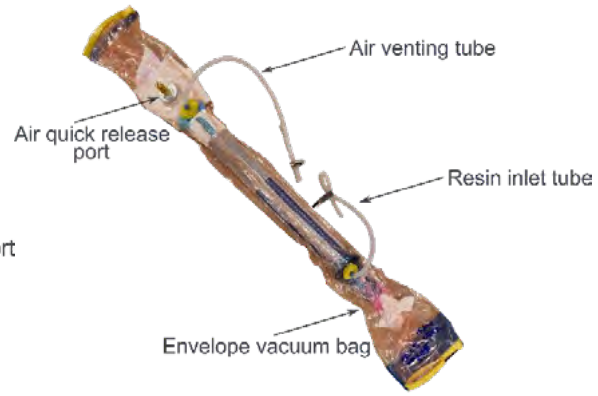

Figure 7. Process layout

Once the curing cycle was completed at ambient temperature, post-curing was necessary; this peaks at a temperature of 90°C for 8 hours. After that, the mould was disassembled and the carbon fiber cylinder was extracted. From each of the produced cylinders, it was possible to extract 3 samples. Each sample was cut to specification employing a water-cooled diamond disk saw. The trimmed sides were then lightly sanded to eliminate the trimming imperfections that occurred during the cut.

After production, each component was weighed and, before testing, specimen quality was assured by CT scanning each sample and checking for porosity, unwanted inclusions, and unexpected premature delamination. No observable defects have been found in the tested samples.
With the formulation found in [9], it was possible to calculate the mean volume fraction of the produced samples. This shows a mean fiber fraction volume of 0.55, compatible with a standard CFRP structure. Tables 1 and 2 show the weighted samples ready for testing. From every cylinder produced, the 3 samples obtained were progressively numbered to retrieve their characterization information. During tests, the specimens have been randomly selected amongst the aforementioned list, in order to avoid the possibility of false behavior due to potential production errors in specific batches.

3. Experimental method

The US Department of Defense (DoD) mandates precise criteria for crashworthy structures, as outlined in MIL-STD-1290A (Military Standards 1290A) [2]. This standard stipulates that airframes must be designed to withstand a minimum vertical impact speed of 8 m/s. Concurrently, other works on braided structures [12], performed impact tests with velocities ranging from 7.21 to 8.51 m/s using the same geometry specimen but in different sample sizes. Those tests were carried out using braided T700S 12K fiber tows and PR520 resin system.
In this particular study, the designated test speed was set at 6 m/s, determined by the maximum energy absorption capabilities of the tested samples. Establishing the permissible energy, allowed for the calculation of parameters crucial for energy determination, namely, the height and total mass of the impacting hammer. While maintaining constant energy, reducing the weight allows for a greater dropping height and, thus, higher initial crushing velocity. However, due to equipment limitations, the minimum weight that could be dropped was ≈ 50 kg. This restricts the drop height to around 1.8 m. The limitation to 6 m/s is then matched onto the Instron 8800 as testing speed, to obtain a comparable value of crushing speed in both test setups.
The crushing speed, coupled with the sample dimensions already provided, showcases a strain rate of 60 s^{-1} which can be considered a mid-high strain rate test and can be compared with other crushing strain rates as reported in the available literature [12][13].

In both test setups, a 3D High-speed DIC (Digital Image Correlation) system is implemented to capture the displacements during crushing. This system uses 2 Phantom cameras, one being a V2640 and the other being a V2512 model. Both cameras use a Nikon AF 24-85mm f/2.8-4 D IF, and are set to 85 mm and f/8 aperture with an exposure time set to 2.5 µs. The frame rate utilized is 35000 fps with frame resolution set to 768x768 pixels. DIC results are not presented in the context of this preliminary analysis.

3.1. Drop tower

A drop weight test rig was utilized to perform the impact, using two different impactors: a conventional flat plate and a conical impactor. For both scenarios, the total impactor mass was around 50 kg (see Table 3 for details), while the drop height was set equal to 1.83 m. With this data, an impact velocity of approximately 6 m/s and an impact energy of almost 900 J were measured. A laser gate system was used to check the correct height for each drop. A load cell with a range of 100 kN was used to capture the impact loads. A digital oscilloscope was used to acquire the displacement data during crush.
The samples were kept in position by a steel support that allowed the cylinders to be fit into position. Figure 8 shows the experimental setup designed for the drop tower.
To correctly capture the images of the crush, the exposure value seen on the camera must be close to 0 EV. As a result, the light needed was provided by 3 Godox SL200// lights at maximum power and two additional high-beam LED lights.

Figure 8. Steel support

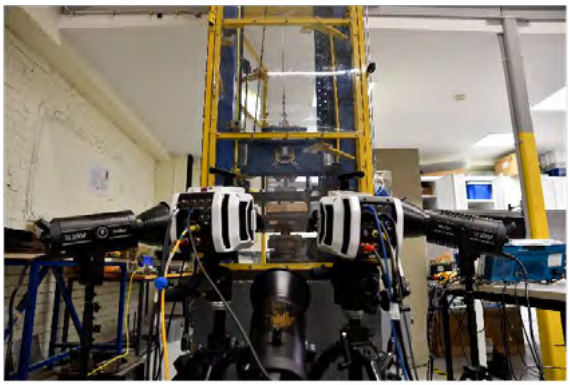

Figure 9. Drop Tower setup

3.2. Very-High speed machine (VHS)

The use of a drop tower will inevitably demonstrate the effect of the deceleration of the impacting mass, as it initially possesses a notable velocity that decreases as the cylinder collapses, absorbing energy. However, a test in which this inertial effect is removed can demonstrate different behaviors of the structure, and must, therefore, be investigated. In this scenario, depicted in Figure 10 and Figure 11, an Instron 8800 very high-speed (VHS) machine was programmed to maintain a constant speed of 6 m/s during the whole crushing stroke. A total crushing displacement of 50 mm was set as input into the machine with an additional displacement of ≈ 20 mm to allow the machine to come to a full stop after the crushing stroke. This experimental setup can reveal the effect that would occur during a crush if the tested component were mounted on an airframe or structure that needs to be protected during an accident. In such a scenario, the airframe (or structure) mass would be significant enough that an immediate deceleration during the collapse would not be observed, unlike in the drop tower tests.

In this setup, the specimen was held in place with a clamping mechanism in which the sample hung from the top, and the crushing head was pushed from the bottom up. All the needed crushing parameters have been provided by the program written into the machine (such as displacement function, crushing speed function, load function, etc).
Compared to the setup used in the drop tower, the camera layout for the high-speed recording in the VHS machine showed some differences: the illumination was provided by 3 high beam LED lights put inside the safety enclosure of the machine, mounted using 3 magic arms that ensure their fine-tuning positioning.

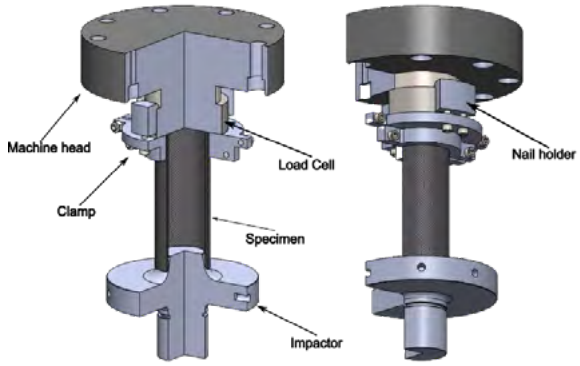

Figure 10. VHS Specimen support

Figure 11. VHS setup

Table 3. Testing setups and machine parameters

	Drop Tower		VHS	
	Conical impactor	Flat impactor	Conical impactor	Flat impactor
Active mass	49,96 kg	49,935 kg	∞	∞
Dropping height	1,83 m	1,83 m	N/A	N/A
Nominal speed	6 m/s	6 m/s	6 m/s	6 m/s
Nr of samples	4	4	4	4

4. Results and analysis

4.1. Crush performances results

Multiple values can be calculated to evaluate the performances of a specific sample geometry and textile architecture during a crush: peak crushing load, steady-state crushing load, specific energy absorption, and crushing efficiency, to name a few.
Among these, the most significant are the energy absorption (or the specific energy absorption), and the peak force, because they are directly correlated to the protective performances. Best practice design requires high energy absorption and low peak force to represent the ideal scenario in a crushing absorption system. Crushing efficiency is classically introduced to represent optimal design performances, it is the ratio between the peak force, which is the highest force measured during crush,

and the steady-state force, which is the mean force at which the crush continues unfolding after the initial trigger is consumed and the passing of the peak force[13].

$$CE = \frac{F_{SS}}{F_{Peak}} \tag{1}$$

The crushing efficiency is helpful to define whether the crush has been characterized by a catastrophic failure or if the crush itself was effective. The first situation is characterized by high peak force and little steady state force (low CE), while the second shows high energy absorbed and a CE close to the unity [14]. The latter is the optimal design scenario in the case of a crush-absorbing structure.
Another design parameter is the Specific Energy Absorption (SEA), which is defined as the energy absorption divided by the mass of the structure, namely the area under the force/displacement curve, divided by the mass of the collapsed structure. The resultant collapsed mass can be defined as the linear density of the structure, ρ_{lin}, multiplied by the crushed displacement, δ.

$$SEA = \frac{\text{Energy absorbed}}{\text{Mass of the collapsed structure}} = \frac{\int_{X_{start}}^{X_{end}} F\,dx}{\rho_{lin} \cdot \delta} \tag{2}$$

These data are presented in Table 4 for better clarity and organization.

Table 4. Testing results

	Drop Tower		VHS	
	Conical impactor	Flat impactor	Conical impactor	Flat impactor
Peak load [kN]	15.16	38.85	15.94	42.88
Steady-state load [kN]	5.33	20.29	12.68	31.49
SEA [J/g]	11.38	41.48	21.74	56.03
CE [-]	0.35*	0.53*	0.80	0.73
Displacement [mm]	79.69	42.07	48.27	57.85

**CE data regarding the Drop Tower have been calculated for completeness. Although, without a steady-state crushing force, the resulting test data do not hold any significance.*

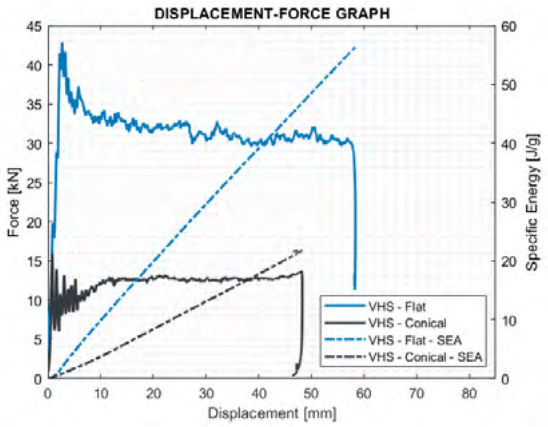

Figure 12. VHS Force - Displacement results

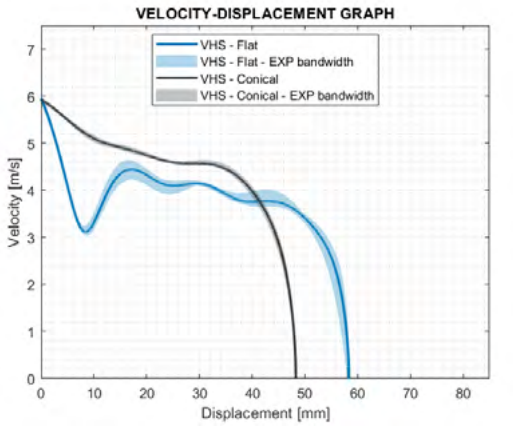

Figure 13. VHS Velocity - Displacement results

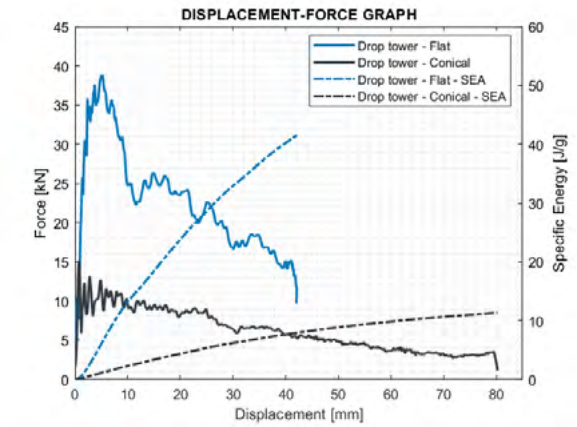

Figure 14. Drop tower Force - Displacement results

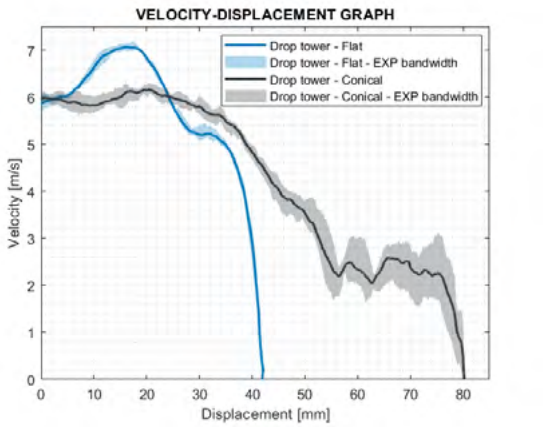

Figure 15. Drop tower Velocity - Displacement results

4.2. Crushing efficiency

The experimental crushing of cylinders using a flat impactor on the VHS reveals a Crush Efficiency (CE) of 0.73. This finding aligns with the literature data available from Pereira et al. [12], who conducted experimental testing on triaxial braided cylindrical samples, and shows higher CE in comparison to Reuter et al. work [7], who performed similar experimental testing using unidirectional $[90_2/(0_2/45_2/\text{-}45_2)_2]_s$ layup carbon-epoxy prepreg. The correspondence with Pereira et al. work suggests that the experimental crushing conducted has been successful, and the collapse of the cylinders has occurred in a manner consistent with an energy-absorbing structure, while it also shows better performances over unidirectional quasi-isotropic lamination of the braided architecture in reducing peak forces during impact scenarios.

If the obtained crushing efficiency of the conical plug and the flat plate impacts on the VHS is compared, the conical impactor has shown a higher CE, reaching a value of 0.80; this is because of the lower peak force at the beginning of the impact on the samples. The reduced peak force is strictly correlated with the easier breaking initiation given by the shape of the impactor. In this case, there is no need to crush an initial amount of material before the activation of the plies delamination of the cylinders, since this is immediately activated by the specific shape of the impactor.

4.3. Peak load and steady-state load

The peak load shows an interesting correlation between the drop tower and VHS test methods, suggesting that the initial crushing speed was, in fact, similar. After the erosion of the triggering geometry, the peak load should not differ under the same impactor geometry, given the same initial impact speed. Regarding the steady-state crushing force, the values differ quite significantly (more than twice the magnitude for the conical impactor and 50% for the flat impactor). This is expected, since in the drop tower scenario there is significant deceleration, while this does not occur for the VHS.

4.4. Specific energy absorption discussion

The Specific Energy Absorption (SEA) extracted from the VHS tests shows a good correlation with available literature data. Work by Pereira et al. [12] calculated a SEA of ≈ 59.5 J/g, with an uncertainty of ±2 J/g. Under similar testing conditions and impactor geometry, the present work found a SEA of 56.03 J/g, suggesting the two energy values are comparable.
Differences were found when the conical impactor was employed, with literature data finding ≈ 34.5 J/g, while this work extracted 21.74 J/g. However, in this scenario, the conical impactor geometry plays a major role in the crushing behavior of the specimen, and, without being able to define the differences between the two impactor geometries, further analysis is not possible.

Regarding the drop tower data, the calculated SEA values show a similar trend to that found for the VHS tests. Available literature data from McGregor et al. [15] shows a good correlation with the flat impactor,

although the test specimen geometry differs. With the use of the conical plug impactor, the literature data findings show the same trend of magnitude reduction but with different values.

4.5. Fracture morphology analysis

The data presented in Table 4 yield several noteworthy observations. When subjected to the flat impactor crush, the material experienced a crushing failure characterized by both internal and external material displacement within the tube. This resulted in the distortion of the fiber braid and failures across the bias, 60°, and -60° tows, as well as along the axial fibers, leading to fiber kinking as a principal failure mechanism (an inter-fiber rupture phenomenon characterized by a shear rupture[4][12][14]. Fiber kinking mechanism leads to the formation of fragmentation debris that are being compacted together, creating a debris wedge. Figure 16 shows the crushing continuation, with the debris wedge pushing the inner hoop layers internally, causing compressive microfractures while, at the same time, the outer hoop is pushed externally, with the continuous instauration of tensile forces that lead the outer hoop to fracture. This is necessary as the cylinder has to expand while the splaying mode is unfolding.

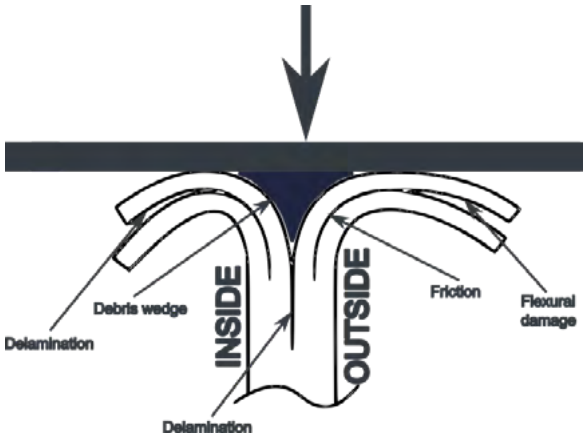

Figure 16. Flat impactor crushing morphology (source [15])

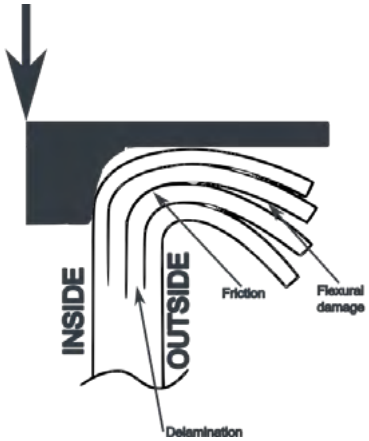

Figure 17. Conical impactor crushing morphology (source [15])

Fiber kinking phenomenon happens because of a reduced curvature radius at the front of the crushing platen where the biaxial fibers lock the axial ones from splaying. At some point, this curvature radius will be so small that the axial fibers have to undergo a shear fracture.

In Figure 17 the failure mechanism of a conical impactor crush is presented. This induces a failure mode wherein all crushed material is predominantly pushed radially outward, forming fronds of uniform width. Notably, this mode led to severe failures of the bias tows but with reduced fragmentation and fewer failures along the axial fibers. In the absence of a debris wedge, the axial fibers tend to be pushed outward with the biaxial hoop fibers that are constraining this splaying from happening. In this scenario, friction and delamination between laminae are the two principal fracture mechanisms that absorb energy, with the absence of the debris wedge compressive and friction forces[4][12][14].
Although this crush behavior is stable, a significantly lower overall force level was obtained when compared to the flat impactor. Conical impactor resulted in a reduction of the initial peak force values typically observed with this impactor in crush experiments. This lower force level also correlated with the reduced SEA threshold of the specimens, likely attributed to diminished fiber fragmentation during the crushing events.
Figures 18 illustrate two examples of crushed cylinders with the VHS, one with a flat impactor and the other with a conical impactor. The left image clearly shows how fragmentation has affected the sample impacted with the flat plate, with the material being pushed both inward and outward. The two detailed views allow for a clear understanding of the debris wedge created due to the material fragments being compacted while the crushing was happening. The sample crushed with the conical plug exhibits a predominantly outward push of the material, resulting in a radial-symmetrical fracture opening. In the

case of the conical impactor, the bias fiber breaking is much more severe (highlighted in the detailed view), with little to no rupture of the axial fibers, which leads them to a splaying mode outward.

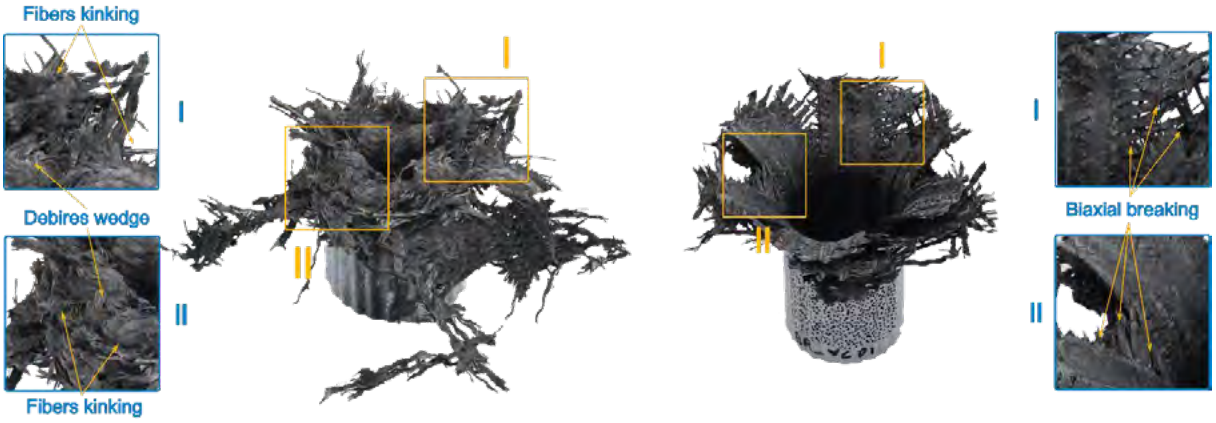

Figure 18. Flat (left) vs conical (right) impacted samples on the VHS

The drop tower test results, depicted in Figure 14, show the differences between using flat and conical plug impactors. Similar to the VHS tests, the flat impactor exhibits a much higher initial peak force compared to the conical impactor. However, in these drop tower tests, the force does not maintain a constant crushing value indicative of progressive crushing. Instead, it tends to reduce as the displacement increases. This is due to the deceleration of the impacting mass, as the energy absorption phase consumes the impactor's velocity during the crush event [15][16].
An important observation is the total displacement of the two different impactors. In these tests, the displacement indicates the portion needed to dissipate all the impactor's kinetic energy (which results almost identical for both impactors) before it comes to a stop or rebounds. A smaller displacement means the sample has a high energy absorption rate, which is desirable for an energy absorption structure. A larger displacement suggests the energy-dissipating mechanisms were less effective. This result suggests a similar energy-absorbing behavior to what was revealed in the VHS tests.

Figure 12 represents the VHS force-displacement diagram for the investigated braided cylinders impacted with a flat impactor and a conical impactor, in blue and black respectively; the dashed line represents the two different specific energy absorption lines vs the crushing displacement.
The velocity vs time diagram produced with the VHS depicted in Figure 13 shows that the speed had not been maintained constant as required by the experimental setup. The inability of the VHS machine to do so could be attributed to multiple reasons; the first could be attributed to the fact that the machine was working on the upper limit of its maximum load capacity, peaking at 45 kN over 60 kN load cell capacity; the second could be related to the data filtering set in place for the data cleanup.
Although the velocity was not constant to 6 m/s as expected, an interval of constant speed, to a lower value, has been established. This velocity value is ≈ 4 m/s for the flat impactor and ≈ 5 m/s for the conical impactor. This constant interval led to a constant crushing load onto the force-displacement graph, which is sufficient to make the necessary considerations regarding an impact at constant velocity.

5. Conclusions

Experimental testing on carbon fiber reinforced composite (CFRC) braided cylinders was conducted using two different test methods and impactor's design.
Experimental results with the flat impactor demonstrated high energy absorption compared to the conical impactor results. However, this setup resulted in lower crushing efficiency due to a higher initial peak force. Characteristic fracture mechanisms such as fiber kinking, fiber fragmentation, and interlaminar delamination surfaces have been observed in a post-impact analysis of crushed composite cylinders with the introduced flat impactor. Conversely, the conical impactor test results revealed lower peak forces and higher crushing efficiency, resulting in a reduced overall energy absorption compared with flat impactor tests. The observed reduction in energy absorption was primarily attributed to less

effective energy-absorbing mechanisms such as interlaminar delaminations and friction between adjacent composite plies compared to the main fracture mechanisms previously characterized.

As experimentally observed, VHS tests avoid the immediate deceleration and velocity reduction that is instead observed in the drop tower tests. This allows for the characterization of the material crushing performances undergoing a progressive crushing scenario.

The study also explored whether the braiding architecture could serve as a crashworthy structure capable of efficiently absorbing energy and maintaining a stable collapse phase during high-energy impacts. Findings showed that braided architectures' specific energy absorption and crushing efficiency are comparable with existing literature on similar crush absorbers and exhibit higher CE if compared to unidirectional structures, confirming their potential for impact scenarios. Nonetheless, the varied performance in SEA and CE with different impactors suggests that the specific requirements of the intended application should dictate the choice between optimizing for energy absorption or minimizing peak force.

Keywords: basalt fibre, star-like polymer, mechanical properties

Abstract
The study investigates the effect of star-like polymers on basalt fibre-reinforced plastic (BFRP) composites. Basalt fibres are chosen for their lower emissions and cost-effectiveness compared to alternatives like glass or carbon fibres, but they lack good adhesion with the matrix, which affects mechanical performance. The research entails mixing different weight percentages of star-like poly(n-butyl methacrylate)-(glycidyl methacrylate) block copolymer into a biobased matrix and reinforced with basalt fibres. Mechanical tests such as dynamic mechanical analysis, tensile, impact, and fracture toughness, were conducted to evaluate the influence of the star-like polymers on the composite's performance. The study demonstrated that adding star-like polymers enhanced the mechanical properties of BFRP specimens, making them comparable to conventional composites. Scanning electron microscopy was performed to help visualise the interlaminar damage caused post mechanical testing.

1. Introduction

Basalt fibres and its properties have been increasingly researched as industries have now been focusing on the development of sustainable composites. Basalt fibres are produced with lower emissions and cheaper in cost in comparison to its counterparts. Furthermore, basalt fibre-reinforced plastic (BFRP) composites demonstrate remarkable resilience to acids, and other corrosive substances, thermal stability, prolonging the lifespan of fibre-reinforced plastics (FRPs) in outdoor settings in contrast to carbon and glass fibre-reinforced plastics (CFRP and GFRP) [1]. The bond between the matrix and fibre is crucial for enabling efficient stress transfer and achieving superior mechanical properties. Star-like polymers have shown to improve adhesion and impact energy absorbing capabilities within carbon fibre reinforced polymer laminate due to a bridging effect [2].

The aim of this study is to investigate the effect of star-like poly(n-butyl methacrylate)-(glycidyl methacrylate) block copolymer on the properties of BFRP. Different wt.% ranging between 0 and 7% are employed to check the influence on addition of the polymer. Dynamic mechanical analysis (DMA) and tensile tests on epoxy (neat and modified) specimens are performed to ascertain the ideal wt.% of star-like polymer that can then be reinforced with basalt fibres for further testing. Interlaminar fracture tests along with scanning electron microscopy post failure are performed to determine the adhesion within BFRP laminates and visualise the damage caused.

2. Materials and Methods

2.1. Materials

The star-like poly(n-butyl methacrylate)-(glycidyl methacrylate) block copolymer, was incorporated into a biobased epoxy matrix reinforced with basalt fibres to enhance the mechanical properties. SR Greenpoxy 33 (Sicomin, France) and LITE 2401 (Cardolite, Belgium) sourced from biobased carbons and cashew nutshell liquid respectively were mixed to create a matrix of bio content of approx. 33%. The star-like polymer was mixed with the resin over 24 hours at 80 °C to produce a masterbatch with a concentration of 10 wt. %. This masterbatch was then diluted to create samples with concentrations of 0.25, 0.5, and 1 wt.% for comparison with the neat matrix. Unidirectional and twill woven basalt fibre fabric (Basaltex, Belgium) was used to fabricate the laminate plates for interlaminar and tensile tests respectively, which were impregnated with the same content of star-like polymer as the epoxy.

2.2. Methods

Dynamic mechanical analysis (DMA) was implemented to study the effect of filler content on the epoxy viscoelastic properties. DMA tests were conducted in a tension mode at a force of 2 N using a Mettler Toledo (Columbus, OH, USA) DMA/SDTA861 instrument to estimate the thermomechanical properties of the investigated materials. All tests were conducted at a frequency of 1 Hz and temperature range between 30-180 °C at a heating rate 3 K/min to ensure slow heating, thus avoiding any temperature gradient. The maximum peak of the loss modulus vs. temperature graphs was used to identify the α-relaxation associated with the glass transition. Subsequently, the temperature corresponding to this point was adopted to determine the glass transition temperature across all examined samples.

Tensile tests were performed on modified epoxy specimens which were fabricated according to ISO-527-1B using H10 KT universal column testing machine (Tinius Olsen, UK), with a crosshead strain rate of 2 mm/min.

For the developed BFRP laminates, Mode I interlaminar fracture toughness tests were carried out according to ASTM D5528 to study the effect of star-like polymers on mechanical properties. The double cantilever beam (DCB) samples were cut from the BFRP plate to have dimensions of 125 × 25 × 3 mm, as shown in Figure 1. Finally, the BFRP samples were prepared for Mode I interlaminar fracture toughness tests by gluing loading blocks. The tests were performed using a Zwick 2.5 testing machine at a crosshead speed of 1 mm/min at room temperature and Canon EOS40D to capture photos every 3 s for the crack propagation analysis until failure occurred. ImageJ 1.38x software was used to estimate the delamination length in DCB samples.

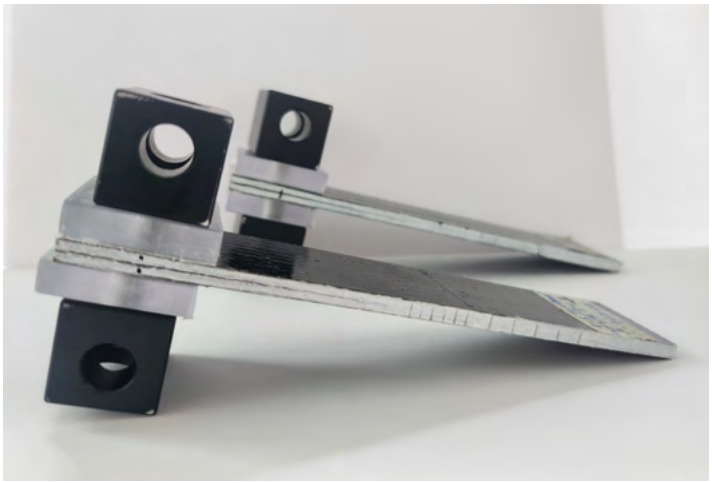

Figure 1. DCB samples of BFRP and epoxy with 0.5 wt.% of star-like polymers for Mode I interlaminar fracture toughness.

Scanning electron microscopy was performed to check the interlaminar damage created post-failure.

3. Results and Discussion

3.1. Tensile properties of BFRP

To investigate the effect of the star-like polymer on the biobased matrix, different wt.% epoxy specimens were fabricated. The tests (Figure 2) showed that with increase in the wt.% of star-like polymers, the properties degrade, owing to the fact that with increase in star-like polymer content, viscosity of the mixture increases. High viscosity causes trapping of bubbling and formation of voids and hence weaker tensile strength. Addition of 1 wt.% of star-like polymer showed the highest improvement in properties.

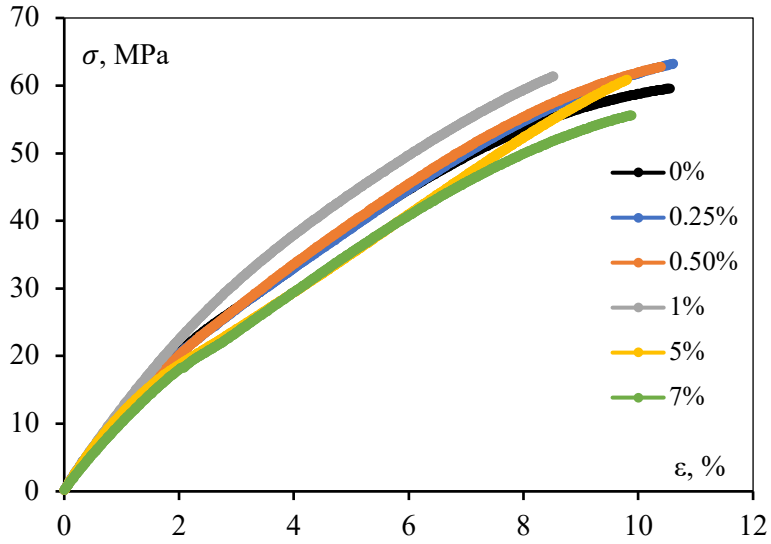

Figure 2. Stress vs strain curves for modified biobased matrix.

3.2.Thermomechanical properties of BFRP

DMA is a commonly employed technique for investigating the viscoelastic characteristics of polymers in response to oscillating forces. It aids in understanding the mobility of polymer chains and provides insights into their thermomechanical properties. DMA plays a crucial role in determining the glass transition temperature of polymers. Amorphous polymers exhibit distinct glass transition temperatures, beyond which they transition from a glassy state to a rubbery state, leading to a significant decrease in stiffness and viscosity.

The representative DMA curves for the storage modulus of the epoxy filled with different content of star-like polymers - 0, 0.25, 0.5 and 1 wt.%, is shown in Figure 3. The storage modulus increased with the increase of the star-polymer content except for 0.25 wt.%, revealing higher resistance to the dynamic loading at all temperatures. The highest storage modulus was registered for epoxy filled with 0.5 wt. % of the star-like polymers.

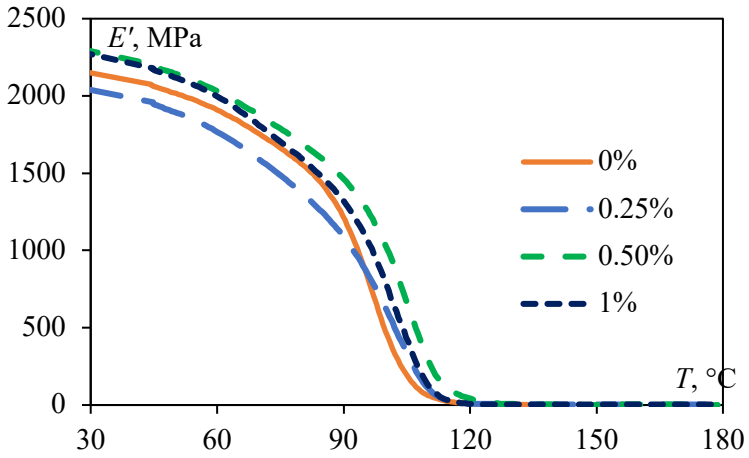

Figure 3. Storage modulus vs. temperature for the epoxy resin filled with the star-like polymers.

Figure 2 shows that the storage modulus decreased dramatically at the glass transition. Thus, evaluated at the maximal value of loss modulus, the glass transition temperature as a function of the star-like polymer content slightly increased by 7.6 °C, proving some reinforcement effect of the filler particles. Small data scattering was obtained for the identical material specimens, proving the repeatability of the results and sufficient quality of the test specimens.

3.3. Interlaminar fracture toughness of BFRP

In the DCB test, as the delamination grows from the insert, the resistance-type fracture behaviour typically develops where the calculated G_{Ic} increases monotonically and stabilizes with further delamination growth. The fracture toughness is assessed by the delamination resistance curve (G_{Ic} versus a) obtained from DCB tests, at the point where deviation from linearity occurs in the load-displacement curve.

To estimate Mode I interlaminar fracture toughness, the modified beam theory equation (Eq. 1) was used to correct the rotation at the delamination front by treating the DCB as if it contained slightly longer delamination, $a + \Delta$, where Δ is determined experimentally by generating a least-squares graph of the cube root of compliance, $C^{1/3}$, vs. delamination length:

$$G\,I\, = \, 3P\delta\,2b\,a + \,\Delta\,\,\,, \tag{1}$$

where P represents the load, δ denotes the displacement at the load point, b stands for the width of the specimen, and a indicates the delamination length of the specimen.

For the specimens incorporating loading blocks, two correction parameters are suggested [3]: a parameter F, which adjusts for the shortening of the moment arm and the tilting of the end blocks, and a parameter N, which compensates for the stiffening effect of the blocks on the specimen:

$$F = 1 - \,3\,10\, \,\delta\,a\,\,\,2\, - \,3\,2\, \,\delta t\, \,a\,2\,\,\,, \tag{2}$$

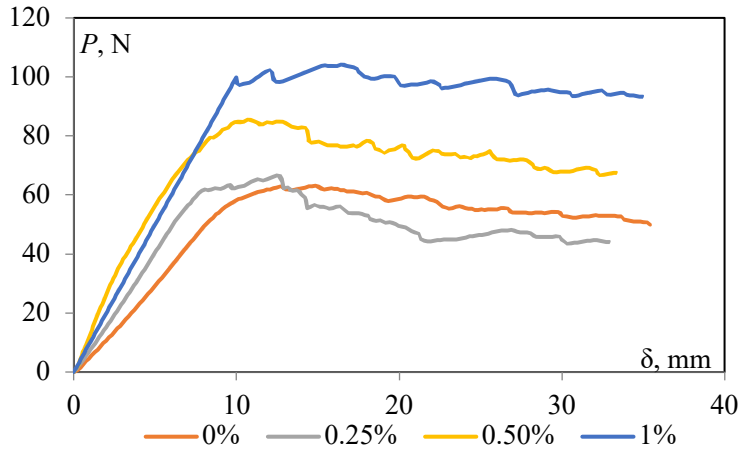
$$N = 1 - \quad L\,'\,\,a\,\,\,3\, - \,9\,8\, \,1 - \quad L\,'\,\,a\,\,\,2\,\,\, \,\delta t\, \,a\,2\,\,\,\, - \,9\,35\, \,\delta t\, \,, \tag{3}$$

where L' and t are the geometrical parameters of the blocks.

Then, the corrected formula for interlaminar fracture toughness by using the modified beam theory method takes the form:

$$G_I = \frac{3P\delta}{2b}\left(a + |\Delta|\right) \cdot F_N. \quad (4)$$

Representative load-crack opening displacement (COD) curves obtained for BFRP impregnated with the epoxy with different star-like polymer content are provided in Figure 4. A rather significant deviation among the data was observed, which is typical for such tests. The fracture toughness evaluated by Eq. (4) for BFRP impregnated with the epoxy is shown in Figure 5.



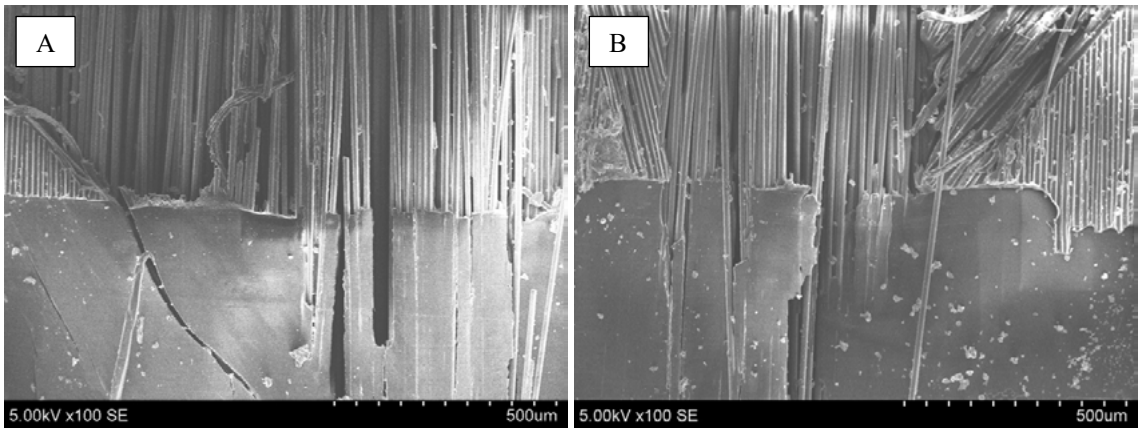


Figure 4. Representative load-COD curves from DCB tests for BFRP impregnated with the epoxy at different contents of star-like polymers as indicated on the graph.

3.4. Characterisation post failure

Scanning electron microscopy on the laminates post interlaminar fracture was conducted. It can be seen in Figure 6 that with increasing wt.% of star-like polymer, less matrix cracking around the edge of the specimen is visible. Neat matrix specimens appear to have larger and highly propagated cracks while modified specimens have smaller crack and a very intact matrix layer.

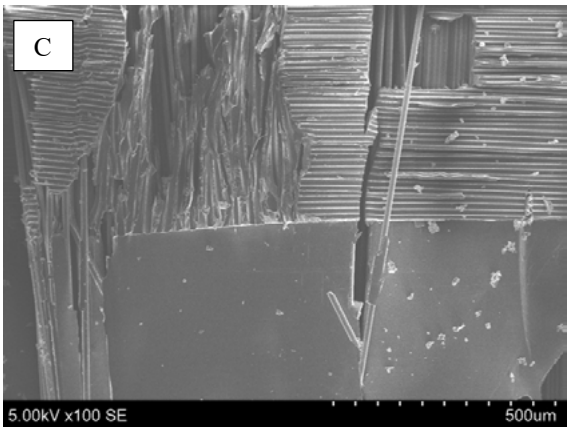

Figure 6. SEM images of damage post interlaminar fracture toughness tests on BFRP **A** - neat epoxy; **B** - 0.5wt.%; **C** - 1wt.%

4. Conclusions

The epoxy resin was modified by the addition of star-like polymers (poly(n-butyl methacrylate)-(glycidyl methacrylate) block copolymer) of different wt.% and used for the impregnation with basalt fibres. Tensile tests showed that smaller weight percentage of the star-like polymer presented better results. It was observed that the effect of star-like polymers on interlaminar fracture toughness properties of BFRP was substantial, leading to an improvement of 68%. Moreover, a slight increase of 7.6°C in the glass transition temperature was observed in the epoxy filled with star-like polymers. This could be ascribed to the heightened crosslink density and toughening impact of the star-like polymer, indicating their integration into the epoxy continuous phase and potentially enhancing adhesion between the epoxy matrix and basalt fibres. Scanning electron microscopy showed more damage in neat epoxy when compared to modified star-like polymer specimens.

Keywords: Carbon/PEEK thermoplastic composite, Automated Fiber Placement (AFP), In-situ consolidation, Representative Volume Element (RVE), Random microstructure.

Abstract
Despite facing certain challenges, the Automated Fiber Placement (AFP) process offers a feasible and cost-effective alternative to costly and time-consuming traditional manufacturing techniques, such as hand lay-up and autoclave processes. The present research focuses on predicting the effective in-plane elastic moduli, E_1 and E_2, of in-situ-consolidated Carbon/PEEK thermoplastic composite material by generating two-dimensional Representative Volume Elements (RVEs) at the micro-scale. In order to consider the influence of fiber volume fraction, void content, degree of crystallinity, and interlaminar resin pockets in the simulation, two sample groups were fabricated using the AFP in-situ consolidation and autoclave re-consolidation techniques. These specimens were evaluated through a micrographic study and thermoanalytical Differential Scanning Calorimetry (DSC) method to gather the necessary inputs for micromechanical analysis. It was shown that the AFP in-situ consolidation may cause decreases close to 7% and 10% in the elastic moduli of Carbon/PEEK thermoplastic composite material in fiber and transverse directions, respectively.

1. Introduction

To manufacture a composite laminate, a robotic arm and a fiber placement head, either thermoset or thermoplastic, work together in the robotic AFP machine that is capable of positioning narrow composite tows close to one another on a mandrel. In this process, heat and compressive force are simultaneously applied using a compaction roller and a heating system, such as a hot gas torch. The lengthy and expensive curing process associated with thermoset composites has prompted a more frequent adoption of their thermoplastic counterparts as substitutes. One notable advantage of manufacturing thermoplastic composites is the potential for in-situ consolidation during the AFP process. However, a significant discrepancy in quality exists between the in-situ-consolidated and the autoclave-treated thermoplastic composites due to crucial factors including fiber volume fraction, void content, interlaminar resin pocket and degree of crystallinity, arising from short AFP processing time [1–3].

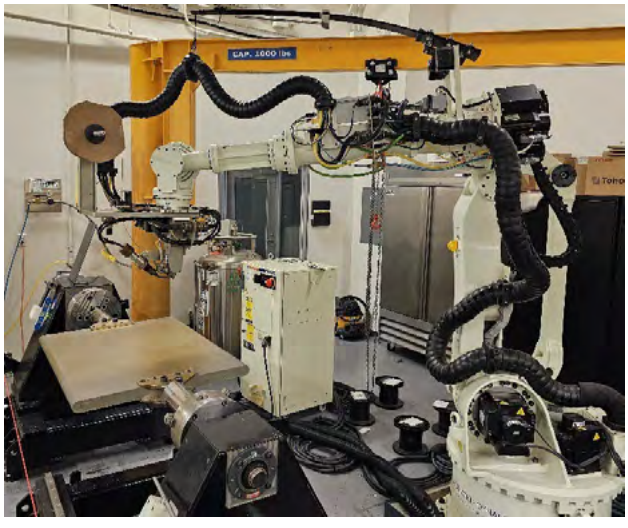
While experimental methods are indispensable for evaluating material properties, mechanical testing of unidirectional thermoplastic composite specimens presents difficulties owing to the warpage occurring throughout the AFP in-situ consolidation process. Micromechanical computational models provide a valuable source to conduct virtual experiments and analyse different material systems in the design

phase. Although the utilization of the Representative Volume Element (RVE) technique allows researchers to simulate diverse microstructures along with their constituents, shapes, orientations and distribution, the generation of an RVE that can accurately capture the mechanical behaviour and response of long-fiber-reinforced composites with high fiber volume fraction poses significant modeling challenges [4]. To achieve this objective, various algorithms have been devised by different researchers, such as Random Sequential Adsorption (RSA) [5], Random Sequential Expansion (RSE) [6], Random Microstructure Generator (RAND_uSTRU_GEN) [7], etc., aiming to enhance the authenticity of the generated RVE model with non-uniform distribution of fibers.

While fiber volume fraction is the determining factor for material response in fiber direction, the existence of voids, interlaminar resin pockets and the variation in the degree of crystallinity have a significant impact on the material properties in the transverse direction. As a result, in the present research work, both longitudinal and transverse cross-sections of Carbon/PEEK thermoplastic composite material were investigated by generating the corresponding 2D Representative Volume Elements (RVEs) with randomly distributed fibers at a micro-scale. To incorporate sufficient details into the micromechanical simulation, micrographic study and thermoanalytical Differential Scanning Calorimetry (DSC) analysis were performed on two groups of Carbon/PEEK thermoplastic composite samples manufactured by in-situ consolidation and autoclave re-consolidation. The RVEs were exposed to Periodic Boundary Conditions (PBCs). The Asymptotic Homogenization Theory (AHT) was employed to predict the effective in-plane elastic moduli of the material resulting from the AFP in-situ consolidation manufacturing process. The modeling procedures were executed using an ABAQUS Scripting Interface (ASI) scripted in the Python programming language, supplemented by MATLAB, which defined the RVE geometry. The obtained results will be very useful in the finite element modeling, analyses, and design of thermoplastic composite laminates that are manufactured by the AFP process.

2. Manufacturing procedure

An HGT-assisted Automated Fiber Placement (AFP) machine comprising a 6-axis Kawasaki articulated robot arm boasting a 125 kg payload, outfitted with a thermoplastic head provided by the Trelleborg Group, is available to researchers at the Concordia Centre for Composites (CONCOM), as shown in Figure 1. Unidirectional AS4/APC-2 tape from the Solvay Group [8] with a weight ratio of 68:32, a fiber volume fraction of 60% and a thickness of 0.140 mm was used for manufacturing two laminates. During the AFP in-situ consolidation, processing parameters of hot gas torch temperature, Nitrogen flow rate, compaction force and deposition rate were set to 875° C, 80 SLPM, 266.9 N and 50.8 mm/s, respectively, which are in good agreement with optimum values suggested in the literature [9].



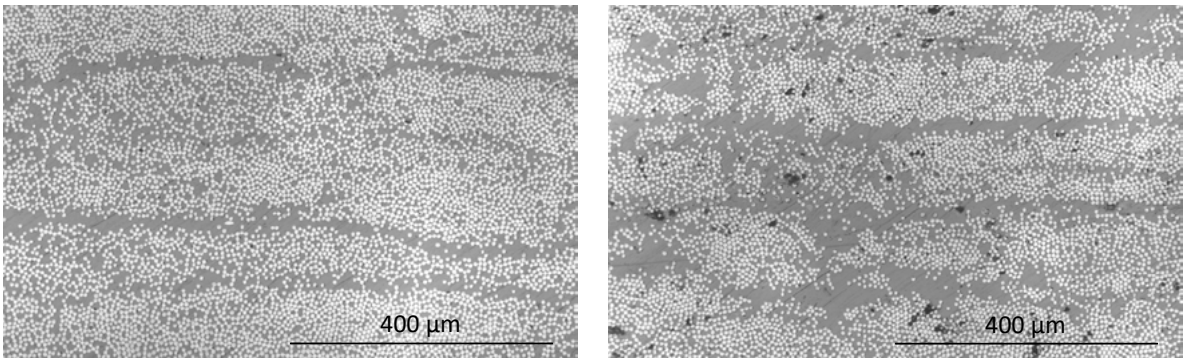


Figure 1. HGT-assisted Automated Fiber Placement (AFP) machine at CONCOM.

The second in-situ-consolidated Carbon/PEEK thermoplastic composite laminate was vacuum-bagged and then treated in an autoclave at temperature and pressure of 390° ± 10° C and 100 ± 5 psi, respectively, for 20 ± 5 minutes to serve as a baseline [8].

3. Micrographic study and DSC analysis

Understanding the microstructure of Carbon/PEEK thermoplastic composite samples fabricated through autoclave re-consolidation and AFP in-situ consolidation can help to identify the causes of distinctions in their mechanical properties. Samples from both types of laminates were cut and polished before being examined under a microscope. Micrographic study of the specimens highlights significant differences between thermoplastic composite laminates produced by AFP in-situ consolidation and autoclave re-consolidation processes in terms of fiber volume fraction, void content and interlaminar resin-rich areas, as depicted in Figure 2, leading the mechanical performance of the final product to be adversely affected. The color thresholding technique, implemented by *ImageJ* software, was employed to calculate void content and fiber volume fraction by differentiating between voids, fibers, and resin. For this purpose, thirty Representative Volume Elements (RVEs) were randomly chosen from diverse positions within the micrographs, each maintaining a consistent size equivalent to the thickness of each composite layer, which is 140 µm. These RVEs were employed to quantify key factors, including fiber volume fraction, void content, and the percentage of interlaminar resin pockets (for more information on how to measure each factor precisely, see Ref. [10]). The mean values of each factor caused by in-situ consolidation and autoclave re-consolidation manufacturing methods are listed in Table 1.

(a) Autoclave re-consolidation (b) AFP in-situ consolidation

Figure 2. Microstructure of Carbon/PEEK samples manufactured by (a) autoclave re-consolidation and (b) AFP in-situ consolidation at 20X magnification.

Table 1. Mean values of fiber volume fraction, void content and percentage of interlaminar resin pocket calculated from the micrographic study.

	Autoclave re-consolidation	AFP in-situ consolidation
Fiber volume fraction (%)	60	56
Void content (%)	0	1.5
Interlaminar resin pocket (%)	0	12

The other influential factor is the degree of crystallinity, quantifiable through Differential Scanning Calorimetry (DSC) analysis. To this end, 10 mg samples from each in-situ-consolidated and autoclave-reconsolidated Carbon/PEEK thermoplastic composite material underwent a heat-cool-heat cycle. The process involved heating at a rate of 10 °C/min, reaching a maximum temperature of 390 °C in a Nitrogen atmosphere, followed by a cooling rate of 5 °C/min. The following equation is used to calculate the degree of crystallinity, X, [1]:

$$X = \frac{\Delta H_m - \Delta H_c}{\Delta H_f (1 - \alpha)} \quad (1)$$

where α is the weight ratio of Carbon fibers in the Carbon/PEEK thermoplastic composite tape. ΔH_m, ΔH_c and ΔH_f denote the enthalpies of fusion at endothermic melting point, at exothermic crystallization peak and for fully crystalline PEEK, respectively. The outcomes of the DSC examination are displayed in Table 2, containing mean values of the degree of crystallinity and melting temperature derived from no fewer than five specimens manufactured by each technique.

Table 2. Mean values of the degree of crystallinity resulting from AFP in-situ consolidation and autoclave re-consolidation processes.

	Crystallinity (%)	SD*	Melting temperature (°C)	SD*
AFP In-situ consolidation	25.07	0.82	345.31	0.17
Autoclave re-consolidation	34.96	0.38	345.52	0.15

*SD = Standard Deviation

The effect of the degree of crystallinity on the elastic modulus of neat PEEK resin was examined in many research works, showing an approximately linear correlation between the degree of crystallinity and the elastic modulus. As a result, for every 5% drop in the degree of crystallinity from the baseline, that is 35%, a 4% decrease in the elastic modulus of neat PEEK resin was taken into consideration in the present study [11].

4. Finite element modeling

Creating randomly distributed fibers in a Representative Volume Element (RVE) with a fiber volume fraction surpassing 50% poses a significant difficulty because programming languages, including MATLAB and Python, have limitations in identifying appropriate locations solely through random generators for adding new fiber center points. The methodology applied in the present work adheres to the algorithm introduced by Melro *et al.* [7] and refined by Ghayoor *et al.* [12], which entails repositioning the most isolated fibers within the RVE to achieve an elevated fiber volume fraction, such as 60%.

To take into account the effect of interlaminar resin pockets on the prediction of in-plane elastic moduli, constraints were imposed on the top and bottom boundaries of the Representative Volume Element (RVE) to keep fibers closer together. This involved limiting the randomly generated center points of fibers within a certain percentage range of the RVE length in the y-direction, such as between 6% and 94% to create a 12% interlaminar resin pocket. While maintaining a constant fiber volume fraction, this process shifted fibers toward the center, resulting in the formation of resin-rich areas at the top and bottom edges of the RVE, resembling the observations from the micrographic study.

Regarding the generation of voids, the Random Sequential Adsorption (RSA) technique [5] was implemented to randomly assign locations for voids inside the RVEs. If the selected position coincides with the area already occupied by fibers, a new point is generated; otherwise, the void radius is randomly chosen within the range of 0 to the distance between the void and its closest fiber. This procedure is repeated until the void content reaches the predetermined threshold, that is 1.5% as listed in Table 1.

To predict the elastic moduli of Carbon/PEEK thermoplastic composite material in the fiber (E_1) and transverse (E_2) directions through two-dimensional micromechanical analysis, distinct Representative Volume Elements (RVEs) are required, generated based on the longitudinal and transverse cross-sections. The finite element analysis conducted for both types of RVEs in ABAQUS is identical, except for the method employed to generate the geometry using MATLAB programming code. For the longitudinal cross-section, fibers may exhibit full radii or be partially visible on the surface of the composite material, depending on their actual position within the structure. To this end, the simulation

approach for the longitudinal-cross-section RVE must involve generating random radii for fibers in addition to their random locations, whereas fibers' radii remain constant in the RVE depicting the transverse cross-section of the composite material. Thus, MATLAB code already written for RVE generation based on the transverse cross-section was developed, particularly in terms of the compatibility conditions to prevent any intersections between either fibers or fibers and voids, to create those inspired by longitudinal cross-section from the ground up. The final geometries of these RVEs, representing AFP in-situ consolidation and autoclave re-consolidation processes, are illustrated in Figure 3 based on their respective cross-sections. It should be noted that in the case of the longitudinal cross-section, the percentage of the fiber volume fraction might be either higher or lower than that calculated in the transverse cross-section, depending on the location of the cut. Therefore, the average values, listed in Table 1, were considered for the generation of longitudinal-cross-section RVEs representing each manufacturing process.

After determining the positions of fibers and voids within the Representative Volume Element (RVE) to meet the specified fiber volume fraction, void content and percentage of interlaminar resin pocket, a micro-scale numerical analysis of both random and periodic microstructures was conducted by considering ideal bonding between fibers and matrix. This analysis was executed using the ABAQUS Scripting Interface (ASI) written in the Python programming language. To this end, the Representative Volume Element (RVE) was defined with a length of 140 µm, aligning with the thickness of individual Carbon/PEEK layers. The Carbon fibers, with a diameter of 7 µm, were positioned at a minimum distance of 0.01 times the fiber radius. Triangular 3-node linear plane strain elements (CPE3) sized at one-fourth of the fiber radius were employed for the analysis [10]. Table 3 presents the material properties of the PEEK resin and Carbon fiber, constituents of the thermoplastic composite material, used in the numerical analysis.

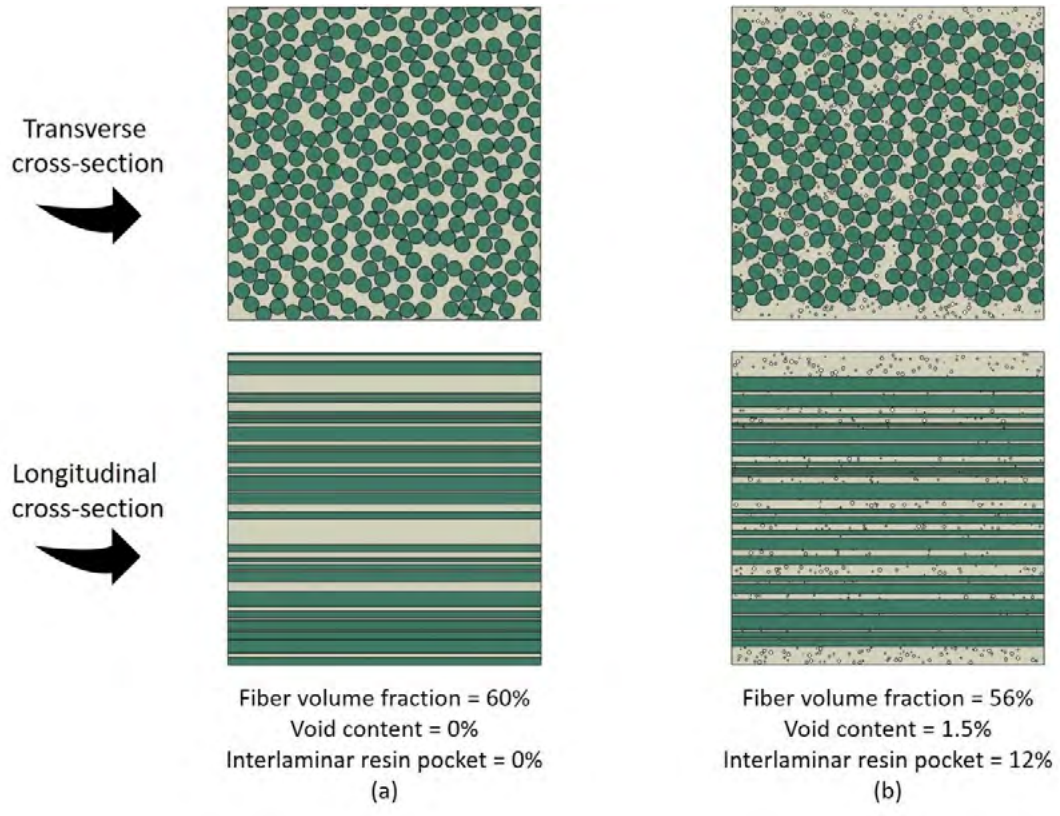

Figure 3. Typical geometry of RVEs by considering the variations of fiber volume fraction, void content and interlaminar resin pocket: (a) Autoclave re-consolidation and (b) AFP in-situ consolidation.

Table 3. Material properties of PEEK resin and Carbon fiber in principal directions [8].

	E_1 (GPa)	$E_2 = E_3$ (GPa)	$\nu_{12} = \nu_{13}$	ν_{23}
Carbon fiber (AS4)	228	22	0.20	0.25
PEEK resin (APC-2)	3.6	3.6	0.38	0.38

Composite materials are commonly modelled as an arrangement of periodic Representative Volume Elements (RVEs), requiring the imposition of Periodic Boundary Conditions (PBCs). These conditions guarantee compatible deformation across all RVEs, preventing overlap or separation between adjacent units. The utilization of Periodic Boundary Conditions (PBCs) in conjunction with the RVE approach proves to be an effective method for homogenization and microstructural analysis. The definition of periodic boundary conditions is as follows [13]:

$$u_i^{j+} - u_i^{j-} = \bar{\varepsilon}_{ik}\left(x_k^{j+} - x_k^{j-}\right) = \bar{\varepsilon}_{ik}\Delta x_k^j \tag{2}$$

where u_i and $\bar{\varepsilon}_{ik}$ denote the displacement and average strain of a point on the RVE boundary, respectively. x_k represents the cartesian coordinate of the point. Superscripts $j+$ and $j-$ are used to index the jth pair of parallel opposite edges in an RVE.

It is generally assumed that the mean mechanical characteristics of the RVE align with those demonstrated by the unidirectional composite lamina at the macrostructural level. Effective material properties of a Representative Volume Element (RVE) can be determined using the homogenization theory based on how it reacts to different loading conditions. The calculation of in-plane elastic moduli entails subjecting the RVE to horizontal displacement. Figure 4 shows the boundary conditions and tension loading case to which the RVEs are exposed. Subsequently, the equations provided below can be utilized to compute E_1 and E_2, depending on the chosen cross-section type in the simulation, whether it is longitudinal or transverse [7]:

$$E_1 = \frac{\bar{\sigma}_{11}}{\bar{\varepsilon}_{11}}, \qquad E_2 = \frac{\bar{\sigma}_{22}}{\bar{\varepsilon}_{22}} \tag{3}$$

where $\bar{\sigma}$ and $\bar{\varepsilon}$ are volume average stress and strain, respectively [13].

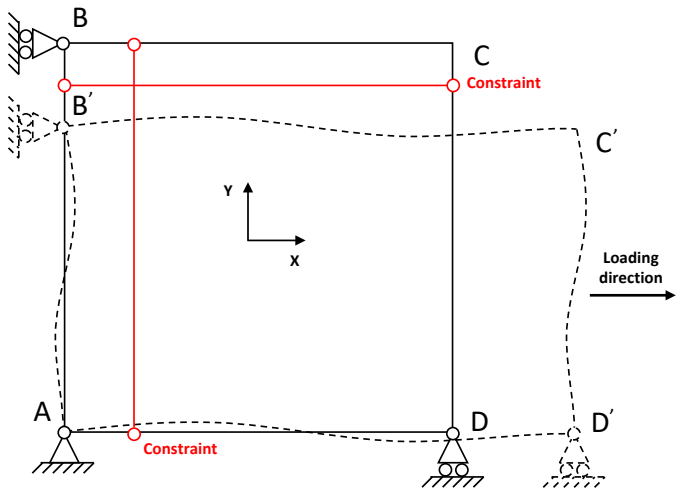

Figure 4. Schematic of an initial and deformed RVE subjected to PBCs under tension loading case.

5. Results

To verify the validity of the results of finite element analysis, Representative Volume Elements (RVEs) were generated with a fiber volume fraction of 60% and without void content and interlaminar resin pockets to simulate autoclave manufacturing conditions. The evaluation of numerical outcomes against the CYTEC technical data sheet [8], as listed in Table 4, demonstrated that the proposed finite element model exhibits proficiency in predicting the effective in-plane elastic moduli of Carbon/PEEK thermoplastic composite material, with an error margin of less than 5%.

Following the validation of the proposed Finite Element (FE) model, the influence of AFP in-situ consolidation manufacturing process can be explored by modifying the values of the four identified key factors. This modification is aimed at generating Representative Volume Elements (RVEs) that accurately simulate Carbon/PEEK thermoplastic composites undergoing in-situ consolidation. The predicted in-plane elastic moduli resulting from the different manufacturing techniques are presented in Table 4. Based on the findings, the application of AFP in-situ consolidation resulted in a reduction of the elastic moduli in the fiber and transverse directions by 6.83% and 10.43%, respectively, in comparison with autoclave re-consolidation.

Table 4. Prediction of in-plane elastic moduli of Carbon/PEEK thermoplastic composite material manufactured by AFP in-situ consolidation and autoclave treatment.

	Cytec Data [8]	Autoclave re-consolidation	AFP in-situ consolidation	Difference* (%)
$E_1\ (GPa)$	138	139.44	129.92	6.83
$E_2\ (GPa)$	10.3	10.45	9.36	10.43

*With reference to the values that correspond to the autoclave re-consolidation process.

It should be noted that although the effects of four factors were attempted to be considered during the simulation of RVEs representing the in-situ consolidation process, their relative significance is not the same in the prediction of E_1 and E_2 using the longitudinal and transverse cross-sections. Since void content, interlaminar resin pockets, and degree of crystallinity are associated with the matrix phase in composite materials, they significantly influence the prediction of the transverse elastic modulus (E_2). However, the primary factor impacting the behaviour of composite material in the fiber direction (E_1) is the fiber volume fraction. To demonstrate this, the fiber volume fraction was reduced to 56% while the remaining three factors were maintained unchanged (i.e., the values resulting from autoclave treatment conditions as detailed in Table 1).

Table 5. Influence of fiber volume fraction on the elastic moduli in fiber and transverse directions.

	60% fiber volume fraction	56% fiber volume fraction	Difference (%)
$E_1\ (GPa)$	139.44	131.36	5.79
$E_2\ (GPa)$	10.45	9.72	6.98

According to the results shown in Table 5, the decrease of (only) fiber volume fraction to 56% caused the elastic modulus in the fiber direction to be reduced by 5.79%, which is the majority part of the reduction presented in Table 4. In other words, the presence of voids and interlaminar resin pockets and the change in the degree of crystallinity have minimal effects on the elastic modulus in fiber direction. Nonetheless, these matrix phase-related factors exert a significant influence on the transverse elastic modulus and take up a good portion of the decline listed in Table 4.

6. Conclusion

The use of in-situ consolidation through Automated Fiber Placement (AFP) presents advantages in terms of time and cost efficiency when compared to the traditional autoclave method for the fabrication of thermoplastic composite materials. Nonetheless, challenges emerge due to the shorter AFP processing time in which heat and pressure are applied, along with a higher cooling rate, in contrast to the more

extended autoclave curing. This constrained exposure has adverse effects on fiber volume fraction, void content, fiber distribution, and degree of crystallinity, which determine the mechanical response of composite materials.

In the present research, two groups of Carbon/PEEK thermoplastic composite samples were manufactured by AFP in-situ consolidation and autoclave re-consolidation techniques. Specimens from both groups underwent micrographic study and DSC analysis to acquire input data required for the micromechanical simulation. Two-dimensional RVEs at the micro-scale were generated in accordance with the longitudinal and transverse cross-sections to predict the in-plane elastic moduli of Carbon/PEEK thermoplastic composite material. The results revealed that AFP in-situ consolidation can lead the elastic moduli in fiber and transverse directions to be reduced by 6.83% and 10.43%, respectively. These variations in material properties are of great importance and must be considered in further numerical analysis of Carbon/PEEK thermoplastic composites manufactured by AFP in-situ consolidation method.

Abstract

The research compares two modular design concepts for T-joints in segmented wind rotor blades, focusing on sustainability and efficiency of the bonding in load-bearing applications. The study incorporates the use of End-of-Life (EoL) material to improve environmental sustainability through recycling and reuse of disassembled rotor blade parts. The first concept uses a high viscous epoxy adhesive with specific additives. Local stress concentrations are reduced by applying adhesive fillets and a machined radius surface to the EoL material. This joint design increases the load capacity of the T-joint. In contrast, concept II combines cleats with a thin layer of adhesive, which enables the use of low viscosity adhesives. The second concept significantly reduces adhesive consumption and improve repair- and reusability. A numerical simulation with volume and cohesive elements has shown that concept II not only reduces adhesive consumption, but also achieves a 50 % higher load capacity per joint weight compared to concept I under bending load. Experimental bending tests of T-Joints were used to validate these numerical results. Thus, concept II with an optimized cleat design and minimized adhesive consumption offers significant advantages for sustainable modularity in segmented rotor blade designs. As a result, global goals like reducing the environmental impact and improving the life cycle management of wind rotor blades can be achieved.

1. Introduction

In relation to the increasing importance of renewable energy resources, the continuous development of wind power turbines is essential. To strengthen the sustainability of wind turbines, the design of conventional wind rotor blades must be reworked. An approach describes the division of wind rotor blades into several manageable segments. This simplifies the transportation and assembly of wind rotor blades as well as the replacement of segments that have been damaged during operation [1]. Even after the product life cycle of a wind rotor blade, the segmentation allows the return of intact components to the life cycle of new wind rotor blades. The modular design thus offers a high recycling potential. Within a research project a modular design for an 8m rotor blade will be developed. The design differs from conventional rotor blades consisting of an outer skin and web components. Instead, the modular rotor blade design is inspired by an aircraft wing, in which the load-bearing structure is formed by a pultruded composite spar and attached ribs. To further increase the sustainability of the design, the rib structure shall be machined from decommissioned wind rotor blade shells.

Within a conventional rotor blade, the final assembly step always produces an undefined blind bonded joint. The final segment is applied to the load-bearing inner structure without ensuring a complete connection between the adherends. The blind bonded joint is assumed to lead to reduced bonding properties. Furthermore, this blind connection consumes more adhesive than a defined adhesive joint. The additional adhesive mass can lead to a break-off during the service life, resulting in a clump of adhesive damaging the inner structure of the rotor blade with every revolution [2].

Mendoza et al. [3] conducted a study on the segmentation of wind rotor blades in which the influence of added masses at different joint connections on the natural frequencies of the rotor blade was investigated. The results show that adhesive joints cause a smaller increase in the total mass compared to mechanical joints. Thus, the influence of adhesive joints on the natural frequencies of a wind rotor blade is less than that of mechanical joints. For an assembly of segments, adhesive bonds should be preferred. A drawback of adhesive joints is the missing option for a non-mechanical debonding. A mechanical debonding often leads to damages on adjacent components and thus prevents a reuse. Another solution is offered by thermal debonding-on-demand adhesives. These adhesives include thermally expandable particles (TEPs) that expand when heat is applied and cause a cohesive separation of the adhesive bond line. This technology allows for a debonding without damaging the individual rotor blade components. However, various studies of quasi-static tests have shown that TEPs can lead to a reduction in tensile and shear strength of up to 15 % [4, 5].
The described technologies and the segmented design results in a wide range of different bonded joints. An important adhesive joint describes the connection of the load-bearing inner structure to the aerodynamic outer skin, which results in a T-joint. This paper will discuss two different concepts of T-joints in terms of design and mechanical performance. For this purpose, numerical models with volume and cohesive elements are developed and the joints are subjected to a bending load. In addition, the influences of different joining materials, adhesives, thermally expanding particles, and adhesive fillet designs are discussed. To reach a final conclusion the two concepts are compared by the load capacity per joint weight.

2. Adhesive T-joint in Segmented Wind Rotor Blades

2.1. Design concepts

Figure 1 presents two potential concepts for the T-joint connection of the rib structure and the outer skin of a modular wind rotor blade. Both concepts show a cut through the rib geometry for better visualization.

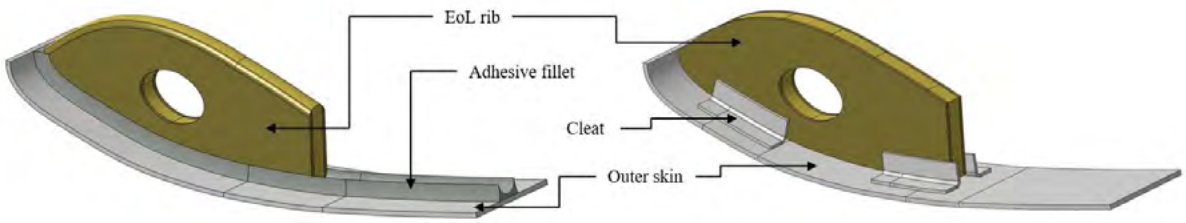

Figure 1. Design concept I (left) and II (right) for an adhesive T-joint in a rotor blade segment

Concept I is based on the vast adhesive joints of a conventional wind rotor blade (e.g. connection of the web structure to the outer shells). Within the rotor blade manufacturing industry there is a need for large bonding gaps between two components. The extensive bonding gaps are due to high safety factors and manufacturing tolerances. To reduce stress concentrations occurring at the corners of the T-joint, so-called adhesive fillets can be applied [6]. For the application of adhesive fillets, an adhesive with a sufficiently high viscosity is required. The range of adhesives is therefore limited. Stress concentrations can be further reduced by machining a radius surface on the bonding surface of the EoL rib [7]. Although this results in a higher production expenditure, it ensures complete and direct load transfer between the adherends. The design from concept I results in a T-joint with fully embedded ribs, see figure 1 left. This increases the likelihood of defects, such as air voids, which can significantly reduce the performance of an adhesive joint [8].
In concept II, the outer skin and the rib structure are not directly connected via an adhesive. The inner structure (EoL ribs) and the outer skin are joined together using cleat structures, to increase the modularity of the segmented wind rotor blades, see figure 1 right. Bhat et al [9] used shaped brackets to connect rotor blade segments, which connect web to web and outer skin to outer skin of conventional rotor blades. Based on cleats from the aviation industry, which connect the rib structure of frames and

stringers with the outer skin of the aircraft, the concept can be transferred to wind rotor blades. Concept II allows a load-optimized cleat design with free choice of material. To reduce the overall weight of the rotor blade, materials with low specific densities, such as aluminum or composites, can be selected. To increase the necessary load capacity, the contact surfaces of the cleats must be enlarged. In contrast to concept I, additional cleat structures allow the use of adhesives that are also suitable for low adhesive thicknesses. This reduces the amount of adhesive used within the rotor blade and therefore the likelihood of defects. Furthermore, the application of adhesive fillets and the machining of a radius surface to reduce stress concentrations is no longer necessary. To further reduce possible stress concentrations, the edges of the cleats can be chamfered [10]. A disadvantage for concept II is the non-planar and low quality surface of the EoL rib and the free-form surface of the aerodynamic skin. However, small deviations in the rib structure surface can be tolerated using a slightly bigger adhesive layer. Contrarily different rib geometries lead to a higher variety of cleat components with different surface dimensions. This increases the acquisition costs of tool molds and the production costs in general.

2.2. Materials

Both concepts use the same two materials for the outer skin and the rib structure to enable a comparison of the results. The rib geometry consists of an EoL glass fiber reinforced plastic (GFRP) sandwich laminate, which is obtained from a decommissioned rotor blade, see figure 2. In the previous product life cycle, the GFRP sandwich laminate formed the outer shell of the rotor blade, which was manufactured using vacuum resin infusion. Depending on the removal position, one of the two face sheets has a slightly bigger laminate thickness. After a pyro analysis of the laminates, a specific layup structure orientated in 0° and ±45° is obtained. The manufacturing process of the vacuum resin infusion also resulted in positions with an increased matrix content, which also influences the laminate thickness of the face sheets. In consequence, the exact laminate structure at every position of the outer skin is not known and can therefore only be assumed theoretically. An open-cell rigid foam with a core thickness of approximately 22 mm was used as the sandwich core. To determine the bending stiffness of the EoL sandwich laminate, three-point bending tests were carried out according to EN 310. This revealed a bending stiffness of approximately 7850 N/mm², see figure 2 right.

Figure 2. EoL rotor blade and bending test according EN 310 from Fraunhofer Wilhelm-Klauditz-Institut (Peter Meinlschmidt – E-Mail: peter.meinlschmidt@wki.fraunhofer.de)

The outer skin of the segmented rotor blade within this study is supposed to be made of a composite material. A carbon fibre reinforced plastic (CFRP) laminate made of pre-impregnated woven fabric is produced by INVENT. The laminate layup consists of a symmetrical, biaxial structure in 0/90°-direction with 24 laminate layers. For concept I the epoxy adhesive Adekit A170-1 was selected. This adhesive has a high viscosity which allows the manufacturing of thick adhesive gaps and geometric fillets. For the debonding case the adhesive is also combined with TEPs of the type Expancel 031 DU40 at 20 w.-%. For the lower bonding gap in concept II, the following adhesives from literature are selected. These include the adhesives Araldite AV138, Araldite A2015, Adekit A170-1 and SikaForce 7752.

3. Numerical Modeling of the Adhesive T-joints

Two numerical models are created to investigate the design concepts, including the various geometrical parameters for adhesive fillet (concept I) and cleat (concept II) (Figure 3). The models have a depth of 60 mm. The EoL rib specimen is perpendicular to the CFRP laminate specimen and is additionally loaded by a transverse load. This is a simplified representation of a load case resulting from the bending of the rotor blade due to the wind or inertial forces acting on it.

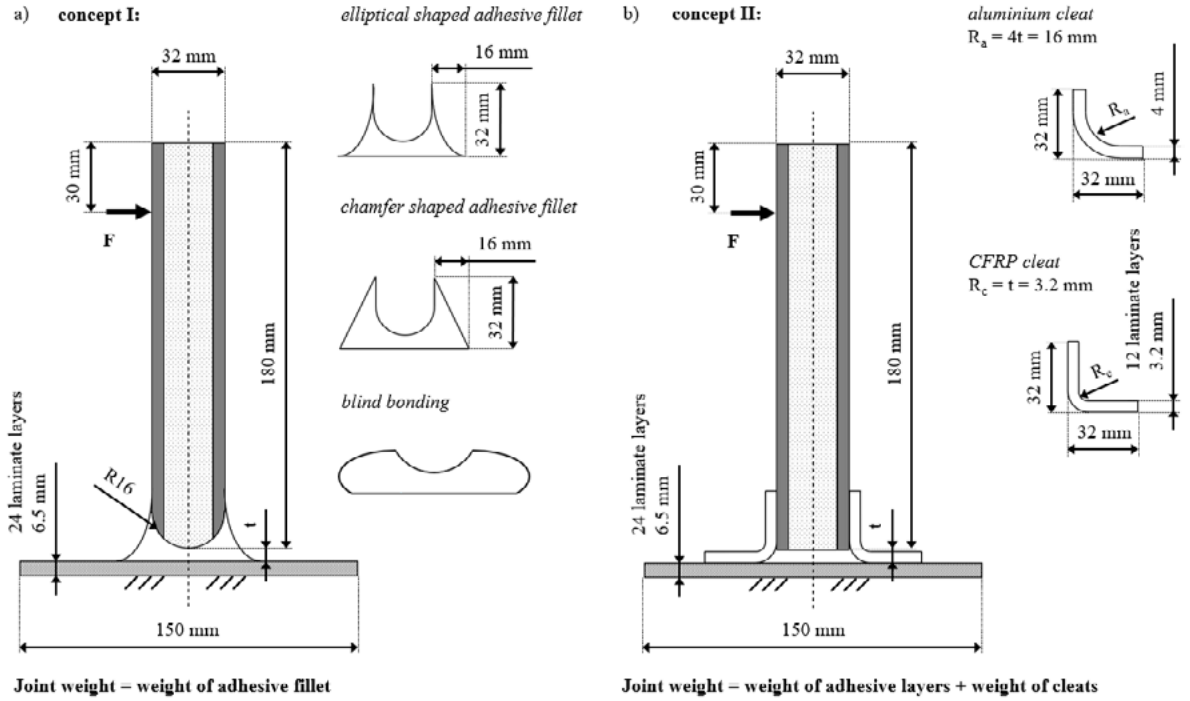

Figure 3. Cross section, dimensions and boundary conditions of the numerical model for design concept I (a) & II (b)

3.1 Material Parameters of the Adherends

To define the material parameters of the EoL material within the simulation software, a sandwich laminate is modeled whose face sheets consists of the layup $[(+45/-45/0)_3$ / core / $(+45/-45/0)_3]$. The bending load is applied to the face sheet with the outer layer of +45°. Each face-sheet has a total thickness of 5 mm. For the individual unidirectional layers of the face sheets, E-Glass fiber parameters from the Ansys database are assumed. An isotropic core body is placed between the face sheets. The shear stiffness of the core is adjusted iteratively until the bending stiffness of the EoL laminate matches the experimental bending tests according EN 310. This ensures a correct modeling of the bending stiffness of the EoL material for the bending load case. In the model, the nodal points of the face sheets and the foam core in contact are connected using a merge constraint type to increase convergence. The characteristic elastic values used for the semi-finished products can be seen in Table 1.

Table 1. Material parameters

Material	E_x [GPa]	E_y [GPa]	E_z [GPa]	ν_{xy}	ν_{yz}	ν_{xz}	G_{xy} [GPa]	G_{yz} [GPa]	G_{xz} [GPa]
GFRP UD	35	9	9	0,28	0,4	0,28	4,7	3,5	4,7
Foam Core	0,046	-	-	0,45	-	-	0,016	-	-
CFRP Woven	50,23	50,23	7,90	0,038	0,42	0,42	3,26	2,78	2,78
EN AW-7020	70	-	-	0,33	-	-	26,4	-	-

3.2 Model of Concept I

The adhesive fillet from concept I is numerically represented by a solid. To avoid inaccuracies in the stress or strain prediction, a mesh with a high meshing density and an element size of 1.2mm is defined [11]. The adhesive fillet is connected to the adherends via two joining surfaces by means of asymmetrical contacts. In addition, a material characteristic with multi-linear isotropic hardening is assigned to the adhesive joint. A maximum strain criterion of 2 % is defined for failure prediction according to the data sheet. Multiple numerical studies are carried out to determine an ideal fillet geometry. Additionally, to the influence of the thickness of the adhesive gap *t* between the adherends, the outer geometry of the fillet is investigated, see figure 4. Experimental tests of the different concept modifications are carried out to validate the simulations.

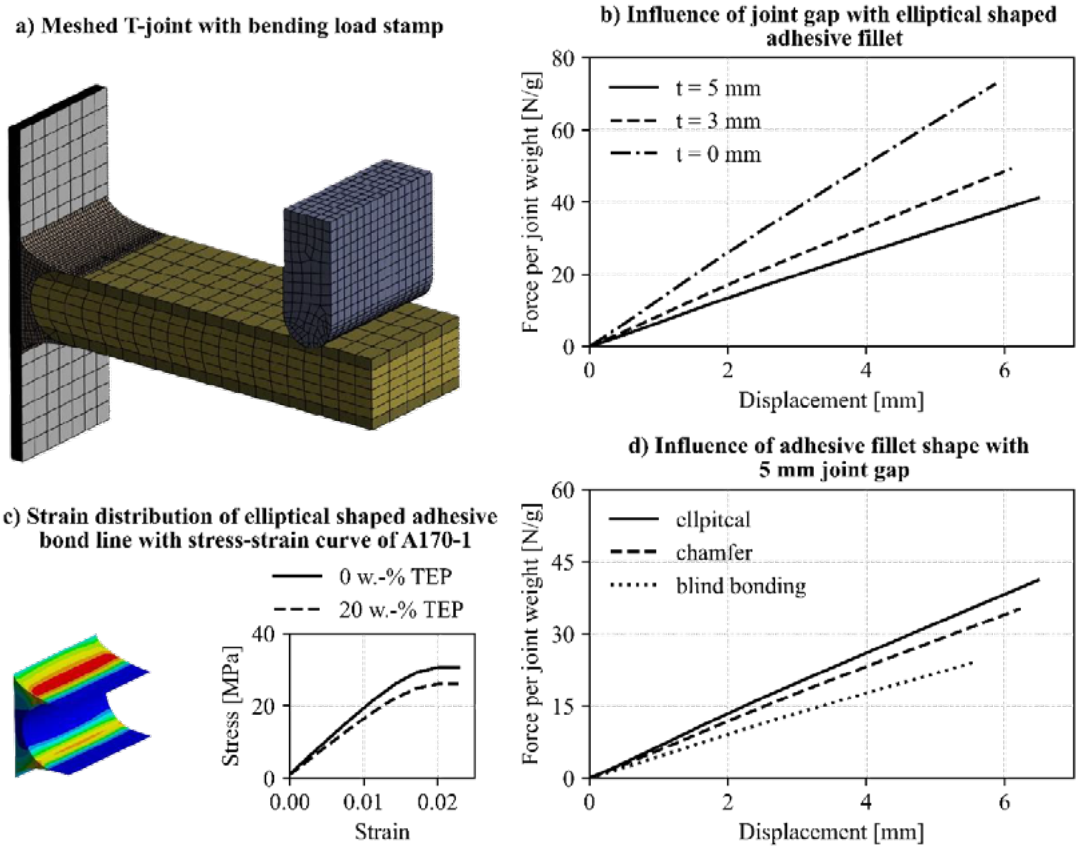

Figure 4. Results of numerical studies for concept I

The simulation demonstrates that for an elliptical shaped adhesive fillet an adhesive gap of 0 mm between the radius of the EoL rib and the outer skin achieves the highest load capacity per joint weight, see figure 4b. The fracture zone within the simulation is in line with the experimental results. A reduction of the adhesive gap with the same fillet geometry leads to an increase in the mass-related strength and stiffness of the T-joint, as there is less unstressed material between the adherends. Furthermore, the numerical simulations show that a fillet with an elliptical shape achieves the highest strength per joint weight and stiffness compared to the chamfer shaped adhesive fillet and the blind bonding, see figure 4d. The blind bonding in particular shows a significant drop in adhesive strength per joint weight by approximately 40 %. The experimental tests confirm this drop in strength. The main factor for the load capacity of the T-joint are the face-sheets of the EoL ribs. Thus, the reason for the decrease in strength is the reduced proportion of adhesive in contact with the face-sheets of the EoL rib. In addition, the test lot for the blind bonding tests show a standard deviation of over 60 %. To counteract this large standard deviation the safety factor should be increased. Blind bonding should therefore be avoided wherever possible.

Furthermore, the experiments exhibit that the use of TEPs results in a loss of strength. This must be considered within the model by scaling the material properties of the adhesive, see figure 4c. The reduction of mechanical properties due to the use of TEPs amounts to approximately 15 % in strength, which corresponds to previous studies from the literature [4, 5]. The corresponding downscaling of the modulus of elasticity is negligible within the simulation.

3.3 Model of Concept II

In the simulation model for concept II, the cleat is connected to the adherends via two contact definitions. These contacts are modeled with a contact modeling failure, which is defined by a bilinear traction separation law (TSL). The contacts represent the adhesive layers in the model using cohesive elements. The bonding gap is set to 0.2 mm and the contacts are assigned a corresponding contact stiffness K_n. The Mode I and Mode II behavior of the cohesive elements is coupled via a weighting parameter of two (default property of ansys). Within the material characteristics the damping factor is set to 0.01 s to increase the stability of the calculation. Finally, tangential sliding of the joining parts under normal pressure is blocked.
A literature review revealed various cohesive-zone model (CZM) material characteristics for structural epoxy adhesives, which are summarized in Table 2 [12]. These include the adhesives Araldite AV138 and Araldite A2015 from Huntsman and the Adekit A170-1 used in concept I. Numerous single lap shear tests were used to create the CZM material properties for the Adekit A170-1. The SF7752 adhesive from SikaForce is the only polyurethane (PU) based adhesive.

Table 2. Material parameters of adhesives for bilinear TSL characteristics [11]

Adhesive	E [GPa]	G [GPa]	t_n^0 [MPa]	t_s^0 [MPa]	G_{IC} [N/mm]	G_{IIC} [N/mm]	K_n [kN/mm^3]
AV138	4,89	1,56	39,45	30,20	0,20	0,38	24,45
A2015	1,85	0,56	21,63	17,90	0,43	4,70	9,25
A170-1	1,90	0,69	17,00	12,00	0,43	3,00	9,50
SF7752	0,49	0,19	11,48	10,17	2,36	5,41	2,45

Within concept II, numerical investigations with regard to the material of the cleats are also carried out. Aluminum EN AW-7020 and CFRP are applied, whereby the laminate structure of the CFRP is varied. Two biaxial laminate structures are chosen. The first is aligned at 0/90° and the second at ±45°.
The results of the numerical investigations in figure 5 show that under a bending load, the stiffness of the T-joint is mainly determined by the stiffness of the cleat. As a result, the CFRP cleats achieve a higher mass-related stiffness and strength compared to the aluminum cleat. A CFRP cleat with a more rigid 0/90°-laminate structure in bending attains the highest mass-related load capacity, see figure 5b. When using a CFRP cleat with a biaxial laminate structure of 0/90°-orientation, the structural epoxy adhesives AV138, A2015 and A170-1 are less effective than the more ductile PU adhesive SF7752 in terms of maximum joint weight-related force absorption, see figure 5c. This can be attributed to the increased fracture energy in Mode I, which delays the peeling of the upper cleat. In concept II it can therefore be assumed that a low strength in Mode I of a ductile adhesive can be compensated by a higher fracture toughness [13]. Furthermore, a PU adhesive should be preferred to a brittle epoxy adhesive for a T-joint under transverse loading.

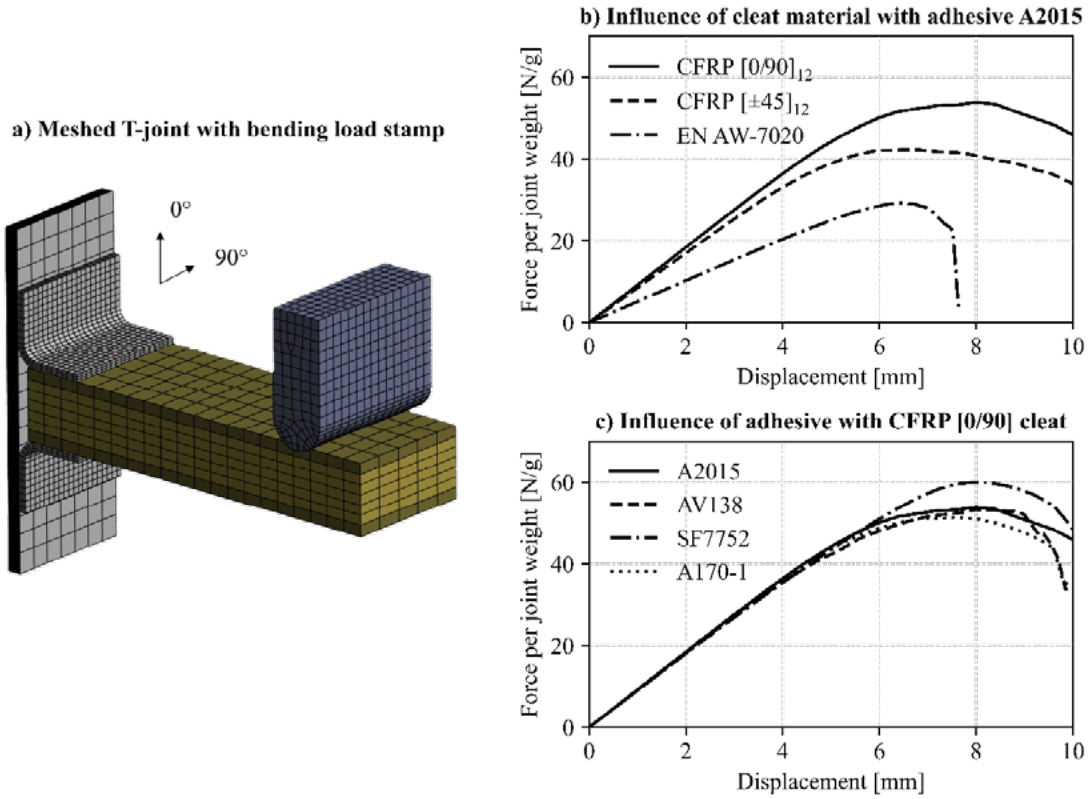

Figure 5. Results of numerical studies for concept II

4. Comparison of the Concepts

For the comparison of the concepts, the elliptical shaped adhesive fillet from concept I and the CFRP cleat with a 0/90°-layup from concept II are used. Both options are computed with regard to the highest maximum force per joint weight. The concepts are simulated with a 5 mm joint gap between the main adherends. The results from the numerical simulations are shown in figure 6 with respect to the force per joint weight, see figure 6a, and mass proportions, see figure 6b. In general, it should be stated that concept II surpasses the maximum strength by joint weight of concept I by approximately 50 %. Additionally, concept II achieves a higher maximum displacement with the more ductile PU adhesive.

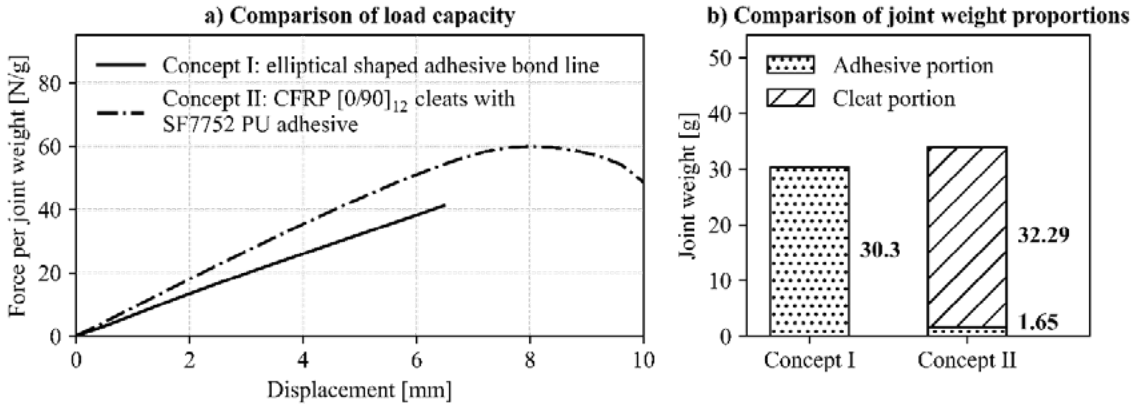

Figure 6. Comparison of configurations from concept I and II with a 5 mm joint gap

Considering the requirements of the industry, concept II is chosen for further development. The reason for this is the high adhesive consumption from concept I. In concept I the TEPs simplify the debonding

through the cohesive destruction of the adhesive bond line after a specific temperature application. The separation enables the reuse of the EoL rib and the FRP outer skin. However, for a new product life cycle, the adhesive fillet must be newly applied with a high adhesive consumption. In contrast, the adhesive consumption of concept II is significantly lower and reduces the amount of adhesive needed by approximately 95 %, see figure 6b. Despite the higher total mass for the joint of concept II, a higher level of sustainability can be fulfilled with less adhesive needed. In addition, both the EoL rib and the cleat can be returned to new product life cycles.

5. Conclusion

The present paper pursued the investigation of two different design concepts for T-joints in segmented rotor blades. Both concepts represent suitable adhesive T-joints for a modular design of a segmented rotor blade to safely absorb a bending load. The study enables the prediction of various parameter influences, which can be applied as design guidelines to specific use cases.
However, it is generally important to align the concept with the requirements and the application itself. Concept II with a CFRP cleat and a PU adhesive achieves the highest load capacity per joint weight. Consequently, concept II will be further explored. For this, the laminate structure, and the size of the adhesive surfaces to the adherends are designed based on a real rotor blade load case. Furthermore, the design of the cleat is extended by a double curvature, which enables a defined starting point for a peeling separation of the cleat from the EoL rib after the product life cycle. Since PU adhesives with increased ductility offer advantages in terms of load capacity under a peeling load, a possible application of adhesive films with higher fracture energy is being considered.

Abstract
Monitoring the structural health of composite materials, specifically carbon fibre composites (CFRP), can be effectively achieved by assessing damage via electrical resistance change. This work proposes a 4 X 4 electrode array to detect damage and determine the minimum detectable crack length for this electrode configuration. This research studies experimentally and numerically, using the finite element method (FEM), the electrical resistance changes due to the presence of a crack in different CFRP laminates. The results showed that the minimum detectable crack length would depend on the monitored area. It was found that the minimum detectable crack length for a central crack in multidirectional laminates, such as [0,90], [+45,-45], and $[0,90,45,-45]_s$ is 27 % of the monitored area, while for a unidirectional laminate is 93 %. Alternatively, the monitored area could be scaled to achieve a required detectable crack length using an array of 4 X 4 electrodes patterned over the area of interest. In conclusion, a small monitored area with four electrodes is able to detect a small crack, and this basic electrode arrangement can easily be scaled and patterned to achieve specific health monitoring requirements.

1. Introduction

One of the methods to monitor the health of composite materials, specifically carbon fibre composites (CFRP), is the electrical resistance change (ERC) method. It is a relatively straightforward and non-intrusive method that could detect damage on large structures such as aircraft, bridges, and ships. ERC faces some challenges, principally because the damage that could lead to failure is generally localised and may have an insignificant effect on the overall ERC [1]. As a result, several electrodes are required to detect small cracks, increasing the cost and possibly the structure's weight, which is relevant in aerospace structures.

Carbon fibre-reinforced polymer (CFRP) composites have been used as structural materials because they have several desirable properties, including a high tensile stiffness-to-weight ratio and chemical resistance. Besides, their electrical properties are measured to detect changes in the material, identifying variables such as stress, strain, damage or temperature [2]. CFRP is electrically orthotropic, and for unidirectional (UD) CFRPs, the longitudinal conductivity is much higher than that in transverse and trough-thickness directions [3].

Although the damage has been successfully detected, a high number of electrodes on a relatively small area to detect small cracks makes this approach very difficult to implement on a full-scale structure. Some studies have used multiple electrodes, establishing a minimum detectable damage size according to a sensing area where it is possible to detect damage. Idris et al. [4] found that the minimum detectable

damage area for a woven carbon plate of 113 mm X 84 mm was about 0.04% of the sensing area using fourteen electrodes and an electrode separation of 26 mm in the X-direction and 16 mm in the Y-direction, as shown in Figure 1(a). On the other hand, Cagáň [5] concluded that using nineteen electrodes on a 100 mm diameter circular plate, as shown in Figure 1(b), the minimum detectable damage area was 0.1% of the total sensing area. Additionally, the data to process and the wiring increase with the number of electrodes to sense damage, increasing the weight and cost of the SHM system and compromising its attractiveness.

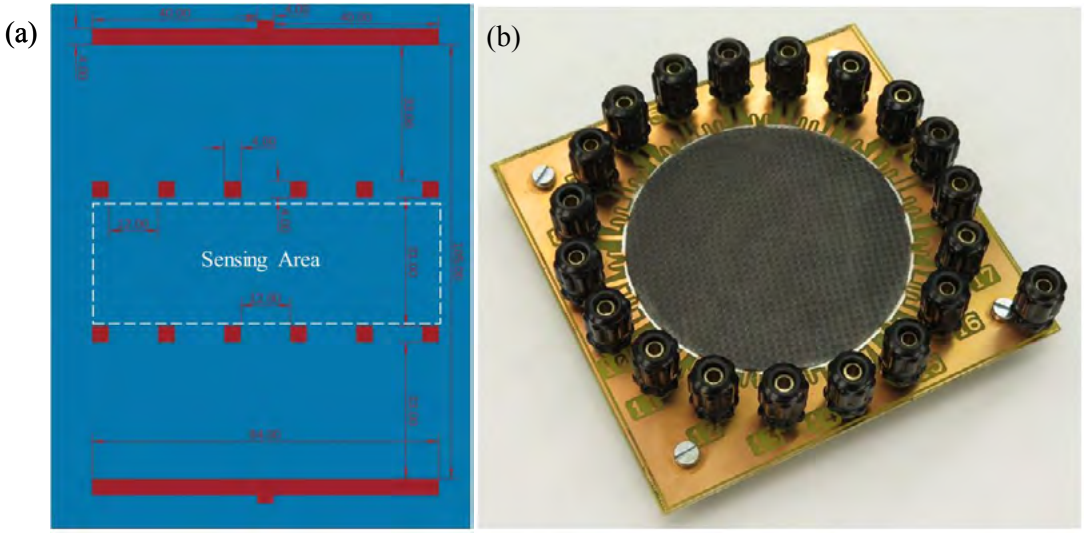

Figure 1. (a) Fourteen [4] and (b) nineteen electrode arrays [5].

Also, electrical resistance change depends on stacking sequence due to the electrical conductivity mechanisms of CFRP laminates, such as conductivity along the fibres and due to contact between fibres, also known as inter-fibre contacts [6]. Then, detecting damage in composite structures depends on the laminate, and different stacking sequences should be evaluated to know the electrical behaviour of each case.

This work proposes an electrode array with the minimum number of electrodes to monitor a rectangular area. Then, a 4 X 4 electrode array is proposed to detect damage and determine the minimum detectable crack length for this electrode configuration in different CFRP laminates, such as unidirectional (UD), cross-ply (CP) [0/90], 45-angle ply (45AP) [45/-45] and quasi-isotropic (QI) $[0/90/45/-45]_S$. The electrical resistance change is experimentally and numerically studied using the finite element method (FEM). Experimentally, the electrical resistance is measured using the two-probe method, minimising the wiring and the amount of data to process, compared to the four-probe method. This simple electrode configuration can be replicated in a structure as much is required to scale their application to achieve specific health monitoring requirements.

2. Concept

CFRPs have demonstrated their capacity to detect damage by changing their electrical resistance [7], [8]. However, reducing the number of electrodes would help to decrease the weight and complexity of the system. Therefore, we propose a simple electrode configuration on a sensing layer that can be replicated in a structure as much is required to be part of an SHM system. Figure 2 shows the schematic of an aeroplane wing to illustrate the concept and how it could be implemented in practice.

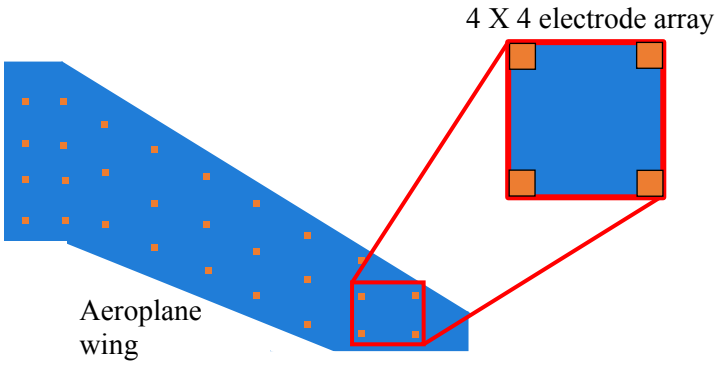

Figure 2. 4 X 4 electrode array concept.

Four electrodes are placed in each corner of the sensed area to maximise the monitoring area with the minimum number of electrodes. These sensing layers are made of carbon plies, and the electrodes are on the top corners. From the four electrodes, A, B, C and D, it is possible to measure the electrical resistance change in six different pairs of electrodes using the two-probe method, A-B, A-C, A-D, B-C, B-D and C-D, as it is illustrated in Figure 3**Error! Reference source not found.** in a cross-ply laminate. Notice that this method can be applied to any laminate, and a few options are explored in this work.

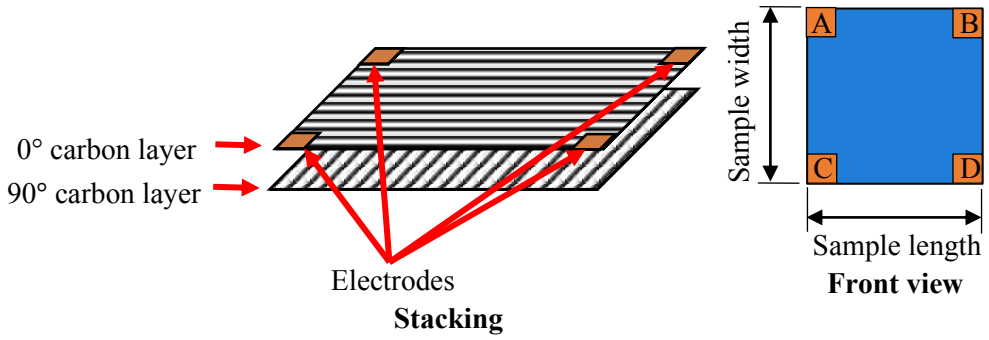

Figure 3. Schematic of (a) a cross-ply laminate with a 4 X 4 electrode array.

3. Method

Many stacking sequences can be studied as sensing laminates. However, fewer plies imply lower prices and weight in the monitored structure. Some of the most common laminates, such as UD, cross-ply (CP), ±45 angle ply (±45AP) and quasi-isotropic (QI) stacking sequences, are numerically evaluated using the Finite Element Method (FEM) to determine the laminate with fewer plies capable that allows detection of damage. Table 1 lists the laminates evaluated in this work.

Then, to validate the numerical model, experiments are performed on the laminate with the fewest plies capable of detecting damage.

Table 1. Evaluated sensing laminates.

Laminate	Layup	Laminate thickness [mm]
Unidirectional (UD)	[0]	0.029
Cross-ply (CP)	[0/90]	0.058
±45 angle ply (±45AP)	[45/−45]	0.058
Quasi-isotropic (QI)	$[0/90/45/-45]_s$	0.236

3.1. Numerical models

A 3D finite element analysis (FEA) is developed in Abaqus software to study the electrical resistance change under specific crack lengths for the proposed laminates. Numerical models of plates of 150 mm X 150 mm were numerically evaluated. First, an undamaged geometry is simulated to know the initial resistance without damage. Models with different crack lengths are created to calculate the resistance change with the new resistance. Then, two parts of the sample were modelled to create the crack, tying them at the edges except for the crack area and thus creating the crack. In this way, the tied areas act as part of a continuum material, and the untied areas act as a crack, as shown in Figure 4.

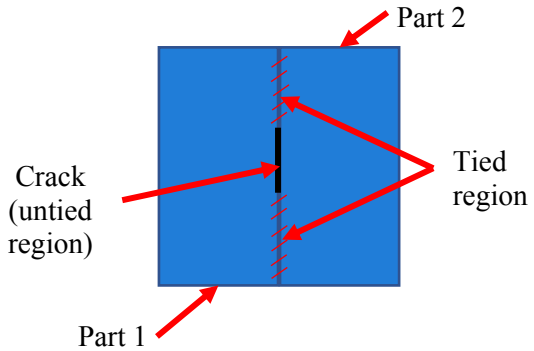

Figure 4. Schematic of the numerical model.

The finite element model was built using individual layers meshed with hexahedral elements type Q3D78 to simulate the electrical behaviour. The mesh size is 1.0 mm, which guarantees a good quality mesh.

CFRP material is modelled as a homogeneous material, which means that the electrical behaviour modelled is the one for a unidirectional ply and not the behaviour for fibre and matrix, separately. The different layers are tied to each other.

Laminates are modelled with four 5 mm X 5 mm X 0.02 mm thick electrodes on the top corners of the plate. An electrical potential difference of 0.6 V between each pair of electrodes is imposed because of the potential difference applied by the multimeter in the experimental tests. This way, the reaction current is obtained by calculating the electrical resistance through Ohm's law, $R = V/I$. Where R is resistance, V is the potential difference, and I is electrical current. The carbon composite chosen for these laminates is the M46JB/513 epoxy, whose electrical properties, like the properties of copper for electrodes, are listed in Table 2.

Table 2: Electrical properties

Material	Longitudinal resistivity [Ωmm]	Transverse resistivity [Ωmm]
M46JB carbon fibre [9]	0.09×10^{-3}	
M46JB/513 epoxy[a]	0.016	24.73
Copper	1.68E-5	

[a] *Found experimentally.*

3.2. Experiments

The material used for the experimentation is UD thin-ply carbon fibre prepreg from North thin-ply technology having M46JB carbon fibre and 513 epoxy resin system with a ply thickness of about 29 microns when cured. The areal weight is 29 gsm with a fibre volume fraction of 53%, as specified in the manufacturer's datasheet [9].

Conventional processes for curing standard prepregs were used. The M46JB/513 cross-ply laminate was stacked up with 20-micron thickness copper electrodes located accurately in the top corners and pressed firmly by hand onto the prepreg layup. Both resin systems have a similar cured cycle. Then, the prepregs were cured in an autoclave for the recommended temperature and pressure cycle for the Hexcel in the 913 epoxy resin, 90 minutes at 125 C and 7 bars.

Three specimens of 150 mm X 150 mm were manufactured. After cured, the electrical resistance was measured on the electrodes with an HMC 8012 digital multimeter with an accuracy of ±0.05-0.005% following the two-point probe method. A central crack was cut in the laminate using a Dremmel tool at 30000 RPM, avoiding extra damage such as delamination. Then, the resistance was measured, and the specimen was cut again, increasing the crack length and repeating the measurement process several times.

4. Results and discussion

Different central crack lengths were simulated to evaluate their effect on the electrical resistance change for UD, CP, ±45AP and QI sensing laminates. Figure 5 shows the increasing electrical resistance change with the crack length between the A-B, A-C and A-D electrodes. The electrical resistance change is defined as $\Delta R/R_i$, where ΔR is the difference between the initial resistance without the crack and the final resistance after the crack. R_i, is the initial resistance, where the sample does not have any crack. Due to the symmetric conditions, the resistance change for the pair of electrodes, C-D, B-D and B-C, is the same as that of A-B, A-C and A-D electrodes, respectively. Therefore, only three of the six pairs of electrodes have all the information required for the analysis.

Each of the evaluated laminates showed different resistance change values. The primary conductive path in UD laminates is along the fibre direction, as shown in Figure 6. For this reason, the resistance change is zero up to a crack length/sample width of 0.93, as shown in Figure 5 (a), where the crack started to interrupt the conductive path between electrodes A and B. CP and ±45AP laminates presented the exact electrical resistance change, then only a graph is presented for both laminates. On the other hand, multidirectional laminates present an increasing change of electrical resistance even at small crack lengths, as illustrated in Figure 5 (a), (b). This increasing electrical resistance change is due to the conductive path combining fibre and transverse direction for multidirectional laminates, as shown in Figure 6. Then, multidirectional laminates are more sensitive to detecting more minor cracks than UD laminates, as shown in Figure 5 (a), (b), and (c).

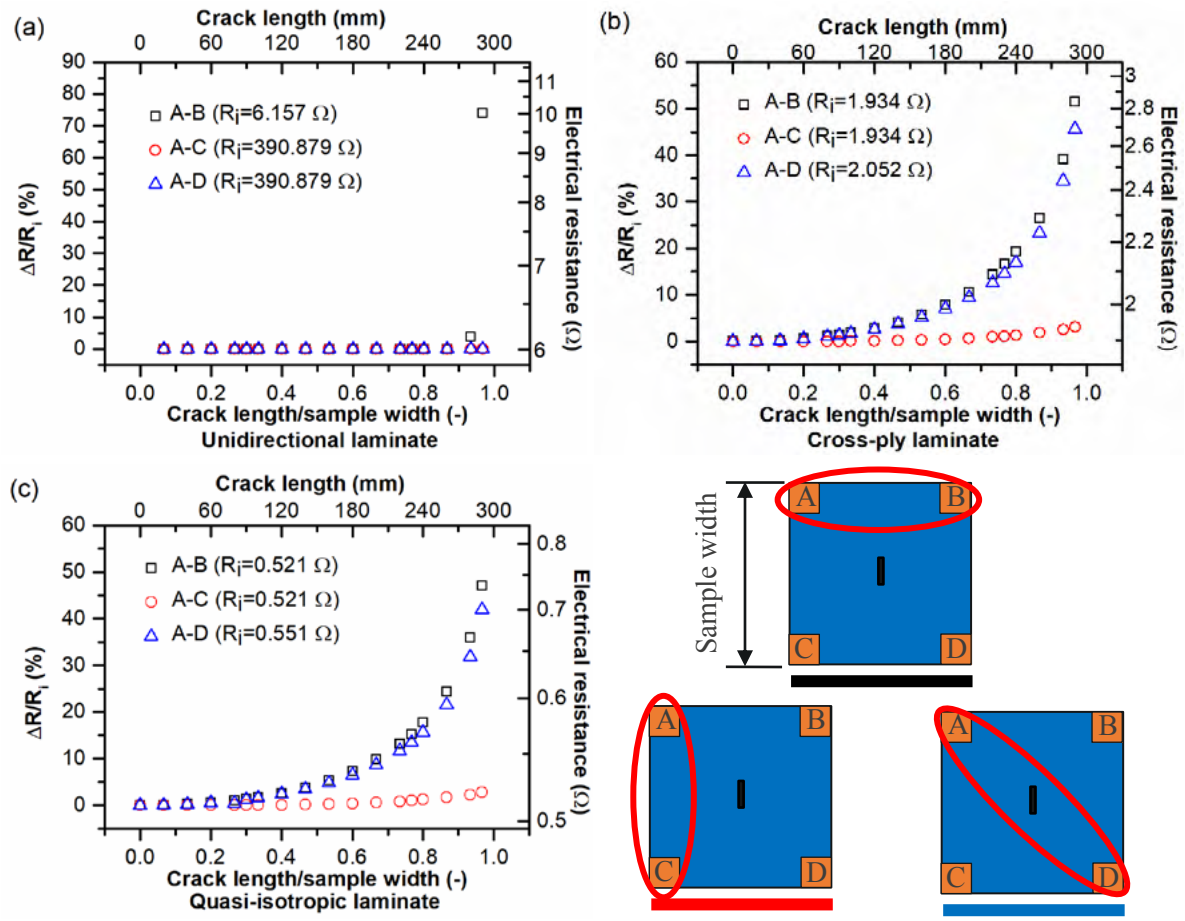

Figure 5. Numerical results for the effect of the crack length in the electrical resistance response in (a) unidirectional, (b) cross-ply, ±45 angle ply and (c) quasi-isotropic laminates.

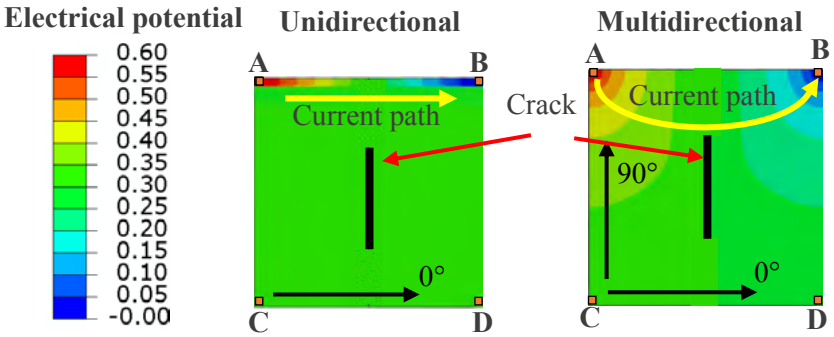

Figure 6. Electrical potential distribution for unidirectional and multidirectional laminates.

The experimental and numerical results for the electrical resistance change vs. crack length/sample width ratio are presented in Figure 7 for the CP laminate. Both results show a similar increment of the resistance change with the crack length. In this way, the FEM model was validated. Additionally, the resistance change increases non-linearly with the crack length. However, electrodes A-C are parallel to the crack orientation. Hence, the resistance change is lower than that of electrodes A-B and A-D because the conductive path is not interrupted directly, as with the other electrodes.

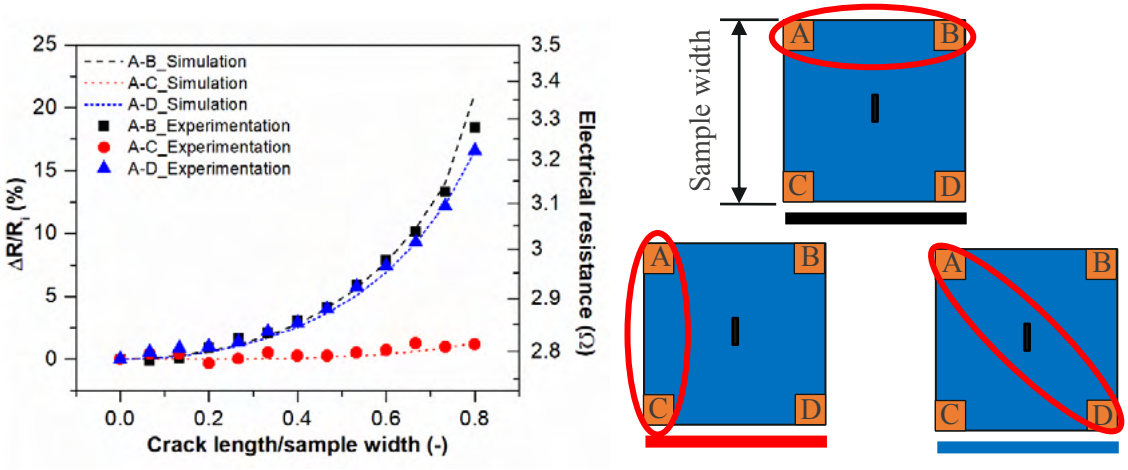

Figure 7. Experimental and simulation results for the effect of the crack length on the electrical resistance.

5. Conclusions

It was shown numerically and experimentally that the 4 X 4 electrode array proposed in this work detects damage. Besides, the minimum detectable crack length for a central crack in multidirectional laminates, such as CP, 45AP and QI, is 27 % of the monitored area, while for a unidirectional laminate is 93 %.

The crack should interrupt the conductive path between electrodes to be detected. Therefore, multidirectional laminates such as CP, 45AP and QI can detect more minor cracks than UD laminates. This response is because the conductive path for UD laminates is mainly along the fibres. In contrast, the conductive path combines electrical conduction along the fibres and transverse direction for multidirectional laminates.

The sensing area is directly related to the minimum detectable crack length. Then, it is possible to design a structural health system to monitor different structures according to their needs.

Abstract

Fibre-reinforced composites are lightweight and possess many attractive mechanical properties such as high specific stiffness, specific strength, and improved fatigue endurance etc. Intriguingly, the compressive strength of unidirectional composites is approximately 30% lower than their tensile strength [1]. The main reason for this asymmetry is related to a unique instability-driven failure mechanism known as 'fibre kinking' under compression, which promotes early structural failure. Fibre kinking is triggered by local fibre misalignments, which, when subjected to compressive loading, promote further fibre rotation, resulting in the formation of a narrow kink band of very high localized shear strain. This eventually propagates, causing a sudden and unstable structural collapse. To simulate fibre kinking in a numerical framework, continuum damage mechanics models are typically employed. However, their smeared stiffness degradation methodology makes it impossible to capture the kinematics of kink formation and evolution accurately. In the current work, a novel three-dimensional semi-discrete continuum damage modelling framework, implemented in commercial software as a user-defined material package, is applied to predict failure in open-hole compression laminates. Several benchmark cases are demonstrated showing the effectiveness of the present kink-band modelling method.

1. Introduction

High demand for the reduction of weight in structures has led to the use of composite materials in the aerospace industry. High-performance structural components with lighter weight can be obtained by using composite materials. The pronounced anisotropy and heterogeneity observed in unidirectional fibre-reinforced composites give rise to distinct failure mechanisms, varying significantly based on the imposed load conditions. The primary mode of failure under longitudinal compression loading is fibre kinking [2]. Understanding, modelling and finally predicting the compressive response of CFRP material is a long-standing and unresolved issue. It is therefore important to develop a robust physically based failure model for progressive analysis of compressive damage. To estimate the compressive strength associated with kink band development, many theoretical models can be found in the literature.

Rosen [3] developed a model on fibre micro-buckling and the fibre's buckling stresses can be obtained by minimizing the internal energy. Rosen's model exhibited an overestimation in predicted outcomes when compared with experimental results [4]. Argon [5] considered kinking as a separate failure mode and proposed the kinking model by assuming initial misalignment angle is the only reason for kinking. Budiansky [6] improved Argon's model by considering the effect of matrix shear yield strain. Kinking is initiated by the formation of a close loop between fibre initial misalignment and shear stress between fibres. Budiansky and Fleck [7] developed fibre kinking theory (FKT) for kink band initiation and propagation. In a numerical framework, Pinho et al. [8,9] developed and implemented a 3D progressive

fibre kinking model. An embedded crack model within a continuum damage framework is usually employed to model fibre kinking. A set of three-dimensional failure criteria for laminated fibre-reinforced composites denoted LaRC04, is proposed [10]. Leone et al. [11] predict kinking using deformation gradient tensor decomposition (DGD) and Bergan et al. [12] created a semi-discrete mesoscale constitutive damage model by considering shear nonlinearity to represent the fibre kinking phenomenon accurately. Jansson and Fagerström [13] formulated the physical behaviour of kinking in a novel way. In contrast to the traditional model, which usually shows a constant plateau after initial softening, their better method provides a characteristic stiffening effect at higher strains.

This paper seeks to advance beyond the limitations of a smeared formulation by introducing a kinematically enriched formulation that implicitly identifies the kink band and the undamaged bulk within a single unified volume. Given the narrow width of the kink band, a smeared formulation fails to capture the strong variation in strain across this region. To address this limitation, our current study employs a two-scale mesoscale continuum damage mechanics model tailored for longitudinal compression. This model explicitly accounts for the strong strain variation within the localized kink band in comparison to the undamaged bulk region [14]. The model's compressive strength is predicted using Finite Element analysis, and then compared to experimental results from literature. Stress-strain curves show excellent agreement between predicted and experimental data.

2. Formulation of two-scale model

In engineering composites, the fibres typically aren't perfectly straight. We incorporate an initial misalignment to address this imperfection in our current model. When these misaligned fibres are subjected to compressive loading, they can trigger fibre kinking (see Figure 1).

2.1. Geometrical description

Kinking, we assume, occurs within a transversely isotropic ply, uni-directional lamina under compressive loading. We consider a volume of the whole continuum, Ω and the length in 1- direction is H. The localization kink band of the thickness (w_{KB}) and volume (Ω_{KB}) surrounded by a bulk material, Ω_B as shown in Figure 1. Assuming that the average cross-section area of localization kink band and

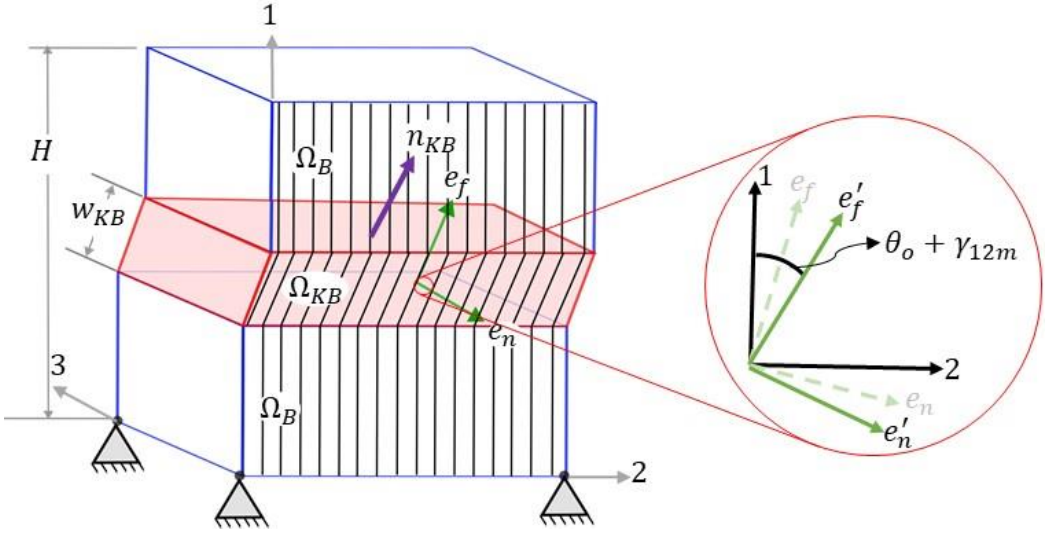

Figure 1. Schematic illustration of kink band formation in Deformed configuration.

outside bulk material is the same i.e. A and volume of the whole continuum is Ω. The volume fraction (η) of the localization zone is:

$$\eta = \frac{\Omega_{KB}}{\Omega} = \frac{w_{KB}A}{\Omega} \tag{1}$$

The characteristic length of considered volume, η is the ratio of considered volume to element length in 1- direction i.e. $H = \Omega/A$, then the volume fraction becomes:

$$\eta = \frac{w_{KB}}{H} \tag{2}$$

The volume fraction η in this configuration can be defined as the ratio length of the localized kink band and the length of the whole element.

2.2. Strain decomposition

Within the entire domain (Ω), the overall stress and strain are represented as $\boldsymbol{\sigma}$ and $\boldsymbol{\varepsilon}$ respectively, while the stress and strain components within and outside the localization band are denoted by $(\boldsymbol{\sigma}_{KB}, \boldsymbol{\varepsilon}_{KB})$ and $(\boldsymbol{\sigma}_{B}, \boldsymbol{\varepsilon}_{B})$ respectively.
The strain rate inside and outside of the localisation band can be expressed by following mixture theory:

$$\dot{\boldsymbol{\epsilon}} = \eta\dot{\boldsymbol{\epsilon}}_{KB} + (1-\eta)\dot{\boldsymbol{\epsilon}}_{B} \tag{3}$$

For a very thin localization kink band ($w_{kb} \ll H$), the rate of inelastic strain [15] within the band can be approximated as:

$$\dot{\boldsymbol{\epsilon}}_{KB} = \dot{\boldsymbol{\epsilon}}_{B} + \frac{1}{w_{kb}}(n_{KB} \otimes [\![\dot{\boldsymbol{u}}]\!])^{sym} \tag{4}$$

Where $[\![\dot{\boldsymbol{u}}]\!]$ is the velocity jump across the opposite sides of the localization band, n_{KB} denotes the localization band's unit normal vector and $\otimes$ is the dyadic product. Solving Eq. (3) and Eq. (4). Strain rate inside and outside of the localisation band can be obtained in terms of incremental macro strain ($\dot{\boldsymbol{\epsilon}}$) and velocity jump ($[\![\dot{\boldsymbol{u}}]\!]$).

$$\dot{\boldsymbol{\epsilon}}_{KB} = \dot{\boldsymbol{\epsilon}} + \frac{1-\eta}{w_{KB}}(n_{KB} \otimes [\![\dot{\boldsymbol{u}}]\!])^{sym} \tag{5}$$

and

$$\dot{\boldsymbol{\epsilon}}_{B} = \dot{\boldsymbol{\epsilon}} - \frac{\eta}{w_{KB}}(n_{KB} \otimes [\![\dot{\boldsymbol{u}}]\!])^{sym} \tag{6}$$

The incremental macro strain in the global frame is determined by solver. To derive the velocity jump, we start by integrating the constitutive equations for stress rate both inside and outside the localization band into the traction continuity equation in its rate form. This equation ensures that the traction rate inside the band ($\dot{t}_{KB}$) matches that outside the band ($\dot{t}_{B}$). The traction continuity equation simplifies to:

$$\dot{\sigma}_{KB} \cdot n_{KB} = \dot{\sigma}_{B} \cdot n_{B} \tag{7}$$

By substituting the stress rates inside and outside the localization band, we get:

$$\mathbb{D}_{KB} : \dot{\boldsymbol{\epsilon}}_{KB} \cdot n_{KB} = \mathbb{D}_{B} : \dot{\boldsymbol{\epsilon}}_{B} \cdot n_{B} \tag{8}$$

where $\mathbb{D}_{B}$ is typically a linear elastic stiffness matrix and $\mathbb{D}_{KB}$ is a non-linear elastic stiffness matrix. Note that the inplane shear response in the current model is assumed to be non-linear. In constitutive response all other components are linear, and only 12 local material direction relations are non-linear. This shear non-linearity can be idealised by using the Ramberg-Osgood [16] type model as follows:

$$\gamma_{ij} = \frac{1}{G_{ij}}\left[\tau_{ij} + \alpha_{pl}\,\mathrm{sign}(\tau_{ij})\left|\tau_{ij}\right|^{n_{pl}}\right] \tag{9}$$

where α_{pl} and n_{pl} are used to fit the experimental data.

2.3. Calculation of macro stress to return the solver

The macro stress behaviour, unlike macro strain behaviour, cannot be described by an averaged form following mixture theory. Instead, it is elucidated from the virtual work equation, which states that the work produced by macro stress and strain rate should equate to the volume-averaged work due to stresses and strain rates inside and outside the localization zone. The macroscopic behaviour inside the localization band and the remaining part can be expressed by the Hill-Mandel [17] equation as follows:

$$\boldsymbol{\sigma} : \dot{\boldsymbol{\varepsilon}} = \eta\, \boldsymbol{\sigma}_{KB} : \dot{\boldsymbol{\varepsilon}}_{KB} + (1-\eta)\, \boldsymbol{\sigma}_{B} : \dot{\boldsymbol{\varepsilon}}_{B} \tag{10}$$

Substituting the value of $\dot{\boldsymbol{\varepsilon}}_{KB}$ and $\dot{\boldsymbol{\varepsilon}}_{B}$ in terms $\dot{\boldsymbol{\varepsilon}}$ of from Eq. (5) and (6) into the Eq. (10) and rearranging the above equation in terms of primary variables (i.e. $\dot{\boldsymbol{\epsilon}}$ and $[\![\dot{\boldsymbol{u}}]\!]$) and applying traction continuity conditions. The macro stress behaviour with two different region's stress can get:

$$\boldsymbol{\sigma} = \eta\, \boldsymbol{\sigma}_{KB} + (1-\eta)\, \boldsymbol{\sigma}_{B} \tag{11}$$

As can be seen from the above Eq. the volume-averaged response forms of both macro stress and strain can co-exist while meeting the Hill-Mandel condition.

3. Single-element test model and material properties

The VUMAT model was implemented in Abaqus to examine various aspects of its behaviour through single-element analysis. This section focuses on highlighting several key features of the model. Specifically, we investigate the influence of kink bandwidth, and the behaviour of the localized region and the bulk region outside of it on the constitutive response of the model. The material used in this study is IM7/8552, and a summary of its properties can be found in Table 1. A single-element model (C3D8R) was employed, with uniform end shortening displacement applied along the longitudinal direction. The element size was set to 0.25 mm on all sides. To ensure compatibility, the applied displacement was supported by a simply supported boundary condition on the opposite face (see Figure 2).

Table 1: Mechanical properties of IM7/8552 [18]

Elastic Properties				
Modulus			Poisson's ratios	
E_{11} (MPa)	E_{22} (MPa)	G_{12} (MPa)	ϑ_{12} (-)	ϑ_{23} (-)
161000	11380	5481	0.32	0.436

4. Results and Discussion

4.1 Constitutive response of single element model (Two scale model)

The constitutive response of the model under longitudinal compression of the single-element model is shown in Figure 3. In this response, the kinking happens to the whole element i.e. the kink bandwidth is 250 μm (same as element dimension). The initial misalignment angle ($\theta_i = 1.26^\circ$) is chosen in such a way that the load curve starts dropping when it reaches material longitudinal compressive strength i.e. $X_c = 1690$ MPa. The constitutive response includes several features like the linear response at small strain, pre-peak nonlinearity, sudden drop in load immediately reaching material strength (post-peak response) due to large fibre rotation (see Figure 3(b)), and plateau in stress at a residual stress level, σ_r, as shown in Figure 3(a).

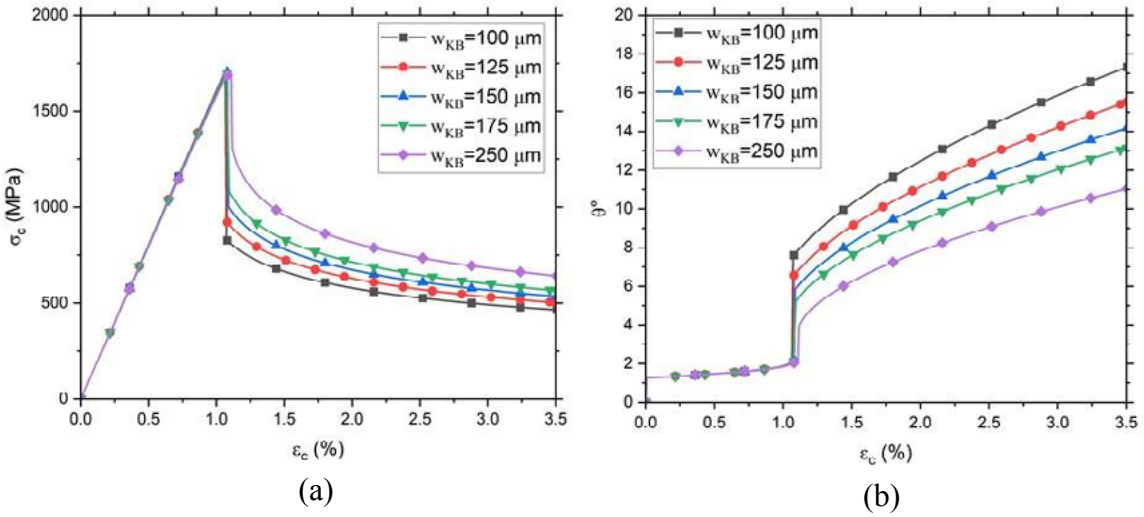
(a) (b)

Figure 3. (a) Stress vs strain and (b) Fibre rotation vs. strain response.

The stress-strain behaviour of the current model is shown as a solid blue line. The linear stiffness, obtained by deactivating the nonlinear shear response, is represented by a black dotted line. The material's strength is indicated by a solid red horizontal line at X_c. Interestingly, the FKT results exhibit a snap-back phenomenon, showing a sudden load drop followed by an asymptotic residual stress level (σ_r). Remarkably, our current model predicts the same response as the FKT [6] results. The stress versus current fibre rotation response, as depicted in Figure 3(b), highlights that fibre rotation remains minimal until the strength limit is reached, after which there is a sudden increase in fibre rotation. This rotation continues to grow as the model approaches the residual stress state.

4.2 Constitutive response of two scale models with varying kink bandwidth

This selection of w_{KB} has a major impact on the post-peak behaviour, for a smaller w_{KB} there is a very large jump on the curve once stress reaches peak load because as we compress it and the instability happens, a large amount of stored elastic strain energy is released by the bulk that causes a large fall in load as shown in Figure 4 (a). Wider kink bands prevent fibres from rotating (see Figure 4(b)), which increases the residual stress that the material experiences during the softening process (see Figure 4(a)). Interestingly, most kink band rotation appeare suddenly after the load decrease that occurs when after peak stress is reached. The residual stresses are sensitive to kink bandwidth.



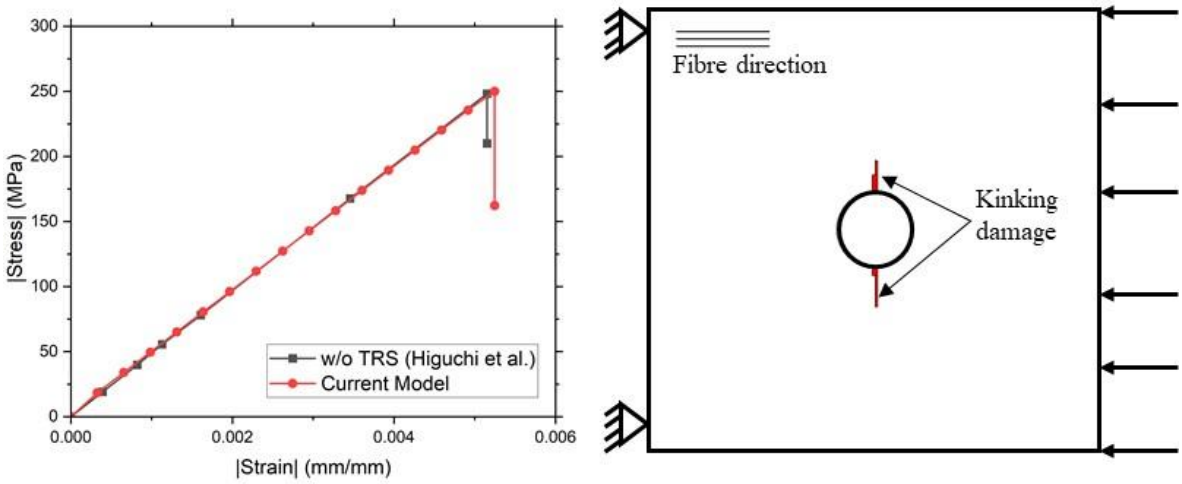


Figure 4. (a) Stress vs. strain and **(b)** Fibre rotation vs. strain response with varying w_KB.

4.3 Open-hole compression example

The geometric configuration of the model is based on Higuchi et al. [19]. It involves a laminate with a width and length of 38.1 and 305 mm, respectively, featuring a central hole of 6.35 mm diameter. The specimen's gauge length is 38.1 mm, but for finite element simulation, only the central portion is considered. The material properties of the T800S-3900-B [20,21,22] prepreg system are adopted. For the laminate stacking sequence, a quasi-isotropic arrangement $[45^{\circ}/90^{\circ}/-45^{\circ}/0^{\circ}]_{2s}$ is employed, with each ply having a thickness of 0.125 mm. A single element per ply is used in the thickness direction, and all plies are meshed with 8-node solid elements, employing reduced integration and hourglass control (C3D8R) to simulate matrix cracks and fibre kinking. Interfaces are modelled using 8-node cohesive elements (COH3D8) to represent delamination, with a resin-rich thickness of 0.01 mm[18]. A fine mesh is applied with an in-plane size of 0.25 mm × 0.25 mm around the hole, covering a sufficiently large rectangular area to capture ply matrix cracks and fibre kinking across all ply blocks. Two regions are defined outside this area: the Far-Field region (FFR) and the Transition region (TR), each with a coarser mesh. The TR employs a mesh size varying from 0.25 mm to 3 mm, while the FFR has an in-plane size of 3 mm × 3 mm. To apply compressive boundary conditions, displacement is imposed in the X-direction at one end of the laminate, while the other end is fixed, with an amplitude that varies smoothly. Additionally, out-of-plane displacements are constrained to zero in the FFR and TR to mimic anti-buckling guides in the OHC test fixture.

An improved fibre kinking model that uses a kinematically separated two-scale formulation is used to simulate compressive damage in the axial plies. Mesh-independent onset and propagation of discrete ply cracks are realized using the directed continuum damage mechanics method (D-CDM) recently proposed by Mukhopadhyay and Hallett [23]. This methodology is used to simulate failure under compression in OHC laminates across a varied range of lay-ups.

The laminate consists of an equal number of plies oriented at 45°, 90°, -45°, and 0° angles. Its load-displacement curve, excluding thermal residual stress, is depicted in Figure 5(a). Upon comparing the stress-strain curve of our current model with that of Higuchi et al. [19], we observe a high level of agreement. The laminate sustains a maximum load of approximately 32 kNAdditionally, at 91% of the peak load, Figure 5(b) illustrates the distribution of internal damage (kinking) within the 0° ply. It's noteworthy that fibre kinking begins near the hole's tip, and as compressive loading increases, kinking is triggered by unstable growth of the kink band in the 0° ply.

(a) (b)

Figure 5. (a) Load-displacement response of current model compared with Higuchi's model [19] without thermal residual stress (w/o TRS), and **(b)** Internal damage (kinking) distribution in 0° ply of quasi-isotropic laminate at 91% of peak load.

5. Conclusions

This work presents a two-scale continuum damage model for compressive failure in composites that captures the kinematics of kink band formation and evolution accurately. The biggest advantage of this model is its simplicity and compatibility with our existing numerical codes. The proposed model captures the kinematics of the strong variation in strain across the kink band in a more accurate way by using the coupled response between the kink band and the undamaged bulk region. The model can effectively capture various aspects of the material's response, such as its compressive stiffness, strength, susceptibility to instability at the onset of kink-band formation, and the stress plateau observed after reaching the peak.

Keywords: Digital Image Correlation, Fibre orientation, Density, Young Modulus, Strength

Abstract
This study examines the influence of fiber orientation variability on the mechanical properties of wood, focusing on veneer clear wood specimens. The research is motivated by the need to develop high-performance composite materials for sustainable transportation applications, particularly in reducing greenhouse gas emissions. The experimental protocol involves manufacturing veneers from beech wood, followed by producing the manufacturing of veneers from beech wood, followed by the production of small specimens with deliberate variations in fiber orientation. Non-destructive measurements of local fiber orientations and global density are conducted, along with tensile tests to determine local mechanical properties, i.e., Young's modulus, strength, and the shear modulus Advanced imaging techniques (DIC) and models for isotropic materials are employed for analysis.
The results reveal that fiber orientation has a significant role in wood variability, with pronounced effects on Young's modulus and strength at low angles. Transversal and shear modulus appear lower than in the literature due to the cracks due to the manufacturing of veneer (peeling process).

1. Introduction

The transport industry is determined to reduce its carbon footprint in order to reduce the problems caused by greenhouse gases. To achieve this goal, high-performance materials made from wood could be used for structural applications. This is the rationale behind the WOOFHI (Wood/natural Fiber High homogeneity/performance composite) project, which aims to produce homogeneous, optimized composite materials made from heterogeneous, variable materials. This application requires the ability to sort wood material according to its mechanical properties, based on non-destructive and quantitative

measurement methods. Visual sorting is standardized but not very efficient, and mechanical properties after sorting are not optimal (Faydi 2017, Duriot 2021). Several studies attempt to predict the elastic modulus and mechanical strength of structural wood products accurately and reliably, as shown by Hakkarainen et al. (2019) using local fiber orientation and global density measured on wood (Viguier et al. 2018). The coefficient of determination obtained is less than 0.7 and few predictive studies concerning veneers and small flawless samples have been made (Pramreiter et al. 2021, Cha 2003).

The aim of this work is to understand the mechanical behavior of clear wood and how local disturbances influence the material's behavior.
An experimental protocol on small specimens made from visually "clear" veneers was set up. First, non-destructive measurements of fiber orientation and density were carried out, then the specimens were loaded to failure in a tensile test.

2. Material and methods

2.1. Experimental protocol

The first stage of the protocol concerns the manufacture of veneers from the peeling process. The species studied is beech (fagus sylvatica) from the Centre Val de Loire region. Secondly, test specimens measuring 350 mm long, 20 mm wide, and 2 mm thick were produced from these veneers using a laser cutting machine. The specimens were stored at a temperature of 24°C with a relative air humidity of 50% in order to stabilize them at a humidity of 10%. The specimens were cut at angles relative to a direction assumed to be 0° to deliberately create variability within the fiber orientation. This distribution is shown in Table. 1. Nearly 40 veneers were required to produce 129 specimens.

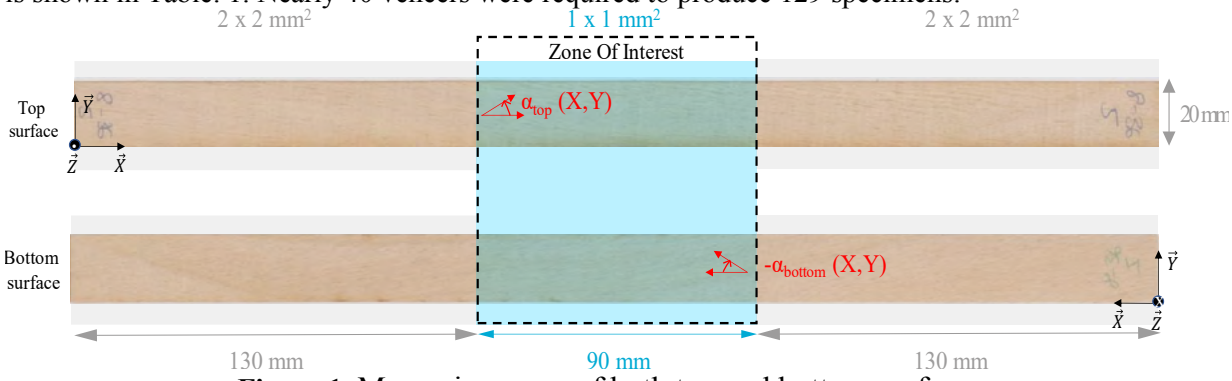

Figure 1. Measuring areas of both top and bottom surfaces

Table 1. Distribution of specimens according to their cutting angle, number of tested specimens, and cross-head speed during the tensile mechanical test

Cutting Angle θ (°)	**0**	**5**	**10**	**15**	**20**	**30**	**45**
Number	40	16	15	11	24	14	9
Cross-head speed (mm.min^{-1})	2	2	1	1	1	0.5	0.5

The samples were then scanned using a machine equipped with a camera and laser pointer, which scanned their entire surface. This technology uses the tracheid effect (Nyström (2003), Simonaho et al. (2002)). This involves projecting a circular laser onto a flat wooden surface. As light scattering is higher in the direction of the wood fiber, a luminous ellipse is formed whose major axis follows this orientation. The top and bottom surfaces of the sample were scanned at different resolutions (Figure. 1) to obtain angle maps (Figure. 2 (a), (c)). The central zone was more highly resolved than the extremities, as this is the zone of interest visible between the tensile jaws. The next step was to scan the specimens using a

conventional scanner to obtain an image with a resolution of 400 Dpi. Figure. 2 shows the overlay of the angle mapping obtained with the scan (Figure. 2(b), (d)).

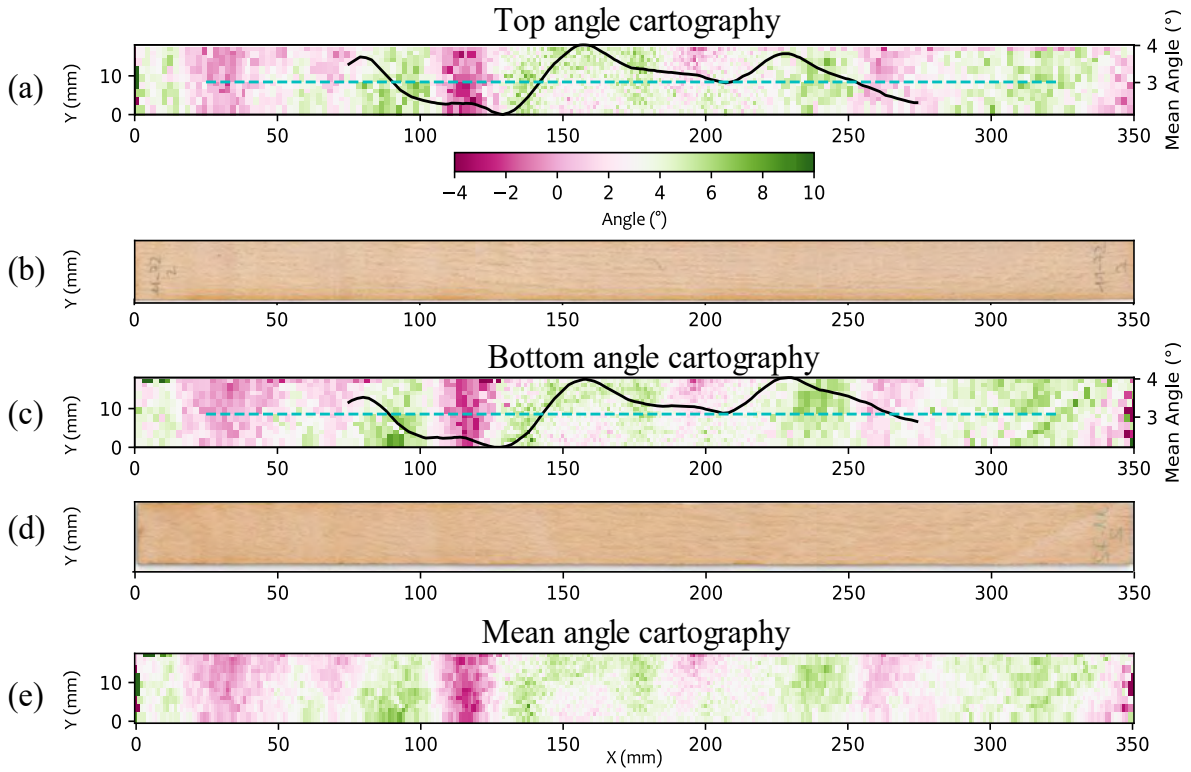

Figure 2. (a) The angle cartography in degrees of the top surface of the specimen. The black curve represents the average value of the grain angle along the Y direction for each X step in the ZOI (Zone Of Interest) with a length of 50 mm, the dashed blue line represents the average angle value within the ZOI (b) color image of the top surface, (c) The angle cartography in degrees of the bottom surface of the specimen, (d) color image of the bottom surface, (e) The average angle cartography in degrees of the top and bottom face angles of the specimen.

Width was measured with a caliper, and thickness with an external micrometer. The samples were then weighed using a balance. These measurements were used to calculate the average density. The tensile test was designed to determine local mechanical properties using a ZWICK-Roell, universal testing machine (250 kN). Displacements were measured by image stereo-correlation using technology developed by LaVision. A preload of 0.1 MPa was applied before testing. The displacement speeds imposed on the specimens are described in Tab.1. Speeds were set to give a test time of between 100 and 180 s to failure.

2.2. Young modulus determination

The equivalent local modulus of elasticity along the specimen can be calculated using a virtual extensometer of length δ (Figure. 3). This modulus was calculated based on the standard (EN 408 2012), i.e. a linear regression is calculated between 10 and 40% of the estimated maximum force.

In the $\vec{X}$ direction, the elastic modulus is calculated according to Eq. 1. Strain was calculated as a rate of increase in displacement as shown in Eq. 2. Displacement was calculated as the average of displacements over the width of the specimen (yellow bands (Figure. 3). Stress is the ratio of force divided by specimen cross-section (Eq. 3). Using this method, a local modulus can be calculated at each point along the length of the specimen. The central zone can be scanned over the 90 mm length of the zone of interest using the virtual extensometer with a length δ = 50 mm. The type of results obtained for one specimen is shown in Figure. 4.

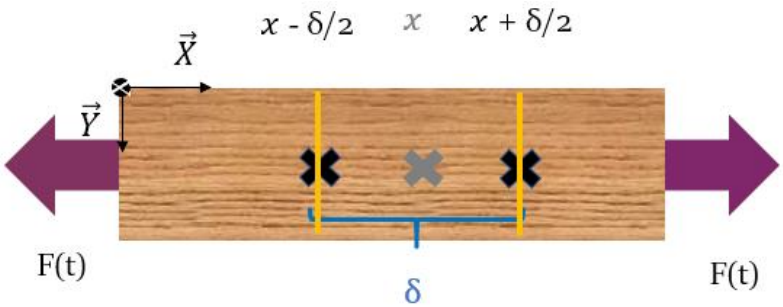

Figure 3. Tensile test with x the position along the length of the specimen at the center of the extensometer, δ the length of the extensometer and F(t) the force as a function of time.

$$E_{xx}(x) = \frac{\sigma}{\varepsilon_{xx}(x)} \quad (1)$$

$$\varepsilon_{xx}(x) = \frac{u(x+\delta/2) - u(x-\delta/2)}{\delta} \quad (2)$$

$$\sigma = \frac{Force}{Section} \quad (3)$$

$$u(x) = \frac{1}{19-1+1}\sum_{i=1}^{19} u(x, y_i) \quad (4)$$

Where $E_{xx}(x)$, $\varepsilon_{xx}(x)$ and σ are respectively the young modulus (in GPa), the strain in the $\vec{X}$ direction, and the stress (in MPa). The force is in N and the section in mm. $u(x)$ is the mean displacement in mm on the yellow band (Figure 3).

2.3 Strengh

Models of mechanical strength using grain angles can be used, such as the Hankinson (1921), Norris (1962), and Tsai-hill (1965) models as shown respectively by Eq. 5, Eq. 6, and Eq. 7.

$$\mathrm{MOR}_H = \frac{F_L \times F_T}{F_L \times \sin(\alpha)^2 + F_T \times cos(\alpha)^2} \quad (5)$$

$$\mathrm{MOR}_N = \frac{1}{\sqrt{\frac{1}{{F_T}^2} \times \sin(\alpha)^4 + \frac{1}{{F_L}^2} \times \cos(\alpha)^4 + (\frac{1}{{f_v}^2} - \frac{1}{F_L * F_T}) \times \sin(\alpha)^2 \cos(\alpha)^2}} \quad (6)$$

$$\mathrm{MOR}_{TH} = \frac{1}{\sqrt{\frac{1}{{F_T}^2} \times \sin(\alpha)^4 + \frac{1}{{F_L}^2} \times \cos(\alpha)^4 + (\frac{1}{{f_v}^2} - \frac{1}{{F_L}^2}) \times \sin(\alpha)^2 \cos(\alpha)^2}} \quad (7)$$

Where F_L and F_T are respectively the tensile strength in the longitudinal, transversal direction (in MPa) and f_v the ultimate shear strength in the plane LT (in MPa) and α is the angle (in degree).

3. Results

3.1 Young modulus

The results obtained for each specimen are shown in Figure. 4, which illustrates the strong correlation between the longitudinal modulus of elasticity and the angle at each point on the map. By superimposing all the specimens on the same graph, the mechanical properties have been determined by considering an orthotropic behavior law (Figure. 5). The longitudinal modulus of 16.14 GPa appears to agree with the literature (OŻYHAR et al. 2012, Ozyhar et al. 2013, Peter et al. 2015) despite a relatively low transverse

modulus and shear modulus, possibly indicating the considerable influence of cracks resulting from the veneer manufacturing process (Pot et al. 2015, Krüger et al. 2023). Moreover, a wide range of the MOE is observed (from 12 to 20 GPa). This variability may stem from density, microfibril angle, tension wood, or the presence of out-of-plane angles.

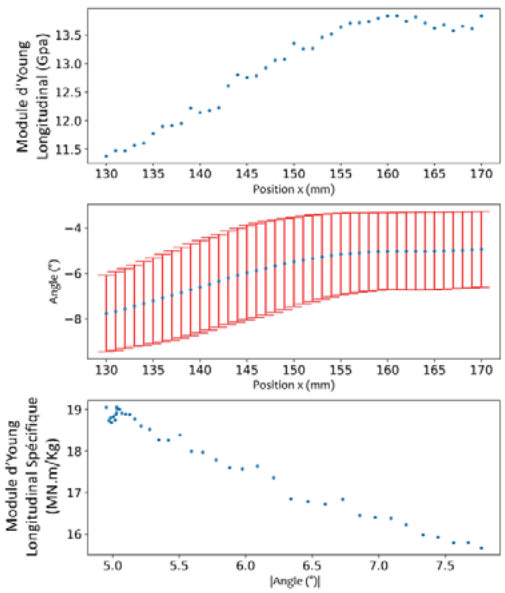

Figure 4 : Example of a specimen result: longitudinal modulus and angle measurement as a function of position along the length of the specimen, specific longitudinal modulus as a function of angle

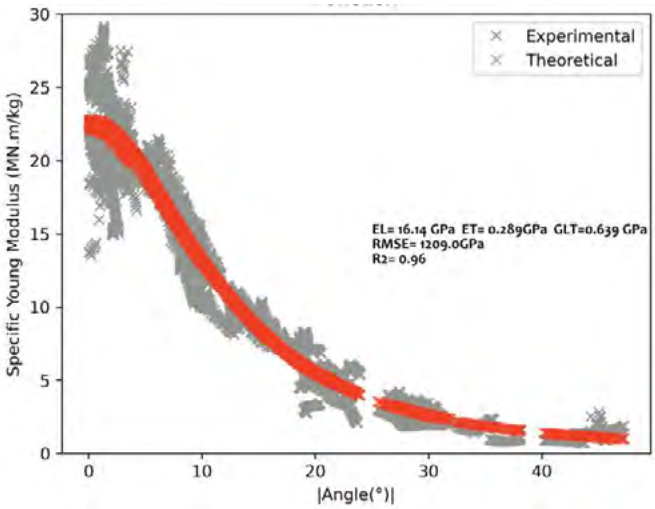

Figure 5 : Optimization and superposition of mechanical properties based on an orthotropic behavior law (RMSE = Root Mean Square Error, R2 = coefficient of determination, EL = longitudinal modulus and ET = transverse modulus, GLT = shear modulus)

3.2 Strength

The relationship between the mean absolute angle and the strength (MOR) within the length of the ZOI measured in step 4 is depicted in Figure 6. Hankinson, Norris, and Tsai-Hill failure criteria (respectively Eq. 5, 6, and 7) were fitted to the experimental data, giving the coefficients in Table 2.

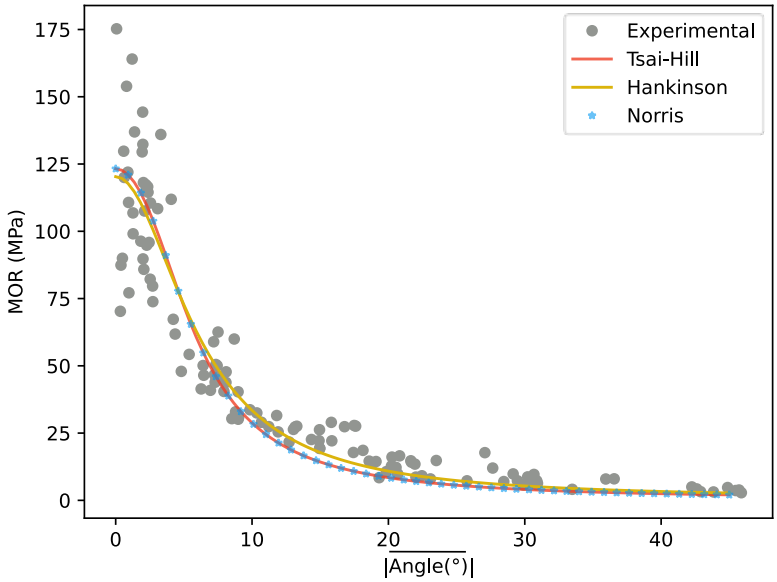

Figure 6: MOR VS $|\overline{Angle}|$

MOR correlates quite well with the measured angle in the ZOI with the three models (Figure 6 and Table 2). For angles close to 0°, there was a wide variation in MOR. The Hankinson (1921) model has a coefficient of determination which is the highest. However, this model only provides longitudinal and transverse mechanical strength, in contrast to the Tsai-Hill (1965) and Norris (1962) models, which also allow to evaluate a shear strenght.

Table 2. Coefficients of rupture models.

Model/Coefficient	F_L (MPa)	F_T (MPa)	f_v (MPa)	R^2	RMSE (MPa)
Hankinson	121	1.0	-	0.90	14.1
Norris	123	1.0	8.0	0.88	15.0
Tsai-Hill	125	1.0	14.0	0.89	15.0

4. Conclusion

Fiber orientation appeared to be an important parameter in wood variability for the young modulus and tensile strength. Large variations in young modulus and strength were more significant for small angles than for large angles. These variations could be due to the locale variation of the density, the out-of-plane angle, or the microfibril angle.
The approach of calculating elastic modulus is rather simplistic for understanding local behavior. Inverse identification of mechanical properties for each specimen using a finite element model incorporating fiber orientation seems essential to understanding strains and local properties.

Keywords: Floor panels, Inserts, Sandwich structures, Cork, Foam core

Abstract

This study investigates alternative fastening methods for aircraft floor panels composed of foam core sandwich structures, aiming to enhance manufacturing efficiency and reduce costs without compromising mechanical performance. Traditional glass fibre-reinforced polymer (GFRP) plugs were compared with polyetherimide (PEI) plugs, EJOT TSSD® inserts, and Bossard MM-Welding® inserts. The research focused on pull-out and shear-out tests to evaluate the mechanical integrity of each fastening solution. Results demonstrated that all fasteners displayed similar performance in pull-out tests, which was predominantly influenced by the face sheet properties of the panels. Among the methods, the GFRP plugs showed marginally superior shear-out strength, but the performance of the Bossard and EJOT fasteners was sufficiently robust, suggesting their potential suitability for use in floor panel applications. Particularly, the EJOT and Bossard methods promise significant enhancements in production efficiency due to their ease of integration into existing manufacturing processes. Further refinements could involve optimizing the contact surface between inserts and the foam core, as well as exploring stiffer insert materials to improve load-bearing capacity. This study underlines the potential of these new fastening techniques to modernize the construction of aircraft floor panels while maintaining essential mechanical properties.

1. Introduction

Floor panels are an important component in the cabin of civil aircraft and they contribute strongly to the CO2 footprint of the aircraft [1]. State-of-the-art aircraft floor panels generally consist of a honeycomb core and prepreg (carbon fibre) face sheets [2]. To assemble the floor panels onto the aircraft's supporting frame structure, special load-introducing elements known as plugs are employed, ensuring a smooth load distribution. These cylindrical plugs, matching the core's thickness, are mostly made from fibre-reinforced prepreg material. Generally, glass fibre is used as reinforcement. The integration of these plugs during the panel layup preparation, before curing, may result in tolerance issues. In the project EcoFloor, we aim to develop a new floor panel with a novel concept that improves both the sustainability of the structure and the efficiency of the manufacturing process. For that purpose, polymeric foam material (Diab Divinycell F) with an additional cork layer is used as sandwich core material. The cork layer is used to improve the acoustic properties and the impact

performance of the panel. Additionally, there are plans to integrate fastening elements post-manufacture, allowing the use of off-the-shelf sandwich panels and increasing the manufacturing rate.

In this work, a screening of available fastening methods has been done. For the screening, pull-out tests and shear-out tests were performed to assess the mechanical performance. In addition to the reference GFRP plug, three fastening methods were investigated: A PEI-plug, an EJOT TSSD® insert, and a Bossard MM-Welding® insert. While the PEI-plug is integrated in a similar way to the reference plug, it is cheaper than the GFRP-plug. The EJOT TSSD® insert is made of PA6 plastic, does not require a pilot hole, and the joining takes place due to frictional heat caused by the rotation and an axial force. The Bossard MM-Welding® fastening method also uses ultrasonic energy to partially liquefy the thermoplastic material and create the connection to the sandwich core, but does so by axial movement, not radial like in the EJOT process. After testing, the results were analysed and a comparison to the reference GFRP-Plug was done in order to estimate the suitability of the new load introduction methods.

2. Experimental Investigations

2.1. Materials and Manufacturing

Sandwich panels with a total thickness of about 10 mm made of two thin carbon-epoxy skins (one layer of HexForce® G0926 D 1304 TCT INJECTEX E01 2F HS06K woven, bidirectional carbon fibre fabric for each side) separated by a closed cell Diab Divinycell F (F50 or F90) and a thin cork layer Amorim Corecork NL25. The panels were manufactured with the Modified Vacuum Infusion (MVI) system as described in [3]. Like previously mentioned, four insert types were investigated: A GFRP-plug and a PEI-plug with a diameter of 18 mm, and an EJOT TSSD® insert, and a Bossard MM-Welding® insert with a diameter of 16 mm. While the plugs were integrated during the manufacturing of the sandwich panel, the Ejot and the Bossard inserts were inserted after the curing of the panel. In order to be able to perform pull-out tests with the Ejot TSSD-insert a washer was used, as the geometry of the insert is not suited for the used screw joint. The tested insert are depicted in Figure 1.

Figure 1. Tested Inserts

In addition to the use of four different inserts, the foam core density and the cork layer thickness were variable. In total seven different specimen configurations were investigated during this test campaign. Table 1 gives an overview about the main characteristics of each configuration.

Table 1. Investigated specimen configurations.

Specimen Type	*Insert type*	*Foam Core*	*Cork thickness [mm]*	*Foam core thickness [mm]*
PEI-Plug	PEI-Plug	F50	1	9
GF-Plug	GFRP-Plug	F50	1	9
EJOT F50	EJOT TSSD	F50	1	9
EJOT F90	EJOT TSSD	F90	1	9
Bossard F50	Bossard MM-Welding	F50	1	9
Bossard F90	Bossard MM-Welding	F90	1	9
Bossard F90-2	Bossard MM-Welding	F90	2	8

2.2. Test setup

In real application, a floor panel is generally mounted on stiff metallic support structure by means of multiple screws with countersunk head and nuts. The Insert is subject to shear loads and pull loads in screw axial direction, where the support creates a kind of resistance against axial deformation (see Figure 2).

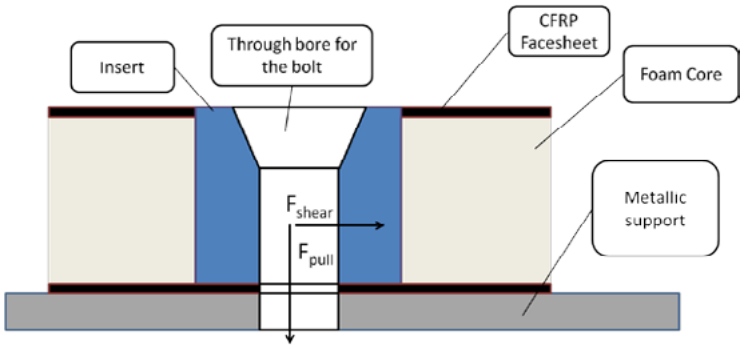

Figure 2. Schematic illustration of a floor panel insert under load

In order to evaluate the performance of the inserts two tests were conducted: pull-out test (see Figure 3 left) and shear-out test (see Figure 3 right). For the conducted tests, there is no specific norm that describes the test procedures. For that reason, the test setup was defined based on the work of Heimbs [4]. The specimen for the pull-out test has a flat surface of 100 x 100 mm². The rigid support structure has a hole with a diameter of 70 mm and it disables the translation of the test specimen in loading direction. The specimen is then loaded in out-of plane direction until rupture. The specimen for the shear-out test has a flat surface of 95 x 95 mm² and is fixed with a picture frame that blocks the translation in loading direction. The shear force is introduced until the first significant load drop appears. For the assessment of the insert performance, the load-displacements diagrams are recorded and the maximum loads at failure as well as the damage modes are analysed.

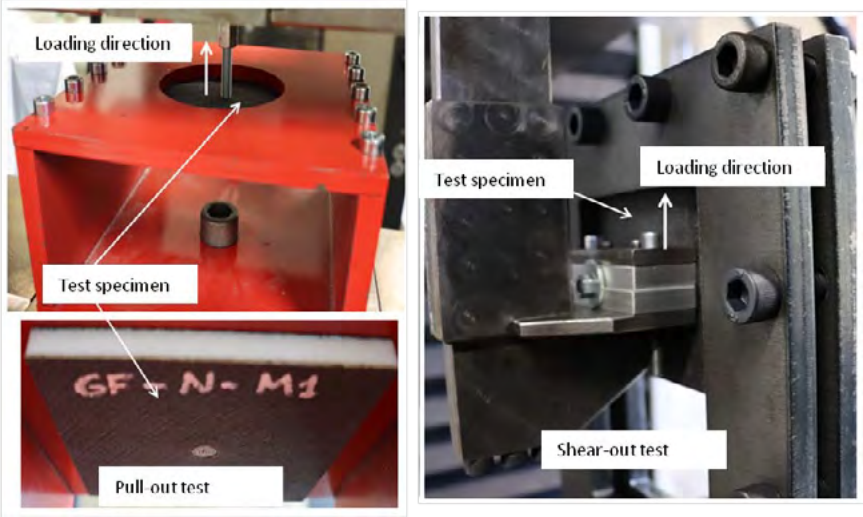

Figure 3. Test Setup of the pull-out test (left side) and the shear-out test (right side)

2.3. Test results

The load-displacement diagram of the specimens "Bossard F50" under pull-out loading is depicted in Figure 4-A. It can be seen that the response is linear until about 2000 N, at which the specimen reached their strength limits. At about 500 N a small kink in the curve is observed, which indicated the initiation of the first damage, which was the failure of the bonding connection between the insert and the core material. All specimen types showed similar load-displacement curves with minor differences and failed at a load of about 2000 N. The highest pull-out strength was measured with the GF-Plugs at about 2200 N and the lowest with the Bossard-Insert at about 1900 N. The EJOT insert has strength similar to the strength of the GF-Plugs, but it should be mentioned that a washer was used to be able to perform the test, which has improved the strength value slightly by increasing the contact surface. A comparison of the measured pull-out-strengths is illustrated in Figure 4-B.

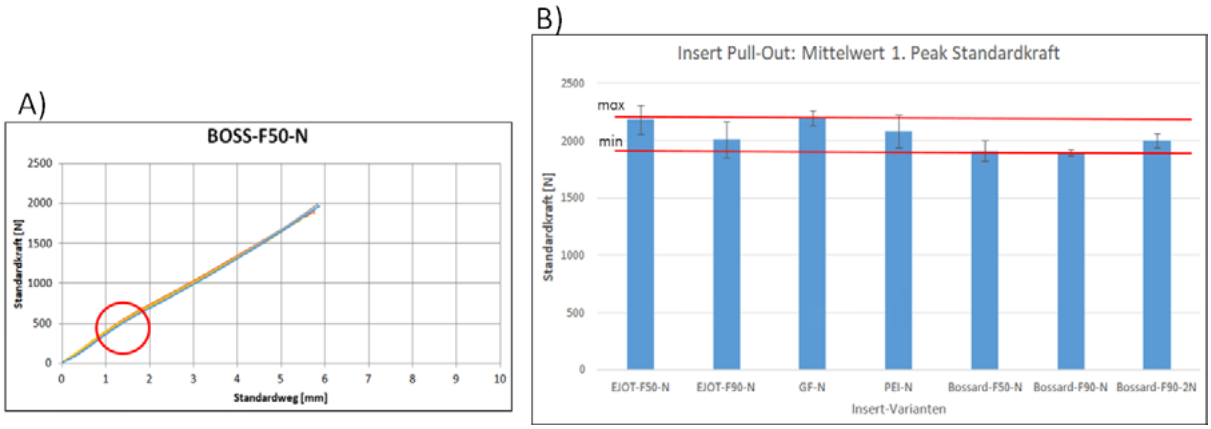

Figure 4. A) Load-displacement diagram with Bossard-insert under pull-out load; B) Measured Pull-out strengths of the tested configuration

Regarding the damage mode (see Figure 5), all tested insert showed similar behaviour. On the tension side, a dent with face sheet damage (fibre breakage) could be observed as the lower face sheet of the sandwich specimen creates a resistance against the insert deformation. On the opposite side, the pressure side (the side with the screw head) we can observe the debonding of the insert and how the insert disconnects from the upper face sheet. From these tests, it can be concluded that the dominant

influencing factors of the pull-out strength the strength of the face sheet and the contact surface between the insert and the lower face sheet.

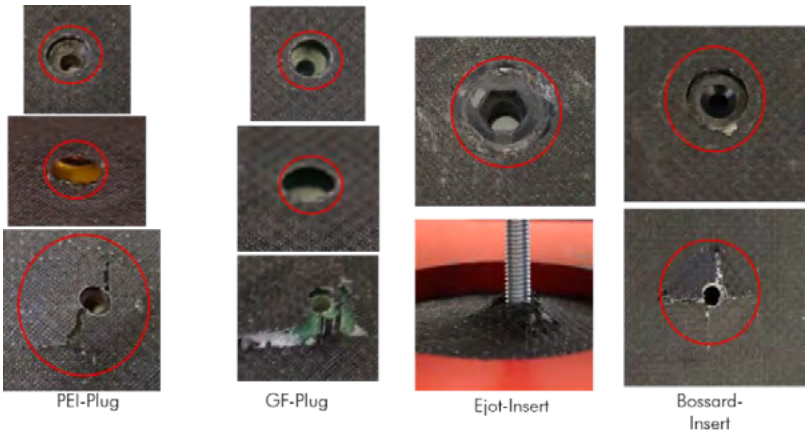

Figure 5. Observed damages due to pull-out loads

Under shear load the shape of the load-displacement diagram (Figure 6-A) looks quite different compared to the diagram of the pull-out test. Due to the complexity of the test setup, it takes between 1.5 mm and 2 mm until the load is correctly introduced and the linear elastic phase starts. The damage is not any more brittle und we can observe a kind of plastic deformation. Regarding the shear-out strength Figure 6-A shows that on the one hand the GF-plug has the highest strength, which reached about 2900 N. The performance of the PEI-plugs was slightly lower compared to the GF-plugs (about 2370 N). On the other hand, the Bossard and the EJOT inserts combined with Diab F50 foam and 1 mm cork have similar values of about 2230 N. Despite increasing the foam core density the strength under shear loads didn´t improve, as we observed a small strength reduction. It can be explained by a poorer bonding strength between the insert and the foam with higher density. Observing the standard deviations shows however that the plugs have large standard deviations, while the EJOT and Bossard insert showed better reproducibility as the standard deviation is much smaller.

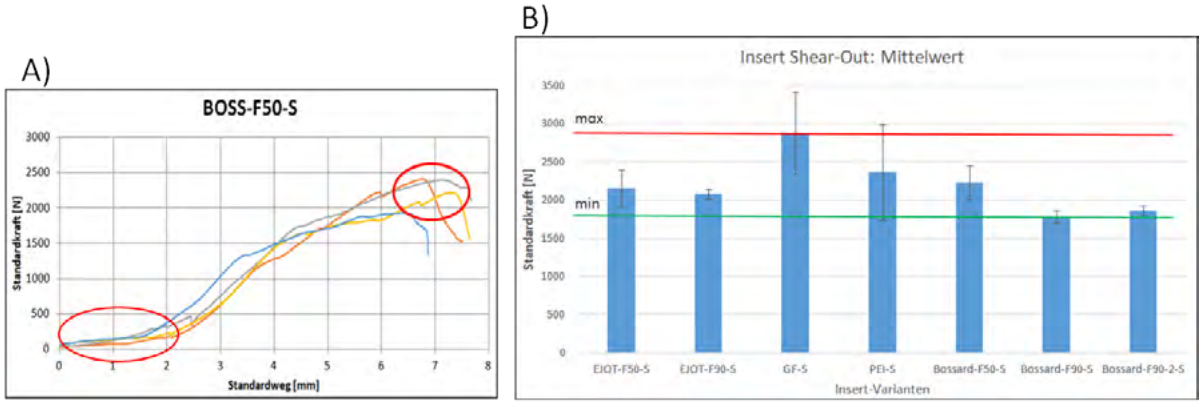

Figure 6. Load-displacement diagram with Bossard-insert under shear-out load; B) measured shear-out strengths of the tested configuration

Figure 7 shows typical insert shear damage consisting of debonding of the skin insert connection, core crushing in the compression side and a sliding of the insert under the skin. In addition, the stiffness of the insert material seems to have a dramatic influence on the plastic deformation of the insert as we

can observe a large widening of the EJOT hole, while no widening could be observed with the GF-plugs.

Figure 7. Observed damages due to shear-out loads

3. Conclusions

In this work, alternative methods for load introduction into floor panels have been investigated in order to find efficient inserts that enable the reduction of production costs and have similar mechanical performance compared to the widely used GFRP-plugs.

The tests demonstrated that all investigated fastening methods perform similarly in thickness direction (pull-out test), with face sheet properties being the dominant factor for pull-out strength. This lies on the loading direction of the specimen. Probably loading in the opposite direction would lead to different results. The shear-out tests show that the GFRP-plugs slightly outperform the other fastening methods. However, the shear-out strengths of the Bossard MM-Welding® and EJOT TSSD® fasteners are likely sufficient to enable their use in floor panels. Using one of these two fastening methods in foam core floor panels would dramatically increase the efficiency of the manufacturing process of aircraft floor panels. Further improvement of the shear-out strength could be reached by increasing the contact surface of the insert with the foam core and by using stiffer insert materials.

Acknowledgments

This work was funded by the German Federal Ministry for Economic Affairs and Climate Action through the Federal Aeronautical Research Program LuFo VI-2 within the project EcoFloor under the Grant No. 20E20101A. The authors wish to acknowledge this support. We thank both the KVT-Fastening GmbH (Multi-Material-Welding, a Bossard company) and EJOT SE & Co. KG for integrating their respective products into the EcoFloor Sandwich Panels, free of charge.

Abstract
Due to incorrect failure during experimental characterisation of high-performance composites, full potential is not measured or correctly obtained using standardised test methods. Structural effects, stress concentrations, experimental uncertainties, and several other parameters influence and interact with the material's performance. Investigations of the geometry, size, and test conditions are needed to obtain a representative and repeatable method. An entire experimental approach is not appropriate due to the complexity of the involved phenomena. For this matter, models are efficient tools to support the development of new methods and designs to tackle encountered experimental issues. This study exposes a dialogue approach between experimental observations and model feedback information to assist in developing a new testing specimen geometry. The steps presented for a 5 mm thick unidirectional pultruded carbon fibre profile led to a new specimen shape with a resulting improved measured compressive strength of 3 %.

1. Introduction

Used in wind turbine blades subjected to bending, pultruded carbon profiles are then loaded in tension or compression. Accurately determining the tensile and compressive properties is essential for designing these structures. The mechanical properties of materials are typically obtained by standardised test methods.
New materials and upcoming composites exhibit improved properties and performance that challenge these methods: following the available standards doesn't allow for measuring the correct potential strength, leading to overdesign [1].

Previous experimental testing campaigns, for instance, from Ferguson et al. [2] showed that constant-width compression specimens exhibit a wrong failure mode in the load introduction region. Specimen geometry has, therefore, been modified to waisted specimens (W6). Even if they are found to carry a higher load, the same conclusion is drawn: the final failure occurs out of the gauge section, in the waisted region, under the tabs, or in the junction with the grips (Figure 1). The failure mechanisms exhibit kink-band and splitting, leading to the final failure of the test specimen, typically observed during compression tests [2,3,4]. Thus, again, the material's full design potential is not captured.

A similar problem is faced during experimental tension strength determination [1,5], and some work has been done to analyse the gain in modifying the test geometries. Parameters linked to specimen geometry, tabs, and the material of the tabs have been explored. Iterations and studies are still ongoing. Regarding compressive tests, it is well known in the literature that the experimental strength measurements depend on experimental parameters, settings, and composite configuration [6]. The "structural effect" of

compressive tests is highlighted by Grandidier et al. [7], explaining that the compressive performance of composites is not an intrinsic material property: it depends on overall parameters such as laminate thickness, lay-up configuration or plies scale.

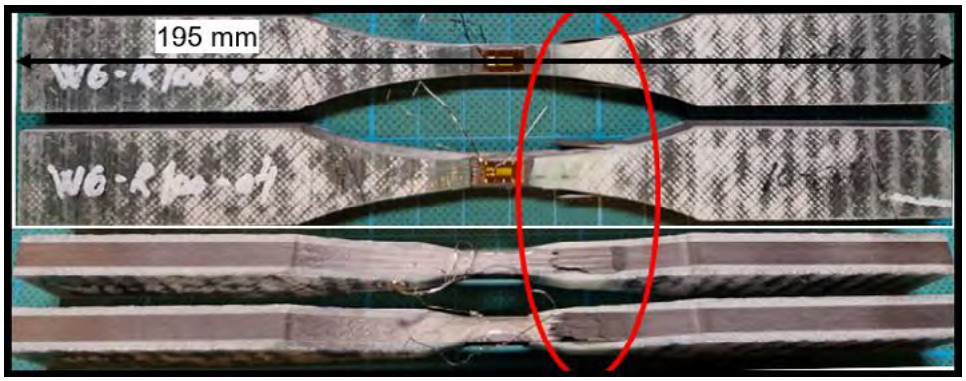

Figure 1. Out of gauge section failure during compressive tests on 5 mm thick pultruded carbon fibre profile specimen – waisted shape, front and side views

Fibre micro buckling and fibre kinking are two main scenarios for compressive failure modes. Several models have been developed to assess the compressive strength of UD composite under compressive loading along the fibre direction [4, 8, 9]. For instance, the Budiansky model [9] for compressive strength prediction is related to the in-plane shear characteristics of the composite and fibre waviness [10, 11]. These approaches mainly concern laminas. Special attention also addresses that the fibre misalignment and void content play a critical role in the compressive behaviour of the composite [2, 12]. Gutkin et al. [13] developed a micro-mechanical finite element model, showing that the failure mechanisms are defined by shear-driven fibre compressive failure with kink-band formation and splitting.

The presented investigation focuses on compression tests of 5 mm thick pultruded carbon fibre profiles and on using a modelling approach to support the development of new test geometries. The objective is to drive the failure into the gauge section by sizing and enhancing the specimen shape/geometry. A modelling-based approach is relevant to tackle this issue, as it constitutes an excellent alternative to long experimental campaigns and allows for a parametric study.

The first step of the study, with a linear model, is to capture the first information about the behaviour and stress repartition. A parametric study is performed, and the stress distribution is compared between different iterations. A dialogue between experimental and numerical is carried out.

2. Description of the model

2.1. Abaqus model – FEM presentation

In this context, a 3D Abaqus Implicit Finite Element (FE) model is built to study the specimen loading in compression and analyse the phenomenon contributing to the early failure. The model consists of modelling the different parts of the specimen (Figure 2), using 3D elements: the specimen, the tabs and the epoxy adhesive layer between the tabs and the specimen. Coinciding nodes link all these parts. 3D elements are also used for the grips. A Surface-to-Surface interaction defines the contact formulation between the grips and the tabs. The contact formulation in the Normal direction is defined as “Hard” contact and allows separation after contact, while the tangential behaviour is given through a penalty friction formulation with a friction coefficient of 0.4. Symmetry is considered in the middle of the specimen following the XZ plane. The boundary conditions reflect the experimental test conditions and are applied through Reference Points (RP). The compression is applied with a concentrated load

distributed over the specimen and grips surfaces through a kinematic coupling between the surfaces and the concentrated force applied on the RP. Grips pressure is applied similarly (representative load defined after measurement on a testing machine). A mesh sensitivity analysis has been performed, and the mesh is refined in the area under the end of the tabs.

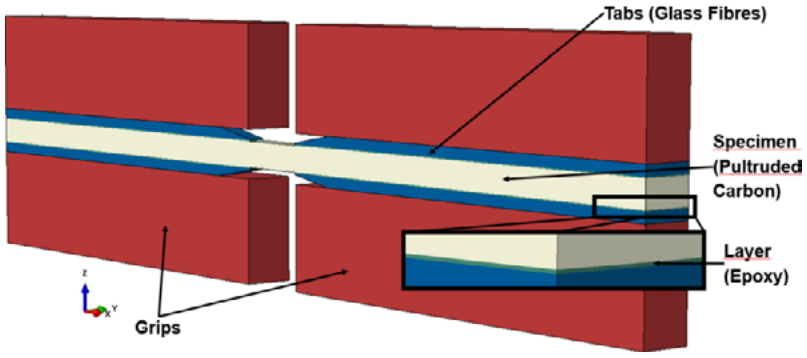

Figure 2. Modelling of Specimen, Epoxy Layers, Tabs and Grips

As a first approach, the 5 mm thick pultruded carbon specimen and the 2 mm biax Glass/Epoxy tabs are simulated using Elastic formulation and Engineering Constants **(**Table 1**)** and the epoxy layer as well as the steel grips with Isotropic elastic formulation **(**Table 2).

2.2. Model of the reference geometry

The reference geometry is a waisted shape specimen, W6, as seen in Figure 1. The modelling conditions and loading represent experimental conditions (defined by the failure load obtained during compressive tests on the reference geometry). Experimentally, the compressive load is applied in the gripping part of the end-tabbed test specimen. It results in a combined compressive and shear load introduced through the tabs. A uniform unidirectional compression load is induced into the gauge section of the test specimen. As previously described for this geometry, the load measured at failure is close to -39 kN, representing a compressive strength of -1300 MPa and strain to failure of ~-0.98 %. With the linear assumption, this load is applied in the static model to screen the stress repartition at failure.
This first model is validated by observing the load introduction and the shear transition between the grips and the tabs. In addition, the compressive stress (S11) in the gauge area corresponds to the expected

stress level (-1300 MPa). Based on experimental observation and the first assumption, stresses of interest are longitudinal stress S11, out-of-plane stress S33, and, initially, shear stress S13, which is considered critical to trigger the failure (direction 3 is the normal pressure on the grips). These stresses are plotted along two paths, as defined in Figure 3.

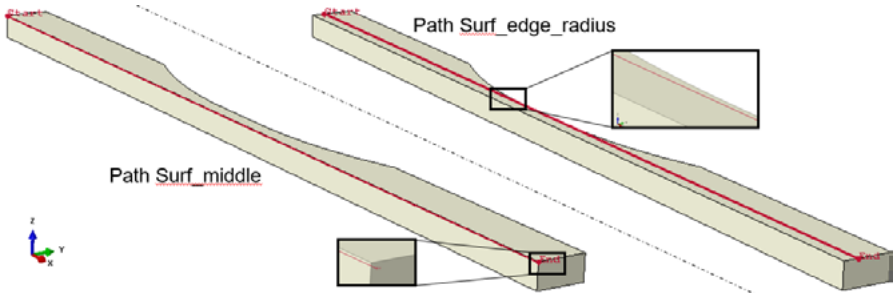

Figure 3. Paths for stress analysis

The specimen's maximum stresses, subjected to numerical singularities, are observed under a compressive load of -39 kN (Table 3).

Table 3. Maximum stresses in the specimen – Reference geometry model

Component	S11	S22	S33	S12	S13	S23
Stress (MPa)	-1588	-18,4	-33,8	-102,4	-42,6	-8,6

Figure 4 gathers the obtained plots. Stress S13 exhibits maximum stress values around the experimental failure's location, supporting the assumption that shear component acts on the fibre and resin leading to final failure.

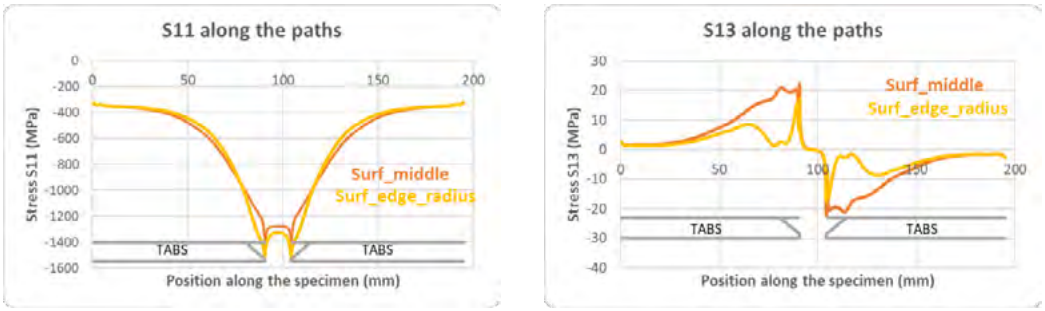

Figure 4. Numerical stresses S11 and S13 along the paths for the reference specimen.

3. Parametric Study: numerical and experimental

3.1. Set up of the study and first iteration

Under the same compressive load, a parametric study is conducted to monitor the influence of specimen geometrical parameters change and the effect on the stress repartition. The objective is to reduce shear stresses in the specimen by modifying parameters such as tab thickness, length of the chamfered area, tab fibre orientation, and radius of the waisted area. To automatise the generation of the model and lead a robust comparison, a Python script is established with all the parameters identified.

As the first results, thicker tabs lead to higher shear stress S13, a higher radius seems to distribute stress along the paths, the length of the tabs' chamfer doesn't really influence the stresses along the edge radius but lower the shear stress in the centre of the specimen. Buckling issues and manufacturing processes are also considered for the proposed solution. Combinations of different modifications are then investigated, and the proposed solution combines a 600 mm Radius and a 20 mm chamfer length. The maximum stresses in the Iteration 1 specimen (Table 4) are lower than in the reference specimen.

Table 4. Maximum stresses in the specimen – Iteration 1 geometry model.

Component	S11	S22	S33	S12	S13	S23
Stress (MPa)	-1487	-10,4	-24,8	-48,8	-23,6	-6,5

Compared to the reference specimen, Figure 5 below also shows a reduction of the S13 stress along the paths.

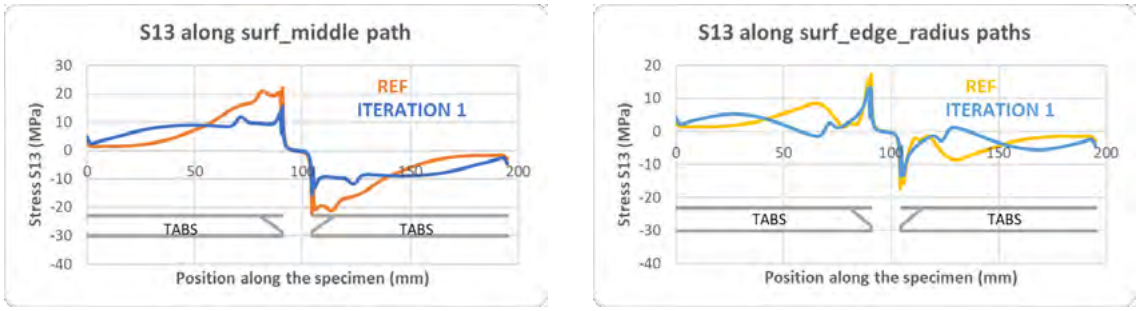

Figure 5. Numerical stress S13 along the paths: Iteration 1 is compared to the reference specimen.

Two specimens are then manufactured to be tested (Figure 6). With a load at failure of -38 kN (compressive strength of -1240 MPa), the results are slightly lower than the reference specimen. The failure generates in the radius of the specimen, as exposed in Figure 6-b), away from the gauge area.

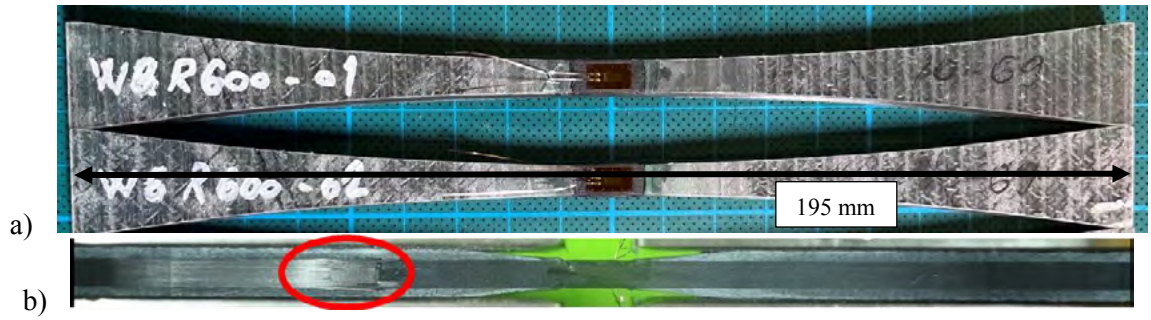

Figure 6. a) Proposed specimen geometry out of Iteration 1. b) Side view of the failure location after compression test on Iteration 1 geometry.

3.2. Second iteration

From these two configurations, the results obtained can be used to provide more information in the numerical/experimental dialogue. From Tables 3 and 4, maximum stress values obtained for S22 and S13 in the specimen enable us to "neglect" the effect of these components. However, from now on, all

numerical stresses are considered, and new analysis paths (surf_edge_circle) are defined (Figure 7). The locations of the failures are also known (in red in the graphs) and are essential information for observing the stresses in these areas.

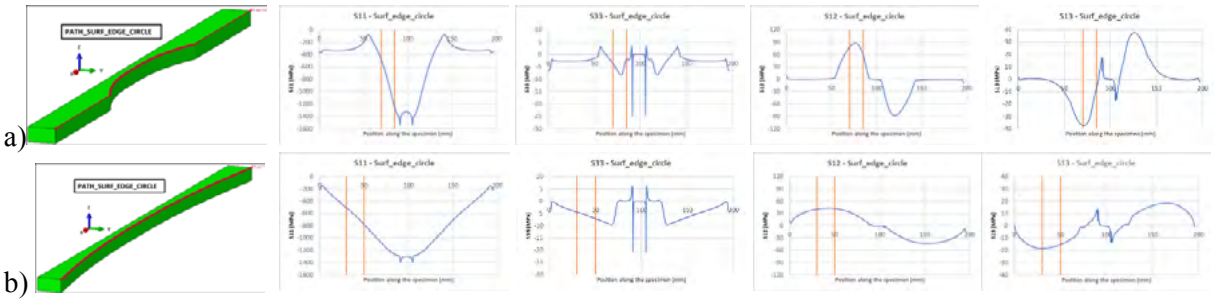

Figure 7. New path for stress analysis along the edge and the associated stress repartition S11, S33, S12 and S13: a) Reference geometry, b) Iteration 1 geometry.

After analysing the effect of different modifications and comparing the stress curves during Iteration 2, a new geometry is proposed with a 300 mm radius, a 20 mm chamfered length, 30 mm external width and 0° fibre-oriented tabs. Figure 8 shows the stresses in comparison with Reference and Iteration 1.

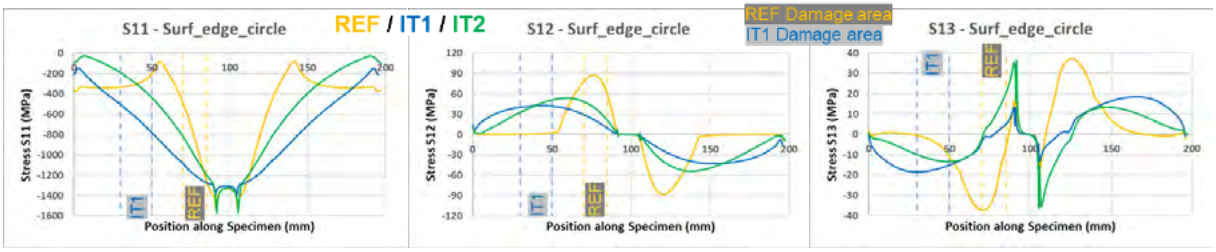

Figure 8. Comparison of the stresses S11, S12, and S13 along the path on edge for the reference (Yellow), Iteration 1 (Blue) and Iteration 2 (Green) configurations, with failure locations for reference and Iteration 1.

Considering the stress combination as a trigger for the failure, this stress repartition is more distributed and seems lower than the compared ones. However, the S13 stress concentration is higher at the tip of the tabs and the beginning of the gauge area. To provide the model with more information at this step, Iteration 2 geometry is then manufactured (specimen shown in Figure 9), and four specimens are tested.

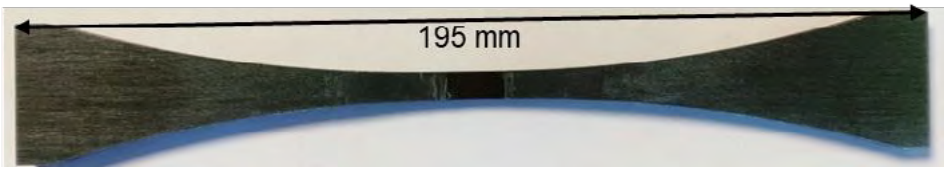

Figure 9. Iteration 2 specimen geometry.

The experimental results drive to a failure around -42 kN and compressive strength of -1345 MPa, corresponding to a 3 % improvement compared to the reference specimens' performance. However, the failure is still not located in the gauge section and occurs at the tip of the tabs for three specimens and in the radius for the fourth specimen.

4. Conclusions

This study presents the initial stages of a modelling approach for designing optimised compression specimens. Results underscore the complexity of compressive behaviour and the importance of shear stress consideration, emphasising the significance of numerical and experimental interactions for a deeper understanding.

At this stage, after iterations on parameters modification and comparison, a new geometry for compressive tests is proposed, leading to a 3% increase in compressive strength. New experimental results will bring extra information to continue the specimen optimisation using numerical study. To build a topology optimisation strategy, the specimen's failure criterion must be defined. The main objective to drive the failure in the gauge section is still to be achieved, leading to a repeatable and representative test method to measure compressive strength of pultruded profiles.

Keywords: delamination, fracture toughness, CFRP laminate, ply discontinuity, stress analysis

Abstract
Carbon fiber reinforced plastics (CFRP) laminates, known for their superior in-plane properties, often exhibit less robust interlaminar toughness, particularly vulnerable at structural complexities such as tapered sections and bolt hole regions. This study explores the use of polyamide (PA) mesh as an innovative method to enhance the interlaminar fracture toughness of CFRP laminates, aiming to improve overall durability by mitigating delamination. By integrating PA mesh between laminate layers, particularly around areas of ply discontinuity, the study evaluates the effectiveness of this approach in suppressing damage initiation and promoting energy absorption during fracture processes. Experimental investigations were conducted using End Notch Flexure (ENF) tests, which demonstrated a significant enhancement in fracture toughness—up to three times that of unmodified CFRP laminates. The microstructural configuration of the PA mesh was found to obstruct crack propagation effectively, thereby increasing the energy absorbed during fracture. Additionally, the study tested two configurations of PA mesh placement: a complete insertion between continuous and discontinuous plies and a localized insertion around the resin pockets. Both configurations prevented the onset of delamination typically initiated by matrix cracks, with a noticeable reduction in delamination propagation under tensile stress.

1. Introduction

Carbon fiber reinforced plastics (CFRP) laminates generally possess strong in-plane properties, while their out-of-plane characteristics, such as interlaminar toughness, are commonly seen as less robust. In the actual structure of CFRP, complex structural elements such as tapered sections for varying thickness and fiber-discontinuous regions due to bolt hole placements for joining become the primary locations for intralaminar damage initiation, which subsequently triggers interlaminar failure [1, 2]. Crack propagation in materials can be suppressed by incorporating features that absorb energy, preventing the initiation and growth of cracks [3, 4, 5]. One of the methods being attempted to improve the interlaminar fracture toughness of CFRP laminates is the placement of high-toughness materials between the layers [6].

©2024 | 3_FIKRY_M. J. Mohammad_TO39P.pdf

In this study, we consider the utilization of polyamide (PA) mesh material as one method to enhance the interlaminar fracture toughness of CFRP. Specifically, to improve the interlaminar fracture toughness and suppress interlayer damage initiation i.e., delamination. This involves addressing the complex structures of laminates with ply-discontinuous regions, implementing localized PA mesh configurations, and verifying damage suppression. In the study, the mechanism of enhancing interlaminar fracture toughness through the incorporation of PA mesh material was examined via double cantilever beam (DCB) and end notch flexure (ENF) tests. The study further confirmed the effective placement of PA mesh within CFRP laminates through experiments involving laminates with ply discontinuity under tensile load conditions. Two distinct configurations were employed for this purpose: firstly, the insertion of PA mesh material as a whole, positioned between continuous and discontinuous plies, and secondly, the insertion of 20 mm cut PA mesh material around the resin pocket (the region of fiber discontinuity), again placed between continuous and discontinuous plies.

2. Fracture toughness evaluation

2.1. Materials and Methods

For the manufacture of test specimens for interlaminar fracture toughness evaluation, prepreg (T700SC/2592, manufactured by Toray Industries) with a thickness of 0.14 mm was used. As the specimens for the interlaminar fracture toughness test, a unidirectional (UD) $[0]_{20}$ laminate was manufactured. The prepregs, each with a thickness of 0.14 mm per ply, were cut into 20 pieces of 200 x 200 mm. These were then stacked up into two sets of 10 pieces each. As shown in Figure 1, a PA mesh, measuring 175 x 200 mm was sandwiched between these two sets of stacked prepregs. The PA mesh used in this study has a fiber diameter of 50 µm, a thickness of 87 µm, and an opening of 95 µm (N-NO175T, NBC Meshtec Inc.). To create an initial crack in the specimen, polyimide film, measuring 25 x 200 mm was also sandwiched in between the upper and lower plies. The polyimide film used was 25 µm thick. An autoclave (DANDELION 2010) was used to cure the laminate at 130°C and a pressure of 0.2 MPa. Laminates were then cut into specimens suitable for DCB and ENF tests.

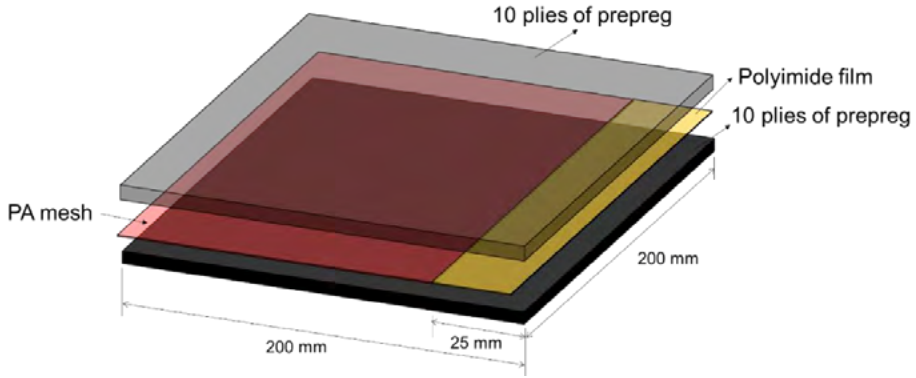

Figure 1. Illustration of the lay-up of a laminate for interlaminar fracture toughness evaluation.

For DCB test, measurements were taken of the load P, crack length a, and crack opening displacement (COD). Five specimens were tested. The first measurement was taken when the crack had propagated 3 mm from the initial crack, and subsequent measurements were made every 3 mm of crack propagation, with a total of five measurements per specimen. The loading speed was set at 0.5 mm/min up to 6 mm from the initial crack, and increased to 1.0 mm/min for crack propagation beyond 6 mm. Mode I interlaminar fracture toughness value G_I, was calculated using the following formula:

$$G_I = \frac{3}{2(2H)}\left(\frac{P_C}{B}\right)^2 \frac{(B\lambda)^{\frac{2}{3}}}{\alpha_1} \quad (1)$$

G_I was determined using the critical load P_C, the compliance of the COD in the elastic portion of the load-COD curve λ, and the slope of the linear approximation of the cube root of the compliance of the normalized crack length per unit width α_1.

For ENF test, measurements were taken of the load P and (maximum) deflection δ. Similar to DCB test, five specimens were tested. The load was applied at the midpoint of the support span with a distance of $2L = 70$ mm, as shown in Figure 2. The test speed was set at 0.5 mm/min. The mode II fracture toughness value G_{IIC} was calculated from Eq. (2). In the equation, a_1 represents an estimated value of crack length at a specific load. Additionally, P_1 represents a specified load, C_0 denotes the compliance of the initial elastic part and C_1 represents the compliance at a specified load, calculated from the load-COD curve. The maximum load $P_{\max}$ was used as P_1 in this study.

$$G_{IIC} = \frac{9a_0^2 P_1^2 C_1}{2B(2L^3 + 3a_1^3)}, \qquad a_1 = \left[\frac{C_1}{C_0}a_0^3 + \frac{2}{3}\left(\frac{C_1}{C_0} - 1\right)L^3\right]^{\frac{1}{3}} \tag{2}$$

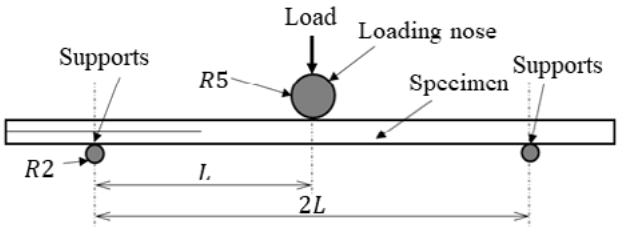

Figure 2. Schematic for ENF test set up.

2.2. Results and Discussion

Figure 3 shows the mode I fracture toughness G_I – crack length relationship for all specimens. Here, the dotted lines show the average G_I values. G_{IC} is the fracture toughness value calculated from the first loading and represents the critical strain energy release rate necessary for the initiation of delamination. It quantifies the energy per unit area required to initiate a delamination under mode I loading conditions. Conversely, G_{IR} represents the average fracture toughness value from the second to the fifth loading. This parameter is the propagation strain energy release rate, which measures the energy required to propagate an existing delamination. The average G_{IC} and G_{IR} for all five specimens are 519 J/m² and 336 J/m², respectively. Figure 4 displays bar charts comparing the G_{IC} and G_{IR} values of neat CFRP laminate (specimen without PA mesh insert) and CFRP laminate with PA mesh insert. The G_{IC} value for the CFRP with PA mesh insert is approximately three times higher than that of the neat CFRP, which has a G_{IC} value of 171 J/m². However, it should be noted that the G_{IR} value is slightly reduced compared to the neat CFRP (366 J/m²). The values of G_{IC} and G_{IR} of neat CFRP were taken from [6].This indicates that inserting PA mesh into the CFRP laminate requires higher strain energy to initiate delamination, but once initiated, the propagation becomes easier under mode I loading conditions. This indicates that the dimensions and configurations of the PA mesh used in this study are not optimal for enhancing the interlaminar fracture toughness performance of CFRP laminates under mode I loading.

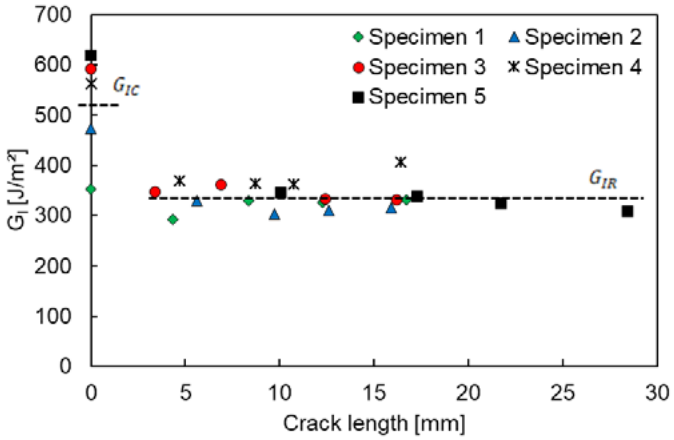

Figure 3. Mode I fracture toughness G_I– crack length relationship for all specimens. Dotted lines show the average G_I values.

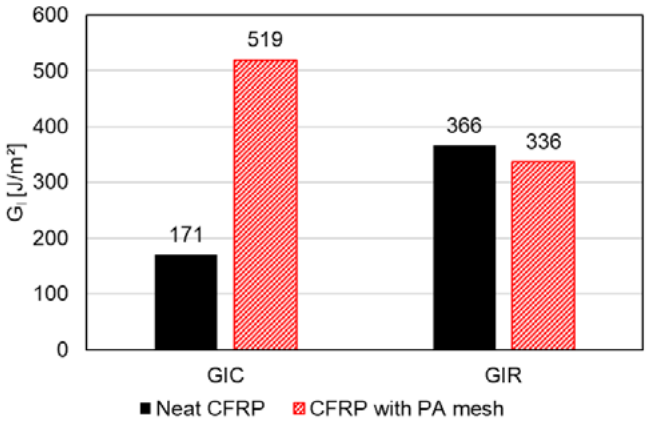

Figure 4. Comparison of mode I interlaminar fracture toughness between neat CFRP laminate and CFRP laminate with PA mesh insert.

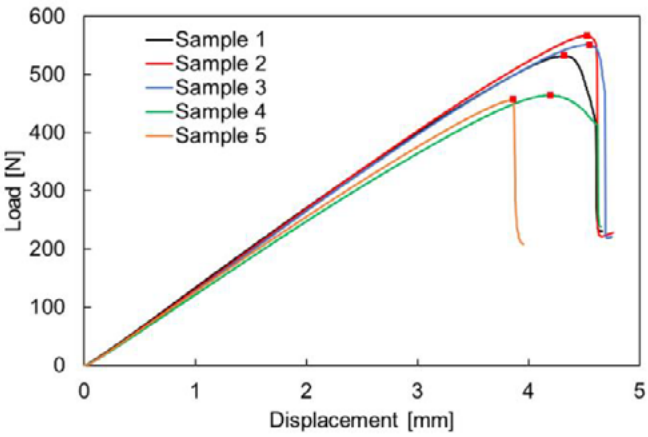

Figure 5. Load – deflection curves from ENF tests. The red dots represent the maximum load point of each test.

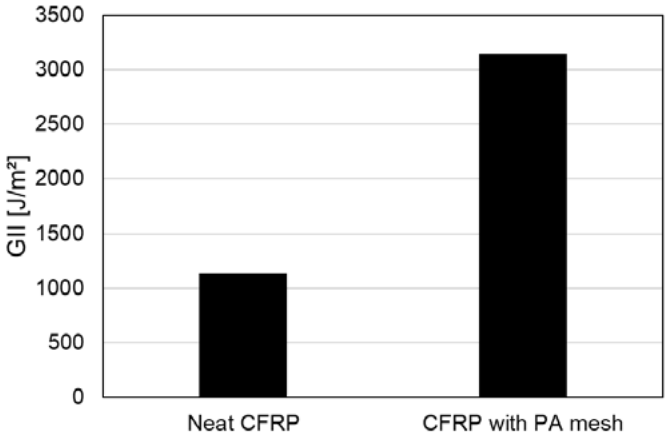

Figure 6. Comparison of mode II interlaminar fracture toughness between neat CFRP laminate and CFRP laminate with PA mesh insert.

Figure 5 presents the load-deflection curves from the ENF test conducted on five specimens. The peak loads for each specimen are highlighted with red dots on the curves. Figure 6 illustrates a comparison of the mode II fracture toughness G_{IIC}, values between CFRP laminates with and without PA mesh inserts. The displayed G_{IIC} values are averaged from five specimens tested. It is apparent that the CFRP laminates incorporating a PA mesh insert exhibit a mode II fracture toughness approximately three times greater than that of the neat laminates. This enhancement can be attributed to the integration of PA mesh

within the CFRP layers, which absorbs the energy and altering the crack trajectory due to its microstructure, under shear stresses (mode II loading).

The total of the G_{IC} and G_{IIC} values suggests that CFRP laminates with PA mesh inserts markedly outperform their neat counterparts in handling diverse loading conditions. Future research should continue to refine the mesh configurations to maximize these benefits across different modes of fracture, ensuring optimal performance and extended usability of CFRP structures.

3. Application of PA mesh in CFRP laminates with ply discontinuities

3.1. Materials and Methods

Laminate configuration of the specimens used in the uniaxial tensile test was $[0_2/PA/0_2]s$. Initially, as illustrated in Figure 7, a stack of four plies of carbon fiber/epoxy UD tape prepreg (Torayca, T700SC/2592), each with a thickness of 0.14 mm, was bisected perpendicularly to the fiber direction into two equal halves. These halves were then aligned with a predefined gap to form a symmetrical laminate structure, with two PA meshes and continuous $[0]_2$ UD laminates attached above and below the gap. The gap or resin pocket length L_0 was set to approximately 1 mm.

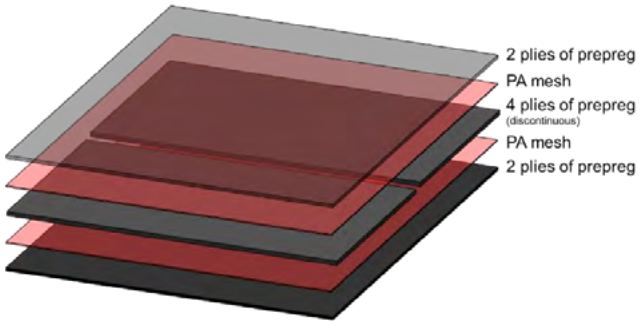

Figure 7. Illustration of laminate with discontinuous plies and PA mesh embedded.

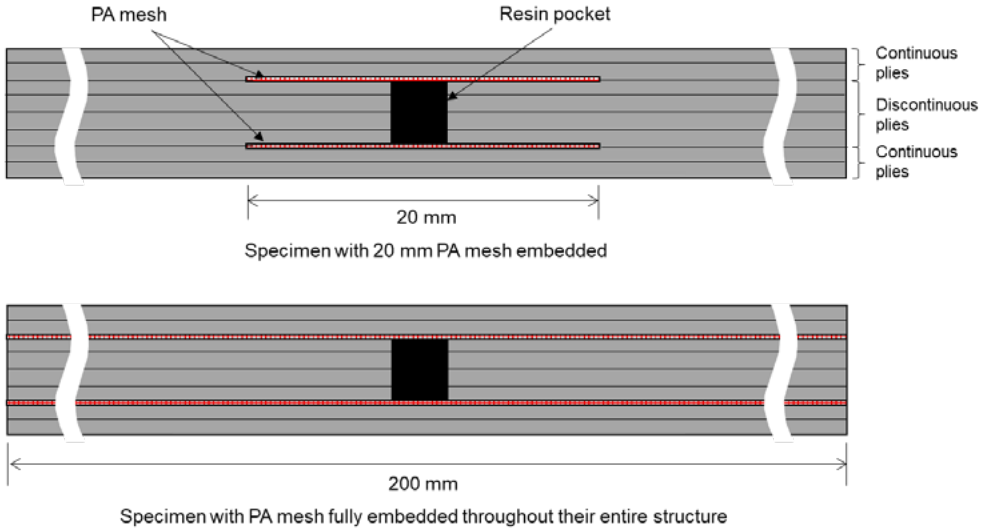

Figure 8. Placement of PA mesh in the specimen.

In this study, the specimens were manufactured with a 20 mm PA mesh embedded and with PA mesh fully embedded throughout their entire structure. A schematic diagram of the structures is shown in Figure 8. The laminate was then cured using autoclave molding at a temperature of 130°C and a pressure of 0.2 MPa. During the curing process, the elevated temperature caused the epoxy resin in its gel-phase condition from the adjacent UD plies to flow into the gap, forming a resin pocket. This resin pocket then cured simultaneously with the rest of the laminate. After cooling to room temperature, the laminates were sectioned into specimens as depicted in Figure 9.

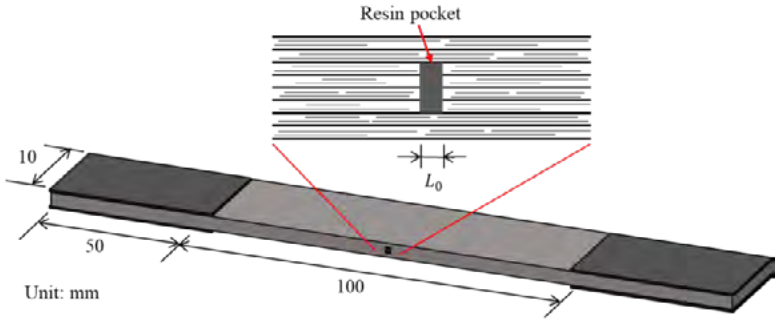

Figure 9. Specimen measurement.

3.2. Results and Discussion

To confirm the suppression of interlaminar delamination by embedding the PA mesh, a tensile test was also conducted on neat CFRP specimens (specimens without the insertion of PA mesh) for comparison purposes. The stress-strain curves and results of edge observations (around the resin pocket area) at specific applied stress levels for a neat CFRP specimen are shown in Figure 10. Results from neat CFRP specimens, referenced from our study [7], revealed an initial crack at 451 MPa. Subsequent matrix cracks were observed at 564 MPa and 679 MPa, with delamination initiating from the crack tip at 564 MPa, confirmed by changes in the stress-strain curve's gradient. Complete delamination between continuous and discontinuous plies was noted at approximately 725 MPa.

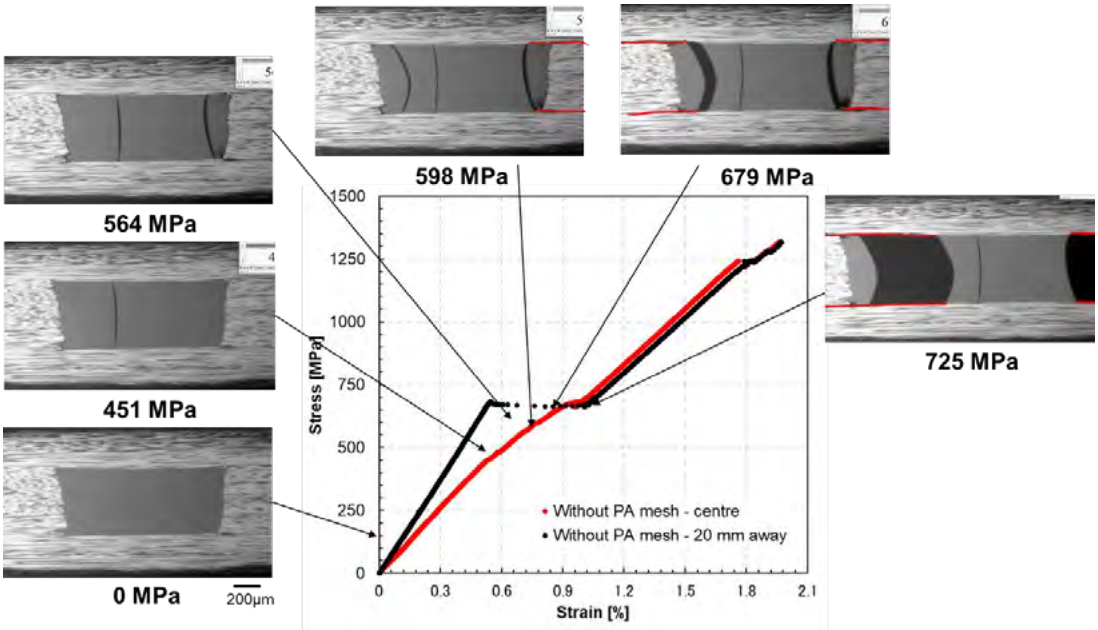

Figure 10. Stress-strain curves and results of edge observations (around the resin pocket area) at specific applied stress levels for a neat CFRP specimen [7].

The uniaxial tensile test results comparing specimens with 20 mm PA mesh inserts to neat CFRP specimens showed significant differences in stress-strain behavior, as presented in Figure 11. Edge observations detailed the progression of damage, particularly around the resin pocket area, with matrix cracks at 456 MPa and 520 MPa, and delaminations starting at 617 MPa. Even with PA mesh embedded locally, delamination was effectively suppressed, demonstrating the mesh's ability to stabilize the laminate structure. Unlike neat CFRP, which showed rapid delamination post-600 MPa, PA mesh specimens maintained a stable stress-strain curve up to higher stress levels. A significant strain jump at 720 MPa indicated sudden delamination, progressing slowly until reaching a critical stress level of 1121 MPa, far higher than the 725 MPa in neat specimens, resulting in complete delamination and fracture. This underscores PA mesh's role in increasing fracture toughness and suppressing delamination in CFRP laminates, even when applied locally.

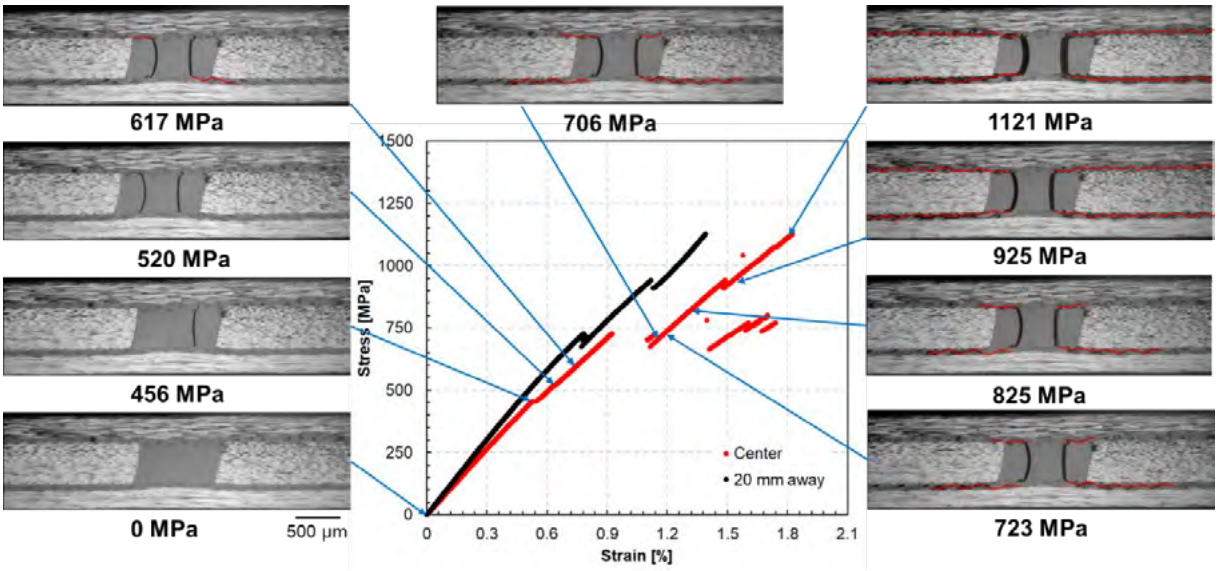

Figure 11. Stress-strain curves and results of edge observations (around the resin pocket area) at specific applied stress levels for a specimen with a 20 mm PA mesh embedded.

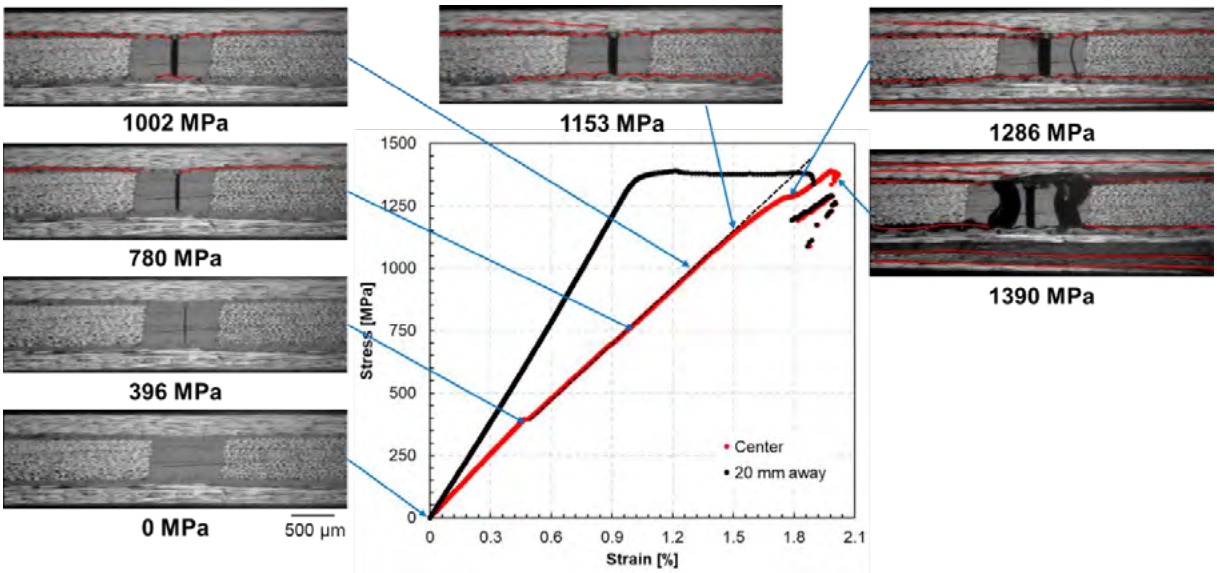

Figure 12. Stress-strain curves and results of edge observations at specific applied stress levels for a specimen with a PA mesh fully embedded throughout its entire structure.

The uniaxial tensile test results comparing laminates with fully embedded PA mesh to neat CFRP specimens showed significant differences in stress-strain behavior, as presented in Figure 12. Edge observations in the figure detailed damage progression around the resin pocket area. The first matrix crack in the resin pocket occurred at 396 MPa, slightly lower than in the neat CFRP specimen. However, the second matrix crack in the fully embedded PA mesh specimen occurred at 1286 MPa, significantly later than in other specimens. Unlike neat CFRP, where delamination progressed rapidly post-600 MPa, PA mesh specimens showed a stable, linear stress-strain curve up to high stress levels, with slow delamination progression. Additionally, compared to the specimen with a 20 mm PA mesh embedded, the specimen with a fully embedded PA mesh shows much later non-linearity in the stress-strain curve and significantly slower propagation of delamination. Delamination was observed at 780 MPa and propagated slowly, reaching 1153 MPa between continuous plies, indicating enhanced interlaminar toughness due to PA mesh. The specimen fractured at 1390 MPa following complete ply separation. As previously mentioned, this substantial enhancement in suppressing delamination is attributed to the PA mesh interrupting crack propagation. The PA mesh absorbs energy and alters the crack trajectory due to

its microstructure during crack propagation. Also, it should be noted that despite the mesh, the material strength remained unaffected, with similar fractured stress and strain compared to neat CFRP specimen.

3. Conclusions

Comparing neat CFRP laminates with those incorporating PA mesh inserts reveals clear differences in delamination behavior and stress-strain characteristics. Neat CFRP specimens show rapid delamination following an initial matrix crack, resulting in a steep decline in the stress-strain curve slope. In contrast, laminates with PA mesh, whether as a 20 mm section or fully embedded, maintain a more stable initial stress-strain curve and exhibit slower delamination, enhancing crack propagation resistance. The fully embedded PA mesh variant performs best, significantly delaying delamination even under higher stress levels while maintaining material strength equivalent to neat CFRP. This improvement can be attributed to the integration of PA mesh within the CFRP layers, which absorbs energy and alters the crack trajectory due to its microstructure. However, the study suggests that the current PA mesh configurations may not yet optimize delamination suppression under mode I loading, indicating a potential for further improvement in mesh dimensions and placement. Future research should focus on optimizing these factors through factorial design experiments to maximize the observed benefits of PA mesh in CFRP laminates.

Abstract
This paper investigates the reversibility of FFRCs' performance under realistic environmental conditions, focusing on semi-structural applications. To achieve this, FFRCs were subjected to cycles mimicking real-world exposure, consisting of 10 days of humid (i.e., salt-fog spray) and 18 days of dry conditions (22°C, 50% RH), repeated three times. The mechanical properties of the composites were monitored throughout the dry phase of each cycle (at 0, 5, 10, and 18 days of drying) by means of quasi-static three-point bending tests. Furthermore, the water absorption and desorption were assessed by tracking the weight changes of composites during the entire aging campaign.

1. Introduction

In recent years, natural fiber reinforced composites (NFRCs) have gained significant attention due to their potential to combine good mechanical performance with environmental friendliness. However, their widespread use, particularly in wet or humid environments, is limited due to some drawbacks associated with natural fibers such as their inherent variability, their high moisture absorption tendency, and their weak adhesion with several polymer matrices.

In such a context, although a wide literature is available on how NFRCs perform in humid or wet conditions [1]-[2], a research gap exists in understanding their behavior in outdoor applications with fluctuating humidity levels. Additionally, there is a lack of knowledge regarding how they recover their performance after drying. In light of this, our recent research focused on the effects of humidity exposure and drying on the performance of composites made with glass, flax, or a combination of both fibers, in simulated marine environments [3]-[5]. Specifically, we investigated the ability of these composites to recover their physical and mechanical properties after a single cycle of exposure to salt fog (humid) followed by drying.

The experimental results showed that these composites experience both reversible and irreversible aging phenomena during the initial humid step. Additionally, they exhibit a noticeable recovery of their mechanical properties during the following dry step, especially for short humid cycles.

Motivated by these interesting findings, and recognizing that the reversibility of performance recovery in flax fiber-reinforced epoxy composites (FFRCs) after consecutive salt spray and dry cycles is not well understood, this work aims to evaluate how three repeated humid-dry aging cycles impact the

reversibility of physical and mechanical properties in FFRCs' manufactured through the vacuum-assisted resin infusion process.

2. Materials and methods

Epoxy composites reinforced with five layers of twill weave woven flax fabric with an areal weight of 318 g/m^2 (shown in Figure 1) were manufactured through vacuum assisted resin infusion process, underwent an initial curing step at 25 °C for 24 hours followed by a post-curing step at 50 °C for 15 hours. A commercial DEGBA epoxy resin (SX8 EVO) mixed with its amine-based hardener (100:30 by weight) was used as the matrix.

Figure 1. Wave architecture of flax woven fabric

The whole aging campaign lasted 3 months (i.e., 12 weeks), consisting of three wet/dry cycles, each lasting 4 weeks: 10 days of foggy environment (wet phase) followed by 18 days of drying (dry phase). In more detail, the wet phase was achieved by exposing composites to salt-spray fog conditions (5 wt% NaCl solution) at 35°C and 100% R.H. using a corrosion chamber (model CC1000IP by Ascott) in accordance with the ASTM B 117 standard. The dry phase was carried out by keeping them under controlled conditions (i.e., 22°C and 50% R.H).

To assess water absorption and desorption, the weight of composite samples was monitored at regular intervals throughout the aging campaign. In particular, three square samples (100 mm x 100 mm) were daily removed from the salt-fog chamber for 10 days, wiped with a dry cloth, and weighed using an analytical balance (model AX 224 by Sartorius). In accordance with ASTM D570 standard, the weight percentage change WC of FFRCs was calculated using the following equation (Eq. 1):

$$WC(\%) = 100(M_i + M_0)/M_0. \quad (1)$$

Where M_0 represents the weight of unaged samples and M_i is the weight of the sample at aging time t_i, which is the sum of the time intervals in the salt-fog chamber and drying.

Quasi-static three-point bending tests were performed after 0, 5, 10, and 18 days of drying, for each cycle, using a universal testing machine (UTM, model Z005 by Zwick-Roell equipped with a 5 kN load cell), according to the ASTM D790 standard. For each condition, five samples (13 mm x 64 mm) were tested by setting the crosshead speed and the support span at 1.4 mm/min and 54 mm, respectively.

The fractured surfaces' morphology was observed using a scanning electron microscope (SEM, model 450 by Quanta). To prevent electrostatic charging, all analyzed surfaces were pre-sputtered with a thin gold layer

3. Results and discussion

3.1. Absorption and desorption measurements

First, the composites were found to experience a progressive increase in weight during the humid step, followed by a decrease in weight during the subsequent dry step, regardless of the cycle number. More interestingly, it is possible to observe an increase in the maximum water uptake values shown at the end of the humid phase with increasing cycle number. On the other hand, the residual weight changes at the end of the dry phases decreased when comparing the first, second and third cycle. Therefore, an increase in the difference between the maximum and minimum weight values reached at the end of the humid and dry phases can be observed as a function of the aging cycle number, as reported in Table 1.

Table 1. Weight changes at varying aging cycles.

Cycle's number	*Maximum WC* (%)	*Residiual WC* (%)	*Difference WC* (%)
1	7.9	1.5	6.4
2	8.2	1.4	6.8
3	8.6	1.2	7.4

These experimental results can be attributed to degradation phenomena occurring during the humid phase of each cycle. Due to water adsorption and diffusion into the bulk material, the microstructure of composites alters as a result of the activation and propagation of microcracks and/or interfacial debonding. This modification becomes more significant with an increase in the number of aging cycles.

3.2. Mechanical characterization

Figure 2 shows the hystogram of flexural strength and modulus values after varying drying times for each imposed aging cycles. The composite progressively reduces in strength and stiffness during the humid phase (i.e., 0D samples), followed by a recovery during the next dry phase. The results acquired at different drying times show that the mechanical performances can be significantly recovered even after just a few days of exposure to a dry environment.

Regardless of the aging cycle, approximately 20-30% of the composite's strength is recovered after 5 drying days (i.e, 5D samples in Figure 2a). This indicates that the degradation mechanisms responsible for the decay of the composite's strength during the humid phase are mainly reversible. While evaluating Figure 2b, although the modulus of the FFRCs also shows a clear increase in its value as the drying time increases, it always remains significantly lower than that of the unaged specimen. At the end of the aging campaign, the average flexural modulus shown by FFRCs is 3.16 GPa, which is about 25% lower than the unaged material (i.e., 4.18 GPa).

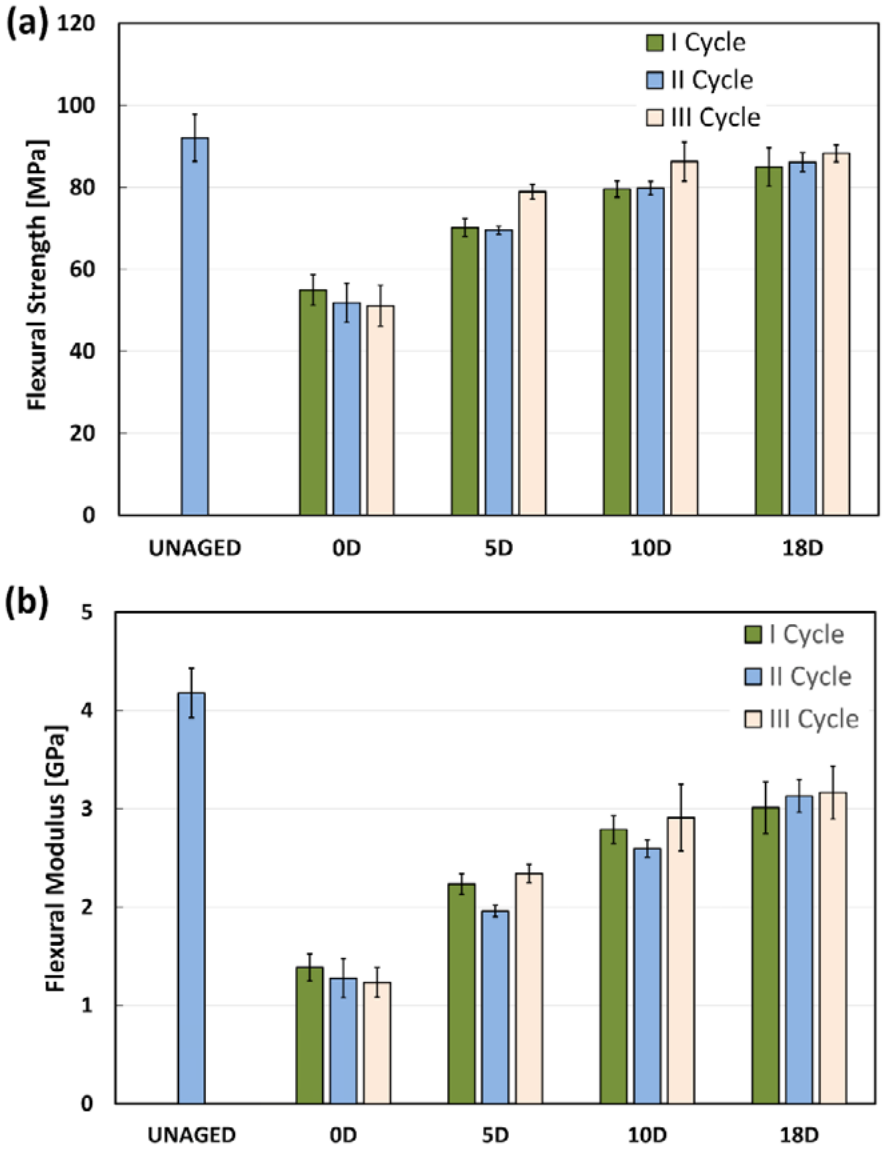

Figure 2. Flexural (a) strength and (b) modulus of FFRCs at increasing drying time for the 1st, 2nd, and 3rd aging cycle

This behavior can be ascribed to diverse degradative mechanisms that play a crucial role in worsening the composites' overall performances. The water absorption could induce swelling of the hydrophilic fibers, triggering the formation of matrix microcracks [6]. These favour local stresses mainly located on the fiber-matrix interface, which further promote crack initiation and propagation. However, limited exposure to salt fog (i.e., 10 days) might not be enough time for many cracks to form. As a result, the damage might be non-permanent. This means the material could recover once removed from the wet environment, thus explaining the observed flexural strength trend.

On the other hand, the decrease in stiffness can generally be related to softening and plasticization phenomena induced in wet NFRCs [7]. This stiffness drop is likely due to a combined effect of both matrix and fiber softening. Dry flax fibers have very stiff cellulose fibrils, where the cellulose molecules are tightly bound together. However, water can permeate the fibers and interact with the hydroxyl groups on the cellulose molecules. This interaction creates weak hydrogen bonds, which weaken the rigid structure of the flax fibers. In essence, the water acts like a lubricant, allowing the cellulose molecules to move more freely and making the fibers more flexible [8]. Furthermore, the epoxy matrix absorbs both free and bound water. Free water molecules have high mobility, diffusing easily through the gaps

and holes inside the thermoset's bulk, thus leading to a reversible sorption effect. Vice versa, bound water molecules are constrained by interaction to the polar groups inside the polymer network, leading to permanent sorption effects [9]. Figure 3 compares the SEM micrographs at high magnification of fractured specimens from flexural tests.

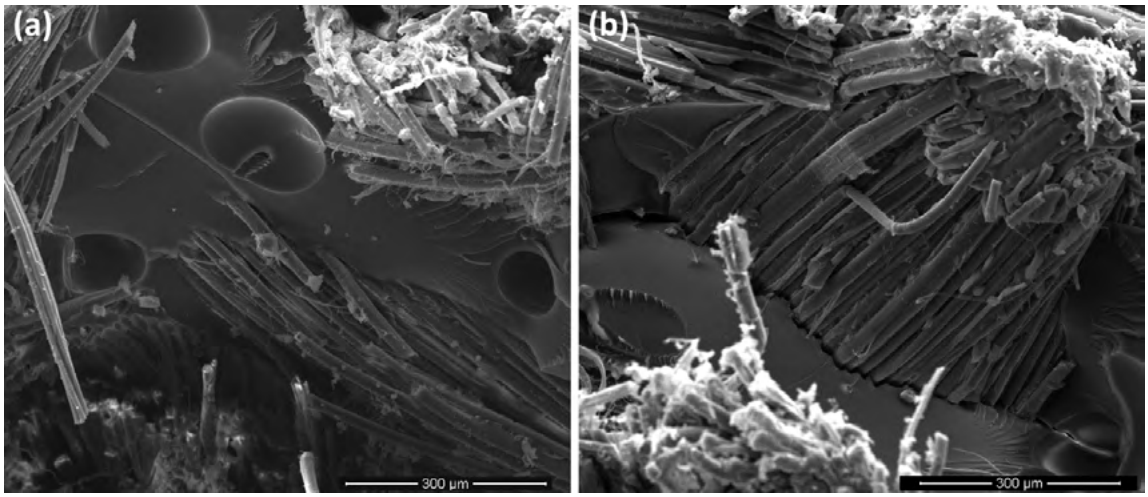

Figure 3. Close-up views of fractured surfaces:(a) unaged and (b) fully aged samples

Quite good compatibility between flax fibers and the surrounding polymer can be identified by observing the morphology of unaged samples shown in Figure 3a. In other words, the epoxy matrix fills the gaps between flax fibers, creating suitable interfacial adhesion and even stress distribution at the fiber/matrix interface, thus preventing cavity formation.

On the other hand, a loss of adhesion at the fiber-matrix interface is evident in the FFRCs after the aging cycle (i.e., after three aging cycles), as clearly shown in Figure 3b. This is likely due to absorbed water, which leads to debonding phenomena at the interface. Consequently, the formation of preferential water pathways at the fiber-matrix interface further weakens the adhesion. These structural discontinuities, formed during the humid phase of each cycle, endure also during the following dry phase, and their relevance increases with increasing cycle number. This limits interfacial stress transfer capability, resulting in the irreversible reduction of the FFRCs' stiffness.

3. Conclusions

The impact of repeated and consecutive humid-dry aging cycles on the mechanical stability and water absorption/desorption behavior of flax fiber-reinforced composites (FFRCs) was assessed in this research paper. To this aim, FFRCs, manufactured through vacuum infusion technique, were exposed for a total period of 12 weeks to three repeated cycles of humid (salt-fog) and dry environments.

The investigated composites showed weight gain during the humid phase of each cycle, followed by weight loss during each drying phase. More in detail, the maximum water uptake values increased at the end of each humid phase, while the residual weight values decreased at the end of each dry phase, with an increasing number of cycles. Therefore, a greater difference between the maximum and minimum weight change values was observed as a function of the aging cycle number. This results can be attributed to the degradation phenomena that occurred during the salt-fog exposure, which became more significant as the number of applied cycles increased.

From a mechanical standpoint, FFRCs weakened when exposed to the salt-fog environment. However, they were also able to recover some of their mechanical stability during the subsequent dry phase of

each cycle, regaining 20-30% of their strength after a few days. This indicates that the strength reduction is almost fully reversible. However, the flexural modulus of FFRCs at the end of the aging campaign (i.e., after three aging cycles) resulted about 25% lower than that of unaged composites.

Keywords: aging CMC, radioactive waste, geological disposal, mechanical study, thermodynamic calculations.

Abstract

This research examines the hydrothermal aging behavior of ceramic matrix composites (CMCs) in the field of deep geological disposal of high-level radioactive waste (HLW) The study focuses on alumina powder as a representative CMC matrix material. Accelerated aging experiments were conducted in aqueous environments (pH > 11.5, T = 70°C and P = 1.3 bar). The research used a cross-disciplinary approach integrating thermodynamic calculations and physicochemical analyses to determine the behavior of alumina with the aqueous aging solution. The characterization of the aged alumina powders revealed the presence of unaltered alumina, an amorphous phase, and calcium carbonate precipitates from the aqueous solution. Thermodynamic calculations indicate: (1) the hydrolysis of alumina to diaspore (2) the formation of an aluminosilicate phase and calcium carbonate. These calculations corroborate the experimental results. Furthermore, thermodynamic calculations demonstrate that variations in pressure and volume have a negligible effect on the evolution of equilibrium in this system at the temperature considered.

1. Introduction

Since 1999, the French national agency for radioactive waste disposal (Andra) has been working on the possibility of long-term deep geological disposal of high-level waste (HLW) and long-lived intermediate-level waste (ILW) [1–3]. The Cigéo project, which is aimed at accommodating HL and ILW waste, encompasses both existing stocks and future waste from current or authorized nuclear facilities. [3]. The proposed solution entails deep geological disposal, which aims to safeguard the environment from radioactive hazards by placing waste in micro-tunnels excavated 500 meters underground within a stable Callovo-Oxfordian (clay) layer, undisturbed for 160 million years [2]. Currently, the

preferred approach involves the use of a cell liner made of low-carbon steel liner, although Andra is investigating alternative materials to potentially further improve the disposal. The collaborative C3N (Composite ceramic nuclear lining) project has successfully overcome the technological challenges associated with ceramic matrix composites (CMC) for tunnel liners. Ceramic matrix composites were initially developed for applications in extreme conditions, including high temperatures, oxidizing environments, mechanical stress, and even irradiation. They combine a unique set of properties such as: mechanical properties, resistance to oxidation, and thermal stability [4]. The behavior of CMCs in geological disposal conditions remains largely unexplored. The objective of this work is to establish a scientific methodology to assess and understand the performance of CMCs in environments that are unusual for such materials, particularly when they are immersed in a highly alkaline aqueous solution. For these reasons, it was decided to initially work on composite made of alumina matrix reinforced with alumina fibers, and more precisely on the alumina powder precursor for this matrix. In this present work, the accelerated hydrothermal aging of alumina is explored. A combination of thermodynamic calculations and physicochemical analyses demonstrates the evolution of the nature of alumina-based matters in the system: aqueous solution and precipitation of additional solid phases.

2. Materials and Methods

2.1. Experiments and starting materials

The powdery precursor of the composite matrix was used to get accelerated conditions of aging through an extended surface exposed to reactions, and thus to determine the behavior of alumina during accelerated aging. The powder sourced from Baikowski was 99.99% pure α-alumina. The average diameter of the alumina grains was approximately 150 nm. The hydrothermal aging test was conducted in a 500 mL PTFE reactor containing an aqueous solution prepared with Milli-Q® water (resistivity = 18.2 $M\Omega.cm$). This latter was prepared in a controlled atmosphere within a glove box. The following salts were used: potassium chloride (KCl), potassium sulfate (K_2SO_4), aluminum sulfate octadecahydrate ($Al_2(SO_4)_3$,$18H_2O$), calcium sulfate dihydrate ($CaSO_4$,$2H_2O$), sodium silicate pentahydrate (Na_2SiO_3,$5H_2O$), sodium bicarbonate ($NaHCO_3$) and sodium hydroxide (NaOH) to achieve a final pH of 11.2. Reactors were placed in a oven at 70°C for seven months.

The prepared aqueous solution was also aged alone at different temperatures (25°C, 50°C and 70°C) to compare its evolution (aqueous part in regard to solid one) without alumina powder and to ensure the aqueous solution's stability for the remainder of the tests. To achieve this, the solution was placed in three different ovens for three months. Once removed from the oven, the reactors containing the solution were quickly transferred in a glove box in an insulated environment to limit the temperature drop. The liquid part was collected to analyze the species present in solution and compare them to the species initially introduced into the mixture. The precipitated species were recovered by evaporating the residual liquid. The soluble and dissolved component into the aged solutions at different temperatures were analyzed by inductively coupled plasma atomic emission spectroscopy (ICP-AES, iCAP PRO Duo – Thermo Scientific).

The search of precipitates formed into an aqueous solution was carried out by X-ray diffraction (XRD, Bruker D8 Advance diffractometers using a Cu Kα anticathode.).

Following the aging period, some of the powder samples were removed from the reactors for analysis, while the remainder was subjected to a longer aging period. The collected samples were divided into two groups: one was rinsed with Milli-Q water and the other was left unaltered. In both cases, the powder was dried. The hydrolyzed surfaces were observed by scanning electron microscopy SEM, FEI Quanta 400FEG) operated at 20 kV equipped with an energy-dispersive X-ray spectroscopy detector (EDX, Ultim Max, Oxford Instruments), and transmission electron microscopy (TEM, JEOL JEM 2200FS FEG HR 200 kV High resolution camera) equipped with an EDX detector. Subsequently, analysis via ICP-AES are done on the aqueous media employed in the post-test phase.

2.2. Thermodynamic calculations

Thermodynamic calculations were carried out to identify and determine the final equilibrium state of a chemical system. These calculations will give the species and phases present at equilibrium.
To get these, the first and second principles of thermodynamics are combined by the extensive state function: the minimization of the free enthalpy G_T of the system given by the Gibbs relation (Eq. 1):

$$G_T = \Delta H^0_{298.15K} + \int_{298.15K}^{T} C_p \, dT - T \left(S^0_{298.15K} + \int_{298.15K}^{T} \frac{C_p}{T} dT \right) \quad (1)$$

where $\Delta H^0_{298.15K}$ is the standard enthalpy of formation at 298.15 K, $S^0_{298.15K}$ is the standard entropy at 298.15K, C_p is the heat capacity as a function of temperature and T is the absolute temperature. The guidance in the evolution of a chemical system is a decrease of the state function G_T. Equilibrium is reached when G_T is minimal ($dG = 0$). The Thermo-Calc software was be used to perform these thermodynamic calculations. This software is based on the Calphad method (calculation of phase diagrams) [5–7]. This method, introduced by Larry Kaufman in the 1960's, is based on various types of experimental data and theoretical values to produce thermodynamic database giving the $G_{T,P}$ of each phase or species in a phase (liquid)(e.g. those derived from first-principles calculations). The calculated data are the states of present phases, solid, liquid and gas and their constituent species, the pH value and the potential value of an aqueous solution.This data can be used to make predictions for multi-component systems of industrial importance.
The chosen approach is to select from the literature the solid phases relevant to the system under consideration and extract the correlated thermodynamic data to compile them in a specific database that complements the following commercial Thermocalc databases: GCE, TCAQ and TCOX [5]. Thus, the development of a complete model is made possible on the evolution of alumina in the aqueous solution under consideration. More than 440 phases have been listed. The free enthalpies (G_T) of these phases are recalculated from data on standard enthalpy ($\Delta H^0_{298.15K}$), standard entropy ($S^0_{298.15K}$) and heat capacities (C_p). [8–19]. Once the database was built, the thermodynamic model was developed step by step from a Python code using the TC-Python library. In the first step, the calculations were completed by considering only the aqueous solution. In a second one, alumina could be introduced into the system, to progress in calculations. The methodology followed was to perform a series of thermodynamic calculation cycles for a temperature of 70°C (corresponding to the aging temperature in the PTFE reactors). The steps in the first simulated aging cycle correspond to: (1) the introduction of one mole of alumina (m = 101.961g) (2) the introduction of one liter of aqueous solutions (3) the start of the calculation to obtain the thermodynamic equilibrium and (4) the identification of the solid phases, aqueous species and gas species formed. For all other simulated cycles, steps become : (5) the conservation of the solid phases obtained in the previous cycle (6) the introduction of one liter of initial aqueous solution (7) the start of the calculation to obtain thermodynamic equilibrium and (8) the identification of solid phases, aqueous species ans gas species formed. Two types of calculations were carried out: the first based on a fixed pressure (to simulate the environment in which the composites would be stored) and the second based on a fixed volume (to represent the aging systems of this research). This verifies that the aging methods chosen are comparable to the real environment. Finally, in both cases a neutral gas (argon) is introduced, since the aging conditions are anoxic.

3. Results and discussion

3.1. Aqueous aging solution

The results of the XRD analysis of the precipitate formed after preparation of the aqueous solution show that it is mainly calcium carbonate. A phase containing sodium potassium aluminosilicate was also identified (Figure 1). ICP analysis of the aqueous solution and the precipitate formed (without alumina) at different temperatures shows that with the exception of aluminum, the amounts of present species do not change significantly, indicating that temperature does not affect the composition of the solution over this three months time interval (Figure 2). The main constituents into the precipitate are calcium, potassium and sulfur. The aluminum concentration in the aqueous solution increases with increasing temperature. These two analyses confirm that calcium carbonate is formed by precipitation from the aqueous solution. It is possible to deduce that a second phase was formed, corresponding to a sodium and potassium aluminosilicate.

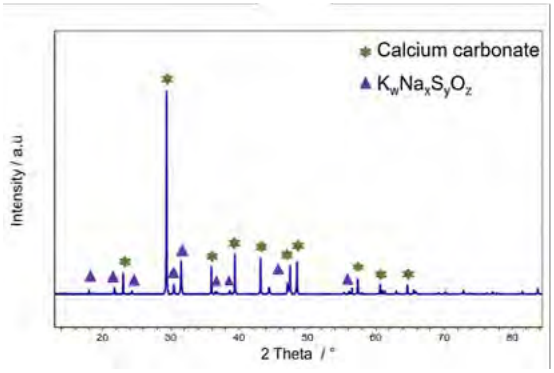

Figure 1. XRD of precipitate formed after preparation of the aqueous solution (K_α Cu)

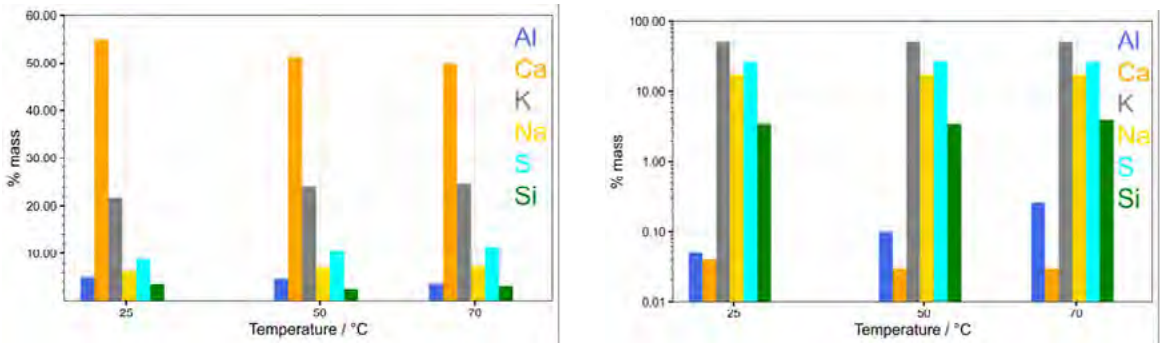

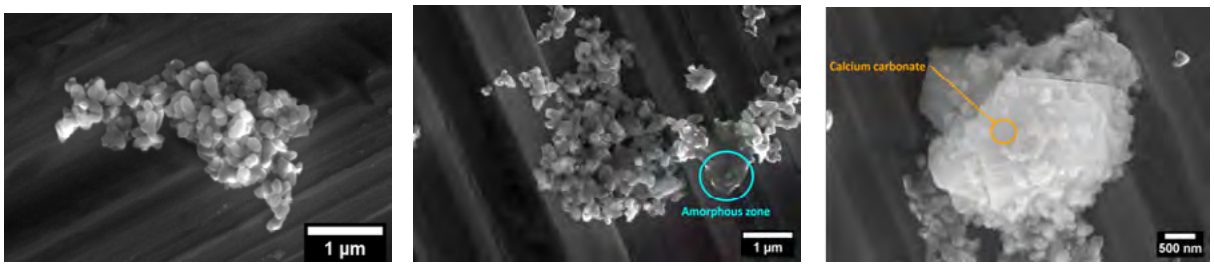

Figure 2. ICP of the aged aqueous solution at different temperatures without alumina. (a) formed precipitate and (b) liquid solution

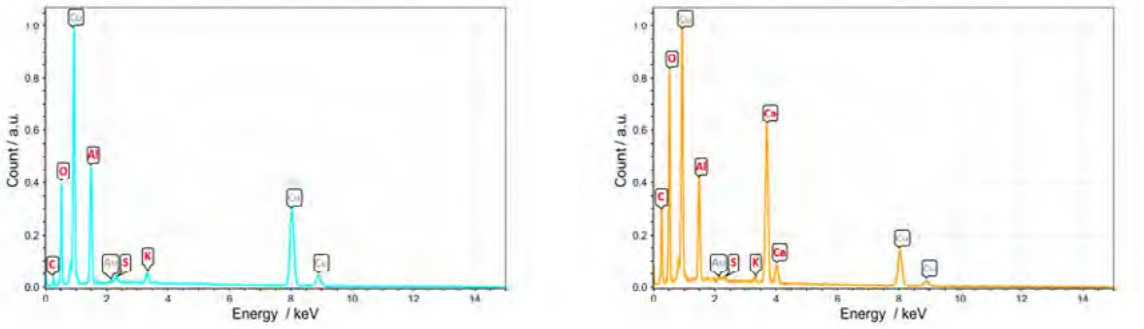
3.2. Aged alumina powder

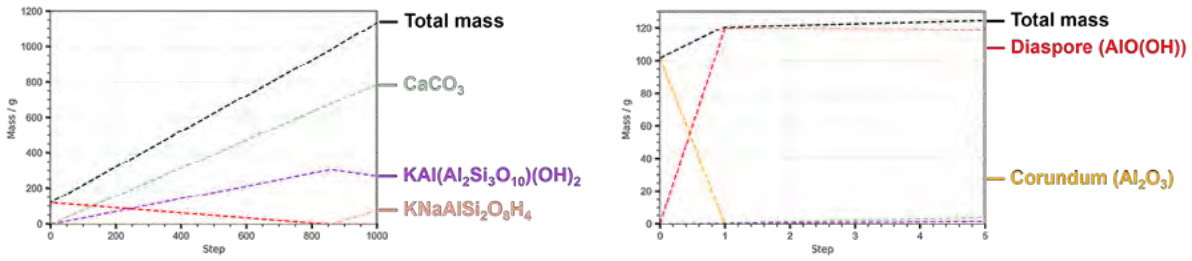


Observations by SEM (coupled with EDX) show the presence of three types of alumina powders areas. One appears to correspond to crystalline alumina, a second area shows an amorphous phase and finally a third one corresponds to calcium carbonate (Figure 3). This carbonate comes from the aqueous solution and is a precipitation product.

(a) **(b)** **(c)**

Figure 3. SEM of initial and aged alumina powder (a) and (b) respectively, (c) calcium carbonate precipitate from the aqueous solution

The EDX analyses corresponding to the circled zone on the Figure 3b show that the amorphous grains are composed of oxygen, aluminum and carbon, but also sulfur and potassium with the atomic proportions O:Al:C:S:K = 57:14:21:3:5. The zone noticed on the Figure 3c shows the presence of majority of calcium carbonate with the atomic proportions Ca:C:O = 20:26:54.



(a) **(b)**

Figure 4. EDX of aged alumina powder (a) amorphous zone and (b) calcium carbonate

3.3. Thermodynamic calculations

On Figure 5 the thermodynamic calculations show the alumina hydrated to diaspore during the first cycle. Over 1000 cycles, the amount of diaspore gradually decreases until it disappear by the 840th cycle, giving way to a solid sodium and potassium aluminosilicate phase. A potassium aluminosilicate phase appears in the second cycle, facilitated by the dissolution of the diaspore and the supply of species from the aqueous solution. This phase decreases after the disappearance of the diaspore. This indicates that the $KNaAlSi_2O_8H_4$ phase is thermodynamically more stable under these conditions. The result of the ICP analysis (Figure 2a) on the precipitated species in the aged solution alone confirms the presence of calcium, potassium and aluminum, in agreement with the thermodynamic calculations. Calcite precipitates during aging, as identified by XRD analysis on the precipitates into the aged solution. A silicate phase is also present, as shown by the XRD and EDS analyses. Finally, at temperatures considered in

the calculations, it can be concluded that volume and pressure do not appear to have any effect on the evolution of the system. These calculations are consistent with the initial results obtained experimentally.

4. Conclusion

This work is part of a broad study aiming at determining the chemo-mechanical behaviour of CMCs under conditions encountered in a deep geological disposal facility, and more precisely in the high-level waste area. In this work, a methodology to assess this behaviour is proposed, and it is first implemented on alumina powders as the major constituent of the studied CMCs. Scanning electron microscopy and other analyses have revealed complex alteration mechanisms, including the formation of calcium carbonates and aluminosilicate phases. In addition, thermodynamic calculations revealed the transformation of alumina to diaspore with the precipitation of calcite and silicate phases from the solution. Under aging conditions, the hydratation of alumina appears to have no real influence on the nature of species into the solution. Perspectives could include studying the phase composition of corrosion products formed on exposed surfaces using advanced analytical techniques such as X-ray photoelectron spectroscopy (XPS) and time-of-flight secondary ion mass spectrometry (ToF-SIMS). Investigations will continue by measuring the evolution of mechanical properties of the CMC and its independent constituents, after accelerated aging, using tensile and bending tests.

Keywords: Sheet Molding Compound (SMC), translucent, epoxy-based, flame retardant, aircraft interior

Abstract
Sheet Molding Compounds (SMC) conventionally consist of chopped reinforcement fibers with a length of 25.4 to 50.8 mm (1 to 2 inch) in combination with a thermoset-based resin paste. They offer high mechanical performance and lightweight potential compared with short processing times. Therefore, SMC materials are used for applications in large-scale serial production in compression molding processes for example in electronics and construction sector as well as in aircraft and automotive. Flame retardant SMC materials for public transport and aircraft interior applications are state of the art. Those materials show a good mechanical performance, but a lack in surface quality and freedom in color, due to their high amount of mineral fillers and flame retarding additives.

In the research project “TRANA”, a new and innovative SMC system, which fulfills flame retardancy requirements, shows a good surface quality and is also homogenously colorable, was developed.
Mechanical properties like Tensile strength and Young’s modulus are up to 25 % higher compared to conventional flame retarding SMC materials and at the same time, their density is about 20 % lower.

1. Introduction

Fiber reinforced polymer composites (FRPC) and their special abilities for high specific strength and stiffness enable a new freedom of design for structural and non-structural components. This class of materials allows a reduction of components weight while improving their mechanical properties. A further very important point regarding the safety of FRPC materials is their flame retardancy behavior. To fulfill specific flame retardant properties, different flame retarding additives can be used. All these options meet the current demands of the industry in terms of material efficiency and CO_2 savings. Sheet Molding Compound (SMC) provide the ability of producing near-net-shape components in parallel controlled compression molding processes in one process step at advantageous costs and short cycle times [1]. These advantages lead to a market share for SMC of almost 20 % in glass fiber reinforced polymer composites (GFRPC) in Europe [2]. A standard glass fiber reinforced SMC mainly consists of an unsaturated thermoset polyester resin, a variety of different processing additives, glass fibers (GF) with a length of 25.4 to 50.8 mm (1 to 2 inch) as reinforcement and different non-functional and functional filler materials, see Figure 1 [3, 4]. GF-SMC semi-finished products exhibit a density of 1.7 up to 2.0 g/cm³ based on the high content (up to 40 wt.-%) of mineral fillers with a density of 1.8 to 2.7 g/cm³ [5, 6].
SMC materials are mainly used for applications in large-scale serial production and are processed in compression molding processes. Main fields of use are for example in the electronics and the construction sector as well as in aircraft and automotive applications. Flame retardant SMC materials

for public transport and aircraft interior applications are state of the art, e.g. HUP63/15 RB-9010, supplied by Polynt Composites GmbH (Miehlen, Germany) [7].

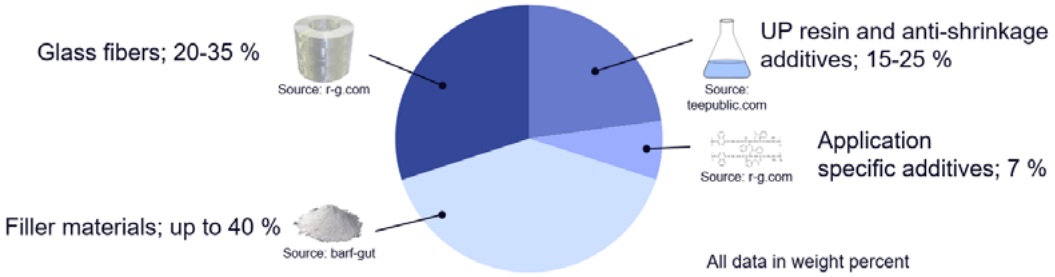

Figure 1: Abbreviated composition of a standard SMC [3]

A big disadvantage of flame-retardant SMC materials is the poor achievable surface quality of the final parts. As these semi-finished products contain very high filler contents of up to 350 phr flame retarding agent related to the resin system, the fillers often emerge at the surface of the parts. So the parts cannot be used for visible or even decorative applications. For this reason, many of those components require a costly and energy-intensive post-treatment. This involves several processing steps in which each component has to be sanded, filled and painted. This increases the component costs and the ecological impact, which severely limits the possible areas of potential applications.
In the research project "TraNa", a new translucent and flame-retardant SMC semi-finished product has been developed, which meets the FST requirements of the aviation sector, in particular FAR 25.853. This SMC material was developed in such a way that it either has translucent properties ("milk glass"-like), but can also homogeneously be colored. Furthermore the material shows very good surface quality and mechanical properties, which can be compared to standard SMC semi-finished products. This can open up new fields of application for SMC components. These could be for example passenger information or lighting applications.
In order to achieve a translucent or even transparent component quality, the scattering of the incident light must be reduced. Therefore the particle size of the (flame-retarding) powdery fillers has to be minimized. This leads to a significant decrease of the scattering of the light: a 10 nm particle scatters around 1 million times less light than a 100 nm particle [8]. Subsequently, the composition of the semi-finished product was adapted in order to obtain a perfect dispersion of the solid modifiers. As a part of the research project, the influence of both, liquid phosphorus-based and state of the art particulate flame retardant additive in combination with newly developed particulate nanoparticles acting as flame retardant additives were investigated. Those results were already published by Kayser, Gortner et al. [9, 10, 11].
This study investigates the effects of particular flame retardant additives in combination with liquid flame retardant additives on the colorability and the resulting mechanical properties of SMC materials.

2. Materials and methods

2.1 Materials

As part of the research project, several EP-based resin systems were investigated with regard to their transparency, thickening behavior and processing properties [9, 10]. In this paper a low viscosity styrene-monomer free epoxy resin (Epikote TRAC 06605, Westlake Epoxy GmbH, Duisburg, Germany) was used according to SMC process requirements. As hardener two catalyzed products (Epikure TRAC 06612 and Epikure TRAC 06624, Westlake Epoxy GmbH, Duisburg, Germany) were studied. Furthermore two air release additives (BYK A500 and BYK W969, BYK Chemie GmbH, Wesel, Germany) and an internal release agent (TRAC 06807, Westlake Epoxy GmbH, Duisburg, Germany) were used. As flame retardant additives a mixture of a powdery (ON904 Huber Advanced Materials Martinswerk GmbH, Bergheim, Germany) and liquid (HF P70, Lehmann & Voss, Hamburg, Germany) additive was utilized.

2.2. METHODS

2.2.1 Resin paste preparation

In a first step all liquid components of the resin paste formulation are mixed to a homogeneous paste with a circular disc stirrer at 600 rpm for 2 minutes. Subsequently, this mixture is evacuated for 1 minute at - 0.08 MPa. In a second step, all powdery components are incorporated to a homogeneous paste also with a circular disc stirrer at 1200 rpm. Afterwards, the resin paste was mixed until a temperature of 40 °C was reached. This temperature was measured contactless with an IR-thermometer. When reaching the predefined temperature, mixing was stopped and the whole mixture was evacuated again at - 0.08 MPa. After evacuation, the resin paste was stored at 40 °C in an oven till processing.

2.2.2 Coloring tests

To examine the colorability of the SMC resin pastes and color accuracy of SMC sample plates, color pastes EP2037 (Altropol Kunststoff GmbH, Stockelsdorf, corresponding to RAL 7035) - light grey and EP2043 (Altropol Kunststoff GmbH, Stockelsdorf, corresponding to RAL 3028) - pure red were mixed with the SMC resin paste with a dosage of 0.5 to 5 wt.-% in 0.5 wt-% steps. After mixing the color paste, the resin paste was evacuated and processed to SMC semi-finished products and sample plates in the same way as the uncolored resin paste.

The color accuracy measurements were carried out by Fraunhofer ISC (Würzburg, Germany) in a CIELab color space using the reflection method on a spectrophotometer (Color i, manufacturer X-Rite, 6 mm diaphragm). In this method, a three-dimensional color space is spanned, which is built up by the brightness (L*), which is on the color plane (a*, b*). The measurable brightness values range from 0 (black) to 100 (white) and from -90 to 90 for a* (red-green) and from -100 to 100 for b* (yellow-blue). The reflection spectrum is measured in the range from 360 to 750 nm, whereby this range is run through in 10 nm steps. Only the range from 400 to 700 nm, which is visible to humans, is considered. The measurement provides both the wavelength and the percentage of reflected light.

2.2.3 Preparation of SMC semi-finished material

The resin paste is transferred to the SMC line (SMCline600, Schmidt&Heinzmann, Bruchsal, Germany [12]). The doctor boxes and the transport belt of the SMC line were electrically pre-heated to 40 °C. The resin paste was filled into the doctor boxes of the SMC line, see Figure 2 left. Within this doctor boxes, a resin film of 1.4 mm was applied and the reinforcement fibers with a length of 25.4 mm were spread randomly and homogenously on this resin film. Afterwards, a second carrier film with a second resin film covered the reinforcement fibers and this stack was running through the compaction unit (Figure 2, middle). After impregnation, the SMC semi-finished product was stored on rolls (Figure 2, right) over night, to foster the thickening process.

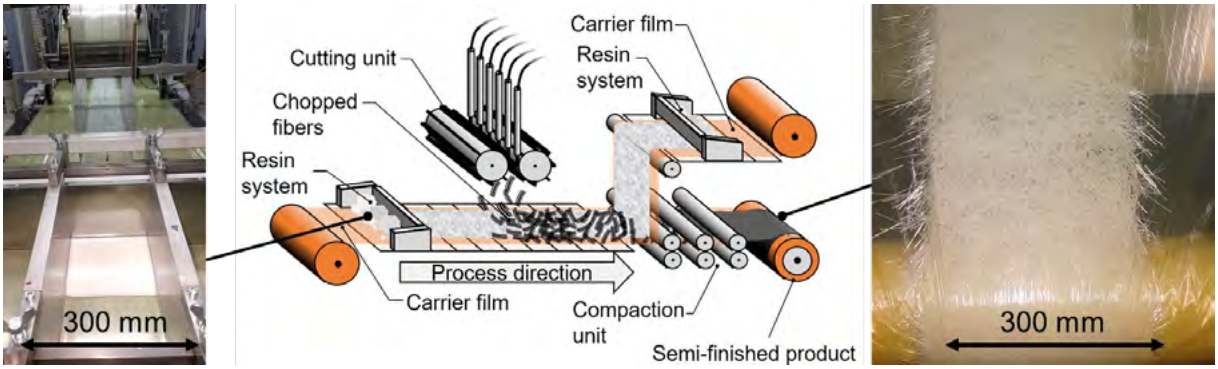

Figure 2: View into the doctor box (left), schematic drawing of SMC processing line (middle) and SMC semi-finished material at the end of the SMC line (right)

2.2.4 Processing of SMC to sample plates

After the thickening process, the SMC semi-finished materials were processed in a compression molding process on a parallel controlled press (Dieffenbacher PHP 800/650). A sealing edge mold with a size of

250 x 696 mm² was used. The SMC material was cut to sheets with a size of 180 x 580 mm², which corresponds to 60 % of the mold size. After cutting, the carrier film of each sheet is was withdrawn and stacks with defined weight were prepared, see Figure 3. These stacks were processed with the processing parameters, given in Table 1.

Figure 3: Stack of SMC semi-finished product in sealing edge mold before processing

Table 1: Compression molding process parameters

Parameter	Unit	Value
Mold temperature	[°C]	140-145
Cycle time	[min]	5
Mold pressure	[MPa]	12
Mold coverage	[%]	60
Closing speed	[mm/s]	1.5

While compression molding process, the viscosity of the SMC material decreases and enables the material to flow and fill-up the mold completely. After curing, the testing plate was removed from the mold. A standard cycle time for SMC-processing is between three and five minutes, depending on the thickness of the sample plates [13].

2.2.5 Mechanical testing

After the SMC semi-finished material was processed to sample plates with the dimensions 250 x 696 x 4 mm³, rectangular specimens for the mechanical characterization were cut out using a diamond-studded circular saw.

Tensile properties were determined according to DIN EN ISO 527-4 [14] in a conditioned laboratory at 23 °C on a Zwick universal testing machine, type 1485 with a 100 kN load cell. Specimen size was 250 x 25 x 4 mm³.

Bending properties were determined according to DIN EN 14125 [15] in a conditioned laboratory at 23 °C on a Zwick universal testing machine, type 1485 with a 100 kN load cell. Specimen size was 80 x 15 x 4 mm³.

2.2.6 Determination of fiber mass content according to DIN EN ISO 1172

For the determination of the fiber mass content, samples were extracted from the material insert position and near the end of the flow area The real fiber mass content in the component was determined using the calcination method in accordance to DIN EN ISO 1172. Method B according to [16] was used in this work. These results can be compared with gray value analyses from micrographs of the light

microscope. The calcination method offers a more precise method than the gray value analysis, as this method can be used based on bulk volume and not singular two-dimensional just cross-section.

3 Results

3.1 Results of coloring test

As the proportion of color additive increases, the brightness of light grey increases slightly and approaches the RAL color tone. The reference RAL color is black framed in Figure 4. Furthermore, as the proportion of color additive increases, the target color intensifies and the yellow component in particular decreases significantly. The measurement of the different color levels, see Figure 5, shows no difference in the reflected light above two weight percent of color additive. This means that the entire color component is reflected in the light visible to humans, making it appear grey. In addition, approx. 50 % of the light is reflected. The deviations at 600 nm are within the range of measurement accuracy.

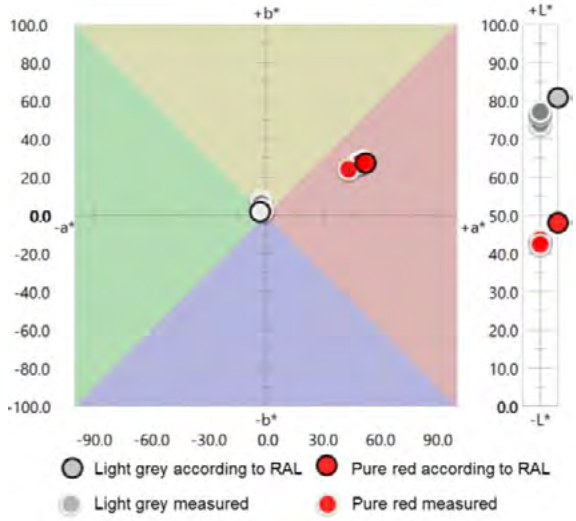

Figure 4: Results of color measurement according to CIELab color chart

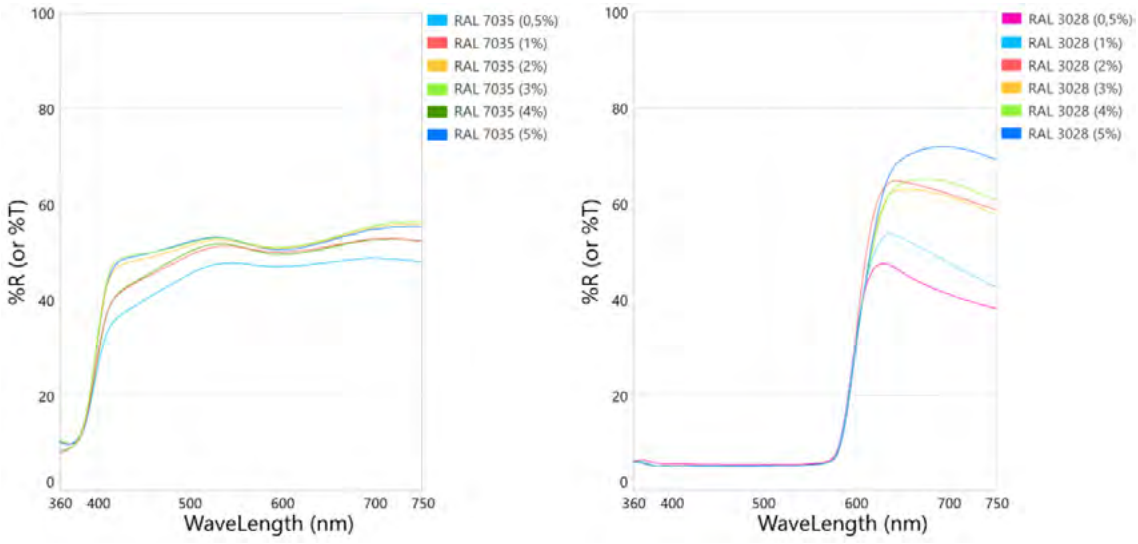

Figure 5: Colored SMC sample plates; left: 0,5 - 3 % grey, middle: 0,5 and 5 % red

The color pure red showed a low scattering in each of the three dimensions for all tested color components. While the brightness only deviates from the target value by 5%, the dimensions a* and b* are significantly further away from the target value. This is particularly evident in the samples with 0.5 and 1 % color additive content, which represents the lowest proportion of red. The measured colors

show only slight differences in the range up to 720 nm and the transmitted or scattered light only splits at a higher wavelength. To the trained eye, however, no significant difference in color fidelity is noticeable with pure red up to 5 wt.-% color content. Nevertheless, it can be seen that a higher proportion of color reflects more light (up to 70 % at 5 wt.-% color proportion).

3.2 Results of fiber mass content analysis

The real fiber mass content was determined using 3 samples taken from the insert area of the SMC stacks. The samples were first dried and then incinerated. Since the ATH fillers cannot be thermally degraded, they were dissolved out of the samples using hydrochloric acid. The target fiber mass content is 25% by weight. The measurements determined a real fiber mass content of 22 +/- 1 % by weight. This corresponds to a deviation from the target value of 3 to 4 %. Figure 6 shows a micrograph of a GF-SMC sample. Based on nine images (transverse and longitudinal), a fiber area content of 9.95 % (±1.66 %) was determined using gray scale analysis. This value can be calculated to a fiber mass content of 21 %. There is a very good accurence of the values of fiber mass content and fiber area content.

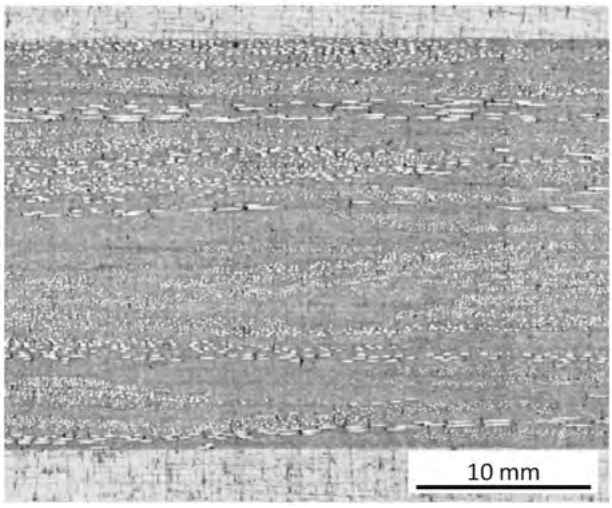

Figure 6: Micrograph of GF-SMC

3.3 Results of mechanical properties

The mechanical properties were determined on colored and non-colored samples. There was no influence in coloring to mechanical properties. The values given in this paper were determined on non-colored samples. In Figure 7 (left), the results for Young's modulus and tensile strength are given in longitudinal (L) and cross direction (Q) of the sample plates. While preparation of the resin paste, two different contents of 10 phr and 15 phr of liquid flame retarding additive HF P70 were used, while dosage of powdery flame retarding additive (ON 904) remained constant.

The mechanical characteristic values achieved for the Young's modulus are between 16.4 and 18.4 GPa in the longitudinal direction and 14.3 to 16.3 GPa in the transverse direction. A clear directional dependence can be seen. When determining the tensile strength, a tensile strength of 150 to 167 MPa in the longitudinal direction and 100 MPa in the transverse direction was detected. The mechanical properties of the SMC semi-finished products developed are significantly higher than the characteristic values of the reference fire protection SMC semi-finished products in terms of both Young's modulus and tensile strength [7]. Furthermore, a clear isotropy can be seen, which indicates an alignment of the fibers during the flow process.

The results of bending properties are given on the right side of Figure 7. In these samples, a distinction is also made between the longitudinal (L) and transverse (Q) directions and the content of the liquid fire retardant additive. A difference between the longitudinal and transverse directions can be seen in all samples. All longitudinally oriented samples have a higher flexural modulus and a higher flexural strength than the transverse samples. Depending on the content of liquid fire protection additive, flexural moduli of 17.3 to 18.8 GPa are achieved in the longitudinal direction and around 16.3 GPa in the

transverse direction. In terms of flexural strength, strengths of 280 to 339 MPa were achieved in the longitudinal direction and 242 MPa in the transverse direction.

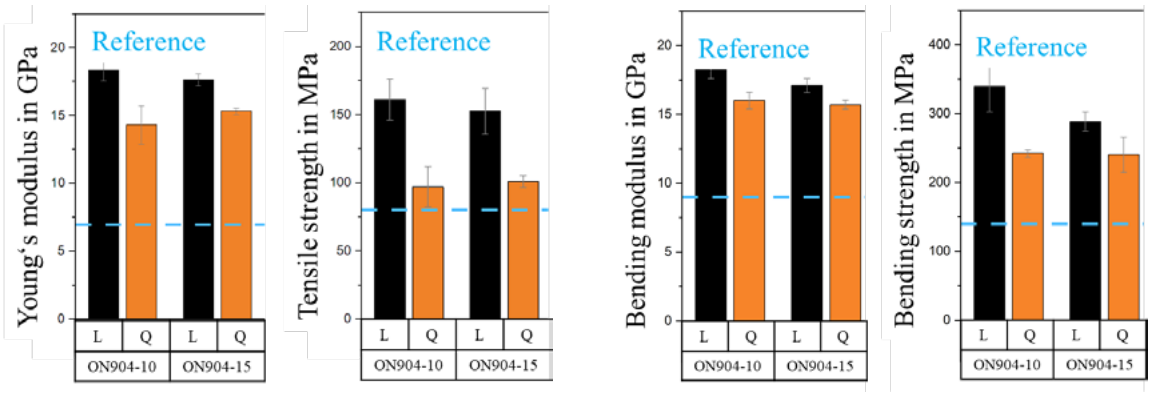

Figure 7: Results of mechanical testing; tensile properties (left), bending properties (right)

4 Discussion and conclusion

An SMC semi-finished product was developed on the basis of an epoxy resin system and glass fibers as reinforcing fibers, which has with 22 wt.-% fiber mass content almost the same fiber mass content as the reference flame retarding SMC system HUP63 (25 wt.-% GF). This semi-finished product achieves significantly higher mechanical properties than the reference material.
Within the new SMC material, a combination of combining liquid and powdery flame retardant additives were used. This enabled the use of a lower overall quantity of ATH, compared to reference material, and leads to a better surface quality of sample plates. The reduced amount of ATH enables a homogenous coloring of the SMC semi-finished materials and sample plates. Furthermore the reference material can be manufactured and processed reliably on a conventional SMC line.
The color fidelity was verified by using spectrophotometer measurements. The components show closed and homogeneous surfaces that do not require any reworking. Due to the homogeneous coloring and the very good surface qualities, no expensive and time-consuming reworking is required. Initial publications [9, 10, 11] have already presented results on translucency and the results of fire protection tests. If the semi-finished products are not colored, it is possible to achieve translucent component properties. The semi-finished products also pass fire tests in accordance with UL 94-V0 no matter whether they are colored or not.

In summary, the "TraNa" research project successfully developed a translucent and fire-protected SMC semi-finished product for aviation interior applications by skillfully combination of powdery and liquid flame retarding additives. Based to the translucent and fire-protected properties, the spectrum of applications for SMC semi-finished products can be expanded, e.g. in the mobility sector.

Acknowledgments
The project “TraNa – Translucent and dyeable flame retardant Sheet Molding Compounds based on novel nanoscale flame retardants for applications in the aerospace interiors” was funded by the Federal Ministry for Economic Affairs and Climate Action - program “LuFo VI-1” on the basis of a decision by the German Bundestag, funding reference: 20Q1902C

Keywords: laminated composite, draping analysis, finite element simulation

Abstract
This paper introduces an effective simulation method for the laminated composite fan blade structure, which takes into account the change in fiber orientations during the manufacturing process. A numerical draping analysis is proposed to estimate the distortion of the fiber angle due to the curvature of the fan blade structure. The middle shell mesh of the fan blade is utilized for lamination modeling and simulation stages. To demonstrate the effectiveness of the proposed draping method, thermal deformation simulation of the laminated fan blade is conducted. A numerical comparison of structural performance, with and without considering draping analysis, is performed to show the efficacy of the present methodology.

1. Introduction

During the manufacturing process, the fiber orientations in a flat ply must be changed to conform with the tool surfaces, that significantly impact the mechanical performance of laminated composite structures. Specifically, for fan blade structures exhibiting double geometric curvatures, accurate prediction of fiber path distortion during the hand lay-up process necessitates a thorough fiber-draping analysis. To address this phenomenon, both finite element analysis (FEA)-based and kinematic methods have been widely utilized. In the FEA-based approach, 3D and shell FE models have been employed to simulate the draping behavior of composite reinforcements [1]. Additionally, hyper-elastic constitutive approaches have been developed to simulate the forming behavior of fibers during the draping process on double-curved surfaces [2]. Accordingly, an accurate correlation of material properties with experimental data is essential when developing the constitutive model for fiber reinforcement. By conceptualizing the textile reinforcement as a unit cell, it becomes possible to naturally account for changes in the direction of fiber-draped orientations [3]. However, these approaches often incur high computational costs.

On the other hand, the kinematic method predicts fiber-draped orientation by utilizing a pin-jointed and net cells approach, based on a provided geometry [4]. This method assumes infinite fiber extensional stiffness and zero shear stiffness. Recently, due to its cost-effectiveness, optimization techniques have been employed to enhance the solution of fiber-draping analysis within the kinematic model [5]. However, since the kinematic model cannot consider boundary and process conditions, it is crucial to validate the algorithm using experimental results. In this study, we develop a numerical method for fiber-draping analysis based on the shell mesh. Shell element curvatures are utilized to estimate changes in fiber-draped orientations during the draping process. These predicted orientations are then applied in thermal deformation simulations of the laminated fan blade. To validate our approach, we investigate numerical findings to underscore the effectiveness of the present method.

2. Simulation method

2.1. Finite element modelling

This study considers a fan blade structure, where the geometric shape and dimensions are described in **Figure 1**. The twisting angle between the tip and root sections is $\pi/4$. Structural thicknesses gradually vary from the root section to the top section of the fan blade, with the maximum thicknesses specified as 4.0 mm for the root section and 2.0 mm for the tip section. The minimum thickness of the fan blade is 0.4 mm. The composite material used in the design and fabrication of the fan blade structure is TC1200/PEEK [6]. It is a unidirectional (UD) tape prepreg incorporating AS4 carbon fibers and polyether ether ketone (PEEK) resin. The material has a volume fraction of 59% and the lamina ply thickness of 0.1 mm.

Cross-section profiles of the CAD solid model are extracted to create the shell mesh for the fan blade structure. In this study, the number of extracted sections is 40. Subsequently, these sections are imported into an in-house pre-processor MATLAB program for the mesh generation. For generating a high-quality shell mesh, a uniform discretization is applied to all sections, ensuring an equal number of nodes for each section. The upper and lower surfaces, along with their middle surface, of the fan blade structure are discretized into quadrilateral shell meshes, as shown in **Figure 1**. Each shell mesh depicted in this figure consists of 1521 quadrilateral shell elements and 1600 nodes. In this study, the middle shell mesh is selected to use for the modeling and analyzing the fan blade structure. To aim this, the thickness of the fan blade structure needs to be converted into nodal thickness represented on the middle shell mesh.

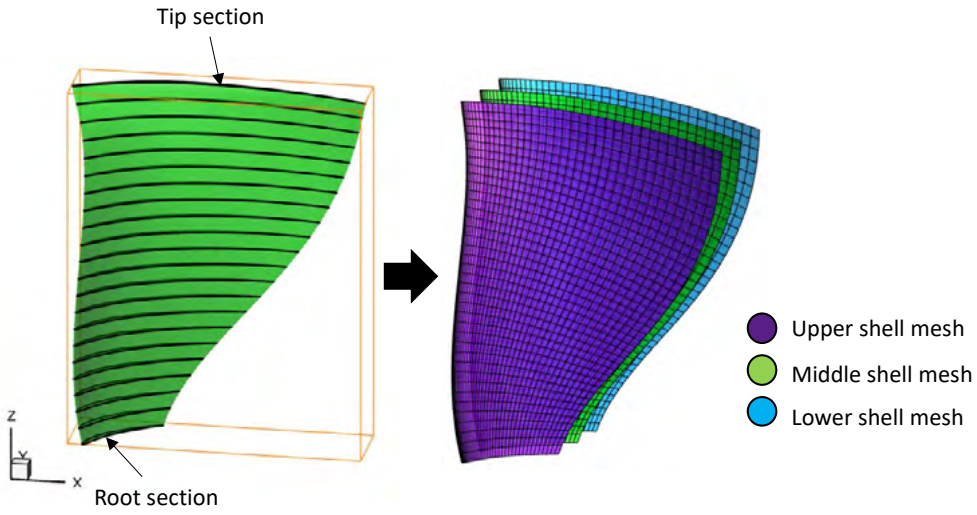

Figure 1. Finite element shell mesh generation.

Figure 2 illustrates the nodal thickness distribution on the middle shell mesh. Based on the thickness distribution of the fan blade structure and the lamina ply nominal thickness, the number of plies on the middle shell mesh can be determined. As a result, the minimum number of plies is 4, and the maximum number of plies is 40. Due to the varying thickness of the fan blade structure, the element groups are generated in descending order from the root section to the tip section, as shown in **Figure 2**. Finally, 10 element groups are genereated on the middle shell mesh.

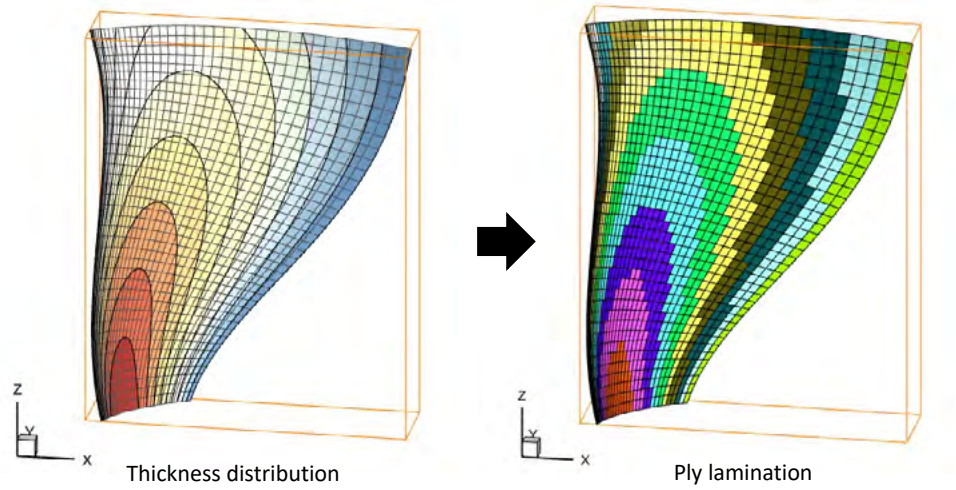

Figure 2. Ply lamination design of the fan blade structure.

2.2. Numerical draping analysis

Due to the double geometric curvature of the fan blade structure, a fiber-draping analysis is required to accurately predict the distortion of the fiber paths that occurs during the hand lay-up process. However, many existing fiber-draping simulation methods pose implementation challenges due to the complexity of their formulations. In this study, to overcome this challenge, we propose a numerical approach for the fiber-draping analysis. The middle shell mesh is used to perform the fiber-draping analysis of the fan blade structure. Based on the curvatures of shell elements, tangent covariant and normal vectors at the shell element center are obtained as

$$\boldsymbol{\varphi}_i(r_1, r_2, r_3) = \frac{\partial \boldsymbol{x}(r_1, r_2, r_3)}{\partial r_i}, \qquad i = 1,2,3 \tag{1}$$

where (r_1, r_2, r_3) is the natural coordinate system, $\boldsymbol{x}$ is the geometric vector. Next, the element draping coordinate system is defined based on the shell curvatures to compute the draped orientation angles of fibers, as illustrated in **Figure 3**. Based on a given global reference material coordinate system, in this figure, in-plane unit vectors of the shell element $\boldsymbol{V}_i^{(e)}$ with respect to the fiber-draping system are computed. The projection operator of an in-plane unit vector on the reference plane as

$$\boldsymbol{p}_i = \text{proj}_{Ox_m y_m}\left(\boldsymbol{V}_i^{(e)}\right) = \boldsymbol{V}_i^{(e)} - \text{proj}_{\boldsymbol{n}}\left(\boldsymbol{V}_i^{(e)}\right), \qquad k = 1,2 \tag{2}$$

where $\boldsymbol{n}$ is the shell element normal vector defined at its center. The prediction of the change in fiber orientation angles for typical directions of $0°$, $90°$, and $\pm 45°$ is expressed as follows

$$\begin{cases} \Delta\emptyset_{[0]} = \tan^{-1}\left(\dfrac{\left(\boldsymbol{e}_1 \times \boldsymbol{p}_1^{(e)}\right)\cdot \boldsymbol{n}}{\boldsymbol{e}_1 \cdot \boldsymbol{p}_1^{(e)}}\right), \\ \Delta\emptyset_{[90]} = \tan^{-1}\left(\dfrac{\left(\boldsymbol{e}_2 \times \boldsymbol{p}_2^{(e)}\right)\cdot \boldsymbol{n}}{\boldsymbol{e}_2 \cdot \boldsymbol{p}_2^{(e)}}\right), \\ \Delta\emptyset_{[\pm 45]} = \tan^{-1}\left(\dfrac{\left[(\boldsymbol{e}_1 \pm \boldsymbol{e}_2) \times \left(\boldsymbol{p}_1^{(e)} \pm \boldsymbol{p}_2^{(e)}\right)\right]\cdot \boldsymbol{n}}{(\boldsymbol{e}_1 \pm \boldsymbol{e}_2)\cdot\left(\boldsymbol{p}_1^{(e)} \pm \boldsymbol{p}_2^{(e)}\right)}\right), \end{cases} \tag{3}$$

where $\boldsymbol{e}_i$ are the unit vector of the reference coordinate system. It should be noted that the advantage of the present method lies in its robustness and ease of implementation, achieved by directly considering the element shell curvatures. In contrast, other existing fiber-draping simulation methods often require numerous steps and complex formulations.

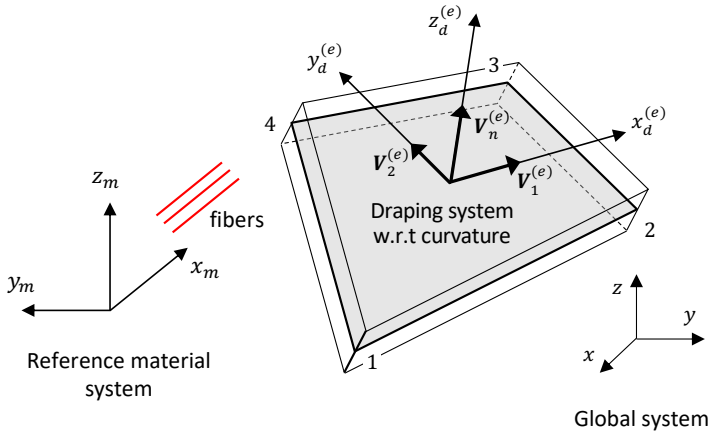

Figure 3. Coordinate systems for the draping analysis.

2.3. Simulation process

In this section, we present the generation of the finite element model used for ABAQUS software. The middle shell mesh is exported to the ABAQUS input format (.inp), including the material orientation system, nodal coordinates, element connectivity, material properties, and shell element sections. For the investigation purposes, two separate shell meshes are exported: one without incorporating fiber-draping analysis and another with fiber-draping analysis, as illustrated in **Figure 4**. Accordingly, in the absence of the fiber-draping analysis, the shell mesh consists of 10 element sets, as shown in **Figure 4**(a). In contrast, when the fiber-draping analysis is considered, each shell element is individually generated into one element set, as depicted in **Figure 4**(b). This export process is executed by an in-house MATLAB pre-processor program.

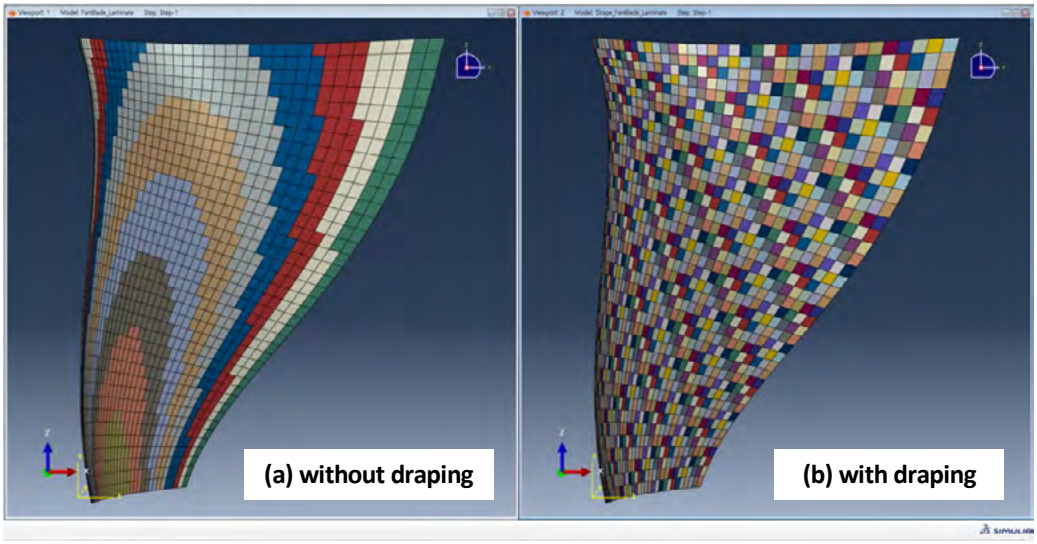

Figure 4. Visualization of finite element model imported from input file (.inp) (a) without draping analysis and (b) with draping analysis.

Thermal deformation of the laminated fan blade structure is conducted, assuming a cooling process for the simulation. Mechanical properties of composite materials, dependent on temperature [7], are utilized. To integrate the temperature profile of the cooling process into ABAQUS, predefined fields are employed to linearly distribute temperatures across the composite fan blade. Specific values are assigned at the maximum temperature of 350°C and the room temperature of 25°C. Additionally, the temperature gradient along the shell section option is chosen, featuring a thickness gradient of 0.1 mm. **Figure 5** illustrates the thermal deformation of the laminated fan blade, highlighting a significant effect of draping analysis on structural behavior.

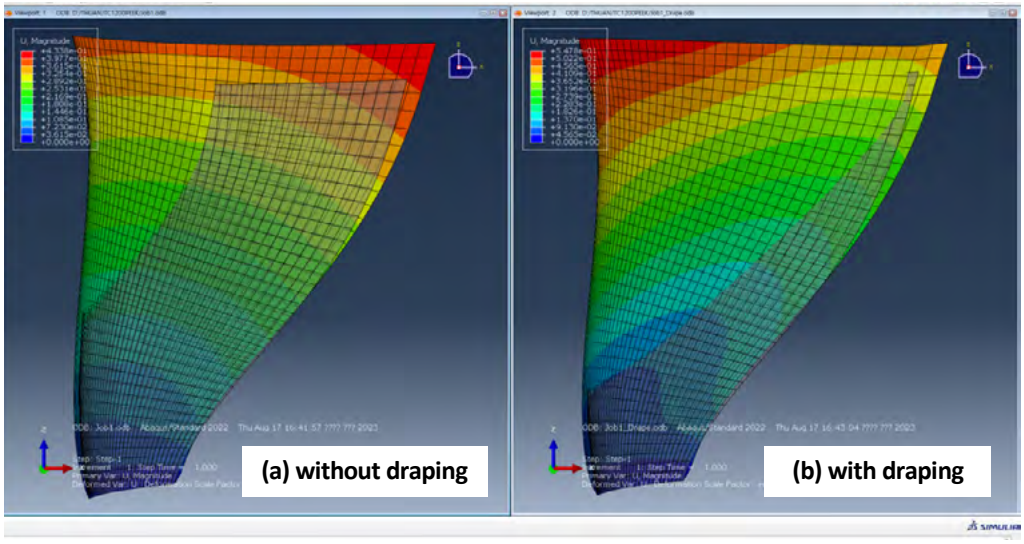

Figure 5. Thermal deformation of laminated fan blade (a) without draping analysis and (b) with draping analysis.

3. Conclusion and future work

In this paper, we presented a robust simulation method for the laminated fan blade structure. The middle shell mesh with nodal thicknesses was considered for structural modeling and simulation. To accurately estimate fiber-draped orientations resulting from the shell curvatures, we proposed a numerical

kinematic method for fiber-draping analysis. This approach allows for a direct estimation of the distortion of fiber orientations in each shell element based on its curvatures. Numerical results highlighted the substantial impact of fiber-draped orientations on thermal deformation.

In future work, to validate the numerical results, the laminated fan blade needs to be manufactured using the lamination autoclave curing process. Subsequently, a comparison between the numerical deformations and those observed in experimental outcomes will be thoroughly addressed.

Keywords: Dissimilar bonding, Delamination, Fracture toughness, Micro bridging

Abstract
Generally, there is a trade-off relationship between strength and toughness. Concerning adhesive structures, reducing the adhesive thickness improves joint strength, while increasing the adhesive thickness enhances fracture toughness. We proposed a technique to significantly improve both bonding strength and fracture toughness in the dissimilar bonding of thermoplastic carbon fiber reinforced plastic (CFRP) laminates and aluminum alloy. The mechanism behind this improvement is examined in this study. The mechanism by which the nanostructure at the interface leads to the formation of numerous plastic deformations in the resin, causing fuzzing, was investigated. A mechanical model was derived to consider the bridging of matrix resin behind the crack tip. It was found that the bridging near the crack tip occurs in a narrow area but has a significant effect on the crack propagation resistance.

1. Introduction

In order to reduce the structural weight of automobiles, aircraft, and other transportation equipment, the technological development for joining composite materials and metals is being promoted. In particular, applications of thermoplastic carbon fiber reinforced plastic (CFRP) are expanding because thermoplastic resins have excellent heat resistance and recycling properties. However, some thermoplastics lack adhesive properties due to their chemical stability. On the other hand, there have been many studies on adhesive thickness and bonding strength and fracture toughness. A thinner adhesive layer improves bond strength, while a thicker adhesive layer improves fracture toughness, and these are trade-offs [1]. The authors have shown that in bonding thermoplastic CFRP laminates to aluminum alloys, both bonding strength and fracture toughness are improved by fabricating nano-convex structures on the aluminum alloy surface and adding silane coupling agents to the surface to improve bonding to the matrix thermoplastic resin [2-4]. A number of resin fluffing was observed on the fracture surface, which is assumed to be a factor, but the mechanism by which the nanostructure at the interface improves fracture toughness is not well understood.

A theoretical analysis of fracture mechanics at the interface between dissimilar materials was performed by Williams [5]. He noted oscillatory stress singularity in the vicinity of the crack tip and unrealistic crack surface interpenetration. Based on his work, Rice and Sih [6,7] derived an exact solution using complex stress functions. Crack propagation characteristics at dissimilar interfaces were also studied intensively in the 1980s and 1990s [8-10]. Fracture of Mode I and Mode II cannot be separated in the evaluation by the stress intensity factor at the crack tip of the dissimilar material interface. Because of the inhomogeneous nature of composite materials, evaluation by total energy release rate or J-integral

is often used rather than by stress intensity factor [11-13]. Davidson et al. [14] proposed the crack tip element approach for mode separation at the interface of dissimilar materials by energy release rate. Wang and Qiao [15] incorporated the effects of transverse shear force and root rotation at crack tip into that approach. Yokozeki [16] extended the model proposed by Wang and Qiao to include the influence of thermal residual stress. In this study, the crack tip element method is extended to evaluate the effect of bridging on crack propagation at dissimilar material interfaces.

2. Experiments

2.1. Materials

Experiments were taken from previous our work [3]. Here is a brief description of the experiment. Plain woven thermoplastic CFRP laminates with polyamide 6 (PA6) matrix resin and aluminum alloy A5052 were used as test materials. For the thermoplastic CFRP laminates, the carbon fiber of Toray T300B-3K was used, and the fiber volume fraction was V_f = 50%. The stacking sequence of the laminate was $[(0/90)_9]$. The thickness of both thermoplastic CFRP and aluminum alloy was 2 mm, respectively.

2.2. Manufacturing procedure of the nanostructure on aluminum alloy surface

Nanostructures were fabricated on aluminum alloy surfaces with the aim of improving bonding strength. The nanostructures were fabricated by two-step processes of anodizing and etching. The conditions of the anodizing and etching processes are shown in Table 1. Removing alumina by etching after the first anodizing treatment allows the pores to grow uniformly in the second anodizing treatment. As a pretreatment, the aluminum alloy surface was degreased in acetone for 10 minutes using an ultrasonic bath. The anodizing treatment was performed in a low-temperature water bath maintained at 10°C and 400 V using a carbon rod as a cathode and an agitator. The etching process was performed in a high temperature water bath at 63°C. The fabricated nanostructure observed using scanning electron microscope (SEM) was shown in Figure 1.

2.3. Manufacturing procedure of the test specimen

To improve the bonding of aluminum alloy to the matrix resin of thermoplastic CFRP, a silane coupling agent was applied to the surface of an aluminum alloy. The thermoplastic CFRP laminate and aluminum alloy were then joined by hot pressing under atmospheric conditions. 12.5 μm thick polyimide film was inserted at the bonding interface at 45 mm from the tip of the specimen as a pre-crack starter notch to perform the DCB test. The hot press conditions were 0.4 MPa at 300°C, pressurized for 3 minutes, and then cooled for about 5 minutes until the temperature reached 50°C.

2.4. DCB test conditions

Double cantilever beam (DCB) tests were performed according to JIS K 7086. The dimensions of the specimen are shown in Figure 2. To apply tensile load, loading blocks were glued to the specimens with adhesive. A universal testing machine equipped with a 10 kN load cell was used for displacement control, and the test speed was 0.5 mm/min. The specimens were pre-cracked from the insert film by applying tensile load to the specimens under the same conditions as in the DCB test to propagate cracks. The length from the load line to the crack tip was defined, and displacement δ and load P were measured. The load point displacement δ measured during the test was assumed to correspond to the calculated crack opening displacement. The area near the crack tip was continuously monitored with a charge-coupled device camera during loading, and the increase in crack length was calculated by digital image correlation method. In this study, the specimen with the nanostructure fabricated on the aluminum alloy and silane coupling treatment applied to its surface is called Si-NS, and the specimen with silane coupling treatment on the aluminum alloy without fabricating nanostructures is called Si-AR.

Table 1. The conditions of the anodizing and etching processes.

Step	Solution	Temperature (°C)	Time (min)
1st anodizing	2 wt% citric acid + 2 wt% ethylene glycol (1:2)	10	540
1st etching	6 wt% H_3PO_4 + 1.5 wt% H_2CrO_4 (1:1)	63	60
2nd anodizing	2 wt% citric acid + 2 wt% ethylene glycol (1:2)	10	540
2nd etching	6 wt% H_3PO_4 + 1.5 wt% H_2CrO_4 (1:1)	63	20

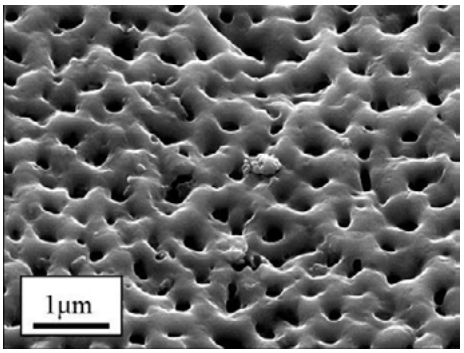

Figure 1. Fabricated nanostructure on aluminum alloy surface.

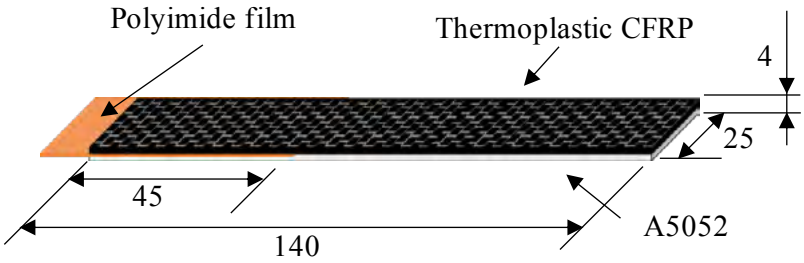

Figure 2. Dimensions of DCB specimen bonded with thermoplastic CFRP and aluminum alloy.

3. Energy release rate associated with delamination growth

The crack tip element method was used to derive the energy release rate associated with crack propagation at the interface of dissimilar materials [15-17]. In this study, the energy release rate associated with interfacial crack propagation was derived by considering the bridging that occurs behind the crack tip. Figure 3 shows the proposed model considered in this study, where N, Q, and M represent axial force, transverse shear force, and bending moment, respectively. The subscripts 1 and 2 indicate the different types of materials. (x) indicates the physical quantity at distance x from the crack tip. The subscript T indicates the sum of materials 1 and 2. Figure 4 (a) shows bridging behind a crack tip and Figure 4 (b) shows the free body diagram at the crack tip. The subscript c represents the interfacial force acting in front of the crack tip. The subscript $i0$ ($i = 1, 2$) indicates the posterior direction of the crack.

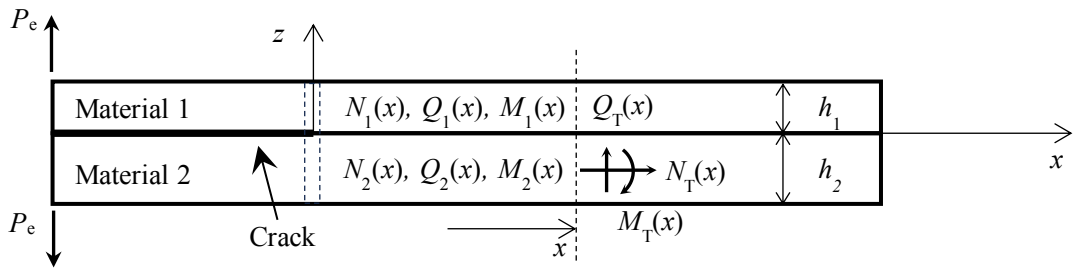

Figure 3. A bi-layer model with cracks under DCB test.

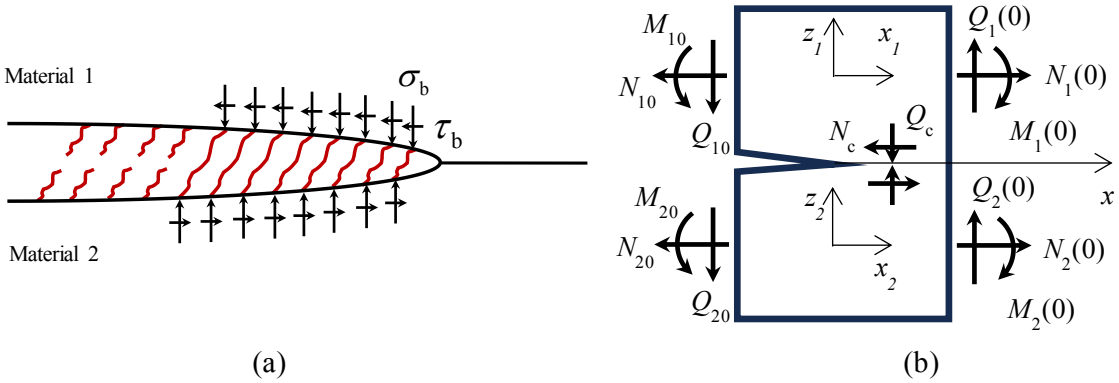

Figure 4. Mechanical state near crack tip: (a) Bridging behind a crack tip; (b) Free dody diarram at crack tip.

The energy release rates for modes I and II can be expressed as follows.

$$\begin{aligned} G_{\mathrm{I}} &= \frac{1}{2B}\left(\frac{1}{\kappa C_1}+\frac{1}{\kappa C_2}\right)Q_{\mathrm{c}}^2 \\ G_{II} &= \frac{1}{2B}\left(a_1+a_2+\frac{h_1^2}{4}d_1+\frac{h_2^2}{4}d_2\right)N_{\mathrm{c}}^2 \end{aligned}, \tag{1}$$

where, C_i is the shear stiffness, κ is the shear factor (=5/6). a_i and d_i are the compliance of each material, and h_i is the thickness of each material. B is specimen width. From Figure 4 (b), the force balance at the crack tip can be expressed by the following equation.

$$\begin{aligned} N_c &= N_1(0)-N_{10} \\ Q_c &= Q_1(0)-Q_{10} \end{aligned}. \tag{2}$$

The forces behind the crack tip considering bridging is expressed as follows.

$$\begin{aligned} N_{10} &= \int_0^b \tau_b(x')\,dx' \\ Q_{10} &= -P_{\mathrm{e}}+\int_0^b \sigma_b(x')\,dx' \end{aligned} \tag{3}$$

where P_e is the transverse load applied to the DCB specimen, b is the length of the bridging region, and x' is the coordinate system in the opposite direction of the x-axis with the crack tip at the origin.

4. Results and Discussions

The DCB test results of the specimens without and with nanostructures on the aluminum alloy surface were compared. The critical energy release rates of the specimens of Si-AR and Si-NS were $G_c = 0.38$ kJ/m^2 and $G_c = 0.98$ kJ/m^2 , respectively. The fracture surface of the Si-AR specimen was smooth and brittle, whereas the surface of the Si-NS specimen showed resin fluffing as shown in Figure 5. This fluffing is considered to have significantly improved the apparent fracture toughness.

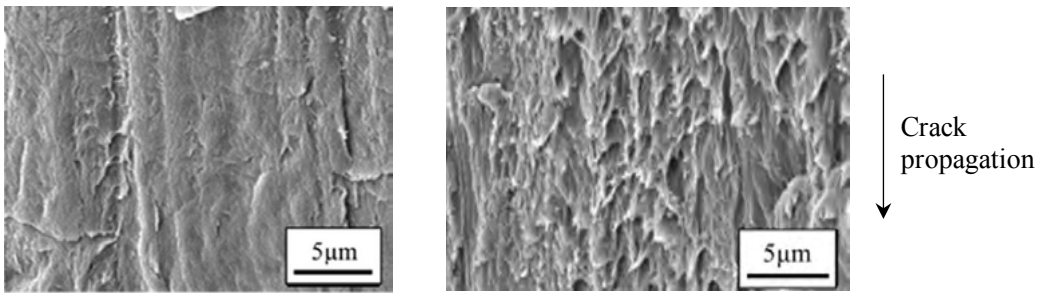

Figure 5. Fracture surfaces observed by SEM: (a) Si-AR; (b) Si-NS.

When the fracture toughness of the bonding interface is too high, the crack propagates into the matrix resin; when the fracture toughness of the interface is too low, the crack propagates along the interface. Therefore, it is considered necessary to have adequate interfacial toughness to produce bridging with fluffing as observed in the experiments. When the interface of the joint is kinked, there may be partially interfacial debonding ahead of the crack tip at angles where the Mode I value is higher. When these conditions are met, the crack may propagate with bridging near the crack tip as shown in Figure 6. The proposed model showed that bridging significantly improves crack propagation resistance.

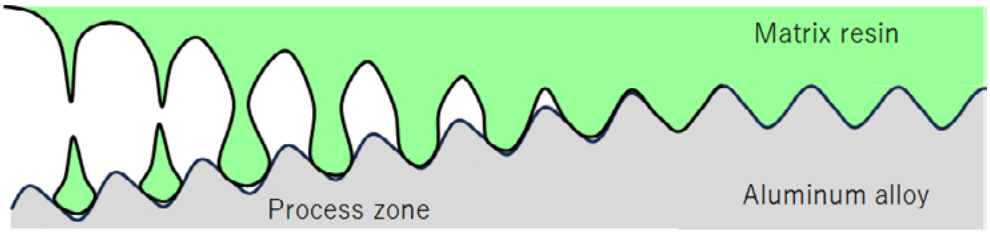

Figure 6. Schematic diagram of resin bridging caused by nanostructures at the bonding interface.

Conclusions

In this study, the influence of the interfacial nanostructure on the crack propagation resistance of thermoplastic CFRP and aluminum alloys was evaluated. Experiments showed that the nanostructure at the interface significantly increased the fracture toughness. This may be due to the large number of matrix resin fluffs at the interface. The micro-bridging caused by the interfacial nanostructure may be due to partially interfacial debonding occurring ahead of the crack tip at the location where the Mode I energy release rate is higher. The energy release rate associated with crack propagation considering the bridging behind the crack tip was derived. The bridging effect contributed significantly to the increase in the crack growth resistance.

Keywords: CFRTP, Ultrasonic Welding, Adhesive Joint, Numerical Simulations, Strength Test,

Abstract
In this study, we propose a comprehensive method for evaluating the joint strength of ultrasonic-welded carbon-fiber-reinforced-thermosetting-plastic (CFRTP). Ultrasonic welding is one of the promising joining methods for CFRTP, which is expected to be applied to joint large parts such as aircraft components, but this welding has not been generally applied. This is because a method to evaluate joint strength quantitatively and comprehensively has not yet been established. Current strength evaluations are based only on experiments such as single lap shear test (SLS) or double cantilever beam test (DCB), however, what is obtained here is only apparent strength that does not consider the stress state, failure mode, or failure initiation point of the joint. Therefore, we suggest a new strength evaluation method that can evaluate true strength not apparent strength. In this paper, we calculate the strength quantitatively and comprehensively by using stress analysis in Abaqus and the preceding failure theory, in addition to strength tests. In this process, the interface strength and the resin strength of the joint are determined separately to get a more accurate strength. Then, these strengths are combined on the same plane to develop a comprehensive failure envelope that enables the evaluation of true joint strength.

1. Introduction

Carbon-Fiber-Reinforced-Plastic (CFRP) is a material widely used in the aerospace industry because of its high specific strength, stiffness, and light weight. In the most cases, thermoset resin composites (FRTS) have been used in the past, but in recent years, thermoplastic resin composites (FRTP) have been used due to their high recyclability and processability. A notable feature of CFRTP is that it can be weld-joined. Today, mechanical joining with bolts or rivets is the main method of joining composite materials in large structures such as aircraft. If composite materials can be joined by welding or bonding, many advantages can be expected, such as weight reduction, improved mechanical properties, and recyclability. Thus, welding and bonding of CFRTP is a remarkable technology, and we aim to apply ultrasonic welding, which is one of the most efficient welding methods [1], to large structures.
Now, three reasons hinder the widespread adoption of ultrasonic welding for CFRTP: (1) welding mechanism is not known, (2) the joint strength is not clear, and (3) the durability is not clear. We have

studied the melting behavior of Energy Director (ED) [2,3], which is used to improve the welding efficiency of ultrasonic welding of CFRTP, to elucidate the welding mechanism. We are now working to clarify the joint strength in ultrasonic-welded CFRTP.
Previously, joint strength of ultrasonic-welded CFRTP has been evaluated by SLS and DCB [4,5]. However, it is known that joints have stress distribution, and that joint fails in a mixed mode of tensile and shear stresses [6]. The conventional evaluation based only on experiments is only an evaluation of apparent strength, because it does not consider the complex stress state and failure type of the joint. Therefore, we propose a new strength evaluation method that can evaluate joint strength quantitatively and comprehensively.
Thus far, we have proposed a new strength test that improved upon the conventional strength test [7] and discussed the most appropriate strength evaluation through numerical analysis [8]. In this paper, we focus on the failure mode at the origin of failure. There are two types of failure modes for adhesive and welded joints: interface failure or resin failure, and consideration of the failure mode is necessary for more accurate strength evaluation. We calculate the interfacial strength and the cohesive strength separately, and finally describe them on the same plane to develop a comprehensive failure envelope to clear true strength. Besides, in addition to experimental results, numerical analysis and failure theory are used to calculate each strength, considering the stress distribution and failure under combined stress conditions.

2. Ultrasonic Welding and Strength test

CF/PEEK prepreg (IMS/PEEK (TEIJIN LIMITED), 1.5 mm thick, 30 mm square (16-ply)) was used as the adherend, and welding tests were performed using an ultrasonic welder (Ultrasonic Welder JP80s, SEIDENSHA ELECTRONICS CO.,LTD., Fig. 1). As shown in fig. 1, three pieces of general-purpose Poly Ether Ether Ketone (PEEK) mesh (#25, (CLEVER CO.,LTD.), thickness 0.13 mm, 30 mm square) were inserted between the adherends as an ED. Four sets comprising two CFRTP laminates and three PEEK sheets were prepared, and ultrasonic-welded CFRTP were made which named specimen No. 1 to 4. CFRTP was successfully bonded to all two specimens.

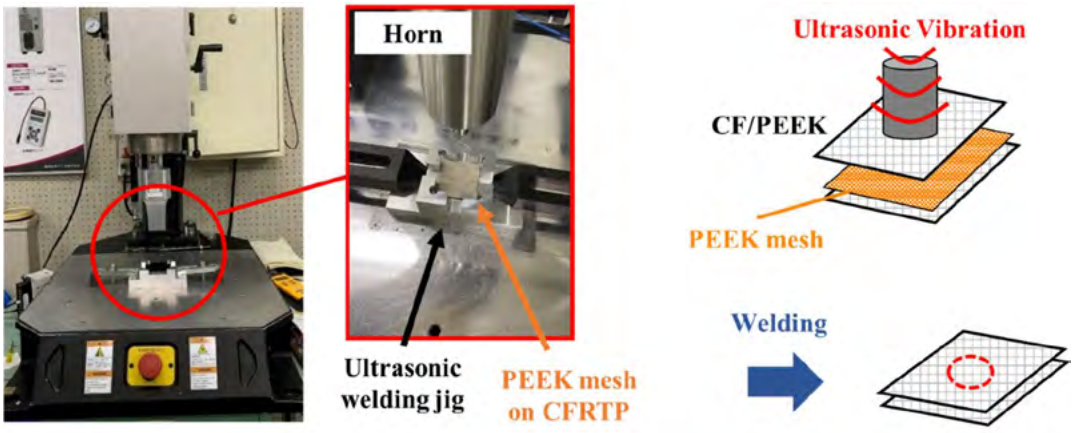

Figure 1. Picture of Ultrasonic welder (JP80s) and Schematic of Ultraconic welding in this study

We performed “Shear Test by Compression” on specimen No. 1 to 4. In this test, one side of the specimen was fixed by a jig and a load was applied to the other side, as shown in fig. 2. A universal testing machine (10 kN) was used for this test. A 20 mm displacement was applied to the load cell at 1 mm/min and the displacement-load was measured. fig. 3 displays images of the fracture surfaces. A summary of all experimental results is presented in table 1. As evident from fig. 3, specimen No. 1 showed only interface failure, No. 2 was dominated by interface failure, and No. 3 and No. 4 showed a mixture of interface and resin failure. This suggests that the failure modes, serving as the origins of failure, vary depending on the condition. Hence, it is important to derive interface strength and resin strength separately and then to evaluate the strength comprehensively. In the following chapter 3.1 and

3.2, the interface strength and resin strength are calculated respectively, and a comprehensive strength evaluation is given in chapter 3.3.

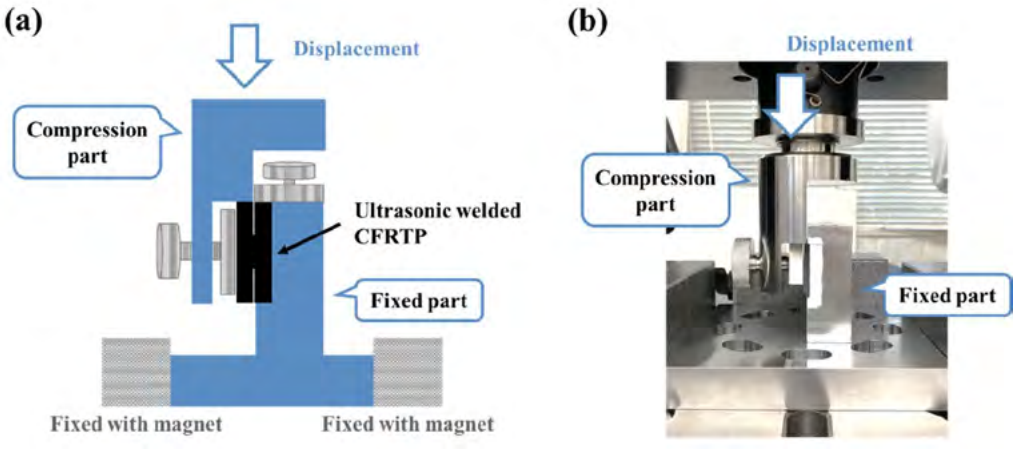

Figure 2. Shear Test by Compression ((a) Schematic diagram / (b) Picture)

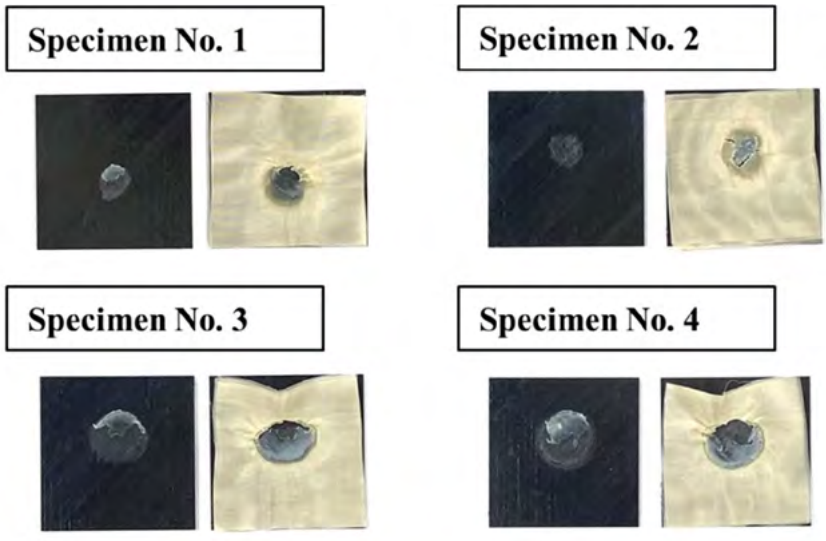

Figure 3. Picture of Fracture Surface after Shear Test by Compression. No. 1 was only interface failure, No. 2 was mainly interface failure, and No. 3-4 showed a mixture of interface and resin failure.

Table 1. Results of Shear Test by Compression. (welding time of each Ultrasonic-welded CFRTP / welded area calculated by using X-ray CT / Failure Load / Failure type (fig. 3))

Specimen No.	Welding time (s)	Diameter of welding area (mm)	Failure load (N)	Failure type
1	3	7.76	1340	interface
2	3	6.00	652	interface
3	5	10.7	4020	interface + resin
4	5	11.7	4780	interface + resin

3. Evaluation of Joint Strength

3.1. Interface Strength

The interface strength was determined by simulating the shear test using numerical analysis (Abaqus 2020). This was based on the experimental results of specimen No. 1 and 2 in which interfacial failure was dominant.

The model consists of two CFRTP laminates of 30 mm square and a circular bonded zone (PEEK) between them (fig. 4(a)), and we inserted a cohesive element between the CFRTP and the resin. The diameter of the joint (α mm) was changed based on the welding condition of the specimen observed by X-ray CT (table 1), assuming the shape of the weld to be a perfect circle. The material properties were shown in table 2-3 and plasticity property was assigned in resin (fig. 4(b)). The test was reproduced by applying boundary conditions in the y-direction to the top and bottom surfaces of the CFRTP on one side and in the z-direction to both sides of the CFRTP, and y-direction displacement to the top surface of the CFRTP on the other side, which was not fixed in the y-direction (fig. 4(a)). The interface strength was calculated by fitting the cohesive properties (table 3 [9]) so that the failure load in the analysis equals the experimental value.

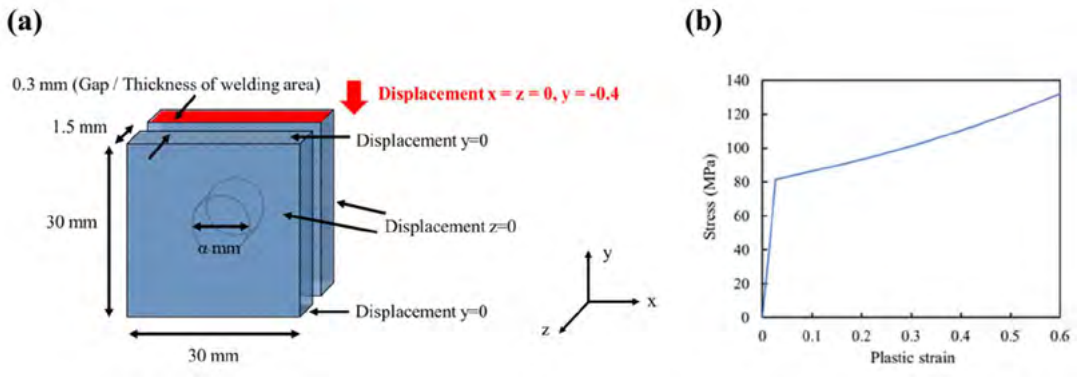

Figure 4. Analysis Conditions ((a) model size and boundary conditions (b) PEEK properties)

Table 2. Material properties (CFRTP / PEEK)

	Young modulus (MPa)	Poisson' ratio
CFRTP	9300	0.2
PEEK	3000	0.37

Table 3. Cohesive properties [9]

	Interface Strength (MPa)		
	Vertical	Shear1	Shear2
Cohesive	$\beta/\sqrt{2}$	β	β

Table 4 shows the strength from experiments and the strength calculated by the analysis. We calculated experimental strength from the X-ray CT (SHIMADZU Co.) images of area of the weld zone and the corresponding failure load ($\text{experimental strength} = \text{failure load}/\text{welded area}$). This apparent strength in experiment, which did not consider the stress distribution, was significantly different from the strength in analysis. Fig. 5 shows the stress state at the interface when the interface fails (specimen No. 1), indicating that stress was concentrated at the edge of the joint. We could also conclude that the failure occurs in a mixed mode of tensile and shear stresses. These results were also observed in the analysis for specimen No. 2.

Table 4. Interface Strength from experiment or FEM analysis

Specimen No.	Shear Strength (MPa)	
	Experiment	FEM
1	28.4	67.9
2	44.6	49.6
Average	36.5	58.8

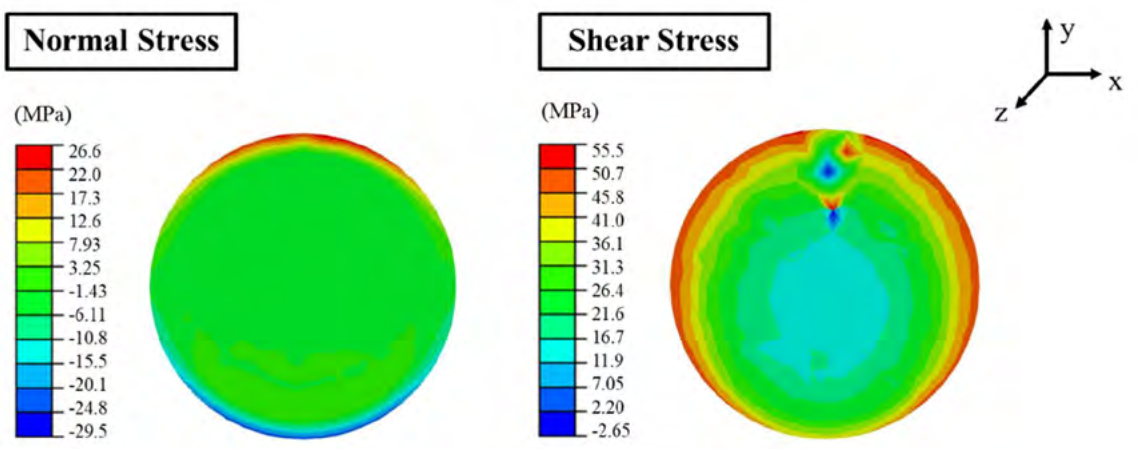

Figure 5. Distribution of Normal and Shear Stresses at the joint interface

Since the interface failure is based on the parabolic criterion [9,10] and the interface strength obtained in this experiment and analysis, the interface strength can be given by the following Eq. 1. According to the parabolic criterion, $c_1 = -7.4 \times 10^{-3}$ and $c_2 = 67.2$ can be calculated. Stress in Normal direction is t_n and Stress in Shear direction is t_s; and this parabola shows the interface strength under combined stress conditions (normal + shear stress).

$$t_n = c_1 {t_s}^2 + c_2 \tag{1}$$

3.2. Resin Strength

The resin strength was derived based on Christensen's failure criteria (Eq. 2 [11,12]). This criterion predicts ductile yielding and brittle failure of isotropic materials in the same equation. C and T are the uniaxial failure stresses in compression or tension and σ is the stress in each direction.

Applying Christensen's failure criterion to the Shear test by Compression in this paper, we can consider Eq. 3 and Eq. 4. This is because only S33 is the normal stress for the adhesive elements, whereas transverse shear stress S13 and longitudinal shear stress S23 are the output of the shear stress, in shear test. As before, t_n is Normal stress and t_s is Shear stress. From the above, $c_3 = 0.303$, $c_4 = 0.952$, $c_5 = 1.2$ can be derived in Eq. 5. We derived Eq. 4 by taking this assumption and the following material properties: $T = 100$ MPa [13], $C = 250$ MPa, $\nu = 0.37$. Eq. 5 shows the resin strength under combined stress conditions.

$$\left(\frac{1}{T} - \frac{1}{C}\right)(\sigma_{11} + \sigma_{22} + \sigma_{33}) + \frac{1}{TC}\left\{\frac{1}{2}[(\sigma_{11} - \sigma_{22})^2 + (\sigma_{22} - \sigma_{33})^2 + (\sigma_{33} - \sigma_{11})^2] + 3({\sigma_{12}}^2 + {\sigma_{23}}^2 + {\sigma_{31}}^2)\right\} \leq 1 \tag{2}$$

$$\sigma_{11} = \frac{\nu}{1-\nu}\sigma_{33}, \qquad \sigma_{22} = 0, \qquad \sigma_{12} = 0 \tag{3}$$

$$t_{\mathrm{n}} = \sigma_{33}, \qquad t_{\mathrm{s}} = \sqrt{{\sigma_{23}}^2 + {\sigma_{31}}^2} \tag{4}$$

$$\frac{1}{T^2}\{c_3 {t_{\mathrm{n}}}^2 + T c_4 t_{\mathrm{n}} + c_5 {t_{\mathrm{s}}}^2\} \leq 1 \tag{5}$$

3.3. Parabolic Criterion

We propose to evaluate strength using comprehensive failure envelope that includes both interface strength and resin strength. Using Eq. 1 and Eq. 5 derived so far, the interface strength and the resin strength were described on the same plane (fig. 6).

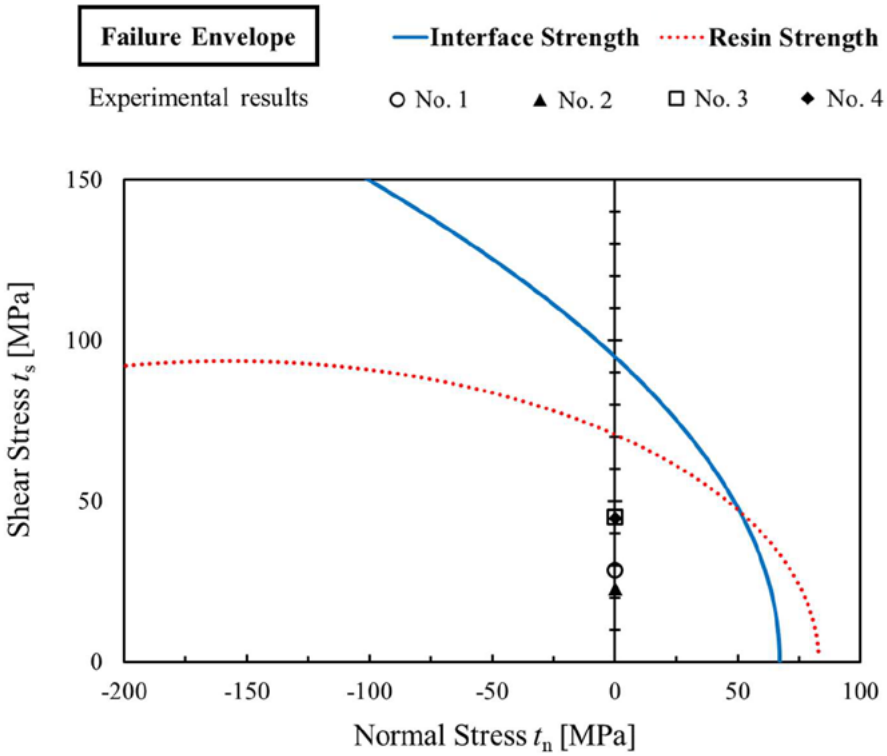

Figure 6. Comprehensive Failure Envelope including both Interface Strength and Resin Strength

Fig. 6 shows that the failure mode differs depending on the stress state of the joint. Using this comprehensive failure envelope, it is possible to evaluate the joint strength of ultrasonic-welded CFRTP considering the following points:

I. Stress distribution (each strength was calculated using numerical analysis and failure theory)
II. Strength under various stress conditions (tensile stress or shear stress)
III. Failure mode at the point of failure (interface failure or resin failure)

4. Conclusions

In this study, we calculated interface strength and resin strength separately, based on strength tests, numerical analysis, and failure theory. Then, a comprehensive failure envelope representing the joint strength of ultrasonic-welded CFRTP was constructed by combining each strength on the same plane. Using this envelope, we were able to quantitatively and comprehensively evaluate the strength of the joints, considering three factors: stress distribution in the joint, failure under combined tensile and shear stress conditions, and failure mode.

Abstract
Lattice or grid-stiffened structures are essential for lightweight designs. These structures consist of ribs that support external and internal loads, utilizing the high stiffness and strength of unidirectional fibers. 3D printing allows for diverse unit cell designs, each with unique stiffness, strength, and energy absorption properties. In this study, the compressive strength of 3D-printed composite lattice structures with three different printing paths was investigated. T300 carbon fiber tow and thermoplastic polylactic acid (PLA) filament were used. The specimens were prepared with printing paths with and without crossing continuous fiber filaments and were printed thick enough to prevent out-of-plane buckling. Compression tests were conducted using the ASTM D3410 fixture. Glass fabric tabs and aluminum blocks were used to extend the specimens to ensure stable and uniform compressive load. The compressive strength was compared for each specimen.

1. Introduction

Composite lattice structures are highly efficient structure for bearing high loads [1, 2]. The structure consists of ribs to endure external loads and enhance buckling performance. External and internal loads in the structure are supported by each rib utilizing the high stiffness and strength of unidirectional fibers. These structures are manufactured through filament winding, automated fiber placement, and hand lay-up. Furthermore, the technology of three-dimensional (3D) printing with continuous fiber is becoming a promising technique for manufacturing composite lattice structures.

Many studies have been conducted on 3D-printed energy absorption structures with different types of unit cells exhibiting different stiffness, strength, and energy absorption properties [3-6]. Wang et al. [3] performed tensile tests on 3D-printed continuous fiber reinforced composite grid structures. Ren et al. [4] performed tensile tests on continuous fiber reinforced grid unit cells to obtain tensile modulus. The measured modulus was used in a path-planning approach to find an efficient and performance-optimized fabrication process for grid-stiffened composite panel. The approach was mainly compared by buckling performance. Habib et al. [5] discussed the effect of 3D-printed honeycomb cell shape on the performance of energy absorption structures. Triangular, quadratic, diamond, hexagonal, octagonal, and circular shapes were compared for energy absorption efficiency. Bokharaie et al. [6] presented an approach to enhance the structural performance of 3D-printed composite materials with different geometries of hexagonal cells. Tensile tests were performed, and the fracture mechanisms weres examined by experimental and numerical procedures. A multiscale homogenization and the Hashin damage model were used.

In the studies above, the tensile properties were main research topic, and joint configuration was not primarily considered for compressive properties. Structures printed with continuous fiber must have joint points between each rib. The printing strategy for these joint points is important for enhancing the compressive energy absorption capacity. Understanding the properties of joint point with different printing paths is necessary before design and manufacturing; however, study on this aspect has not been sufficiently reported.

In this study, the compressive properties of a 3D printed composite lattice structure with three different types of printing paths was investigated. T300 carbon fiber tow and thermoplastic polylactic acid (PLA) filament were used in the fabrication process. The purpose of this test is to investigate the in-plane properties of the specimen, and the specimen was printed with a sufficiently thick thickness to prevent out-of-plane buckling and deformation. Compression tests on the printed specimens were conducted using the ASTM D3410 fixture. Glass fabric tabs were attached to the top and bottom areas of the specimen, and a stable and uniform compressive load was applied to specimen by shear force from the fixture. The compressive strength was compared for specimens with different joint shape.

2. Compression test

2.1. Specimen and test procedure

Specimens were fabricated using T300 carbon fiber tow and PLA filament. The carbon fiber tow and PLA filament were printed together from the nozzle of 3D printer. Three specimens with different printing path were prepared, as shown in Figure 1. In Pattern I as shown in Fig 1 (a), the filaments with carbon fiber tow are crossed at the joints on the same layer. The filament can pass through the previously printed filament because PLA was in a liquid state during printing. Pattern II is similar to Pattern I. The filament in one direction was printed first, and that in the other direction was printed at the upper layer. The number of layer of Pattern I is twice of Pattern II. There are empty spaces between the filaments and those were subsequently filled by the melted PLA. In Pattern III, the filaments were printed without crossing. At the joints, the printing path was set to turn around without crossing. The number of layer is 15 for Pattern I and III, and 8 for Pattern II. The width of printed filament is 3 mm, and total thickness is 6 mm to observe in-plane behavior without out-of-plane deformation. Total heith and width of the specimen is 35 mm. Joint area of left and right side at middle height was cut to obtain compressive property of single unit cell.

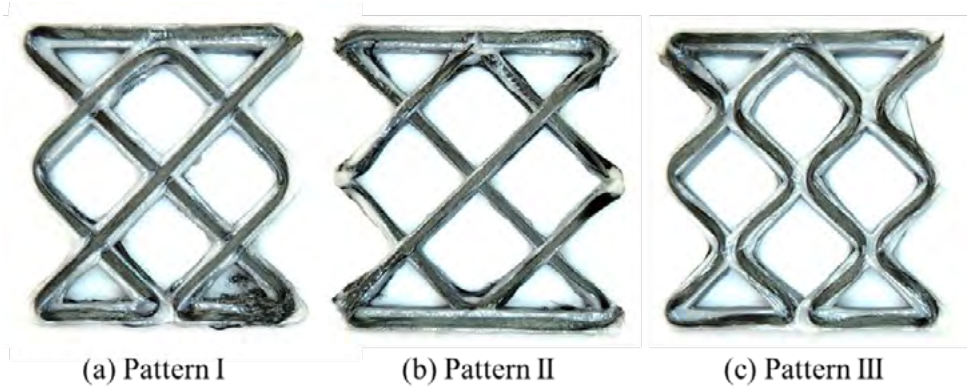

Figure 1. Specimens with different printing path.

To ensure uniform and stable compressive load for the specimen, the ASTM D3410 test fixture was used (Figure 2). The specimens were extanded by glass fabric tab and the empty space was filled with an aluminum block (Figure 3). The surface of glass fabric tab was contacted with the jaw surface of test fixture. Test was perfomed with displacement control and speed set to 1 mm/min. Universal testing machine with 30 kN capacity was used.

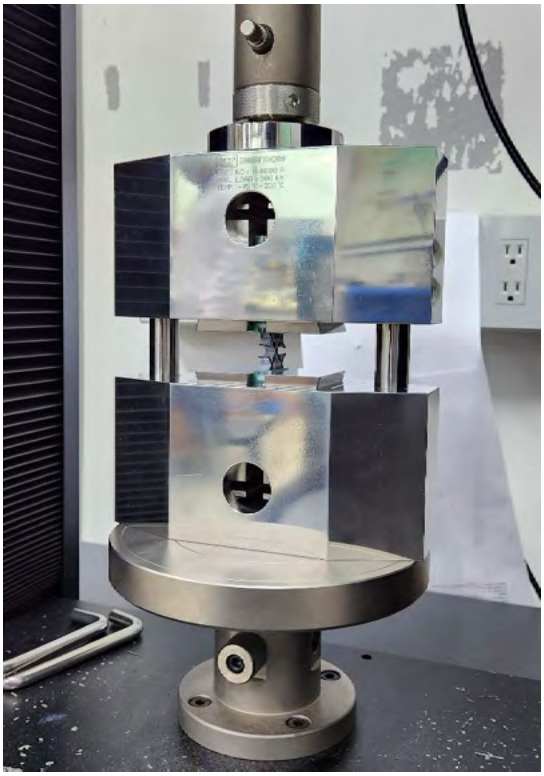

Figure 2. Compression test using ASTM D3410 test fixture.

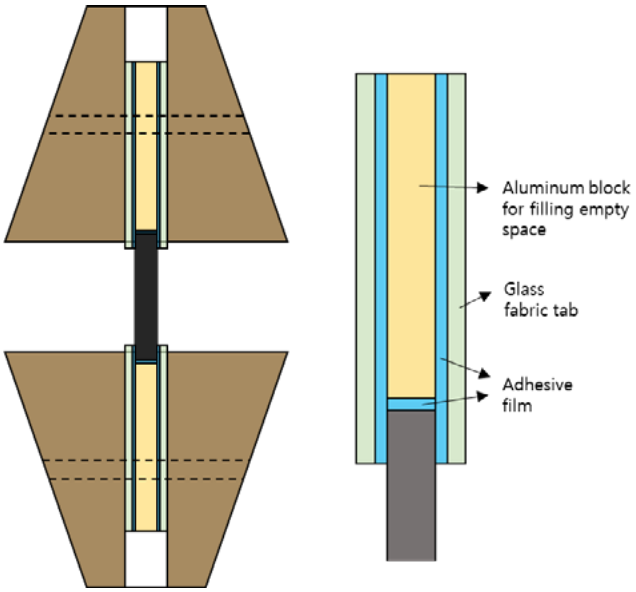

Figure 3. Extended specimen with glass tab and aluminum block.

2.2. Test results

Compression test results are shown in Figure 4, and the maximum loads of each specimen are listed in Table 1. It was confirmed that Pattern I had the highest compressive strength, while Pattern II had the lowest strength. The number of layers in Pattern II is half that of the other specimens, and the space between each layer is not sufficiently filled with resin. Consequently, the out-of-plane shear stiffness is too low, the compressive rigidity and strength are significantly reduced. The initial stiffness of Pattern III is slightly higher than that of Pattern I, but the bifurcation point due to fracture occurred at a lower load, resulting in a maximum strength lower than that of Pattern I.

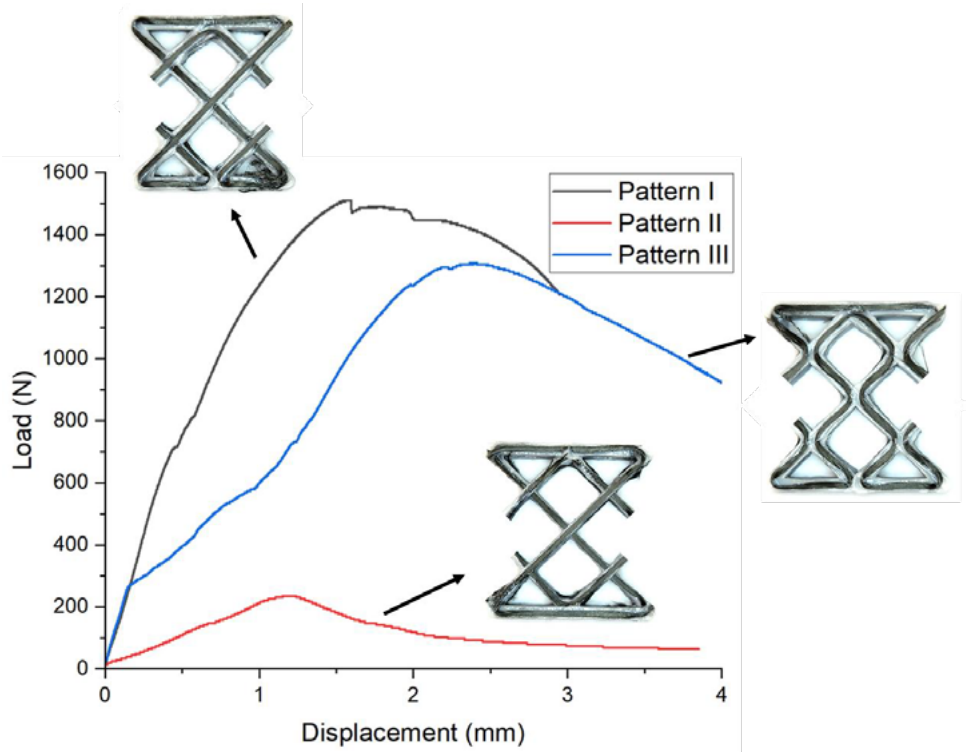

Figure 4. Measured load-shortening curve.

Table 1. Maximum load of each specimen.

Path-1	Path-2	Path-3
1510 N	235 N	1309 N

3. Conclusions

In this study, compression tests were performed on composite lattice unit structures fabricated using continuous fiber printing. Specimens were fabricated with three different printing paths, and their compressive strengths were compared. To apply a stable compressive load to the specimens, tabs were attached, and a jaw block type compression test fixture was used.

The compressive strength was highest in the pattern with intersecting fibers. The initial stiffness did not show a significant difference depending on whether the fibers crossed or not. The specimens printed to maintain a uniform shape of the laminated fibers with the crossing fiber filament exhibited the lowest performance due to insufficient lamination in the thickness direction.

Further work will involve fabricating specimens with various angles and conducting additional tests to compare and analyze the stiffness and strength according to the angles and printing paths. Additionally, finite element analysis will be utilized to propose criteria for defining buckling and bifurcation points.

Abstract

Design of variable stiffness (VS) laminates, featuring curvilinear fiber paths, requires efficient methodologies to attain structural performance levels beyond those of conventional constant stiffness (CS) composites. However, optimization and fabrication of VS laminates pose significant challenges. This problem is addressed in the present study, where lamination parameters (LPs) and spectral Chebyshev approaches are incorporated to obtain a multi-step design framework for symmetric and balanced composites. Initially, master points were defined to attain optimal LP distributions, which were subsequently used to retrieve the discrete fiber angles. Then, to obtain the continuous fiber paths, streamline and equidistant fiber path planning methods were implemented. For modal testing, laminate samples with the optimal fiber paths were fabricated via the automated fiber placement technique. The results show that the designed VS panels provide up to 8% performance improvement over optimal CS laminates. The experimental fundamental frequencies were found to be around 20% lower than the simulation results on average.

1. Introduction

The superior mechanical properties of laminated composites have been boosting their use across various industries. Traditional laminates reinforced with straight fibers result in constant (in-plane) stiffness (CS) [1]. Recently, advanced composite fabrication techniques, such as automated fiber placement (AFP), have enabled the fabrication of variable stiffness (VS) laminates having curvilinear fibers. This concept enhances the load distribution within the structure; however, it also significantly enlarges the design space, necessitating efficient optimization and path-planning approaches [2]. One prevalent method for defining fiber paths involves using predefined equations, which ensure smoothness while restricting design space [3]. Conversely, treating fiber angles as design variables at discrete points enables obtaining more diverse laminate configurations exhibiting greater performance [4]. However, this expansion of design space simultaneously brings significant challenges in terms of optimization complexity and computational cost.

VS laminates can also be designed using a multi-step design strategy based on lamination parameters (LPs) [5,6]. Using LPs as design variables provides a compact representation of the laminate stiffness

and convex responses for most mechanical responses such as the fundamental frequency [7,8]. However, this approach necessitates a post-processing (or an additional optimization) step to determine fiber angles. Furthermore, another process is typically required to obtain manufacturable fiber paths, for which different path-planning methods have been proposed in the literature [9–12].

Finite element analysis (FEA) is commonly used for designing composite structures due to its adaptability and precision [13,14]. However, accurate modeling of VS laminates requires finer meshes, leading to high computational costs. To overcome this problem, we implemented a meshless analysis method based on the Chebyshev polynomials. The LPs at sampling locations or selected master points are set as design variables. We used the design framework to maximize the fundamental frequencies of panels with different aspect ratios and boundary conditions. Discrete fiber angles were retrieved from optimal LPs via trigonometric formulations. Then, continuous fiber paths satisfying the manufacturing constraints were derived using the streamline and equidistant path planning techniques. Finally, symmetric and balanced VS laminates composing 8 and 24 layers were fabricated for modal testing, and the experimental eigenfrequencies were compared with the simulation results to validate the proposed methodology.

2. Model development

The geometry of the studied thin VS laminated composite plates is illustrated in Fig. 1a. The dimensions of the laminate along $\boldsymbol{x}$, $\boldsymbol{y}$, and $\boldsymbol{z}$ directions are $\boldsymbol{L_x}$, $\boldsymbol{L_y}$, and $\boldsymbol{h}$, respectively. Applying Hamilton's principle, the governing equations for free vibration can be obtained as

$$\int_{t_1}^{t_2}\left\{\int_{\mathbb{A}}\int_{-h/2}^{h/2}\left(\rho\,\ddot{\boldsymbol{q}}^{\mathrm{T}}\delta\boldsymbol{q}+\boldsymbol{q}^{\mathrm{T}}\boldsymbol{B}^{\mathrm{T}}\boldsymbol{C}\boldsymbol{B}\delta\boldsymbol{q}\right)\mathrm{d}z\mathrm{d}\mathbb{A}\right\}\mathrm{d}t=0 \tag{1}$$

where ρ is density, and $\boldsymbol{q}=\{u_0;v_0;w_0;\phi_x;\phi_y\}$ is the deflection vector based on the first-order shear deformation theory (FSDT). The variables u_0, v_0, and w_0 correspond to the displacements along x, y, and z axes, while ϕ_x and ϕ_y are the rotations in the xz and yz planes, respectively.

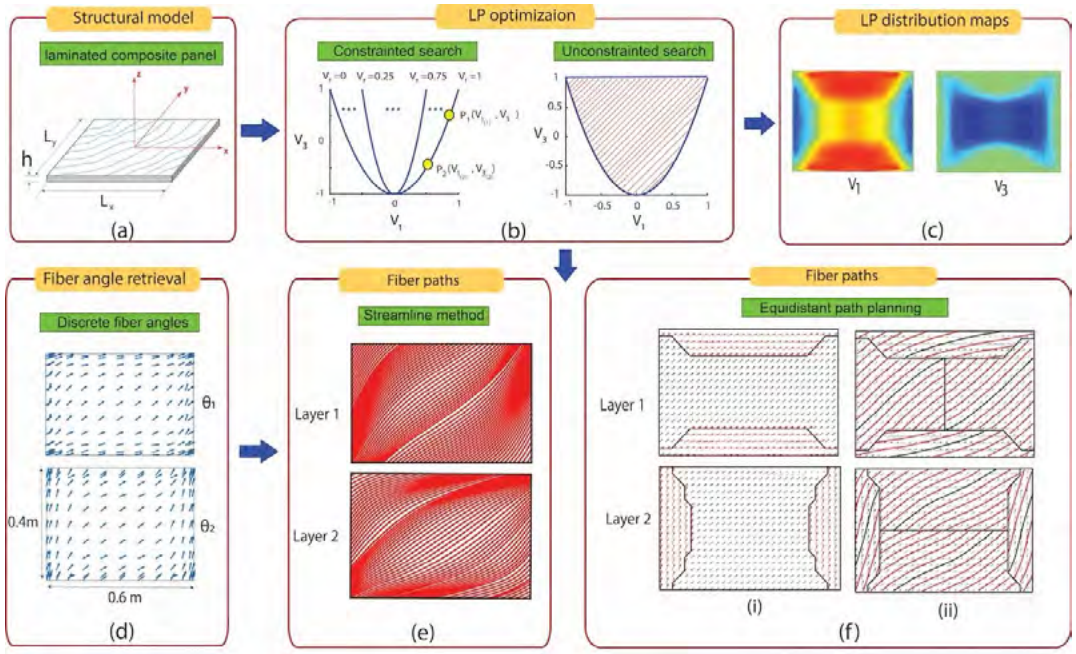

Figure 1. Flowchart of the developed multi-stage design framework for VS laminates.

The $\boldsymbol{B}$ ($\boldsymbol{\epsilon} = \boldsymbol{Bq}$) and $\boldsymbol{C}$ ($\boldsymbol{\sigma} = \boldsymbol{C\epsilon}$) matrices relate strains to the displacements and stresses, respectively. The constitutive matrix ($\boldsymbol{C}$) consists of material invariants and LPs. For symmetric and balanced laminate configurations that are homogeneous through the thickness, the constitutive matrix can be formulated using only two LPs, V_1 and V_3. The design domain is defined by the trigonometric relations between the LPs [15], and it is demonstrated by the Miki's diagram (see Fig. 1b).

2.1. Solution method

A meshless technique based on Chebyshev polynomials is employed to numerically solve Eq. (1). The deflection of the laminate is expressed through a double expansion of Chebyshev polynomials:

$$q(x,y) = \sum_{k=1}^{N_x} \sum_{l=1}^{N_y} a_{kl}\, \mathcal{T}_{k-1}(x)\, \mathcal{T}_{l-1}(y) \tag{2}$$

Here, a_{kl} and $\mathcal{T}$'s denote the expansion coefficients and Chebyshev polynomials, respectively. The variables N_x and N_y are the polynomial numbers used along x and y directions, respectively. The problem domain is discretized using the Gauss-Lobatto sampling points. To perform the derivative and the integral operations, differentiation matrices ($\boldsymbol{Q_x}$ and $\boldsymbol{Q_y}$) and inner product matrix ($\boldsymbol{\mathcal{V}}$) are calculated, respectively [11,15]. The equation of motion for shells with free boundary conditions can be expressed as $\boldsymbol{M\ddot{q} + Kq = 0}$. The $\boldsymbol{M}$ and $\boldsymbol{K}$ are the mass and stiffness matrices of the laminate, respectively:

$$\boldsymbol{M} = \rho \begin{bmatrix} h\boldsymbol{\mathcal{V}} & 0 & 0 & 0 & 0 \\ 0 & h\boldsymbol{\mathcal{V}} & 0 & 0 & 0 \\ 0 & 0 & h\boldsymbol{\mathcal{V}} & 0 & 0 \\ 0 & 0 & 0 & \frac{h^3}{12}\boldsymbol{\mathcal{V}} & 0 \\ 0 & 0 & 0 & 0 & \frac{h^3}{12}\boldsymbol{\mathcal{V}} \end{bmatrix} \quad \boldsymbol{K} = \boldsymbol{B}^T \begin{bmatrix} h\boldsymbol{\mathcal{V}_{11}} & h\boldsymbol{\mathcal{V}_{12}} & h\boldsymbol{\mathcal{V}_{13}} & 0 & 0 \\ h\boldsymbol{\mathcal{V}_{12}} & h\boldsymbol{\mathcal{V}_{22}} & h\boldsymbol{\mathcal{V}_{23}} & 0 & 0 \\ h\boldsymbol{\mathcal{V}_{13}} & h\boldsymbol{\mathcal{V}_{23}} & h\boldsymbol{\mathcal{V}_{33}} & 0 & 0 \\ 0 & 0 & 0 & \frac{h^3}{12}\boldsymbol{\mathcal{V}_{44}} & \frac{h^3}{12}\boldsymbol{\mathcal{V}_{45}} \\ 0 & 0 & 0 & \frac{h^3}{12}\boldsymbol{\mathcal{V}_{45}} & \frac{h^3}{12}\boldsymbol{\mathcal{V}_{55}} \end{bmatrix} \boldsymbol{B} \tag{3}$$

The essential boundary conditions for the clamped (C) and simply supported (S) edges are applied using the projection matrices. The system mass and stiffness matrices after imposing the boundary conditions can be obtained as $\mathbb{M} = \boldsymbol{P}^{\mathrm{T}}\, \boldsymbol{M}\, \boldsymbol{P}$ and $\mathbb{K} = \boldsymbol{P}^{\mathrm{T}}\, \boldsymbol{K}\, \boldsymbol{P}$, respectively. Here, $\boldsymbol{P}$ is the projection matrix. The laminate natural frequencies ω_n and the corresponding mode shapes ($\boldsymbol{u}$) can be calculated by solving the eigenvalue problem $(\mathbb{K} - {\omega_n}^2 \mathbb{M})\boldsymbol{u} = \boldsymbol{0}$.

2.2. Optimization of lamination parameters

We used two different approaches to optimize the laminate stiffness. First, LPs at each sampling point are treated as design variables. This approach, which is here named global lamination parameter optimization method (GLPM), results in a total number of design variables: $2 \times N_x \times N_y$. Second, to decrease the number of design variables, we introduced several master points on the structure to calculate the LP distribution based on the distance between any location and master points. Here, we used three sub-techniques: (i) LP interpolation method (LPIM), (ii) LP extrapolation method (LPEM), and (iii) relaxed LP interpolation method (RLPIM). The GLPM generally provides higher performance since LPs can be changed freely within Miki's diagram; however, it generates sharp LP variations. On the other hand, the distance-based methods achieve smoother LP distributions by constraining the domain by volumetric ratio (V_r) curves defined as follows:

$$V_1 = (2V_r - 1)\sqrt{\left((V_3 + 1)/2\right)} \tag{4}$$

Distance-based techniques involve defining design variables such as the coordinates of master points $(\boldsymbol{x_m}, \boldsymbol{y_m})$, associated LP values $(\boldsymbol{V_{3m}})$, and volumetric ratios $(\boldsymbol{V_r})$. The primary distinction between these methods stems from the constraints imposed on these design variables and the $\boldsymbol{V_r}$ curves [11]. The total number of design variables is $\boldsymbol{3m+1}$ for LPIM/LPEM and $\boldsymbol{4m}$ for RLPIM, where $\boldsymbol{m}$ represents the number of master points that is set to 2 in the present study.

2.3. Fiber path retrieval

Initially, fiber angles are determined at each sampling point using trigonometric relations between LPs. As a result of the Gauss-Lobatto sampling, a nonuniform distribution of fiber angles with a dense concentration at the boundaries is obtained. Thus, the optimal angle distribution is interpolated to create a uniform field over the domain. The angles are then transformed into smooth and manufacturable fiber paths. Two methodologies are employed for this purpose: the streamline and equidistant path planning. In the former approach, a manufacturing constraint (denoted as α) is applied to ensure the continuity and smoothness of the fiber paths [10,15]:

$$\left[\boldsymbol{\mathcal{V}} + \alpha\left(\boldsymbol{Q_x}^T \boldsymbol{\mathcal{V}}\, \boldsymbol{Q_x} + \boldsymbol{Q_x}^T \boldsymbol{\mathcal{V}}\, \boldsymbol{Q_x}\right)\right]\boldsymbol{\theta'} = \boldsymbol{\mathcal{V}\theta} \tag{5}$$

Here, θ and θ' represent the fiber angles obtained after the interpolation and application of the α constraint, respectively. In the latter approach, we use a clustering method to divide the in-plane domain into regions with similar fiber angles, and we subsequently apply a continuous path planning approach to obtain a VS laminate composed of CS or VS [16].

3. Fabrication and experimental setup

Symmetric and balanced VS laminates composed of 8 and 24 layers were fabricated using AFP based on the obtained fiber path distributions. In the AFP, we used OM12LT slit tape, and the fabricated panels were cured around 115-125 ℃ in autoclaving process. To validate the optimized fundamental frequencies, modal tests were performed on fabricated laminates using the experimental setup depicted in Fig. 2. As shown in the figure, the panel was excited using an impact hammer, and the response of the system was measured using an accelerometer. Finally, the identified fundamental frequencies from the measured frequency response functions were compared to the computational results.

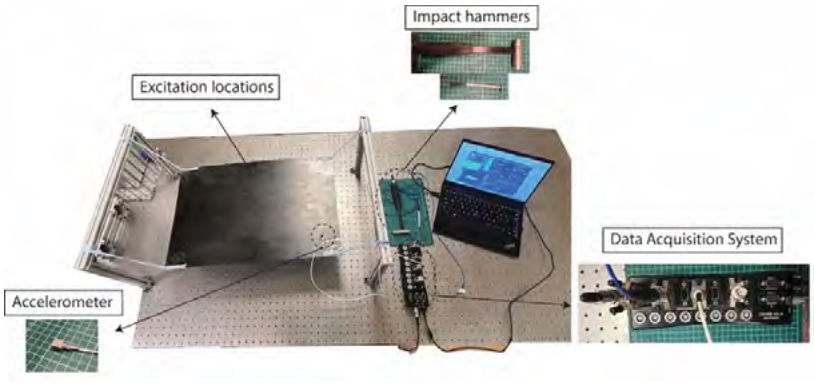

Figure 2. The experimental setup used for modal testing.

4. Results and discussion

We performed several case studies to compare different optimization approaches and validate the accuracy of the modeling technique. Prior to those investigations, a convergence analysis was performed, and the required polynomial numbers $(N_x \times N_y)$ were found as 13×13 and 13×11 for square and rectangular panels, respectively.

4.1. Validation of modeling framework

We investigated square $(L_x/L_y = 1.0)$ and rectangular $(L_x/L_y = 1.5)$ VS flat panels with fully clamped (CCCC) and fully simply supported (SSSS) boundary conditions, respectively. The thickness ratio is set as $h/L_y = 0.01$ for both panels. The material properties used in this section are $E_{11}/E_{22} = 25$, $G_{12}/E_{22} = 0.5$, $G_{23}/E_{22} = 0.2$, and $\nu_{12} = 0.25$ [17]. For each case, the laminates were optimized, and the corresponding first three non-dimensional natural frequencies were compared with the results from the FEA and literature (see Table 1). The optimal LP distributions are depicted in Fig. 3.

Table 1. The first three non-dimensional natural frequencies of fully clamped (CCCC) square $(L_x/L_y = 1.0)$ and simply supported (SSSS) rectangular $(L_x/L_y = 1.5)$ flat VS laminates with the thickness ratio of $h/L_y = 0.01$.

Method	CCCC, $L_x/L_y = 1$			SSSS, $L_x/L_y = 1.5$		
	$\overline{\omega_1}$	$\overline{\omega_2}$	$\overline{\omega_3}$	$\overline{\omega_1}$	$\overline{\omega_2}$	$\overline{\omega_3}$
LPIM	35.25	51.79	78.19	16.04	22.77	33.13
FEA	35.16	51.77	78.33	15.99	22.85	33.27
LPEM	37.13	64.45	74.09	16.46	20.86	30.53
FEA	36.97	64.22	74.55	16.43	21.25	30.94
RLPIM	40.08	74.57	75.73	16.44	21.08	30.78
FEA	39.82	74.65	75.93	16.42	21.46	31.20
GLPM	42.54	70.44	70.45	16.52	21.61	32.20
FEA	41.94	71.26	71.27	16.44	21.97	32.31
Ref. [18]	42.70	73.00	73.00	-	-	-

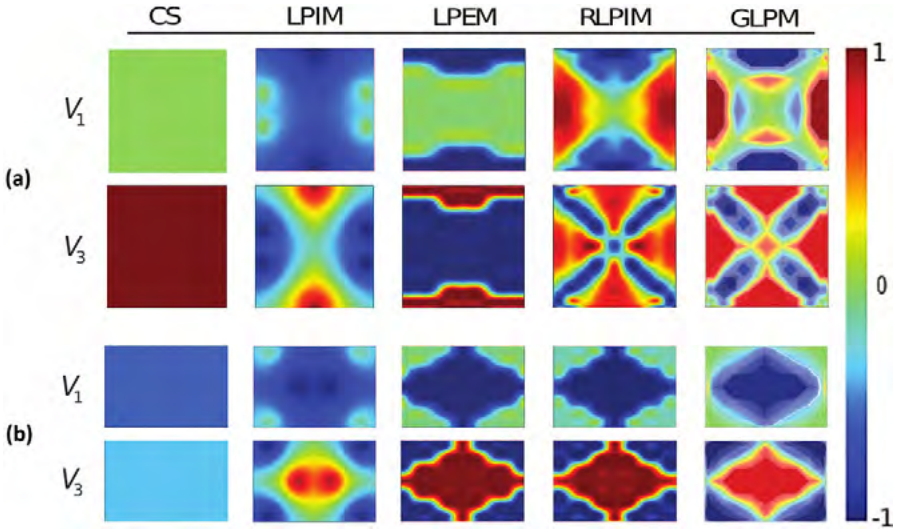

Figure 3. Optimal LP distributions for the (a) fully clamped square $(L_x/L_y = 1.0)$ and (b) simply supported rectangular $(L_x/L_y = 1.5)$ panels.

The analyses revealed a close agreement between the results calculated through the developed framework and FEA as well as those documented in the literature. The GLPM method enabled the highest improvements levels, which are 28.4% and 9.8% for square and rectangular panels, respectively. Although distance-based techniques yielded lower frequency values, the optimal solutions were found much faster due to the reduced design variables. Those methods also provide smoother LP distributions since they impose additional constraints on the design space.

4.2. Fabrication

For the fabrication of CS and VS flat panels, the panel geometry was set to $L_x = 0.6$ m, $L_y = 0.4$ m, and $h = 0.0013$ m (corresponds to 8 layers) or $h = 0.0038$ m (corresponds to 24 layers). Prior to design and experimental studies, material characterization tests on the composite material were conducted, and the material properties were obtained as $E_{11} = 131.34$ GPa, $E_{22} = 8.04$ GPa, $G_{12} = 3.66$ GPa, $G_{23} = 1.46$ GPa, $\nu = 0.265$, and $\rho = 1450$ kg/m^3. Then, optimal designs for the unconstrained panels were determined and compared to optimal CS laminates (see Table 2).

Table 2. Optimal fundamental frequencies (Hz) of unconstrained CS and VS flat laminates with dimensions of $L_x = 0.6$ m and $L_y = 0.4$ m.

Method	$h = 0.0013$ m		$h = 0.0039$ m	
	ω_1	Diff. (%)	ω_1	Diff. (%)
CS	23.10	-	65.35	-
LPIM	23.31	0.91	65.98	0.96
LPEM	23.29	0.82	65.86	0.93
RLPIM	23.56	1.99	67.09	2.66
GLPM	23.80	3.03	68.37	4.62

Although free (unconstrained) laminates lead to lower performance improvements compared to CCCC and SSSS panels, the main motivation behind selecting this boundary condition was its convenience for the modal testing. The computed optimal LP distributions (see Fig. 1c) were transformed into discrete fiber angles (see Fig. 1d). These angles were then converted into curvilinear fiber paths using streamline method and path planning technique based on clustering (see Figs. 1e and f, respectively). Note that the path planning approach involves segmentation of the panel into four clusters comprising either straight fibers (CS clusters) or curvilinear fibers (VS clusters) as depicted in Fig. 1f (i) and (ii), respectively.

Following the design procedure, multiple symmetric and balanced laminates were manufactured. Initially, 24-layered plates featuring two independent layers ($[(\pm\theta_1)_3, (\pm\theta_2)_3]_s$) were fabricated using a streamlined method. Figure 4 shows (a) a CS design together with the (b) first and (c) final layers of an equally thick VS laminate. For the CS case, the fiber angles were determined as $\pm 18^\circ$ and $\pm 48^\circ$. The first VS layer demonstrates gaps, overlaps, and wrinkling occurring due to the fiber curvatures; while the complete VS plate reveals accumulated overlaps that thicken the structure and affect its behavior.

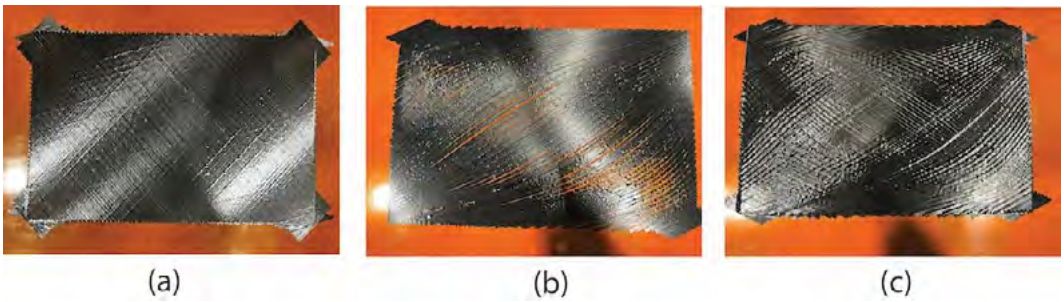

Figure 4. Fabricated 24-layered composite laminates with dimensions $L_x = 0.6$ m, $L_y = 0.4$ m and $h = 0.0039$ m: (a) CS, (b) VS-streamline - First layer, and (c) VS-streamline - Last layer.

To overcome the mentioned fabrication problems, the designs based on the clustering and equidistant path planning approach were used in the second case to manufacture an 8-layered VS laminate with the layup $[\pm\theta_1, \pm\theta_2]_s$ (see Fig. 5). Again, an equally thick CS laminate with the optimal fiber angles of $\pm 18^\circ$ and $\pm 48^\circ$ was also fabricated. As seen in the figure, this method eliminates the gaps and overlaps between fiber paths within the cluster domain and effectively addresses curvature constraints. Yet,

discontinuities at cluster boundaries potentially present other manufacturing challenges that need to be investigated.

Figure 5. Fabricated 8-layered composite laminates with dimensions $L_x = 0.6$ m, $L_y = 0.4$ m and $h = 0.0013$ m: (a) CS, (b) VS-streamline - First layer, and (c) VS-streamline - Last layer.

4.3. Modal tests

From the initial optimization step to experimental analysis, the results obtained throughout the entire process for the 8-layer laminate having two independent fiber angles ($[\pm\theta_1, \pm\theta_2]_s$) are summarized in Table 3. For each design, the fundamental frequency values obtained via five different approaches were calculated and compared with those of the initial design. The first column shows the optimization results obtained by optimizing LPs to maximize the fundamental frequency. In the second column, the values after retrieving fiber angles at sampling points are provided. In the third column, the frequencies obtained considering the full constitutive matrix (i.e., both in-plane ($V^A_{1,2,3,4}$) and bending ($V^D_{1,2,3,4}$) LPs) in stiffness formulation are given. The fourth column contains the FEA results obtained using COMSOL with the full constitutive matrix for validation purposes. The last column shows the fundamental frequencies obtained through modal testing.

Table 3. Comparison of fundamental frequencies (Hz) of simulated and fabricated laminates.

	2 LP		8 LP		
	Opt. ($V_{1,3}$)	Fiber retrieval	($V^A_{1,2,3,4}$, $V^D_{1,2,3,4}$)	FEA	Exp.
CS	23.10	22.78	18.07	18.06	16.00
VS - CS clusters	23.80	22.88	21.46	21.49	17.20
VS - VS clusters	23.80	22.78	21.53	21.51	16.80

The conversion of the obtained LPs into straight and curved fiber distributions evidently leads to a decrease in the maximum fundamental frequency for both CS and VS laminates. However, when 8 LPs are used, the CS plate exhibits a significant decrease in dynamic performance with respect to the VS case (comparing the results for 2 and 8 LPs in Table 3) because of the additional bending stiffness terms. The primary reason behind this drop is expressing the obtained optimum LP distribution with only two independent layers (using three independent layers for that CS case leads to a stacking sequence of $[\pm 41^\circ/\pm 2^\circ/\pm 48^\circ]$ and the fundamental frequency value of 21.73).

5. Conclusions

This study demonstrates a multi-step design framework for optimizing eigenfrequencies of variable stiffness laminates. The composite stiffness properties are expressed in terms of lamination parameters. The governing equations are solved using a meshless modeling approach based on Chebyshev polynomials and FSDT kinematic relations. Different design techniques are investigated to optimize lamination parameter distributions. Actual fiber paths are determined using streamline or continuous equidistant path planning methods.

The presented design approach was used to maximize the fundamental frequency of the variable stiffness laminates. The modeling accuracy was validated by comparing the results to those obtained via FEA and available in the literature. Furthermore, for a selected case, different laminates were fabricated using AFP for modal testing. The 8-layered VS laminates with constant and variable stiffness clusters yielded 7.5% and 5% performance improvements over CS designs, respectively. Experimental investigations also demonstrated that dynamic performance of CS plates is lower than VS plates.

Keywords: 3D woven composite, 3D mechanical properties, finite element method, fiber-based continuum analysis, measurement method

Abstract
3D composites provide superior properties in the thickness direction, expanding their application potential across various industries. However, accurately characterizing their full 3D behavior presents several challenges. First, the absence of standardized testing methods for through-thickness properties complicates comprehensive evaluation. Additionally, complex weaving patterns, such as fixed and wrapping warp bundles, require tailored assessment approaches. These bundles enhance the composite along the x axis and z axis during weaving, forming proper layer boundaries and structure. Furthermore, producing test specimens to standard specifications and securing a sufficient number of samples for analysis are also challenging. To address these issues, we developed a detailed mechanical model using fiber based continuum analysis. This model defines the 3D woven structure at each material point within the composite and assigns material properties via a constitutive law. It successfully calculates key properties such as tensile modulus, shear, and delamination strength, and developed a new measurement method for accurately determining the tensile strength in the thickness direction.

1. Introduction

Composite materials have played a pivotal role in advancing material engineering, evolving from 2D laminates to sophisticated 3D composites. These advanced materials are known for their enhanced properties in the thickness direction, offering significant improvements over their 2D counterparts. The unique characteristics of 3D composites make them particularly suited for high-performance applications across a range of industries including aerospace, automotive, and construction.

One of the primary challenges in the deployment of 3D composites lies in the absence of standardized testing methods for accurately assessing through-thickness properties. Traditional testing methods are often inadequate, as they predominantly focus on 2D material characteristics and fail to address the complexities introduced by the third dimension. Additionally, the intricate 3D weaving patterns, exemplified by fixed and wrapping warp bundles, introduce an added layer of complexity. These patterns influence the mechanical behavior of the composite in ways that are not yet fully understood, thus complicating the prediction and analysis of their performance under real-world conditions.

Given these challenges, there is a critical need for tailored testing methodologies that can accurately measure important properties such as tensile modulus and strength in the thickness direction. This need is amplified by the growing demand for composites that can reliably perform under the rigorous conditions faced by the aerospace, automotive, and construction industries. Addressing this gap requires a fresh approach to both testing and modeling of 3D composites.

In recent years, various numerical analysis of 3D woven were performed. Because of their complex structures, research has progressed in various directions. Among these, computational analysis using homogenization methods have been extensively studied. Homogenization techniques have been successful for out-of-plane failure and damage[1]. Various studies have been conducted depending on which parts are homogenized and which are modeled. For modeling, the first part of 3D woven

composite modeling was their geometric modeling[2]. 3D modeling for 3D woven composites was examined[3]. The structure of 3D woven composites significantly influences their properties, and the closer the modeling is to reality, the more accurate the calculations can be. However, there is a need for research which focuses on less modeling when considering the simplicity of computation and cost reduction. so the mechanical properties of 3D composites were predicted with 3D unit cell approach[4]. And also failure analysis has been investigated with unit cell approach[5].

The objective of this research is to develop a detailed mechanical model using fiber-based continuum analysis. Ahn. [6] developed a new numerical model to analyze the mechanical properties of 3D textile composites based on continuum mechanics framework. He assumed that fiber structure can be defined at every point and its properties were evaluated using a layer method, Puck's criterion, and modified ply discount method. Our laboratory can manufacture 3D woven composites with various structures and we have adopted continuum analysis method to predict the elastic property and failure. The goal of our research is to establish measurement method for 3D woven composites through thickness direction and predict the mechanical behavior. User subroutine material code was implemented into ABAQUS software and used in this study.

2. Experimental and results

Carbon fiber yarns (A-38, A-42, DOWAKSA, Turkey) were used, and the tensile strength of each carbon fiber yarn was 3800 MPa and 4200 MPa. 3D woven structures were fabricated using warp, weft, and z-binder yarns of 6K (A-38), 12K (A-42), and 3K (A-38) carbon fibers, respectively.

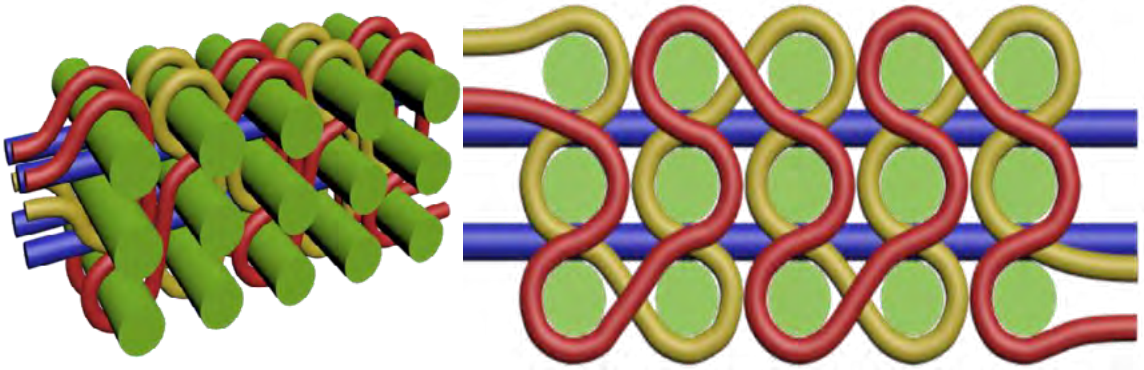

Figure 1. The image of 3D woven fibers and their structures

Figure 1 shows the weaving pattern of 3D woven structure. 2 different warps are weaved wrapping the weft yarns. 3D woven composites were manufactured with this structure using vacuum-assisted resin transfer molding. And the specimens were prepared according to the ASTM D3039 standard for tensile test. Specimen size was 100 X 15 X 2mm^3 and gauge length was 600mm. tensile test was performed at a loading speed of 2mm/min with a 100kN load cell.

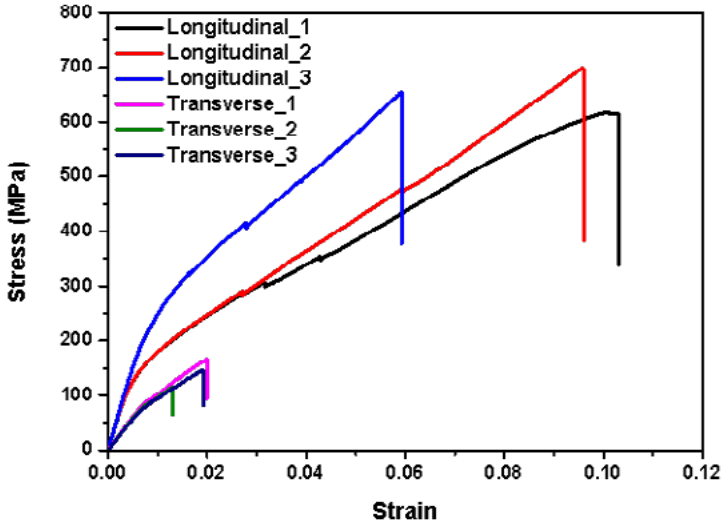

Figure 2. S-S curve of tensile test of 3D woven composite

Figure 2 shows the Stress-Strain curve of 3D woven composite tensile test through longitudinal and transverse directions. Longitudinal tensile strength is 650MPa and transverse tensile strength is 140MPa. Both tensile strength is lower than conventional 2D composites because the volume fraction for each direction is much lower than 2D laminate composites.

To simulate the S-S curve of transverse direction tensile test, UMAT code was implemented to ABAQUS program. In UMAT code, the combination of warp yarns, z-binder yarns, and weft yarns were expressed by the transformation of braiding angle and crimp. The periodic boundary condition was used for the simulation. Eight-node brick elements (C3D8) were used to model the composites. And the implicit solver was used for simulations. The result of simulation was showed in figure 3.

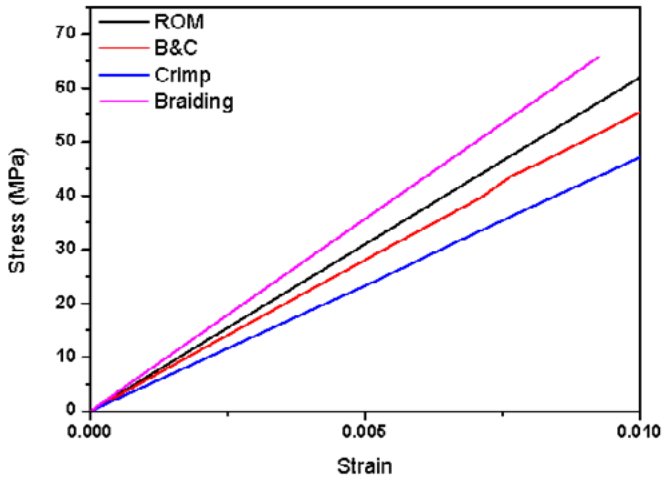

Figure 3. The simulation result of braiding and crimp transformation

The result compares the stress na dstrain curves of rule of mixture, braiding angle transformation, crimp transformation and both transformation. Both transformation works well and total transformation stiffness is lower than the stiffness of rule of mixture. Slight discrepancy between simulation and

experiments is observed. The reason is that model expressed z-binder yarns angle into simple wavelength function. We created a minimal model that contains information on one braiding angle and one crimp angle within a single unit cell. However, increasing the amount of information could lead to more accurate results.

3. Conclusion

A numerical analysis using fiber-based continuum model was developed to predict 3D woven composites mechanical properties. It is useful when the model is considered in macroscale level. The analysis and experiments were compared to achieve validity of developed method. As a result, the simulation and experimental values showed similar results. And through this, the properties in the thickness direction were studied.

Keywords: syntactic foam, sandwich composites, state-vector formulation, differential quadrature method

Abstract
Syntactic foams are particulate composites that have hollow glass or ceramic microspheres embedded in a matrix usually thermoset polymers. These closed cell structural foams possess significantly higher specific mechanical properties than traditional foams used in sandwich structures. Sandwich structures with syntactic foam core demonstrate excellent damage tolerance, residual strength and dynamic performance. In this paper, an exact state vector based elasticity formulation is developed for the free vibration response of sandwich panels with syntactic foam core. In this formulation, a state vector is defined to include both displacements and transverse stresses. The state vector can be augmented with other field variables such as temperature and heat flux for modelling multiphysics response. A parametric study of the free vibration response of these panels is presented for two different boundary conditions. The solutions are obtained using a combination of closed-form analytical solutions (SSM) and meshless differential quadrature method (SSDQM). The effect of volume fraction and geometry of the microspheres on the natural frequencies is examined. The combined approach provides exact or highly accurate results for the natural frequencies.

1. Introduction

Sandwich composite plates and shells are extensively used to meet the high performance demands in aerospace, marine and general transport vehicle structures due to their high specific stiffness and strength ratios, ease of manufacturing, and flexibility in design [1]. In recent years, syntactic foams have gained considerable attention as core materials in sandwich structures. Syntactic foams are essentially closed-cell foams and particulate composites obtained by filling a matrix (commonly polymers) with hollow spherical inclusions [2]. These closed-cell structured foams have an excellent combination of mechanical and non-mechanical properties that make them very attractive as core materials for both structural [3, 4]and multifunctional sandwich structures [5]. On a macro scale, syntactic foams behave nearly like isotropic material. Graded foam cores can be also be fabricated by varying the diameter or wall thickness of the dispersed inclusions.

The static and dynamic response of sandwich composites are commonly modelled using equivalent single layer (ESL) plate and shell models that assume apriori displacement field and aim to include the transverse shear effects in different ways. These theories usually underestimate transverse deflections while overestimating the critical buckling loads and natural frequencies, particularly for thick laminates. There are also layer-wise (LW) theories in which the laminate is treated as an assembly of individual layers with an assumed displacement field, and these individual layers are combined by the interlaminar relationships to keep the displacement continuity and stress equilibrium. Special sandwich panel theories (HSAPT, EHSAPT) have also been developed [6, 7] to improve upon the inaccuracies of the conventional ESL theories and capture the localized effects particularly in a flexible core. However,

these theories usually demand a large number of variables in direct proportion to the number of plies, and increase the computing cost [8].

In such a scenario, the three-dimensional elasticity formulation, which doesn't include any apriori assumption on the field variables, plays a crucial role in the accurate modelling and analysis of these structures. They not only serve as benchmark solutions but become necessary in the case of sandwich panels with considerable variation in elastic modulus among the layers, high thickness-to-span ratio, functional gradation in material properties, presence of localized loads, etc.

The state space method (SSM) involves grouping displacements and out-of-plane stresses to create a state vector [9]. In-plane stresses become derived variables that are dependent on the state vector. The key idea is to transform the boundary value problem into an analogous initial value problem in thickness coordinates by using the initial and final values of the state vector obtained from the lateral boundary conditions. While analytical solutions of this exact formulation are restricted to simple boundary conditions, SSM can be easily combined with finite element method (FEM) or differential quadrature method (DQM), etc. to provide highly accurate numerical solutions to various edge boundary conditions.

This paper presents an exact state-space formulation (SSM) for the dynamics of rectangular sandwich composites plates with syntactic foam core and a study of the free vibration for different edge boundary conditions using the hybrid state space differential quadrature method (SSDQM).

2. Exact state space formulation and solution methodology

2.1. State space approach (SSA)

For an orthotropic material, the three-dimensional linear elastic stress-strain relations, in matrix-vector form in the principal cartesian axes is given by the generalized Hooke's law below.

$$\begin{aligned}
&\sigma_i = C_{ij}\varepsilon_j \quad i,j = 1,6 \\
&\sigma_1 = \sigma_{11}, \sigma_2 = \sigma_{22}, \sigma_3 = \sigma_{33}, \sigma_4 = \tau_{23}, \sigma_5 = \tau_{31}, \sigma_6 = \tau_{12} \\
&\varepsilon_1 = \varepsilon_{11}, \varepsilon_2 = \varepsilon_{22}, \varepsilon_3 = \varepsilon_{33}, \varepsilon_4 = \gamma_{23}, \varepsilon_5 = \gamma_{31}, \varepsilon_6 = \gamma_{12}
\end{aligned} \tag{1}$$

The elastic stiffness matrix and the linear strain-displacement relations are given by

$$[C] = \begin{bmatrix} C_{11} & C_{12} & C_{13} & 0 & 0 & 0 \\ C_{12} & C_{22} & C_{23} & 0 & 0 & 0 \\ C_{13} & C_{23} & C_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & C_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & C_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & C_{66} \end{bmatrix} \text{ and } \begin{Bmatrix} \varepsilon_1 = \varepsilon_{11} \\ \varepsilon_2 = \varepsilon_{22} \\ \varepsilon_3 = \varepsilon_{33} \\ \varepsilon_4 = \gamma_{23} \\ \varepsilon_5 = \gamma_{13} \\ \varepsilon_6 = \gamma_{12} \end{Bmatrix} = \begin{Bmatrix} u_{1,1} \\ u_{2,2} \\ u_{3,3} \\ u_{3,2} + u_{2,3} \\ u_{1,3} + u_{3,1} \\ u_{1,2} + u_{2,1} \end{Bmatrix} \tag{2}$$

$$\frac{\partial \sigma_{ji}}{\partial x_j} = \rho \frac{\partial^2 u_i}{\partial t^2} \quad i,j = 1,3. \tag{3}$$

The displacements (u_1, u_2, u_3) and transverse stresses $(\sigma_{33}, \sigma_{13}, \sigma_{23})$ are combined to form a state vector $\boldsymbol{\delta}$. Combining and rearranging the set of Eq. (1) – (3), the state equations are derived in the matrix form as given below.

$$\frac{\partial}{\partial x_3}\{\delta\} = [G]\{\delta\}$$

where the state vector δ and the coefficient matrix G are defined as (4)

$$\delta = \{\sigma_{33} \quad u_1 \quad u_2 \quad u_3 \quad \sigma_{13} \quad \sigma_{23}\}^T \text{ coefficient matrix } [G] = \begin{bmatrix} 0 & A \\ B & 0 \end{bmatrix}$$

$$[A] = \begin{bmatrix} \rho\partial_t^2 & -\partial_{x_1} & -\partial_{x_2} \\ -\partial_{x_1} & \frac{1}{C_{55}} & 0 \\ -\partial_{x_2} & 0 & \frac{1}{C_{44}} \end{bmatrix}, \quad [B] = \begin{bmatrix} \frac{1}{C_{33}} & -\frac{C_{13}}{C_{33}}\partial_{x_1} & -\frac{C_{23}}{C_{33}}\partial_{x_2} \\ -\frac{C_{13}}{C_{33}}\partial_{x_1} & B_{22} & B_{23} \\ -\frac{C_{23}}{C_{33}}\partial_{x_2} & B_{23} & B_{33} \end{bmatrix} \tag{5}$$

where

$$B_{22} = \rho\partial_t^2 - \left(C_{11} - \frac{C_{13}^2}{C_{33}}\right)\partial_{x_1}^2 - C_{66}\partial_{x_2}^2 \quad B_{23} = \left(-C_{66} - C_{12} + \frac{C_{13}C_{23}}{C_{23}}\right)\partial_{x_1 x_2}^2$$
$$B_{33} = \rho\partial_t^2 - C_{66}\partial_{x_1}^2 - \left(C_{22} - \frac{C_{23}^2}{C_{33}}\right)\partial_{x_2}^2 \tag{6}$$

2.2. Analytical solutions for SSM

The above formulation is a system of first order differential equation in the state vector with constant variables. The solution can be written for the state vector as a function of the 'z' coordinate as in Eq. (7)

$$\{\delta(z)\} = e^{[G]z}\{\delta(0)\} = \mathbf{T}(z)\{\delta(0)\}$$
$$\{\delta(0)\} \text{ is initial value of state vector at } z = 0. \tag{7}$$
$$\mathbf{T}(z) \text{ is called the transfer matrix.}$$

For given boundary conditions on the lateral surfaces of a plate [0, h] , state vector can be solved for any location z through the thickness. The in-plane field variables can be computed from the other relations. The formulation can be applied for any type of plate construction, including homogeneous single layer or multilayered and sandwich plates, isotropic, anisotropic and heterogeneous plates. For multilauyered plates, a local transfer matrix is obtained for each layer and need to combined to apply the global surface boundary conditions on the plate. But, analytical solutions of the formulation are limited to few boundary conditions such as simply supported edges.

Consider the free vibrations response of a rectangular plate with in-plane dimensions a, b and thickness h, in the reference coordinate system (x,y,z) simply supported on all four edges. A double series expansion of the state variables can be assumed for the state vector as given below with the coefficients being unknown functions of the thickness coordinate.

$$\begin{Bmatrix} \sigma_z \\ u \\ v \\ w \\ \tau_{xz} \\ \tau_{yz} \end{Bmatrix} = \sum_{m=0}^{\infty}\sum_{n=0}^{\infty} \begin{Bmatrix} Z_{mn}(z)\sin\left(\frac{m\pi x}{a}\right)\sin\left(\frac{n\pi y}{b}\right) \\ U_{mn}(z)\cos\left(\frac{m\pi x}{a}\right)\sin\left(\frac{n\pi y}{b}\right) \\ V_{mn}(z)\sin\left(\frac{m\pi x}{a}\right)\cos\left(\frac{n\pi y}{b}\right) \\ W_{mn}(z)\sin\left(\frac{m\pi x}{a}\right)\sin\left(\frac{n\pi y}{b}\right) \\ X_{mn}(z)\cos\left(\frac{m\pi x}{a}\right)\sin\left(\frac{n\pi y}{b}\right) \\ Y_{mn}(z)\sin\left(\frac{m\pi x}{a}\right)\cos\left(\frac{n\pi y}{b}\right) \end{Bmatrix} e^{i\omega_{mn}t} \tag{8}$$

The above expansion can be substituted in Eq. 4 to get the matrix equation

$$\frac{\partial}{\partial z}M = \bar{\mathbf{T}}(z)M,\ \bar{\mathbf{T}}(z) = \begin{bmatrix} 0 & \bar{A} \\ \bar{B} & 0 \end{bmatrix}$$
$$M(z) = \{Z_{mn} \quad U_{mn} \quad V_{mn} \quad W_{mn} \quad X_{mn} \quad Y_{mn}\}^T \tag{9}$$

$$\left[\bar{A}\right] = \begin{bmatrix} -\rho\omega_{mn}^2 & \left(\frac{m\pi}{a}\right) & \left(\frac{n\pi}{b}\right) \\ -\left(\frac{m\pi}{a}\right) & \frac{1}{C_{55}} & 0 \\ -\left(\frac{n\pi}{b}\right) & 0 & \frac{1}{C_{44}} \end{bmatrix}, \left[\bar{B}\right] = \begin{bmatrix} \frac{1}{C_{33}} & \frac{C_{13}}{C_{33}}\left(\frac{m\pi}{a}\right) & \frac{C_{23}}{C_{33}}\left(\frac{n\pi}{b}\right) \\ \frac{C_{13}}{C_{33}}\left(\frac{m\pi}{a}\right) & \bar{B}_{22} & \bar{B}_{23} \\ \frac{C_{23}}{C_{33}}\left(\frac{n\pi}{b}\right) & \bar{B}_{23} & \bar{B}_{33} \end{bmatrix} \tag{10}$$

$$\bar{B}_{22} = \rho\omega_{mn}^2 + \left(C_{11} - \frac{C_{13}^2}{C_{33}}\right)\left(\frac{m\pi}{a}\right)^2 + C_{66}\left(\frac{n\pi}{b}\right)^2$$
$$\bar{B}_{23} = -\left(-C_{66} - C_{12} + \frac{C_{13}C_{23}}{C_{23}}\right)\left(\frac{m\pi}{a}\right)\left(\frac{n\pi}{b}\right) \tag{11}$$
$$\bar{B}_{33} = \rho\omega_{mn}^2 + C_{66}\left(\frac{m\pi}{a}\right)^2 + \left(C_{22} - \frac{C_{23}^2}{C_{33}}\right)\left(\frac{n\pi}{b}\right)^2$$

The above equation can be used to get the global equation relating the top and bottom surfaces of a single layer plate. For multilayered plates, the conventional transfer matrix method, (CTMM) [10] uses the interlayer continuity and equilibrium conditions on the state vector elements to obtain the global transfer matrix relating the state vector at the top and bottom faces through multiplication of the transfer matrices for the individual layers. Enforcing the traction free load conditions on the plate lateral faces gives the non-trivial solution for the free vibration problem. For a plate comprised of p layers, through matrix multiplication of local transfer matrices, we get as in Eq. 12

$$\delta_1^{(p)} = \mathbf{T}\delta_0^{(1)}, \quad \mathbf{T} = \mathbf{T}_p \mathbf{T}_{p-1} \ldots \mathbf{T}_2 \mathbf{T}_1$$
$$\det \mathbf{T} = 0 \tag{12}$$

An alternative has been used in this work to overcome the numerical instabilities that may be encountered with CTTM for certain configurations and also in SSDQM. In this approach, all transfer relations between the state vectors at the upper and lower surfaces of the individual layers are assembled rather than translated into a global relation in equation through matrix multiplications.

2. 3 Semi-analytical solutions using SSDQM

The DQM transforms a differential equation defined at all points in a domain into an analogous set of algebraic equation by expressing at each grid point the operator value of a function with respect to a coordinate direction at any discrete point as the weighted linear sum of the function's values at all discrete points chosen in that direction.

Consider a two-dimensional rectangular domain, where a solution to a differential equation is needed in terms of the function $f(x,y)$. Any arbitrary order partial derivative of $f(x,y)$ with respect to coordinates x and y at any grid point (x_i, y_i) is given as:

$$\frac{\partial^p}{\partial x^p} f(x_i, y_j) = \sum_{k=1}^{N_x} X_{ik}^{(p)} f(x_k, y_j), \quad \frac{\partial^q}{\partial y^q} f(x_i, y_j) = \sum_{k=1}^{N_y} Y_{jk}^{(q)} f(x_i, y_k)$$
$$\frac{\partial^{p+q}}{\partial x^p \partial y^q} f(x_i, y_j) = \sum_{k=1}^{N_x} X_{ik}^{(p)} \sum_{r=1}^{N_y} Y_{jr}^{(q)} f(x_k, y_r) \tag{13}$$

N_x and N_y are the total number of sampling points in the grid along the x- and y- directions respectively.

The accuracy of the DQM is sensitive to the distribution of the grid points amd the weighting coefficients. A non-uniform grid distribution is found to give more accurate results when compared to uniform grids with the same number of grid points The most commonly used are the Chebyshev–Gauss–Lobatto grid points. The procedure to obtain the weight coefficients for first-order derivatives and the recurrence relations for higher order derivatives are outlined in Shu [10]. The use of DQM in the original state space equations yields different state equations for each type of edge boundary conditions [11].

To apply the SSDQM for the sandwich plates, while the SSM is applied in the thickness direction, at each thickness location the DQM is applied in the corresponding lateral surface. Depending on specific plate edge boundary conditions a complete 2D dimensional (x,y) grid or only a 1-D grid along the x- or y- directions may be required for the DQM with a series solution assumed in the other direction. Hence each comnbination of plate boundary conditions yields a different form of the state equation and corresponding transfer matrix.

3. Results and discussion

The formulation was applied for the analysis of the dynamic behaviour of a [0°/90°/core/90°/0°] sandwich plate with syntactic foam core [12]. The face sheets are woven glass-epoxy laminates with elastic properties: $E_1 = E_2 = 21.7$ GPa, $E_3 = 8.5$ GPa, $G_{12} = 3.91$ GPa, $G_{13} = G_{23} = 4.1$ GPa, $\nu_{12} = 0.169$, $\nu_{13} = \nu_{23} = 0.28$, $\boldsymbol{\rho_f} = 1720$ kg/m^3. The syntactic foam core is made of hollow glass inclusions and epoxy resin with $E_m = 2.8$ GPa, $\nu_m = 0.41$, $\rho_m = 1180$ kg/m^3, $E_g = 70.11$ GPa, $\nu_g = 0.23$, $\rho_g = 2600$ kg/m^3. The inclusion radius $R_p = 25$ µm, inclusion wall thickness $t_p = 1$µm, and filler volume percentage $V_f = 60\%$. All the inclusions are of the same size and shape, randomly distributed in the matrix and free of voids. The effective properties of the syntactic foam core were obtained using a homogenization method [2].

3.1 Validation Study

The formulation was implemented in MATLAB™ and validated initially on a syntactic foam core sandwich plate with cross-ply graphite/epoxy laminate facesheet simply supported on all its four edges [12]. The results were compared with those obtained from FEA and the analytical multiple-scale asymptotic expansion method. The fundamental frequency parameter is non-dimensionalized as

$$\bar{\omega} = \omega \frac{a^2}{h} \sqrt{\frac{\rho_f}{E_f}} \tag{14}$$

Table 1. Non-dimensional fundamental frequency with varying (a/h) for $t_c/t_f = 10$

a/h	Present (SSM)	Asym. Method [12]	FEM
10	8.779	8.841	8.780
5	6.780	7.914	6.780

Table 2. Non-dimensional fundamental frequency with varying (t_c/t_f) for $a/h = 10$

t_c/t_f	Present (SSM)	Asym. Method [12]	FEM
5	9.340	10.051	9.341
2	9.397	10.941	9.397

3.2 Effect of volume fraction and wall thickness of microspheres on the natural frequency

The free vibration response of the symmetric square syntactic foam sandwich plate with glass/epoxy cross-ply laminate subjected to two different edge boundary conditions is investigated for $a/h = 20,\ t_c/t_f = 20,\ a = 1.0\ m$. The effect of volume fraction and wall thickness of the microspheres on the fundamental natural frequency of the sandwich plate was obtained for different plate boundary conditions. The SSDQM results obtained with 15 grid points are presented alongside the exact SSM result for the SSSS condition and shown in Tables 3 and 4 respectively.

Table 3. Variation of fundamental frequency (Hz) with V_f

Boundary conditon	Volume fraction of the microspheres (V_f)						
	0.1	0.2	0.3	0.4	0.5	0.6	0.7
SSSS (exact)	122.473	126.473	130.879	135.768	141.242	147.432	154.518
SSSS	122.473	126.473	130.879	135.768	141.242	147.432	154.518
SCSC	182.122	188.160	194.808	202.184	210.440	219.778	230.469

Table 4. Variation of fundamental frequency (Hz) for different values of t_p

Boundary conditon	Wall thickness of the microsphere (V_f)					
	0.5	1	1.5	2	2.5	3
SSSS (Exact)	147.983	147.432	145.979	144.354	142.765	141.280
SSSS	147.983	147.432	145.979	144.354	142.765	141.280
SCSC	218.944	219.778	218.164	215.970	213.697	211.518

It is observed from Table 3 that the natural frequency of the panel increases with the increase in the volume fraction of the inclusions of the syntactic foam as expected. Also, the SCSC panel is the most stiff, while the SSSS panel is the least stiff.

From Table 4, it can be inferred that the natural frequency decreases as the inclusion wall thickness increases. Both the effective stiffness and density of the syntactic foam increase with the wall thickness of the microsphere. However, the density increment dominates the stiffness increment resulting in a drop of fundamental natural frequencies.

3.3 Effect of plate aspect ratio and ratio of core to facesheet thickness on the natural frequency

The effect of varying the aspect ratio of the plate aspect for a given core-to-facesheet thickness ratio on the natural frequency is given in Table 5 below.

Table 5. Variation of fundamental frequency (Hz) with aspect ratio *a*/*h*

Boundary conditon	Thickness ratio (a/h)				
	100	50	25	20	10
SSSS (Exact)	30.046	59.948	74.801	147.432	279.447
SSSS	30.046	59.948	74.801	147.432	279.447
SCSC	46.334	92.019	114.433	219.778	385.770

For a fixed core-facesheet thickness ratio, the fundamental frequency decreases with increasing aspect ratio. The effective stiffness and mass of the panel decrease as the thickness ratio increases. However, the drop in the effective stiffness of the panel outweighs the mass decrement, resulting in a lower fundamental frequency. The SSSS panel has a lower stiffness and thus lower fundamental frequency. On the contrary, the stiffer SCSC panel has a fundamental frequency of almost 1.5 times that of the SSSS panel for a thickness ratio of 100. The same factor is observed even for the thickness ratio of 10.

Table 6. Variation of fundamental frequency (Hz) with h_c/h_h

Boundary conditon	Ratio of the thickness of core and facesheet (h_c/h_f)					
	50	25	20	10	5	2
SSSS (Exact)	119.091	130.118	134.286	147.432	156.913	158.321
SSSS	119.091	130.118	134.286	147.432	156.913	158.321
SCSC	176.163	193.633	200.081	219.778	233.110	234.768

The variation of the natural frequency with $\frac{h_c}{h_f}$ is given in Table 6. The natural frequency decreases with the increase of $\boldsymbol{h_c/h_f}$. As the $\boldsymbol{h_c/h_f}$ ratio increases for a certain plate thickness, the effective stiffness and density of the panel decrease due to the softer material used for the core. A reduction in effective stiffness prevails over the reduction in density, leading to lower frequency. For larger $\boldsymbol{h_c/h_f}$, the facesheets are too thin relative to the core to contribute to the plate's stiffness. Furthermore, the SSSS plate has the lower stiffness when compared to SCSC conditions. The SCSC panel's fundamental frequency is nearly 1.5 times that of the SSSS panel for all $\boldsymbol{h_c/h_f}$ ratios.

4. Conclusions

In the present study, the state space differential quadrature technique formulated from the exact theory of 3D elasticity was successfully applied to model the free vibration analysis of a syntactic foam core sandwich plate with arbitrary edge boundary conditions. The accuracy of the model was demonstrated

by comparing the results of the present method with those obtained with the finite element method and multiple-scale asymptotic method. The method demonstrated a fast convergence using only a few grid points. The influence of varying plate aspect ratio and core-facesheet thickness on the natural frequency is evaluated. More significantly, the effects of the volume fractions and geometry of the microspheres on free vibration analysis were investigated.

Abstract
In this study, recycled non-woven carbon fibers were successfully implemented as reinforcing filler material for reinforced material for functional parts in pressure vessels. Using recycled carbon fiber nonwoven efficiently and sustainably allows the reduction of the amount of new fibers used to the necessary minimum per component. Despite the high requirements on the material in carbon fiber reinforced pressure vessels, the fittings (endcaps/bosses) enable possibilities to integrate a significant amount of recycled material without reducing the design or performance capability. The integration of both, recycled and UD materials will be realized through a sandwich-like structure, wherein the recycled material fills the core while the load-bearing fabric layer serves as the outer shell. For this study, a tensile strength of 12.8 MPa in the machine direction and 17.4 MPa in the transverse direction was achieved using the resin transfer moulding (RTM) process for the finite element modelling and compared with the material properties from the vacuum assisted resin infusion (VARI) process.

Keywords: Pressure vessel, CFRP boss, recycling, nonwoven

1. Introduction

Due to the growing use for carbon fibers, the need for possibilities for recycling carbon fibers is increasing [1]. There are various ways of processing recycled carbon fibers into semi-finished products, including the production of nonwovens from carbon fibers using the carding process [2] [3]. In this process, dry offcuts and pyrolyzed carbon fibres are chopped up, combed and laid down to form a thin fibre pile. Afterwards, the pile is duplicated and needled to increase compatibility and stability. One of the challenges associated with recycled carbon fibres is the anisotropic and fluctuating mechanical properties of nonwoven composites [4]. In addition to technical feasibility, finding areas of application for recyclates is also a major challenge for carbon fiber recycling. Because of the rising influence of hydrogen for energy storage, pressure vessels made of CFRP for lightweight transport are becoming more widespread and the demand is increasing.
In the production of CFRP tanks via filament winding [5], bosses made of aluminum are used in state of the art [6]. Considering the lower density of CFRP compared to aluminum [7], transitioning the boss material to CFRP is generally preferred. Moreover it has to be stated that another huge benefit comes from the lower CTE mismatch between CFRP-CFRP over CFRP-aluminum [8].

The tank wall consists mainly of highly stressed CFRP rovings [9], the layer structure of which is adapted to the load for the design.
Due to the fluctuations in the material properties and missing unidirectional alignment of the fibers [10], recycled nonwoven is not usable in the highly stressed tank wall. However, since bosses made of CFRP are feasible [11] and there is the possibility of using recycled fibers in the bosses, as there are areas in the center of the boss with a high volume but decreased load conditions. This paper presents a possible method for integrating recycled carbon fiber nonwoven into pressure vessels, which replaces a portion of the carbon fiber material with nonwoven and allows adjustment of the mechanical properties of the component via wrapped fabric layers.

2. Material and Method

2.1 Material Characterization

For the integration of carbon fiber nonwoven into CFRP boss structure, it is crucial to determine the mechanical properties of the recycled nonwoven material. It must also be determined whether the material properties differ in the machine direction (MD), the production direction during nonwoven production, compared to the cross direction (CD), 90° to the production direction. Therefore, sample plates were produced in vacuum assisted resin transfer molding (RTM) process. After stacking six layers of nonwoven with 100 gsm and similar production direction, the textile preform is infused with resin in in a mould with a pressure of 6 bar.
Then samples are produced according to DIN EN 2561 standard and the sample geometry A, which has a width of 10 ± 0,5 mm and a height of 2 ± 0,2 mm. The GFRP end tabs have a length of 60 mm each.
To also evaluate the potential of non-pressure assisted manufacturing, VARI was used to prepare alternative samples. A comparison of the RTM plate with the sample plate from the VARI process shows a significantly more uneven surface. In addition, vacuum infusion results in an irregular increase in sample thickness, which can be attributed to the expansion of the nonwoven due to internal stresses caused by the production process. This results in the need for external space limitation, particularly regarding the shape quality. These results are also reflected in the fiber volume contents (FVC), which are determined using loss on ignition method. The results of the mechanical tests and the determination of the FVC are shown in Table 1. Due to the thickness ondulations of the infused sample plate, the minimum thickness is used for the calculation of the Young's modulus (E) and the tensile strength (σ), since the samples fail at these points.

Table 1. Results of the tensile and loss ignition tests of CFRP-nonwoven

Specimen Type		E_1 (GPa)	σ_1 (MPa)	FVC (%)
RTM	Machine Direction (MD)	12.8	183	42
	Cross Direction (CD)	17.4	239	
VARI	Machine Direction (MD)	7.6	98	22
	Cross Direction (CD)	13.2	163	

2.2 Boss Concept

In order to integrate recycled carbon fiber nonwoven into CFRP bosses, the boss is divided into two different material areas. on the inside of the boss, carbon fiber nonwoven is placed as the core material (Figure 2). The nonwoven provides a volume filling function, compared to a sandwich structure. Fabric layers are placed around the nonwoven core, which define the desired mechanical properties of the boss by changing the number of layers. The sandwich structure of high-performance continuous fiber-reinforced layers and the recycled, lower-performance layers in between means that fabric layers can be saved and loaded more efficiently compared to a CFRP boss made exclusively from fabric layers.

To validate the concept, a finite element method (FEM) model of the component cross-section is created based on these requirements. Regarding a production in an RTM mold, the fabric layers are placed horizontally to the component boundaries and enclose the nonwoven core. To make the mechanical characteristics of the nonwoven as isotropic as possible for the rotationally symmetrical component, a quasi-isotropic layer structure is selected. Therefore, it is placed in the mold with a layer-structure of (0/90/±45) horizontal to the orientation shown in Figure 1. For the fabric, E_1, E_3 is assumed as 28000 MPa and E_2 = 6000 MPa. A load is applied on the boss analog to the load situation described in [12] by applying inner pressure on the laminate and the boss.

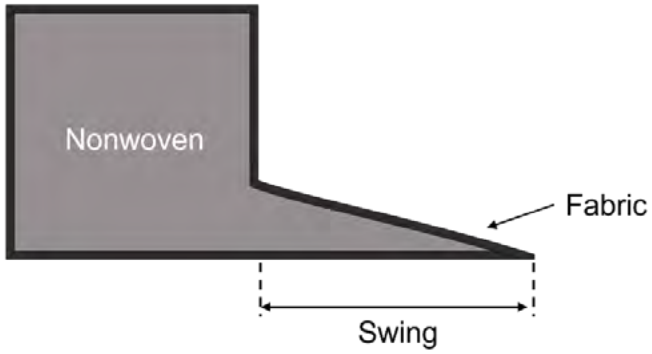

Figure 1. Concept and qualitative calculation of sandwich structure consisting of internal nonwoven with external fabric.

3. Results and Discussion

The qualitative analysis of the FEM model as depicted in Figure 2, reveals that the lower modulus of the fabric results in a greater load bearing capacity of the outer fabric as compared to the inner core of the nonwoven. This is illustrated by the jump between the tensions in the fabric layer and the nonwoven in the core. By changing the layer thickness of the fabric, the mechanical behavior of the boss part can be adjusted to minimize the proportion of fabric to increase the amount of recycled material as much as possible. This is shown by the concentration of high maximum principal stresses in the area of the fabric layers, which generally result from the load situation due to internal pressure on the boss and the CFRP laminate (Figure 2). A clear stress peak can be seen on the upper side of the boss wing. In contrast, the remaining fabric layers apart from the one on the swing arm exhibit moderate to low stresses. The core material exhibits the lowest stresses.

Based on the calculation, it can be concluded to place the fabric exclusively in the area of the boss wing, as this is subject to particularly high loads and, in contrast, the loads are low, especially in the direction of the boss opening. Table 2 shows the layer heights and areal weight of the nonwoven in relation to the different processing forms of the dry fiber layer, the layer in the RTM process and in the infusion process as well as in relation to the fiber volume content from Table 1.

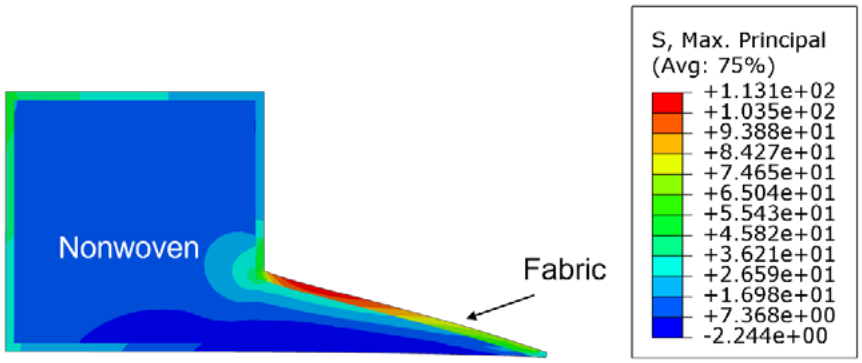

Figure 2. Concept and qualitative calculation of internal nonwoven with external fabric with a load situation as in [12] by applying inner pressure on the laminate and the boss

Due to the elastic behaviour of the dry nonwoven, the number of layers required for a CFRP bump is quite large, which leads to a high degree of compaction of the dry fibres that have to be applied during an infusion process through the RTM mould or a vacuum setup. This leads to a susceptibility to possible displacements of the fibres within the structure, which are not visible before infusion. This results in the risk of fiber-free areas in the component or unevenness in the deposition of overlying fabric layers.

Table 2. Manufacturing data of the nonwoven

Areal weight	100 g/m^2
Layer hight dry	2.8 mm
Layer hight infused	0.72 mm
Layer hight RTM	0.25 mm

Based on these investigations, the CFRP boss with fabric covering is manufactured in an RTM mold and cutted in cross-section and polished for examination (Figure 4). The fine white line in the laminate in the lower area of the boss shows that the interlaminar unevenness of the nonwoven during the process leads to the formation of undulations in the component. However, when looking at the outer contour on which the fabric is placed, there are no significant deviations, so that the main load-bearing fabric layer can be assessed as intact and even. Inserts can be fitted in this area to enable a transition to the piping of the tank. Pull-out tests can be used to design this interface area, which would leads to a determination of the number, size and type of thread inserts.

Figure 4. CFRP bosspart with a nonwoven inner core.

4. Conclusion

This paper demonstrates the feasibility of integrating recycled carbon fibers in the form of nonwovens into pressure tanks without sacrificing structural integrity. This is achieved by incorporating the nonwoven material as a core within the boss and overlaying it with fabric layers of adjustable thickness. These covering layers are mainly relevant for the mechanical strength due to their significantly higher mechanical properties. This means that high-quality semi-finished products made from continuous fibers can be saved efficiently and existing fibers can be used effectively. This contributes to a more ecologically valuable production without hindering design-relevant sizes.
This approach supports environmentally conscious production while maintaining the essential design parameters.
This study has presented first investigation on application of recycled fibres for a major pressure tank component manufactured in RTM and VARI. Regarding production, the significant differences in volume and fiber volume content between the dry single layer and the resin-impregnated layers of the infusion and RTM process present challenges in terms of tool construction and scalability for automation processes, which require further investigation. Overall, the construction of sandwich structures from recycled and continuous fibre-reinforced plastic composites offers great potential for further investigations into the use of recycled carbon fibre nonwoven as a core material for sandwich-like structures for applications such as CFRP bosses.

Abstract

This study presents an advanced modelling technique to precisely simulate various damage modes caused by low-velocity impacts on fibre-reinforced composite structures. This method utilises a novel kinematically enriched continuum damage mechanics approach to model semi-discrete intralaminar cracks with solid elements, enabling cracks to grow independently of fibre-oriented ply mesh pattern. That greatly simplifies the meshing effort and eliminates the necessity of tie constraints due to mesh mismatch at ply interfaces. The approach incorporates crack kinematics by distinguishing cracked and uncracked domains at the constitutive level. Inter-ply delamination is modelled using cohesive elements. The methodology is applied to quasi-isotropic laminate. The results demonstrate the capability of the proposed method to simulate solution-dependent multiple discrete cracks and crack-delamination interactions with reduced computational time and complexity, compared to a reference model employing ply-oriented mesh and pre-seeded cracks at predetermined locations.

1. Introduction

Fibre-reinforced polymer (FRP) composites are highly used in aviation and automobile industries due to their combination of lightweight and impressive strength. Despite numerous advantages, composite structures are prone to catastrophic failure due to their innate brittleness, which is a significant concern for aviation and transportation sector where passenger safety is paramount. One common damage event for composite structures is low-velocity impact (LVI). External aircraft components may experience unforeseen impact loads in diverse scenarios, ranging from ground operations to encounters with birds. This type of impact typically affects the interior of the laminate, leaving the exterior seemingly undamaged upon visual inspection. Therefore, it is also referred to as Barely Visible Impact Damage (BVID). Advanced structural health monitoring techniques are commonly required to identify the location and extent of this type of damage experimentally, which increases inspection cost and time. Computational realization of LVI events incorporating accurate damage models provides an alternate route to understand better this type of damage in a quick and inexpensive way.

In a Finite Element (FE) framework, modelling of damage under LVI commonly involves the utilization of continuum damage mechanics (CDM) framework at ply-level and cohesive zone models (CZM) for interface damage. However, the conventional CDM method degrades material stiffness over the entire element volume. This smeared damage approach results in an overall softening response but fails to represent the 'discrete' nature of ply cracks and crack-delamination interaction. Another drawback of the classical CDM is the mesh direction bias [1]. To circumvent these problems, a local fibre direction-oriented mesh is often employed for each ply [2,3,4], which increases meshing efforts significantly and

causes mesh mismatch at ply interfaces. This necessitates the imposition of tie constraints to maintain assembly integrity which significantly increases computational time.

The present work employs a kinematically enriched directed CDM (D-CDM) approach [5,6], to numerically simulate the onset and growth of damage under LVI in a multidirectional laminate. The D-CDM enhances traditional CDM by incorporating an accurate kinematic representation of the sharp crack topology of ply matrix cracks at the constitutive level. Additionally, a crack tracking algorithm is applied to eliminate mesh orientation bias in ply crack growth, reducing meshing efforts. The removal of tie constraints further contributes to a reduction in analysis time. This technique is implemented as a 3D user-defined material in Abaqus/Explicit [7]. The numerical results obtained through this novel method are compared with experimentally obtained damage patterns reported in the literature [2].

The architecture of the paper is organised as follows: Section 2 dictates the material models of intra-ply cracking and interface delamination. In this work, fibre damage is not considered because, under LVI test case matrix crack, delamination and their interaction are reported to be the most dominant failure modes [2]. In Section 3, modelling details of multidirectional laminate are described. Results are discussed in Section 4. Finally, conclusions of this work are presented in Section 5.

2. Constitutive damage law and methodology

In this analysis, accurate modelling of matrix cracks is achieved by considering embedded discontinuity within a continuum medium, drawing inspiration from the work of Nguyen et al. [8] as shown in Figure 1. Interface damage, on the other hand, is captured using a linear traction-separation cohesive formulation outlined by Jiang et al. [9] considering the effect of compression enhancement [2,3]. Comprehensive details regarding these formulations and overall methodology are extensively covered in a recent publication authored by Kumar and Mukhopadhyay [6]. This paper extensively utilizes the present formulation to simulate damage during a quasi-static indentation test. Interested readers are encouraged to consult the referenced article for a more comprehensive understanding of the concepts elucidated herein.

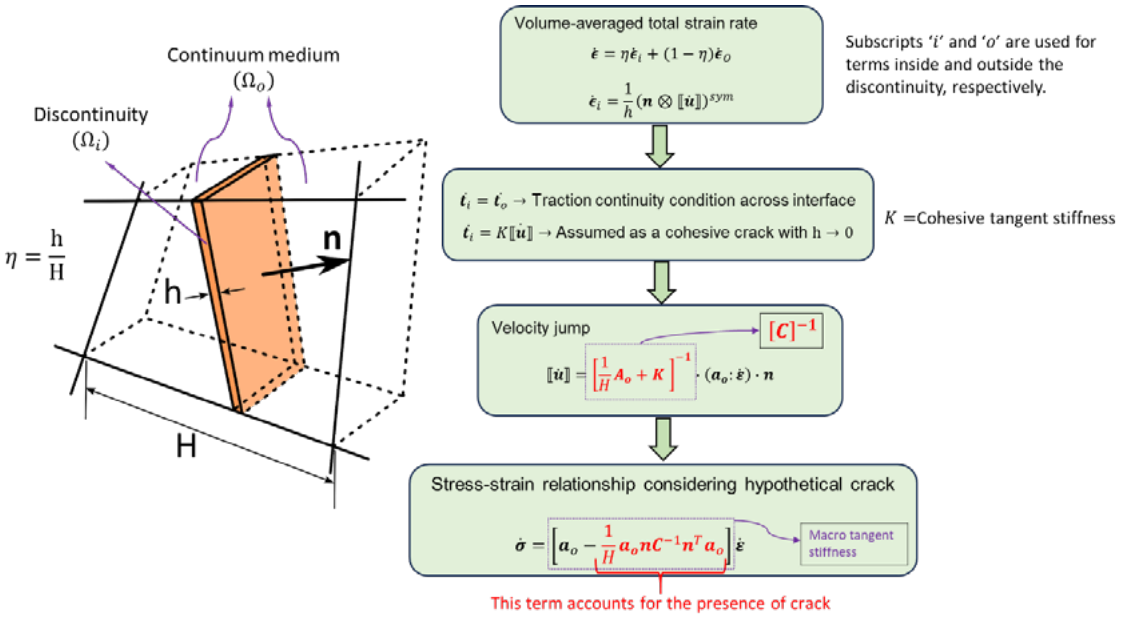

Figure 1. Kinematically enriched CDM formulation.

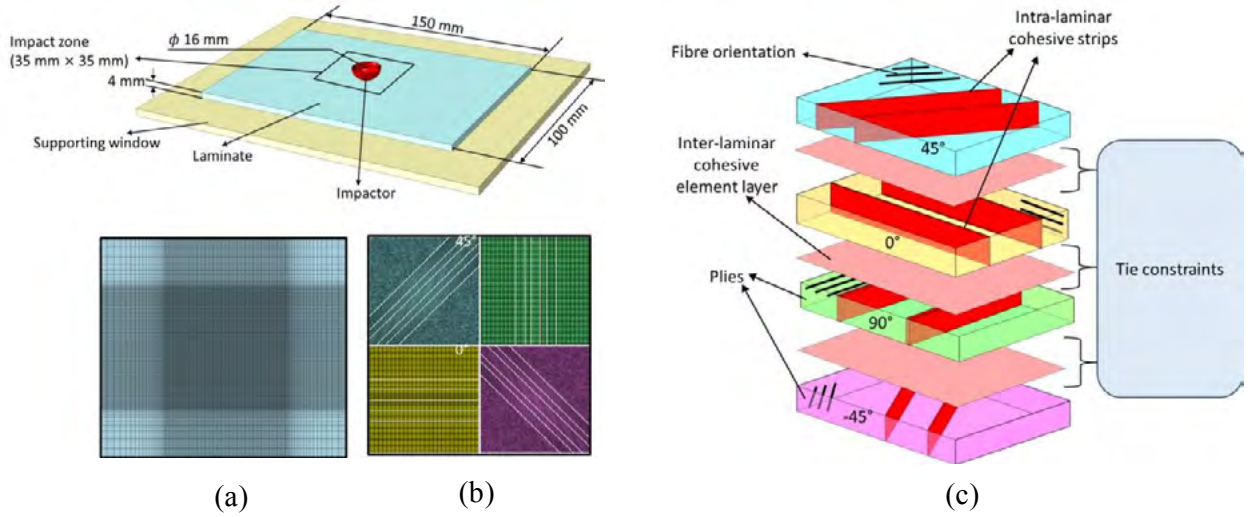
3. Finite element model

To investigate damage during LVI, the experimental work reported in [2] on the ply-blocked scaled specimen is numerically reproduced here. This particular case is selected for its representative nature, showcasing damage patterns in a multidirectional laminate and highlighting the strong interaction between ply cracks and delamination. The modelling specifics are outlined in Figure 2, with the laminate featuring a stacking sequence of $\left[45_2^\circ/0_2^\circ/90_2^\circ/-45_2^\circ\right]_{2S}$, and material properties are detailed in Table 1. For comparison purposes, two distinct modelling approaches are considered. The first approach employs the presently developed method as discussed in Section 3.1. The second approach follows the methodology presented in [2,3], where ply cracks are explicitly represented by strategically inserting cohesive 'split' elements at predetermined locations within a fiber-oriented mesh.

3.1 D-CDM-based model with uniform ply mesh



The modelling intricacies of the laminate, depicted in Figure 2(a), are outlined as follows: each doubled-up ply block, with a thickness of 0.25 mm, is represented by a single layer of solid C3D8R finite elements with hourglass control. The interfaces between ply blocks are modelled using cohesive COH3D8 elements, each with a thickness of 0.01 mm. To account for localized deformation, a fine mesh with an in-plane element size of 0.2 mm is implemented within the central region of the laminate where impact is anticipated. Beyond this region, mesh density is relaxed to optimize computation, with maximum element sizes extending up to 3 mm near the laminate periphery. This mesh pattern is kept the same for all the plies and interfaces in the laminate. The total number of elements in the model approximates 1.5 million.

Numerical simulation of LVI adheres to the ASTM drop weight impact standard [10]. The laminate, with in-plane dimensions of 100 mm × 150 mm, is supported by a rigid rectangular plate that has a rectangular opening of in-plane dimensions of 75 mm × 125 mm. A rigid hemispherical impactor of mass 6.35 kg with 16 mm diameter is impacted on laminate. For the low-velocity impact, a low-impact energy of 10 J is provided to the impactor by prescribing the initial velocity of 1.75 m/s. Surface-to-surface contact formulation [7] governs the interaction between the impactor and laminate, employing a penalty contact stiffness of 10^5 N/mm in the normal direction and a sliding contact in the tangential direction, characterized by a friction coefficient of 0.3. The same contact formulation is applied between the supporting window and the laminate, with the window held fixed in all directions.

Preceding impact, a thermal load step is introduced to simulate the laminate's cool-down from the cure temperature (180°C) to room temperature (20°C) and to simulate the generation of residual stresses. This step is crucial as incorporating cure-induced residual stresses enhances solution accuracy. Notably, the impactor is positioned at a distance of 1.88 mm from the upper surface of the laminate, facilitating simultaneous movement of the impactor and cooldown of the laminate.

3.2. Fibre-oriented cohesive split model

In this instance, while the model geometry remains the same, adjustments are made to the meshing to align with conventional practices. Each ply mesh pattern is oriented along the local fibre direction, as illustrated in Figure 2(b). This adaptation inevitably introduces mesh mismatches at ply interfaces which is handled by implementing kinematic tie constraints between solid and cohesive element layers at these interfaces, as depicted in Figure 2(c). Within this model, cohesive elements serve the dual purpose of simulating both delamination and ply matrix cracks. Following the methodology outlined in [2,3], six cohesive strip layers are strategically pre-seeded between solid ply elements at predefined locations within each ply. The cohesive damage formulation, incorporating compression enhancement with a factor of 0.58 as detailed in [2,3,9], is applied to both delamination and matrix cracking. To ensure a fair comparison of computational costs, the total number of elements in this model remains consistent with the D-CDM model. All other modelling parameters remain unchanged from those specified in Section 3.1.

Mesh details of the impact zone (below): (a) Uniform grid mesh for all plies in the D-CDM model, (b) Fibre-oriented cohesive split model (Splits are shown by white lines) and (c) Exploded view of laminate showing mesh details in the cohesive split model.

Table 1. Elastic material properties of unidirectional IM7/8552 ply material [11,12].

Ply material properties	E_{11} = 161 GPa, E_{22} = E_{33} = 11.4 GPa ν_{12} = ν_{13} = 0.3, ν_{23} = 0.436 G_{12} = G_{13} =5.17 GPa, G_{23} =3.98 GPa Thermal expansion coefficients $\alpha_{11} \approx 0$, $\alpha_{22} = \alpha_{33} = 3\times10^{-5}$ mm/°C Density = 1.6 g/cm^3
Interface material properties	σ_{IMAX} = 60 MPa, σ_{IIMAX} = 90 MPa, G_{IC} = 0.2 N/mm, G_{IIC} = 1.0 N/mm, $K_I = K_{II} = 10^5$ N/mm^3, Power law exponent = 1.0, Compression enhancement factor = 0.58 Density = 1.0 g/cm^3

4. Results

In this section, numerical results of D-CDM models are compared with cohesive split model and experimental [2] results by force-time curve, and damage response of laminate.

4.1. Overall laminate response

Figure 3 presents a comparative analysis of the force-time curves generated by two distinct models alongside experimental data. Evidently, both models closely follow the experimental curve. The critical load value projected by both the D-CDM and cohesive split models is consistent, approximately 4.87 kN, which is marginally lower by 3% compared to experimental value. Notably, both models adeptly capture the magnitude of load drop and each force oscillation. The reason for load drop is discussed in section 4.2. However, there is a slightly prolonged impact duration in the finite element (FE) simulations compared to the experimental setup. Furthermore, it's elucidated that the peak force prediction in FE simulations is higher than the experimental results due to the predicted delamination area being smaller than observed in experiment, as depicted in Figure 4 for both FE simulations. In this context, the cohesive split model gives better results owing to its explicit modelling of matrix cracks. Nonetheless, it's acknowledged that explicit modelling of matrix cracks may not always be feasible.

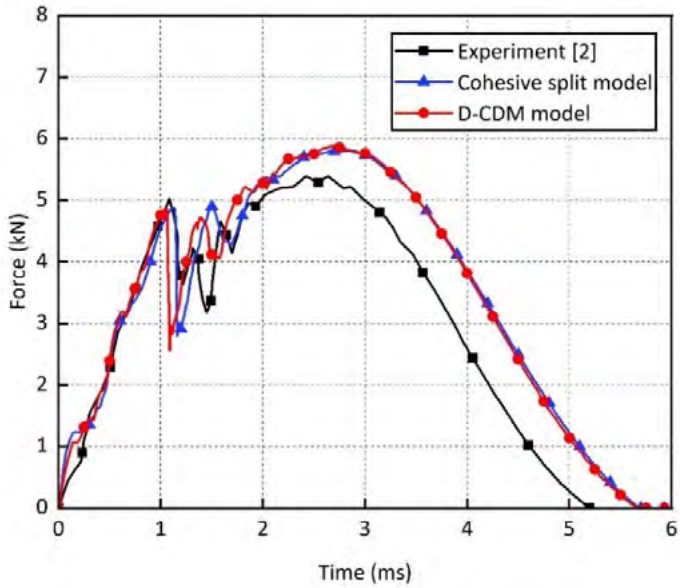

Figure 3. Comparison of force-time curve between experimental and finite element results.

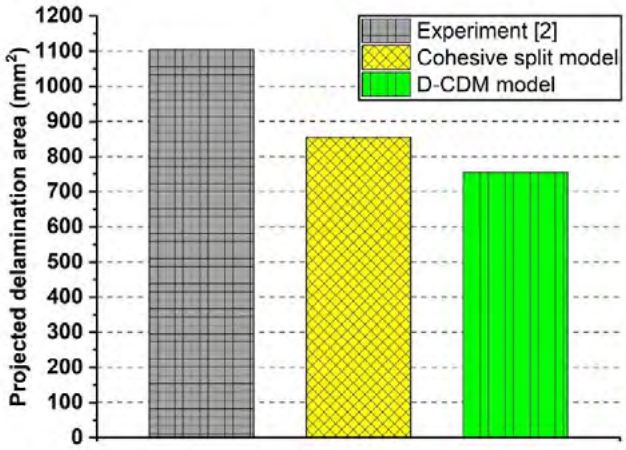

Figure 4. Comparison of projected delamination area between experimental and finite element results.

4.2. Damage response

A comparison of the delamination pattern interface-by-interface comparison throughout the entire thickness of the laminate is undertaken between experiment and two models as illustrated in Figure 5. Figure 5(a), sourced from [2], displays a CT scan where colour-coded interfaces highlight the impact zone with isolated delamination pattern. Notably, beneath the impactor, a region exhibits suppressed delamination due to compressive normal stresses [2,3], effectively inhibiting delamination initiation. Both the D-CDM and cohesive split models successfully capture this 'delamination-free' region, courtesy of the compression enhancement effect integrated into the cohesive law. Additionally, the overall size and shape of the delaminated area closely align between the two models (Figure 5(b) and (c)) and with the experiment. It's elucidated by Sun et al. [2] and Figure 5 that within this laminate, the major load drop results from complex interaction between ply matrix cracks and delamination, as well as large delamination area in 90° ply interface.

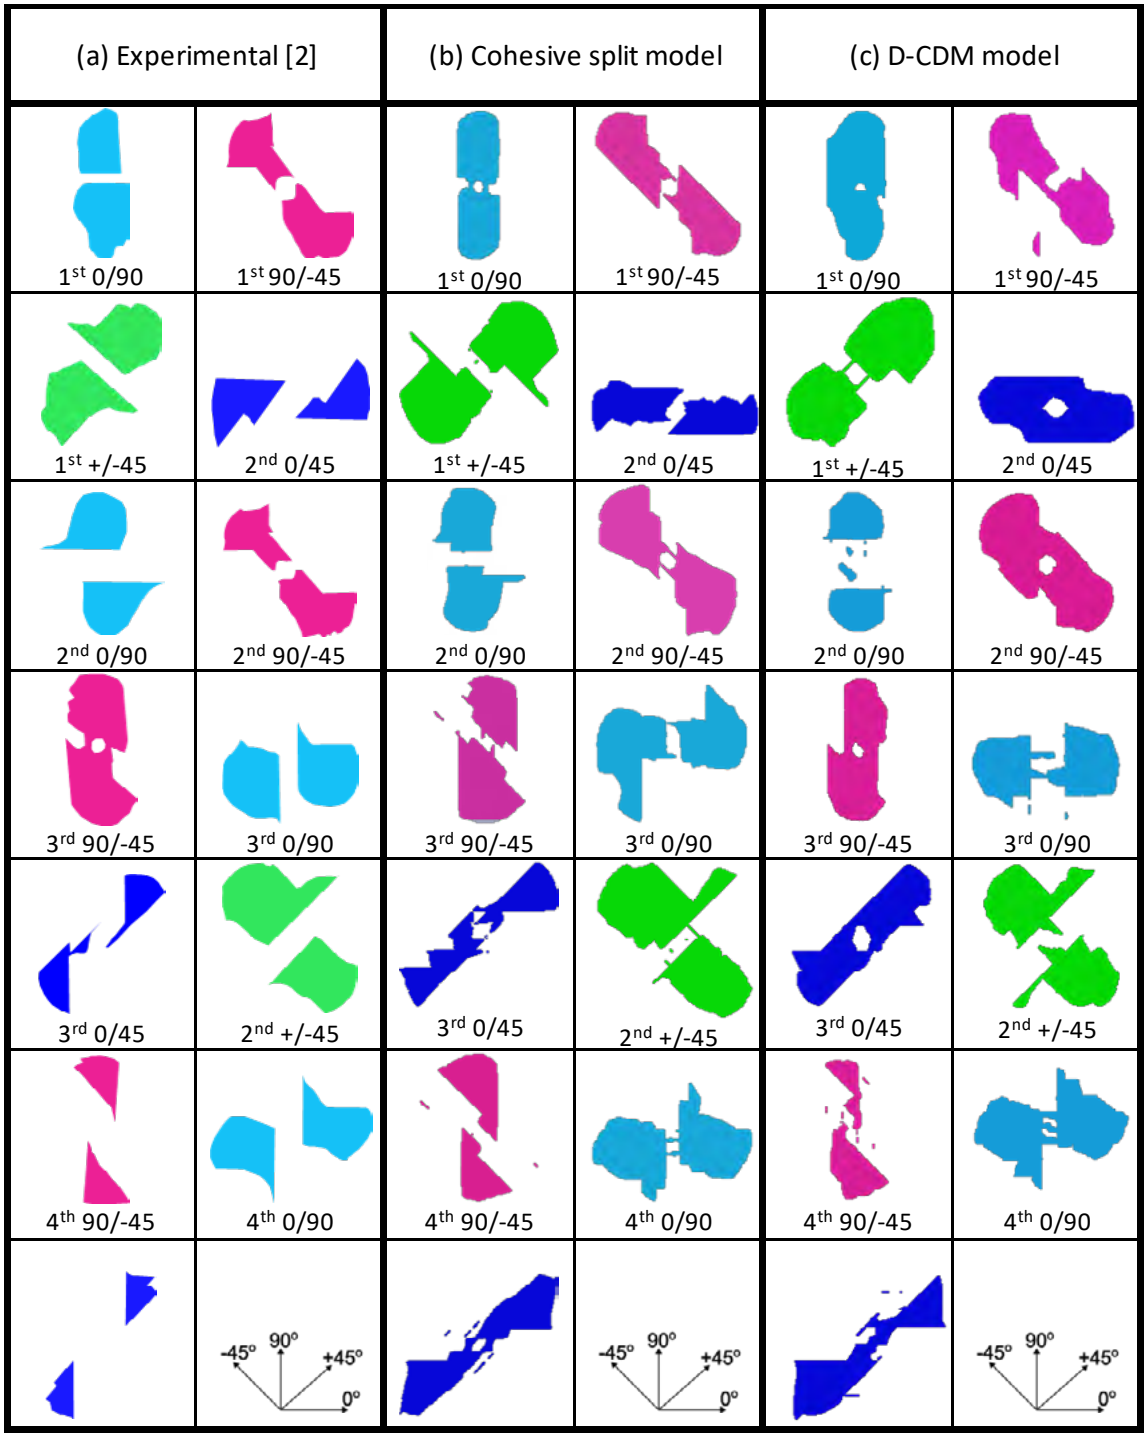

Figure 5. Comparison of individual interface delamination pattern.

In Figure 6, formation of matrix cracks is depicted across all ply interfaces within the laminate. The crack spacing is 3 mm, with a maximum allowance of 6 cracks. A dedicated investigation, detailed in a recent publication [6], utilized a D-CDM-based model. This study aimed to explore the effect of varying parameters such as ply crack spacing and maximum cracks per ply on the overall load-displacement behaviour. Surprisingly, no significant disparities were noted in the global response. Nevertheless, the research highlights the D-CDM method's capacity to accurately simulate densely distributed, parallel 'sharp' crack networks with numerous cracks across a large-scale model, all while maintaining numerical stability which is difficult to achieve with eXtended finite element method (XFEM) type discrete crack models.

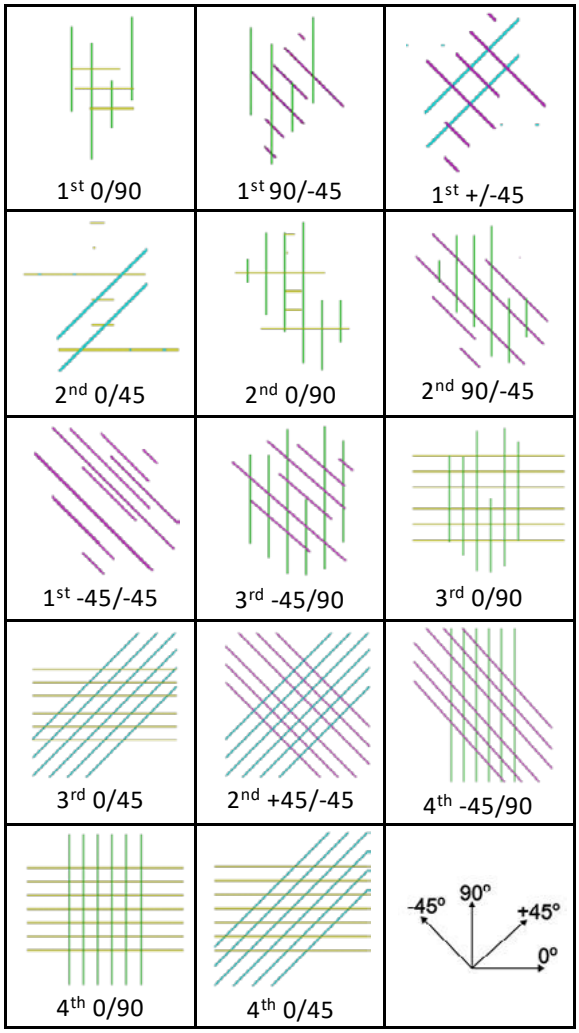

Figure 6. Ply matrix cracks captured by D-CDM model.

4.3. Numerical efficiency

The utilization of D-CDM presents a notable advantage in simplifying the meshing process for the entire laminate, thereby saving time during model construction. Further, D-CDM obviates the need for seeding cohesive elements within the ply mesh at predetermined locations to simulate ply cracks, thus further simplifying meshing procedures and enhancing the versatility of the model. Moreover, the D-CDM approach significantly accelerates the analysis process. All simulations are carried out in a cluster computer running parallelly with 40 cores of Intel® Xeon 5218R CPU with 2.10 GHz base frequency. D-CDM model demonstrates a runtime of approximately 67 hours. In contrast, the reference model, utilizing fiber-oriented mesh and pre-inserted cohesive splits, requires roughly 108 hours under identical conditions. This substantial 38% reduction in computational time with D-CDM model is primarily attributed to the elimination of tie constraints at every ply interface with mismatched ply mesh patterns.

5. Conclusions

In this study, an enhanced modelling approach is introduced aimed at accurately simulating the progressive damage occurring in composites under LVI. D-CDM-based semi-discrete ply crack model can generate and propagate multiple sharp cracks within multidirectional laminates similar to XFEM. This approach maintains the simplicity and reliability of continuum damage mechanics while allowing for the initiation and growth of solution-dependent cracks. One notable advantage of the approach is its "mesh-independent" characteristic. This feature offers two significant benefits to analysts: simplification

of mesh design and elimination of the need for tie constraints or tie-based cohesive contact at mismatched mesh interfaces. This not only simplifies the modelling process but also reduces computational time by approximately 38%, as demonstrated in the case study. Furthermore, this method effectively captures the interaction between intra and interlaminar damage by virtue of the discrete nature of D-CDM matrix cracks. This capability results in a highly accurate prediction of the load history behaviour, enhancing the overall fidelity of the simulation.

Keywords: composites, GFRP, flame-retardant, mechanical properties, shipbuilding, fire safety

Abstract
The flammability of the organic polymer matrix of fiber-reinforced plastics is currently a major obstacle for their use as lightweight construction materials. Additive fire retardants improve the fire resistance, but also influence the mechanical behavior. The influence on the mechanical properties is currently difficult to quantify, which often leads to the oversising of fire protection-relevant components.
The aim of this work is to quantify the influence of a flame retardant on the mechanical properties of a glass fiber reinforced plastic. In order to evaluate the influence of fire retardants, quasi-static tensile, compression and flexual tests are carried out on quasi-isotropic laminates with and without fire retardants. In addition, shear tests on biaxial laminates are performed.
The test results are quantified for various parameter and load combinations and given in the form of reduction factors. For example, while the strength and stiffness of flame retardant specimens under tensile load decrease compared to the reference series without fire retardants, the mechanical properties under shear load are less or even positively affected. Furthermore, the results show that the manufacturing process in combination with the flame retardant influences the degree of consolidation, the fiber volume content and thus the mechanical properties. The derived reduction factors can be used for the material-specific design of components, taking into account the adapted mechanical properties.

1. Introduction

Due to their high lightweight construction potential, fiber-reinforced plastics (FRP) can help to reduce fuel consumption and emissions in the mobility sector [1]. In shipbuilding, the use of FRP instead of the commonly used steel can reduce the mass, which saves fuel and thus either reduces CO_2-emissions or enables a higher cargo load with the same fuel requirement. Furthermore, FRP has advantages over steel in terms of corrosion resistance and freedom of design. In commercial shipping, however, the strict fire safety regulations of the International Maritime Organisation (IMO) in SOLAS (International Convention for the Safety of Life at Sea) apply [2]. According to these regulations, only materials that are classified as non-combustible can be used in safety- and structurally relevant areas. Consequently, the low thermal resistance of the organic polymer matrix is a major obstacle to the use of FRP in shipbuilding [3, 4]. Under the influence of temperature, the strength and stiffness of the matrix decrease, whereby its protective and supporting properties are lost, leading to failure of the composite [5]. In addition, the organic plastic matrix can burn at temperatures as low as approx. 300-400 °C with a strong release of heat [5, 6], producing toxic fumes such as carbon monoxide [3].
In order to meet the safety requirements of the IMO and to use FRP in shipbuilding, an equivalent level of safety to that of steel structures must be demonstrated (Chapter II-2/17 of SOLAS [2]). To increase the fire resistance of a FRP, either external insulation is used, flame-retardant coatings are applied or reactive or additive fire retardants are added to the resin of the FRP [6–8]. Flame retardant additives are a particularly popular variant to improve the fire resistance of an FRP, as no additional design measures are required. However, in order for additives to improve the fire resistance of a FRP large quantities must be added [9–12]. For example, tests by Shekarchi et al. [10] show that substituting 20 % or 40 % of the matrix component with the flame retardant additive ammonium polyphosphate reduces the flexural and tensile strength of the composite, which the authors attribute to reduced fiber-matrix

adhesion. The decrease in strength and stiffness increases with the test temperature. Studies by Petersen et al. [11] confirm the decrease in tensile, compressive and shear strength and stiffness due to the addition of the flame retardant alumina tri-hydrate.
However, it is not only the reduction in mechanical properties that currently inhibits the use of flame-retardant FRP in shipbuilding. Another problem is the complex production of FRP with flame retardant additives. Tests on the process-optimised production of FRP components with a combination of aluminium-trihydroxide and ammonium-polyphosphate demonstrate the difficulty to ensure the homogeneous distribution of the flame retardant in the laminate [13]. While the flame retardant only settles between the individual layers of the semi-finished fiber product during manual application (hand lay-up), the flame retardant concentration decreases along the flow front during vacuum infusion, as the fibers filter out the mineral components from the FRP matrix mixture.
As shown above, the production and use of fiber composites with uniform flame retardancy in shipbuilding is still associated with great challenges. In addition to the reduced mechanical properties, uniform distribution of the flame retardant in the FRP is particularly problematic, as this not only results in uneven fire protection properties but also high standard deviations in the mechanical parameters [10, 12]. The latter complicates the design of fiber composite constructions with flame retardant additives. Fire protection-relevant components are therefore often oversised, which contradicts the concept of lightweight construction and is associated with increased resource consumption.
In the present work, the problems are countered by using a pre-impregnated semi-finished product (prepreg) with a flame retardant additive already mixed into the resin. The mechanical production of flame-retardant prepregs improves the uniformity of the subsequent laminates and thus the resulting mechanical and fire protection properties. At the same time, the use of prepregs improves occupational safety and enables large-scale production of fiber composite components. The different manufacturing processes used in the work (vacuum bag moulding and hot pressing) for processing the prepregs have a direct influence on the resulting mechanical properties of the test specimens. By referencing the results to a comparative series without flame retardant, not only the influences of the manufacturing process but also those of the flame retardant are revealed.

2. Material and methods

2.1. Test methods and standards

The experimental test program consists of a series of quasi-static tests on quasi-isotropic and biaxial laminates with and without fire retardants (Chapter 2.2). In each case, one laminate was produced using hot pressing technology (Chapter 2.3) and one laminate using vacuum bag moulding (Chapter 2.3). Table 1 provides an overview of the mechanical tests carried out, including the standards applied. All quasi-static tests were carried out on the Zwick/Roell universal testing machine (Z50). For the displacement measurement, a videoextensometer with a measurement pattern on the specimen was used. For the flexual tests at 90 °C, the testing area of the testing machine was enclosed using a temperature chamber (Zwick/Roell TE-TC12.00).

Table 1. Test type, conditions, standards and determined values for mechanical tests

Test type (temperature)	Test standard	Determined values
Tensile (23 ± 3 °C)	DIN EN ISO 527-4	Stress/Strain, Strength, Modulus
Compression (23 ± 3 °C)	DIN EN ISO 14126	Stress/Strain, Strength
Shear (23 ± 3 °C)	DIN EN ISO 14129	In-plane Stress/Strain, Strength, Modulus
Flexual (23 ± 3 °C)	DIN EN ISO 14125 Three-point flexure	Stress/Strain, Strength, Modulus (large deflections)
Flexual (90 ± 3 °C)	DIN EN ISO 14125 Three-point flexure	Stress/Strain, Strength, Modulus (large deflections)

In addition, microscopic and energy dispersive X-ray spectroscopy (EDX) analyses were carried out on certain laminates in order to enable a correlation between the mechanical properties and the microstructural composition of the material. Therefore a scanning electron microscope (SEM) JSM-IT100 from the manufacturer JEOL Ltd. was used.

2.2. Material and laminate structure

A glass fiber-reinforced prepreg with a ±45°-biaxial non-crimp fabric (areal weight 810 g/m^2) and with 40 % resin content (535 g/m^2) was used to manufacture the laminates. For the series with flame retardant, a powdered flame retardant with aluminum-trihydroxide and ammonium-polyphosphate was added to epoxy resin *CP003* (*c-m-p GmbH*) by 33 wt.-% of the resin (177 g/m^2) before the impregnation of the semi-finished fiber product. For the reference series without flame retardant, the same biaxial glass fiber reinforced prepreg was used but without additive. A quasi-isotropic laminate structure $[0°/90°/+45°/-45°]_s$ was used for the quasi-static tensile, compression and flexual tests. The specimens for the in-plane shear tests were taken from biaxial laminates $[+45°/-45°/+45°/-45°]_s$.

Fiber volume content: During the production of the laminates, the fiber volume content (FVC) should be kept as constant as possible within the series with and without fire retardants in order to eliminate one of the main factors influencing strength and stiffness. The degree of consolidation and thus the FVC of the laminates depends on the selected manufacturing process. In the vacuum bag moulding, consolidation is achieved by the vacuum pressure. Thereby, the resulting FVC of the laminates is influenced by various parameters, including the number of fleece-layers in the vacuum bag (Chapter 2.3), the viscosity profile of the epoxy resin and the quantity and distribution of the flame retardant [12, 13].
While the FVC of laminates without fire retardants can be determined by means of thermal calcination in accordance with DIN EN ISO 1172, the flame retardant in the series with fire retardants prevents the residue-free ashing of the matrix. The fiber volume content of series with fire retardants are therefore determined by calculation and on the basis of the measured thickness of the cured vacuum bag moulding laminates. As the thickness of the laminates can be adjusted much more flexibly in the hot pressing process using the compression force, the thicknesses of the vacuum bag laminates are crucial. The FVC φ is calculated using Formula (1):

$$\varphi = \frac{n * G}{\rho * d * 1000} \tag{1}$$

where n is the number of prepreg-layers, G is the fiber areal weight (810 g/m^2), ρ is the fiber-density (2.6 g/cm^3) and d is the laminate thickness in mm.
In pre-tests, a thickness of approx. 2.5-3.0 mm was measured for vacuum bag moulding laminates without flame retardant and a thickness of approx. 3.0-3.5 mm for laminates with fire retardants. In the hot pressing process, the thickness of the laminates can be adjusted by using spacers. In order to achieve the thickness of the series without fire retardants from the vacuum bag moulding process, a spacer of 2.75 mm was chosen. For the series with fire retardants, spacers with a thickness of 3.3 mm were used.

2.3. Manufacturing and curing

Before the laminates are produced, the prepreg was removed from the freezer (-20 °C) and cut into size. The prepreg-blank was conditioned for 24 h in a normal climate (23 °C, 50 % RH). The biaxial layers of the prepreg were laid down and pressed down with a squeegee. An peel ply (PA6, 85 g/m^2) was applied on both sides of the laminate. The laminates were initially tempered for 8 h at 85 °C, with a heating rate of 1 K/min (cooling uncontrolled). For final curing, the laminates were tempered once again at 110 °C for 12 h (1 K/min, cooling uncontrolled) in an universal tempering oven (*Memmert UF750plus*).

Vacuum bag moulding: The laminates in the “vacuumpressing” series were produced on a heatable laminating plate coated with a release agent (*PARTALL® Hi-Temp Wax*). The vacuum structure was

created using a perforated film made of fluoropolymer, a vacuum foil (*VACF 465B*), a vacuum sealing tape (*Airseal 3WT*) and a non-woven fleece (*Breatex*™, 150 g/m²). The non-woven fleece served simultaneously as a breather and bleeder and made a significant contribution to resin flow and consolidation. After initial curing, the laminates were demoulded and post-cured.

Hot pressing: The laminates in the "hotpressing" series were produced in a hot press with an aluminum tool heated on both sides. Release agent (PARTALL® Hi-Temp Wax) and peel ply (PA6, 85 g/m²) were used on both sides for easier demoulding. Initially, the biaxial layers of the prepreg were applied and pressed down with a squeegee. Spacers were placed between the aluminum plates of the forming tool to adjust the laminate thickness (Chapter 2.2). With the help of a bolted frame and a pressure pad press, a sufficiently high pressing pressure was applied so that the moulds rested on the spacer. After initial curing, the laminates were demoulded and post-cured.

3. Results and Discussion

The quasi-static properties are determined in accordance with the test standards (Chapter 2.1). For each series and load type (tension, compression, flexual, shear) force-displacement-curves are recorded and stress-strain-curves are derived.
As an example, the stress-strain-curves from the tensile test according to DIN EN ISO 527-4 are presented in Figure 1. The curves of each series are linear up to around 50 N/mm² or 0.25 % strain. Thereafter, all curves show a bend that extends to around 100 N/mm², which indicates a partial failure of the 90°-fiber layers of the composite running transverse to the direction of loading. Subsequently, the curves are linear again and have different slopes and different maximum stresses depending on the series. These differences show the influence of the flame retardant content and the manufacturing process on the mechanical behavior of the FRP under quasi-static tensile load. In concrete terms, the two series with fire retardants run below the series without fire retardants. Furthermore, it can be seen that the vacuum bag moulding process has a positive impact on the strength and stiffness of the laminates without fire retardants while hot pressing leads to higher strengths in laminates with fire retardants.

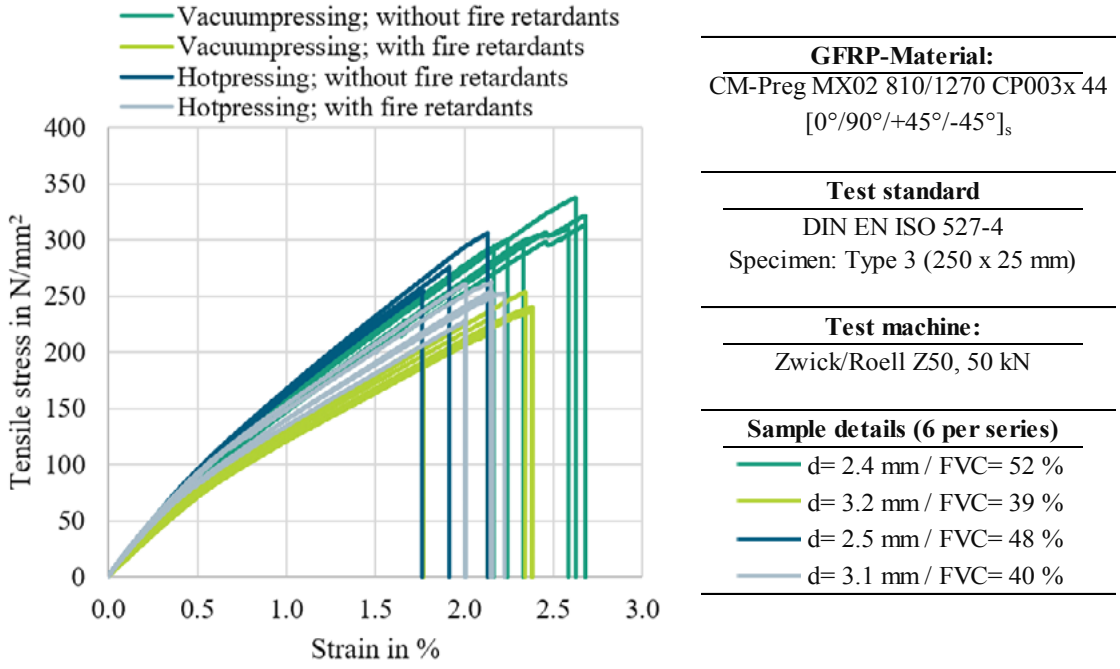

Figure 1: Tensile stress-strain-curves to investigate the tensile behaviour depending on the manufacturing process and flame retardant content

Figure 2 shows the tensile strength and Young's modulus of the four series as bar chart with specification of the corresponding reduction factors. The lower gradient of the curves without flame retardant in the initial range <50 N/mm² (Figure 1) is due to a lower stiffness of the test specimens. The Young's modulus (Figure 2) decreases by 6.5 % for the vacuum-pressed test specimens and by 11.5 % for the hot-pressed test specimens. This decrease appears to be directly related to the flame retardant, which reduces the stiffness of the matrix component and thus the modulus of the composite material. In addition, it becomes clear that the tensile strength and the Young's modulus of the vacuum-pressed laminates decrease more than those of the hot-pressed laminates due to the fire retardant content.

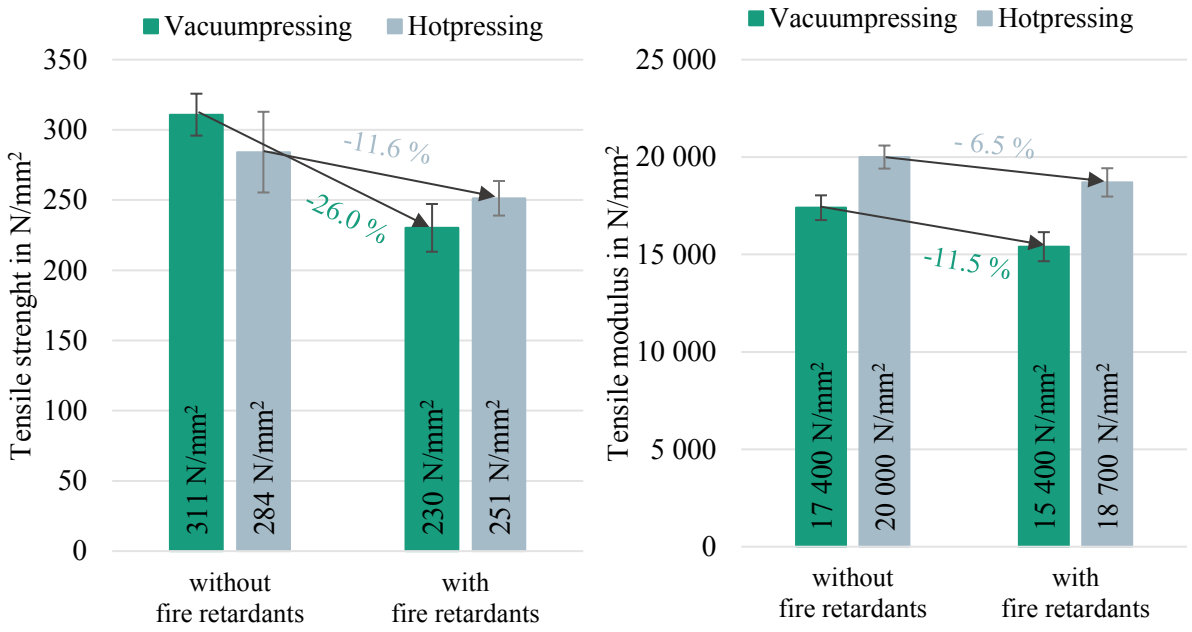

Figure 2: Comparison of tensile strength (left) and tensile modulus (right) with and without flame retardant differentiated according to the manufacturing process

Table 2 shows the strength and Table 3 the stiffness of the four series under tensile, compressive, shear and flexual loads as well as the reduction factors in strength and stiffness due to the addition of the flame retardant. The compressive strength of the four series decreases with the addition of fire retardants in the same way as the tensile strength. Under compression, the negative influence of the flame retardant on the strength is almost similar between the two manufacturing processes (-16.1 % and -16.5 %).
The results of the flexural tests at room temperature and at 90 °C also show a decrease in the characteristic values with the addition of the flame retardant additive. The percentage decrease is slightly greater for the hot-pressed laminates than for the vacuum-pressed ones. In principle, the outer layer of the test specimens is decisive for the mechanical integrity under flexual loading, as this is where the maximum elongation of the matrix and fibers occurs. Due to the flame retardant, the fiber volume content in the load-bearing unidirectional outer layers is lower than in the laminates without flame retardant. This could lead to the strong decrease in mechanical properties. The significant decrease in mechanical integrity in the flexual specimens is also confirmed by the decrease in flexural modulus (Table 3).
For all characteristic values dominated by fibers (tension, compression, flexual), the compression in the manufacturing process, the resulting specimen thickness and the difference in the FVC associated with the specimen thickness have a significant influence on the mechanical strength and stiffness. Therefore, it should be noted that the FVC of the series with flame retardant is almost 10 % lower than that of the reference series without flame retardant (Figure 1).

Table 2: Strength properties of the series vacuumpressing (VP) and hotpressing (HP) with and without fire retardants (fr)

Strength in N/mm²					
	VP without fr		**VP with fr**		**Reduction Factor**
	Mean	SD*	Mean	SD*	(%)
Tensile	311	15	230	17	-26.0
Compression	304	35	255	21	-16.1
Shear (in-plane)	50	0.6	48	0.7	-4.0
Flexural (23 °C)	651	64	549	65	-15.7
Flexural (90 °C)	392	36	222	42	-43.4
	HP without fr		**HP with fr**		**Reduction Factor**
	Mean	SD*	Mean	SD*	(%)
Tensile	284	29	251	12	-11.6
Compression	339	18	283	26	-16.5
Shear (in-plane)	48	1	47	1	-2.1
Flexural (23 °C)	725	76	572	18	-21.1
Flexural (90 °C)	497	58	223	7	-55.1

*SD= standard deviation

The shear strength (Table 2) and the shear modulus (Table 3), on the other hand, are matrix-dominated. These characteristic values are less influenced by the FVC. Instead, the mechanical properties of the matrix have a significant influence on these properties. Interestingly, the shear strength (-9.0 %) and the shear stiffness (+0.6 %) are only slightly or even positively influenced by the fire retardant. On the one hand, the larger cross-sectional area of the specimens with fire retardants should decrease the shear properties. On the other hand, the fire retardants seem to cause a stiffening effect.

Table 3: Modules of the series vacuumpressing (VP) and hotpressing (HP) with and without fire retardants (fr)

Modulus in N/mm²					
	VP without fr		**VP with fr**		**Reduction Factor**
	Mean	SD*	Mean	SD*	(%)
Tensile	17 400	636	15 400	745	-11.5
Compression	-	-	-	-	-
Shear (in-plane)	3 440	41	3 130	79	-9.0
Flexural (23 °C)	22 900	1 742	19 600	1 654	-14.4
Flexural (90 °C)	19 300	656	14 100	331	-26.9
	HP without fr		**HP with fr**		**Reduction Factor**
	Mean	SD*	Mean	SD*	(%)
Tensile	20 000	592	18 700	727	-6.5
Compression	-	-	-	-	-
Shear (in-plane)	3 180	77	3 200	54	0.6
Flexural (23 °C)	23 100	987	20 200	894	-12.6
Flexural (90 °C)	21 100	985	15 700	252	-25.2

*SD= standard deviation

The results show that the mechanical properties are strongly influenced by the manufacturing process. The compression of the prepreg layers and the evacuation of the air pockets in the early stages of curing are crucial. The compression force during vacuum processing is low compared to the hot pressing process. As a result of the low pressure, the flame retardant agglomerates between the reinforcing fibers inhibiting the resin flow in the direction of the laminate thickness (Figure 3).

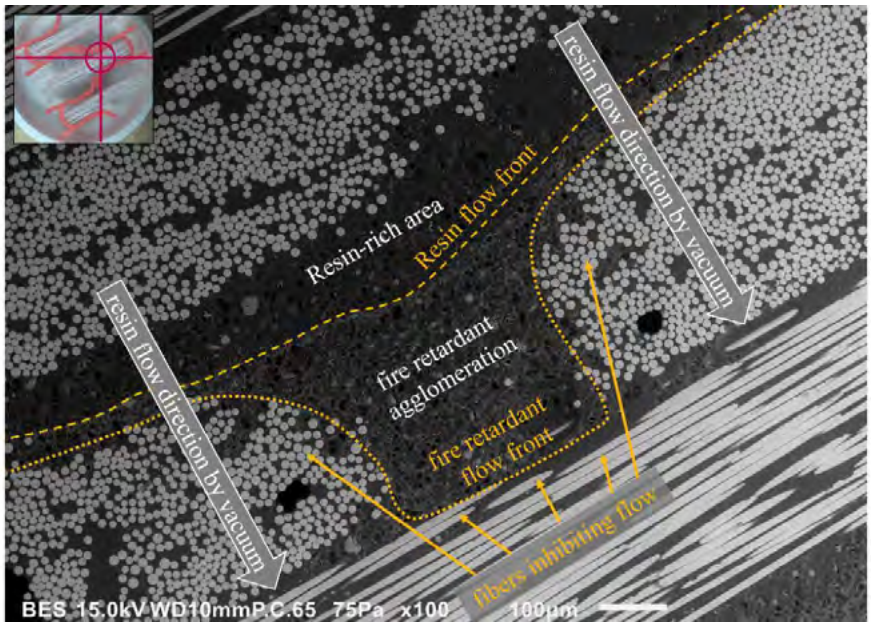

Figure 3: SEM image for the analysis of resin and flame retardant accumulations

In vacuum bag moulding, the presence of the flame retardant therefore leads to thicker laminates with lower FVC and lower cross-sectional properties. As a result, fiber-dominated properties such as tensile, compression and flexural properties are strongly influenced by the laminate thickness variations. In the hot pressing process, a strong resin flow in the laminate thickness direction is inherently excluded due to the mould. Instead, the resin flows out of the material along the prepreg layers, taking some flame retardant with it. The pressure is high enough that the laminate is compressed to the thickness of the spacers. As a result, the difference between the thickness and the FVC of the laminates with and without flame retardant is smaller impairing fiber-dominated characteristic values such as tensile strength and Young's modulus to a lesser extent.

4. Conclusion

The results of the quasi-static tests show that the mechanical properties are strongly influenced by the manufacturing process (Vacuum bag moulding / hot pressing technology) and the presence of the flame retardant. Based on a SEM image, it is shown that the combination of flame retardant and semi-finished fiber product restricts the resin flow if the compression force is too low. The fiber-dominated properties such as tensile, compression and flexural properties are negatively influenced by the variations in the restricted resin flow, the remaining laminate thickness and the fiber volume content. The situation is quite different for matrix-dominated characteristic values such as shear strength and shear modulus. The low decrease in strength and the slight increase in shear modulus indicate that the presence of the flame retardant could have a stiffening effect.
It can be concluded that the influence of the flame retardant cannot be generalised. Even though fire retardants lead to an increase in sample thickness and a decrease in fiber volume content not all strength and stiffness properties are impaired. Instead, the type of loading must always be taken into account. The negative influence of the flame retardant is greater for fiber-dominated characteristic values (tension, compression and felxual) than for matrix-dominated ones (shear). Accordingly, the reduction factor must be selected depending on the type of load.

Keywords: Polymer matrix composites (PMCs), Micro-scale simulation, Residual stress, Failure mechanism, Finite element analysis (FEA)

Abstract
The structure of carbon fiber resin matrix composites (CFRP) introduces residual stress (RS) due to the differences in the performance evolution of the constituent materials during the manufacturing process, which in turn affects their failure strength and mechanisms. In this study, the viscoelastic constitutive parameters of the resin curing process were obtained through experimental methods. Using micromechanical computational methods, this paper establishes a finite element (FE) model that combines RS with the representative volume element (RVE) at the microscale. The model simulates the distribution pattern of RS and the form of matrix crack propagation in 90° unidirectional laminates (UD), and calculates the failure results of the UD under typical loading conditions. The findings reveal that under the influence of RS, debonding between the fiber and the matrix occurs after the curing process is completed. Additionally, it was observed that the transverse tensile ultimate strength increased, the failure strain and ultimate strength in transverse compression slightly decreased, and the failure strain in longitudinal shear slightly increased while the ultimate strength remained almost unchanged. Hence, it is both significant and imperative to account for the effects of RS in the strength design of composite materials.

1. Introduction

The manufacturing of composite structures introduces residual stress (RS) that are not visible to the naked eye, and the presence of these RS can affect the mechanical properties of composite structures[1]. Excessive RS can cause initial delamination and matrix cracks, leading to damage before the structure is subjected to loading[2, 3]. RS typically impacts the failure strength of composites, and using micromechanical models can reveal the mechanisms by which RS causes structural damage[4]. Establishing micromechanical models for composites involves not only finite element geometric modeling but also the accurate characterization of the mechanical properties of each constituent material, including stiffness, strength, and failure processes.
Many researchers have achieved significant results in the field of micromechanical analysis of composites. For fibers, brittle failure is typically considered; for resin matrices, the Drucker-Prager (D-P) criterion is often used to describe the plasticity of pressure-sensitive materials[5–7], and the ductile

criterion is used to describe the damage process[8]. For the interface between the matrix and fibers, the traction-separation law is commonly used to describe the damage process[8,9]. These models can effectively describe the failure behavior at the microscale of composites.
Some researchers have also studied the impact of RS on the mechanical properties of composites. For example, Hui[8] used a linear elastic constitutive model to characterize the resin matrix, introduced RS, and investigated its effect on transverse tensile strength, finding that RS increases the transverse tensile strength of unidirectional laminates. Xu *et al.*[10] examined the mechanical response of unidirectional laminates under transverse compression with and without considering RS and discussed the effect of random fiber distribution on the results.
While these studies have explored the impact of RS, they lack precise introduction of RS and detailed discussion under various loading conditions. Therefore, this paper aims to address these aspects.

2. Methods

Considering that the longitudinal performance of unidirectional laminates is primarily governed by the fibers and that the magnitude of RS is relatively small, this paper focuses on discussing the impact of RS on the transverse mechanical properties of unidirectional laminates.

2.1. Experiment analysis

The subject of this study is the M40J/HT-280 high-modulus CFRP. To investigate the impact of RS on the transverse mechanical properties of unidirectional laminates, it is essential to first obtain an accurate distribution of RS in the micromechanical model. The fibers are assumed to undergo no chemical changes during the curing process, maintaining constant mechanical properties. The resin is modeled using a simplified viscoelastic constitutive model that accounts for stress relaxation, with specific parameters obtained through experimental methods.
The experiment conducted was Dynamic Mechanical Analysis (DMA) using the NETZSCH DMA 242 E dynamic mechanical analyzer, as shown in Figure 1.

Figure 1. NETZSCH DMA 242 E Dynamic mechanical analyzer

The coefficient of thermal expansion (CTE) of the resin varies slightly in different states during curing. However, studies indicate that the thermal expansion and contraction of uncured resin contribute minimally to RS. Therefore, only the CTE of the fully cured resin at different temperatures is tested, assuming that the CTE of the resin remains the same in different curing states. The experimental equipment used is the NETZSCH DIL 402C dilatometer.

2.2 Constitutive Model of the Material

To accurately simulate the impact of RS on the transverse performance of composite materials, it is essential to first determine the load-bearing and failure behaviors of the constituent materials, including the fibers, matrix, and fiber-matrix interface. Under transverse loading, the mechanical behavior of the fibers remains linear-elastic until overall failure. Therefore, the fibers are modeled as transversely isotropic linear elastic solids, characterized solely by their elastic parameters. The specific parameters for the fibers are listed in Table 1.

Table 1. M40J fiber paremeters[11]

E_{1f}/GPa	$E_{2f}=E_{3f}/GPa$	$\nu_{12f}=\nu_{13f}$	ν_{23f}	$G_{12f}=G_{13f}/GPa$	G_{23f}/GPa
356	16.2	0.212	0.266	10.2	6.4

The matrix constitutive model is defined as an isotropic elasto-plastic model, with the plastic behavior governed by the Drucker-Prager yield criterion.

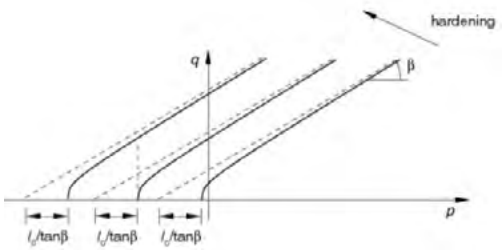

Figure 2. Hyperbolic Drucker-Prager yield criterion[12]

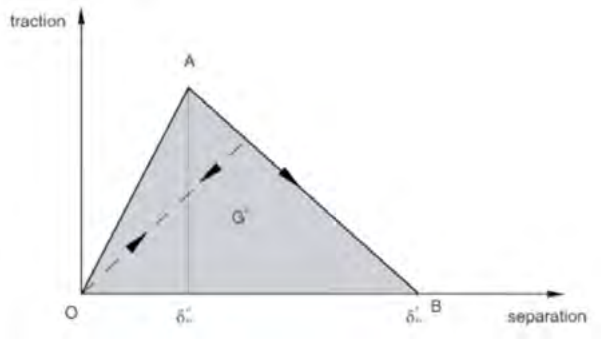
The initiation of damage in the resin matrix is determined using the Ductile criterion. The mechanical properties of the resin are presented in Table 2.

Table 2. Mechanical parameters of resin HT280[11]

E_m(GPa)	ν_m	σ_{mt}(MPa)	σ_{mc} (MPa)	$\beta(°)$	$p_t\|_0$ (MPa)	G_C $(\frac{J}{m^2})$
4.283	0.35	56	360	42.36	13.8	3

The interfacial mechanical behavior is characterized by the Cohesive model, which is effective in representing crack behavior, especially the mechanical behavior at the interface between two different materials. In this study, a bilinear traction-separation criterion, as illustrated in Figure 3, is employed. Prior to damage initiation, the mechanical behavior is linear elastic, with an initial stiffness denoted by K. In the post-damage stage, the evolution of damage is represented by stiffness degradation. The mechanical behavior in the pre-damage initiation stage is defined by the following equation:

$$\begin{Bmatrix} t_n \\ t_s \\ t_t \end{Bmatrix} = \begin{bmatrix} K_{nn} & & \\ & K_{ss} & \\ & & K_{tt} \end{bmatrix} \begin{Bmatrix} \delta_n \\ \delta_s \\ \delta_t \end{Bmatrix} \quad (1)$$



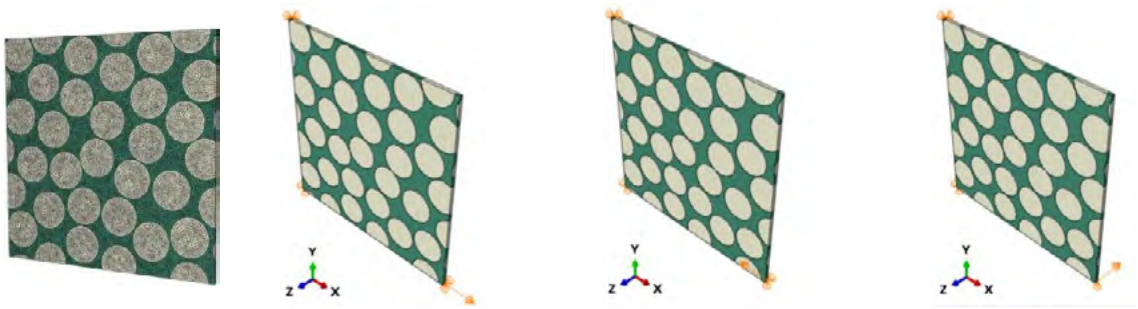


Figure 3. Law of traction-separation

2.3 Micro-scale FE simulation

The geometric model is consistent with the literature[11], as shown in Figure 4, and can be considered a representative volume element of a unidirectional plate. It contains a total of 30 fibers, with a fiber radius of 2.57 μm and a fiber volume fraction of 65%. Considering that the geometric shape along the fiber direction is generally consistent and has minimal impact on the results, the model's dimension along the fiber axis is set to one-tenth of the fiber diameter. The model consists of three parts: fibers, matrix, and fiber-matrix interface, where the fiber-matrix interface is represented by zero-thickness Cohesive elements. These parts are connected through Tie constraints to form a complete finite element model. Convergence analysis indicates that a mesh size of 0.3 μm yields accurate results while maintaining computational efficiency. Periodic boundary conditions are employed to ensure the continuity of stress at the boundaries of the representative volume element.
The loading conditions include three common forms: transverse tension, transverse compression, and longitudinal Shear. Due to the periodic boundary conditions, applying displacement loads at the master control point achieves uniform loading across the model. The boundary conditions are depicted in Figure 4. The mesh types for the fibers and matrix are C3D8R and C3D6R, respectively, while the mesh type for the fiber-matrix interface is COH3D8.

3. Result and Discussion

3.1 Experimental result

(a) DMA test main curve (b) Results of thermal expansion coefficient test

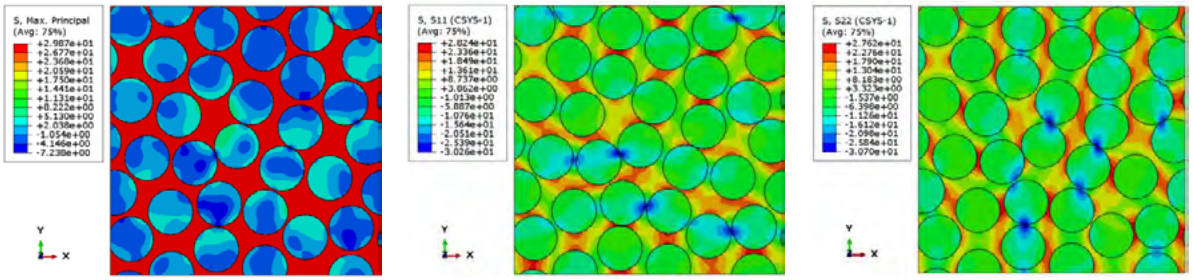

Figure 5. Experimental result

Based on the analysis and fitting of the DMA master curve results shown in Figure 5(a), the characteristic temperature T_c in the simplified constitutive model considering stress relaxation is determined to be 106°C. The test specimens are fully cured resin blocks, with the testing temperature range from room temperature to 250°C and a heating rate of 2°C/min. After processing the data, the results for the thermal expansion coefficient are shown in Figure 5(b).
It can be observed that the data exhibit some scatter but generally follow a nonlinear trend with temperature. A third-order polynomial function is used to fit the experimental results, and the resulting formula is:

$$\alpha_m = 2.62 \times 10^{-11} T^3 - 1.06 \times 10^{-8} T^2 + 1.30 \times 10^{-6} T^2 + 2.02 \times 10^{-5} \quad (2)$$

3.2 RS analysis and distribution results

The RS calculation results are shown in Figure 6. The maximum principal stress results are depicted in Figure 6(a). Due to the transverse thermal expansion coefficient of the fibers being smaller than that of the matrix, the matrix is generally in a tensile state, while the fibers are in a compressive state. The maximum residual principal stress in the matrix is approximately 29.9 MPa, while the maximum residual principal stress in the fibers is about 7.24 MPa.As shown in Figures 6(a), (b), and (c), within the in-plane transverse RS distribution of the laminate, significant tensile stress appears in the matrix near the top and bottom vertices of the fibers, and considerable compressive stress appears in the matrix near the left and right vertices of the fibers. Furthermore, smaller tensile stress is observed at locations farther from the left and right vertices.

(a) (b) (c)

Figure 6. Calculation results of RS in the microscopic model

3.3 Influence of RS on mechanical properties

The stress-strain curves for transverse tension, transverse compression, and longitudinal shear of the unidirectional plate, considering and not considering RS, are shown in Figure 7. It can be observed that

for tensile loading, the overall stiffness before damage is nearly identical in both cases. In the stage approaching the stress peak and near failure, overall nonlinear behavior appears. When considering RS, the overall failure strain significantly increases from 0.46% to 0.50%, and the strength also increases notably from 37.0 MPa to 39.7 MPa. For compression loading, nonlinearity occurs earlier. With RS taken into account, the overall failure strain markedly increases from 2.06% to 2.34%, and the strength also rises significantly from 182 MPa to 201 MPa. For shear loading considering RS, the overall failure strain increases significantly from 2.34% to 2.50%, and the strength slightly increases from 70.1 MPa to 72.0 MPa.

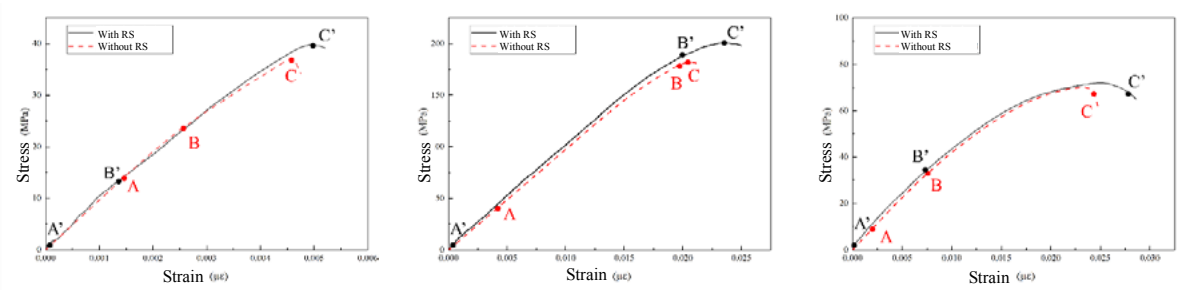

Figure 7. Stress-strain curve for unidirectional plate under typical loading

When RS is not considered, it is assumed that there is no RS distribution in the model at the beginning of loading. The progressive damage process is shown in Figure 8, with corresponding curve positions marked in Figure 7. The matrix damage locations are uniformly distributed near the equator of adjacent fibers, thus the initial location of interface damage determines the position of the overall fracture plane, propagating along the shortest path of matrix damage from the interface damage location. The initial location of interface damage also corresponds to the stress concentration positions at times A and B.

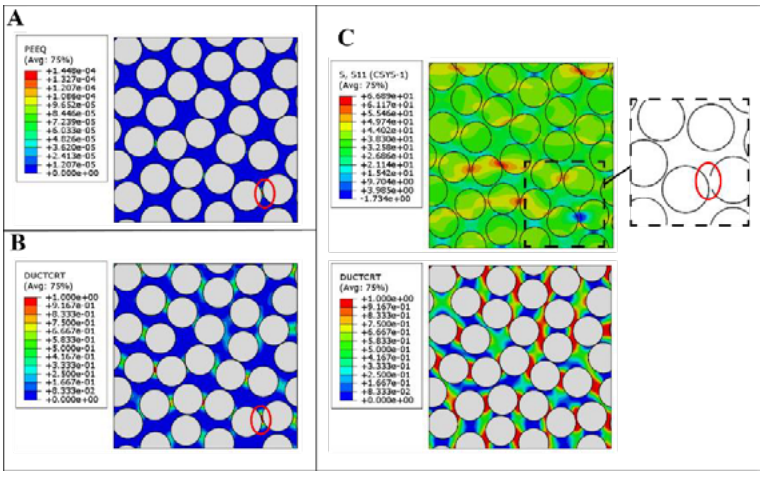

Figure 8. The progressive damage process without RS under tension load

When RS is considered, it is assumed that there is a RS distribution in the model at the beginning of loading. The progressive damage process is shown in Figure 9, with corresponding curve positions marked in Figure 7. At time A' (strain 0%, stress 0% σ_{max}), plastic deformation of the matrix occurs even before loading, indicating that RS itself induces plastic deformation in the matrix, causing it to

appear earlier. With further loading, at time B' (strain 0.14%, stress 4.44% σ_{max}), matrix damage occurs earlier compared to the case without RS. As loading continues, at time C' (strain 0.50%, stress 100% σ_{max}), interface damage appears and rapidly connects with matrix damage, forming a fracture crack perpendicular to the loading direction. Due to the presence of RS, most of the matrix is under tensile stress in the loading direction even before loading, causing significant nonlinear behavior in the overall mechanical response before time C'. Additionally, interface damage is delayed due to compressive RS, resulting in a larger strain at time C', increased overall strength, and a different location of interface damage, altering the final fracture plane position as shown in Figure 10.

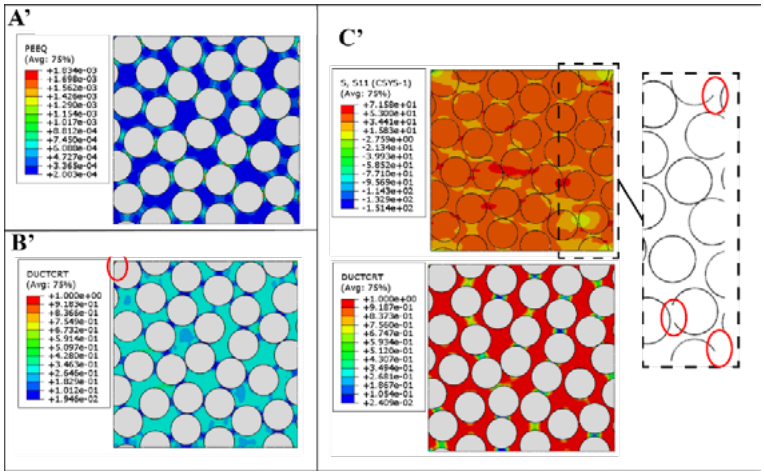

Figure 9. The progressive damage process with RS

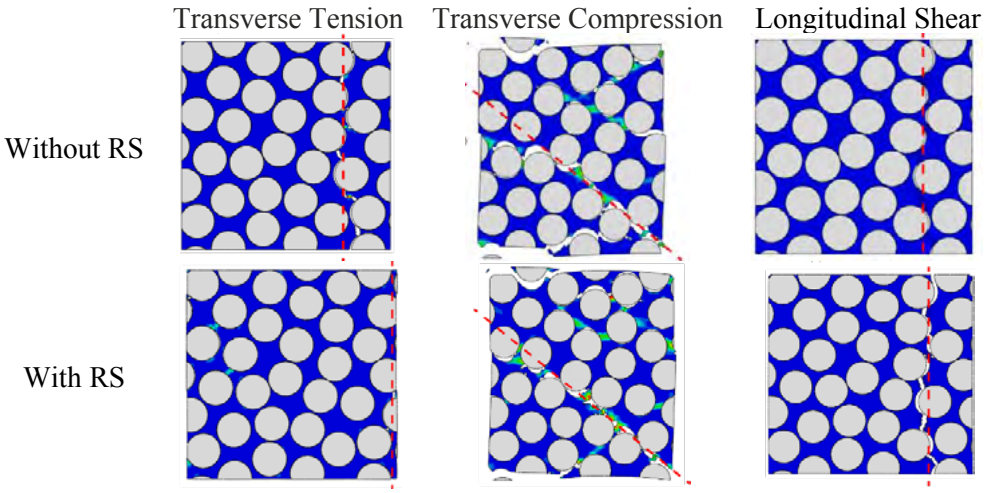

Figure 10. The progressive damage process with RS

In summary, for the transverse tensile performance of the unidirectional plate, the presence of RS leads to earlier plastic deformation and initial damage in the matrix, with changes in their locations. However, RS causes most of the matrix to enter a damaged state before overall fracture, resulting in nonlinear behavior and delaying the occurrence of interface damage. This increases the overall failure strain and ultimate strength. For compressive performance, the presence of RS essentially does not affect the occurrence of interface damage but delays the initial damage in the matrix. Consequently, this increases the overall failure strain and ultimate strength. For shear performance, RS delays the widespread occurrence of interface damage, which in turn delays the stress redistribution caused by interface

damage. This results in later matrix damage and increases the overall failure strain. However, since the overall unloading and fracture are primarily determined by the matrix, and RS does not have a shear component, the ultimate strength and the load level at the onset of fracture are not significantly affected.

4. Conclusions

This study discussed the viscoelastic constitutive parameters for simulating curing-induced RS in composite materials. By calculating microscale RS, the distribution pattern in 90° unidirectional plates is determined, and RS are integrated into the microscale model. The analysis under transverse tension, compression, and longitudinal shear loads reveals that RS increases the ultimate strength in transverse tension; slightly decreases the ultimate strain and strength in transverse compression; and slightly increases the ultimate strain in longitudinal shear, but has minimal impact on ultimate strength.

Keywords: eVTOL, Crashworthiness, CFRP Crash tubes, FEM, Testing

Abstract
This study examines the design, analysis, and validation of carbon fibre-reinforced polymer (CFRP) crash tubes for energy absorption in electric vertical take-off and landing (eVTOL) aircraft seats, aiming to optimize configurations for enhanced passenger safety. It incorporates static and dynamic testing of various CFRP tubes with differing diameters and layer orientations. Static tests focused on force-displacement characteristics, deriving crucial design parameters such as peak and plateau loads, and energy absorption. Dynamic tests, performed with a drop tower, mimicked eVTOL crash scenarios to observe tube behavior under realistic conditions. Results indicated that increasing unidirectional layers and tube diameter improves load capacity and energy absorption. Conversely, changing weave orientation from 0°/90° to ±45° reduces energy absorption, underscoring the significance of layup configuration. These insights facilitated the refinement of tube specifications to meet safety goals. Additionally, a finite element model (FEM) developed using the Altair Radioss solver validated the experimental findings, accurately capturing crash behavior and supporting design iterations with reduced physical testing needs. This study confirms that tailored CFRP crash tubes can significantly enhance eVTOL crashworthiness, with combined experimental and simulation approaches offering a robust iterative methodology for optimizing aviation safety systems and reducing the need for extensive material characterization.

1. Introduction

New urban air mobility (UAM) systems could be able to emerge the aviation market in the next three decades, as the needs to shorten travel times and to avoid traffic jams in mega cities are increasing. Based on a Roland Berger´s study [1], it is estimated that more than 160.000 flying vehicles will be part of our air transport ecosystem. Most of these aircrafts will use electric motors for propulsion to avoid CO2-emissions and will have vertical take-off and landing capabilities to enable point-to-point transportation. This creates a new aircraft class called electric vertical take-off and landing vehicles (eVTOL). The rapid increase of air traffic participants in an urban area would increase the risk of air accidents and adds new challenges regarding the crashworthiness of the aircraft and the safety of the passengers.

In order to protect the passengers, the kinetic energy of the aircraft during an accident should be absorbed. Part of the kinetic energy could be absorbed by the collapse of specific parts in the aircraft that are specially designed to absorb energy at constant load level, which would reduce the load

experienced by the aircraft occupants [2]. Examples of typical energy absorbing elements are sandwich components with aluminium honeycomb core or crash tubes made of aluminium or carbon composites (CFRP) [3]. In addition to the high specific strength and specific stiffness of carbon composite materials, CFRP crash tubes offer the flexibility to shape the crushing properties following the defined requirements, such as the absorbed energy, the peak load and the average crushing load, which could be adjusted by simply modifying the laminate layup and the diameter of the crash tube [4].

Energy absorbing systems (E/A) for passenger-seats are designed to absorb a part of the kinetic energy and to reduce the acceleration transmitted to the passengers. Different concepts for E/A-systems are possible. In this study, the results of an approach to design CFRP crash tubes for eVTOL-seats are presented. The design specifications were obtained from the CS-27 certification document for small VTOL aircrafts. CFRP crash tubes with different layups and diameters were manufactured. Afterwards they were crushed statically and impacted dynamically, in order to obtain the energy absorbing characteristics. A finite element model is then developed using the explicit dynamic solver in Radioss. The experimental dynamic results were used to validate the numerical model. The model can capture the damage occurrence and the load displacement reaction with high accuracy and small simulation effort. Finally, a suited crash tube design was obtained.

2. Materials und manufacturing

For the investigation of the energy absorbing properties of CFRP tubes ten different tube setups were manufactured. The first and the last layers of the tubes consist of carbon twill weave with areal weight of 200 g/m² (ECC Style 452). The layers in the middle are unidirectional carbon layers with an aerial weight of 329 g/m² (ECC eUD320CHT-A) oriented in the same direction as the tube main axis (loading direction). Both materials are obtained from C. Cramer & Co GmbH Germany. The epoxy resin Sika Biresin CR122 with the hardener Sika Biresin CR122-5 was used for the manufacturing. The impregnated carbon layers were manually winded over an aluminum tool with the desired diameter and then compacted with a shrinkable peel ply tape to improve the compaction of the CFRP tubes. The following features were modified: the tube diameter, the number of the UD-layers and the orientation of the inner and outer weave layers. The length of the tubes is the same (150 mm). In order to enable a proper damage initiation a 2x45° chamfer on one side of the tube (the side for load introduction) was created. A detailed overview of the investigated CFRP tubes is listed in Table 1.

Table 1. Manufactured CFRP-tubes for the static and dynamic tests

Specimen	Diameter (mm)	Number of UD-layers	Weave orientation (°)
01	20	2	0/90
02	20	3	0/90
03	20	4	0/90
04	25	2	0/90
05	25	3	0/90
06	25	4	0/90
07	25	3	+/-45
08	30	2	0/90
09	30	3	0/90
10	30	4	0/90

3. Static component testing

The crash tubes were simply supported in a test fixture that eliminate the transition of the supported edge in x- and y-direction. The loading in the cylinder axial direction was introduced at a deformation rate of 25 mm/min. The force-displacement diagrams were recorded and two specimens were tested for every crash tube configuration (see Figure 1). From the force-displacement diagrams three key parameters could be extracted that are relevant for the design of the E/A-system: the pick load, which is important for the damage initiation of the E/A-system, the plateau load that has a huge influence on the estimation of passenger injury and the absorbed energy, which gives an estimation about the required tube length.

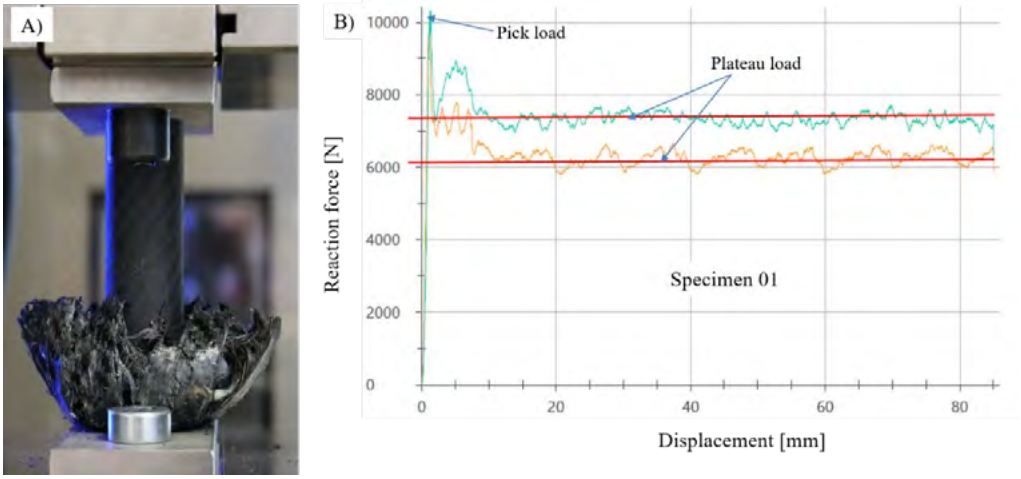

Figure 1. A) A CFRP-tube under static load; B) Force-displacement of CFRP-Tube Nr. 01

The assessment of the results depicted in Figure 2 shows that the increase of the UD-layers and the tube diameter would increase the plateau load, the pick load and the amount of absorbed energy. Changing the orientation of the weave layers from 0°/90° to ±45° led however to the reduction of the energy absorption and the load level. In order to choose the right crash tube, the CFRP tube should absorb the defined kinetic energy within the available length and the load levels should not exceed or deceed the specified values to avoid injuries or early activation of the E/A system. With the static test, a predesign could be defined. However, dynamic impact tests are mandatory for the final design as the structure response may change under dynamic loads.

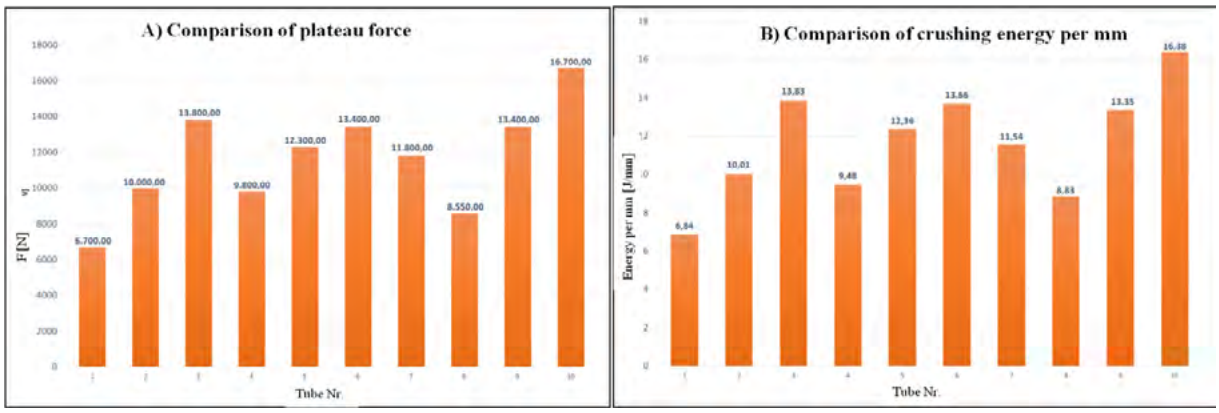

Figure 2. A) Comparison of plateau force; B) Comparison of crushing energy per crushed mm

4. Dynamic component testing

The tests under dynamic loads were carried out using a drop tower test bench with a guided sled. Figure 3 shows the test setup with all its components.

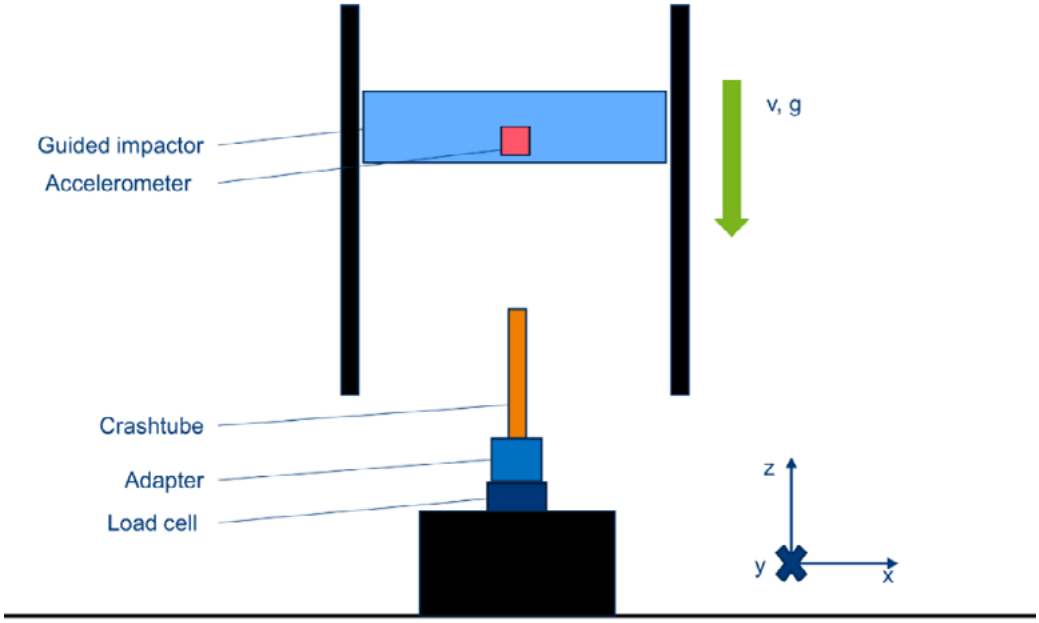

Figure 3. Drop tower setup for dynamic tests.

During each test three measurement data sets with frequency of 10,000 1/s were taken. First of all, the force under the crash tube was measured using a uniaxial load cell. To achieve certain redundancy and to check the plausibility of the measured force. The acceleration of the impactor was also documented. Furthermore, a laser distance sensor was used to measure the deformation of the specimens. To document and analyse optically the crash behaviour of the tested crash tubes, high-speed videos of each experiment were also taken with frequency of 2000 frames per second (fps).

The boundary conditions of the performed tests were established based on requirements defined in the document CS-27 regarding the emergency landing scenarios and the E/A systems. In the considered test constellation, the generated kinetic energy should be set to approximately 1200 J for a single crash tube. This assumption was formulated based on the considered seat design in the project and is not necessarily valid for other scenarios.

In order to achieve the required amount of kinetic energy, an adjustment of two parameters, which are offered by the drop tower test bench, can be made. Consequently, the impactor's velocity was set to 7.9 m/s and its weight was determined to be 40 kg. That corresponds with the calculated vertical velocity vector regarding the specifics of the dynamic landing conditions and with 50% of the mass of a 77 kg passenger with a 3 kg seat structure. The mass of the impactor was reduced by 50% intentionally because of the application of two energy absorbing crash tubes in the seat structure.

Table 2 shows all the results that have been obtained in this test series. Specimen 01 was not able to absorb the generated kinetic energy, which led to a total damage of the crash tube. Therefore, the results of specimen 01 are not conclusive and not shown in the following table.

Table 2. Results of dynamic tests on CFRP-tubes

Specimen	Peak Force [kN]	Plateau Force [kN]	Deformation [mm]
01	-	-	-
02	17.96	13.00	99
03	19.30	17.00	96
04	17.98	12.50	101
05	17.90	14.50	98
06	21.97	19.70	71
07	20.71	17.00	87
08	17.44	14.50	96
09	22.22	17.90	73
10	26.19	22.50	68

The results show that the flexibility of the layup has an extensive advantage regarding the design of the E/A-system. Adjustment of its properties can lead to an optimal solution for various use cases. The influence of the orientation of the weave has also proved a usable potential in terms of increasing forces and decreasing deformations if needed.

In two additional tests that are not listed in Table 2, the weight of the impactor was reduced from 40 kg to 25 kg to simulate the interaction of a smaller passenger (e.g., 5% female ATD) with the E/A-system. Figure 4 shows a comparison of force-displacement-curves between two tests. Both tests were carried out on the specimens with the same geometry and laminate layup and the same boundary conditions except for the impactor mass. Diagram a) correlates with the impactor mass of 40 kg, while diagram b) refers to the impactor mass of 25 kg. The speed of impact was set in both cases to 7.9 m/s.

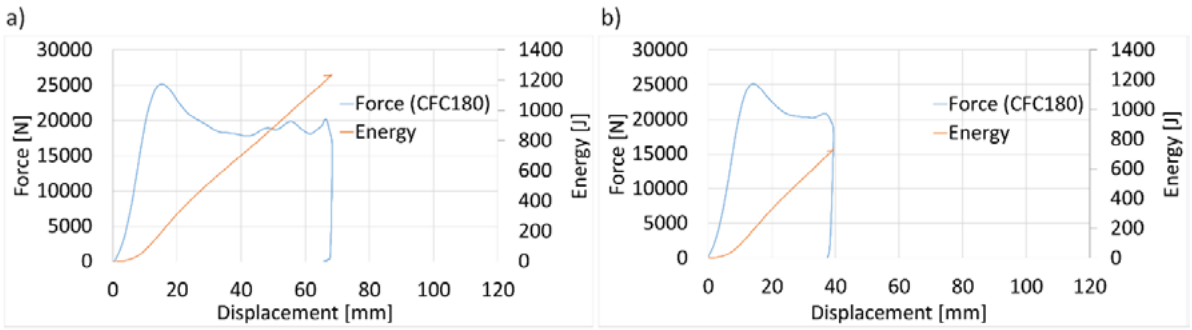

Figure 4. Test results of specimen 10 (force, displacement and energy) with impact velocity of 7.9 m/s and a) 40 kg and b) 25 kg fall weight.

The reduction of the impactor mass has no influence on the characteristics of the initial energy absorption. The peak force and the plateau force stay on the same level. Only the deformation was proved to vary due to the lower kinetic energy generated by the lighter impactor and absorbed by the crash tube.

5. FE Models of CFRP Crash Tubes

This study uses the finite element method (FEM) to analyse the process of energy absorption of CFRP crash tubes with the purpose of determining their optimal geometry while taking into consideration parameters as material, laminate layup, available space in the seat for installation and all restrictions and requirements defined by European Union Aviation Safety Agency (EASA) in CS-27 regulation

regarding velocity and weight of occupant. The explicit solver that was used for this study is Altair Radioss.

Because of complexity of the seat structure, the energy and the loads that occur in the case of a crash spread over many of its parts. It is an important fact regarding the initial load that causes the activation of the E/A-system. It must not be extensively high in order to avoid injuries of occupants but on the other hand, it must not be too low in order to avoid random activation without a crash. Furthermore, the desired energy absorption depends on the loads that affect the E/A-system. A FE model of the whole seat system with a seatbelt and an 50% anthropomorphic test device (ATD) with its weight of 77 kg was created in order to establish the actual initial load and the further loads that occur in the E/A-system under the dynamic landing conditions described in CS-27. Furthermore, using those loads and the maximum available space for the E/A-system in the seat structure, the desired energy absorption by the E/A-system was determined. Based on this data, a FEM model of a crash tube was developed to determine the best geometry and laminate layup.

The length and the diameter of the tube must not exceed 150 mm and 30 mm respectively, because the available space in the seat structure is limited. To determine the optimal constellation of tube diameter and number of unidirectional layers, those two parameters were successively adjusted in the simulation. Furthermore, the weave orientation was examined using values of +/-45° and 0°/90°. As a result, after performing sufficient number of simulations, the most promising variants of crash tube geometry and its laminate layup were defined with regard to the requirements and the specification of the considered seat system. The weave orientation in nine of ten variants is +/-45°, which led to promising results. In spite of that, one variant with diameter of 25 mm and 3 unidirectional layers has weave with orientation of 0°/90°, which also delivered acceptable results and was pursued to examine the influence of this parameter more closely using results from real tests.

Figure 5 shows the FE model of a crash tube, its boundary conditions, and its dimensions. In this example, the diameter is 30 mm and the following laminate layup is shown: 0°/90° weave – three unidirectional layers – 0°/90° weave.

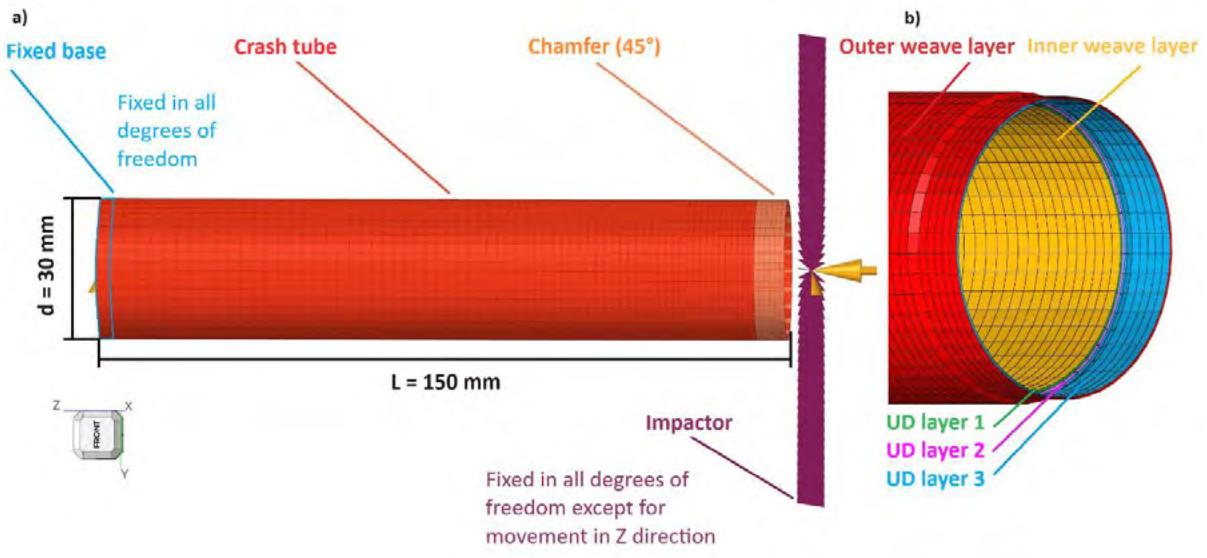

Figure 5. a) FE model of a crash tube with applied boundary conditions and its dimensions displayed; b) Stacking of the laminate

In Figure 5 b) a 45° chamfer of the crash tube on its top is also displayed. The purpose of this chamfer is to reduce the initial load that occurs to initiate the first stage of the desired damage process. This

feature was also taken into account in the manufacturing process of the crash tubes. All ten variants that were considered in the FE analysis are presented in Table 1.

Figure 6 shows an optical comparison between the FE simulation and the dynamic drop tower test regarding the specimen Nr. 10 with four UD layers and 30 mm of diameter.

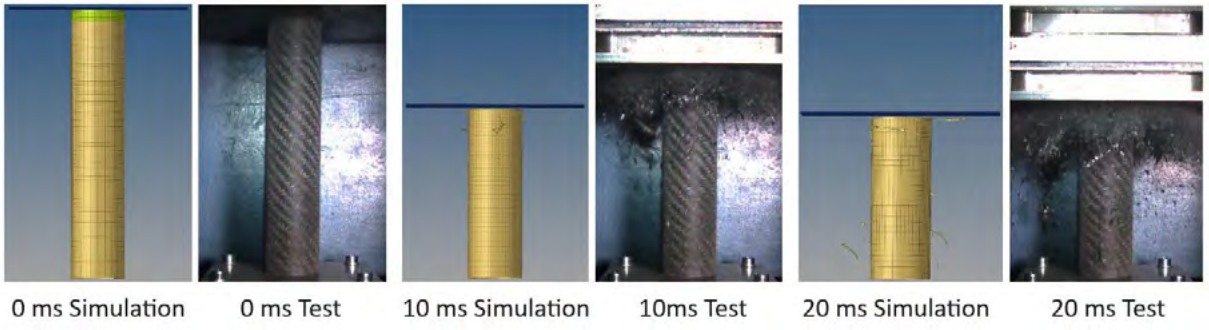

Figure 6. Optical comparison between the results of a dynamic test and the simulation (specimen 10)

The simulation based exclusively on material parameters obtained from material tests delivered satisfying results compared to the real tests. That can be also seen in Figure 7 that presents a comparison regarding the force and the kinetic energy absorbed by the specimen 10. After a validation process a very realistic FE model of the energy absorbing structure in form of a crash tube was created, which will be used for further analysis in order to establish an optimal geometry and composite layup using a model of the whole seat-dummy-system, which addresses all relevant injury criteria e.g., the lumbar load and the energy absorption potential of the other components of the seat.

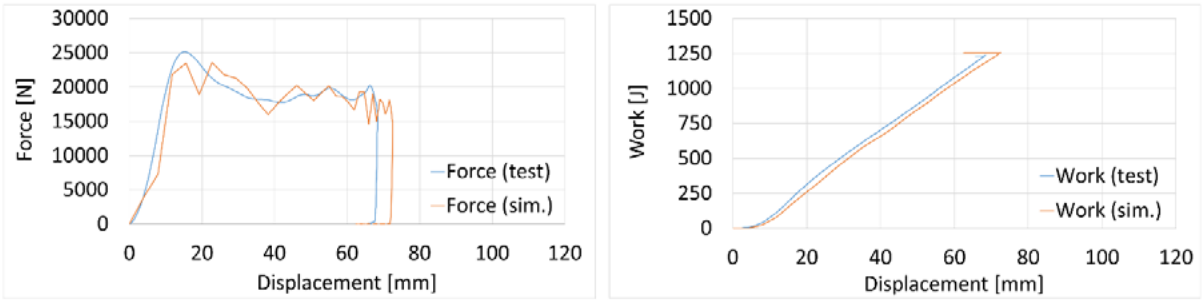

Figure 7. Comparison of force-displacement and work: dynamic test vs. simulation

6. Conclusions

In this work, it was possible to compare the dynamic tests results with the static ones and identify how we can use the static results to define a first layout of the crash tube. This would reduce the number of dynamic tests and the simulation effort. The results shows that the energy absorption and the load levels under dynamic loads are slightly higher compared to the static result. That means using the static results would lead to a conservative design of the E/A system.

The numerical simulation could be used to increase the efficiency of the crash tube design and reduce the number of dynamic tests, as they are more expensive. It is important to note, that when designing an E/A system for an aircraft seat, a huge amount of the kinetic energy will be absorbed by the seat structure and the occupant, so that design should be verified with the simulation of the whole system.

An FE analysis with the whole seat-dummy-system was done in this study and showed that in the crash scenario defined by EASA only 30 % of the kinetic energy that is generated with the whole system

including ATD under dynamic landing conditions can be absorbed by the E/A-system. The rest is absorbed by the other system components. Simulating only the crash tube would not be enough to achieve a robust design. Therefor the design of the E/A crash tubes must be adjusted by verification loops with the system (seat + ATD) model.

Keywords: Anodizing, Additive Manufacturing (AM), AlSi10Mg, Adhesive joint, Fiber reinforced composite

Abstract
In this work, an innovative joint between the aluminium alloy (AlSi10Mg) manufactured trough Additive Manufacturing (AM) and basalt fabric-reinforced epoxy composite substrates was evaluated through modifications of the surface morphology. Macroscopic arrow-shaped pins were printed on the AM surface. Then, a sulfuric acid anodizing (SAA) technique was applied to enhance the metal to composite adhesion and corrosion resistance of the metallic substrate. Scanning electron microscopy (SEM) and electrochemical impedance spectroscopy (EIS) were evaluated to study the nanoscopic morphology on the treated surface of the pins and to assess how the corrosion resistance changes with anodising. A single-lap shear test was performed to investigate the influence of anodising on the macroscopic mechanical performance of the joint. SEM images and EIS measurements show that anodising in SAA generates a porous layer of aluminium oxide that increases corrosion resistance. Single-lap shear tests revealed no change in mechanical performance after anodizing. This is likely due to the pin's shape, which promotes failure within the composite substrate's interlayer instead of at the metal-composite interface.

1. Introduction

Nowadays, the demand for more efficient materials in terms of sustainability leads the industry to confront new challenges. Lightness is a key point in terms of fuel consumption in a moving structure. In this context, composite materials have played an important role in the last decades, ensuring high mechanical performance with low weight. However, it is difficult to create a complex object with a single material. For this reason, it is necessary to couple materials of different nature. Historically,

metals rule in every industrial sector as useful material, but their processing presents certain difficulties when the geometry is very complex. Today, thanks to the additive manufacturing (AM) this problem has been overcome. Indeed, the shape is no longer an issue as the material is created layer by layer [1–4]. Currently, different metal AM processes are available on the market and Powder Bed Fusion-Laser Beam (PBF-LB) is certainly among the most used ones. In the latter, metal is deposited in powder form and melted by a laser, layer by layer, creating the shape designed before printing. Through this technique, it is possible to create several metallic parts having mechanical properties close to those obtained with the conventional processes. AlSi10Mg is a common aluminium alloy powder for AM. Many papers on its application can be found in the literature [5–7]. Compared to the conventional process PBF-LB is the most used thanks to its potentialities and flexibility that allow parts to be produced sustainably and with enhanced properties. However, anisotropy, porosity, residual stress, and other defects are some of the disadvantages of the applications of this material [8]. These defects could be overcome by means of post-processing technique. A challenge that has not been answered yet is the possibility of reducing the high surface roughness after processing when the geometry is very complex. For example, Scherillo [9] developed a two-step chemical etching, consisting of so-called chemical machining (CM) and chemical brightening (CB). In this work, CM step is useful for removing irregularities from the surface of the component, while the CB process smooth the surface, without any change in chemical composition of the AlSi10Mg alloy.

Surface roughness is crucial in the context of the coupling of different materials through adhesive joints. Nowadays, the ability to combine polymeric-reinforced composites to additively manufactured metals, opens up a new way of realising structures, creating new possibilities for complex shape with high performance and lightness. Based on this, process engineering can be considered as the fine-tuning of the metal surface so that it best fits at the interface with the composite. Traditionally, there are different ways to improve the surface between two different materials. From the metals point of view, mechanical treatment with sandblasting or sandpaper is the simplest one but it is not so effective to increase the mechanical properties and, at the same time, to protect the joined component from the surrounding aggressive environments during its service life. In the latter case, chemical treatment by using coupling agents or anodizing can be considered more suitable approaches [10,11].

Anodizing technique on AM AlSi10Mg is a challenge today due to the non-uniformity of the chemical composition with the presence of silicon. Revilla et al. [12,13] examined how Al-Si alloys, manufactured through the PBF-LB method, behave during anodization. They found that the silicon particles underwent complete oxidation because of their exceptionally small size in comparison to those in cast alloys of identical chemical makeup. Consequently, a substantial portion of the anodic charge was utilized during anodization, leading to a notably slower growth rate of the anodic layer in the PBF-LB samples compared to the cast alloy.

In addition to chemical or electrochemical technique, with AM, the fine-tuning of the surface could take place through the creation of a complex macroscopic texture to increase the bond with the adhesive. For example, Zou et al. [14] create a surface structure printed on a titanium alloy. They demonstrated that the AM structure with diamond or honeycomb shapes increase the mechanical interlock with ultra-high molecular weight polyethylene (UHMWPE). Furthermore, they pointed out that the structure complexity and the defects in additive manufacturing should be considered when designing the surface structure. In fact, a simpler structure such as honeycomb instead of diamond, generated better filling efficiency and stability.

The aim of this work is to create a joint between epoxy reinforced composite with basalt fabrics and AM AlSi10Mg substrates. A fine-tuning of the surface of the metal substrate was carried out through the creation of macroscopic arrow-shaped pins to evaluate their influence on the performance of the joint. In addition, the aluminium surface was electrochemically treated to improve adhesion and corrosion resistance of the AM substrate. The anodising technique was evaluated by studying its feasibility due to the high surface roughness of the AM metal and its composition.

2. Experimental

2.1. Materials

Commercially available AlSi10Mg spherical powder, with particle sizes ranging from 25 µm to 65 µm, supplied by EOS GmbH (Krailing, Germany), was used to create the metal substrates of the joints. The powder was processed by EOS GmbH system with the following process parameters:

- Layer thickness: 30 µm
- Laser spot size: 100 µm
- Scanning speed: 800 mm/s
- Laser power: 195 W
- Hatch distance: 0.17 mm
- Scanning strategy: Stripes 67°
- Platform temperature: 100 °C

The AlSi10Mg substrates were then subjected to a stress relieving heat treatment at 310 °C for 1 hour followed by furnace cooling. The substrates were then removed from the build plate using Electrical Discharge Machining.
Geometrical dimension of the final substrate was 80 mm long, 25 mm wide and 3 mm thick.
Furthermore, samples had macroscopic pins in an area of 25x25 mm, with 15 pins for each edge, i.e., a total amount of 225 pins in the area. The geometry of the pin is showed in Figure 1.

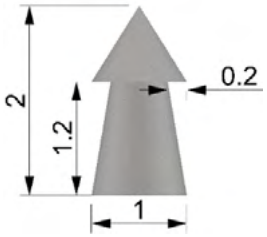

Figure 1. Geometry detail in mm of a single pin printed on the surface of AlSi10Mg substrate.

On the other hand, the polymeric composite was produced with a lay-up of 18 layer of silanized basalt fabric 220 g/m^2 with (3-Aminopropyl)trimethoxysilane and an epoxy matrix supplied by R*Concept with a commercial name of Polar. This resin is a bio-based epoxy with a bio-content higher than 28% and recyclable. The chemical recyclability works thanks to the nature of the curing agent which is a “cleavable” amine, that can open the cross-link if the composite is immersed in a mild acid solution. After the recycling process, it is possible to recover entirely the reinforcement because the epoxy matrix became a thermoplastic material that precipitate in the solution.

2.2. Surface treatments on AlSi10Mg substrate

Electrochemical technique of anodising was used in this work to enhance the interlocking between aluminium alloy surface and polymeric composite and its corrosion resistance. An aqueous stirred solution of sulfuric acid (H_2SO_4) 3M was employed as electrolyte in a cell composed by a galvanostat, an aluminium counter electrode and the sample dipped in the solution. Current density of 10 mA/cm^2 was imposed for 20 minutes, hence the process was carried out galvanostatically. The growth curve of the porous oxide layer, V vs time, is plotted in Figure 2. In the following, this treatment is named SAA.

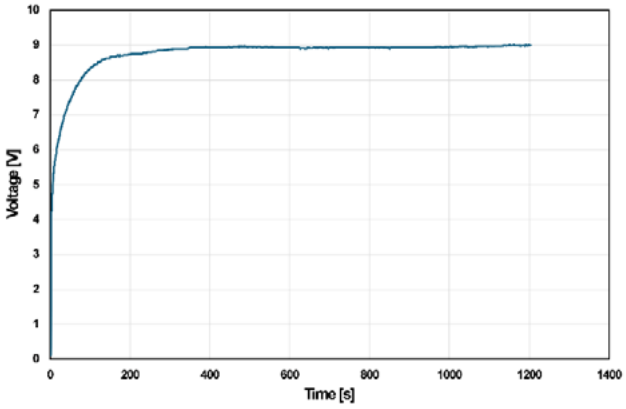

Figure 2. Growth curve of SAA samples with pins.

2.3. Manufacturing of the joint

Single lap co-cured joints were manufactured by vacuum infusion process. Five metallic substrates were placed in a plain mould and the dry basalt fabrics were then laid out over them in the overlapping area (25x25 mm) and in a vacuum bag. Subsequently, the epoxy resin was infused due to the pressure difference between the vacuum bag and the exterior. The curing process proceeded for 24 hours at room temperature and under vacuum. Then, the samples were post-cured in oven at 100 °C for 3 hours. Finally, single lap samples were cut with a rotative blade Bosch GCM 800 SJ. The final geometry of the samples is showed in Figure 3.

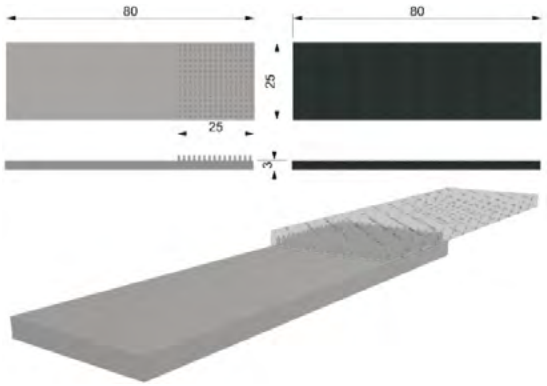

Figure 3. Geometry detail of the single lap configuration in mm. The transparency of the composite substrate in the draw is simply used to highlight interlocking with Pins.

The following nomenclature was used to identify the specimens: PIN-AP, PIN-AN. The acronym AP is referred to “As Printed”, meaning the samples have not received any treatment. AN refers to “ANodized”, i.e., the AP specimens that undergo the anodizing process in SAA.

2.4. Morphological characterization and corrosion resistance measurements

The structure of the porous layer formed through the anodization process was examined using a scanning electron microscope (SEM) model Tescan S900G. Microstructural differences between PIN-AP and PIN-AN samples were investigated by comparing their morphologies after the electrochemical process. The corrosion resistance of the samples was measured by electrochemical impedance spectroscopy (EIS). The samples were immersed in a 3.5% NaCl solution and connected to a Parstat 2273 potentiostat in a three-electrode configuration consisting of the sample, a platinum counter and an Ag/AgCl reference. The open circuit potential (OCP) was measured in the cell for 30 minutes. Subsequently, the

EIS measurement was performed by imposing a sinusoidal potential with an amplitude of ±10 mV referred to the OCP value, varying the frequency from 100 kHz to 100 mHz.

2.5. Lap-shear test

Five single lap samples for each type were tested with the geometry exposed in Figure 3. Universal testing machine Wance ETM-C equipped with a 50kN load cell was employed. The crosshead speed was set as 1.27 mm/min. The maximus force in kN was compared between the samples. The lap-shear strength in MPa was not evaluated due to the 3D shape of the joint surface.

3. Results and discussions

3.1. Comparison of AM surfaces

SEM images were useful to evaluate the morphology of the AM surface with the pins and how the anodization process change it during the process. In Figure 4 are exposed all the detailed shape of the metal surface.

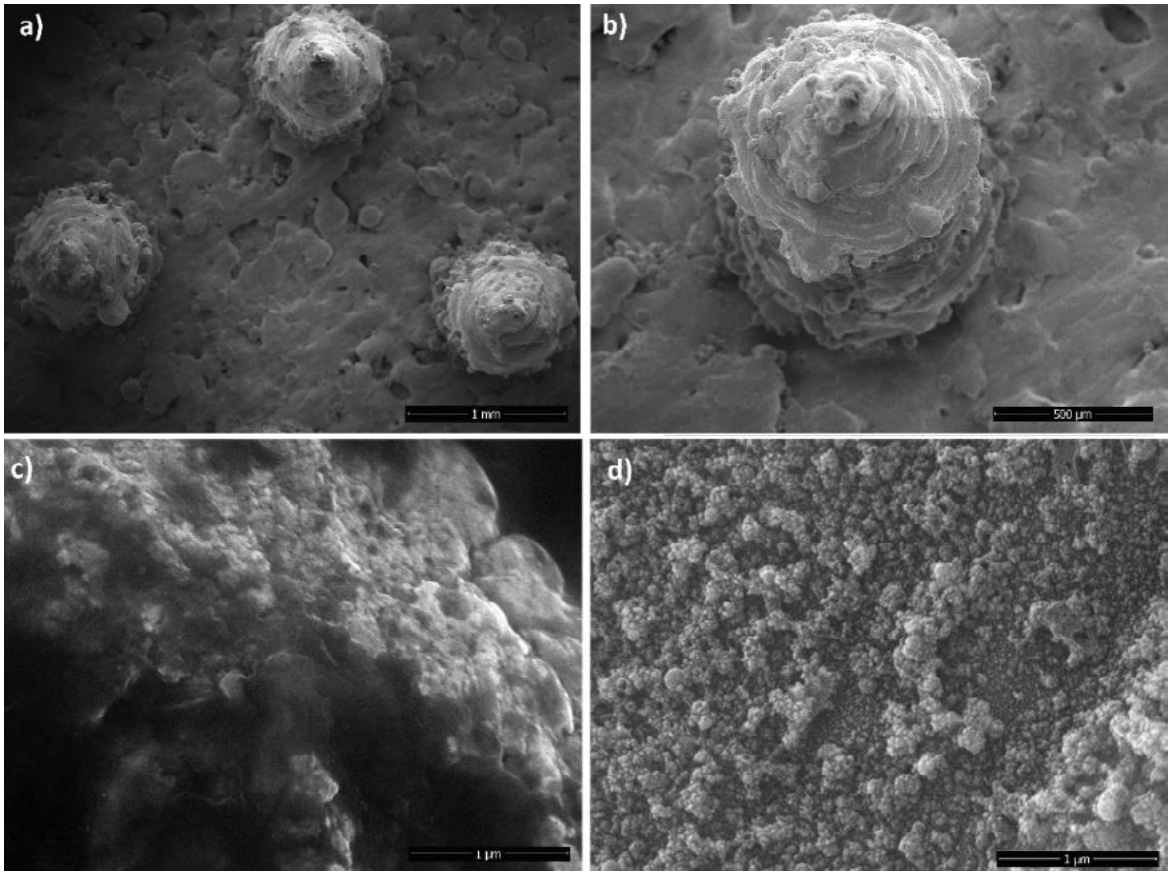

Figure 4. a) PIN-AP at low magnification; b) PIN-AP details of the single pin; c) surface morphology of the pin edge of PIN-AP at 100kX magnification; d) surface morphology of the pin edge of PIN-AN at 100kX magnification.

In Figure 4a and b it can be seen that the macroscopic morphology of the samples is very discontinuous and rough, especially the surface of the individual pin, due to the difficulty of stacking the powder layer by layer in such small parts. Moving to high magnification, in Figure 4c, it can be noted that the surface of the pin edge is rough but uniform, with no differences between the silicon and aluminium parts, due to the very fine silicon powders in the mixture. In contrast, after anodising (Figure 4d) it is possible to

observe the brighter part that is the silicon structure and the darker part that is the porous alumina layer. In this case, unlike cast aluminium structures, anodising, through the oxidation of silicon, which requires a lot of current generating a thinner layer of alumina, creates this porous layer surrounded by silicon.

3.2. Corrosion resistance of the AM samples

EIS measurements are useful to generate the Nyquist diagram where the impedance of the system was plotted with its imaginary and real part normalized by the area immersed in the solution. The curves in the graph are semi-circle where the diameter is the polarization resistance. This value is strictly correlated to the resistance against the corrosion current. The greater the polarisation resistance, the larger the semicircle size, the greater the corrosion resistance of the samples. In Figure 5 PIN-AP and PIN AN are exposed in the Nyquist diagram.

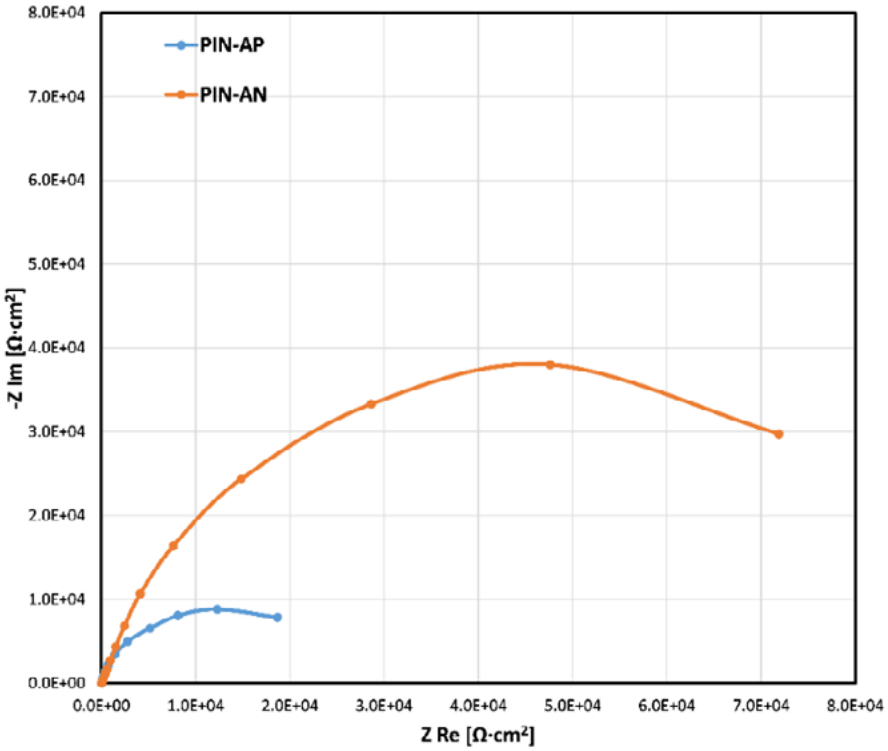

Figure 5. Nyquist diagram for PIN-AP and PIN-AN evaluating the corrosion resistance.

As can be seen in Figure 5, the PIN-AN curve is four times larger than that of PIN-AP. This is related to the effective growth of the anodic porous layer on the metal surface after the anodising process. The difference is not very large due to the presence of silicon structures, as mentioned in the previous paragraph. The anodising current is partly consumed by the anodising of the silicon rather than the formation of the porous alumina layer, resulting in a thinner and therefore less protective porous layer against corrosion. However, although thin, the porous alumina layer exists and because of it, the corrosion resistance of PIN-AN is greater than that of PIN-AN.

3.3. Single lap shear results

The results of the single lap shear test are shown in Figure 6.

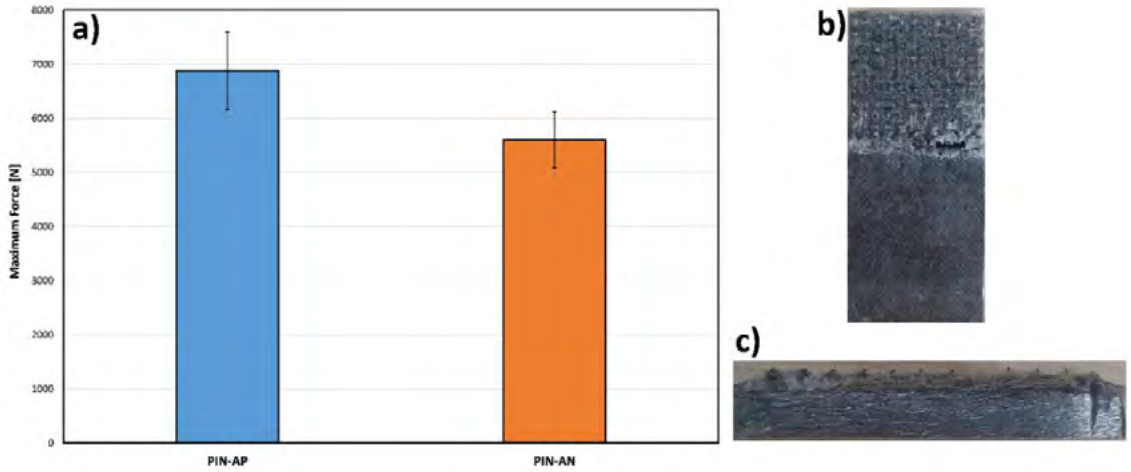

Figure 6. a) Maximus force in the single lap tests for the samples; b) top view of the fracture surface of PIN-AN; c) lateral view of the fracture surface of PIN-AN.

By means of single lap shear tests, it is not possible to highlight the influence of anodising on the mechanical performance of joints. This is due to the failure mode visible in Figure 6b and c. The presence of 2 mm high pins within a 3 mm thick composite generates a fracture between the composite layers. This phenomenon is clearly visible by observing the section of the fracture surface (Figure 6c). Here, the top of the pins is visible, indicating that the layer that has collapsed is the one between the top of the pins. For this reason, the achieved value of the maximum force represents the mechanical resistance of the composite layer against the crack propagation within the layer generated by the presence of the pins. In this case, the effect of the nano-porous layer is not macroscopically observable and the decrease shown in Figure 6a cannot be related to the anodizing process, but rather to the variability of the resistance in the inter-layer of the composite substrate.

4. Conclusions

In this work, the effect of the anodising technique on an aluminium AM (AlSi10Mg) substrate with macroscopic pins was evaluated by bonding it to an epoxy matrix reinforced with basalt fabrics in a co-cured single-lap joint configuration. The surface morphological structures were evaluated through SEM observations. In addition, the corrosion resistance of the specimens was estimated with EIS measurements. Finally, single-lap tests were conducted to highlight the influence of anodising on the AM metallic surface. The results showed that the presence of the porous anodic layer is confirmed by SEM images through the change in morphology. In addition, a silicon structure is visible that generates a negative interference in the formation of the anodic porous layer. However, the EIS results with the Nyquist diagram showed that the corrosion resistance of the PIN-AN sample is four times higher than that of PIN-AP, meaning that the porous layer exists and is efficient against the corrosion current. Due to the size of the pins, the mechanical testing couldn't detect any influence of the presence of the anodic layer. In conclusion, despite the irregularity and roughness of the AM substrate, anodising in SAA creates a porous alumina layer that can increase the corrosion resistance of AM samples. Probably by changing the size of the pins, avoiding the interlayer failure, the effect of the presence of the pins could also be assessed in the mechanical strength, since the porous layer was formed correctly.

Keywords: CFRP, Water absorption, Cellulose Nanofibers, Impact Energy

Abstract
The objective of this study was to clarify the effect of water absorption under high temperature and pressure conditions on the impact energy of cellulose nanofiber (CNF)-added CFRP. In this study, the water absorption rate was measured by adjusting the pressure, CNF additive rate, and water absorption time, and the changes in water absorption were compared. Izod impact tests were also conducted to evaluate the effect of water absorption under high temperature and pressure conditions on the impact properties of CNF-added CFRP. The results showed that the water absorption rate of CFRP without CNF and CFRP with CNF tended to increase with the water absorption time and then saturated at a certain value. The water absorption rate and impact energy tended to increase as the pressure during water absorption increased, and as the CNF addition rate increased, the water absorption and impact energy increased compared to the condition without CNF. It is suggested that in contrast to hydrophobic CFRP, water absorption in CFRP may be enhanced by the addition of hydrophilic CNF. The results indicate that the addition of CNF to CFRP, under high-temperature and high-pressure conditions, improves impact energy compared to CFRP without CNF.

1. Introduction

Carbon fiber reinforced plastics (CFRP) are used in a wide range of fields such as automotive and aerospace industries due to their high specific strength. However, it is known that polymeric materials are easily affected by water when used in harsh environments such as high temperature and high humidity, and the mechanical properties of CFRP are also significantly affected by these environmental factors. Katougi et al. investigated the flexural strength of CFRP that had absorbed water in a high-temperature environment and reported that water absorption reduced the flexural strength of CFRP by 2.3% [1]. On the other hand, since CFRP used in these fields requires high impact resistance, studies on water absorption of CFRP have been conducted to improve impact resistance. Hironaka et al. reported that long-term water absorption of CFRP improved the impact value by up to 8% compared to the value before water absorption [2]. Therefore, it is expected that the impact resistance of CFRP can be improved by increasing its water absorption. Therefore, in this study, we focused on water absorption under high temperature and pressure conditions.

In recent years, research has been conducted to improve the mechanical properties of CFRP by adding nano-sized or micro-sized fibers to the base material of CFRP [3]. Various fibers such as sub-micron glass fibers [4] and carbon nanotubes [5] have been used as additives. Among them, cellulose nanofibers (CNFs) derived from plants have attracted much attention because of their low environmental impact. Hayashi et al. reported that the addition of CNF to CFRP improved the flexural properties and interfacial

bond strength [6]. Nomura et al. also showed that the addition of CNF improved the vibration damping properties of CFRP. Therefore, the addition of CNF is expected to improve the impact strength of CFRP [7]. However, the effect of water absorption under high temperature and pressure conditions on the impact properties of CNF-added CFRP has not been clarified. Therefore, the objective of this study was to clarify the effect of water absorption under high temperature and pressure conditions on the impact energy of CNF-added CFRP.
In this study, the water absorption rate was measured by adjusting the pressure, CNF addition rate, and water absorption time, and the changes in water absorption were compared. Izod impact tests were also conducted to evaluate the effect of water absorption under high temperature and pressure conditions on the impact properties of CNF-added CFRP.

2. Experimental method

2.1. Test specimens

The test specimens were composed of plain weave PAN-based carbon fiber Torayca Cloth (CO6343, Toray Industries, Inc.) as the reinforcement material, epoxy resin (jER828, Mitsubishi Chemical Corporation) and epoxy resin curing agent (jER Cure Lv11, Mitsubishi Chemical Corporation) as the matrix material. In this study, an aqueous solution containing 2 wt.% CNF (BinFi-s WFo-10002, Sugino Machine Co., Ltd.) was used to mix with the epoxy resin. CNF aqueous solutions were prepared by diluting this solution to 0.03 wt.%, 0.05 wt.% and 0.1 wt.%. Here, the ethanol displacement method [2] was used to remove the water contained in the CNF, as it is very difficult to add CNF aqueous solution to the epoxy resin. The CFRP was fabricated using the hand lay-up method. The fabricated CFRP was made into test specimens with a length of 80 ± 2.0 mm, a width of 10 ± 0.2 mm and a thickness of 4.0 ± 0.2 mm according to JIS K 7110.

2.2. Method of water absorption

In this study, the CFRP specimens were placed in a 5.5 L pressure cooker with purified water for research purposes and the specimens were allowed to absorb water. The test conditions are shown in Table 1. The specimens were allowed to absorb water under four different pressure conditions (101 kPa, 161 kPa, 201 kPa, and 247 kPa). The water absorption temperatures were 100 °C, 114 °C, 120 °C, and 127 °C, respectively, in order of decreasing pressure. The water absorption time was 6, 12, 24, and 48 hours at each pressure condition, and the number of tests was five. After the specimens absorbed water, the water absorption was calculated using the following equation (1) according to JIS K 7290.

$$C = \frac{m_1 - m_0}{m_0} \times 100. \quad (1)$$

Table 1 Conditions of water absorption.

Specimen Type	Pressure p (kPa)	Temperature T (°C)	Absorption time (hrs)
A	101	100	6, 12, 24, 48
B	161	114	6, 12, 24, 48
C	201	120	6, 12, 24, 48
D	247	127	6, 12, 24, 48

2.3. Izod impact test

The impact energy of the water-absorbed specimens was measured using a DG-IB digital impact tester (Toyo Seiki Mfg. Co., Ltd.) in accordance with JIS K 7110. Here, an I5.5J hammer was used and the direction of impact was flatwise. The ambient temperature was room temperature, and the samples were used within one hour of removal from the pressure cooker.

3. Results and discussion

3.1 Change of water absorption rate with respect to CNF additive rate

Figure 1 show the relationship between water absorption and water absorption time for CFRP without CNF and CFRP with CNF in the Izod impact test. Here, (a), (b), (c), and (d) in Figure 1 represent the results at pressures of 101 kPa, 161 kPa, 201 kPa, and 247 kPa, respectively, during water absorption. With increasing water absorption time and pressure, the water absorption of CFRP without CNF and CFRP with CNF increased. For water absorption times other than 48 hours, the water absorption rate tended to increase with increasing CNF additive rate. It was found that water absorption of CFRP without CNF and CFRP with CNF both tended to increase with increasing water absorption time and pressure.

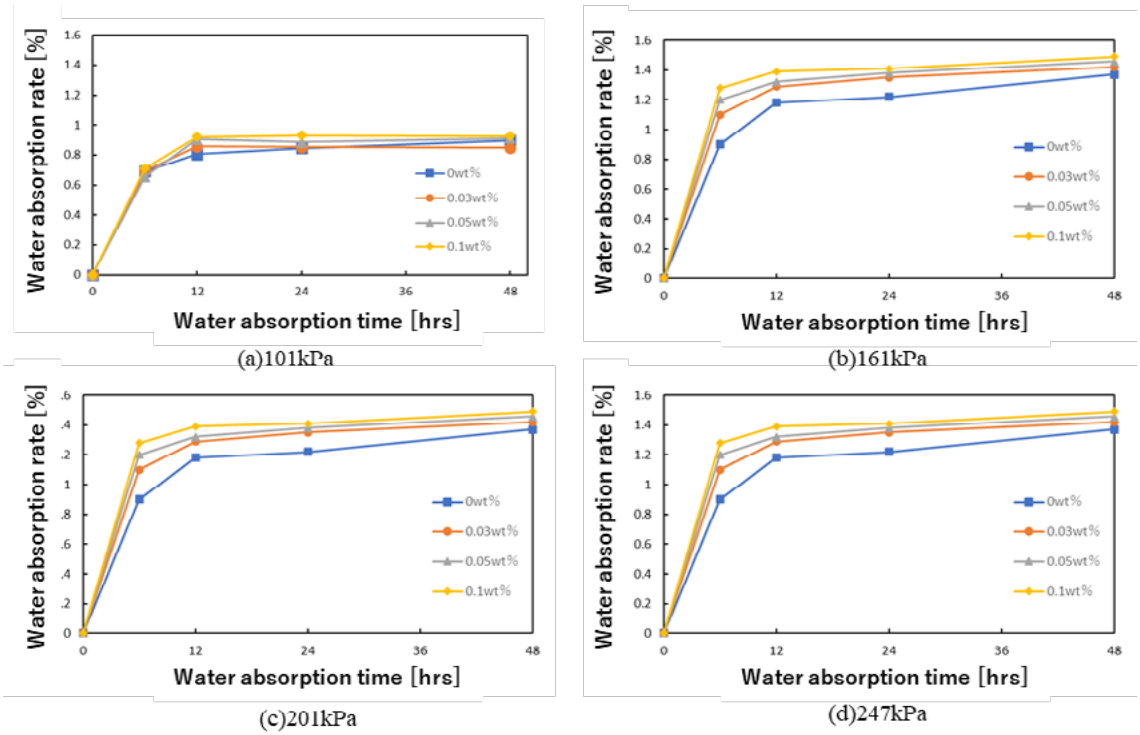

Figure 1 Changes of relationship between water absorption rate and immersion time with respect to pressure during water absorption.

3.2 Change of water absorption rate with respect to CNF additive rate

Figure 2 show the relationship between water absorption and impact values of CFRP without CNF and CFRP with CNF after water absorption and without water absorption. Here, (a), (b), (c), and (d) in Figure 1 represent the results at pressures of 101 kPa, 161 kPa, 201 kPa, and 247 kPa, respectively, during water absorption. While water absorption at a pressure of 247 kPa increased the impact value of CFRP without CNF by 59.7%, the addition of CNF increased the impact value by a maximum of 102% when water was absorbed at a pressure of 247 kPa. In addition, the results of the comparison of impact values for different additive rate of CNF showed that the impact energy tended to improve as the additive rate of CNF increased, as shown in Figure 2.Since the water absorption rate also increases with an increase in the addition rate of CNF according to Section 3.1, it was found that both the water absorption rate and impact energy can be improved by adding CNF and increasing the pressure during the water absorption process.

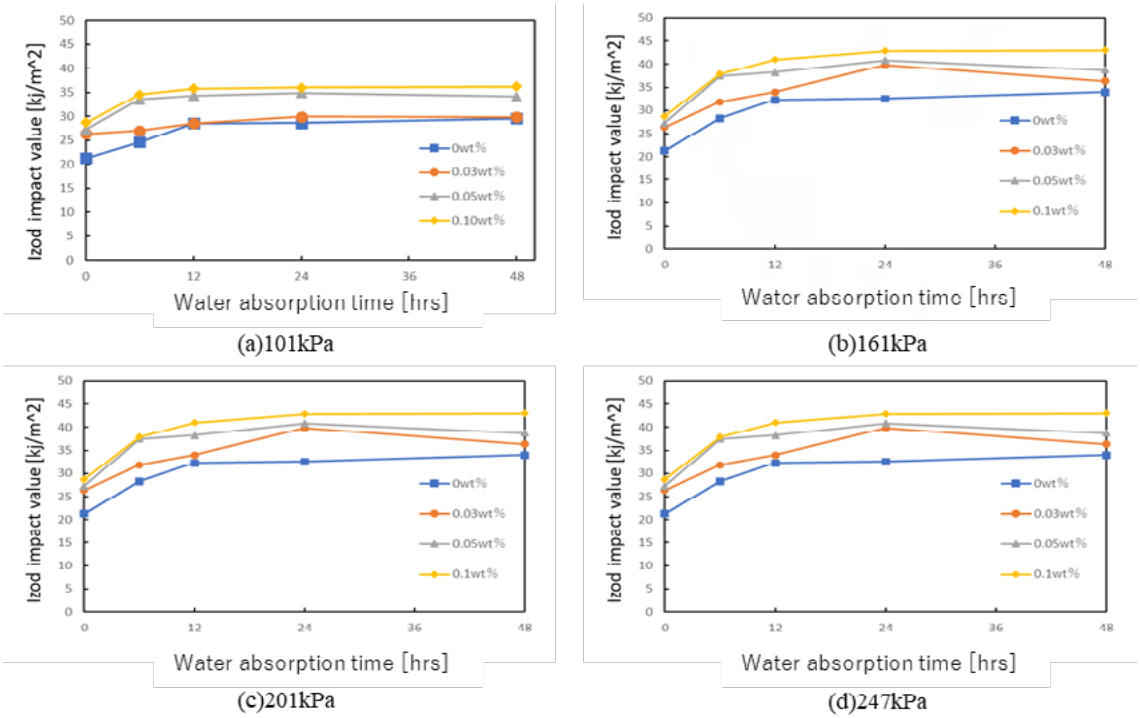

Figure 2 Changes of relationship between Izod impact value and immersion time with respect to pressure during water absorption.

3.3 Fracture surface of water-absorbed CFRP

Figure 3 show the SEM observation of CFRP after impact test. Here, (a), (b), (c), and (d) in Figure 3 represent the results at pressures of 101 kPa, 161 kPa, 201 kPa, and 247 kPa, respectively, during water absorption. Observation results showed that the amount of epoxy resin remaining on the fiber surface tended to decrease as the pressure increased. This indicated that the adhesive strength between the fiber and the resin was decreased as the water absorption rate became higher, and that interfacial fracture was more likely to occur.

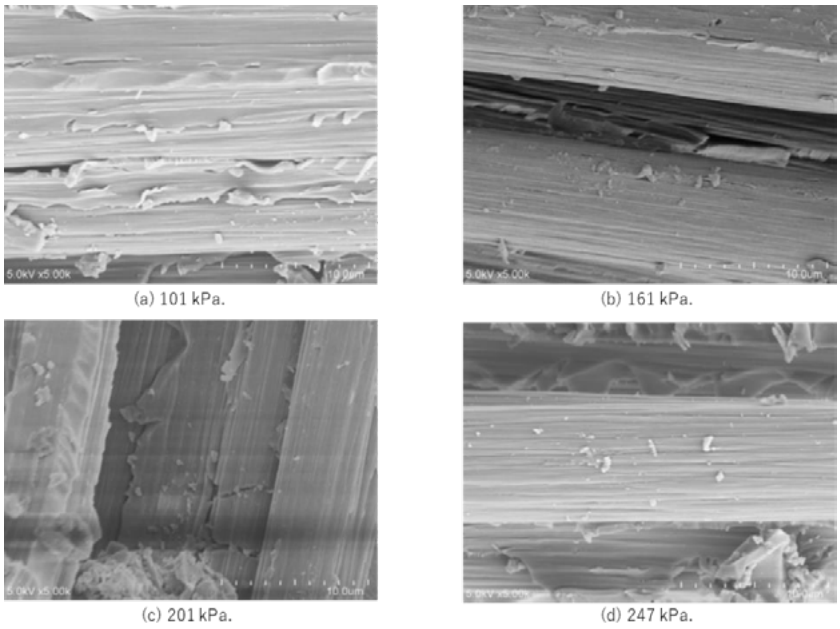

Figure 3 Change of impact fracture surface of CFRP with respect to pressure during water absorption at 0.1 wt.% of CNF additive rate.

Figure 4 also show the SEM observation of CFRP after impact test. Here, (a), (b), (c), and (d) in Figure 4 represent the results at CNF additive rate of 0 wt.%, 0.03 wt.%, 0.05 wt. %, and 0.10 wt.%, respectively, during water absorption. Observation results showed that the amount of epoxy resin remaining on the fiber surface tended to decrease as the pressure increased. It was considered that as the amount of hydrophilic CNF increased, the adhesive strength between the fiber and the resin decreased, which affected the impact energy of the CFRP.

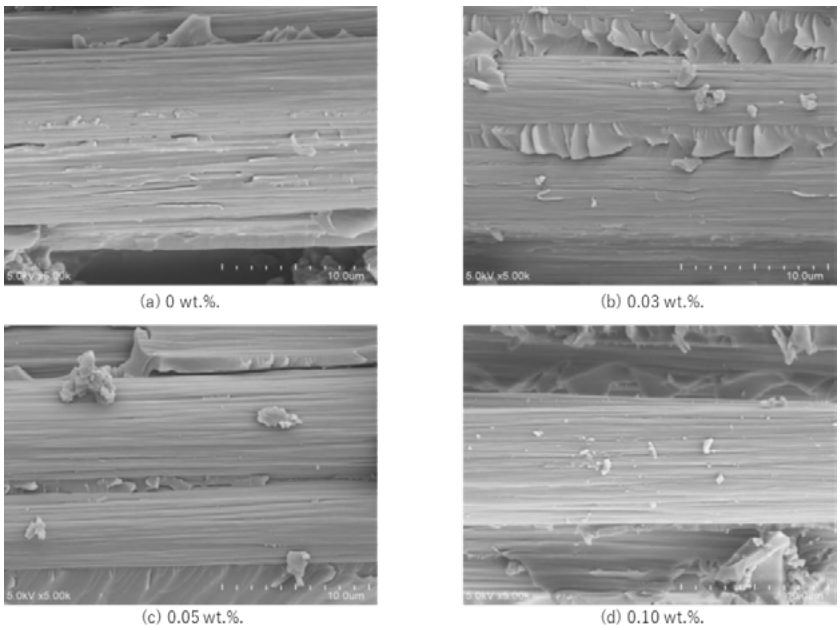

Figure 4 Change of impact fracture surface of CFRP due to the addition of CNF under the condition of water absorption at 247 kPa.

4. Conclusions

The following conclusions are obtained from this study.

[1] The results indicate that the addition of CNF to CFRP, under high-temperature and high-pressure conditions, improves impact energy compared to CFRP without CNF.

[2] The improvement in the impact characteristics of water-absorbed CFRP due to the addition of CNF can be attributed to the hydrophilic property of CNF.

Keywords: Composite lightweight design, manufacturing of composites, carbon fibre prepreg, epoxy resin, curing of fibre-reinforced plastics, film-based sensor

Abstract

Fibre-reinforced plastics are commonly used as lightweight design materials due to their high specific mechanical properties. However, manufacturing methods such as autoclave methods require significant amounts of energy and time to produce these structures. The aim of this research is to develop a film-based sensor that can realise an in situ measurement of the curing processes of epoxy resins. The sensor measures physically variable parameters, such as the electrical capacity of the epoxy matrix during curing. The measured values are correlated with the degree of curing or other process parameters. For this purpose, the sensor remains in the material and should not be structurally damaging. Therefore various films are being investigated as sensor carrier materials as part of the research.

1. Introduction

Fibre-reinforced plastics are versatile lightweight design materials that are commonly used in different applications and branches of industries. The autoclave process is a common method for manufacturing structures from these composites, but it is associated with long cycle times, and high production costs. For the manufacturing of these lightweight structures, prepregs are often used as semi-finished products. Prepregs consists of fibres that are pre-impregnated with matrix materials like epoxy resins. During the autoclave process the prepregs are laid into molds and cured under pressure and elevated temperature. Proper adjustment of process parameters is crucial. If the resin curing reaction occurs too quickly or at too high a temperature, voids and pores can be formed in the final product. That results in a significant decrease in quality. [1, 2] Conversely, if the curing reaction occurs too slowly, it results in significantly higher costs, including energy costs for providing pressure and temperature, machine costs as the autoclave is occupied for a longer period, and overall production costs, e.g., due to waiting and delivery times. [3, 4]

Currently, the industry often relies on empirical values or guidelines for designing an autoclave process. This research aims to develop a film-based sensor to adjust process parameters in real-time using in situ measuring during the curing of the prepreg-material. It is based on environmental conditions, such as resin reactivity, local tool temperature, ambient temperature, and other process parameters. The aim is to incorporate small film-based sensors into fibre-reinforced laminates to measure physical quantities like temperature and capacitance during curing (Figure 1). This enables precise adjustments to achieve the desired properties. The current state of the art uses sensors to measure ion viscosity. This measured value is based on an electrical resistance which depends on changing viscosity due to the chemical reaction during the curing reaction. [5, 6, 7, 8]

The study evaluates different film materials based on their properties to determine their suitability for the application. Common used materials for film-based sensors are actual polyimide (PI) films. [9, 10] A major challenge is to develop sensors, that can be applied to structurally loaded composite structures and remain inside the laminate during the use of the component. This means that the sensor and the film material must not be structurally damaging. [11]

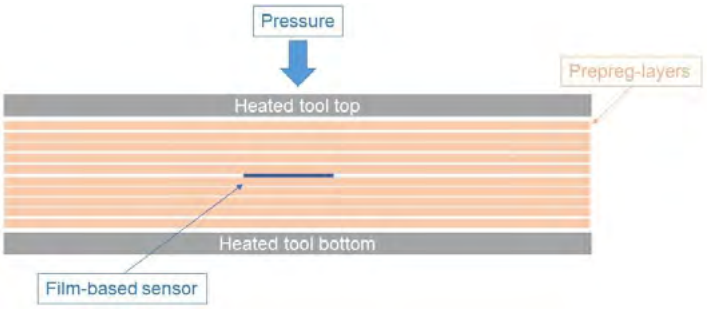

Figure 1. Non-structurally damaging film-based sensor between prepreg layers

2. Requirements for the film material and test methods

In order to facilitate the development of the sensor, it is essential to define the requirements for the film material, as this material exerts the greatest influence on the damaging process in the subsequent component, as outlined in chapter one. Consequently, the initial step in the process is to define the boundary conditions for the film material. This is followed by the selection of appropriate test methods to assess the various plastics for the desired properties. [12]

The main objective of the investigations was to find and characterize a film material for the further sensor that meets several requirements. These requirements include a mandatory temperature resistance of up to 200 °C, which corresponds to the temperature cycles in the autoclave process e.g. in the aerospace industry. Additionally, the film should have a rough surface to maximise adhesion between the prepreg resin and the film. Furthermore, a high surface roughness enables good printability of the film material using silver conductive paste in order to precisely realize a sensor structure. The sensor pattern or meander structures will be applied afterwards using this method. [2]

Different film materials were selected for the investigations and evaluated based on the above-mentioned requirements. The materials for the analyses were polyethylene (PET) with acrylic resin, PET, PET with PI coating, polyetherimide (PEI), PI, polycarbonate (PC) and polyethylene naphthalene (PEN) as shown in Figure 2.

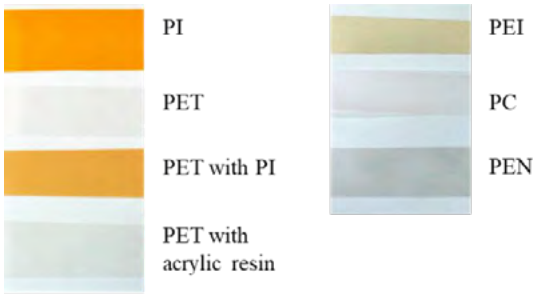

Figure 2. film materials

To ensure high measurement accuracy, the humidity absorption of the film materials is tested in accordance with ISO 62, as the accuracy of the electrical resistance measurement depends heavily on it. Therefore it is important to keep the humidity absorption of the films as low as possible. [13]

A further criterion is the material thickness of the film, which should be as low as possible to minimise the defect introduced by the subsequent sensor in the composite. As the material thickness can be influenced by the film manufacturers, it should also be analysed when checking the data sheet characteristics, but should not be selected as the decisive criterion for the film material. It can be measured with a micrometer screw. As an adhesion promoter (HV) is often used to apply the silver conductive paste, the film properties should be investigated with regard to the influence of the adhesion promoter. The material is a single-component material for processing in the printing, injection moulding and forming process up to 240 °C according to the data sheet. It is expected that the adhesion promoter will have an effect on the surface roughness of the films.

Thermal analyses are conducted to evaluate the temperature resistance of the materials. Differential scanning calorimetry (DSC) is suitable for determining the melting and glass transition temperatures of materials. As not all materials to be analysed exhibit a melting or glass transition temperature, a thermogravimetric analysis (TGA) is also performed. In this use case, the DSC is employed for the thermoplastic materials in the tests. The TGA is primarily utilized for the thermoset materials. The DSC analyses were carried out in accordance with DIN EN ISO 11357-1 and the TGA analyses in accordance with DIN EN ISO 11358-1. [14, 15]

3. Results

The purpose of this study was to analyse typical film materials with regard to their application in structurally non-damaging film sensors. Consequently, the requisite specifications for the film material were delineated, followed by the selection of distinct analytical methodologies to assess the diverse materials as in the previous chapter described. Based on this, a carrier material for the silver conductive paste of the sensor can be selected.

In addition, the influence of an adhesion promoter will be analysed. This will be used to apply the conductive silver paste on the film-material. It is expected that the adhesion promoter will not affect the properties of the film material in terms of surface roughness. The aim is to determine whether the applied adhesion promoter has a positive or negative effect on the adhesion between the prepreg material and the sensor.

3.1 Differential scanning calorimetry (DSC)

The DSC measurements were performed with a Netzsch DSC 204 F1 Phoenix. The DSC is comprised of a preciously defined measuring cell, which contains a reference pan and a sample pan. The system employs the heat flow principle in order to determine specific temperatures. All experiments were carried out in accordance to DIN EN ISO 11357-1 with a constant nitrogen flow of 20 l/min and the sample weight was between 4 – 8 mg. A concave pan was used and the DSC cell was pre-cooled to 0 °C. The measurement cell was heated to 450 °C following a cooling at 0 °C and a second heat and cooling phase at 450 °C and 0 °C. The heat rate was every time 10 °C/min. [14]

Figure 3 displays the results of the DSC analyses. The temperature ranges indicating a change in the plastic are important for material selection. This can be either the melting temperature or the glass transition temperature, depending on the material. The diagram specifies the melting temperature for all film materials except PEN, for which the glass transition temperature is more pronounced and shown in the diagram. The measurement evaluation indicates that the adhesion promoter has no significant effect on the melting temperature of any sample. The PEN film has a glass transition temperature of approximately 120 °C, while the PC film has the lowest melting temperature of approximately 152 °C. The PET films have the highest melting temperatures at approximately 255 °C. The melting temperature

of the PEI film was approximately 220 °C, and the different coatings of the PET film had no effect on its melting temperature. The PI film was not analysed because it is a thermoset material that does not have a melting temperature, but rather a decomposition temperature.

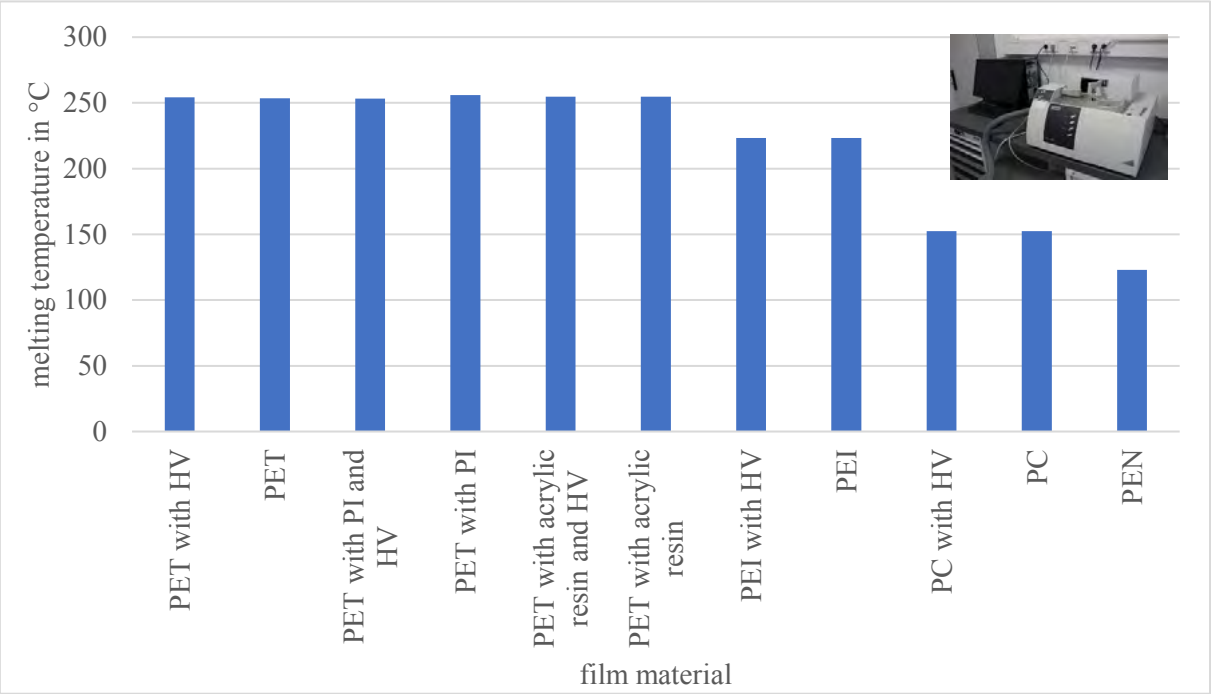

Figure 3. DSC-analysis

The results of the DSC analyses indicate that the adhesion promoter does not affect the melting or glass transition temperature of the film materials, as expected. Therefore, the adhesion promoter was not extensively analysed during the TGA (Figure 4). The DSC analyses also revealed that the film materials PC and PEN are not temperature-resistant up to 200 °C, while all other film materials meet the requirements. No difference in melting temperatures was observed between PET films with and without coatings. This can be explained by the fact that the base material, PET, has a lower melting temperature compared to the two coating materials, and therefore, the influence of the base material is predominant.

3.2 Thermogravimetric analysis (TGA)

The TGA measurements were performed with a Netzsch TG 209 F1 Libra. In the TGA the mass of a small sample is measured during temperature change. All experiments were carried out in accordance to DIN EN ISO 11358-1 with a constant nitrogen and oxygen flow of 20 l/min and the smple weight was between 4 – 8 mg. The sample was heated up to 950 °C. [15]

The TGA analyses indicate that the PI film has the highest decomposition temperature at 585 °C. The PET and PEN films show the lowest decomposition temperature at approximately 410 °C due to the covalent bonds between the molecular chains and the pronounced intermolecular cross-linking structure. The DSC analyses do not reveal any influence of the coatings on the PET films, which can be attributed to the lower decomposition temperature of the PET compared to the coating materials. The results of both analysis are therefore logically comprehensible and reflect expectations. According to the first analyses carried out, the PI film has the best properties as a carrier material for the sensor. PET films and PEI films are also well suited.

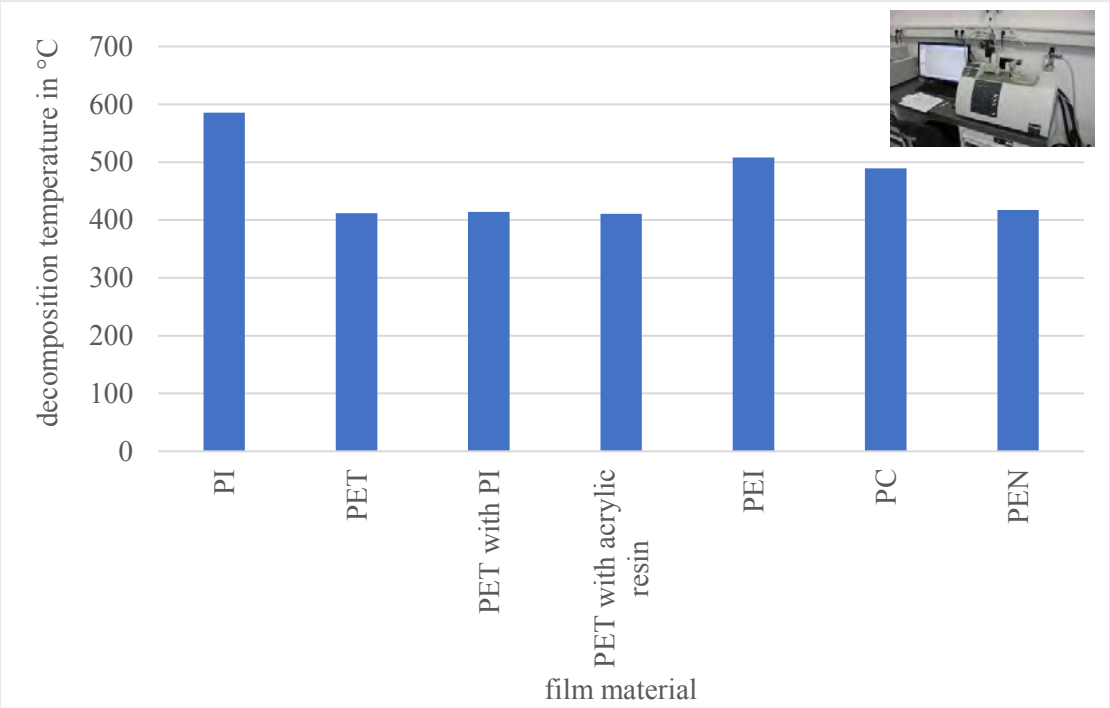

Figure 4. TGA-analysis

3.3 Surface roughness

The measurement of the surface roughness were performed with a Mitutoyo Surftest SJ-310. A diamond tip is drawn over a surface at 0.75 mN at an angle of 60°. The centre roughness value can be determined using the induction method.

The analyses of the surface roughness of the film materials produced varying results (Figure 5). It was anticipated that differences between the coatings of the PET film would be measurable when analysing the roughness. Additionally, an influence of the adhesion promoter is assumed, as it acts like a coating on the films. The PC films exhibited the greatest roughness at approximately 0.52 µm, followed by the PI films at approximately 0.32 µm and the PEI films at approximately 0.19 µm. The roughness of the PET film was lowest when it was not coated. The measurements showed that coating the PET films has an impact on their roughness. Specifically, the PET film coated with acrylic resin had a surface roughness around 15% greater than the base material, while the PET film coated with PI had a surface roughness around 25% higher than the base material.

In almost all cases, the adhesion promoter reduced surface roughness. When inserting films wetted with adhesion promoter into the prepreg material for sensor development, it is important to consider the overall objective.

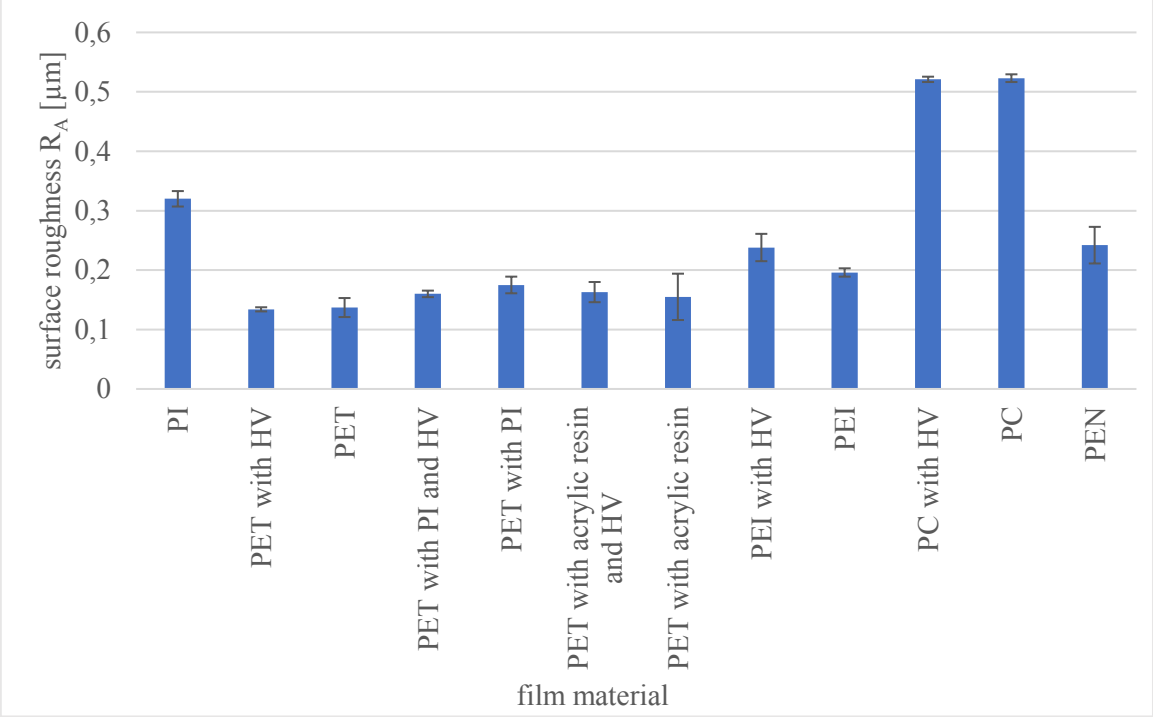

Figure 5. Average surface roughness R_A

3.4 Humidity absorption

The measurement of the humidity absorption (Figure 6) were performed in a climate cabinet CTS C-40/200 in accordance with ISO 62. First all samples were dired for 8 h at 70 °C. The weight of the samples were mearued before and after drying. Following the drying the samples were in a humid environment for 24 h. After that the samples were weighed again and the humidiy absorption could be calculated. [13]

When analysing humidity absorption (Figure 6), it was assumed that the coatings on the PET films could have an influence on the measurement. The PI film exhibits the highest humidity absorption. This observation is confirmed when comparing the PET films with coating, where the PI-coated film also shows increased humidity absorption. In comparison, the PET film with acrylic resin coating exhibits slightly lower humidity absorption than the pure base material, while the PC film exhibits the lowest humidity absorption. The PEN film falls within a similar range to the PET films. The PEI film exhibits the highest water absorption after the PI film.

Therefore, it can be concluded that the use of PET, PEN or PC films best meets the requirements. The measured results could be validated using the data sheets of the film manufacturers.

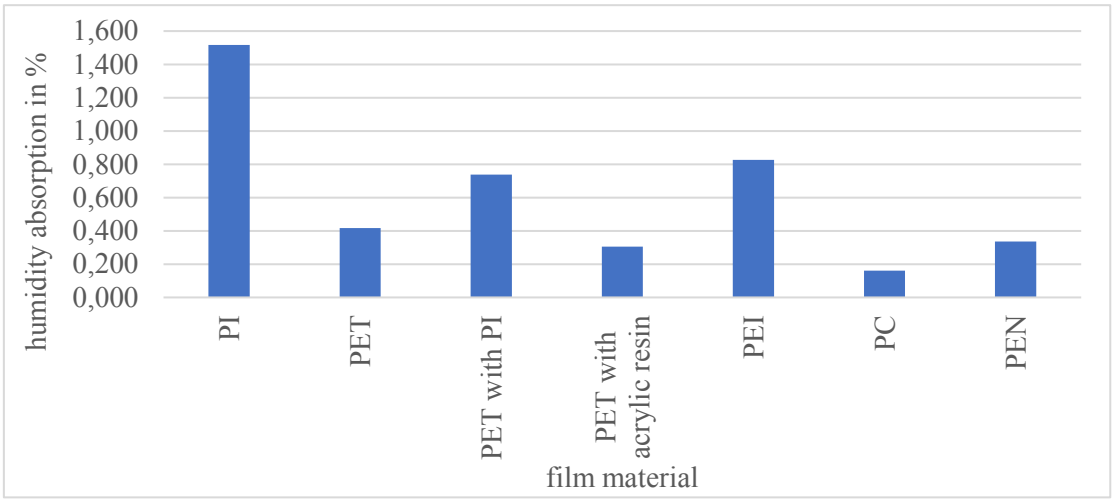

Figure 6. Humidity absorption

3.5 Material thickness

Figure 7 shows the results of determining the material thickness of the films produced. It was measured with a micrometer screw. The PI film has the lowest material thickness at approximately 0.064 µm, while the PC film has the greatest material thickness at approximately 0.25 µm. There is no difference found between coated and uncoated PET films, and the application of the adhesion promoter also has no measurable effect on the material thickness. These measurement results are confirmed by comparing them with the data sheets for the film materials.

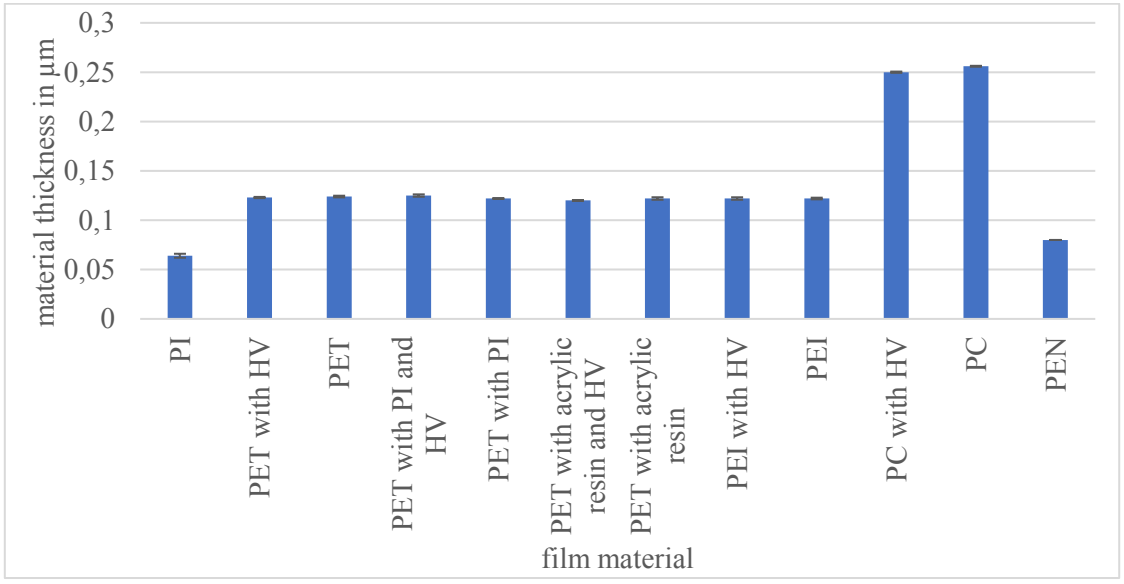

Figure 7. Averaged material thickness

4. Discussion and Conclusion

The tests conducted helped to limit the selection of film materials suitable for use in film sensors, that can be integrated into composite laminate structures. A PI film is highly recommended due to its high

decomposition temperature, temperature resistance, high roughness, and low material thickness. However, it should be noted that this film material has increased humidity absorption, which must be taken into account. PET-based films can be used as an alternative to this film as they performed well in all tests. In a direct comparison of the base material with the two coatings, the acrylic resin coating is a good carrier material. PEI films are also suitable as a carrier material, according to the tests carried out. However, it is important to consider the exact area of application when using PEI film as a sensor due to its melting temperature being close to the specified 200 °C. Additionally, it has a tendency to absorb more humidity. Further tests are planned to finalise the definition of the film, including delamination properties in the prepreg material, printability with silver conductive paste, and measuring accuracy in the prepreg.

Acknowledgments

This Project is supported by the Federal Ministry for Economic Affairs and Climate Action (BMWK) on the basis of a decision by the German Bundestag.The authors would like to thank the BMWK for the funding and Roos GmbH and 3D ICOM GmbH for supporting this research.

Abstract
The problem of vibration-based progressive fatigue damage detection and classification for thermoplastic coupons is addressed under population and experimental uncertainty. The study is based on a population of 6 thermoplastic coupons subjected to tension-tension fatigue which is interrupted at 10 000 cycles long intervals. The methodology employs Multiple Model Representations of the uncertain dynamics using parametric ARMA random vibration modeling. The results of the study provide: (a) A clear demonstration of the effects of fatigue on the coupon structural dynamics, with almost monotonic dependence on the number of fatigue cycles, (b) excellent fatigue damage detection performance characterized by 100% correct detection for all coupons under any fatigue state, and (c) a very good fatigue state classification performance reaching an aggregate (over all coupons) correct determination rate up to 90%. The outcomes of the study demonstrate the potential of the method for automated detection and classification of fatigue damage in thermoplastic aerostructures under population and experimental uncertainty.

1. Introduction

Composite materials, particularly thermoplastics, have emerged as dominant materials in the aerospace industry, overcoming thermosets due to their distinct advantages such as advanced impact performance, recyclability, and weldability [1]. Despite composite materials' expected superior fatigue lifetimes, fatigue remains a critical issue in the design process, especially for structures subjected to dynamic loads [2]. The anisotropic nature of fiber-reinforced polymers introduces complexity to fatigue damage characterization, encompassing various damage modes like matrix cracks, delamination, and fiber breakage [3]. Structural Health Monitoring (SHM) methods, including vibration-based techniques, have witnessed significant advancements, offering alternatives to traditional non-destructive testing (NDT) methods [4]. These facilitate continuous, online, monitoring, presenting a departure from offline approaches such as X-rays. Vibration-based methodologies, including global modal parameter based analysis, methods based on the wavelet transform and on AutoRegressive (AR) modeling, enable comprehensive fatigue damage assessment for composite structures [5,6]. Each methodology offers unique advantages and limitations, ranging from macroscopic insights provided by global modal parameters to the nuanced detection facilitated by wavelet transform and AR modeling.

Key studies in the field have demonstrated the efficacy of vibration-based methods in fatigue damage assessment within composite structures. These studies, utilizing techniques such as global modal properties [7,8], frequency response functions (FRFs) [9,10], wavelet transform [11,12], and AR models [13,14], have significantly contributed to the understanding and characterization of fatigue damage initiation, propagation, and accumulation.

Although the significant contribution of the aforementioned studies, lack is located to a complete and comprehensive study of progressive fatigue damage initiation and evolution using exclusively on-line methods, which part of this, is covered by the present study. This study presents an extensive experimental process for investigating progressive fatigue damage in quasi-isotropic thermoplastic coupons subjected to tension-tension fatigue. Utilizing non-contact vibration tests, the study presents a comprehensive detection and classification of fatigue damage, highlighting the potential of vibration-based methods for monitoring progressive fatigue damage in thermoplastics.

2. Experimental set-up

2.1. Material and coupons

The coupons are of dimensions $250\,mm \times 25\,mm \times 2.24\,mm$, and the bonded tables are $50\,mm\ x\ 25\,mm\ x\ 2.24\,mm$. The coupons and the tabs are made of thermoplastic TC 1225 LM PAEK prepreg plies with a fiber volume fraction of 66%. The 0.14 mm-thick plies are stacked in a quasi-isotropic stacking sequence with a lay-up of $[-45/0/45/90]_{2s}$.

2.2. Experimental procedure

Three types of mechanical tests were conducted: Quasi-static tension tests (Coupons #1-5) on virgin coupons based on the ASTM D3039 standard [15], non-interrupted tension-tension (T-T) fatigue tests (Coupons #6-10), and interrupted tension-tension (T-T) fatigue tests (Coupons #11-16), both based on the ASTM D3479 standard [16]. For all mechanical tests, an MTS Landmark machine with a 100 kN load cell was used. Initial tensile tests were conducted for material characterization. In the interrupted T-T fatigue tests, every 10,000 cycles the coupons were subjected to random vibration tests. This procedure was repeated until fatigue failure of each coupon. The equipment for the vibration test comprised a laser vibrometer (OFV-505), its controller (OFV-5000), a NI-9230 acquisition card, speakers, and a PC. The excitation is acoustic, MATLAB-generated, white noise, while the coupons were supported by elastic chords (free-free boundary conditions). Fig. 1 illustrates the experimental setup for the random vibration test. Six coupons were used for the vibration tests, which thus accounted for population (mass, geometry), operational (set-up, excitation), and environmental (temperature) uncertainty. Fatigue and random vibration test parameters are outlined in Table 1.

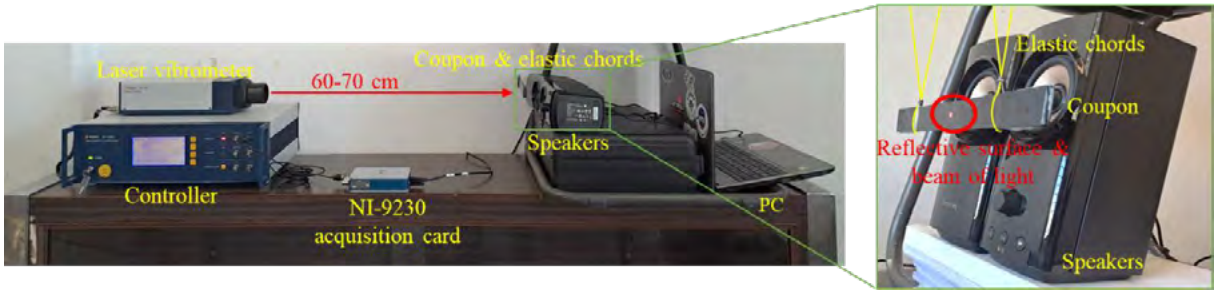

Figure 1. Experimental set-up for the random vibration test.

3. Fatigue damage detection and classification methodology

Fatigue damage detection and classification are realized through a vibration-data and Multiple Model Representation (MMR) based methodology. This is a data-based methodology encompassing a *Training or Baseline Phase,* performed once and initially in order to make proper selections, and an *Operational or Inspection Phase* during which diagnostic decisions are made. While the Baseline Phase requires

vibration response signals obtained from experiments with various coupons, the Inspection Phase is based on a single signal obtained from any specific coupon, potentially under normal structural operation. In this context it should be clarified that the term *detection* refers to the confirmation of the presence of damage in a coupon, while the term *classification* refers to inferring the precise *Fatigue State (FS)* for any coupon based on the measured vibration signal.

Table 1. Fatigue test parameters and random vibration signal characteristics.

Fatigue test		Random vibration test (Signal Characteristics)	
Parameter	Value	Parameter	Value
f	5 Hz	Sampling frequency f_s	12,800 Hz
σ	$0.6\sigma_{max}$	Signal duration	60 s
R	0.1	Signal bandwidth	0-6,400 Hz

3.1. Damage detection

The dynamics of the healthy population of specimens are modeled via an MMR consisting of a number of ARMA models of a properly selected order. In the *Baseline Phase* a number, say p, of vibration response signals are obtained from various healthy coupons. Let each one of them be designated as $m_{0,i}$ $(i = 1, \dots, p)$, with the estimated AR/MA parameter vector following a Gaussian probability density function with mean the obtained point estimate $\boldsymbol{a}_{0,i}$ and covariance matrix $\boldsymbol{\Sigma}_{0,i}$. In the *Inspection Phase*, given a new vibration response signal from any coupon, the objective is to detect the presence of damage by examining whether or not the underlying coupon dynamics is represented well by the MMR m_0, in which case the current coupon is declared as healthy; else, as damaged. For this purpose a new ARMA model (of the exact same orders), say m_u, is estimated, and then its proper pseudo-distance from m_0, say $D(m_0, m_u)$, is determined. Decision making is then based on a test of the form:

$$\begin{aligned} D(m_0, m_u) \leq l_{lim} &\Longrightarrow Healthy\ Coupon \\ D(m_0, m_u) > l_{lim} &\Longrightarrow Damaged\ Coupon \end{aligned} \tag{1}$$

The pseudo-distance $D(m_0, m_u)$ is presently defined as the minimum of the individual distances of m_u from all elements of m_0, that is:

$$D(m_0, m_u) := \min_k \left[d(m_{0,k}, m_u) \right] \tag{2}$$

with $d(m_{0,k}, m_u)$ designating the distance between two individual models. Two types of such distances are employed, as discussed below.

3.1.1. The Mahalanobis distance

The Mahalanobis distance is defined as:

$$d(m_{0,k}, m_u) := \sqrt{(\boldsymbol{a}_{0,k} - \boldsymbol{a}_u)^T \boldsymbol{\Sigma}^{-1} (\boldsymbol{a}_{0,k} - \boldsymbol{a}_u)} \tag{3}$$

in which the superscript T designates transposition and $\boldsymbol{\Sigma}$ the sample covariance of the AR/MA parameter vectors within the MMR m_0, with the individual covariances $\boldsymbol{\Sigma}_{0,k}$ $(k = 1, \dots, p)$ and $\boldsymbol{\Sigma}_{\boldsymbol{u}}$ considered negligible compared to $\boldsymbol{\Sigma}$.

3.1.2. The cosine similarity distance

The cosine similarity distance is defined as:

$$d(m_{0,k}, m_u) := cos(\boldsymbol{a}_{0,k}, \boldsymbol{a}_u) = \frac{\boldsymbol{a}_{0,k} \cdot \boldsymbol{a}_u}{\|\boldsymbol{a}_{0,k}\| \cdot \|\boldsymbol{a}_u\|} \quad (4)$$

in which the dot designates inner product and $\|\cdot\|$ the Euclidean norm of the indicated vector.

3.2. Damage classification

Following fatigue damage detection, Fatigue State (FS) classification follows. This is performed in a similar manner, with the exception that now each FS is modeled in the *Baseline Phase* and then a number of tests of the form (1) (each for each FS) are included in the *Inspection Phase*. Two bounds, at 5% and 10%, are included in the limits corresponding to each FS.

The first 20 parameters are included in each parameter vector for detection and classification using both metrics. Concerning fatigue damage detection, a set of 4 among 6 healthy coupons is selected, referred to as baseline coupons, for use in the method's Baseline (Training) phase. The remaining 2 healthy coupons and the 6 damaged coupons are referred to as inspection coupons – considered as 'unknown' structural state – and are reserved for the method's assessment in the Inspection (Diagnosis) phase. The employed combinations are designated as employed sets of baseline coupons and lead to different sets of baseline coupons.

4. Results

4.1. Preliminaries

A set of 4, among a total of 6, healthy coupons are selected for use within the *Baseline Phase*; these are also referred to as *Baseline Coupons*. The remaining 2 healthy coupons, along with 6 progressively damaged coupons, are used for testing the method in the *Inspection Phase* and are referred to as *Inspection Coupons*. By exchanging healthy Baseline Coupons with healthy Inspection Coupons, a number of rotations are implemented, leading to a total number of 280 healthy baseline coupons and 140 baseline coupons per FS.

The ARMA modeling of the vibration response signals for the healthy coupons leads to models of selected orders (80,50), that is ARMA(80,50) models. Models of the same orders are employed for all Fatigue States as well. Based on these a preliminary analysis of the influence of the FS on the coupon dynamics, as captured by the ARMA models, is undertaken. In this context, the decreasing value of the natural frequency at around $3500\ Hz$ (for the healthy state), the increasing value of the corresponding damping ratio, and the increasing spectral distance - the log-spectral distance involves the transformation of time-series signals into the spectral domain, and the distance of ARMA estimated Power Spectral Density (PSD) Welch spectrums of each damaged state from the healthy one is calculated - (from the healthy state) with increasing Fatigue State for Coupon #1 (based on all 70 Healthy and 35 per Fatigue State cases), are, along with their uncertainties, presented in Fig. 2. The high uncertainty associated with Fatigue States 1 and 2 is due to the uncertain nature (among the coupons) of fatigue damage evolution in the initial stages. This behavior is also reflected in PSD Welch estimates obtained in our preliminary work [17]. The main conclusion from this analysis is that the progression of fatigue damage significantly influences the coupon structural dynamics as captured by the ARMA models; while, furthermore, this influence is almost monotonically dependent on the Fatigue State. The implication of this is that both damage detection and FS classification should be possible by the method; this is to be formally discussed in the sequel.

Finaly note that only the first 20 parameters of the AR/MA parameter vector are subsequently used for damage detection and classification.

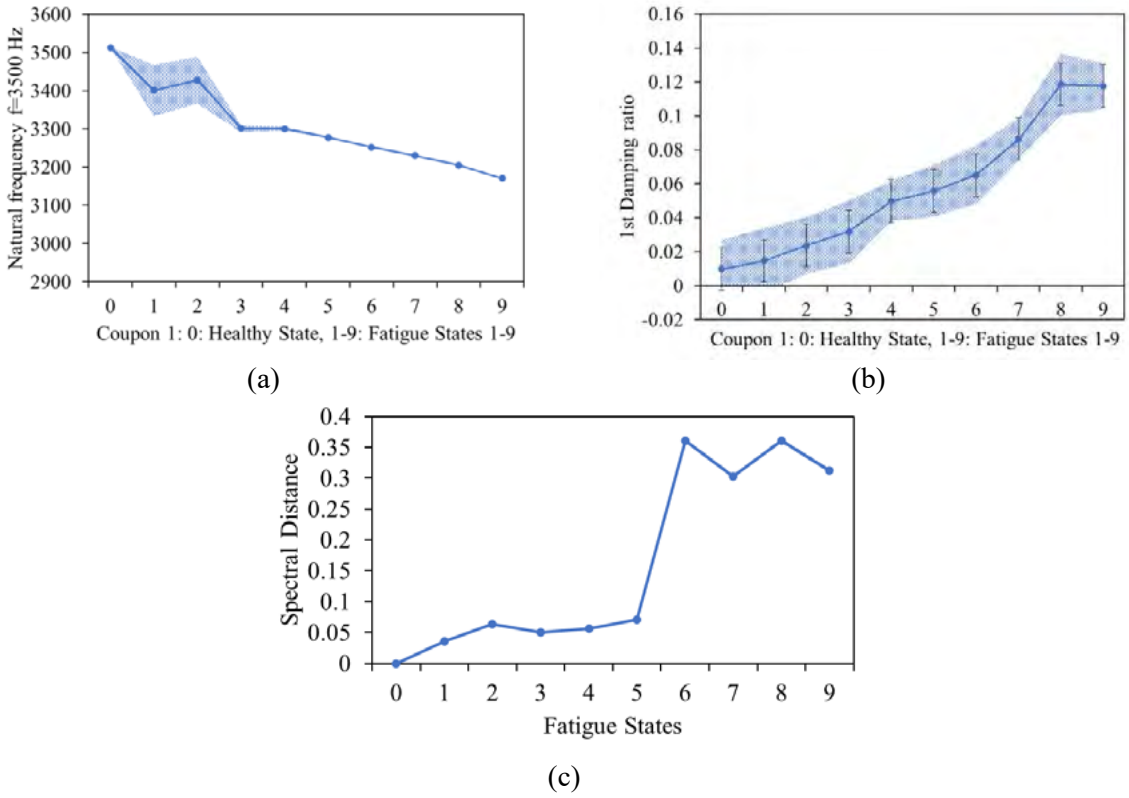

Figure 2. Evolution of the natural frequency at around 3500 Hz (a), the damping ratio (b), and spectral distance (c) with Fatigue State for Coupon #1 (0 corresponds to the Healthy state and i=1,…,9 to the corresponding Fatigue States).

4.2. Fatigue damage detection results

Fatigue damage detection results, using the Mahalanobis and the cosine similarity distances are presented in Figs. 3 and 4 for hundreds of Inspection Experiments. The results are excellent as the Distance metric *D* is, for all damaged cases, much higher than that of the healthy cases.

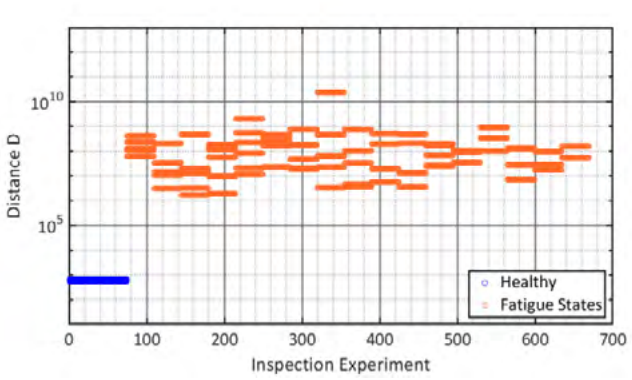

Figure 3. Random vibration-based progressive fatigue damage *detection* in the Inspection Phase using the *Minimum Mahalanobis Distance*: The Distance *D* for all Inspection Experiments for Coupons # 11 – 16 starting from the Healthy State and progressing towards Fatigue State 17 (70 Detection Test Cases per Coupon under the Healthy State and 35 under each Fatigue State).

4.3. Fatigue damage state classification results

Correct and incorrect classification rates for each coupon across all fatigue damage states (FSi,

i=1,…,17) using the Mahalanobis distance and the cosine similarity distance metrics are depicted in Fig. 5 and Fig. 6, respectively, while correct and incorrect classification rates are reported in Table 2. As observed, using the 5% limits provides higher performance.

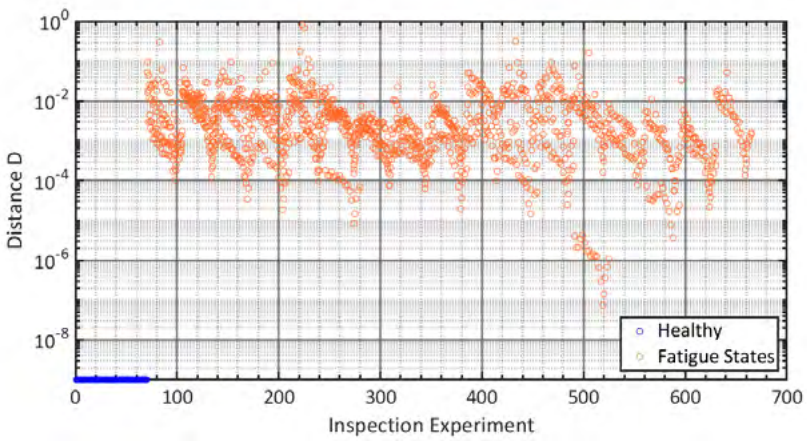

Figure 4. Random vibration-based progressive fatigue damage *detection* in the Inspection Phase using the *Minimum Cosine Similarity*: The Distance D for all Inspection Experiments for Coupons # 11 – 16 starting from the Healthy State and progressing towards Fatigue State 17 (70 Detection Test Cases per Coupon under the Healthy State and 35 under each Fatigue State).

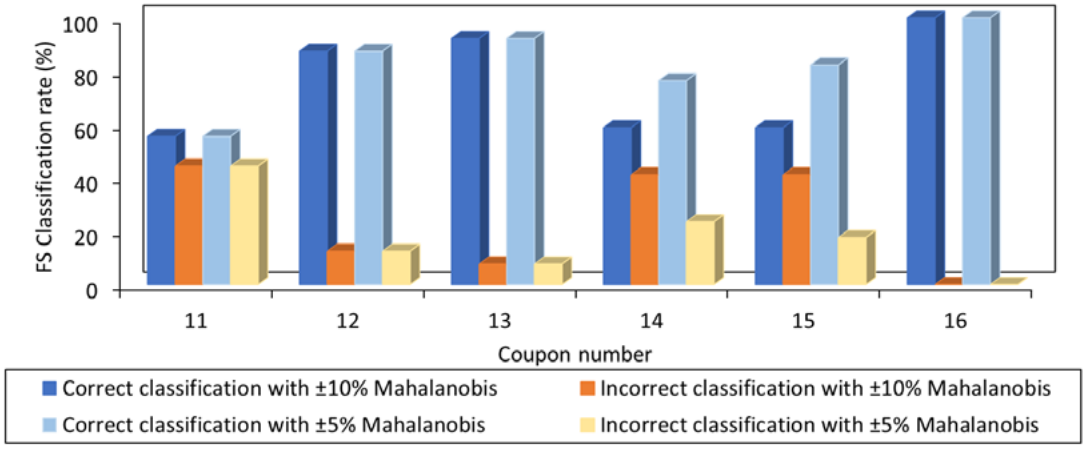

Figure 5. Random vibration-based Fatigue State *determination* results in the Inspection Phase using the *Minimum Mahalanobis Distance*: Correct (blue) and incorrect (orange) classification rates for Coupons # 11 – 16 for all Fatigue States ($FS_i, i = 1, \dots, 17$). Aggregate results in the rightmost part. (35 Test Cases per Coupon and Fatigue State; results based on $\pm 5\%$ and $\pm 10\%$ limits are shown.)

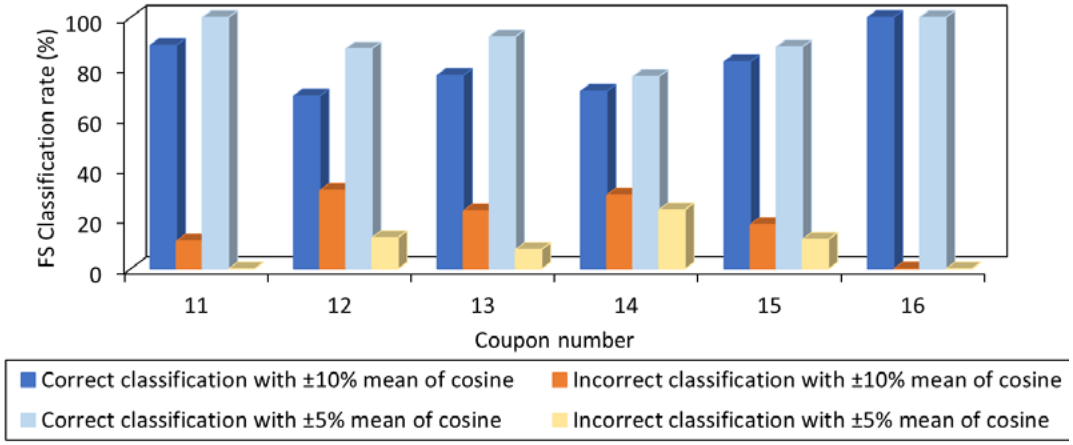

Figure 6. Random vibration-based Fatigue State *determination* results in the Inspection Phase using the *Minimum Cosine Similarity Distance*: Correct (blue) and incorrect (orange) classification rates for Coupons # 11 – 16 for all Fatigue States ($FS_i, i = 1, \dots, 17$). Aggregate results in the rightmost part. (35 Test Cases per Coupon and Fatigue State; results based on $\pm 5\%$ and $\pm 10\%$ limits are shown.)

Table 2. Summary vibration-based Fatigue State *determination* results in the Inspection Phase in terms of correct and incorrect classification rates for Coupons # 11 – 16 for all Fatigue States ($FS_i, i = 1, \dots, 17$) using either the Minimum Mahalanobis or Cosine Similarity Distance (35 Test Cases per Coupon and Fatigue State; results based on $\pm 5\%$ and $\pm 10\%$ limits are shown).

Fatigue State Classification Method	Correct Classification Rate (%)
Minimum Mahalanobis Distance ($\pm 5\%$ / $\pm 10\%$ limits)	82.36 / 75.50
Minimum Cosine Similarity Distance Metric ($\pm 5\%$ /$\pm 10\%$ limits)	90.75 / 81.25

5. Conclusions

An investigation on random vibration-based progressive fatigue damage monitoring for thermoplastic coupons has been carried out. The work has been based on 6 nominally identical coupons subjected to interrupted (every 10 000 cycles) fatigue and random vibration tests. The main conclusions of the study may be summarized as follows: (i) The effects of fatigue damage on the coupon structural dynamics, with almost monotonic dependence on the number of fatigue cycles, have been demonstrated; (ii) fatigue damage detection has been flawless; (iii) fatigue damage classification has been very good, characterized by an aggregate (over all coupons) correct classification rate up to 90%. Overall, the results of the study are indicative of the method's high potential for fully automated, in-operation, fatigue damage monitoring for thermoplastic structures, without the need for interrupting regular service and in the presence of population and operational uncertainty.

Keywords: Thermal expansion coefficient, Thermal strains, Effective field methods, Composites, Modeling

Abstract

In the present study a novel methodology for modeling thermal strains in composite materials is introduced. Initially, a new formulation for calculating the thermal strains from the effective coefficient of thermal expansion (CTE) is presented. This formulation is then implemented both analytically and numerically. Subsequently, the analytical formulation based on effective field methods (EFMs) is introduced followed by the numerical models developed using the finite element (FE) method. Finally, two case studies for particulate and fibrous composites are discussed, and comparisons between analytical and numerical results are provided, demonstrating great agreement.

1. Introduction

Fibrous composites are widely used in many sectors of the industry due to their remarkable specific properties. However, their distinct constituents have varying coefficients of thermal expansion (CTEs), causing them to expand or contract differently when exposed to temperature changes. This creates internal stresses, leading to structural damage, compromised performance, and compromised safety [1].

Modeling thermal strains allows predicting the manner that composites respond to temperature variations. Analytical and computational models can be employed to simulate the behavior of composites under thermal stress by the prediction of the CTE. This predictive ability is important during the design phase, enabling optimization of material selection, layup configurations, and manufacturing processes to mitigate thermal effects [1].

Various models have been proposed over the years to predict the effective CTEs of composite materials.

Turner's model [2] assumes negligible shear deformation and uniformity of strain across components, providing a heuristic relation based on volume fractions of phases, bulk moduli, and CTEs. Thomas' model [3] offers a phenomenological equation with an adjustable parameter allowing for the extraction of volume averages of CTEs or their inverses. Arthur and Coulson's model [4], later corrected in [5], interrelates Young's modulus and Poisson's ratio based on an empirical relationship, contributing to an understanding of their role in determining the CTE. Levin's model [6] establishes a link between effective bulk modulus and CTE for isotropic composites. Schapery's model [7] derives bounds on effective CTEs using extremum principles of thermoelasticity, providing insights into composite behavior under thermal stresses. Tummala and Friedberg's model [8] considers spherical inclusions without interaction between inhomogeneities, offering insights into simple composite microstructures. The aforementioned models utilize either empirical relations or are derived for simple composite microstructures. The most accurate model built on a solid physics background and able to consider composites with arbitrary microstructures is the model of Sevostianov [9]. This model is based on property contribution tensors which define the proper microstructural parameter in terms of which an effective property (e.g., the CTE) is derived. For these reasons, this model is utilized in the present study.

Modeling thermal strains in composite structures presents inherent challenges due to the complexities arising from the shape, orientation, and properties of the matrix and inhomogeneities. The aim of this work is to address these challenges by presenting a novel methodology for modeling thermal strains in composite parts. In Section 2., the formulation for calculating the thermal strains from the effective CTE is presented. This formulation is general and can be implemented both analytically and numerically. In Section 3.1.1, the analytical formulation based on effective field methods (EFMs) is presented accounting for the general case of anisotropic inhomogeneities of arbitrary shape and orientation within an anisotropic matrix. In Section 3.1.2, numerical models developed using the finite element (FE) method are presented. Finally, two case studies for particulate and fibrous composites are discussed and comparisons between analytical and numerical results are provided.

2. Analytical formulation

Consider the case of an infinite three-dimensional medium, of volume V containing an inhomogeneity with a volume V^*. The properties utilized for the inhomogeneities and the matrix are denoted by '*' and '0' respectively. The angle brackets $\langle ... \rangle_V$ express average over the indicated volume V. The volume V is subjected to a uniform temperature change T, and its boundary remains free of traction. According to Sevostianov [9], the thermal expansion contribution tensor H_T of the inhomogeneity in relation to the volume average thermal strain $\langle \varepsilon_{ij} \rangle_V$ and the thermal expansion tensors of the matrix α_{ij}^0 and the composite α_{ij}^{eff} is expressed as:

$$\langle \varepsilon_{ij} \rangle_V = \alpha_{ij}^0 T + H_{ij}^T T = \alpha_{ij}^{eff} T. \tag{1}$$

$H_{ij}^T T$ represents the induced strain perturbation $\Delta\varepsilon_{ij}$ due to the presence of the inhomogeneity in the matrix. Additionally, the volume average stress of the composite can be expressed as:

$$\frac{V^*}{V}\langle\sigma_{ij}\rangle_{V^*} + \frac{V-V^*}{V}\langle\sigma_{ij}\rangle_{V-V^*} = 0, \tag{2}$$

where $\langle\sigma_{ij}\rangle_{V^*}$, $\langle\sigma_{ij}\rangle_{V-V^*}$ denote the volume average stress of the inhomogeneities and the matrix, respectively. The volume average strain (eq. (1)) can also be expressed using Hooke's law for the constituents as:

$$\langle\varepsilon_{ij}\rangle_V = \frac{V^*}{V}(S^*_{ijkl}\langle\sigma_{kl}\rangle_{V^*} + \alpha^*_{ij}T) + \frac{V-V^*}{V}(S^0_{ijkl}\langle\sigma_{kl}\rangle_{V-V^*} + \alpha^0_{ij}T), \tag{3}$$

where S^*_{ijkl} and S^0_{ijkl} denote the compliance tensor of the inhomogeneity and the matrix, and α^*_{ij} denotes the CTE of the inhomogeneity.

Solving eq. (2) for $\langle\sigma_{ij}\rangle_{V-V^*}$ and substituting in eq. (3) leads to:

$$\langle\varepsilon_{ij}\rangle_V = \frac{V^*}{V}((S^*_{ijkl} - S^0_{ijkl})\langle\sigma_{kl}\rangle_{V^*} + (\alpha^*_{ij} - \alpha^0_{ij})T) + \alpha^0_{ij}T. \tag{4}$$

Using eq. (4) and eq. (1), $\langle\sigma_{kl}\rangle_{V^*}$ can be obtained as:

$$\langle\sigma_{kl}\rangle_{V^*} = (S^*_{ijkl} - S^0_{ijkl})^{-1}\left(\frac{V}{V^*}(\alpha^{eff}_{ij} - \alpha^0_{ij}) - (\alpha^*_{ij} - \alpha^0_{ij})\right)T. \tag{5}$$

$\langle\sigma_{ij}\rangle_{V-V^*}$ can be obtained using eq. (2) and eq. (5). $\langle\varepsilon_{ij}\rangle_{V-V^*}$, $\langle\varepsilon_{ij}\rangle_{V^*}$ can be calculated using:

$$\langle\varepsilon_{ij}\rangle_{V-V^*} = S^0_{ijkl}\langle\sigma_{kl}\rangle_{V-V^*}, \quad \langle\varepsilon_{ij}\rangle_{V^*} = S^*_{ijkl}\langle\sigma_{kl}\rangle_{V^*}. \tag{6}$$

Utilizing eqs. (2), (5), and (6) one can use α^{eff}_{ij} to calculate $\langle\varepsilon_{ij}\rangle_{V-V^*}$ and $\langle\varepsilon_{ij}\rangle_{V^*}$. The evaluation of α^{eff}_{ij} can be done either analytically or numerically as elaborated below.

3. Case Studies

One particulate and one fibrous composite are used as case studies. The particulate composite is comprised of a copper matrix with diamond spherical inclusions (SP) [9] and the fibrous composite is comprised of an epoxy-resin matrix with unidirectional glass fibers (UD) [10] and their properties are given in Table 1. The thermal strains are calculated using analytical and numerical means for both cases based on the formulation of Section 2.

Table 1. Young's modulus E, shear modulus G, Poisson's ratio v, and CTE of copper, diamond, epoxy-resin and glass.

Material Type	E (GPa)	G (GPa)	v (-)	α ($^{\circ}C^{-1}$)
Copper	134.4	50.2	0.34	16.6×10^{-6}
Diamond	904.8	364.8	0.24	1.1×10^{-6}
Epoxy-Resin	3.1	1.1	0.40	66.0×10^{-6}
Glass	71.6	28.6	0.25	4.8×10^{-6}

3.1 Evaluation of effective thermal expansion coefficient

3.1.1 Effective field methods

EFMs are utilized to analytically evaluate the α_{ij}^{eff} of the two composites. The EFMs used are the Mori-Tanaka method and the Maxwell method. The Mori-Tanaka method [11] assumes that each inhomogeneity experiences an effective field equal to the average over the matrix thus capturing interactions between inhomogeneities. The Maxwell method [12] considers that a domain of shape Ω containing inhomogeneities is embedded within the matrix material to model interactions among the inhomogeneities [13]. The effective CTE within the framework of the Mori-Tanaka method and the Maxwell method can be expressed as [9]:

$$\alpha_{ij}^{eff} = \alpha_0 \delta_{ij} + H_{ijkl}^{A} (S_{klmn}^{*} - S_{klmn}^{0})^{-1} (\alpha_{mn}^{*} - \alpha_{mn}^{0}), \tag{7}$$

where δ_{ij} denotes the Kronecker delta and H_{ijkl}^{A} is the compliance contribution tensor evaluated for each EFM A (i.e., Mori-Tanaka (MT), Maxwell (MX)) as:

$$H_{ijkl}^{MT} = \left((1 - \frac{V^*}{V})(H_{ijkl}^{NI})^{-1} + (S_{ijkl}^{*} - S_{ijkl}^{0})^{-1} \right)^{-1}, \quad H_{ijkl}^{MX} = \left((H_{ijkl}^{NI})^{-1} - Q_{ijkl}^{\Omega} \right)^{-1}, \tag{8}$$

with:

$$H_{ijkl}^{NI} = \frac{V^*}{V} \left((S_{ijkl}^{*} - S_{ijkl}^{0})^{-1} + Q_{ijkl}^{*} \right)^{-1}, \quad Q_{ijkl}^{*} = (S_{ijmn}^{0})^{-1} (I_{mnkl} - s_{mnkl}^{*}), \tag{9}$$

where H_{ijkl}^{NI} is the compliance contribution tensor evaluated using the Non-Interaction EFM [14], I_{ijkl} is the fourth-rank identity tensor, s_{ijkl}^{*} represents Eshelby's tensor [15], and Q_{ijkl}^{Ω} can be calculated by following the methodology in [16].

For this study, the Mori-Tanaka method and Maxwell method are employed to determine the effective CTE for both the UD and the SP composites. Volume fractions ranging from 0.01 to 0.7 are considered for both methods. Then, the formulation of Section 2. is utilized to extract the volume average strain for the inhomogeneities $\langle \varepsilon_{ij} \rangle_{V^*}$ and the matrix $\langle \varepsilon_{ij} \rangle_{V-V^*}$.

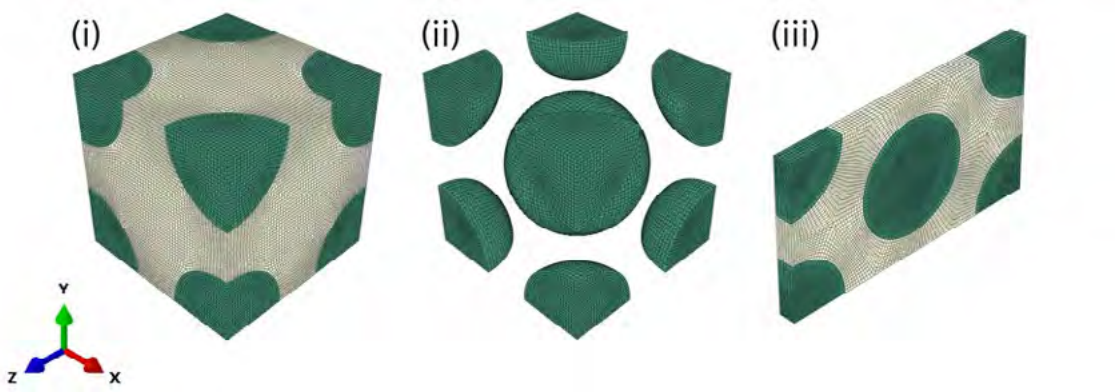

Figure 1. (i) FE model after the meshing process generated for the SP composite with a volume fraction 0.4. (ii) Visualization of the inclusions in the SP model with the matrix elements excluded. (iii) FE model after the meshing process generated for the UD composite with volume fraction of 0.4. Green and beige regions denote the inhomogeneities and matrix, respectively.

3.1.2 Finite element modeling

Two different composite geometries (SP, UD) are created in ABAQUS [17] FE software. The concept of the representative volume element (RVE) is employed to define a unit cell representing the microstructure. In this case, the inhomogeneities are defined based on the type of composite being modeled; spherical inhomogeneities for the SP composite and cylindrical for the UD composite. Five inhomogeneities are periodically positioned in each model. Subsequently, periodic boundary conditions are imposed using the methodology in [18]. The simulations are conducted for volume fractions of 0.1, 0.2, 0.3, 0.4, and 0.5. The analysis utilizes 20-node reduced integration brick elements (referred to as C3D20R elements in ABAQUS). A uniform temperature field of 1 degree is applied to the RVE to simulate expansion. An example of the meshed geometry for both composites is illustrated in Figure 1.

Once the simulations are completed, α_{ij}^{eff} is evaluated as:

$$\alpha_{ij}^{eff} = \langle \varepsilon_{ij} \rangle_{V^*} = \frac{1}{V^e} \sum_e \varepsilon_{ij}^{(e)} V^{(e)}, \tag{10}$$

where e refers to each FE.

Substituting the numerically evaluated α_{ij}^{eff} from eq. (10) to the formulation of Section 2., one can evaluate the strains of the inhomogeneities and the matrix.

As a verification, the volume average strain for the inhomogeneities $\langle \varepsilon_{ij} \rangle_{V^*}$ and for the matrix $\langle \varepsilon_{ij} \rangle_{V-V^*}$ can be calculated as:

$$\langle \varepsilon_{ij} \rangle_{V^*} = \frac{1}{V^*} \sum_{*e} \varepsilon_{ij}^{(*e)} V^{(*e)}, \quad \langle \varepsilon_{ij} \rangle_{V-V^*} = \frac{1}{V-V^*} \sum_{0e} \varepsilon_{ij}^{(0e)} V^{(0e)}, \tag{11}$$

where $(*e), (0e)$ refer to the elements of the inhomogeneities and the matrix, respectively.

4. Results

The results of the formulation using the EFMs and the FE models are presented in Figure 2 for the SP and the UD composites. Mori-Tanaka method, Maxwell method, FE, and verification denote the results achieved using eqs. (7), (10), and (11). Note that the SP composite demonstrates an isotropic behavior whereas the UD composite a transversely isotropic behavior. Hence, the respective parts of the thermal strain tensors are presented. The direction $1,2,3$ refer to x,y,z of the coordinate system illustrated in Figure 1.

In general, a great agreement is presented between the analytical and the numerical results. This demonstrates that the formulation presented in Section 2. can be used with high accuracy in estimating the thermal strains of composites.

Interestingly, the thermal strains of the SP composite present an almost linear drop with increasing volume fraction both for the inhomogeneities and the matrix. However, for the UD composite, ε_{11} of the inhomogeneities shows an exponential drop while ε_{22} increases. ε_{11} of the matrix shows also an exponential drop but ε_{22} first increases until a volume fraction of 0.2 and then drops almost linearly.

Finally, an interesting note can be given regarding the comparison between the EFMs that shows perfect agreement. This is attributed to the fact that the inhomogeneities in each case study are of the same shape as the domain Ω used in the Maxwell method. Under this condition the results of the Mori-Tanaka method and the Maxwell method coincide.

5. Conclusion

The aim of this study was to present a novel methodology for modeling thermal strains in composite materials. A new formulation was provided for computing thermal strains from the effective CTE and was implemented both analytically, by utilizing EFMs, and numerically, by utilizing the FE method. Two case studies were presented, one with particulate and one with fibrous composites. The results for both composites demonstrated great agreement validating the accuracy of the methodology provided.

Keywords: Effective field methods, Property contribution tensors, Thermoelastic materials, Specific heat, Homogenization

Abstract

The present work investigates the influence of local stress and strain effects on the homogenized (effective) specific heat of multi-phase composites. A new formulation is developed using property contribution tensors and the specific heat contribution tensor (scalar) is derived in the framework of the Non-Interaction, the Mori-Tanaka, and the Maxwell, effective field methods (EFMs). The novel formulas are presented for the general case of an anisotropic matrix with anisotropic inhomogeneities of diverse shapes and orientations. Two limited cases of particulate and fibrous two-phase composites are discussed and the results of the novel formulation are compared to results of experiments and finite element models, and exhibit a great agreement.

1 Introduction

Effective properties can be obtained via analytical, numerical, and semi-analytical methodologies [1]. Commonly, these methodologies are used for the evaluation of the effective stiffness (or compliance) tensor [2] and coefficient of thermal expansion [3], the thermal conductivity (or thermal resistivity) tensors [2], and the magnetic permeability (or electrical conductivity) tensors [4].

The specific heat is another property that is important to be evaluated [5]. The specific heat is the amount of heat that is needed in order to increase the temperature of one mass unit of a material by one degree and it appears in heat flow problems. In composite materials, effective specific heat is regularly evaluated by volume [6] or mass [7] averaging. This is mentioned as the rule-of-mixture (ROM) model [8] and it is indeed a logical assumption for applications to composites whose properties exhibit a linear dependency on the volume (or mass) of their constituents.

Despite this fact, Rosen and Hashin [5] argue that this can result in inaccuracies. The authors state that the imposition of a uniform temperature rise in a composite for the evaluation of the effective specific heat results in zero average (over the volume of the composite) stresses or strains under conditions of constant surface tractions or displacements, respectively. Nevertheless, the values of stresses and strains locally are, in general, non-zero and depend on the material and geometric parameters of the constituents. The material parameters are the elastic properties and the thermal expansion of the matrix and the inhomogeneities whereas the geometric parameters are the orientation and shape of the inhomogeneities.

This work aims to investigate the initial assumption of Hashin and Rosen regarding the influence of local stresses and strains on the effective specific heat. To this end, a novel formulation based on effective field methods (EFMs) is developed for multi-phase composites as elaborated below.

2 Analytical modeling

Consider first the coupled constitutive equations of thermoelasticity [2]:

$$\varepsilon_{ij} = S_{ijkl}\sigma_{kl} + \alpha_{ij}T \quad s = \alpha_{ij}\sigma_{kl} + \chi T, \tag{1}$$

where ε_{ij}, σ_{ij}, S_{ijkl}, α_{ij} denote the strain, the stress, the compliance, and the coefficient of thermal expansion tensors and T the uniform temperature. s and χ denote the entropy and the specific heat, which are scalar quantities. Eq. (1) is applicable to any solid or system of solids, such as a composite material.

Consider now the single inhomogeneity (particle, fiber, etc.) problem where an inhomogeneity of volume $V^{(p)}$ is embedded in an infinite and homogeneous matrix of volume $V^{(0)} = V - V^{(p)}$, with V the total volume of the composite. Note that the superscripts (p) and (0) denote properties of the inhomogeneity and the matrix, respectively.

For an imposed constant and uniform temperature field T, the volume average entropy $\langle s \rangle_V$ can be written as:

$$\langle s \rangle_V = \frac{V^{(p)}}{V}\langle s^{(p)} \rangle_{V^{(p)}} + \frac{V - V^{(p)}}{V}\langle s \rangle_{V-V^{(p)}} = \bar{\chi}T. \tag{2}$$

Note that the notation $\langle \cdot \rangle_V$ is the volume average operator with respect to volume V and that $\bar{\cdot}$ denotes an effective property. Therefore, $\bar{\chi}$ denotes the effective specific heat. Furthermore, note that the classical expansion problem that is assumed here considers a traction-free boundary, i.e., the average traction on the surface of the composite and, by extent, the volume average stress of the composite $\langle \sigma_{ij} \rangle_V$ are zero, i.e.:

$$\langle \sigma_{ij} \rangle_V = \frac{V^{(p)}}{V} \langle \sigma_{ij} \rangle_{V^{(p)}} + \frac{V - V^{(p)}}{V} \langle \sigma_{ij} \rangle_{V - V^{(p)}} = 0, \tag{3}$$

Using eq. (1) and (2), the volume average entropy $\langle s \rangle_V$ can be written as:

$$\langle s \rangle_V = \frac{V^{(p)}}{V} \left[\alpha_{ij}^{(p)} \langle \sigma_{ij} \rangle_{V^{(p)}} + \chi^{(p)} T \right] + \frac{V - V^{(p)}}{V} \left[\alpha_{ij}^{(0)} \langle \sigma_{ij} \rangle_{V - V^{(p)}} + \chi^{(0)} T \right]. \tag{4}$$

The volume average entropy can be written as a sum of the entropy of the matrix $\langle s \rangle_{V - V^{(p)}} = \alpha_{ij}^{(0)} \langle \sigma_{ij} \rangle_{V - V^{(p)}} + \chi^{(0)} T$ and a perturbation $\Delta s = \frac{V^{(p)}}{V} H^{(Sp)} T$ due to the presence of the inhomogeneity p as:

$$\langle s \rangle_V = \langle s \rangle_{V - V^{(p)}} + \Delta s = \alpha_{ij}^{(0)} \langle \sigma_{ij} \rangle_{V - V^{(p)}} + \chi^{(0)} T + \frac{V^{(p)}}{V} H^{(Sp)} T. \tag{5}$$

with $H^{(Sp)}$ being the specific heat contribution tensor. Solving eq. (5) for $H^{(Sp)}$ and substituting eqs. (3) and (4), $H^{(Sp)}$ can be evaluated as:

$$H^{(Sp)} T = \frac{V^{(p)}}{V} \left[\left(\alpha_{ij}^{(p)} - \alpha_{ij}^{(0)} \right) \langle \sigma_{ij} \rangle_{V^{(p)}} + \left(\chi^{(p)} - \chi^{(0)} \right) T \right]. \tag{6}$$

Note that the specific heat contribution tensor is a rank 0 tensor, i.e., a scalar value.

Finally, using eqs. (2) and (6), the effective specific heat is given as:

$$\bar{\chi} = \chi^{(0)} + \frac{V^{(p)}}{V} H^{(Sp)}. \tag{7}$$

Due to eq. (6) and (7), the effective specific heat depends on the local effects of stresses of the inhomogeneities due to $\langle \sigma_{ij} \rangle_{V^{(p)}}$.

Eq. (6) can also be used to express $H^{(Sp)}$ in terms of the thermal expansion contribution tensor $H_{ij}^{(Tp)} = \frac{V^{(p)}}{V} \left[\left(S_{ijkl}^{(p)} - S_{ijkl}^{(0)} \right) \langle \sigma_{kl} \rangle_{V^{(p)}} + \left(\alpha_{ij}^{(p)} - \alpha_{ij}^{(0)} \right) T \right]$ derived in [3]. After some tensor algebra $H^{(Sp)}$ is written as :

$$H^{(Sp)} = H_{ij}^{(Tp)} Q_{ijkl}^{(p)} \left(\alpha_{kl}^{(0)} - \alpha_{kl}^{(p)} \right) + \left(\chi^{(p)} - \chi^{(0)} \right), \tag{8}$$

with $Q_{ijkl}^{(p)} = C_{ijmn}^{(0)} \left(I_{mnkl} - \mathsf{S}_{mnkl}^{(p)} \right)$ and $\mathsf{S}_{mnkl}^{(p)}$ being Eshelby's tensor [9]. $H^{(Sp)}$ is directly linked to the compliance contribution tensor $H^{(p)}$. Using:

$$H_{ij}^{(Tp)} T = H_{ijkl}^{(p)} \left(S_{klmn}^{(p)} - S_{klmn}^{(0)} \right)^{-1} \left(\alpha_{mn}^{(p)} - \alpha_{mn}^{(0)} \right), \tag{9}$$

$H^{(Sp)}$ becomes:

$$H^{(Sp)} = H^{(p)}_{ijkl}\left(S^{(p)}_{klmn} - S^{(0)}_{klmn}\right)^{-1}\left(\alpha^{(p)}_{mn} - \alpha^{(0)}_{mn}\right)Q^{(p)}_{ijrs}\left(\alpha^{(0)}_{rs} - \alpha^{(p)}_{rs}\right) + \left(\chi^{(p)} - \chi^{(0)}\right). \tag{10}$$

Eq. (10) can be used to evaluate the effective specific heat using the Non-Interaction (NI), the Mori-Tanaka (MT), and the Maxwell (MX) methods. As explained in [3], the form of (10) allows to simply substitute the compliance contribution tensors of the three EFMs. These are given as [3]:

$$\begin{aligned} H^{(NIp)}_{ijkl} &= \left[\left(S^{(p)}_{ijkl} - S^{(0)}_{ijkl}\right)^{-1} + Q^{(p)}_{ijkl}\right]^{-1}, \; H^{(MTp)}_{ijkl} = H^{(NIp)}_{ijmn}\left[I_{mnkl} - \sum_p \frac{V^{(p)}}{V} Q^{(p)}_{mnrs} H^{(NIp)}_{rskl}\right]^{-1}, \\ H^{(MXp)}_{ijkl} &= H^{(NIp)}_{ijmn}\left[I_{mnkl} - Q^{(\Omega)}_{mnrs}\sum_p \frac{V^{(p)}}{V} H^{(NIp)}_{rskl}\right]^{-1}, \end{aligned} \tag{11}$$

where tensor $Q^{(\Omega)}_{ijkl}$ can be obtained via the methodology presented in [4].

3 Case studies

Two case studies are presented in this article to further investigate the applicability of the formulas derived in section 2. The first case study considers the case of overall isotropy of a particulate composite of polypropylene with copper particles. The second case considers two fibrous composites, a glass and a carbon fiber-reinforced epoxy composite.

This section presents first the development of the FE models (section 3.1) for the particulate and the fibrous composites and then the results (section 3.2) of the analytical formulas, the experiments, and the FE models.

3.1 Finite element modeling

Two geometries, one representing a particulate composite and one a fibrous composite, were created in the ABAQUS FE software [10]. For the particulate composite, the geometry of the inhomogeneities is spherical, whereas for the fibrous composite, it is cylindrical. Periodic boundary conditions (PBCs) were imposed using the methodology presented in [11]. The volume fraction of the inhomogeneities in each geometry was taken as 0.1, 0.2, 0.3, 0.4, and 0.5. The 20 node reduced integration brick elements (C3D20R elements by the terminology of ABAQUS) were used for the analysis. An example of the geometry of the particulate and the fibrous composite is given in Figure 1. The mesh was determined by mesh convergence studies.

A uniform temperature field of 1 degree was imposed on each geometry so as to simulate expansion. After the solution of the problem, the volume average stress of the inhomogeneities $\langle\sigma_{ij}\rangle^{(p)}_V$ and the matrix $\langle\sigma_{ij}\rangle^{(0)}_V$ were calculated by:

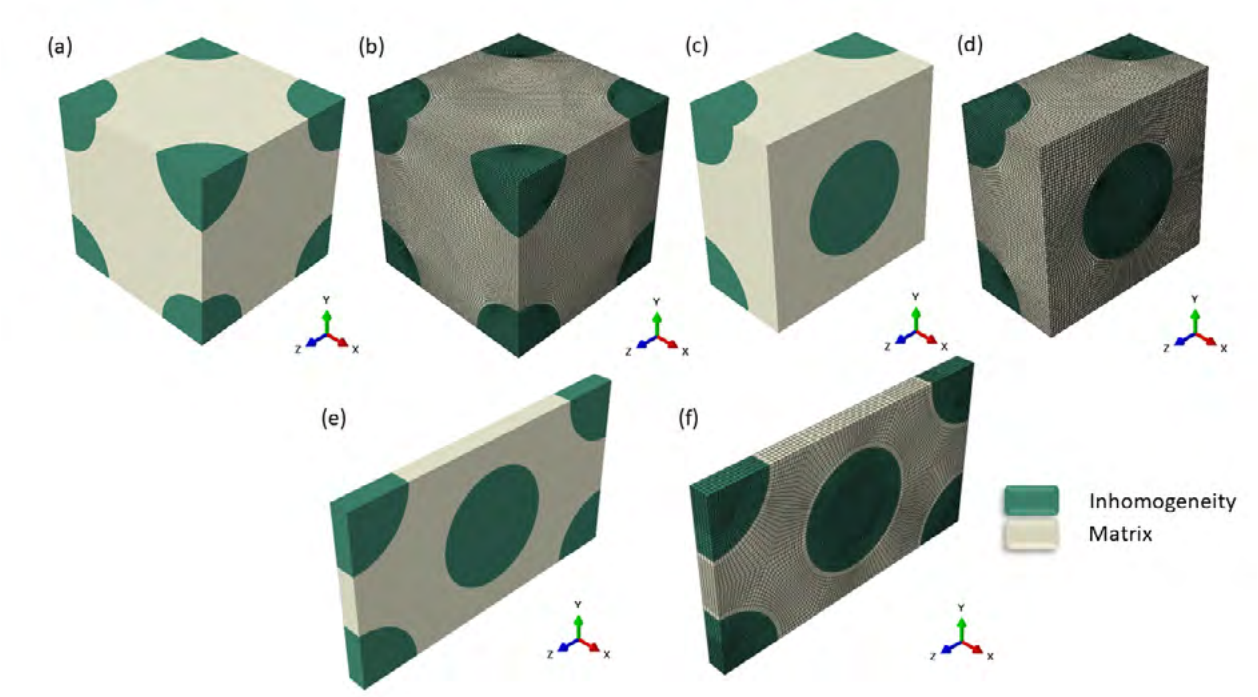

Figure 1. Example of the FE models generated for the particulate ((a)-(d)) composite with volume fraction 0.2 and the fibrous ((e) and (f)) composite with volume fraction of 0.4. (a), (c), and (e) present the geometry before and (b), (d), and (f) after meshing. (c) and (d) show a cross-section of the model.

$$\langle \sigma_{ij} \rangle_{V^{(p)}} = \frac{1}{V^{(p)}} \sum_e \sigma_{ij}^{(pe)} V^{(pe)}, \quad \langle \sigma_{ij} \rangle_{V^{(0)}} = \frac{1}{V^{(0)}} \sum_e \sigma_{ij}^{(0e)} V^{(0e)} \tag{12}$$

where $\sigma_{ij}^{(pe)}$ and $\sigma_{ij}^{(0e)}$ are the stress of element e of inhomogeneity p and of the matrix 0 and $V^{(pe)}$ and $V^{(0e)}$ their volume. The solutions of $\langle \sigma_{ij} \rangle_{V^{(p)}}$ and $\langle \sigma_{ij} \rangle_{V^{(0)}}$ were then substituted in eq. (4) in order to obtain the volume average specific heat of the composite as $\bar{\chi} = \langle s \rangle_V / T$.

The properties (elastic, thermal expansion, and specific heat) of the polypropylene [6], the copper particles [6], the glass fibers [12, 13], the carbon fibers [12, 14], and the epoxy resin [12] are taken from the literature and are given in Table 1.

3.2 Results

3.2.1 Particulate composites

Data from [6] is used for the polypropylene with copper particles (PP/Cu) composite. The authors prepared two types of samples with different sizes of copper fillers (PP/Cu_a and PP/Cu_b) and determined the effective specific heat of the composite using differential scanning calorimetry (DSC). Since the size of the particles is not considered in the presented formulation of section 2 or the FE models of section 3.1, the analytical

Table 1. Properties (elastic, thermal expansion, and specific heat) of polypropylene, copper particles, glass fibers, carbon fibers, and epoxy resin. E_{11}, E_{22}, G_{12}, and G_{23} in GPa, ν_{12} in -, α_{11} and α_{22} in $10^{-6}/K$, χ in $J/(kg.K)$.

	E_{11}	E_{22}	G_{12}	G_{23}	ν_{12}	α_{11}	α_{22}	χ
Polypropylene	1.35	1.35	0.52	0.52	0.30	166.00	166.00	1731
Copper	110.00	110.00	42.30	42.30	0.30	17.00	17.00	381
Glass fibers	68.00	68.00	27.20	27.20	0.25	9.00	9.00	803
Carbon fibers	234.00	15.00	15.00	7.00	0.20	-1.35	6.84	600
Epoxy	3.00	3.00	1.15	1.15	0.30	57.50	57.50	1400

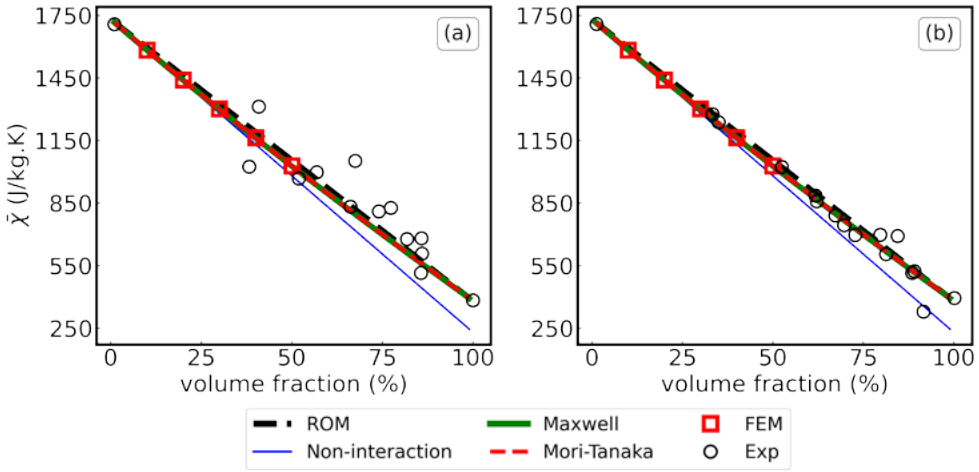

Figure 2. Comparison of the effective specific heat (in J/kg.K) from experiments [6] (with permission from Elsevier) with the predictions of the Non-Interaction, the Mori-Tanaka, and the Maxwell EFMs and the results of the ROM and FE models. PP/Cu$_a$ specimens are presented in (a) and PP/Cu$_b$ specimens in (b).

formulas and the FE models are applicable to both types of samples. For specifics regarding the experimental process, the reader is referred to their work [6].

The results of the three EFMs, the Non-Interaction, the Mori-Tanaka, and the Maxwell, and the FE models compared to the experimental data (average values) of [6] for the effective specific heat of the two types of specimens PP/Cu$_a$ and PP/Cu$_b$ are presented in Figure 2 for increasing values of the volume fraction of copper particles. The figure also contains the estimates of the ROM model, so that it can be compared to the newly derived analytical formulas and the FE models.

The comparison reveals a great agreement of the analytical and the numerical models with the experimental data. For volume fractions below 0.5 the Non-Interaction method gives also good predictions and does not deviate drastically from the Mori-Tanaka and the Maxwell methods and the ROM and FE models. However, it is evident that the Non-Interaction method provides physically inaccurate estimates for high volume fractions since the upper limit of volume fraction 1.0 must coincide with the specific heat of the inhomogeneities. This can be explained by the inability of the method to capture interactions between inhomogeneities. The predictions of the Mori-Tanaka and the Maxwell methods are also in good agreement with the ROM model.

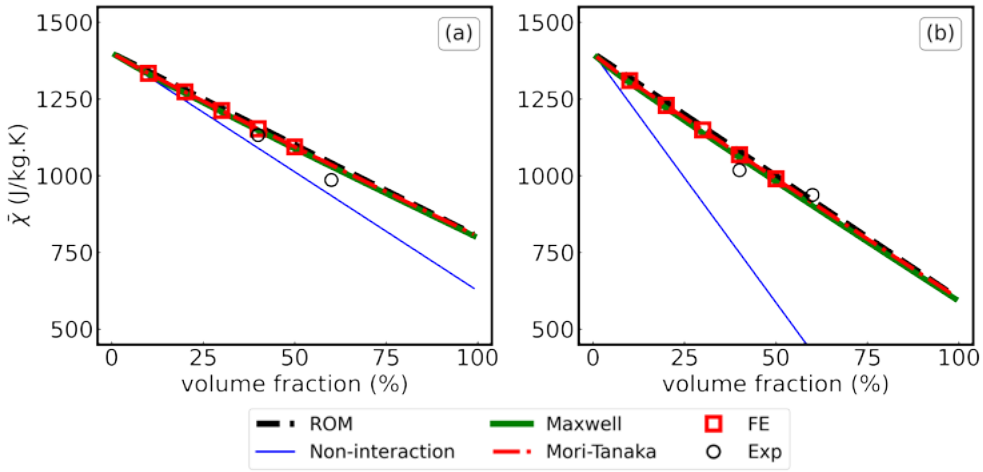

Figure 3. Comparison of the effective specific heat (in J/kg.K) from experiments [12] with the predictions of the Non-Interaction, the Mori-Tanaka, and the Maxwell EFMs and the results of the ROM and FE models. GFRP specimens are presented in (a) and CFRP specimens in (b).

A small deviation is demonstrated with slightly lower values of effective specific heat being predicted by the two EFMs. The results of the FE model are in perfect agreement with the Mori-Tanaka and the Maxwell methods.

3.2.2 Fibrous composites

Two types of (unidirectional) fibrous composites, one of epoxy reinforced with glass (GFRP) and one reinforced with carbon (CFRP) fibers, are examined in this section. The results of laser flash diffusivity tests from [12] are presented in Figure 3 for fiber volume fractions of 0.4 and 0.6 and compared to the analytical and numerical models.

The majority of the analytical methods (apart from the Non-Interaction method) follow well the experimental data. The Non-Interaction method presents differences due to its inaccuracy in estimating the compliance contribution tensor which is used in eq. (10). The Mori-Tanaka and the Maxwell methods are in good agreement with the ROM model. The two methods demonstrate also a perfect agreement with the results of the FE models.

4 Conclusions

The aim of the work was to investigate the influence of local stresses and strains on the effective specific heat. This was achieved by a novel formulation of EFMs and comparison with numerical and experimental results. The main conclusions of this work can be summarized as follows. The formulation shows that the effective specific heat depends not only on the volume fractions and the specific heats of the constituents but also on local effects of stresses. However, these local effects are negligible.

Abstract
The research aims to explore the feasibility of using electrical measurements to monitor damage in single-lap bonded joints. To begin with, an analytical model is developed to estimate the increase in electric resistance across the joint bond surface due to damage. The model's accuracy is validated numerically using Finite Element Analysis and experimental fatigue tests are conducted on single lap joints with Aluminium adherends and a conductive epoxy adhesive. Following tests on Carbon-epoxy composite laminates highlight the importance of considering actual damage mechanisms. To this end, a procedure is presented, where crack-surface electrical conductivity evolves with crack length. A final test case demonstrates the model's effectiveness in continuously monitoring damage presence in bonded joints through electrical measurements.

1. Introduction

In recent years, the adoption of fibre-reinforced polymer composites for structural purposes has seen significant growth, driven by industries such as aerospace and automotive. When using composite materials in structural applications, the need arises to join various components together. Among the available joining methods, adhesive bonding stands out as an excellent choice due to its lightweight and cost-effective connections, and unlike other techniques, adhesive bonding avoids the need for drilling holes in composite parts. However, designing bonded connections to withstand static and, primarily, fatigue failure is a challenging task.

A significant challenge lies in dealing with defects of purely bonded connections: some defects (such as voids, pre-cracks, or cracks formed during service life) can be detected through periodic inspections and managed with appropriate design tools, yet defects related to poor bonds (due to contaminating agents) remain undetectable. Consequently, proving the integrity of purely bonded connections before putting them in service becomes impossible, leading to uncertified applications in critical industrial sectors. To mitigate uncertainties, companies often resort to combined bonded/bolted joints, sacrificing the economic, weight, and performance advantages of adhesive bonding. As a result, there is a growing focus on simulating fatigue damage initiation and evolution accurately in bonded connections and developing effective crack-stopping mechanisms and health monitoring methods [1-4].

In the context of this study, the objective of the paper is to develop models and methods for continuous Structural Health Monitoring (SHM) of bonded connections. The electrical method was the chosen SHM strategy, since it has shown promising results for monolithic composite parts [5-11]. This approach, that requires only properly positioned electrodes connected via cables to the component, leverages the irreversible increase in electrical resistance caused by damage formation, specifically bondline cracks in bonded joints. Naturally, this method relies on the use of electrically conductive materials for both adherends and adhesive. Carbon fibre-based composites inherently exhibit conductivity, while for glass fibres, a matrix nano-modification using conductive fillers can be employed.

2. Methodology overview

As a first step, an analytical model of the damage-induced increase of the electric resistance across the single-lap joint bond surface is developed for inferring the crack length. The model analytically depicts the electric field within the joint and it is able to estimate the resistance increase due to damaging following adherend/adhesive debonding in the configuration shown in Figure 1. To this end the model assumes that the crack faces are perfect insulators. After a numerical validation by means of Finite Element Analysis, further proof of the model accuracy is provided by experimental tests on single lap joints, where the adherends are made of Aluminium and the adhesive is a conductive epoxy. In more detail, the joint stiffness reduction is periodically evaluated during fatigue cycles, at fatigue ratio 0.1, by means of digital image correlation, and it is compared with the prediction of a Finite Element model of the joint created accounting for the damage information determined by the analytical model. In order to account for residual electrical conductivity across crack faces, the model is modified, and its predictions are compared with the results of tests on bonded joints obtained with adherends made of Carbon-epoxy composite laminates where, due to fibre-bridging and damaging running inside the adherend, the crack faces exhibit a residual electrical conductivity. Eventually, a comprehensive procedure is presented, where the evolution of the crack-surface electrical conductivity as a function of crack length is represented by a parameter evaluated by best-fit of a preliminary sub-set of joints. A final test case proves the model efficacy in continuously monitoring the presence of damage in bonded joints through electrical measurements.

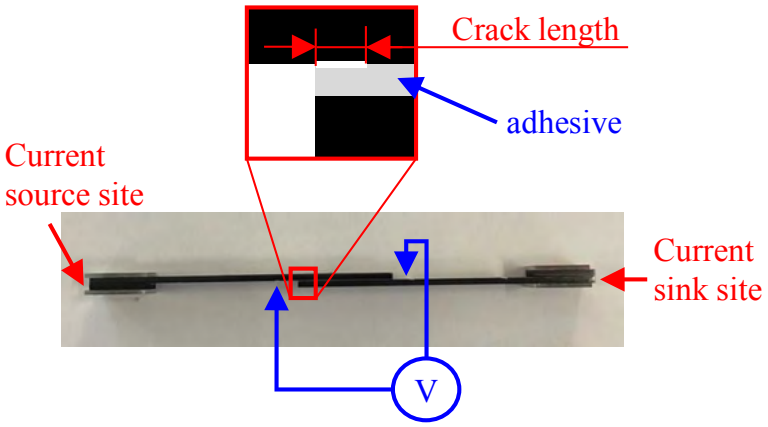

Figure 1. Investigated bonded joint configuration. The image highlights the position of current sink and source sites, as well as the position of the voltage measurement probes.

3. Analytical model

The model relies on the electrical scheme reported in Figure 2. The upper adherend is considered as constituted by a fixed resistance, Ra^{U}, and a variable resistance, Ra^{U*}, and the same applies to the lower adherend, with Ra^{L} and Ra^{L*} respectively. The adhesive is represented by another variable resistance, Rad. In the undamaged configuration, Ra^{U*} and Ra^{L*} are zero. As soon as damage takes place, the current is supposed to be unable to cross the crack faces, and the adherends behaves as if they elongated by an amount equal to crack length: the associated increase in the electrical resistance is represented by Ra^{U*} and Ra^{L*}. At the same time the contact surface between the adherends and the adhesive is reduced, thus resulting in an increase of Rad.

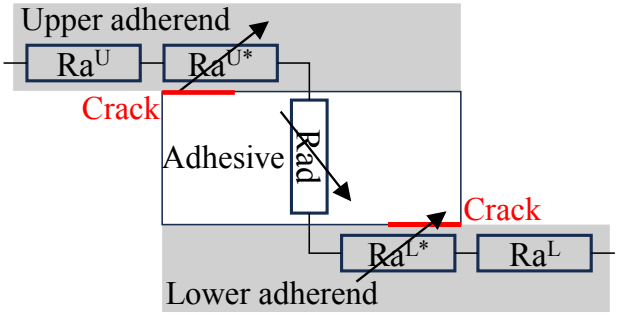

Figure 2. Simplified electrical scheme of the joint.

Upon a closer analysis, to properly model the electrical field between crack tips it appears that the abovementioned model is not accurate enough. In fact, the electricity is not instantly transferred from the adherend to the adhesive, but there is an electrical field along the joint length also within the adherend portion that is still attached to the adhesive.
Following these considerations, it is possible to build a system of differential equations that represents the electrical current density variation along the joint length, redefining Rad as the electrical resistance of the joint between crack tips, thus considering both the adhesive and the adherends (see Figure 3).

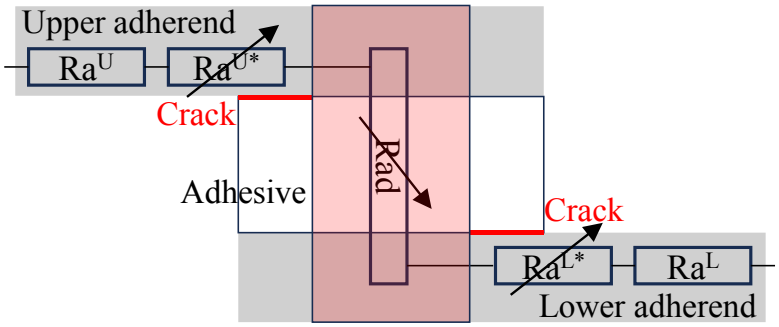

Figure 3. Electrical scheme of the joint considered in the analytical model. A red overlay highlights the material considered for the analytical model.

The differential equation of the current density through-the-thickness (z direction) j_z is represented by the following equation (Eq. 1), valid for both adherends and adhesive:

$$j_z = -\frac{1}{\eta_z}\frac{\partial V(z)}{\partial z} \tag{1}$$

where η_z represents the material out-of-plane resistivity. It is then possible to evaluate through-the-thickness average values of the electric potential in each layer $\overline{V}$ by means of (Eq. 2):

$$\overline{V} = \frac{1}{t}\int_0^t V(z)\,dz \tag{2}$$

with t the layer thickness (both for adherend and adhesive).
It is then possible to describe the current flow along the joint length (x direction), leveraging on the charge conservation principle, as (Eq. 3):

$$\begin{cases} \dfrac{\partial j_x^{(1)}}{\partial x} - \dfrac{1}{t_1} j_c^{(1-2)} = 0 \\ \dfrac{\partial j_x^{(2)}}{\partial x} - \dfrac{1}{t_2}\left(j_c^{(2-3)} - j_c^{(1-2)} \right) = 0 \\ \dfrac{\partial j_x^{(3)}}{\partial x} + \dfrac{1}{t_3} j_c^{(2-3)} = 0 \end{cases} \tag{3}$$

where superscript (1) refers to the upper adherend, (2) refers to the adhesive, and (3) refers to the lower adherend. j_c is the current density moving in z direction at the interface of the layers.

Following these assumptions, it is possible to derive an analytical expression of the current field. The complete framework is under publication in Structural Health Monitoring journal, published by Sage.

It is worth noting that if the adhesive electrical resistance is significantly higher than that of the adherends, the expression of the joint electrical resistance following damage, R, simplifies to (Eq. 4):

$$R = R_0 \frac{w}{w - \left(a^U + a^L \right)} \tag{4}$$

where R_0 is the electrical resistance in the undamaged configuration, a^U and a^L are the crack lengths at adhesive/upper-adherend interface and adhesive/lower-adherend interface respectively, and w is the initial adhesive ligament length along the joint-length direction.

4. Numerical validation

The model was initially validated by means of Finite Element Analysis, using Ansys Mechanical APDL. The material properties used in the analysis are reported in Table 1.

Table 1. Electrical material properties used for numerical validation.

Material	in-plane resistivity, η_x [Ω mm]	through-the-thickness resistivity, η_z [Ω mm]
Aluminium	2.82E-11	2.82E-11
CNT-modified GFR laminates	6.15E+04	7.08E+04
Araldite ® adhesive	1.37E+07	1.37E+07
CNT-modified epoxy adhesive	2.42E+04	2.42E+04

In Figure 4 a comparison between the FEA and the analytical results is shown. Two different material pairs were considered: Aluminium adherends and Araldite adhesive, case I, and CNT modified GFR laminates with CNT modified epoxy adhesive, case II. For case I Eq. 4 is enough to describe the joint behaviour, given that the lines of the prediction of the full analytical model and of the simplified model overlap. It appears that the proposed model is effective in predicting the electrical resistance variation due to damaging in both configurations. Moreover, the FEA analyses prove that the relative length of a^U and a^L do not influence the resistance variation, which is affected only by their sum: i.e. the overall damage extent.

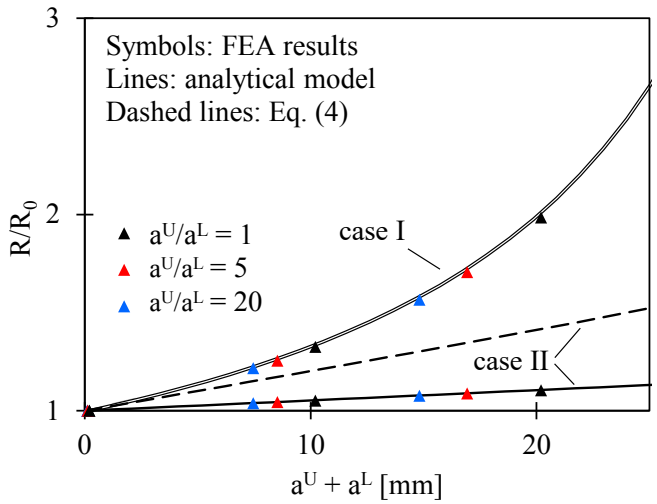

Figure 4. Comparison between FEA results and analytical model for different joint geometrical configurations and materials.

5. Experimental validation

Two material pairs for the joint adherends and adhesive were evaluated: the first one considers adherends made of Aluminium with Huntsman Araldite® 40300 adhesive, whilst the second one makes use of CFR UD laminated adherends with the same adhesive. Araldite® is a conductive epoxy adhesive that contains Miralon® particles. The assessment of the damage evolution was done measuring the joint stiffness reduction during cyclic loadings.
The Aluminium adherends have a thickness of 1.85 mm and have been obtained from a flat panel, while the CFR UD laminate is obtained stacking 4 layers of a UD HS600 – ET445 – 35% prepreg and processing them in autoclave.
Tabs made of the same material of the adherends were then applied to the specimen ends, followed by additional Glass/Epoxy tabs to ensure electrical insultation between the sample and the grips of the testing machine.

In Figure 5 the procedure used for validating the model is depicted. The samples have been loaded with fatigue ratio 0.1 by a servo-hydraulic machine and data was collected in terms of force, displacement field of the joint, and electrical conductivity. Conductivity measurements allow the use of the analytical model for estimating the total crack length. Then, the estimated crack length can be used in a Finite Element virtual twin of the joint to assess its loss of stiffness, here represented as the stiffness of the damaged configuration, K, divided by the stiffness of the undamaged configuration, K_0. The value of K/K_0 so predicted can then be compared to the experimental joint stiffness reduction.

The electrical properties of the materials used for manufacturing the joints are reported in Table 2.

Table 2. Electrical material properties used for experimental validation.

Material	in-plane resistivity, η_x [Ω mm]	through-the-thickness resistivity, η_z [Ω mm]
Aluminium	2.82E-11	2.82E-11
CFR UD laminate	2.00E-01	2.70E+04
Araldite ® adhesive	1.37E+07	1.37E+07

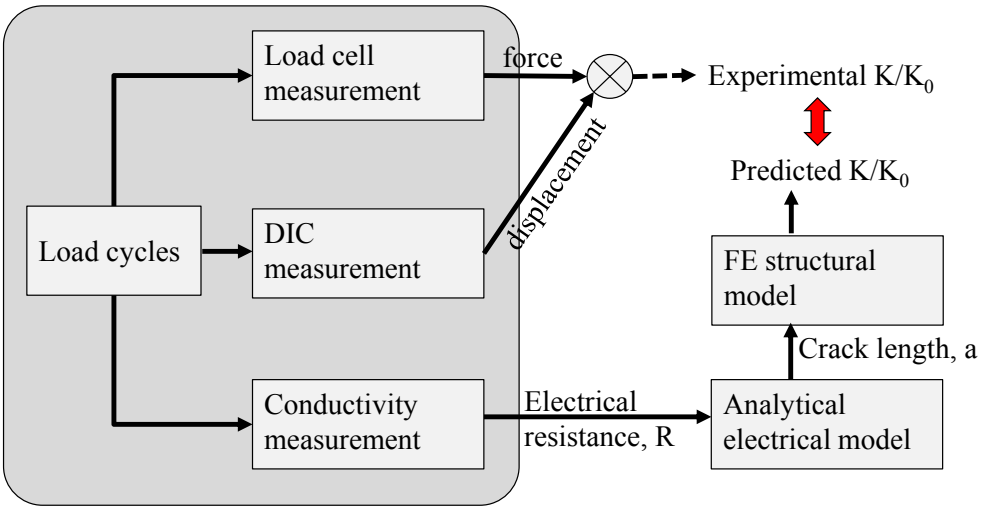

Figure 5. Scheme of the dataflow used for validating the model.

The proposed comparison for a sample joint made of Aluminium adherend is reported in Figure 6. It appears that the model is fully capable of predicting the stiffness reduction by means of electrical measurements.

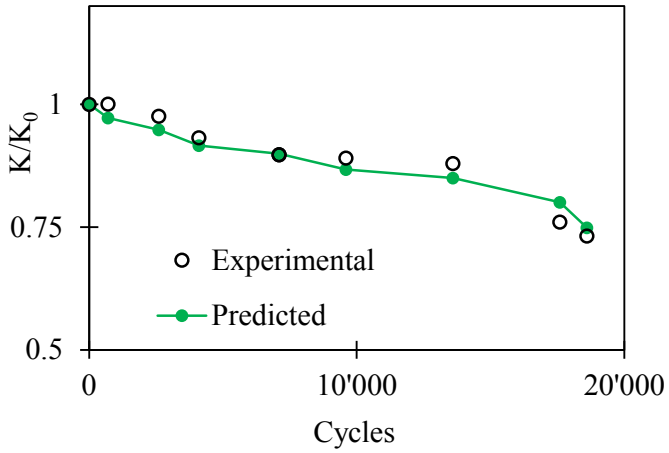

Figure 6. Comparison of experimental and predicted results for a specimen made of Aluminium adherends.

5. Model modification and validation

The methodology presented so far relies on the hypothesis that crack faces are fully insulating, thus there is a direct relationship between the load-carrying surface and the electricity-conducting one. However, it is well known that in the case of fibre-reinforced laminates fibre bridging takes place, and its direct consequence is that electricity can flow across the crack surfaces. Another common damage mode that can take place is that crack tilts from the adherend-adhesive interface to the inside of the adherend, thus resulting, again, in a reduced electrical insulation.

To account for these behaviours, Eq. 4 can be modified into (Eq. 5):

$$\frac{R}{R_0} = \frac{w}{w - a_{TOT}(1-\varphi)} \tag{5}$$

where φ is a parameter that quantifies the residual electrical conductivity across crack faces. In more details, φ can be expressed as (Eq. 6):

$$\varphi = \frac{1}{\left(1 + \frac{r_i}{\eta_a \cdot t_a}\right)} \tag{6}$$

where r_i is the interface resistance, η_a is the adhesive electrical resistivity, and t_a is the adhesive thickness. The same hypotheses standing for Eq. 4 apply.

It is important to consider that φ actually depends on the crack length, since fibre bridging mechanism requires some crack extension to develop. As such, in order to apply the method, it is necessary to calibrate φ with an experimental campaign on the target joint, so that its value is known for each crack length. In the following, the calibration was performed by testing 3 specimens and evaluating φ average value and standard deviation.

Finally, to use the proposed model to estimate a joint stiffness reduction, Eq. 5 can be applied. Since the crack extension influences the value of φ, an iterative numerical procedure is required. The results for a test specimen are reported in Figure 7, where the band represents the predictions associated to φ values at 10% and 90% probability, according to standard distribution.

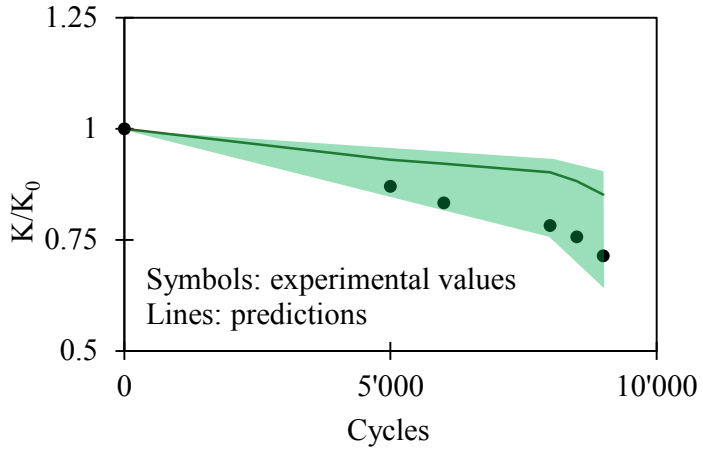

Figure 7. Comparison of experimental and predicted results for a specimen made of CFR UD adherends.

Even though the scatter of the forecasts is not irrelevant, it appears that the model is able to follow the experimental data trend. Such scatter is the result of unpredictability in the damage mode in the considered joints. In more details, the event of the crack tilting inside the adherend affects relevantly the experimental trend, but the occurrence of that event is not predictable, thus requiring a probabilistic approach.

6. Conclusions

The current manuscript explored the feasibility of using electrical measurements to monitor damage in single-lap bonded joints. An analytical model was presented to estimate the increase in electric resistance across the joint bond surface due to damage, accounting for the differential equations describing electrical fields in the joint. The model's accuracy was proved numerically using Finite Element Analysis, considering both high-conductivity and low-conductivity adherends with different crack length. Later on, experimental fatigue tests were conducted on single lap joints with Aluminium adherends and a conductive epoxy adhesive, showing that the ability of the model in inferring the damage extent using data from electrical monitoring can be put in use in a FE structural model to predict

the joint stiffness reduction. To account for residual electrical conductivity across crack faces in fibre reinforced adherends, the model was modified, and following tests on Carbon-epoxy composite adherends showed the model was still able to assess the joint stiffness reduction. At the same time the tests highlighted the importance of employing a probabilistic approach to account for the actual damage mechanisms.

Keywords: Thermoplastic Composite Pipe, Phased Array Ultrasonic Testing, Computed Tomography

Abstract
A collaborative effort is underway to establish standardized methods for ensuring the structural integrity of composite pipes, focusing on thick fiber-reinforced composite pipes like thermoplastic composite pipe (TCP) and reinforced thermoplastic pipe (RTP). These flexible pipes offer advantages over metal counterparts, including high strength-to-weight ratios and corrosion resistance, making them ideal for various industries, including oil and gas and renewable energy. However, non-destructive testing (NDT) of thick composites utilizing the widely used ultrasonic testing (UT) technique presents challenges. Current technologies, developed primarily for metal and thinner composites, struggle to effectively detect defects in multi-layered materials. This project addresses this limitation by utilizing phased array ultrasonic testing (PAUT) with the implementation of the classical time-corrected gain (TCG) method. The proposed technique demonstrated reliable detectable signals with good signal-to-noise ratios (SNR). Subsequently, it successfully detected and characterized delamination and impact damage. The defect morphology reported by the proposed method was further validated using X-ray computed tomography (CT). Although this imaging-based technique faces practical limitations for field use due to size, portability, and cost constraints, it offers more detailed, three-dimensional visualizations of the internal structures of the tested materials. Overall, the UT technique shows promise for immediate practical applications, while X-ray CT remains more suitable for laboratory or controlled environments.

1. Introduction

TCP and RTP gradually replace traditional metal pipes due to their non-corrosive nature, flexibility, and high strength-to-weight ratio. These qualities make them ideal for reducing maintenance and overall installation costs while extending service life. However, despite these advantages, both materials are susceptible to various defects, including delamination within composite laminate layers, debonding at interfaces between different layers, fiber breakage, matrix deformation, matrix degradation, and thinning of protective layers due to external forces. Thus, the need for NDT techniques to reliably detect these anomalies remains crucial. NDT techniques that can be applied directly onsite are essential. While ultrasonic wave-based methods are widely used in the market, they were primarily developed for isotropic and homogeneous materials like metals. The main challenge faced when applying UT to polymer and polymer composite materials is severe attenuation due to absorption in polymer materials, which is four orders of magnitude greater than that of metals [1], and the scattering at fiber-matrix interfaces in random directions [2].

As composite materials gain prominence in industries such as aerospace and automotive, the demand for reliable NDT techniques for structural integrity assessment has surged. UT has been extensively studied and proven effective in identifying defects such as delamination [3][4][5] and impact damage [6][7][8] in thin composite structures. The relatively short propagating distance in thin structures compensates for the severe attenuation of ultrasonic waves. However, thick TCP and RTP pose additional challenges due to their increased thickness and the presence of thick thermoplastic covers and inner liners. Limited research was performed to study the UT capability related to this specific application, particularly concerning thick multi-layered composite structures [9][10]. Using standard procedures employed for metals or thin composites is insufficient, as increasing instrument gain not only amplifies the signal of interest but also amplifies noise from multiple layers of composite laminate. This study focuses on overcoming the limitations of current PAUT technology in inspecting such materials by incorporating the classical TCG method to compensate for spatial signal attenuation and a focusing technique for improved defect characterization. Additionally, X-ray CT scans are conducted to obtain a three-dimensional representation of delamination and impact damage for comparison with UT results.

2. Materials

2.1 TCP and RTP

This study investigated two types of composite pipes, which are TCP and RTP, each comprising three distinct layers. These layers include a thermoplastic outer cover, multiple fiber-reinforced composite laminate layers, and a thermoplastic inner liner. In the production of TCP, prepreg tapes are wound around a thermoplastic pipe at a typical winding angle of ±55°, forming multiple composite laminate layers. These prepreg tapes are made of continuous glass or carbon fiber reinforcement with a similar thermoplastic material as in the cover and liner as matrix materials. Subsequently, a thermoplastic outer cover is applied around these composite layers, and they are melt-fused to establish strong bonding between each layer, creating the cover-laminate and liner-laminate interface layers. Despite the matching acoustic impedance between these layers due to the presence of similar thermoplastic materials, which theoretically facilitates the transmission of ultrasonic energy through the boundary, severe attenuation occurs due to absorption in the polymer material and multiple reflections within the fiber-reinforced composite laminate layers, posing significant challenges to the UT technique. Meanwhile, RTP is produced by helically wrapping two layers of continuous and twisted aramid yarns, over the thermoplastic liner at ±55° angles. Subsequently, a thermoplastic cover layer is extruded over these layers after heat bonding. Unlike TCP, there is no bonding between the aramid yarns and thermoplastic matrix material because the fibers are not impregnated, posing an additional challenge to the UT technique.

Figure 1. (a) Glass fiber reinforced TCP with FBH (measurements are in millimeters), (b) carbon fiber reinforced TCP with delamination, and (c) aramid fiber reinforced RTP with impact damage.

2.2 Anomalies

In the first scenario, a glass fiber reinforced TCP sample was cut longitudinally along its axial centerline. Then, a flat bottom hole (FBH) was bored from the internal side of the sample until within the composite laminate layer, as illustrated in **Figure 1**(a). The FBH represents a one-sided delamination with a

perfectly flat base perpendicular to the ultrasonic wave propagation. At the material-air interface, total reflection of ultrasonic energy occurs due to a significant acoustic impedance mismatch [2]. In the second case, a carbon fiber reinforced TCP sample was subjected to axial compression using a hydraulic testing machine, inducing delamination within the composite laminate layer, as depicted in **Figure 1**(b). For the third scenario, impact damage was inflicted on two aramid fiber reinforced RTP samples by dropping a sharp impactor aligned perpendicularly to the axial length of the pipe. The weight and drop height of the impactor were carefully selected to ensure that the impact energy was sufficient to damage the highly ductile thermoplastic material. This damage extended to the fiber reinforcement layer in one sample when subjected to an impact energy of 0.97 kJ, whereas it penetrated through the entire thickness in the other sample when impacted with 1.88 kJ of energy, as shown in **Figure 1**(c).

3. NDT Methods

This study aimed to compare the capabilities of radiographic imaging and ultrasonic wave-based NDT techniques, utilizing X-ray CT and PAUT. The former was selected for its ability to provide detailed three-dimensional and cross-sectional radiographic images that closely resemble actual anomalies in size and shape. Conversely, PAUT was chosen due to its accessibility and widespread use in the field.

3.1 X-Ray CT

X-ray CT scan was conducted on the carbon fiber reinforced TCP and aramid fiber reinforced RTP samples using the Nikon XT h 225 ST scanner. The sample was positioned between the X-ray source and a flat panel detector during the scan. To ensure consistent imaging along the pipe's length, the sample's longitudinal axis was aligned perpendicular to the X-ray beam. Multiple two-dimensional projection images were captured at various angles around the pipe, encompassing a complete 360° sample rotation. These images were then processed to reconstruct a detailed three-dimensional image of the sample, enabling cross-sectional views on three-perpendicular planes within the internal structure. This reconstruction facilitated a comprehensive analysis of any damages present. The reconstructed datasets were visualized and analyzed using the open-source myVGL software.

3.2 PAUT

PAUT was conducted using multiple transducers with varying numbers of elements and frequencies, ranging from 1.0 MHz to 5.0 MHz, supplied by Olympus. The raw data was captured using the Olympus OmniScan SX flaw detector and analyzed using the OmniPC 5 software, a complimentary companion software for the Olympus OmniScan series [11]. A notable challenge in inspecting multi-layered composite materials with PAUT is the significant signal attenuation beyond the first interface layer. Consequently, standard inspection methods typically used for metals are not directly applicable to TCP and RTP. Therefore, this study proposed implementing the classical TCG method to compensate for the severe spatial attenuation. The TCG method gradually increases system gain over time so that successive signal amplitudes are at the same height as the initial signal amplitude, irrespective of their distance from the transducer. However, this inherent limitation proves beneficial for implementing the TCG method, as the repeated signal from the first interface layer, which could superimpose with defect signals located beyond it, is minimal and negligible. This method is not applicable for inspecting multi-layered structures made of metals due to challenges in data interpretation. There will be a mixing of received signals beyond the first interface layer, comprising multiple consecutive echoes of the first interface layer, discontinuities, the second interface layer, and signals from the back wall, which could cause y lead to erroneous data interpretation.

In addition to the TCG method, this study incorporated the focusing technique to enhance the characterization of impact damage in RTP. Focusing the ultrasonic beam at a specific focal point within the inspected object intensifies the sound energy per unit area, thereby enhancing sensitivity to small reflectors within the area. Consequently, this approach provides a better characterization of damage dimensions and morphology. To ensure accurate measurements, sound velocity calibration was conducted individually on each sample using a two-point calibration method. The thickness of the outer cover or the inner liner, as well as the total sample thickness, served as the lowest and highest thickness references, respectively. Since ultrasonic waves propagates through multiple dissimilar materials with

varying velocities due to differences in density and elasticity, the calibrated velocity utilized in this study represents an average velocity value. It is important to note that this calibrated velocity is applicable only to samples with similar constructions [10].

4. Results and Discussions

4.1 PAUT Results After Implementing TCG Method at Defect-Free Region

Figure 2 illustrates the typical PAUT signal when the transducer is placed at the defect-free area of the glass fiber reinforced TCP (upper row) and carbon fiber reinforced TCP (lower row), comprising two types of signal representation. The left side displays an A-scan view, while the right side presents an E-scan view, depicting the real-time cross-sectional image of the inspected object. This real-time imaging is captured by the phased array electronically scanning the area under the active aperture without moving the transducer. Before implementing the TCG method, only the signal from the first interface layer is discernible, as shown in **Figure 2**(left column). In contrast, the signal from the second interface layer and the back wall are severely attenuated. Additionally, the repeated signal from the first interface layer is considered to fully dissappear due to severe attenuation. This phenomenon is advantageous because the unwanted repeated signal can be suppressed when the gain is partially increased at specific TCG points corresponding to the signals of interest beyond the first interface layer, marked with red points in the A-scan view. Consequently, a defect can be detected if it is located in that position. Following the TCG implementation, the signals from the second interface layer and the back wall increase to the same level as the first interface layer, as shown in **Figure 2**(right column). At the same time, the background noise exhibited a linear increase between two TCG points.

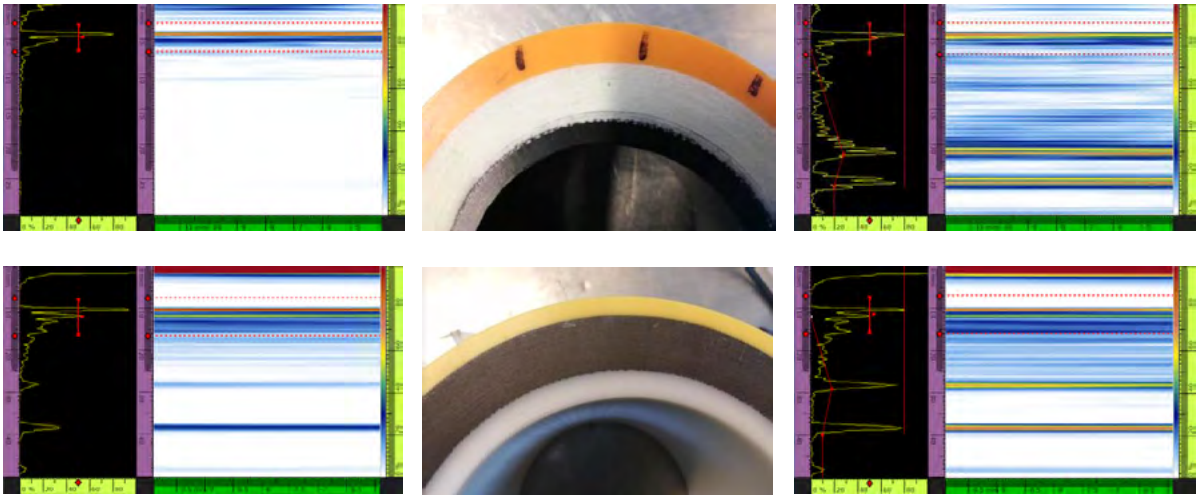

Figure 2. Typical PAUT signal on glass fiber reinforced TCP (upper row) and carbon fiber reinforced TCP (lower row), before (left column) and after (right column) implementing the TCG method.

4.2 FBH on Glass Fiber Reinforced TCP

The proposed technique, while positioning the transducer on the outer surface of the sample using a direct contact method, demonstrates its capability to detect the FBH on the glass fiber reinfoced TCP. The transducer is positioned in such a way that one half of the active aperture lies above the FBH position, while the other half covers the defect-free region, ensuring accurate detection. **Figure 3** shows the PAUT result. The left side of the E-scan view displays the signal from the FBH measured at 15.0 mm compared to the actual position of 15.2 mm. Meanwhile, the right side of the E-scan view represents the defect-free region. The A-scan view corresponds to the aperture selected by the user-controlled blue vertical cursor on the E-scan view, indicating the center aperture at approximately the FBH's edge. Additionally, the result clearly indicates that the FBH is located within the composite laminate layers, as its measured distance is between the signal of both interface layers. Despite the linearly increased background noise after implementing the TCG method, the FBH is reliably detected with a good SNR,

exceeding the practical standard minimum of 3 required for a signal to be considered an indication [12]. The comprehensive details of the study on FBH detection will be outlined in [13].

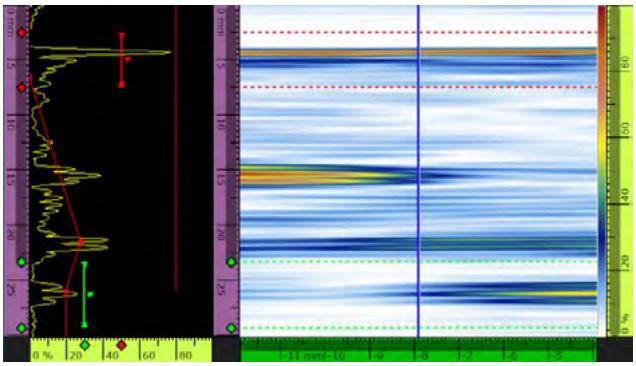

Figure 3. PAUT result of the FBH on glass fiber reinforced TCP.

4.3 Delamination on Carbon Fiber Reinforced TCP

The proposed technique was further employed to detect delamination on carbon fiber reinforced TCP. A mechanical encoder recorded the measured distance and provided information about the damage dimension. In **Figure 4**(a), a representative B-scan view of a defect-free region without the TCG method reveals only the signal from the first interface layer, with signals from the second interface layer and the back wall significantly attenuated. This cross-sectional view provides a two-dimensional illustration of variations in the thickness of each layer across different positions. After implementing the TCG method, signals from the second interface layer and back wall are increased, and the signal from the delamination, denoted as Delam01, appears as well, as represented by **Figure 4**(b). Multiple B-scan views can be stacked together generating a three-dimensional C-scan that illustrates a plan view of the sample with information about the thickness of each layer plotted over position both horizontally and vertically. A corresponding C-scan is generated by placing an electronic gate over the pulse width of the delamination, as shown in **Figure 4**(c). In addition to Delam01, another smaller delamination, oriented parallel to the fiber direction, is detected and denoted as Delam02.

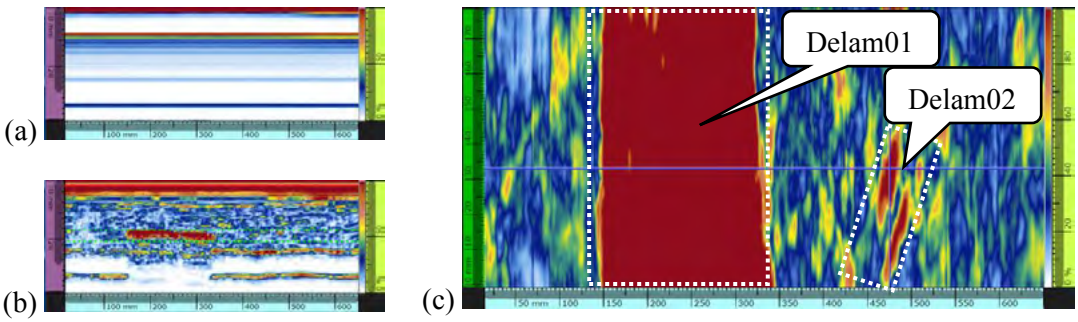

Figure 4. PAUT results of the delamination on carbon fiber reinforced TCP.

The reconstructed radiographic image obtained from the X-ray CT scan clearly displays both delaminations, as depicted in **Figure 5**. This image represents a cross-sectional view of the sample within a single plane perpendicular to the axial direction, positioned approximately at the midpoint of the sample to capture both delaminations. Multiple additional planes are adjacent to this plane in both directions, and their space between each other depends on the scanning resolution. Further investigation reveals that by selecting planes towards one end of the sample, the relative position of Delam02 to Delam01 reduces, implying that Delam02 runs parallel to the fiber direction and progressively closer toward Delam01. The comprehensive details of the study on the detectability of the delamination will be outlined in [14].

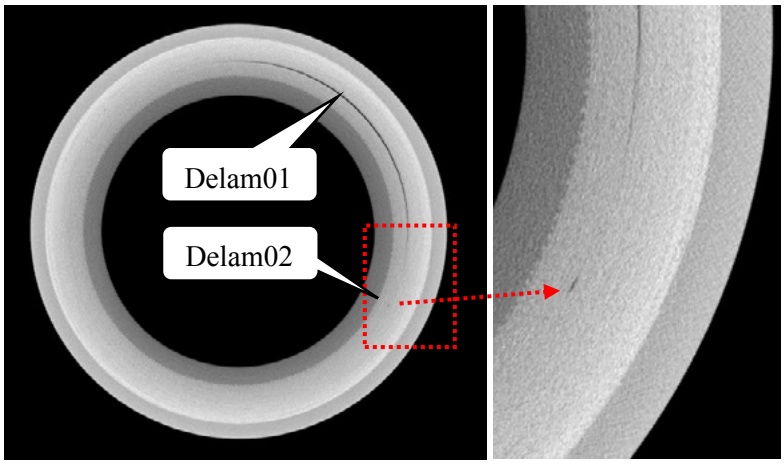

Figure 5. X-ray CT results of the delamination on carbon fiber reinforced TCP.

4.4 Impact Damages on Aramid Fiber Reinforced RTP

PAUT was conducted from the internal side of the RTP sample in an attempt to detect external impact damage. The immersion technique was implemented in away that the sample was partially submerged in water, and the transducer was not fully immersed and fixed in a stable position while the sample was rotated for scanning. This approach allowed for clear detection of the water-sample interface and the fiber reinforcement, while the TCG method was applied to enhance the severely attenuated back wall signal. Additionally, the ultrasonic beam was focused at the back wall and reinforcement layer to increase the amount of energy interacting with the impact damages oriented not perpendicularly to the wave propagation like FBH or delamination. **Figure 6** presents a comparison between the cross-sectional radiographic images from the X-ray CT scan on the left column and the ultrasonic B-scan view with unfocused and focused ultrasonic beams on the middle and right columns, respectively.

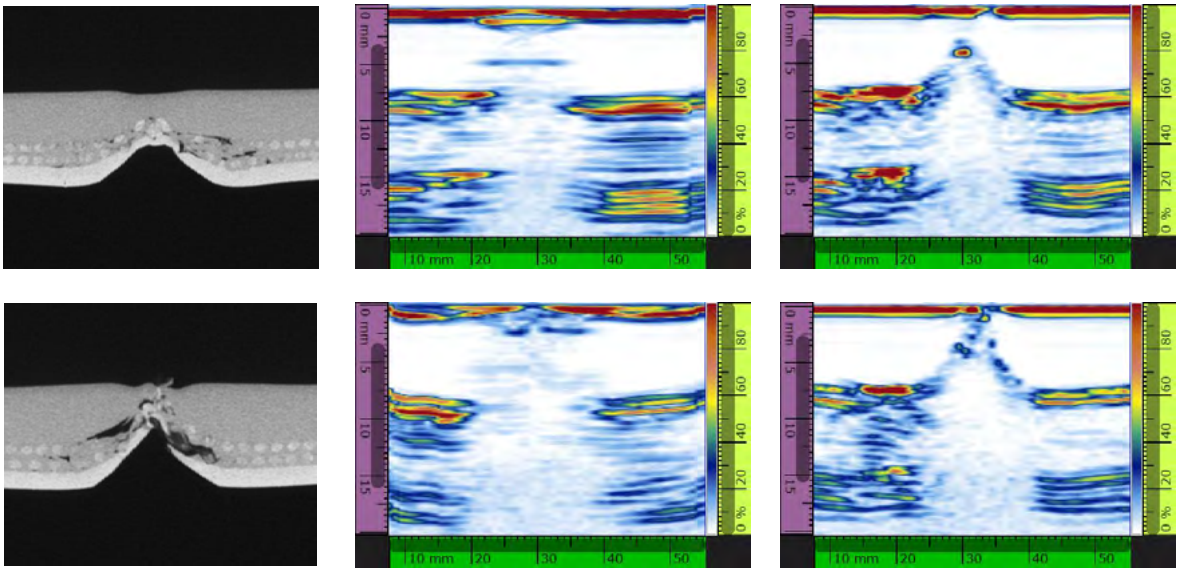

Figure 6. NDT results of impact damages on aramid fiber reinforced RTP under 0.97 kJ (upper row) and 1.88 kJ impact energies (lower row); cross-sectional radiographic images (left column), B-scan images using unfocused (middle column), and focused ultrasonic beams (right column).

A 0.94 kJ impact energy penetrates the RTP up to a few millimeters (upper row), while a 1.88 kJ impact energy penetrates all through (lower row). Reflectors perfectly perpendicular to wave propagation reflect off energy efficiently when the ultrasonic beam is not focused. In contrast, reflectors not oriented favorably to wave propagation cause ultrasonic signal attenuation because they reflect this propagating

in random directions. However, this study found that even reflectors oriented unfavorably to the propagation of the wave can reflect some amount of energy with a focused ultrasonic beam, which leads to generation of cross-sectional ultrasonic B-scan images similar to the radiographic images captured by the X-ray CT scan. There is good agreement between the B-scan data generated by the focused ultrasonic beam and the cross-sectional radiographic images. The comprehensive details of the study on the detectability of the impact damages will be outlined in [15].

The outcomes derived from a comprehensive series of studies examining the detection capabilities of PAUT with the implementation of the TCG method indicate its immediate applicability in either manufacturing or field operations for identifying fabricated and in-field damages. While an X-ray CT scan offers a better representation of defects than PAUT, its practical field application presents formidable challenges. This limitation is primarily due to the need to rotate either the entire testing apparatus or the kilometer-long pipe to capture multiple two-dimensional radiographic images, subsequently reconstructed into virtual slice images for generating three-dimensional data.

5. Conclusion

This paper summarizes a series of ongoing studies on detecting various damage types in two types of composite pipes, thermoplastic composite pipes (TCP) and reinforced thermoplastic composite pipe (RTP). Each pipe comprises a thermoplastic outer cover, fiber reinforcement layers, and a thermoplastic inner liner.

The study leverages the radiographic imaging and ultrasonic wave-based NDT techniques, specifically comparing X-ray computed tomography (CT) and phased array ultrasonic testing (PAUT). While X-ray CT provides detailed three-dimensional images, PAUT was selected for its accessibility and widespread use in the field. This study proposed implementing the classical time-corrected gain (TCG) method to compensate for the severe attenuation of ultrasonic energy propagating in multi-layered polymer and polymer composite materials. It is worth noting that the TCG method is not applicable to similar multi-layered structures made of metals due to mixing of multiple repeated signals beyond the first interface layer.

The study evaluated the capability of PAUT with the TCG method to detect defects in composite pipes, including flat bottom hole (FBH), delamination, and impact damages. The results showed that PAUT with TCG method not only enhanced defect detection but also allowed for accurate localization and characterization. FBH detection in glass fiber reinforced TCP demonstrated the method's precision, detecting FBHs within composite laminate layers with a good signal-to-noise ratio (SNR). Delamination detection in carbon fiber reinforced TCP indicated the method's ability to identify small and large delamination within the composite laminate layers. Additionally, X-ray CT scans corroborated these findings, giving information about multiple cross-sectional radiographic views of the sample parallel to the axial direction.

Furthermore, the proposed technique successfully detected impact damages in aramid fiber reinforced RTP, a scenario where the damages are not favorably oriented to wave propagation. The use of focused ultrasonic beams improved detection sensitivity, generating cross-sectional B-scan images comparable to X-ray CT scans. This highlights the immediate applicability of PAUT technique in identifying various damages and overcoming challenges associated with X-ray CT's practical field application, despite its superior detection capability.

Keywords: Johnson-Cook, Constitutive Model, Ballistic Impact, Unidirectional Composites, Finite Element Analysis

Abstract
In this study, the ballistic characteristics of unidirectional glass-epoxy (UD-GE) composites, employing both experimental and numerical approaches underpinned by the rate-dependent Johnson-Cook (J-C) constitutive model, are examined. Finite element analysis (FEA) integrates the J-C plasticity and damage model to forecast stress-strain behavior and failure mechanisms during high-velocity impacts. Utilizing a UD-GE laminate prepared using a hand layup technique with a thickness of 3.6±0.1 mm and $[0]_6$ stacking sequence, reference velocities for numerical simulations were established at the ballistic limits, namely V_0, V_{50}, and V_{100}. Experimentally, mean velocities of 88 m/s, 108 m/s, and 124 m/s respectively were determined for V_0, V_{50}, and V_{100}. The observed damage patterns in the optical images of the experimented samples closely mirror those predicted by numerical simulation outputs. Building upon prior research, this study underscores the efficacy of rate-dependent constitutive models in accurately anticipating the response and damage evolution of fiber-reinforced polymer (FRP) composites under high-velocity impact conditions.

1. Introduction

Due to the relevance in various fields such as space sciences and military technologies for personal and structural protection, as well as in high-speed impact dynamics, the study of ballistic impact behavior of materials is of considerable interest across experimental [1], theoretical [2, 3], and numerical [4] research domains. Armors made with traditional materials like steel were commonly utilized due to their cost-effectiveness, but they suffered from high weight. Polymer matrix composite armors, particularly laminated composites, present a promising alternative owing to their superior weight-normalized mechanical properties, including stiffness and strength [5–8]. Consequently, much of the research in ballistic studies has focused on understanding the behavior of laminated composite structures when subjected to impact, which is a crucial yet intricate challenge. This complexity arises from the interplay of various factors, such as material behavior, failure mechanisms, and load transfer mechanisms, all of which entail numerous uncertainties [9–11]. Consequently, accurately predicting impact behavior remains a quest, prompting investigations employing diverse methodologies, from simplistic empirical models to highly intricate numerical techniques. Proposing a method that utilizes fewer data inputs is necessary to streamline computation.

Numerous researchers [12–14] have devised analytical models reliant on experimental data. Several studies have addressed different aspects of ballistic impact and armor performance. Porwal and Phoenix [15] investigated the effects of system dynamics due to ballistic impact on flexible, multilayered targets without inter-layer bonding with a cylindrical projectile. They discovered that V_{50} and residual velocity are influenced by the arrangement of layers with varying mechanical properties, and the V_{50} velocity upsurges with the layers strain-failure ratio. Cuniff [16] advanced a parametric model to predict the performance of body armor systems against steel projectiles, utilizing nonlinear regression analysis of Kevlar 29 test data. Roylance et al. [17] utilized a finite difference method (FDM) to simulate ballistic impact on fabric, modeling the fabric as an interconnected mesh assembly with artificial buckup springs playing a role in ballistic limit determination. Landa et al. [18] formulated an analytical model for predicting the impact behavior of soft armors against rigid projectiles, making basic assumptions about projectile movement and material behavior. Billon and Robinson [19] proposed a model (analytical) for ballistic impact on fabric armor, neglecting inter-layer interaction and maximizing ballistic limit velocity by using layers made from materials with the ballistic limit velocity highest for single-layer.

The epoxy material properties being influenced by strain rate are well known in the research community, but information on how yarn properties are affected by strain rate is scarce. In our previous study [20], Abaqus software was used to numerically assess the impact of yarn's strain-rate dependency. A finite element composite model was employed featuring square prismatic-shaped split Hopkinson pressure bar (SHPB) samples. The yarn properties were homogenized to mimic those of a high fiber volume fraction composite. Both the bulk epoxy and yarn material properties were described using the Johnson-Cook (JC) constitutive model, while the failure mechanism was characterized using the JC damage model. This model was chosen because of its widespread availability and ease of implementation in various finite element analysis (FEA) simulation software. Three scenarios were examined: one where both yarn and bulk matrix properties were strain-rate dependent, another where only the bulk matrix showed strain-rate dependency and a third where both yarn and matrix were strain-rate independent. It was observed that the model incorporating complete strain-rate dependency exhibited peak stress and strain values comparable to experimental results, outperforming the other models in this aspect.

In this study, the JC material and damage model will be used for estimating the ballistic response of the UD glass epoxy composite laminate. The ballistic limit velocities are the prime focus. The three important Ballistic limit velocities are V_0, V_{50} and V_{100}. The greatest velocity at which no full penetration will take place is V_0. The velocity at which both full and incomplete penetration have an equal chance of happening is known as V_{50} and the lowest velocity at which there is a complete chance of full penetration is regarded as V_{100}. Experimental iterations were done to find out these velocities, and numerical analysis were done for the same values for comparison. The applicability of the JC model with the used parameters will be discussed properly in this article.

2. Experimental Procedure

2.1. Material Selection and Sample Preparation

The epoxy (diglycidyl ether bisphenol A type) resin, commercially known as Lapox (L12), and the hardener (triethylenetetramine), commercially known as K-6, were sourced from Atul Industries Ltd in India. The epoxy resin exhibits a density of 1.15 g/cc, a tensile elastic modulus ranging between 3.25 and 4.0 GPa, and a tensile strength ranging from 55 to 70 MPa. An E-Glass fiber UD mat was utilized in this study as reinforcement.

Six layers of UD-GE fabric mat were utilized to fabricate a GE laminate using the hand lay-up method. The ratio of epoxy resin to hardener was maintained at 10:1 (by weight) in accordance with the manufacturer's guidelines. Subsequent to laminate preparation, compression was applied, and the laminate was left for curing in a similar state at room temperature (RT) for twenty-four hours. Afterward, the samples underwent precise cutting and polishing to attain the specified dimensions and square geometry, ensuring precision within a tolerance of ±0.1 mm. Furthermore, a post-curing process was

carried out in an oven set at 140°C for 6 hours, followed by gradual cooling to room temperature inside the oven [21]. The fiber volume fraction of the resultant samples was assessed using the resin burn-off test, yielding a value of 0.56 ± 0.01.

2.2. Ballistic Setup

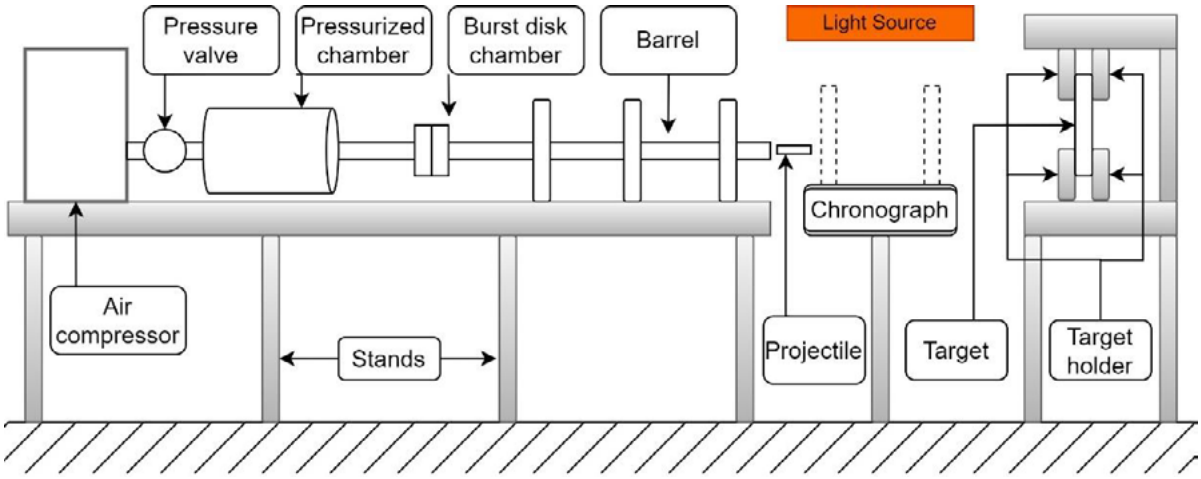

Figure 1. Schematic representation of the ballistic testing apparatus used in this study.

The impact behavior of targets was assessed utilizing a single-stage gas gun setup, employing 6.3 mm flat-end cylindrical steel projectiles of length 30 mm. Figure 1 is the schematic representation of the ballistic setup used. The setup featured a burst disk mechanism. Pressure regulation was achieved using an air compressor supplied by BAUER KOMPRESSOREN. Burst disks of varying thicknesses were utilized to control pressures and velocities. Projectile velocities were recorded using a chronograph. Composite targets were securely clamped between steel plates and the ballistic responses were examined. Prior to conducting the experimental test, the alignment of the barrel and target was verified.

3. Numerical Details

The laminated UD-GE composite was initially modeled at the yarn-level homogenization using ANSYS DesignModeler. Following this, the model underwent meshing, application of boundary conditions and analysis within the ANSYS Workbench environment. Additionally, the material behavior of the matrix-impregnated yarn and bulk matrix was characterized by incorporating strain-rate dependency, utilizing the J-C constitutive and damage model. The subsections below discuss this approach in detail.

3.1. Yarn-Level Finite Element Modeling

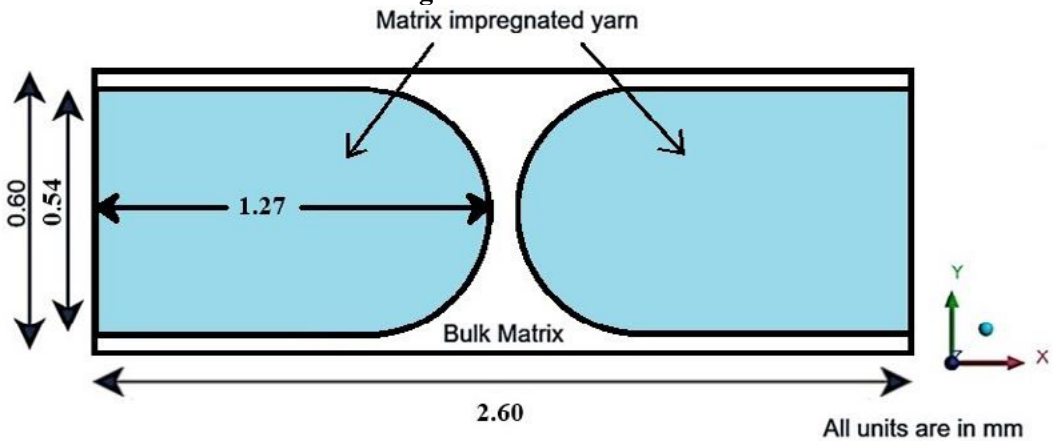

Figure 2. RUC schematic representation of the composite laminate at yarn level modeled for FEA

To define the yarn's cross-section, a 2-dimensional (2D) near representation was obtained by sectioning it with a perpendicular plane to its length. This cross-section, typically exhibiting a buldging shape towards ends, encapsulates the smallest segment of the yarn containing all fibers and is assumed to be uniform along its length. Figure 2 presents a schematic depiction of the representative unit cell (RUC) illustrating the cross-section of the yarn that was used for the modeling of the composite plate. The cross-sectional profile of the yarn was modeled in Ansys design modeler using the oval (four edges) tool. The material properties of the matrix-impregnated yarn and bulk epoxy utilized the J-C constitutive and damage model, the parameters of which were kept the same as estimated in our previous research work [20]. The details of the material behavior model and parameter fitting can be found there.

3.2. Simulation Details

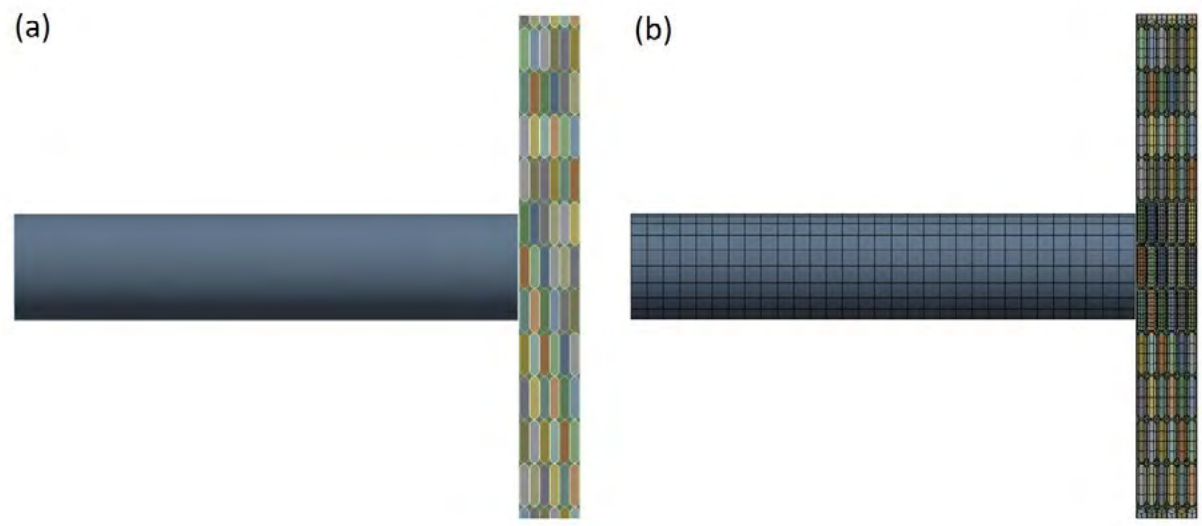

Figure 3. Numerical UD-GE target plate and projectile (a) geometrical model (b) meshed model.

In the FEA performed, the target exhibits identical geometrical characteristics to those employed in the experiment, ensuring a direct and accurate comparison. Figure 3a illustrates the geometrical model analyzed. In the experiment, the open square window for the target measured approximately 30 mm along the edge, which was replicated in the numerical modeling by providing appropriate boundary conditions. Fixed support were provided along the edges. The projectile material and dimesion were also kept identical to the experiment, and a coefficient of friction of 0.42 was provided between the projectile and the target. In Figure 3b, the mesh size and pattern at the cross-section of the UD-GE laminate are depicted. In order to make this study computationally efficient, the yarns coming under direct impact of the projectile under all the layers were meshed finer compared to the rest of the yarns. The numerical model comprised a total of 381,297 nodes and 252,481 elements. There was an initial 0.1 mm distance between the target plate and the projectile geometry. The projectile was imparted with an initial velocity of 88 m/s, 108 m/s and 124 m/s and directed to strike the target (UD-GE laminate) in line with the axis of the setup.

4. Result and Discussions

After a number of ballistic impact iterations on the UD-GE samples, the ballistic limits were determined, as shown in Figure 4. The average values observed for V_0, V_{50} and V_{100} were 88 m/s, 108 m/s and 124 m/s with a decent standard deviation as shown in the bar graph. The same velocities were taken as a reference for the ballistic simulation in the Ansys explicit dynamics software and the projectile fired were given initial velocities accordingly.

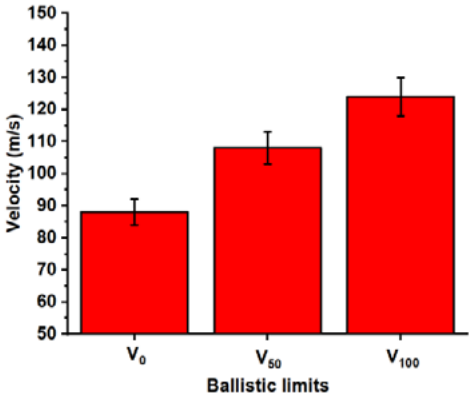

Figure 4. Ballistic limits obtained using experimental investigation

Figure 5 shows the deformation pattern observed at different ballistic limits. It is quite clear from the image that when a projectile impacts a UD-GE laminate, the deformation pattern varies depending on the velocity of the projectile and the ballistic limits. When we talk about the V_0 ballistic limit, it indicates a 0% risk of penetration or the limit velocity at which the laminate can stop the projectile without penetration. At V_0, the laminate experienced some deformation, but it was able to withstand the impact without allowing the projectile to pass through. The deformation pattern included localized delamination, fiber breakage, and some bulging or denting of the back side of the laminate. The V_{50} ballistic limit represents a higher velocity at which the laminate can still stop the projectile sometimes without penetration, but in half of the cases, the projectile is able to get through. At V_{50}, the deformation pattern became more severe compared to V_0. There was more extensive fiber breakage, significant bulging and denting of the laminate. However, in a few cases, the laminate could still be able to prevent penetration by the projectile. Finally, the V_{100} ballistic limit indicates a 100% risk of penetration or the limit velocity at which the laminate cannot stop the projectile and there will be a complete penetration. At V_{100}, the deformation pattern was the most extreme. The laminate experienced severe delamination, extensive fiber breakage, and significant deformation, including large-scale tearing of the material. At this velocity the laminate could not prevent the projectile from penetrating through.

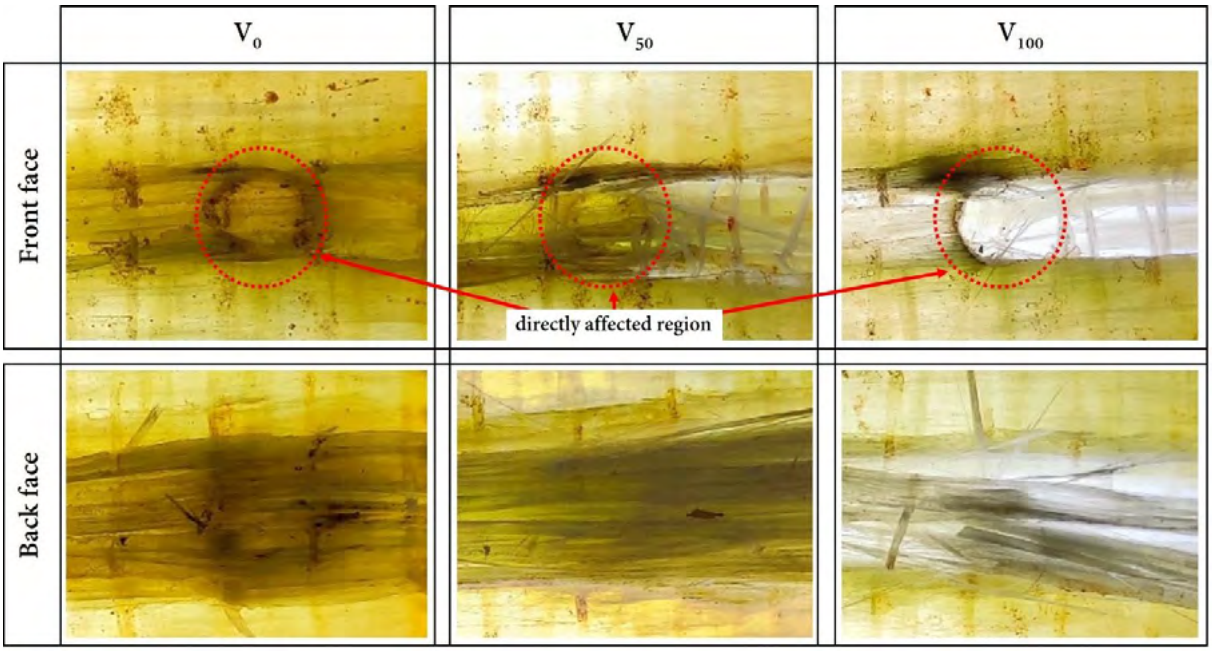

Figure 5. Photographs near the impacted area of UD-GE samples tested at the ballistic limits.

The simulation results shown in Figure 6 obtained using Ansys closely mirror the observed damage patterns depicted in Figure 5. Through numerical simulations, we effectively captured the deformation

behavior of UD-GE laminates under varying ballistic limits, reflecting the impact of projectile velocity on material response. At the V_0 ballistic limit, the simulations demonstrated localized delamination, fiber breakage, and minor bulging or denting on the back side of the laminate, consistent with the experimental findings. Moving to the V_{50} ballistic limit, numerical simulations depicted a progression towards more severe damage, with extensive fiber yarn breakage, significant bulging and even penetration, and denting evident. The simulations aligned with the observed trend of increased damage severity compared to V_0 & showed complete projectile penetration. Finally, at the V_{100} ballistic limit, numerical simulations showcased the most extreme deformation patterns, echoing the experimental results of severe delamination, extensive fiber yarn breakage, and significant material tearing. Consistently, the simulations highlighted the inability of the laminate to prevent projectile penetration at this velocity, in line with the experimental observations. Overall, the numerical simulations effectively replicated the deformation patterns observed in the experimental data, providing valuable insights into the ballistic performance of UD-GE laminates under different impact velocities.

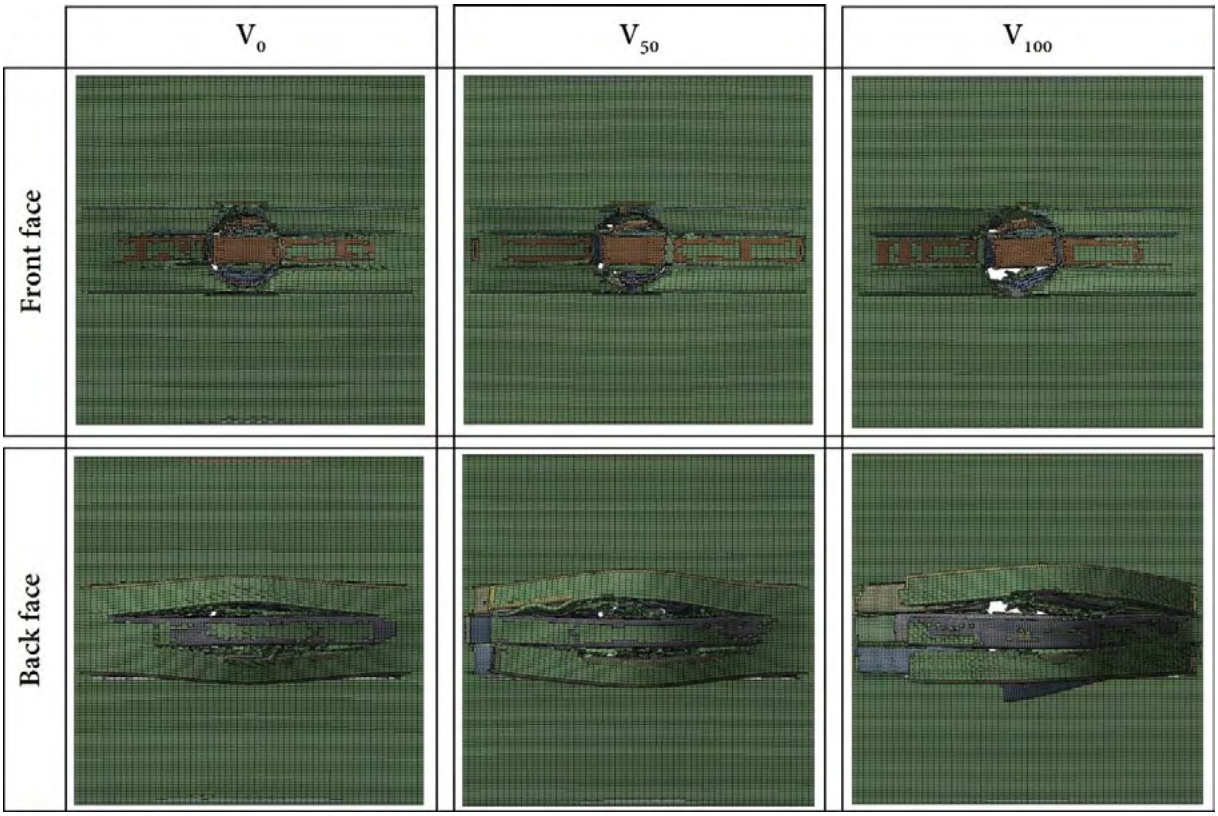

Figure 6. Simulation results of UD-GE samples tested at the ballistic limits.

5. Conclusions

This study concerns the ballistic response of UD-GE composites, employing a combination of experimental analysis and numerical simulations utilizing the rate-dependent Johnson-Cook (J-C) constitutive and damage model. Through a series of ballistic impact iterations and subsequent experimental investigations, the ballistic limits of the laminates were determined. These limits, characterized by V_0, V_{50}, and V_{100} velocities, represent crucial thresholds delineating the ability of the laminate to withstand projectile impact without penetration. Our experimental findings showcased distinct deformation patterns at these ballistic limits, ranging from localized delamination and fiber breakage at V_0 to severe delamination and extensive fiber breakage at V_{100}. Furthermore, our numerical simulations using Ansys explicit dynamics software closely mirrored these observed damage patterns. The simulations effectively captured the progressive deterioration of the laminates integrity with increasing projectile velocity, aligning with the experimental observations. Specifically, at the V_0 ballistic limit, simulations demonstrated minor damage consistent with experimental findings, while at

V_{50} and V_{100} limits, simulations depicted increasingly severe damage patterns, culminating in complete projectile penetration. Drawing from prior research, this study underscores the efficacy of rate-dependent constitutive models in accurately predicting the response and damage incurred by fiber-reinforced polymer composites under high-velocity impacts. Validation against experimental data bolsters the credibility of the findings and ensures alignment between simulation results and real-world observations. Further advances in this approach may be applied to make it even more close to real scenario.

Keywords: Woven composite, Damage tolerance, BVID, CT scanning

Abstract
3D woven composite materials provide key mechanical performance advantages over their laminated counterparts, such as higher resistance to out-of-plane loading, as well as higher damage tolerance. Consequently, it is important to investigate the effect of barely visible impact damage (BVID) on their mechanical behaviour. In this study, experimental investigations are carried out to study how BVID affects the tensile performance of 3D woven composites. Interrupted quasi-static indentation tests are first carried out, and the damage at each level is characterised. The damage level, most representative of BVID, is identified and used for subsequent static tensile testing. It is found that the presence of BVID causes a reduction in tensile stiffness, but does not have a significant influence on the failure tensile strength and strain. The experimental results presented in this work give further insight on the damage tolerance of 3D woven composites.

1. Introduction

3D woven composite materials are seeing increasingly wider use in engineering applications such as automotive, renewable energy, and aerospace structures. This category of composites provides several economic and performance advantages over their laminated counterparts and metal alloys. 3D woven composites are usually prepared in near net-shape preforms before being infused by resin and cured to form the final structure, eliminating the costs associated with the layup of laminated composites or with the use of expensive prepreg materials. Additionally, 3D woven composites provide some key mechanical performance advantages, such as higher resistance to out-of-plane loading, as well as higher damage tolerance [1]. Consequently, the main area of application for these composites involves impact. The presence of barely visible impact damage (BVID) can be detrimental when structures are subjected to subsequent static and fatigue loading. It is therefore necessary to investigate the effect of BVID on the mechanical performance of these composites. In the present work, experimental investigations were carried out to determine how the presence of BVID affects the tensile performance of carbon/epoxy with a layer-to-layer 3D weave.

2. Materials and Methods

2.1. Materials Description

The considered 3D woven composite has a layer-to-layer reinforcement, characteristed by the interlacing of warp, weft, and binder yarns in 3D space. The weave architecture is shown in Figure 1. The woven yarns are made from HexTow IM7 24k tows, and the nominal dimensions of the representative volume element (RVE) are 9.1 mm, 14.5 mm, and 4 mm, in the warp, weft and through-thickness directions, respectively. Dry woven preforms of size 490 x 220 mm were infused with RTM6 epoxy resin through resin transfer moulding (RTM), and cured to produce flat composite panels. The specimens used for mechanical testing were cut from these panels using a diamond saw blade.

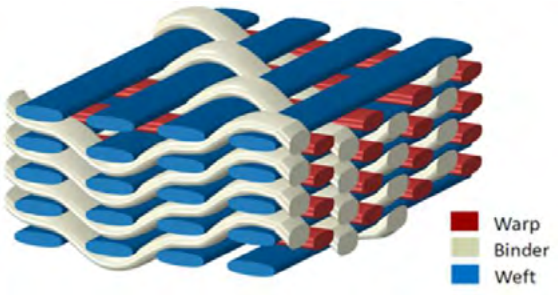

Figure 1. 3D layer-to-layer weave architecture.

2.2. Quasi-Static Indentation

The aim of this study is to investigate the effect of the presence of BVID on the mechanical behaviour of 3D woven composites. Therefore, a level of damage, which is representative of BVID, had to first be identified and introduced into the specimen before subsequent testing. In this study, BVID was imparted using quasi-static indentation (QSI) tests. The specimen dimensions used were 50 x 75 mm, with a 37.5 x 62.5 mm support window, a hemispherical indenter of 8 mm diameter, and a displacement-controlled loading at a rate of 1 mm/min. With these dimensions, several RVEs are present across the width and length of the specimen, promoting the representative behaviour of the woven material.

The level of damage at different indentation levels were characterised. First, the extent of damage was characterised by Ultrasonic C-scanning in pulse echo mode. X-ray Computed Tomography (CT) scanning was then performed, to better investigate the damage mechanisms present. A Nikon XTH320 was used for this purpose, obtaining a voxel size of around 24 μm.

2.3. Static Tension Tests

To assess the influence of BVID on the static performance, tensile tests were performed on both undamaged and post-BVID specimen. Uniaxial tensile tests were performed on a servo-hydraulic test machine (Instron 1342) with a 250 kN load cell. The specimen were loaded at a constant crosshead speed of 1 mm/min, up to failure. Stereo digital image correlation (DIC) was employed to obtain extension and strain data during the test.

3. Results and Discussion

3.1. Quasi-Static Indentation Tests

The typical load-displacement behaviour of 3D woven composites under QSI is illustrated in Figure 2a, where three distinct stages are identified: (A to B) a linear elastic stage up to damage onset, (B to C) knee point followed by damage propagation, and (after C) load drop due to yarn failure on the tension side [2]. Several QSI tests were interrupted along the damage propagation region, as shown in Figure 2b, and the damage at each level was characterised by non-destructive testing (NDT) methods.

The ultrasonic C-scanning of the interrupted QSI specimen illustrated the extent of damage at each indentation level. However, it did not provide information about the actual damage mechanisms present. Therefore, X-ray CT-scanning was carried out to better understand the development of damage mechanisms. Figure 3 illustrates examples of CT scan slices taken through the damaged region. Different damage mechanisms can be identified, namely matrix cracks, intra-yarn transverse cracks, and yarn debonding. The figure shows that as the indentation level increases, there is an increase of transverse cracks in the weft yarns and the resin-rich regions, as expected. There is no evidence of yarn debonding at indentation level 1. However, yarn debonding initiated before indentation level 2, and

became significant at indentation level 3. Since indentation level 2 exhibited diffused damage, it was deemed as the most representative of BVID. Therefore, it was selected as the damage level to be used in subsequent static testing.

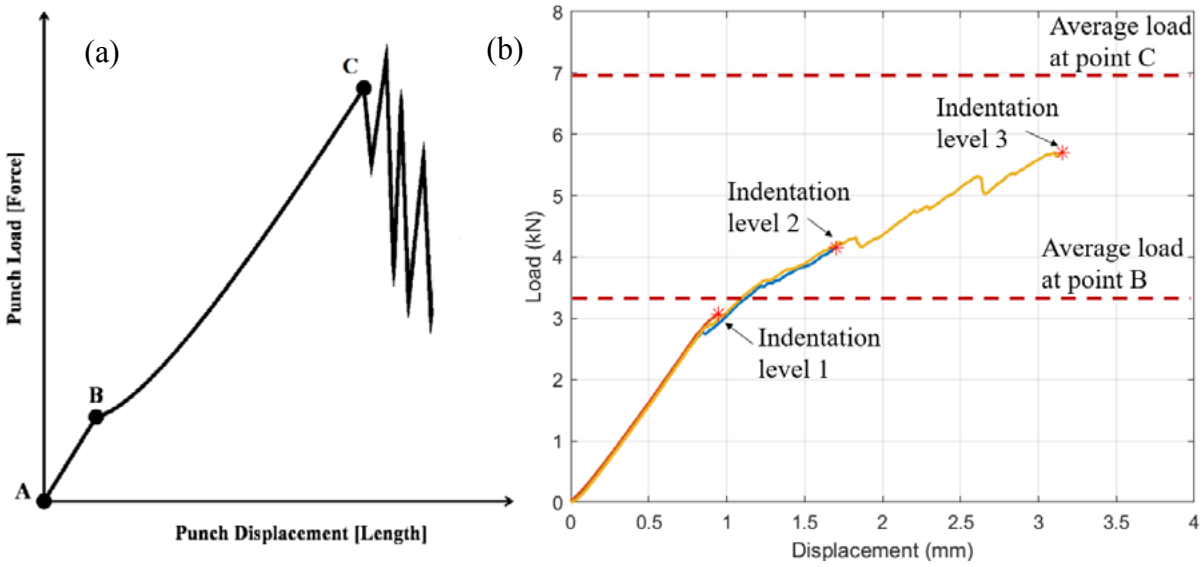

Figure 2. (a) Typical load-displacement response of 3D woven composites (Adapted from [3]); (b) Load-displacement results for interrupted QSI tests.

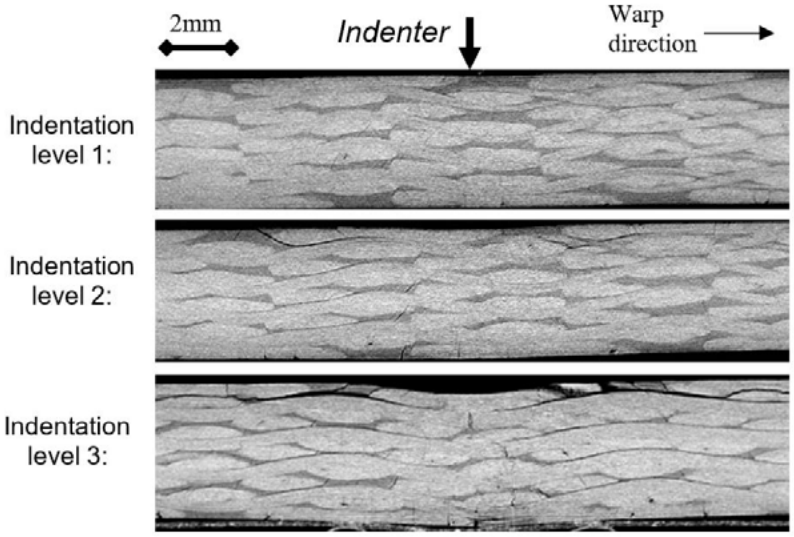

Figure 3. CT-scan 2D slices showing damage at different indentation levels.

3.2. Static Tensile Tests

Several undamaged and damaged specimen were subjected to uniaxial tensile testing up to failure. The weft direction was oriented with the loading axis. Table 1 illustrates the effect of the presence of BVID on the mechanical properties of the tested 3D woven composites. It can be noted that the presence of BVID has no significant effect on the tensile strength and strain-to-failure. This highlights the

insensitivity of these woven materials to the presence of BVID, which is one of the main benefits of such materials. The stiffness was reduced by around 5% with the presence of BVID. This is because the open cracks present within the BVID region increase the compliance of the specimen when subjected to tension.

Table 1. Static mechanical properties of specimen with and without BVID.

Specimen Type	Youngs Modulus (GPa)	Tensile Strength (MPa)	Strain-to-Failure (%)
Undamaged	53.60 ± 0.63	474.6 ± 12.3	1.35 ± 0.06
With BVID	51.00 ± 0.82	482.7 ± 8.3	1.37 ± 0.04

4. Conclusions

In this study, experimental investigations were carried out to study how the presence of BVID affects the tensile performance of carbon/epoxy with a layer-to-layer 3D weave. Woven composite specimens were first subjected to interrupted QSI tests, and the level of damage was characterised by NDT techniques. The damage level, most representative of BVID, was identified and used in subsequent static tests. The damaged specimen were then subjected to static tensile tests, and compared to the performance of undamaged specimen. It was shown that the BVID caused a reduction in stiffness, but did not have a significant influence on the failure strength and strain. The experimental results presented in this work give further insight on the damage tolerance of 3D woven composites.

Abstract

Transitioning from standard jet-fuel to liquid hydrogen holds promise for zero-emission aviation, eventually requiring lightweight storage solutions. Carbon-fiber reinforced polymer (CFRP) composites offer an attractive alternative to heavy metallic tanks, but their susceptibility to damage and leakage in cryogenic environments (CT) presents challenges. Existing literature often overlooks the critical aspect of damage onset in CFRP materials for liquid hydrogen tanks, focusing predominantly on failure properties of unidirectional and birectional standard lamiantes. To address this gap, a study conducted *in-situ* cryogenic tensile testing on cryogenic-design unidirectional and quasi-isotropic thin-ply CFRP laminates to assess properties and damage onset behavior. Using an extensometer sensitive to damage, it was observed that the CFRP material sustained major delamination damage up to 0.8% strain-load and 650-750 MPa stress-load at 77 K, indicated initial delamination damage. Microscopy analysis validated these findings, revealing critical views of delamination between 90° and 45° plies once 0.8% strain-load in 77 K is applied to the laminate. No major damage was detected prior to 0.8% of strain-load. This study contributes to designing and characterizing CFRP materials tailored for cryogenic storage tanks, enhancing their viability for emerging aviation technologies.

1. Introduction

The International Energy Agency (IEA) highlighted recently the CO2 emission of the aviation section in approximately 2-3% on a global level, which are likely to increase with increasing demands of commercial passenger and freight flights. [1] It is therefore a current critical matter to find alternative solutions for reducing the overall emission, such as transitioning from standard jet-fuel to hydrogen. Carbon-fiber reinforced polymer (CFRP) composites are increasingly favored for lightweight materials in cryogenic storage tanks for commercial aircraft due to their exceptional strength-to-weight ratio [2,3]. The ability of CFRP vessels to withstand the extreme conditions of storing liquid hydrogen (LH2), as low as 20 K, is crucial for their successful use. However, exposure to ultra-low temperatures presents challenges such as thermal fatigue and embrittlement, leading to microcracking and material damage [2]. Reliable CFRP materials for cryogenic temperature (CT) applications require thorough *in-situ* testing to understand their behavior under operational conditions. Immersion testing (*in-situ*), which simulates the storage environment, is essential to assess how CFRP composites will perform in CT.
Current studies in the literature focus on failure criteria and mechanical performance of CFRP composites in CT. [4-6] Gong M. et al. [4] reported a 20% increase in CFRP strength when tested at 77 K, attributing this to increased stiffness of the matrix material. They described the failure as brittle, emphasizing embrittlement due to ultra-low temperatures. Wang W. et al. [5] studied the static tensile stress-failure of T700 and T800 carbon-fiber based CFRP, observing increased strength in both 0° and

90° unidirectional laminates in a 77 K environment, likely due to overall stiffening effects. Aerospace studies have explored thermal fatigue effects on reinforced composites in CT environments [7-9]. These studies, using high-temperature epoxy matrix systems like BMI, show that increasing thermal cycles and temperature range leads to higher microcrack density and clearer damage visibility. However, most research focuses on 0°/90° bidirectional laminates, which differs from the typical quasi-isotropic (QI) laminates used in LH2 tank manufacturing, limiting practical applicability of these results.
Understanding the practical use of QI CFRP laminates for actual LH2 tanks are typically uncovered, as focus is given to unidirectional and bidirectional stacking configurations. Thermal residual stresses (arising from curing to cryogenic temperatures) significantly influence damage progression and failure criteria, which is a consequence from the crossply stacking configuration, making this analysis important. In QI CFRP composites, damage often starts with 90° ply failure, progressing through other orientations until 0° ply failure occurs, identifiable by signals like acoustic emissions or structural deformations known as "Puck's knee," marking the onset of damage. Hohe et al. [10] investigated static stiffness and strength tests in helium (LHe), 4 K, finding microscopic residual stresses at the single-ply level influenced by thermally induced residual stresses in multidirectional laminates. However, no overall loss of stiffness was found through the tensile testing, indicating no structural implication of the local damage event. Yuanchen et al. [11] examined mechanical behavior of QI CFRP laminates at low temperatures, highlighting embrittlement and delamination characteristics. A macroscale model was created based on the results. Regardless, research still mainly focuses on ultimate stress-strain failure and matrix improvements against embrittlement, often using standard materials and uni- or bi-directional laminates, lacking of LH2 tank representation.
This study aims to investigate tensile properties of cryogenic-designed thin-ply CFRP laminates in unidirectional and QI configurations for CT tensile testing. Tensile properties are particularly crucial for materials used in storage tanks, as their membrane condition state is constantly under tensile stress. Furthermore, to evaluate and discuss the process of damage onset for QI laminates *in-situ* (immersed in liquid nitrogen) and use microscopy methods to correlate damage signals with the laminate microstructure. The results should provide insights for methodology with CFRP cryogenic testing and damage onset observation for specific LH2 storage tank material design.

2. Materials and Methods

2.1 Prepreg tape and laminate

In this study, aerospace-grade unidirectional carbon fibers (HexTow® IM7) from Hexcel Corporation were impregnated with a low-tackiness epoxy resin designed for CT operation (EPCr), thin-ply manufacturing and AFP process. Further information on the cryogenic-designed epoxy resin can be found in Hübner et al. [12,13]. The prepreg tape manufacturing process was conducted using a hot-melt prepreg impregnation unit by Roth Composite Machinery GmbH (Steffenberg, Germany). The prepreg tape was produced with a fiber area weight of 70 g/m^2 (gsm) as continuous tapes. The target carbon fiber volume content (FVC) in the prepregs was set at 60%. The laminate CFRP material is then named as EPCr-IM7 throughout this work. Subsequently unidirectional longitudinal ([0°]), transversal ([90°]), and symmetric quasi-isotropic laminates ([0°,+45°,90°,-45°]$_s$) from these prepreg tapes were manufactured using hand layup and autoclave curing at 130 °C. Laminates were cut into tensile specimens using an oscillating cutting machine Servocut 602 from Metkom Instruments Inc. (Bursa, Turkey).

2.2 Tensile testing and damage onset in cryogenic

The tensile testing procedure was conducted using a 100 kN universal testing machine, customized with polytetrafluoroethylene (PTFE) molds to create a controlled 77 K environment within liquid nitrogen (LN2). Before each specimen test, the mold was carefully sealed with silicone to prevent LN2 leakage from the specimen's cavity. An illustrative schematic of the adapted testing can be found in **Figure 1**. Testing procedures and specimen characteristics followed D3039 guidelines. To accurately capture local strain up to ultimate failure, an cryogenic-resistant axial extensometer from Sandner messtechnik GmbH

(Biebesheim am Rhein, Germany) was employed. This sensitive extensometer not only measures the laminate strain but also detects strong vibrations emitted by the specimens during testing, which have been linked to the onset of damage. In a different approach to validate the onset of damage, incremental levels of tensile load were applied to the specimens in CT, following 0.2%, 0.5%, and 0.8% strain-load. These systems were subsequently evaluated in optical and scanning microscopy, to observe a correlation between damage detected *in-situ* testing and after the incremental loads.

Figure 1 – Illustrative and schematic view of the *in-situ* tensile testing with LN2 incorporating the cryogenic-resistant extensometer.

3. Results

3.1 Static tensile testing

For the tensile stress-strain behavior of EPCr-IM7 laminates in 0° and 90° orientation, a representative curve of each laminate is shown in **Figure 2** for RT and CT environments is shown, respectively. At RT, the behavior of 0° CFRP specimens primarily reflects the influence of the carbon fibers. Due to the already optimized state of the fibers, exposing these specimens to cryogenic temperatures does not significantly increase their stiffness. However, the compression of the resin surrounding the fibers still elevates significantly the Young's modulus and tensile strength of the material. The strain behavior of a laminate in CT is believed to be reduced due to the embrittlement of the matrix. However, in 0° laminates, the failure mode remains controlled by the fibers rather than the matrix. This results in the same elongation level of CT and RT. A study [14] experienced increase elongation at break, claiming that cracks accumulate in CT but cannot reach to the complete material failure. This would result in multiple cracks spread throughout the structure and a brittle fracture behavior.
The 90° unidirectional specimens have a stronger influence from the testing temperature, as the behavior is led by the matrix and matrix-interface. As a consequence of the matrix stiffening, the Young's modulus here increases by more than 50%, rising the stress response of the material at 77 K. The strain however, is reduced due to the matrix embrittlement and heightened sensitivity to irregularities within the laminate (residual strain, waviness, porosity, fiber-rich zone). This sensitivity is exemplified by the stress concentration at the tabs, which was a predominant factor in failure at 77 K. Accordingly, as the tensile failure of the 90° specimens where similarly found in the range of 70-80 MPa in both tensting conditions, the strain at 77 K was significantly reduced from 1.20% to 0.70%.

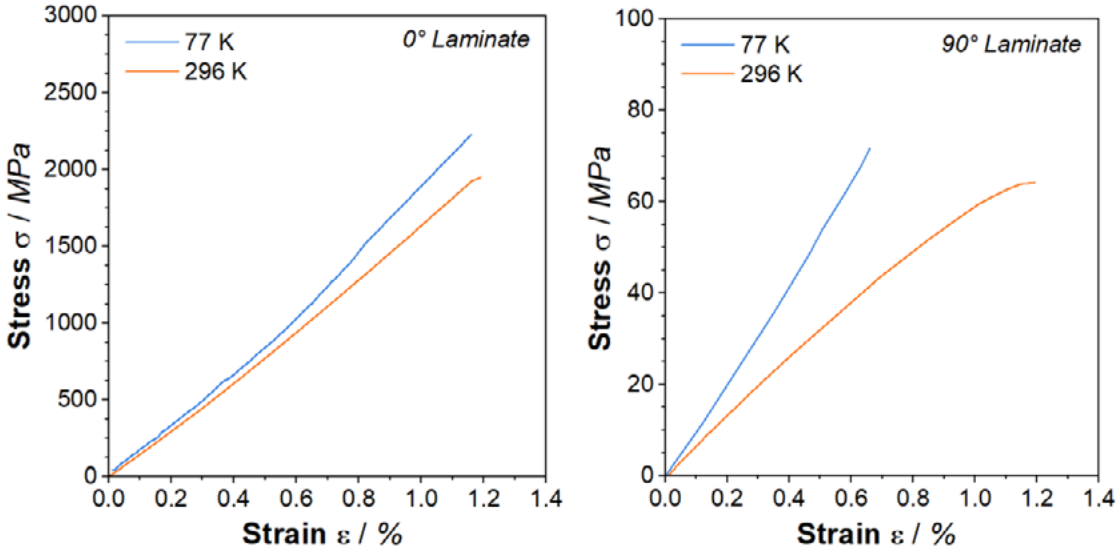

Figure 2 – Stress-strain representative curves of the EPCr-IM7 laminate as 0° configuration (left) and 90° configuration (right) in RT and CT tensile testing.

The representation of the QI laminates tested in RT and CT environments are shown in **Figure 3**, alongside a representative image of their macroscopic failure. The mechanical behavior of QI laminates at low temperatures, specifically at 77 K reveals complex failure mechanisms influenced by thermal stresses and material properties. A macroscale model analysis was carried out by [11] for QI at 93 K testing, suggesting that the concentration of thermal stresses leads to significant transversal damage on the material. This would cause a matrix tensile damage due to their lower strength. When observing **Figure 3**, the tensile strength of the QI laminate slightly decreases as temperature drops, primarily attributed to significant residual stress among the different orientation plies. Given the significant temperature differential (326 K) between the curing process and subsequent CT testing, ply shrinkage contributes substantially to the generation of strain within the laminate prior to testing. This pre-existing strain significantly influences the material's behavior during testing, partially predisposing it to failure. As a result, despite exhibiting a higher modulus in cryogenic conditions, specimens ultimately demonstrate a lower stress-strain response.

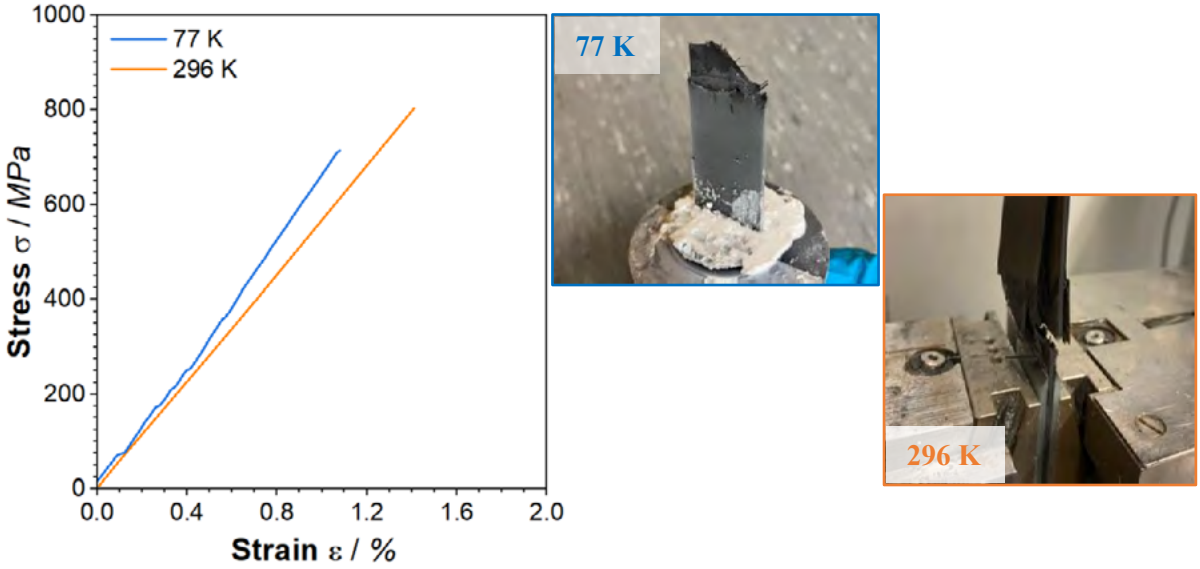

Figure 3 – Stress-strain representative curves of the EPCr-IM7 laminate as quasi-isotropic configuration (left) and observed failure modes (right) in RT and CT tensile testing.

At RT, laminates exhibit progressive failure with extended delamination, allowing for a longer stress-strain response before ultimate failure. In contrast, CT conditions result in brittle failure due to matrix embrittlement, where cracks propagate rapidly without significant delamination. The low temperatures induce significant residual stresses, contributing to reduced stress-strain behavior. The fracture behavior further reflects temperature dependence, with CT specimens showing clear perpendicular fracture planes indicative of brittle failure, while RT specimens exhibit ductile behavior with extensive signs of delamination. The Young's modulus is slightly effected by the temperature within the QI laminates. A summary of the measured tensile properties is shown in **Table 1**.

Table 1 – Summary of tensile properties of 0°, 90° and QI EPCr-IM7 laminates in RT and CT.

Laminates	Elastic modulus (GPa)		Failure stress (MPa)		Failure strain (%)	
	296 K	77 K	296 K	77 K	296 K	77 K
0°	158 ± 4	164 ± 2	2130 ± 157	2407 ± 35	1.19 ± 0.01	1.16 ± 0.03
90°	7 ± 1	11 ± 2	71 ± 2	75 ± 5	1.20 ± 0.07	0.70 ± 0.10
QI	55 ± 3	68 ± 6	830 ± 14	774 ± 64	1.48 ± 0.06	1.07 ± 0.05

3.2 Damage onset

In **Figure 4**, two representative curves of the EPCr-IM7 laminate measured in CT exhibit how the damage onset was obtained. The original curve, incorporating the signal shift due to damage, and the normalized curve (which corrects the damage shift) are presented. The normalized curve is derived from a baseline projection of the original curve using linear regression, precluding the damage-induced signal shift. This methodology does not conflit with Puck's failure criterion, as Höhe et al [3] shown that no significant loss of stiffness is found for CFRP testing in CT. Notably, laminate damage does not substantially reduce material stiffness, as evidenced by the maintained slope of the curve post-damage occurrence, consistent with the results in **Figure 3**.

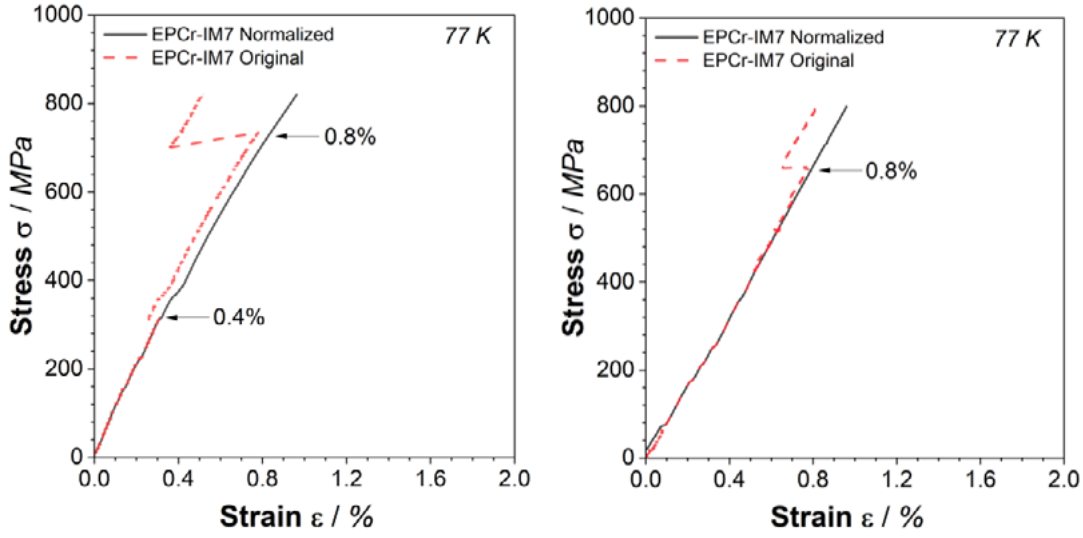

Figure 4 – Stress-strain representative curves of EPCr-IM7 QI laminate measured in CT with original and normalized curves.

The mechanisms of tensile failure in QI laminates involve multiple interactions between plies. Typically, these laminates exhibit progressive damage mechanisms such as transverse cracking and delamination when subjected to tensile loading. Transverse cracking often initiates due to high tensile stress in the 90° ply, which can stem from matrix cracking or fiber/matrix interfacial debonding. This type of damage however is apparently not causing vibration enough so signal-shift is detected during the test. The transverse cracking is espected to happen rapidly in CT environments due to the embrittlement. Standard

epoxy CFRP systems (such as BMI) can exhibit transverse cracks within the 90° plies immediately as immersed in CT, where the thermal strain proves to be enough. Cryogenic designed matrix (such as EPCr) should be able to withstand further. Delamination, on the other hand, is triggered by shear stress concentration between adjacent plies, moving the whole testing setup enough to cause a signal shift differ. The first sign of delamination under low-temperature conditions often occurs at this interface. All the EPCr-IM7 QI specimens exhibit a signal shift in the range between 0.7-0.8% strain and 650-750 MPa stress. This indicates that the failure of the 90° plies (seen in the range of 0.7% in **Figure 2**) is acting on the adjacent 45° plies. Noticebly, not long after the first signal of damage is detected, the 0° plies seem to fail in similar range (1.0-1.1% strain, 750-850 MPa stress). Another feature detected in some cases was a small signal shift within 0.4% strain. As no signs of damage were found in this range in the microscopy analysis, it is likely that this damage signal was a failure within the taps of the specimen.
Overall, it is important to highlight that there was only a slight difference observed in the initiation of damage and ultimate strength of the EPCr-IM7 thin-ply QI laminate. These findings indicate that when employing a cryogenic-design QI laminate into 77 K, the composite's damage response resembles that of a homogeneous and brittle solid. This behavior contrasts with the traditional patterns seen in standard ply-thickness composites tested in RT, where early first ply failures and delamination propagation are typically observed.

3.3 Damage under progressive load

A progressive tensile load at 77 K testing was applied to different EPCr-IM7 QI specimens, which were subsequently analyzed by scanning electron microscopy (SEM). The microscopy evolution of 0.2%, 0.5%, and 0.8% of tensile-load strain can be seen in **Figure 5**.

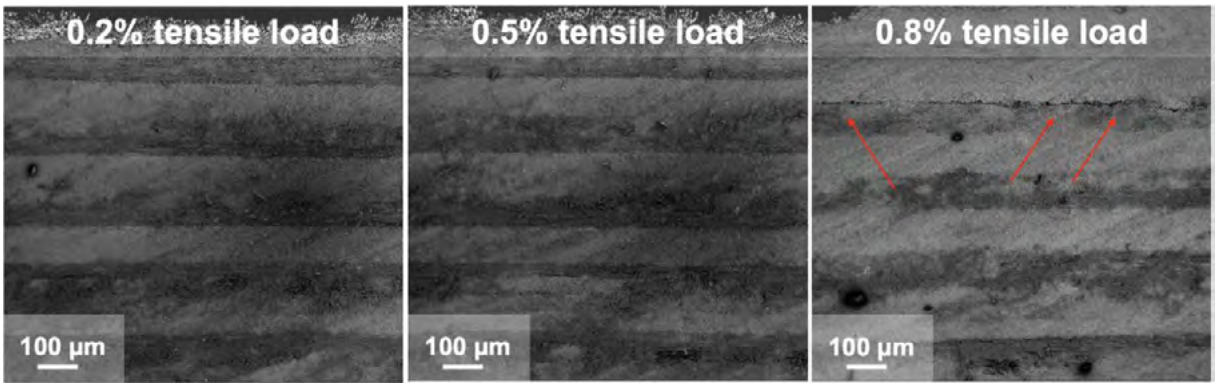

Figure 5 – SEM images of incremental levels of tensile strain-load in CT testing within the transversal view of the QI specimen.

At 0.2% strain, no visible signs of damage were detected in the microscopy specimens. This outcome was anticipated, as previous tensile measurements did not indicate any damage, suggesting that the material's microstructure remained intact under this level of strain.
Upon increasing the strain to 0.5%, some specimens exhibited signs of damage during tensile testing (see **Figure 4**), although microscopy images did not reveal any discernible structural changes. Overall, no damaged area could be found in the laminate structure. This matched the hypothesize that the detected damage from the testing was likely due to the failure of the adhesive used to attach the specimen tabs, which eventually delaminated under increased stress.
As the strain was further increased to 0.8%, clear evidence of delamination damage was observed in the microscopy images, aligning with the evaluated damage signals in the tensile testing. The damage was always located at the interface between 90° and 45° plies. These finding confirmed that at the 0.8% strain level, the material experienced its initial delamination failure, marking a critical point in the material's response to mechanical stress. At this stage, the 0° plies have a short range of functionally until the material fails completely.

As a final observation, microscopy images of the 0.8% loaded specimen were studied to identify the extent of transversal cracks within the plies, particularly focusing on the 90° plies. **Figure 6** show the images in a 500× magnification, as a broad overview (left) and as localized representation (right). Remarkably, the toughened material design for cryogenic environments did not exhibit any sign of transversal cracks, even at the interlaminar delamination stage. This suggests that the EPCr matrix is suitable for cryogenic environments and that the QI stacking configuration of the thin-ply CFRP laminate provides an efficient stress distribution. According to G. Guillamet [15], the occurrence of transverse cracks and free-edge delamination can be postponed or suppressed in regions without ply clustering, with a significant influence from the direction of the off-axis stress. This effect is expected to be more noticeable in 77 K environment, where sensitivity and residual stress levels are notably heightened before load is even applied.

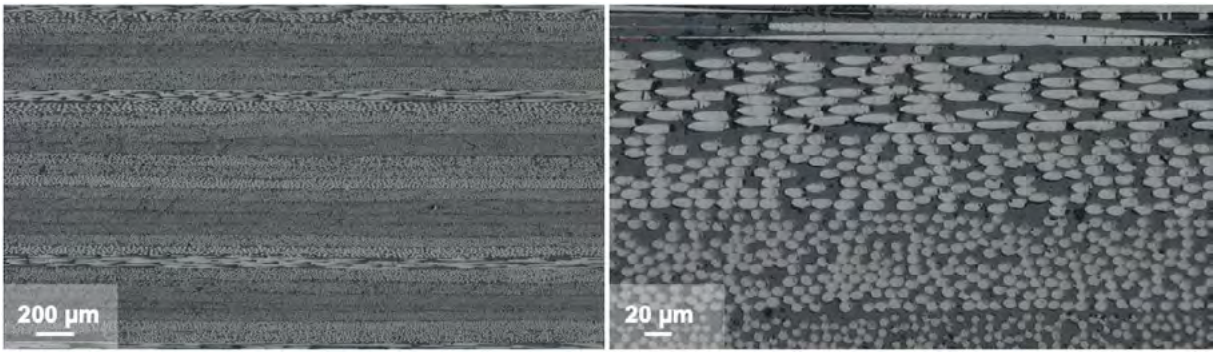

Figure 6 – Optical microscopy images of the 0.8% strain-loaded specimen in 77 K as 500×.

3. Conclusions

In this study, the investigation of a cryogenic-design CFRP material within a QI representative configuration of a CFRP storage tank was carried out. The aim was to explore its performance in cryogenic environments and to establish an alternative method for determining the damage onset of the material at 77 K, which represents a possible limit for its use as a LH2 storage tank.

The properties of the material exhibited significant differences between RT and CT environments, clearly showing stiffening and embrittlement effects caused by ultra-low temperatures. Surprisingly, the 0° configuration laminates demonstrated comparable strain-failure behavior in both CT and RT conditions, likely attributed to the excellent crack distribution capability of the thin-ply cryogenic-composite laminate. The modulus increased from 158 GPa at RT to 164 GPa in CT, rising the strength from 2130 to 2400 MPa in stress as strain was maintained in the range of 1.2%. On the other hand, the 90° oriented laminates exhibited extreme sensitivity to defects and stress concentration at the tabs, leading to anticipated failures. Additional to the material embrittlement, all 90° specimens failed at the tabs when tested in 77 K, suggesting that values can be even higher than the former 0.70% evaluated. QI laminates exhibited similar values of stress failure, with significant reduced responses in CT testing (774 MPa stress and 1.07% strain) compared to RT (830 MPa stress and 1.48% strain), likely due to embrittlement effects and increased sensitivity. The failure modes observed in CT and RT differed significantly. In RT QI samples, extensive delamination was observed, maximizing energy transfer between plies. In contrast, CT samples exhibited a more brittle, monolithic failure mode with less delamination, characteristic of less ductile environments. The *in-situ* damage onset method provided valuable insights into material functionality, detecting major signs of damage such as ply failure and delamination that correlated with the damage onset of QI laminates at 77 K. Evidently, no failure occurred until 0.8% strain-load was applied, indicating this a critical threshold where the 90°/45° crossply structure could no longer withstand the tensile load without partial delamination.

Overall, this study offers comprehensive insights into a material specifically designed for LH2 tanks, covering tensile properties and failure behavior. Importantly, it introduces a reliable method for understanding damage onset mechanics in QI laminates, essential for optimizing CFRP materials for LH2 tank applications, and providing valuable tools to the design process.

Abstract
The production process of textile preforms involves a friction behavior that is exceedingly non-linear. This behavior is governed by several factors at the yarn level, which are in turn driven by interactions at the fiber level. The prediction approach for fiber and yarn level is an essential component in the process of enhancing the mechanical properties of the composites that have been produced. To optimize the production process, it is also a technique that is cost-effective. The friction that occurs between yarns has been shown to have a major impact on the velocity of friction, the amount of force that is applied, and the starting tension, according to study that was recently conducted on the subject of improving mechanical properties. It is possible to see these effects using either experimental or theoretical means. However, a single approach is not appropriate to investigate the causes of friction since there are several factors that are interrelated with one another. It should be considered to utilize a combination of modeling and experimental methodologies, based on the findings of past research, to accurately estimate the friction mechanism in complex situations.
The present research introduces an innovative multi-scale modeling approach that accurately predicts the friction and wear characteristics of fiber. The modeling approach encompasses the utilization of both geometric and mechanical components. A micro–meso scale yarn model is created by utilizing the Timoshenko beam element. The objective of the local geometry modification method is to enhance the robustness of contact behavior by utilizing yarn distance functions based on micro-CT reconstruction technology. Moreover, a stochastic damage mechanical model of the yarn was developed to replicate the friction and wear characteristics of the fiber, resulting in an improved depiction of actual situations. This modeling approach is used to determine the orthogonal friction behavior with various yarn constructions. Furthermore, the effectiveness of the simulation is validated by the experimental methodology. The model validation demonstrates that the suggested simulation technique properly predicts friction behavior. The friction and wear characteristics of yarn in various preform architectures are anticipated based on geometry and mechanics. This modeling method provides a helpful tool for understanding the mechanical response of yarns.

1. Introduction

Textile composites have gained a wide range of applications in the aerospace, automotive, energy and sports equipment industries, where their mechanical and lightweight properties are utilized to advantage. Textile composites consist of reinforcement and matrix components, where the reinforcement component plays a major role in load bearing and therefore the mechanical properties of the reinforcement are decisive for the mechanical properties of the final composite product. The textile reinforcement phase is made of several yarns interwoven according to a certain law, which inevitably undergo damage, stretching, bending, shearing and friction during the molding process. According to previous studies, yarn damage due to friction can be as high as 9-12% [1]. Furthermore, yarn consists of hundreds of fibers whose failure behavior is discontinuous due to inconsistencies in the mechanical

properties of the fibers. Thus, the research on the friction of fiber and yarn is quite meaningful to develop fiber-reinforced composites, especially for the prediction of friction and wear behavior of fibers and yarns [2,3].

In existing fiber/yarn friction testing methods, researchers usually carry friction and wear test instruments and build up experimental equipment close to the actual working conditions through customized fixture platforms. This kind of experimental method can effectively solve the problem of difficulty in testing accurately under complex mechanical conditions and can further explore the influence of multiple factors on friction and wear behavior [4,5]. However, due to the randomness of fiber properties, the experiments often show large inter-group differences and unstable results. Therefore, a numerical simulation model needs to be developed to efficiently predict the friction and wear behavior [6].

To accurately predict the frictional wear characteristics of fibers/yarns, an improved constitutive model based on damage-plasticity theory and a geometrical model similar to that of the actual yarns are developed. The model is demonstrated on HMWPE yarn using the explicit solver Abaqus/Explicit. Meanwhile, geometric and mechanical results were verified by micro-CT and experiments. Furthermore, the yarn wear behavior can be predicted for different force conditions, and the wear behavior will be predicted for different yarn geometrical parameters, including twist, twist direction, and Tex, and applied to the reinforced-phase molding process.

2. Simulation investigations

2.1 Constitutive law

According to the damage-plasticity theory, the strain tensor is split into an elastic part and a plastic part:

$$\varepsilon = \varepsilon^e + \varepsilon^p \tag{1}$$

where the superscripts “e” and “p” denote the elastic part and the plastic part. The parts should be analyzed, respectively [7].

For the elastic stage, the stress and strain can be expressed based on the generalized Hooke’s law as:

$$\sigma_{ij} = 2G\varepsilon_{ij}^e + \delta_{ij}\lambda\sum_k \varepsilon_{kk}^e, \quad i,j = 1,2,3 \tag{2}$$

$$\varepsilon_{ij} = \frac{1}{2G}\sigma_{ij}^e - \delta_{ij}\frac{\nu}{E}\sum_k \sigma_{kk}^e, \quad i,j = 1,2,3 \tag{3}$$

where the v is the Poisson ratio.

For the plastic stage, the introduction of a yield function Φ can be defined as:

$$\Phi(\sigma_{ij}, \sigma_y) = q - \sigma_y \tag{4}$$

where σ_y is yield stress and q is equivalent stress, which can be shown as:

$$q = \sqrt{\frac{3}{2}}\left\|S_{ij}\right\| \tag{5}$$

where S_{ij} is the deviatoric stress tensor, which can be expressed as:

$$S_{ij} = \sigma_{ij} - \frac{1}{3}\delta_{ij}\sigma_{kk} \tag{6}$$

It should be noted that, at any stage, no stress level is allowed above the current yield stress, Thus, any admissible stress must satisfy the restriction. Indeed, the yield criterion can be expressed by:

$$\Phi(\sigma_{ij}, \sigma_y) < 0 \Rightarrow \dot{\bar{\varepsilon}}^p = 0$$

$$\Phi(\sigma_{ij}, \sigma_y) = 0 \Rightarrow \begin{cases} \dot{\bar{\varepsilon}}^p = 0 & elastic \quad unloading \\ \dot{\bar{\varepsilon}}^p \neq 0 & plastic \quad loading \end{cases} \tag{7}$$

The plastic strain rate can be obtained, which is positive under tension and negative under compression.

$$\dot{\bar{\varepsilon}}^p = \dot{\gamma} sign(\sigma) \tag{8}$$

where γ is termed the plastic multiplier, which is non-negative. The sign is the signum function, which is distinguished +/-. Eventually, a phenomenon, the evolution of the yield stress accompanies the evolution of the plastic strain, is achieved. The yield stress is a given function.

$$\sigma_y = \sigma_y\left(\bar{\varepsilon}^p\right) = \sigma_y\left(\int_0^t \dot{\bar{\varepsilon}}^p dt\right) \tag{9}$$

Based on the plastic flow rule, the equivalent plastic strain rate is shown:

$$\dot{\bar{\varepsilon}}^{p} = \dot{\gamma} = \sqrt{\frac{2}{3}\dot{\varepsilon}_{ij}^{p} \cdot \dot{\varepsilon}_{ij}^{p}} \tag{10}$$

The ductile damage degradation model is adopted. The ductile criterion is a phenomenological model for predicting the onset of damage, which is used in current research. The model assumes that the equivalent plastic strain at the onset of damage, $\bar{\varepsilon}_{D}^{p}$, is a function of stress triaxiality and strain rate:

$$\bar{\varepsilon}_{D}^{p}(\eta, \dot{\bar{\varepsilon}}^{p}), \tag{11}$$

where η is the stress triaxiality, which is defined as:

$$\eta = \frac{\|S_{ij}\|}{q} \tag{12}$$

where q is the Mises equivalent stress. Furthermore, the displacement at failure can be shown as:

$$\bar{u}_{f}^{p} = \frac{2G_{f}}{\sigma_{y}} \tag{13}$$

where G_f is the fracture energy, which can be expressed as:

$$G_{f} = \int_{0}^{\bar{\varepsilon}_{f}^{p}} \sigma_{y} d\bar{u}^{p} \tag{14}$$

A damage variable d is introduced as:

$$d = \begin{cases} 0 & \sigma \le \sigma_{y} \\ \dfrac{2}{1+\exp\left(-d_{f}\left(\sigma-\sigma_{y}\right)^{2}\right)} - 1 & \sigma > \sigma_{y} \end{cases} \tag{15}$$

Where d_f is the damage factor, which can be explained as an input parameter according to the Weibull distribution law. The yarn stress after initial damage can be defined as:

$$\sigma = (1-d)\sigma_{y} \tag{16}$$

The detailed derivation process of the damage evolution equations can be referred to in the literature [8,9]. The above damage model is carried out by the user subroutine VUMAT of Abaqus.

2.2 Geometric description of virtual yarn

Fiber geometry plays a crucial role in determining the mechanical properties of yarns. Previous research has established that the arrangement of fibers at the quasi-fiber scale affects the geometry of the yarns [10]. However, to effectively model the mechanical behavior of yarns, it is important to simulate the virtual yarns with a high degree of accuracy. To achieve this, the authors of this study utilized a virtual yarn to model the mechanical behavior of a realistic yarn. The virtual fiber was modeled using chain-like beam elements in the Abaqus software, with each beam element representing a small segment of the fiber chain. By assembling a certain number of virtual fibers with twist angles, the authors were able to create a twisted yarn using a Python script. The assembly process was executed on Abaqus 2021 to ensure the accuracy of the simulation.

The central routine (f(u), g(u), h(u)) and cross-section (c(w,v)) of fibers are used to establish the geometric model:

$$\begin{cases} X = f(u) + c(\omega, v) \\ Y = g(u) + c(\omega, v) \\ Z = h(u) + c(\omega, v) \end{cases} \tag{17}$$

To maintain the proper alignment of the beam nodes, equations (19) and (21) were employed, which reflected the constraint relationship between them. The use of virtual yarns allowed the authors to model the mechanical behavior of yarns under different conditions and study the impact of fiber geometry on the properties of the yarn. The virtual yarns developed in this study provide a reliable means of simulating the behavior of real-world yarns, enabling researchers to study the impact of different parameters, such as fiber arrangement and twist angles, on yarn properties.

$$\theta_{0} = \pi - n \times \arcsin(z_{0} / r_{point}) \tag{18}$$

$$\begin{cases} x' = x_0 + \kappa \times Le \\ y' = r_{point} \times \cos\left(\theta_0 + \kappa\theta_t\right) \\ z' = r_{point} \times \sin\left(\theta_0 + \kappa\theta_t\right) \end{cases} \tag{19}$$

where, x', y' and z' are coordinates along x, y and z directions, separately. κ is the number of the element. $r_{point} = \sqrt{x_0^2 + y_0^2}$ is the distance between the node and the center of the circle on the section. θ_t and θ_0 are the twist of yarns and deflection angle of the element, which usually is normalized by n. Furthermore, the number of fibers can be obtained:

$$\pi \times \left(\frac{D_f}{2}\right)^2 \times n_f = \frac{\rho_f}{\phi_f} \tag{20}$$

where n_f and D_f are the amount and diameter of virtual fibers in the yarn, ϕ_f and ρ_f are the volume density and linear density of realistic yarn.
Particularly, the equations reflect the constraint relationship between beam nodes based on the rectangular coordinates:

$$\begin{bmatrix} y \\ z \end{bmatrix}^T \begin{bmatrix} \frac{1}{a^2} & 0 \\ 0 & \frac{1}{b^2} \end{bmatrix} \begin{bmatrix} y \\ z \end{bmatrix} = Q^T A Q = 1 \tag{21}$$

The Eigenvectors of $\boldsymbol{A}$ can be obtained as:

$$\mu_1 = \begin{bmatrix} 1 \\ 0 \end{bmatrix} \qquad \mu_2 = \begin{bmatrix} 0 \\ 1 \end{bmatrix} \tag{22}$$

3. Materials preparation and micro-CT

HMWPE (High Molecular Weight Polyethylene) of 135 Tex yarns composed of hundreds or thousands of fibers were selected as the experiment object, which is produced by Honeywell International, Inc., USA. All samples are both twisted yarns, according to the references showed that the strength of high-performance fiber yarns can be improved by a slight twist. The label “tpm” represents twist per meter of yarn. Each twist level of HMWPE yarns exhibits different tensile mechanical properties.
The Micro-CT technology was employed to observe the geometry of yarn. One 100tpm (twist per meter) yarn sample with a length of 50 mm was scanned by an X-ray CT machine (Xradia-510 versa, Zeiss). The X-ray source emitted a cone-beam which passed through the sample and was then absorbed by the receiver plate. The radiographs were acquired with a voxel size of 5 μm, a beam energy of 50 kV and a current of 80 μA. A total of 1160 projections were acquired and then stitched for the image reconstruction. Model reconstruction and image processing were carried out through Dragonfly software (version 2020.1, Object Research Systems (ORS) Inc.)

4. Consistency analysis

4.1 Geometric verification

To validate the precision of the model, a thorough analysis was conducted, comparing the simulation results with experimental data. This analysis encompassed several aspects, such as the geometric properties and mechanical response. The intersection area is determined as a distinctive indication of the geometric properties of the yarn. Figure 1 (a) and (b) display a Micro-CT picture and a simulation model of yarns. The statistical data for each cross-section is represented by the cross-section regions, such as in Figure 1 (c). This figure displays a scattering map that illustrates the link between the experimental value and the two averages: the average of simulation and the average of experimental data. Each point in the figure corresponds to a distinct intersection value. The blue dot represents the experimental value, the blue line represents the simulation's average, and the green line represents the experimental average. The data illustrates a discrepancy of 7.4% between the average obtained from the experiment and the average obtained from the simulation.

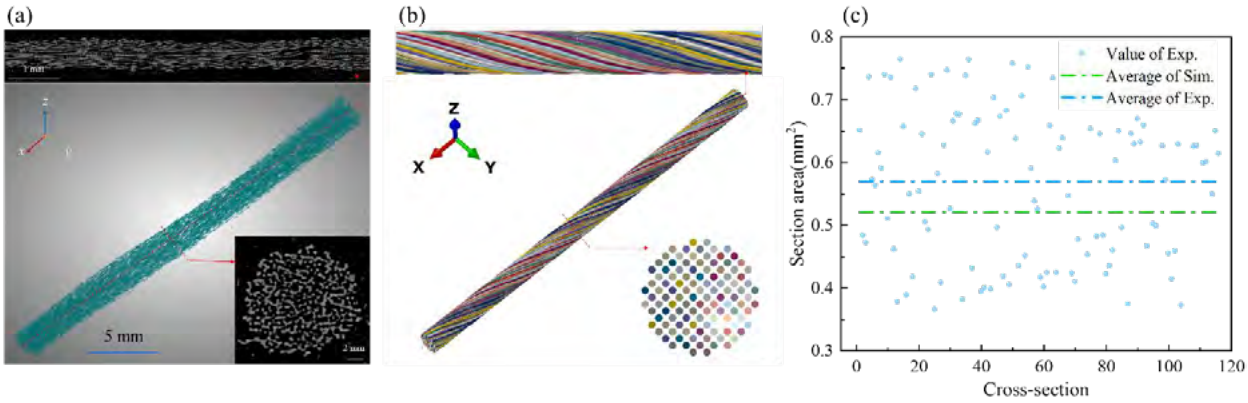

Figure 1. The geometric comparison results between simulation and experiment: (a) the experimental value, (b) the simulated value and (c) cross-sectional statistics.

4.2 Mechanical verification

Figure 2 illustrates the correlation between the friction force and the yarn's location. The green and blue core points represent experimental and simulated data points. They clearly illustrate the difference between static and active friction, as well as the turning point or mutation point on the curve. These points indicate the transition from static to motion friction, reflecting a change in the state of the friction force. Generally, the correlation between friction and shift is not always linear, as friction can vary with increasing shift, particularly in situations involving distinct friction stages, such as static and moving friction. To facilitate a comprehensive comparison between the experiment and simulation findings, an adjustment operation was conducted. The experimental and simulation corrections are depicted by the green and blue curves, respectively, in Figure 2. Additionally, the expected intervals of the results are also displayed. The simulation results may be derived from the diagram, which falls within the expected range of the experiment. This suggests that the simulations exhibit some resemblance to the experiment and provide a more accurate characterization of the yarn friction behavior. The overall friction strength steadily increases as the shift increases, reaching maximum static friction during the active friction phase, and then declines to attain stability. During the time of active friction, there is a 13% disparity in the friction of the yarn.

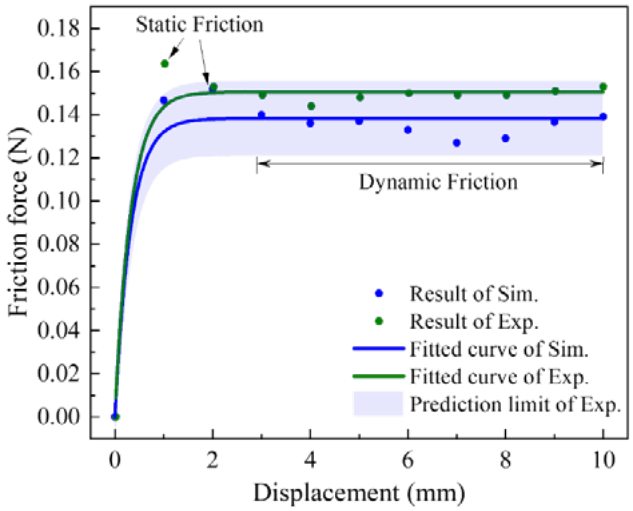

Figure 2. Experiment and simulation results of friction behavior.

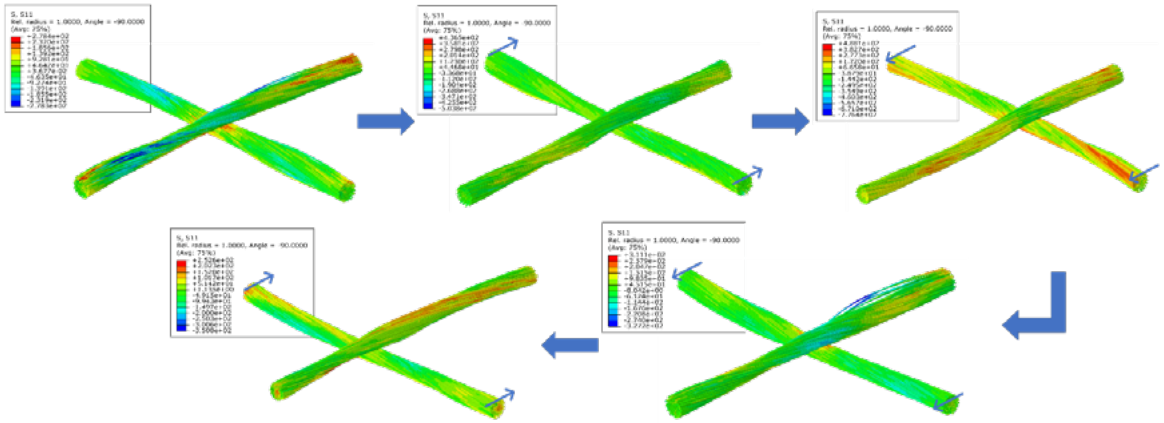

Figure 3. Morphology of different stages of friction simulation.

Figure 3 shows the evolution of stress along the longitude of yarn direction during the orthogonal friction. The upper yarn is applied to the normal load by displacement, and the lower yarn is applied to the cyclic displacement. The maximum longitudinal stress (S11) was close to the tensile strength of warp yarns before the breakage. As the friction force increased, the damage accumulation occurs for each fiber. Eventually, the fiber will completely fail.

5. Conclusions

This paper proposes a novel friction simulation model for twisted yarns, based on the Timoshenko beam principle and damage-plasticity theory. The proposed model is able to effectively predict the friction wear behavior considering the contact behavior. Further, the effect of yarn parameters on friction and wear behavior can be explored. There is excellent agreement in characterization parameters including the mechanical and geometrical behavior between the experimental measurement and the simulation. Furthermore, the model adds a damage factor to consider the damage behavior, furthermore, the yarn wear behavior can be predicted for different force conditions, and the wear behavior will be predicted for different yarn geometrical parameters, including twist, twist direction, and Tex, and applied to the reinforced-phase molding process.

allows design engineers to immediately test a new workflow using different failure models and routines – allowing for faster dissemination and reach of the state-of-the-art models.

This framework was developed building on the existing experience of the team on building composite failure models for large structures and coarse finite element models. It aims at reducing the researcher development overhead while retaining all the performance benefits, and usability of user subroutines. We present the framework using well-known and well-tested failure models against a comprehensive set of suitable of finite element models across the scale and complexity spectra. We believe that this framework has the potential to promote composite failure model development, interoperability between composite researchers and composite engineers, and benchmark and testing of the state-of-art on composite failure analysis.

2. The framework

2.1. Architecture and concept

The concept makes use of the best hardware in the most efficient way possible. This means that all the computational grunt work needs to be off-loaded into distributed computing systems, alleviating the computational burden off the engineer/researcher (Figure 1).

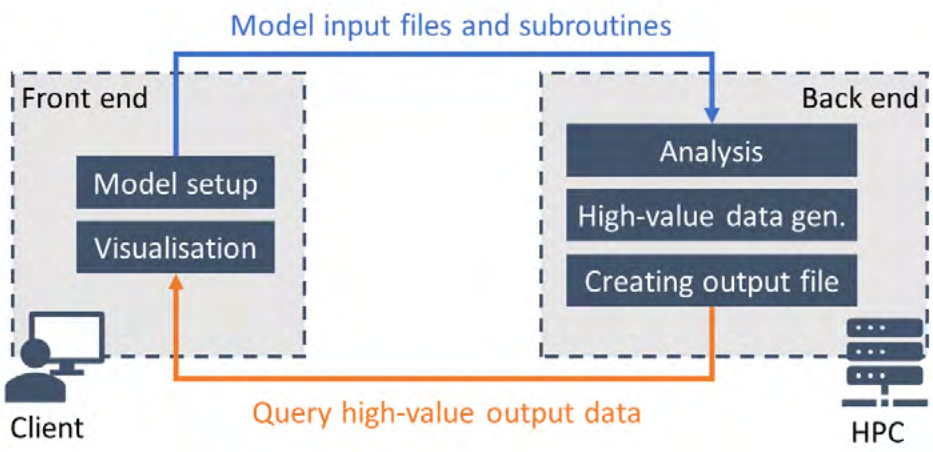

Figure 1. Separation of concerns: HPC platform handles the heavy computations; the user machine is tasked only with visualization.

We implemented the proposed framework within Abaqus but in a such way that is solver backend agnostic. This leaves the possibility of supporting multiple solver backends (both commercial and open-source).

2.2. Implementation

The framework builds up modularly from core abstractions (matrices and math algorithms) all the way to fracture plane rotations and stress transformations. These modules or components that make up the framework allow the developer to express the physical processes in a cleaner way. The framework currently defines two simulation modalities: (i) damage initiation – computes the failure indices for all damage modes and prints output; (ii) damage evolution – uses the failure indices to simulate the propagation of failure across the plies and the elements. What modules or components are used will depend on how the solver interface is implemented, and what simulation modality the user requires. The organization of the framework is depicted in Figure 2.

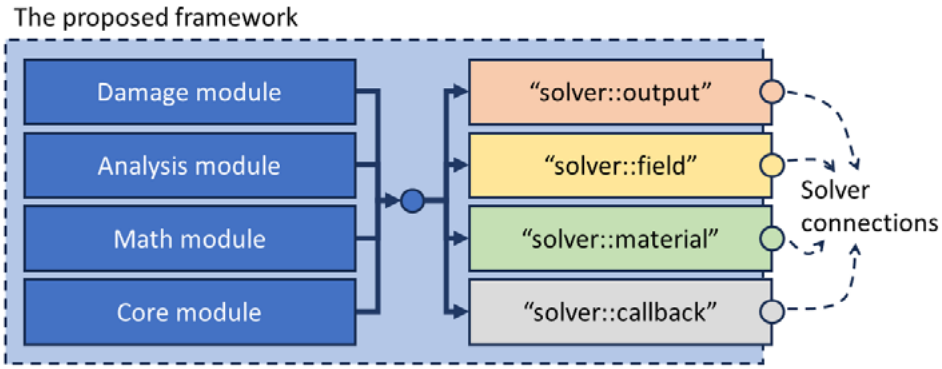

Figure 2. Modular architecture and solver agnostic connection points

The implementation of the Abaqus Standard interface to the proposed framework makes use of user subroutines and the new "uniquelibs" feature that allows libraries to be loaded at runtime (rather than copying source files, or compiled user subroutine binaries). In this way, the user subroutines can utilize all the tools and abstractions the framework provides.

Currently the Abaqus interface to the framework has the following entry points:

- For "solver::output" – UVARM (damage initiation);
- For "solver::field" – USDFLD (damage evolution – uses the previously converged strain and stress state);
- For "solver::material" – UMAT (damage evolution – uses the current strain state).
- For "solver::callback" – UEXTERNALDB (used for debug purposes only).

These Abaqus user subroutines act as interfaces that make use of the damage initiation and evolution algorithms within the framework as depicted in Figure 3.

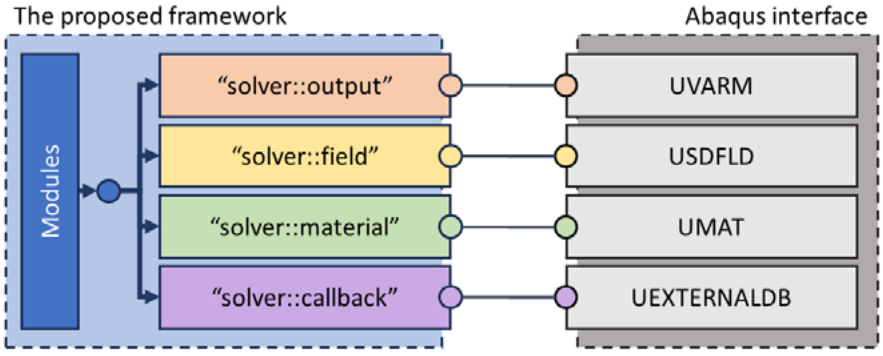

Figure 3. Abaqus interface and visual representation of the interaction with the framework

2.3. Use cases

The framework is built as an open-source project with the intention of promoting community interaction. This will ensure continuous evolution of the framework in a way that best serves the composite material community.

Therefore, we anticipate the following use cases:

- Basic user – only wants to use the framework for simulation and make use of all the failure models implemented;
- Researcher – someone who will use the framework but also develop their own models, extensions or algorithms;
- Developer – someone interested in the technology that wants to help maintain, improve the framework.

Additionally, the framework is designed to enable interaction in the form of feedback, models, code, or even with ideas and suggestions.

3. Examples

We have used the framework to run several models with both simulation modalities (damage initiation and evolution). The failure models used in the following examples are described in detail in [3].

This framework was built with the intention of running very large industrial-scale models (such as an entire wing-box). Figures 4 and 5 show that the framework can handle a full wing-box model with 15 million degrees of freedom (model from [1,2]).

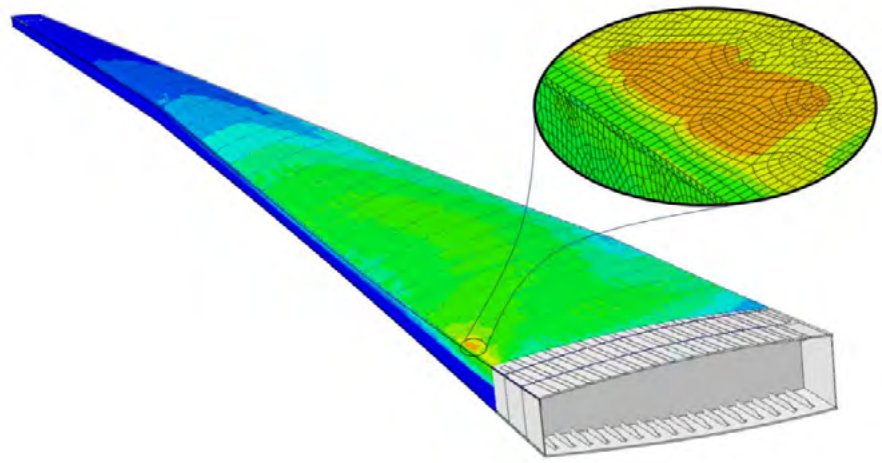

Figure 4. Compressive damage developing on upper cover of wing-box (with mesh detail)

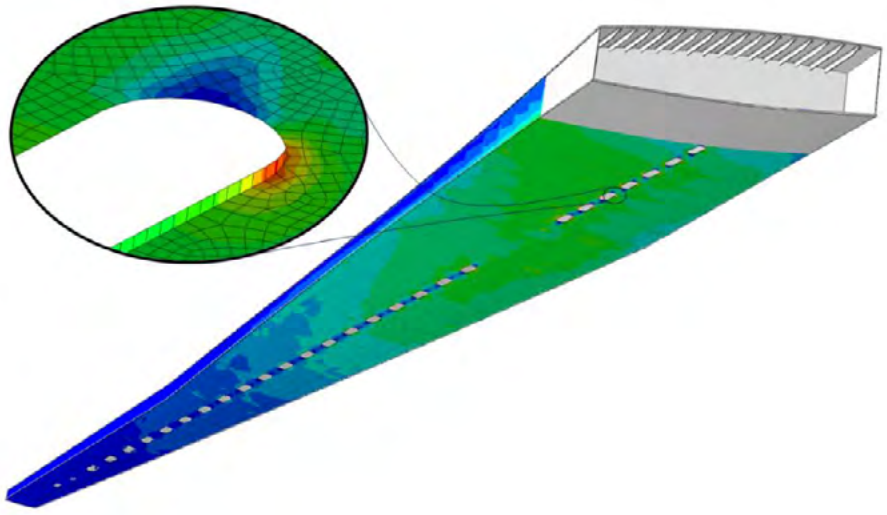

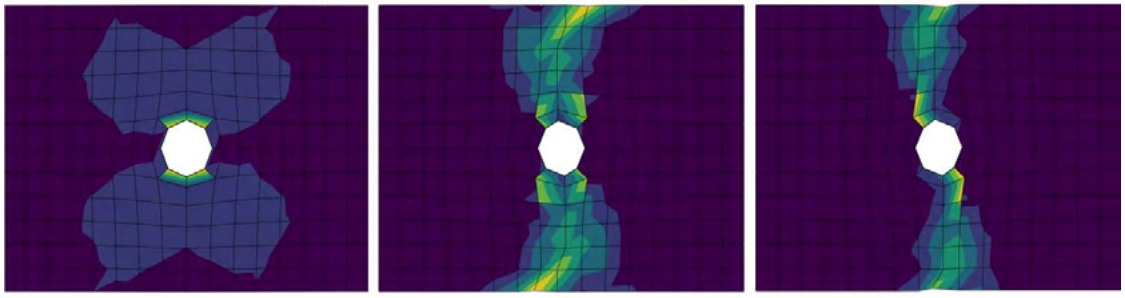

Figure 5. Tensile damage developing on manhole on lower cover of wing-box (with mesh detail)

In addition, the framework is also meant to work across scales. Therefore, we also studied what can be small structural details in the very large model of the wing-box, meshed with an equivalent level of detail. See Figure 6 for representative results. The model presented here is an open-hole compression (OHC) specimen based on [4] using the IM7-8552 material system.

a) UVARM b) USDFLD c) UMAT

Figure 6. Through-thickness maxima of fibre kinking damage index and variables of OHC models at the last increment (compression loading along horizontal direction). OHC models meshed in accordance with the level of detail of full-scale wing-box model.

3. Conclusions

This work introduces a new composite damage analysis framework targeting HPC platforms. The new framework creates a platform for researchers to implement their existing and new composite failure models such that:

- All failure models are tested under the same conditions and compared/benchmarked in a structured manner;
- The failure models – containing only the high-level physical model for different failure modes – makes direct use of the HPC capabilities of the architecture;
- Engineers can readily test various models and implementations; thus, bringing state-of-the-art research closer the real-world applications.

When compared to traditional Abaqus user subroutine workflows, this framework provides the following advantages:

- Modern C++ codebase following proven coding standards and practices and with easy interoperability with a huge ecosystem of external C/C++ libraries;
- Comprehensive test suite and visualisations;
- A set of useful abstractions to make writing failure models faster and safer.

We believe that this framework has the potential to become an important tool for the design of composite structures. Furthermore, with suitable community support and interaction, the proposed framework can bring together decades of knowledge into a user-friendly and robust library of failure models.

Keywords: CFRP composites, Woven prepregs, Crush plugs, Axial-crushing, Finite element analysis

Abstract
In this study, an investigation of the effects of innovative crush plugs on composite circular tubes subjected to axial quasi-static crushing is presented. The composite tube specimens in the study are manufactured from Carbon-Fibre Reinforced Plastic (CFRP) plain weave woven fabric prepregs. The crushing characteristics of composite tubes are investigated both experimentally and numerically using Finite Element Method (FEM) simulations for axial crushing tests. After FE model is validated with experimental results, the effect of the suggested novel plugs are investigated numerically using the FE models. Suggested novel plug geometries includes two crushing zone curves and channels that steers the crushed tube through during crushing and can lead to more fragmentation behavior and higher energy absorption characteristics along with progressive crushing. FEM simulations are carried out in Abaqus/Explicit software with stacked-shell approach, using cohesive zone method (CZM) to model delamination and using a built-in subroutine for continuum damage mechanics (CDM) of fabric composites to model intralaminar damage.

1. Introduction

CFRP composites are increasingly replacing traditional metallic materials in various industrial applications due to their promising attributes. Their outstanding mechanical properties and lightweight nature render them highly advantageous, particularly in crashworthy structures. In such applications, components must possess high specific energy absorption (SEA) capacity and stable progressive crushing behavior to effectively mitigate the impact of crash incidents. Well-designed CFRP composite crashworthy structures meet these criteria owing to their superior characteristics. However, estimating energy absorption values and predicting the crushing behavior of composite structures poses significant challenges due to the involvement of numerous complex damage modes, including in-plane and interlaminar damages, which encompass fiber and matrix damage, as well as delamination respectively [1-5].

A review of literature reveals studies investigating the progressive crushing behavior and morphology of CFRP structures, commonly categorizing the progressive crushing behavior into three modes: splaying, fragmentation, and local buckling [1, 2, 6]. These modes may occur simultaneously during a crushing incident. Various design parameters of CFRP structures significantly influence energy absorption characteristics and crushing behavior. These parameters include composite material in-ply properties, microstructure, geometry of the composite structure, crushing conditions, and trigger mechanisms [1, 2 ,5-10].

Trigger mechanisms play a pivotal role in composite crashworthy structures, influencing both the initial peak force in load displacement curves and crush reaction forces, thereby affecting the energy absorption rate of CFRP structures. They initiate the crushing of composite structures and facilitate stable, progressive crushing behavior by aiding in the initial crushing of tubes, thereby averting catastrophic failure. Trigger mechanisms are typically classified into two types: conventional trigger mechanisms and external trigger mechanisms. Conventional trigger mechanisms are commonly integrated into composite structures by shaping the structure's tip through machining, often forming steeple or chamfered shapes.

External trigger mechanisms involve an external structure that guides the composite component during crushing, facilitating progressive crushing behavior. Typically applied to tubular composite structures, their geometry affects the crushing behavior and can enhance energy absorption characteristics. Several studies in the literature examine the effects of external crush plugs. Siromani et al. [11] studied the axial crushing behavior of circular graphite/epoxy tubes with chamfered ends using basic outward and inward crush plugs with varying crushing zone radii. They found that inward crush plugs exhibited the best performance, and the energy absorption rate could be adjusted based on the crushing zone radius. Jiang et al. [12] explored the crushing of CFRP fabric square tubes with various plugs including circular convex, circular concave, square convex, square concave plugs, and ditch plugs with narrow and wide channels. They suggested that ditch plugs offer superior performance, although the load-displacement curves fluctuate more due to the observed progressive folding behavior of the tubes. Ren et al. [13] investigated the effects of different triggers applied to the tip of the tube, such as sawtooth, chamfer, square holes, and channel holes triggers, on square tube CFRP composites crushed with ditch-type plugs. They also observed folding behavior in the crushing morphology of the specimens. Tong and Xu [14] examined the crushing of CFRP braided circular tubes with innovative crush plugs, including conventional outward plugs and outward plugs with semi-circle cavities, which guide the tube downwards after the crash event.

This study examines the crushing behavior of Ø40 mm CFRP fabric composite tubes employing various innovative crush plugs. Recently, Demir et al. [15] investigated the axial quasi-static crushing of composite tubes and explored the effects of different modeling techniques, including mesh density and the virtual debris wedge approach in FEM simulations. In this current investigation, similar manufacturing and testing methods, as well as modeling techniques, are adopted to investigate the effect of crush plugs. Initially, Ø40 mm composite tubes are experimentally tested under quasi-static axial crushing conditions. The experimental setup includes crushing the tubes without using any crush plug and utilizing basic outward and inward crush plugs with a 2 mm radius on the crushing surfaces. In the numerical study, the model is validated by comparing with the experimental results. The crushing simulation of composite tubes is conducted using FEM with Abaqus/Explicit software. Following validation, the model is utilized to simulate and analyze the crushing behavior of tubes employing channel crush plugs.

2. Experimental Study

Ø40 mm CFRP composite tubes are fabricated using KORDSA OM10 carbon fiber prepregs, featuring a plain weave of 3K carbon fiber tows and an epoxy matrix. The prepregs have a nominal areal weight of 200 g/m² [15]. The manufacturing process involves roll-wrapping six layers of prepregs onto an aluminum mandrel, followed by the application of heat shrink tapes on the surface. The roll-wrapped tubes are then cured in a vacuum oven at 130°C, following the recommended curing cycle. Upon completion of the curing process, the products are released from the aluminum mandrels and cut into smaller specimens with a length of 40 mm using a water-cooled diamond disc. The dimensions of the circular tube specimens are depicted in Figure 1.a. These specimens undergo quasi-static compression tests at a constant crushing rate of 2 mm/min [15]. The tests include axial crushing using basic inward and outward crusher plugs with a 2 mm radius on the crushing zone, as well as crushing without plugs using only test rigs. The test setups are illustrated in Figure 1.b-d.

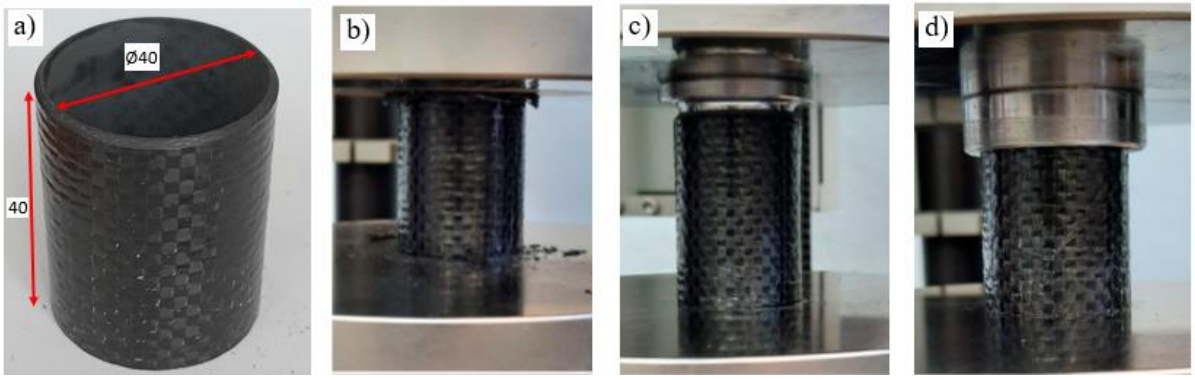

Figure 1. Manufactured crush tube specimen and test setups; a) Whole specimen b) Test setup without using crush plug, c) Outwards crushing test setup, d) Inwards crushing test setup.

Tip of the tube specimens are 45° chamfered using a lathe as illustrated in Figure 2.a, to prevent catastrophic failure during tests. During the crushing tests, the crush plugs are placed at the top of the tubes. Basic outwards and inwards crush plugs utilized in tests are illustrated in Figure 2.a and 2.b.

Figure 2. Trigger mechanisms on experimental tests; a) Chamfer trigger, b) Outwards crush plug, c) Inwards crush plug.

3. Finite Element Analysis

Following the same modelling method stated in Demir et al.'s study [15], the axial crushing of composite tubes are modelled in Abaqus/Explicit software adopting the stacked shell model approach. Interlaminar behavior of plies are modelled with Cohesive Zone Method (CZM) by generating cohesive interactions between the surfaces of the plies. In the CZM method used to model interlaminar delamination behavior, cohesive contacts based on traction-seperation law are generated between surfaces of the plies. To model mixed delamination, damage initiation behavior is modelled by quadratic stress damage initation criterion and damage evolution is modelled according to Benzeggagh-Kenane damage evolution law. Softening behavior is set as linear softening in the model and B-K coefficient is selected as 2.284 [15, 17]. Interlaminar behavior properties are listed in Table 1.

Table 1. Interlaminar material properties of composite tubes [15, 17]

Description	Mode I	Mode II	Mode III	Unit
Penalty Stiffness	2×10^6	1×10^6	1×10^6	[N/mm³]
Damage Initiation	54	70	70	[MPa]
Fracture Energy	0.504	1.566	1.566	[kJ/mm²]

Intralaminar damage behavior of the composite plies are modelled by using built-in ABQ_PLY_FABRIC subroutine [15-17]. ABQ_PLY_FABRIC built-in subroutine defines the material behaviour of composite plies adopting a continuum damage material model. Input values of the intralaminar properties of composite tubes are illustrated in Table 2.

Table 2. Intralaminar material properties of composite tubes [15, 17]

Description	Symbol	Value	Unit
Density	ρ	1.56	g/cm³
Young Modulus along fiber direction 1	E_1	65.1	GPa
Young Modulus along fiber direction 2	E_2	64.4	GPa

Hardening equation power term	p	0.41	-
Element deletion flag	1DelFlag	1	-
Maximum value of damage variables	d_{max}	0.99	-

In constructing the FE models, each ply is first modeled individually as solid layers and then meshed with continuum shell elements (SC8R) using the stacked shell modeling approach, thereby representing the plies as homogeneous orthotropic layers. These continuum shell elements possess the geometric attributes of 3D elements while exhibiting constitutive behavior akin to conventional shell elements. To expedite FEM simulation results, composite tubes are modeled using a quarter-model approach. Material properties are defined by assigning homogeneous continuum shell sections to each ply, thereby specifying ply orientations.

Individual plies are modelled with a thickness of 0.2 mm and meshed with approximately 1.0×1.0 mm sized elements. A rigid plate is generated to model the test rig beneath the composite tube. Tie contacts are used between the bottom nodes of the tube and bottom rigid surface, which is meshed with R3D4 rigid elements and fixed boundary condition. Crushing rate is choosen to be 1 m/s as recommended in the literature [15]. In order to define the interaction between applied rigid crush plugs and tubes, “Tangential Behaviour” contact with penalty stiffness and “Normal Behavior” contact is defined between the tubes and rigid parts. The friction coefficient is selected as 0.2 for the interaction between parts. Also contacts with “Tangential Behaviour” and “Normal Behavior” are defined for the cohesive interactions between plies with friction coefficient of 0.3 [15]. Semi-autoamtic mass-scaling method is

used and applied to whole model with the target increment of 1e-7. To be able to model delamination, crushing behavior and initation of crushing, the surfaces of the upper elements of last 2 mm's are not included into cohesive interactions. CAE model of the quarter-model composite tubes and rigid bottom plate is illustrated in Figure 4.

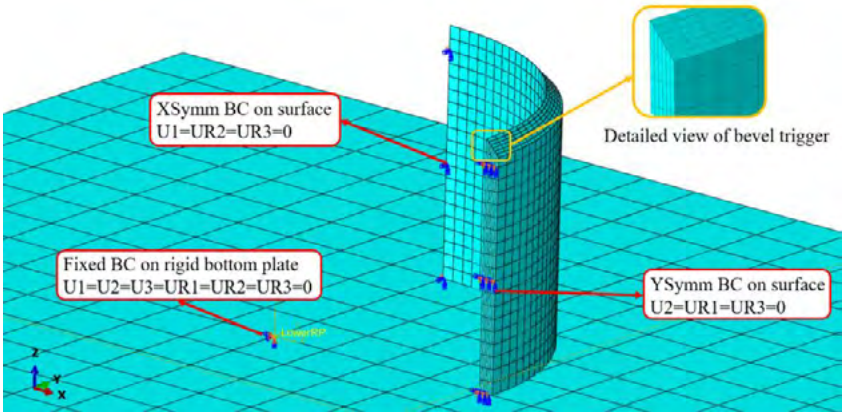

Figure 4. CAE model of the quarter-model of composite tubes and rigid bottom plate

To integrate crush plugs into the simulations, the inner surfaces of the plugs, which come into contact with the specimen during crushing are modeled using rigid surfaces that are meshed with R3D4 elements, with dimensions of 0.2×0.2 mm in critical radius zones and 0.5×0.5 mm in flat surfaces. The model for the axial crushing of Ø40 mm composite tubes is validated by comparing experimental tests with FE simulations. For modeling axial crushing using only test rigs, the virtual debris wedge method is applied, as recommended in the literature [15, 18, 19, 20]. Following validation, the performance of novel plugs is investigated through FEM simulations. These novel plugs include a channel that guides the composite tube wall through two curves with a 2 mm radius. Two novel channel plugs, crushing the tubes outward and inward, respectively, are examined. The rigid surfaces representing benchmark plugs and virtual debris wedge rigid surfaces are depicted in Figure 5, along with the rigid surfaces of the novel plugs.

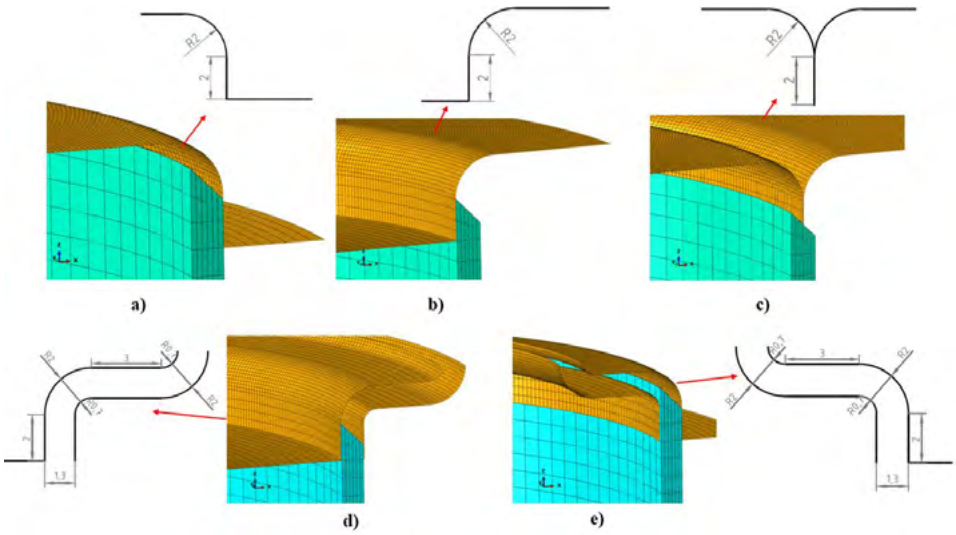

Figure 5. Rigid upper surfaces generated to model crush plugs and virtual debris wedge; a) Inwards crush plug (ICP), b) Outwards crush plug (OCP), c) Virtual debris wedge (VDW), d) Outwards channel crush plug (OCCP), e) inwards channel crush plug (ICCP)

4. Results and Discussion

In the first phase of the study, the experimental and simulation results of the benchmark specimens are compared. Load-displacement curves and SEA-displacement curves obtained from FEA simulations and experimental tests are illustrated together in Figure 6 for inwards crushing, outwards crushing and crushing without plugs respectively. The experimental tests without any plugs are compared with virtual debris wedge simulations.

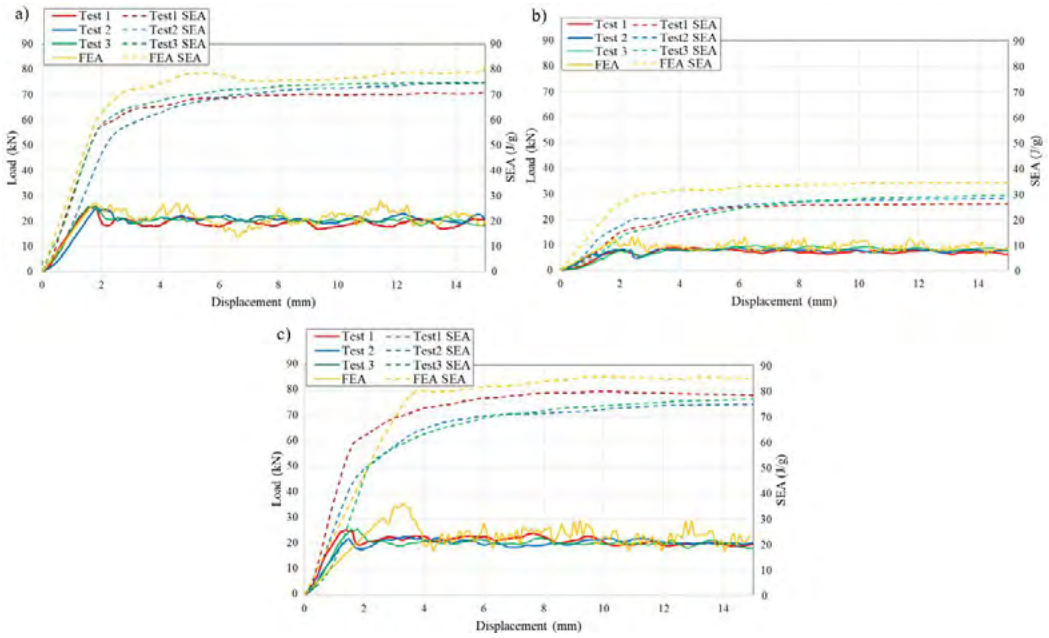

Figure 6. Load-displacement, SEA-displacement curves of benchmark models; a) crushing with no plugs (virtual debris wedge simulation (VDW)), b) Outwards crushing (OCP), c) Inwards crushing (ICP)

Evidently, the load-displacement curves derived from FEA simulations closely match those observed in the experimental tests, particularly during the progressive crushing phase. However, simulations incorporating outward and inward crushing plugs show slightly elevated peak forces compared to the experimental results. As a result, the SEA-displacement curves in these simulations also exhibit a minor deviation. Furthermore, the crushing morphologies obtained from FEA simulations accurately mirror the experimental morphologies, as depicted in Figure 7.

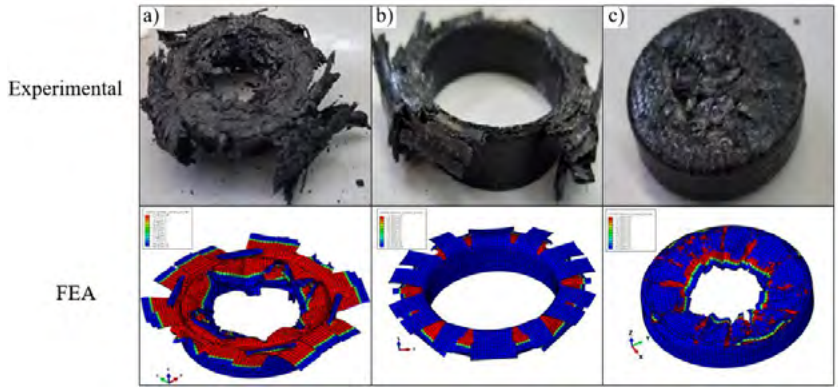

Figure 7. Experimental and FEA crush morphologies for benchmark specimens; a) crushing with no plug, b) outwards crushing, c) inwards crushing

After benchmarking study completed, the numerical simulations of the novel plugs are carried out. The load-displacement, SEA-displacement curves and crushing morphologies are illustrated in Figure 8. Novel outwards and inwards plug simulation results are also compared with basic outwards and inwards plug test results in Figure 8.

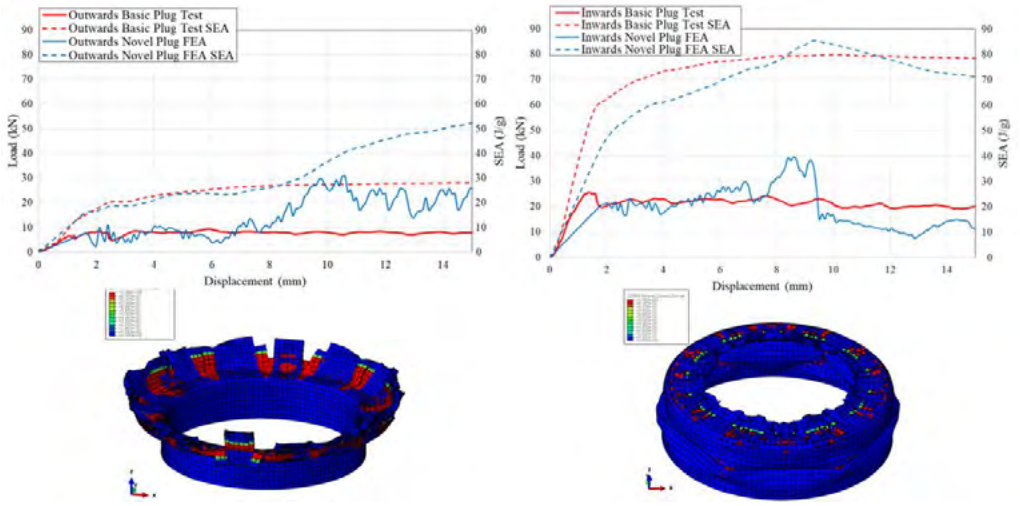

Figure 8. Load-Displacement, SEA-Displacement curves of novel plug simulations compared with basic plug test results and crush morphologies of the novel plug simulations; Outwards Channel Crush Plug (OCCP) (left), Inwards Channel Crush Plug (ICCP) (right)

Analyzing the load-displacement curves reveals that the simulations using the novel channel plugs exhibit similar behavior to those with the basic plugs within the first 8 mm. However, once the tube reaches the second turn in the channel section, the loads begin to increase. Upon examining the crushing morphologies, it is observed that the tube crushed with the outward channel plug takes on the shape of a crown, whereas the tube crushed with the inward channel plug shows signs of local buckling before the composite tube reaches the second radius. Following buckling, the loads tend to decrease, resulting in a reduction in SEA-displacement curves as well. The SEA values for all simulations and the mean values of experimental tests are evaluated in Table 3.

Table 3. SEA values of the experimental tests and simulations

	No Plug Test	OCP Test	ICP Test	VDW Sim.	OCP Sim.	ICP Sim.	OCCP Sim.	ICCP Sim.
SEA (J/g)	73.59	28.74	76.66	77.61	34.39	84.64	52.47	70.88

5. Conclusion

This study examines the impact of novel inward and outward crusher plugs on the axial crushing behavior of CFRP woven composite tubes using Abaqus/Explicit FEA software. Initially, the models are validated against experimental tests conducted with basic crush plugs and without any plugs. The simulation results obtained with the novel channel plugs demonstrate behavior consistent with the conventional plugs during the initial phase of crushing. However, once the tube reaches the second turn in the channel section, the loads, hence SEA values begin to increase. Evidently, crush plugs featuring channels significantly influence the crushing behavior and energy absorption values of composite tubes. As a future endeavor, optimizing crush plugs utilizing channel geometries could be explored to achieve more efficient crashworthy structure assemblies, suitable for use in transportation vehicles and various industries.

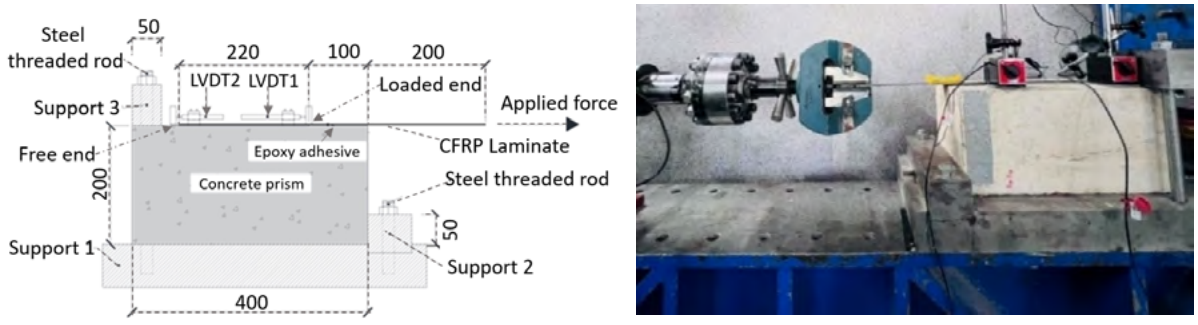
Keywords: Numerical modeling, Carbon fiber, Concrete, Epoxy adhesive, Water exposure

Abstract
In the context of structural rehabilitation of concrete structures, carbon fiber reinforced polymer (CFRP) composites are usually bonded to concrete substrates using the externally bonded reinforcement (EBR) technique. Although this is a commonly used method in various applications, only a few studies have investigated the long-term performance of such joints. In this study, numerical models to simulate the short- and long-term performance of the EBR CFRP-to-concrete bondline are developed. Using these models, the performance of the bonding before and after four years of water exposure is assessed. The numerical results from both models are compared with results from an experimental investigation previously performed by the authors' research group, which shows a good agreement.

1. Introduction

Concrete is used extensively in engineering structures that need to be in operation for several decades. Various strengthening techniques have been implemented in the past to extend the service life of reinforced concrete (RC) structures. One of the best candidate materials for strengthening RC structures is carbon fiber reinforced polymer (CFRP) composites. CFRP composites show excellent durability performance; furthermore, they possess very high stiffness and high strength-to-weight ratios [1]. There are two main strengthening techniques using CFRP composites for the strengthening of RC structures: (i) externally bonded reinforcement (EBR) and (ii) near-surface mounted (NSM) [1][2]. In both techniques, an epoxy adhesive is required to bond the CFRP to the concrete substrate. In the case of the EBR technique, the CFRP laminate is bonded to the concrete substrate, whereas in the case of NSM, the CFRP laminate is inserted in a groove pre-cut into concrete [3].



Despite the successful application of the above techniques, the existing literature still lacks sufficient data about the durability/long-term response of the applied strengthening techniques. In fact, the question of how long the epoxy adhesive can keep binding the concrete to the CFRP laminate, allowing the composite action between both parts, needs to be addressed to better understand the durability and long-term performance of EBR and NSM techniques. This work attempted to develop numerical models addressing the durability of the EBR CFRP-to-concrete bond for up to 4 years of water exposure. Experimental data on the durability of the EBR CFRP-to-concrete under accelerated aging test protocols already exist, e.g., [4], as well as under natural aging test protocols [5] [6] [7]. However, a very few numerical models addressing bond durability exist, e.g., in [8][9] and are unfortunately based on short-

term experimental data. Hence, the developed models in the present work contribute to increasing the availability of numerical data regarding the durability of the EBR CFRP-to-concrete bond by using data from long-term exposure. Constitutive models for each bond constituent material (concrete, epoxy adhesive, CFRP laminate) are first developed considering the yearly degraded properties of the materials. These constitutive models are developed referring to existing equations in the literature. Both concrete and epoxy adhesive are modeled using the well-known concrete damage plasticity (CDP) model [10], while the CFRP laminate is assumed to behave linearly up to failure. The added novelty lies in assessing the effects of the degradation of the material properties themselves on the bond performance by using the properties of the materials at the bondline rather than adopting the commonly known cohesive model. That is, the constitutive models are developed referring to the data from material property testing. This work comprises of the following sections: Section 1 introduces the existing work, highlights the gap, and the strategies used for addressing the gap; Section 2 describes the materials and methods adopted. Furthermore, results are presented and discussed in Section 3, followed by conclusions in Section 4.

2. Materials and methods

2.1. Experimental Program

An experimental campaign was previously conducted by the authors' group [6] where, in the first phase, 3 concrete cylinders, 5 epoxy adhesives, 6 CFRP laminates, and 2 concrete elements strengthened with CFRP laminates according to externally bonded reinforcement (EBR) technique (each element being strengthened by two CFRP laminates yielding to 2 tests per element), were tested to examine their responses before water exposure. In the second phase, the specimens were immersed in tap water controlled at 20 °C for up to four years. That is, 12 concrete cylinders, 20 epoxy adhesives, 24 CFRP laminates, and 8 concrete elements (strengthened with CFRP laminates) were immersed in water for later testing. Each year, these specimens were tested to assess the effect of water ingress on their long-term mechanical properties. The results from testing of concrete, epoxy adhesive, CFRP laminates, and bond in the strengthened elements are provided in the recently published work by the authors' research group [6] (i.e., see E2 data in Table 3, Table 4 and Table 5 of [6]). The bond test (single lap shear test) procedure for the elements with EBR is summarized in Fig. 1, and more details of this test can be found in [6].

(a) (b)

Figure 1. Single lap shear test: (a) specimen geometry and test setup (all units in [mm]), (b) photograph of the full test configuration [6].

2.2. Developed numerical models

A summary of the constitutive models used in this study is provided in Fig. 2. Concrete behavior under compression and tension was predicted using Saenz model [11] and the model by Horjidik [12] as shown in Fig. 2a,b respectively. The input parameters for both models were as follows: for concrete under compression and tension, the experimentally recorded maximum concrete compressive and tensile

strengths and elastic modulus before exposure (short-term value) and after each year of exposure (long-term values) for up to 4 years (see values for E2 in the previously published work [6]) were used in developing the relations shown in Fig. 2a,b.

Furthermore, epoxy adhesive behavior under compression and tension was modeled using the Saenz [11] and Belarbi and Hsu [13] models, as in Fig. 2c,d, respectively. The CFRP laminate was modeled as a linear elastic material up to failure. Similar to the case of concrete model, the input parameters for the adhesive from experimental results before and after water exposure (compressive strength, tensile strength, and elastic modulus) were used as inputs to produce the relations shown in Fig. 2c,d.

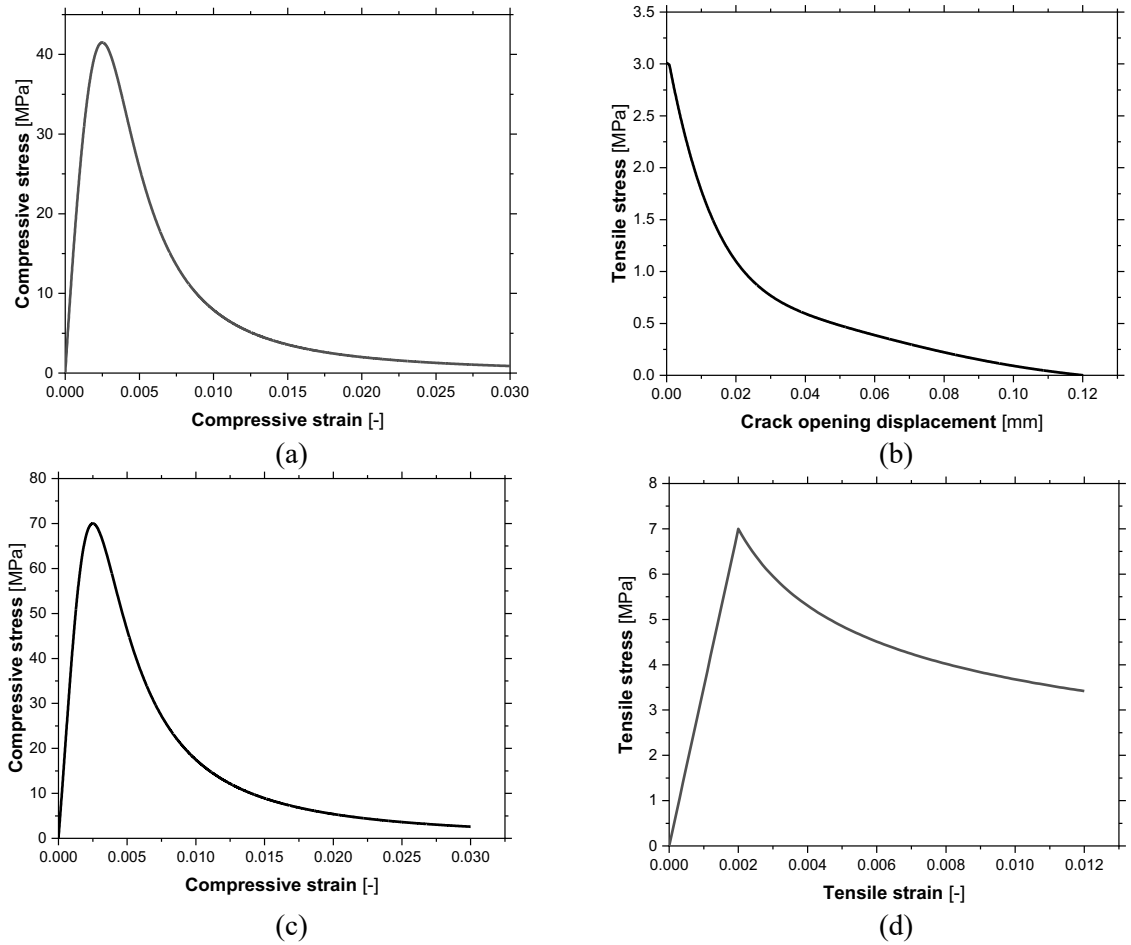


Figure 2. Developed material constitutive models: (a) concrete in compression, according to Saenz et al. [11], (b) concrete in tension, according to Horjidk [12], (c) epoxy adhesive in compression, according to Saenz et al. [11], (d) epoxy adhesive in tension, according to Belarbi and Hsu [13].

2.2.1. EBR CFRP-to-concrete model

The finite element method (FEM) using ABAQUS software was used to simulate the short and long-term performance of the bond between concrete and CFRP laminate. A perfect bond was assumed between the concrete-epoxy adhesive and the CFRP laminate-epoxy adhesive interfaces. Therefore, tie constraints were used to tie the materials at these defined interfaces. The material parameters used for defining the CDP model [10] and other input properties to the EBR CFRP-to-concrete bond model are summarized in Table 1.

Table 1. CDP model parameters used for concrete and epoxy adhesive

Material	Concrete damage plasticity (CDP) model parameters										
	Plasticity flow parameters					Compression			Tension		
	D_a	e	fb_0/fc_0	K	V_p	CC_C			CC_t		
						SS_C	ε_{in}	d_c	SS_t	ε_{Tcr} or w_t	d_t
Concrete	38	0.1	1.16	0.6667	0.0	Saenz et al. [11]			Horjidk [12]		
Adhesive	38	0.1	1.16	0.6667	0.0	Saenz et al. [11]			Belarbi and Hsu [13]		

D_a: Dilation angle, e: eccentricity, fb_0/fc_0: the ratio of initial equibiaxial yield stress to initial uniaxial yield stress in compression, K: ratio of the second stress invariant on the tensile meridian to the one on the compressive meridian, Vp: viscosity parameter, , CC_C: constitutive law in compression, CC_t: constitutive law in tension, ε_{in}: inelastic strain, d_c: compression damage, SS_C: stress-strain curve in compression, SS_t: stress-strain (or displacement) curve in tension, w_t: crack opening width, ε_{Tcr}:cracking strain, d_t: tension damage.

3. Results and Discussion

The results from the EBR CFRP-to-concrete bond are analyzed in this section. Comparative graphs between experimental and FE model curves are shown in Fig. 3 for the short-term behavior of the studied strengthening system. The maximum values are also compared in Table 2. It can be seen that experimental and FEM data are in very good agreement (with only a 5% difference). Particularly, the average curve in Fig. 3a corroborates well with the FEM model curve shown in Fig. 3b, which shows the model is very promising in predicting the behavior of non-exposed specimens.

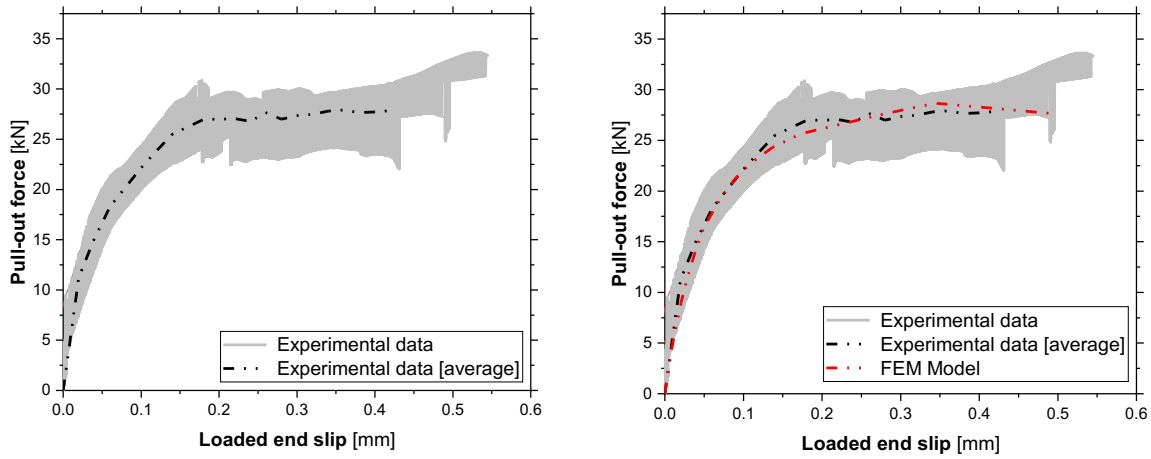

Figure 3. Short-term EBR CFRP-to-concrete bond responses: (a) experimental data (shaded area represents the four curves from four tests), (b) experimental *vs.* FEM model data before exposure

The pull-out force *vs.* loaded end slip relationships for the case of long-term exposure are presented in Fig. 4 (that is, experimental *vs.* FEM model results for the first (Fig. 4a), second (Fig. 4b), third (Fig. 4c), and fourth (Fig. 4d) years of exposure), and their average maximum pull-out values are compared with those from experimental tests in Table 2. Based on Fig. 4., the FEM predicted responses agree well with the experimental results as the FEM curve falls within the shaded area representing the four curves from the experimental tests, though there is a slight difference in terms of the average experimental data and the numerical FEM data curves. Despite this, it can be noted that the results from the FEM model are promising as the maximum values and those from experimental tests are close to each other. This is clearly shown in terms of percentage difference that varies between 1.68 and 11.96% (Table 2).

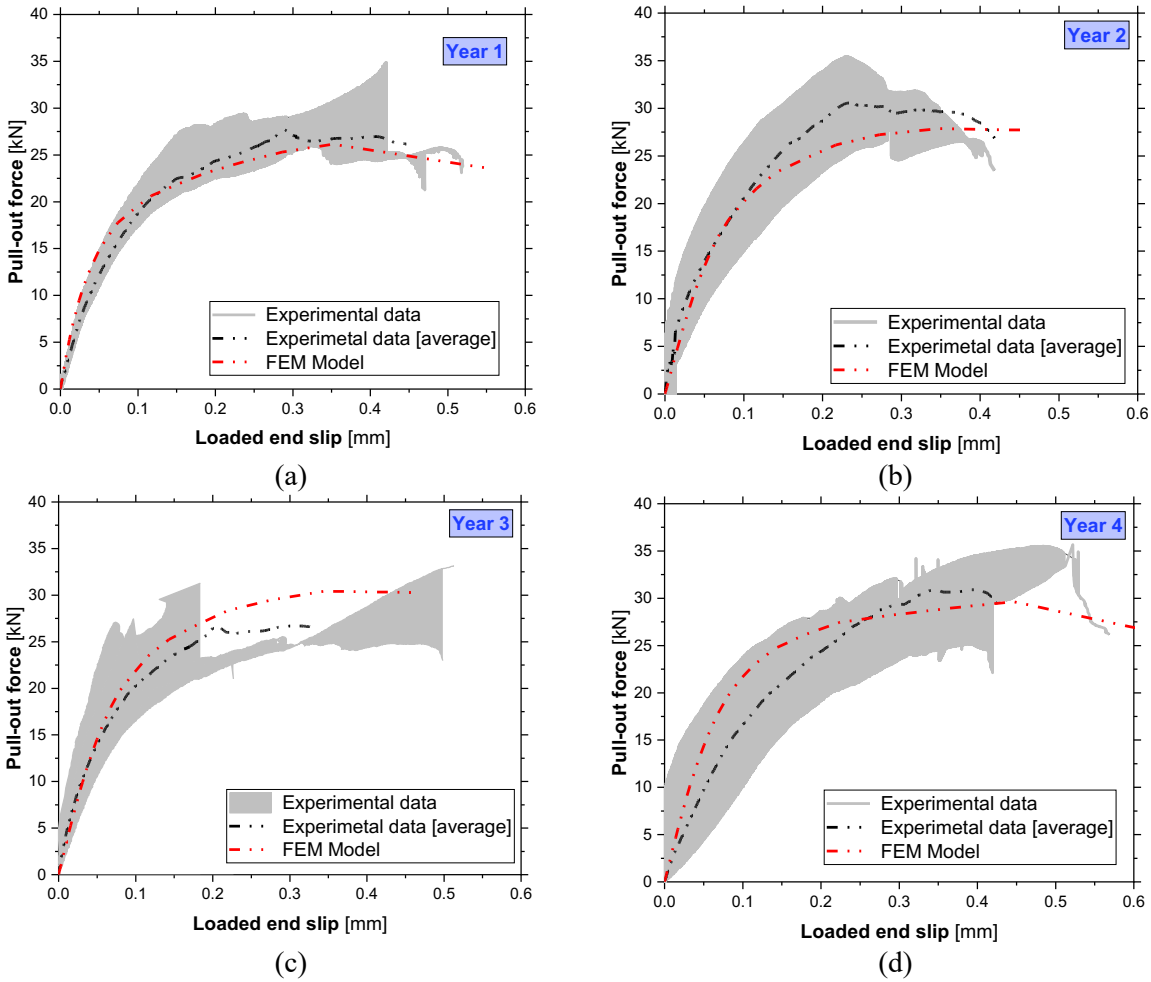

Figure 4. Long-term EBR CFRP-to-concrete bond responses: Experimental *vs.* FEM model data (a) after 1 year, (b) after 2 years, (c) after 3 years, and (d) after 4 years of exposure

Table 2. Comparison of pull-out forces (kN) from experimental tests with those from FEM modelling

Exposure time (in years)	Experimental result	FEM model result	Difference (%)
0	30.20	28.67	5.07
1	27.86	26.14	6.17
2	31.06	28.52	8.18
3	27.18	30.43	11.96
4	29.14	29.63	1.68

On the other hand, comparison of the concrete substrate's tension and compression damages, as well as the substrate displacement at the failure stage for the case of non-exposed specimens, are presented in Fig. 5a,b, and c, and for the case of water exposed specimens (at the fourth year of exposure) in Fig. 5d,e, and f. respectively. It is observed, for both non-exposed and exposed specimens, that concrete damages severely at the loaded end and this damage propagates toward the free end, thereafter, reaching a complete failure, which is the concrete cohesive failure. This type of failure was also observed during the experimental tests. Hence, it can be noted that the type of failure is well predicted by the developed model; also, the failure mode for the specimens immersed in water does not change with time.

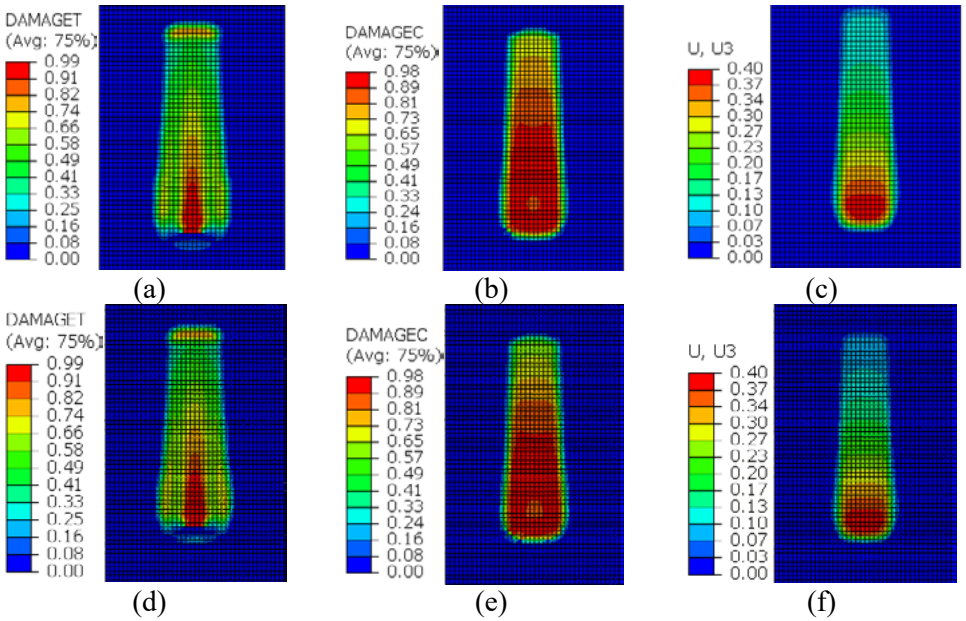

Figure 5. Failure modes from the FEM model: i) Before exposure: concrete (a) tension and (b) compression damages, and (c) concrete substrate displacement [mm]; ii) after 4 years of exposure: concrete (d) tension and (e) compression damages, and (f) concrete substrate displacement [mm].Note: The direction of the applied pull-out force is from the top to bottom of each image.

4. Conclusions

In this study, finite element modeling of the bond between concrete and carbon fiber reinforced polymer (CFRP) laminates applied using externally bonded reinforcement (EBR) technique was developed. The developed models addressed the bond performance under short-term (before water exposure) and long-term (after water exposure) cases. These models were validated using experimental data previously published by the authors' group. The key findings are as follows.

1. The numerical models of the CFRP-to-concrete bond in non-immersed and immersed (in tap water conditioned at 20 °C for different exposure durations) cases are developed. The yearly predicted pull-out force *vs.* slip curves corroborated well with those observed during the experimental program.

2. The developed models revealed that the damage of concrete started from the loaded end and propagated toward the free end. Concrete cohesive failure was predicted as the prevailing failure mode for all considered exposure durations and matched with that observed during experimental program.

3. The developed model that only considers the material properties (without using cohesive model) led to a very good agreement with the observed data from the experimental program. This shows that modeling the epoxy adhesive with its own properties rather than using the commonly known cohesive model is promising.

Abstract
This study examines the effect of annealing on carbon fiber-reinforced polyether ketone ketone (CF/PEKK) composites under flexural and compressive loads using reference, pre-damaged, and annealed specimens. Annealing recovers pre-existing damages in the composite specimens in both loading scenarios. Additionally, annealing increases glass transition temperature (T_g) and degree of crystallization, as a result of dynamic scanning calorimetry (DSC) analysis. Furthermore, acoustic emission (AE) inspection reveals that CF/PEKK composite specimens are dominated by fiber-related failure under flexural loading and matrix-related failure under compressive loading. Pre-damages influence the failure cumulative counts and initiation times, but annealing restores cumulative count percentages to reference specimens' levels by relieving residual stresses and changing microstructure.

1. Introduction

Thermoplastic composites (TPCs) offer key benefits over thermoset composites, including mechanical properties meeting aeronautical standards, room temperature storage, weldability, recyclability, and efficient processing methods [1]–[3]. Within the thermoplastic polymer options for aircraft components, the Polyether-ketone-ketone (PEKK), a semicrystalline polymer becomes prominent due to its features with a glass transition temperature (T_g) of 160°C, a moderate processing range (330–380°C), and high strength and stiffness, and strong mechanical properties [4].

The Vacuum Bag Only (VBO) process is known as a rapid and cost-effective manufacturing method, generally used for thermoset composite manufacturing. However, there are few studies about TPCs manufacturing by the VBO process. Zhang et al. [5] studied void reduction during VBO processing of high-performance carbon fiber-reinforced thermoplastic composites of varying thicknesses, establishing a processing window for thick composites with low void content. Swamy et al. [3] described process design strategies to enhance air removal during VBO consolidation of CF/PEKK laminates.

It is important to understand failure behavior in thermoplastic composites (TPCs) to ensure safety and reliability, particularly since micro-cracks in the matrix can trigger catastrophic failure [6]. The AE method, a passive non-destructive evaluation (NDE) technique, is commonly used to identify and classify damage types, aiding in the monitoring of damage formation and evolution under diverse loading conditions by recording elastic waves generated by sudden energy release due to damage [7].

During both the manufacturing and service life of composite structures, various types of damage can occur under different loading conditions. Composite structures are engineered to endure different loading types, notably flexural and compression loads, each leading to distinct failure modes critical for structural performance during phases like takeoff, landing, turbulence, and maneuvers [8]. Repair methods are essential for the repair of damages, maintaining the structural integrity of composite materials, and minimizing. TPCs can be reshaped and repaired quickly due to their ability to melt and

reform with heat [9]. Annealing is a significant thermal treatment conducted above the glass transition temperature (T_g) of the semicrystalline thermoplastic matrix. Annealing reduces residual effects, and increases crystallinity, leading to enhanced structural performance [10]. While annealing typically served as a post-manufacturing process [11], [12], it holds potential as an effective repair method for addressing widespread matrix damages occurring during the operation or manufacturing of large-scale TPCs.

This study aims to explore how annealing affects pre-damages in TPCs and understand their mechanical behavior using AE inspection of CF/PEKK composites made through the VBO process. To achieve this, pre-damages are induced in composite specimens based on identified loads from AE inspection and subsequently, these specimens are subjected to annealing. Three-point bending, and compression tests are carried out to analyze how pre-damage and annealing affect the mechanical performance of CF/PEKK specimens. Mechanical tests are assisted with AE inspection to highlight the damage mechanism of reference, pre-damaged, and annealed CF/PEKK composite specimens. Moreover, dynamic scanning calorimetry (DSC) analyses are performed to assess the microstructural and thermal quality of the VBO-manufactured thermoplastic composite, including changes in glass transition temperature (T_g) and crystallization degree due to annealing.

2. Materials and Method

2.1. CF/PEKK Composite Manufacturing

CF/PEKK composites are produced using the vacuum-bag-only (VBO) process with Toray Cetex®TC1320 carbon fiber reinforced poly-ether-ketone-ketone unidirectional tape as shown in Figure 1. The layup configuration follows a quasi-isotropic and symmetric pattern with a stacking sequence of $[0/45/90/(-45)_2/90/45/(0)_2/45/90/-45]_s$. After the vacuum bag layup is completed, the vacuum is set at 1 atmosphere (atm) and maintained for 24 hours for debulking before being placed in the oven, and the vacuum level is maintained at this pressure during the oven cycle. The oven temperature is gradually increased to 250°C at a rate of 4°C/min, then further increased to 378°C at a rate of 3°C/min. The laminates are held at this temperature for 90 minutes before being cooled to room temperature at a constant rate of 3°C/min.

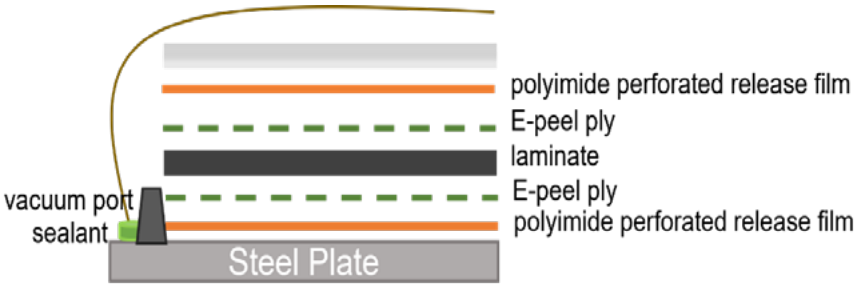

Figure 1. VBO process

2.2. Thermal and Mechanical Characterization of CF/PEKK Composites

DSC measurements are conducted using the Mettler Toledo DSC^{+3} instrument to assess thermal behavior and determine the degree of crystallization.
Three-point bending and compression tests are conducted on Instron 5982 Universal Testing Machine with a 100kN load cell, followed by ASTM D790 and ASTM 6641 standards, respectively.

2.3. Failure Monitoring by Acoustic Emission (AE) Inspection

Three-point bending and compression tests are assisted with AE inspection to detect detailed failure. During mechanical characterization experiments, AE data are continuously captured using a system equipped with two wideband piezoelectric sensors (PICO-200–750 kHz, Mistras) and AEwin PCI2 software. These sensors are positioned on the composite laminates during tests, and placed equidistant from the supporting spans for both three-point bending and compression tests Figure 2. Post-processing

involves using Noesis 7 software to extract waveforms and MATLAB for clustering acoustic events using the Calinski-Harabasz criterion to determine optimal clusters based on amplitude and peak frequency [13]. The k-means clustering algorithm categorizes acoustic events by assigning data points to the cluster with the nearest mean [14]

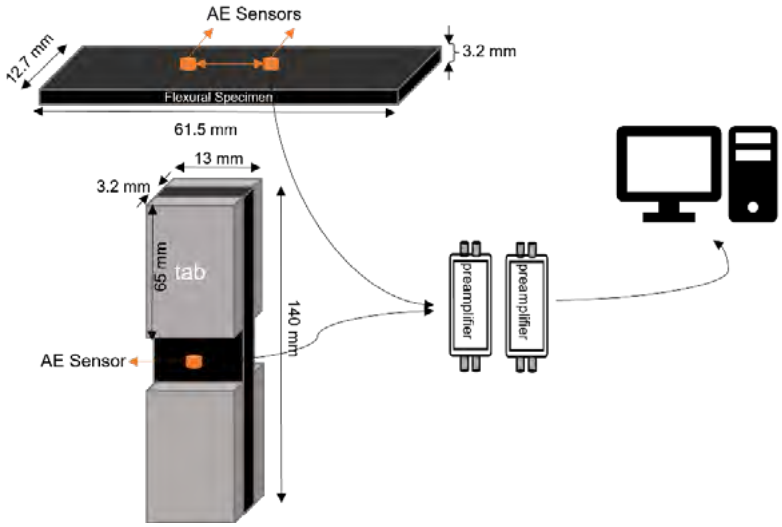

Figure 2. The mechanical test setups with acoustic emission sensor placements for a. three-point bending and b. compression tests

AE analysis is also used to determine optimal pre-load levels for generating pre-damage under bending and compressive loads. Three clusters are identified to address matrix, interface, and fiber-related failures under both loadings. The preloads are identified according to the corresponding load to strain level which failure initiates, therefore pre-loads of 1200 N and 19000 N are selected for flexural and compression specimens, respectively.

2.4. Annealing

Annealing is carried out to mitigate pre-existing damages and restore mechanical integrity, thermoplastic composite specimens undergo annealing in an oven for one hour at 180°C which is 20°C above the T_g of PEKK resin [11], with heating and cooling rates maintained at 8°C/min.

3. Results and Discussion

The compressive stress-strain and AE cumulative count curves of CF/PEKK specimens are presented in Figure 3. The reference CF/PEKK specimen is demonstrated a maximum compressive strength of 548 MPa, and the compressive strength of the CF/PEKK specimen is decreased by 7.66% to 506 MPa due to pre-damages, followed by a 2.00% improvement to 516 MPa after annealing. Additionally, pre-damages significantly affected the compressive strain properties of the specimens and decreased to 1.08% which indicates increased brittleness of the thermoplastic matrix. Cumulative count results are revealed that CF/PEKK specimens predominantly fail due to matrix cracking under compressive load. However, the response is slightly different in the pre-damaged specimen. Induced pre-damages are led to a reduction in the cumulative counts of matrix cracking, but an increase in the interface and fiber-related failures significantly. In contrast, the annealed sample maintains a high percentage of matrix-related failure, since annealing strengthens the matrix, enhancing composite resilience under compressive loading.

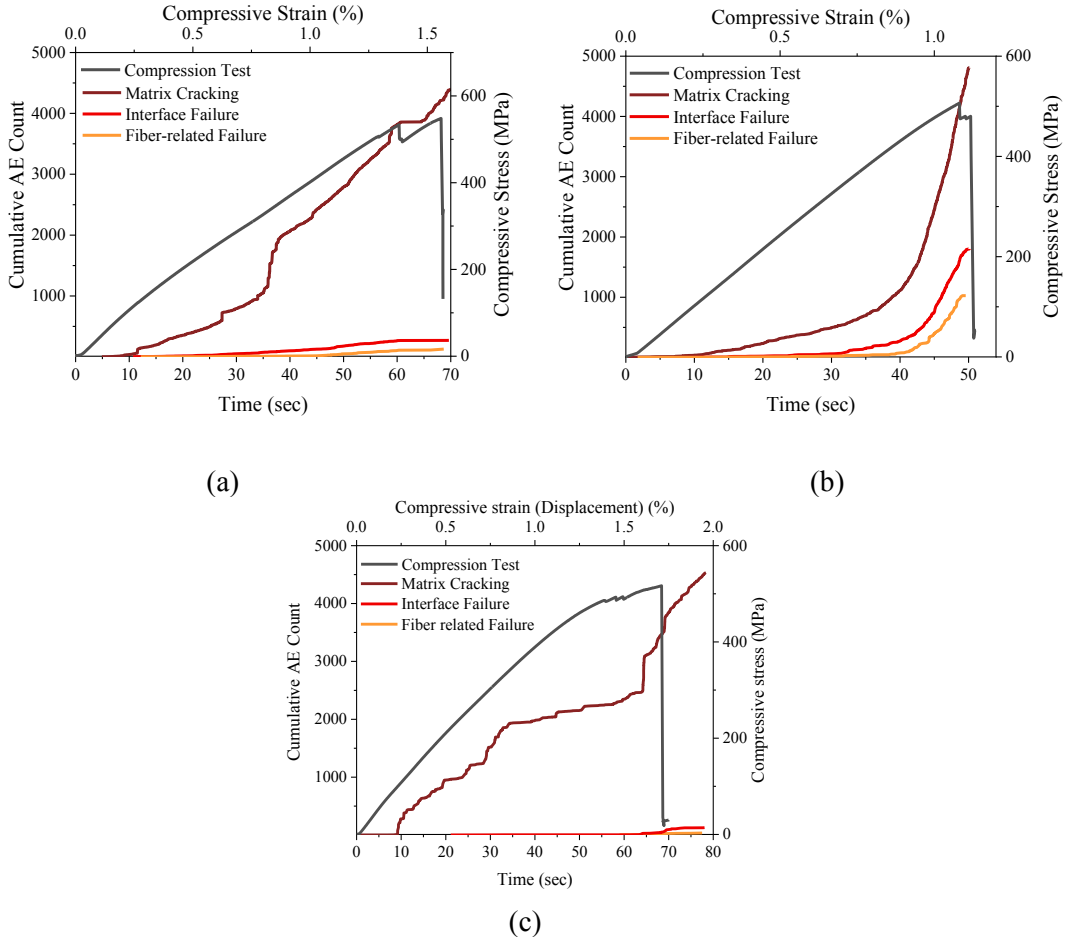

Figure 3. Cumulative AE counts and compression stress-strain curves for; (a) reference, (b) pre-damaged, (c) annealed CF/PEKK composite specimens

The bending stress-strain and AE cumulative count curves of CF/PEKK specimens are presented in Figure 4. Similar to compressive properties the reference specimen is exhibited the highest flexural strength with a strength value of 955 MPa and the flexural strength is decreased by 10% to 859 MPa in the pre-damaged specimen. After annealing the strength is recovered to 865 MPa. The cumulative acoustic counts are revealed that all samples predominantly fail due to fiber-related issues under bending load, highlighting the strong influence of fiber quality on composite performance. The cumulative counts of matrix and interface-related failures are increased significantly in the pre-damaged sample which indicates micro-crack formations in the matrix by preload. Annealing is reduced the cumulative counts of matrix cracking and interface-related failure, demonstrating improved bonding between fibers and matrix.

The mechanical analysis and AE inspection results are showed that the presence of damage, particularly in the PEKK matrix, acted as a stress concentrator, limiting the even distribution of applied load during analysis. The initiation of micro-cracks from the pre-damage led to failure at a lower strength under both loading conditions [15]. However, annealing redistributed internal stresses and induced stress relaxation, influencing the overall mechanical and failure behavior.

The mechanical results are also supported by DSC analysis, with a glass transition temperature (T_g) and degree of crystallinity (X_c) improvement. The annealed specimen is exhibited an X_c of 21.61% compared to the reference specimen's crystallinity degree, 19.70%. This increase is attributed to the annealing process which induces partial melting and recrystallization. As a result, the more ordered crystalline structure restricts the mobility of the amorphous chains, leading to an increase in T_g to 160.93 °C from 155.59 °C in the reference specimen.

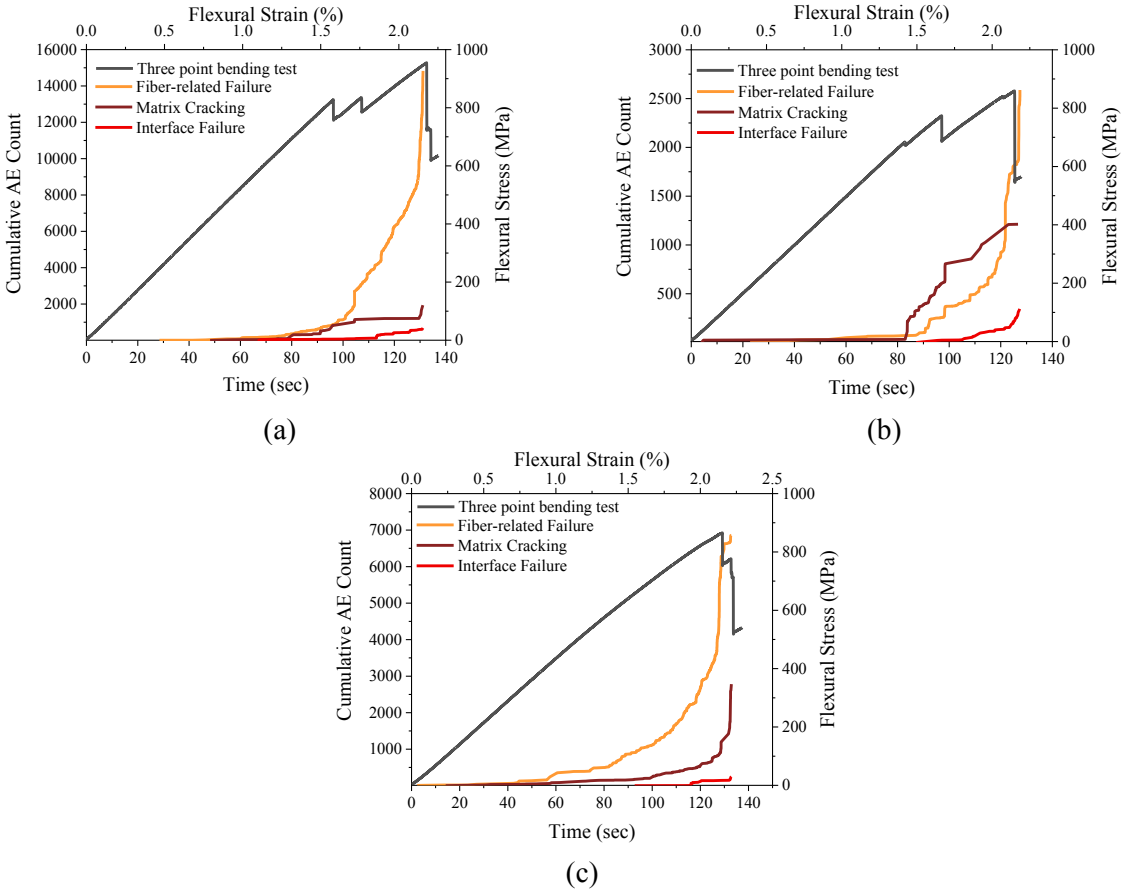

Figure 4. Cumulative AE counts and bending stress-strain curves for; (a) reference, (b) pre-damaged, (c) annealed CF/PEKK composite specimens

Conclusion

This study investigates how annealing affects pre-existing damages and the mechanical behavior of CF/PEKK composites. Three-point bending and compression tests assisted with acoustic emission (AE) inspection provide insights into pre-existing damages and annealing effects. Fiber-related failures dominate under bending load, while matrix-related failures prevail under compressive loading. However, cumulative count results demonstrate annealing improves structural integrity and mechanical behavior, valuable for repair methods in aerospace and other industries.
