Abstract
Due to the success of glass fiber-reinforced polymers (GFRP) in many industries, their durability, reliability, and sustainability are increasingly important requirements. The polymer matrices and multi-scale composites undergo various fracture and aging processes during their service life. The already complex damage behavior is additionally influenced by harsh environmental conditions (humidity, water, temperature). However, there is little consensus in the literature on how environmental conditions affect the damage tolerance of different composite materials. Obviously, polymer type, fiber type, interphase, layer structure, etc. have an enormous influence and can sometimes even lead to opposite effects. Therefore, the present study specifically investigates the aging and temperature related changes in mode I and mode II fracture toughness and energy release rates (ERR) of epoxy infused GFRP laminates based on thick non-crimp fiber fabrics It is shown that mode I and II properties mostly follow opposite trends when exposed to high temperatures or water aging. Furthermore, the effects of temperature and wet-aging clearly affect the damage pattern and propagation in response to low-velocity impacts. However, residual compressive strength is shown to be little affected, as the main drivers strength and fracture toughness follow opposite trends.

1. Introduction

Because of their favorable specific mechanical properties and comparatively attractive price/performance ratio, glass fiber-reinforced polymers (GFRP) are the most widely used composites in energy, mobility, and civil applications. However, the composites are often exposed to harsh environmental conditions in most relevant applications [1]. Consequently, the structural design must take into account the potential degradation caused by aging processes under the given service conditions. In this context, damage- and fracture-related parameters such as fracture toughness and energy release rates (ERRs) are of particular importance as they are essential for structural integrity and durability during service life. However, comparably few studies have been published on the effects of temperature or water aging on these properties [2-4]. In addition, the studies that have been conducted show conflicting results. This may be due to the dependence on several potentially conflicting factors, such as matrix strength and ductility [5], the additional influence of composite layup, layer thickness, fiber volume fraction, fiber distribution or type, and specific interphase properties [6].
Therefore, the present study investigates the effects of various ambient temperatures between -30 °C and 70 °C, water absorption, and specific interphase aging [7] on the damage tolerance of GFRP laminates made from current E- and E-CR glass fibers. Experimentally, single-edge-notch bending (SENB), double cantilever beam (DCB), end-notch flexure (ENF), and low-velocity impact (LVI) tests are performed and analyzed. Based on the test campaign, matrix- and interphase-driven changes of the fracture behavior are identified and separated.

2. Materials and Methods

2.1 Materials and Manufacturing

Three different types of commercially available glass fibers with epoxy compatible sizings are used for the preparation of 4 mm thick GFRP laminates using a vacuum assisted resin transfer molding (VARTM) process. For DCB (ASTM D5528) and ENF (ASTM D7905) tests, SE 2020 E-CR glass (3B-Fibreglass, Belgium) and NEG 2002 E-glass (Nippon Electric Glass, Japan) based fiber fabrics (U-V-E, Saertex GmbH & Co. KG, Germany) with a nominal areal weight of 1166 g/m² are used as input for unidirectional laminates. To introduce an intrinsic pre-crack, polytetrafluoroethylene (PTFE) film stripes of 10 µm thickness (Goodfellow GmbH, Germany) are placed in the symmetry layer between the second and third plies. The laminates for the LVI tests are based on bi-axial fabrics (X-E, Saertex GmbH & Co. KG, Germany) with a nominal areal weight of 610 g/m² and E-CR glass fibers E6 396 (Jushi, China). All laminates, $[0]_4$ and $[\pm 45/90/0]_{2s}$, are infused with EPIKOTE™ Resin MGS™ RIMR 135 and the amine hardener EPIKURE™ Curing Agent MGS™ RIMH 137 (Westlake Epoxy., USA). Therefore, the mold filled with the dry fabrics is pre-heated to 50 °C and the resin is subsequently drawn through under full vacuum. The curing involves two steps: Curing at 50 °C for eight hours under overpressure of two bar followed by a post-curing at 80 °C for 15 hours. Both types of laminates have a fiber volume fraction of 46-47 % and a dry glass transition temperature (T_g) of about 89 °C.
Pure, 4 mm thick epoxy plates are manufactured using the same VARTM setup and curing cycle. The SENB specimens (ASTM D5045) are machined using an Euromod 35 mill (Isel Germany AG, Germany) with 1.8 mm diamond-coated bits. The sharp crack is introduced with a razor blade immediately prior to testing.

2.2 Aging and testing methods

In order to investigate different types of environmental aging effects on the fracture toughness and damage tolerance GFRP and its constituents, three different kinds of aging approaches are applied. In addition to the classical aging of the composites immersed in a distilled water bath at room temperature (RT) for almost half a year (165 days), a novel fiber pre-aging method is applied to the fiber fabrics [7] in the case of the DCB and ENF tests. Contrary to the classical method, this specific sizing and interphase aging method allows to obtain composites with aged interphase properties (aging of the fabrics in humid air at 50 °C and 80 % relative humidity (RH) for five weeks). The results of the pre-aged specimens are marked with PreHA. After fiber pre-aging, the fabrics are dried and then infused with resin using the same VARTM process as described above. As a result, these laminates have the same dry matrix properties, but only weakened interphases. Further details on the process, the fabrication and the effects on the static and fatigue properties (tensile, transverse tensile and tensile-tensile fatigue) of unidirectional (UD) GFRP composites can be found in Gibhardt et al. [7]. Here, it was also shown that the pre-aging process has no negative effects on the fiber strength. All DCB, ENF and SENB tests are performed on a Z10 universal testing machine (Zwick-Roell, Germany) equipped with a thermal chamber and the specific test setups.
The 150x100x4 mm³ laminates for the LVI tests were aged in distilled water at 40 °C for 69 days to accelerate the absorption process without affecting the aging behavior by too high temperatures. Dry and aged specimens are impacted with LVI according to ASTM 7136 using an Instron 9450 weight impact tower and an impact energy of 18 J. The impactor had a semi-spherical tip with a diameter of 16 mm. In addition, the specimen chamber is equipped with a thermal conditioning system to cool or heat the ambient air. Specimens are held at the specific impact test temperature for at least ten minutes prior to impact. Compression after impact (CAI) tests were then performed in accordance with ASTM 7137 using a Z400 universal testing machine (Zwick-Roell, Germany) equipped with a CAI fixture in accordance with the standard. Both the fracture mechanics-related parameters and the impact behavior are additionally analyzed under the influence of different ambient test temperatures (between -30 °C and 70 °C).

3. Results and Discussion

The critical ERR (G_{IC}) for the neat resin and the SE 2020 based UD composites are shown in Figure 1 for several different testing conditions. With about 800 J/m² the ERR of the RIMR135/H137 epoxy is within the range typically reported in the literature [2,8,9]. The results show a clear increase in fracture

toughness with increasing temperature and water aging. These results are consistent with those proposed by authors such as Pitaressi et al. [3] and Han et al. [2]. During wet aging, the epoxy absorbed approximately 3.1 m% water to saturation. This increases the G_{IC} value by about 30 % and corresponds to a temperature increase of about 20-30 °C in dry conditions. Considering also the results at higher temperatures (e.g., 145% increase at 70 °C), a clear nonlinear behavior is evident. The increased mobility of the polymer network at temperatures close to the T_g leads to more pronounced yielding and softening of the epoxy. At high temperatures and due to water absorption, the plasticizing effects reduce brittleness and also increase the damage tolerance of the epoxy. At low temperatures, however, the effects are less pronounced. This is because the mobility of the network is not significantly reduced beyond a certain distance from the T_g.

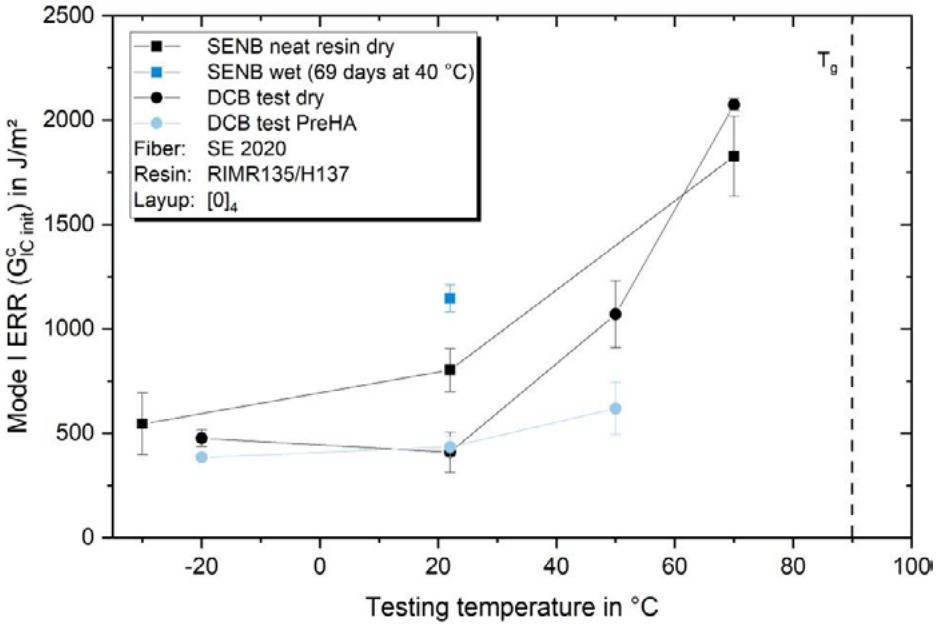

Figure 1: Mode I ERRs of the neat epoxy and the SE 2020 based composites in relation to the testing temperature and aging condition.

Comparison with the DCB tests indicates that the mode I composite fracture properties closely follow the matrix properties over the temperature range tested. The fracture analysis of the dry composites showed that the matrix failure was mainly in the resin-rich region between the middle layers. The use of the novel fiber pre-aging method additionally allows to analyze the effect of a weak interphase. Here, it can be highlighted that the toughness increase of the epoxy matrix is only decisive if the interphase is sufficiently robust. In the case of the SE 2020 composite, it can be seen that the RT and cold temperature behavior is not changed. However, as the test temperature increases, the weakened interphase is unable to transfer the increased resin ERR to the composite. Under these conditions, fracture occurs more frequently at the fiber/matrix (F/M) interphase.
The test results for the DCB mode I and ENF mode II tests of the composites are shown in more detail in Figures 2 and 3. First, it becomes clear that the effects of the individual conditions under mode II loading exhibit a uniform trend for both composites, while under mode I, there are more pronounced differences for the NEG system. The mode I initiation ERRs in dry conditions at RT are with about 400 to 550 J/m² well in line with typical values reported for GF/EP composites at crack initiation [4,10]. Wet aging of the composite at RT for almost half a year and wet pre-aging of the fibers reduce the mode I ERR of the NEG composite by about 16 % and 35 %, respectively. Consequently, the reduction by combining both pre-aging and additional wet-aging is even higher at about 42 %. This indicates that the mode I ERR depends on the matrix and the interphase properties. However, a weak interphase quality (strength) significantly reduces the mode I ERR of the NEG 2002 composite.

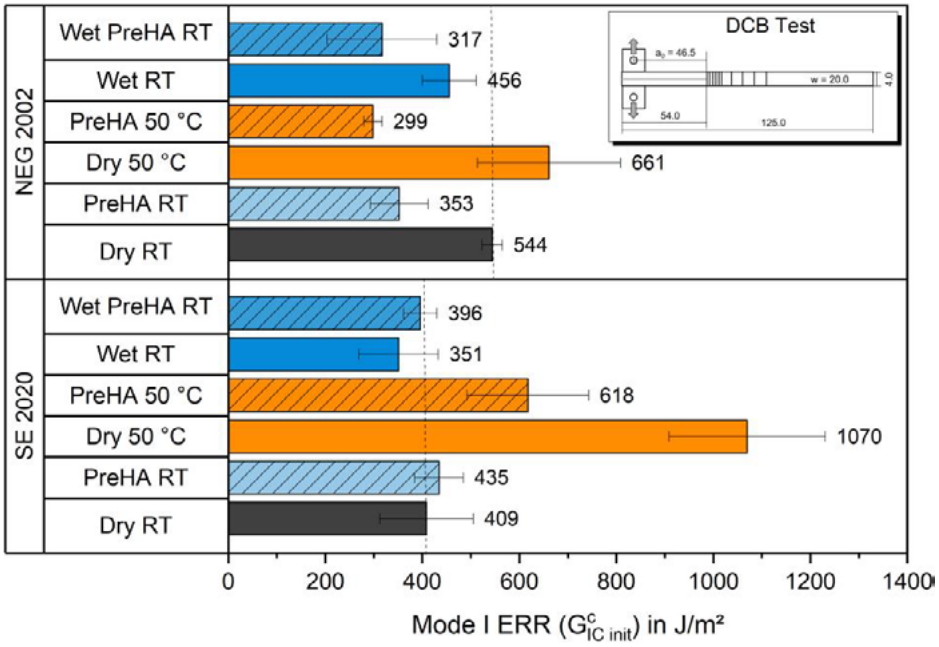

Figure 2: Mode I ERRs of the the SE 2020 and NEG 2002 based composites (aging 165 days at RT).

This observation can be confirmed for the SE 2020 composites only in the case of the tests at elevated temperatures (50 °C), where again, a reduction of about 42 % was found due to humid pre-aging. The RT tests showed only marginal differences in the mean values with overlapping standard deviations. Reasons for this could be both the significantly higher residual interphase strength (≥ 40 MPa after pre-aging and ≥ 50 MPa after wet aging at RT [7]) of the SE 2020 system, a potentially lower T_g of the pre-aged interphase, and the relatively small number of three samples per configuration. The fact that the SE 2020 reference and the pre-aged composites have the same initiation ERR is noteworthy because the crack surfaces after pre-ageing show mainly blank fibers after pre-aging. Consequently, it could be hypothesized that the majority of the energy consumed in the DCB test is associated with matrix fracture in the resin-rich regions and the geometry influence of, for example, the stitching. In this case, the difference between mode I crack growth in the brittle resin or in the interphase with still acceptable quality is small.

The results obtained by ENF tests demonstrate that the mode II ERR is more related to the F/M interphase properties than the mode I ERR. Humid pre-aging and the resulting lower interphase strength reduce the mode II ERR uniformly for both composites. The fracture toughness increase and yield strength decrease of the matrix due to water absorption and testing at elevated temperatures affect the mode II ERR in combination less within the tested range. These effects could partially neutralize each other. The reduction in mode II composite fracture toughness due to the decrease in interphase strength caused by wet pre-aging is between 12 % and 22 % for dry tests at RT. Increasing the test temperature alone reduces mode II fracture toughness by about 16 %, while the combination with weakened interphase results in reductions between 30 % and 40 %. Wet aging of the composite slightly increases the mode II ERR by about 5 %. Furthermore, the weakening effect of a weakened interphase predominates for the combination of both aging procedures (reduction between 22 % and 28 %). The pronounced differences between the wet-aged and pre-aged conditions and between the wet-aged standard and pre-aged composite also highlight the resilience of the F/M interphase to water aging at moderate temperatures ≤ 22 °C.

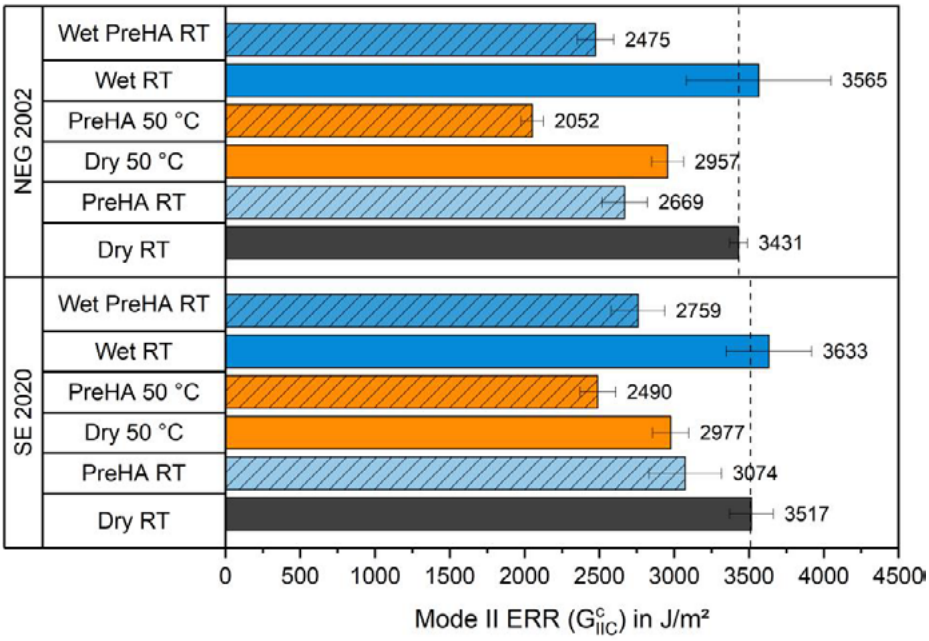

Figure 3: Mode II ERRs of the the SE 2020 and NEG 2002 based composites (aging 165 days at RT).

Looking at the fracture analysis of the mode II fracture paths, it is clear that the number of mode II matrix fractures increases with temperature and water absorption. Contrary to what is intuitively expected, the occurrence of this type of fracture reduces the mode II ERR. Thus, it consumes less energy than the pronounced interphase delaminations found for the reference. This behavior is associated with a significant decrease in the shear yield strength, which appears to dominate the global mode II ERR of the composite. Typically, for all failure paths, ply jumps and mode II cracks under 45° can be detected at the stitching yarns. Depending on the quality of their interfacial bond with the resin, these areas can either be the origin of damage or partially stop crack growth. Finally, it should be noted that crack growth in an ENF test is usually unstable after the maximum load is reached. The higher the nonlinearity of the stress-strain curves, the more likely stable crack growth is. For the GFRPs tested, a non-linear flattening or plateau followed by a drop is the norm for all conditions.

The results of an LVI test series are presented and discussed below to provide a first insight into the effects of the typical operating conditions of temperature and moisture absorption described above on damage resistance. Damage is evaluated in terms of the projected delamination area on the front surface and the projected crack propagation area on the back surface based on high resolution transmitted light scans. The results are shown in Figure 4. The effects of temperature and water absorption are clearly visible for both types of damage. Wet laminates always show slightly less delamination and crack propagation area than dry laminates at the same impact temperature. Temperature has the most significant effect on backside matrix crack propagation, as the affected area decreases by about 40 % from -30°C to 70°C. These results can be explained by a combination of increased resin mode I ERR and strain to failure in contrast to the simultaneous decrease in resin strength and stiffness with increasing temperature and water content. As a result, the deformation at high temperatures is much more localized, resulting in a greater indentation depth at the front and a greater dome height at the back. The interlaminar stresses are not high enough to cause large delaminations in the upper half of the composite, which is consistent with the findings of Körbelin [11] for high performance CFRP composites.
Pure resin fracture in the resin-rich regions between the fiber bundles is completely suppressed at elevated temperatures due to the high fracture toughness and correspondingly high allowable strain to failure. Intralaminar matrix fracture, if it occurs, is confined to the dense bundles. The small effect of temperature and water absorption on the delamination size in the lower half is due to the opposing effects of decreasing mode II ERR at the delamination surface and simultaneously decreasing global stiffness

of the laminate. The higher the temperature, the lower the resulting stresses between the plies. Therefore, delaminations at low temperatures, which imply higher mode II ERR and higher interlaminar stresses, grow to a similar extent as those at high temperatures, which imply lower mode II ERR and lower interlaminar stresses. Figure 5 gives a detailed view of the LVI damage by microscopic images of the cross section through the central impact region.

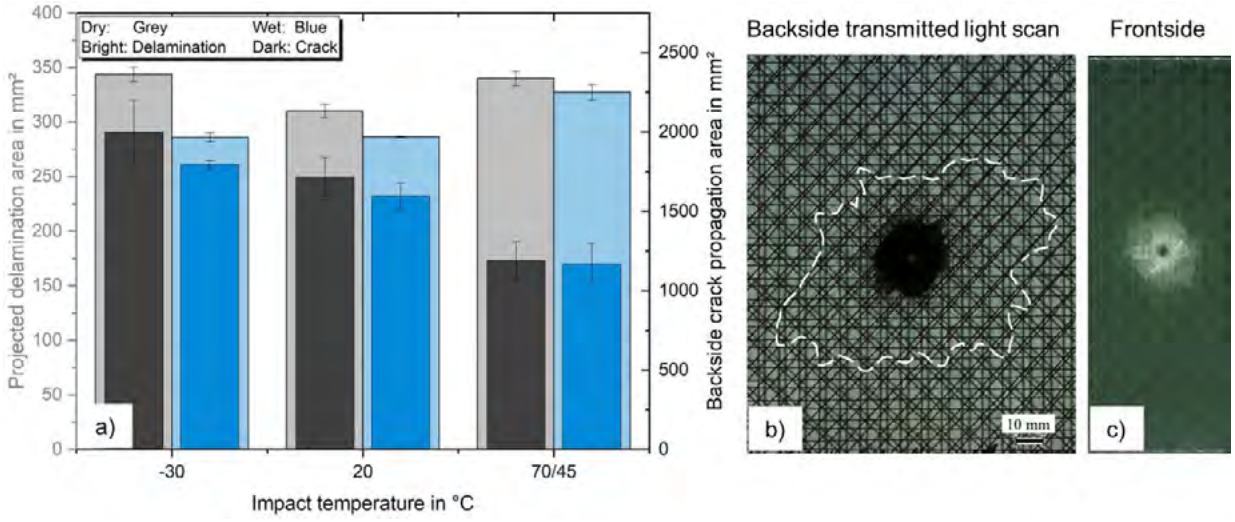

Figure 4: Projected delamination (bright) and backside crack propagation (dark) areas of dry (grey) and wet (blue) QI-composites after a low-velocity impact with 18 J a). Backside transmitted light scan b) and frontside reflected light scan c) after impact at 20 °C under dry reference conditions.

The effects of impact damage on residual compressive strength and typical failure by local buckling around the impact area are shown in Figure 6. Similar to the results of Körbelin [11] for CFRP, the residual compressive strength of dry GFRP at room temperature is not significantly affected by the impact temperature. The standard deviations of all dry tests overlap. Similarly, there is no difference between the wet laminates, but the residual strength is always slightly lower than for the dry laminates. These results can be explained by the relatively similar size of the delaminations near the neutral plane, which is related to the global buckling resistance [12]. In the wet case, the reduced flexural stiffness and the reduced fiber and interphase strengths affect the compressive strength of the composite. However, the global effect is relatively small after short-term aging at 40 °C for 69 days.

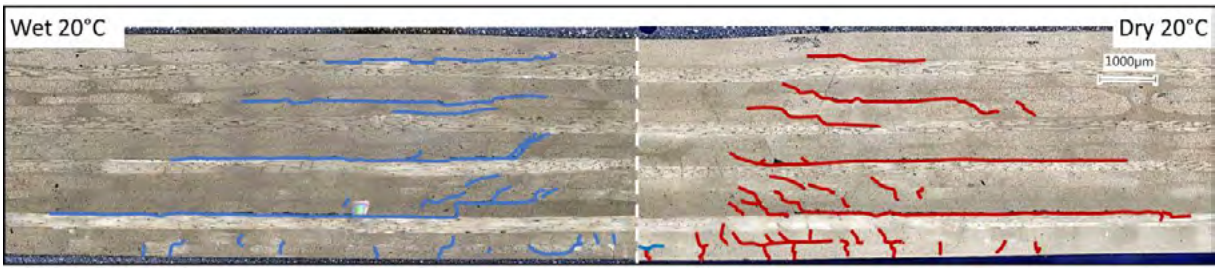

Figure 5: Comparison of representative microscopic cross sections of the impacted area (central cut) after impact at 20 °C for dry and wet conditions. Delaminations and cracks are highlighted.

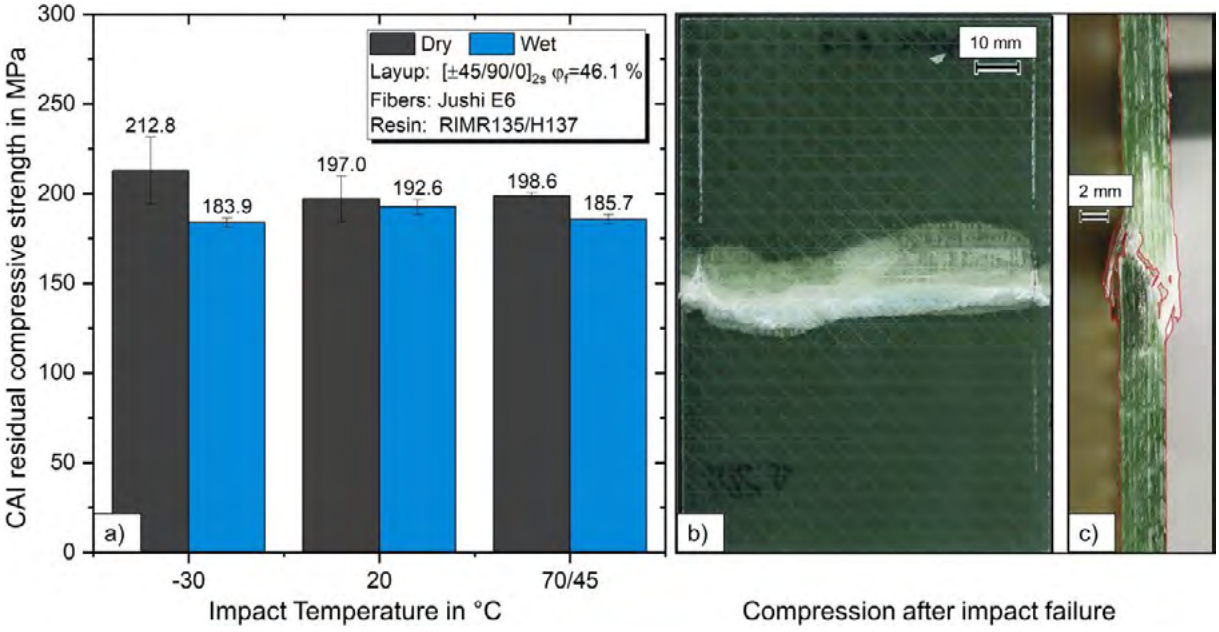

Figure 6: Residual compressive strength of the different GFRP/impact configurations after an 18 J low-velocity impact a) and representative pictures of the CAI test failure b, c).

4. Conclusions

Investigations of the interlaminar fracture properties highlighted the opposing effects of ambient temperature and water-induced aging on mode I and II ERR. Water absorption and increasing temperatures increase the fracture toughness of the resin and significantly delay damage initiation, which dominates the mode I ERR of the composite. Mode II ERR, on the other hand, is controlled by the shear yield strength and stiffness of the resin and especially of the interphase. Their decreasing tendency outweighs the increasing fracture toughness of the resin at the composite level. For fabric-based composites with highly inhomogeneous fiber (volume) distributions (dense bundles vs. interspace), the interphase effects are limited because a significant amount of matrix resin is always involved in the fracture process.

Furthermore, the damage and fracture-related effects of temperature and water-based aging could be successfully transferred to explain the change of LVI damage appearance in GFRP. It became clear that the impact damage depends on the structural response of the laminate, which in turn is also related to the environmental temperature and aging condition. As the main driving factors of fracture toughness and strength are subject to a contradictory dependence, the residual compressive strength determining largest delaminations grow to a similar extent. Consequently, no significant effect of the laminate condition during the impact event on the residual strength could be detected, even though the micro- and macroscopic damage differs significantly.

Acknowledgments

The authors would like to thank J. Körbelin for the in-depth discussions and valuable input about the fracture toughness and damage behavior of composites.

Abstract
Traditional thermosetting composites have high specific strength and stiffness but exhibit poor damage tolerance. To address this, fibre hybridisation emerges as a cost-effective strategy. This study investigates the transverse shear failure of fibre-hybrid unidirectional composite laminae, specifically primary E-glass fibres with secondary fibres embedded in an epoxy matrix (*i.e.,* E-glass/secondary/epoxy). The study employs a 2D plane-strain hexagonal fibre-packing to estimate micro-stress fields, transverse shear modulus, and transverse shear strength of the fibre-hybrid unidirectional composite laminae. By predicting and comparing the properties and micro-stresses of fibre-hybrid unidirectional composite laminae to non-hybrid E-glass/epoxy unidirectional composite laminae, this research aims to understand the influence of matrix plasticity and secondary fibre properties on the transverse failure of fibre-hybrid unidirectional composite laminae. It also aims to enhance the understanding of the phenomena that contribute to the increased damage tolerance of fibre-hybrid composite laminae.

1. Introduction

Experimentally, fibre hybridisation has been successfully used to enhance thermosetting composite damage tolerance by introducing energy dissipation (*i.e.,* conducive failure modes) mechanisms to hinder crack grow from the micro (*i.e.,* fibre-matrix debonding and matrix cracking) to the meso-level (*i.e.,* delamination) [1–3]. Katnam, Dalfi and Selver used E-glass and S-glass fibres commingled with PP fibres in an epoxy matrix and tested the compression after impact behaviour of different UD and woven composites [1–3]. However, even if experimental work has been conducted certain aspect remain novel and computational models have not been fully explored to examine those aspects [4,5]. Therefore, this study aims to investigate the effect of matrix plasticity on the transverse shear behaviour of different fibre-hybrid composite laminae using 2D plane strain computational micromechanical models with periodic microstructure.

2. Methodology

2.1. Hexagonal RUC

Fibre-hybrid unidirectional laminae are investigated using two-dimensional repeating unit cell (2D RUC) models to predict the lamina's transverse shear elastic modulus, strength, and matrix micro-stress

fields. In this study, 2D RUCs with a periodic microstructure (*i.e.,* hexagonal fibre packing) are generated in *Abaqus/Standard*. These 2D RUCs accommodate fibre hybridisation by incorporating a secondary fibre in the middle of the RUC, surrounded by primary E-glass fibres at the corners. The stiffness ratio between the secondary and primary fibres is defined as β_E. Figure 1 illustrates a hybrid lamina with intra-laminar fibre hybridisation, featuring primary E-glass fibres and secondary fibres, Figure 1 (a), along with a 2D RUC with a periodic hexagonal packing microstructure used for micromechanical analysis Figure 1 (b). The coordinate system (x_i) in Figure 1 aligns with the principal material coordinate system of the unidirectional fibre-hybrid lamina.

Constituent material properties (*i.e.,* fibres and matrix) [6,7] are given in Table 1, where σ_{sut} and σ_{suc} are the tensile and compressive strength, respectively. Table 2 presents the stiffness of the secondary fibre, with the Poisson's ratio of the secondary fibre being the same as that of the primary fibre.

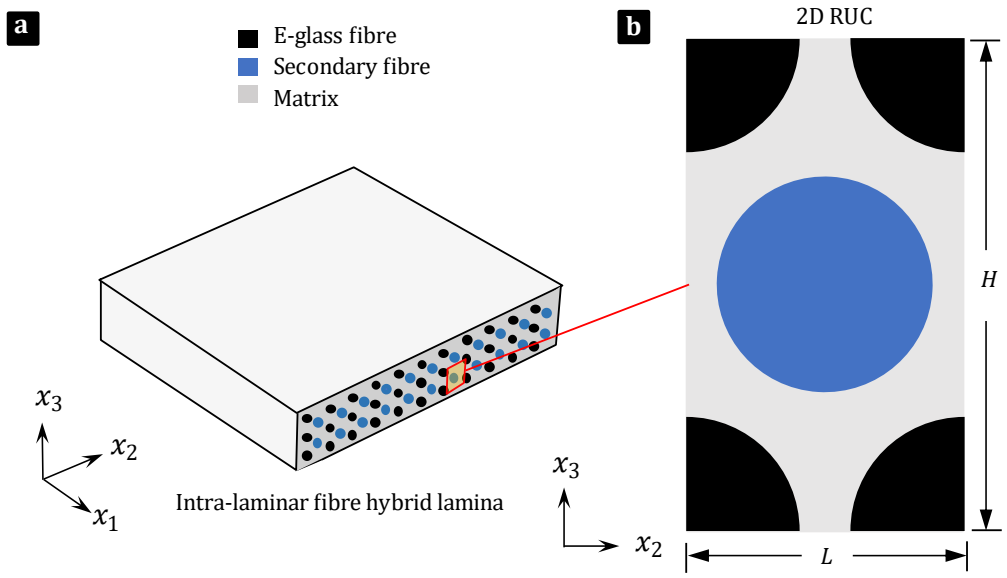

Figure 1. The fibre-hybrid modelling approach: (**a**) Lamina and (**b**) 2D fibre-hybrid hexagonal RUC with E-glass/secondary/epoxy.

Table 1. Material properties of the constituents [6,7]

	E (GPa)	ν	σ_{sut} (MPa)	σ_{suc} (MPa)
Epoxy	3.35	0.35		
E-glass	74	0.2	80	120

Table 2. The secondary fibre stiffness in comparison with that of the primary E-glass fibre.

$\beta_E = E_{fS}/E_{fG}$	5	1	0.1	0.03
E_{fS} (GPa)	370	74	7.4	2.22

Within the model, the fibres are assumed to be continuous, homogeneous, isotropic, and defect-free with circular cross-sections. The matrix is considered homogeneous, isotropic, elastic-plastic, and void-free. A perfect fibre-matrix interface is assumed. The variation in material properties and diameter of each fibre type is considered negligible. Both the fibres and the matrix are assumed to be linear elastic. The diameters of the primary (E-glass) and secondary fibres are assumed to be 10 µm. The total fibre volume

fraction (V_f), which is the sum of the E-glass fibre volume fraction (V_{fG}) and the secondary fibre volume fraction (V_{fP}), is assumed to be 0.6 in all the laminae analysed. Matrix plasticity has been implemented using the Drucker–Prager yield criterion [7,8], (Eq. 1):

$$t - p\tan\gamma - c = 0 \tag{1}$$

In Eq.1, p is the hydrostatic stress, t is the deviatoric stress, γ is the slope of the linear yield surface in the $p-t$ stress plane, c is the cohesion of the material. The matrix is assumed as linear elastic perfect plasticity, *i.e.,* no hardening is considered.

2.2. Periodic Boundary Conditions

The RUC model is implemented in *ABAQUS/Standard*. A *python* script is used, and the displacement-based periodic boundary conditions (PBCs) are imposed by generating matching nodes on the opposite edges. Considering plane strain conditions, the 2D RUC is analysed with a structured quad mesh with CPE4R (a 4-node bilinear plane strain element with reduced integration). Figure 2 (a) shows the partition strategy used to guarantee the generation of a periodic mesh, Figure 2 (b), and the simple shear loading boundary condition, Figure 2 (c). The domain is meshed such that all the nodes $n^-$and n^+ on the opposite edges are perfectly aligned, Figure 2 (b) [5].
The periodic displacement conditions are imposed by using Eq. 2 [9]. Periodic boundary conditions guarantee traction and displacement continuity conditions between opposite edges.

$$u_i(\boldsymbol{x} + \Delta\boldsymbol{x}) - u_i(\boldsymbol{x}) = \hat{\varepsilon}_{ij}\Delta x_j \qquad (i,j = 1,2,3) \tag{2}$$

In Eq. 2, u_i is the displacement in the x_i direction, $\boldsymbol{x} + \Delta\boldsymbol{x}$ and $\boldsymbol{x}$ are the position vectors of the points on the opposite faces of the RVE, and $\hat{\varepsilon}_{ij}$ is the macro-strain components. In the case of a 2D domain as in Fig. 2, the application of PBCs can be defined by Eq. 2 [7,10]:

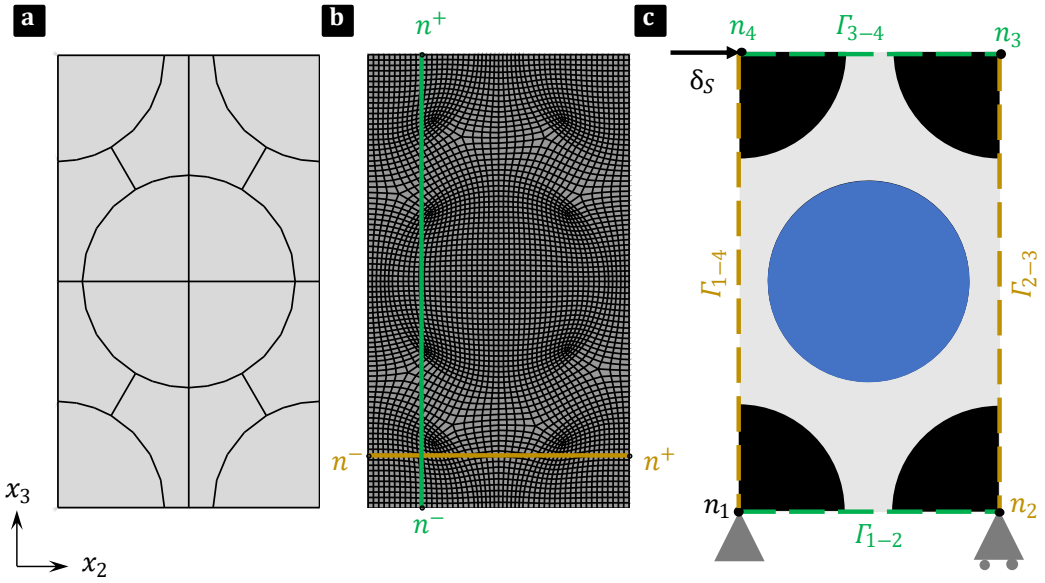

Figure 2. Modelling strategy used: (**a**) model partition (**b**) mesh generated and (**c**) shear loading boundary conditions.

2.3. Homogenization

With the periodic displacement conditions (Eq. 2), the homogenised lamina properties are obtained by applying a uniform macro-stress ($\hat{\sigma}_{ij}$) or macro strain ($\hat{\varepsilon}_{ij}$) state and then calculating the unweighted volume average of the micro-stresses (σ_{ij}) and micro-strains (ε_{ij}) within the RVE volume (Ω), using Eqs. 3 and 4 [5] .

$$\hat{\sigma}_{ij} = \frac{1}{\Omega}\int_{\Omega} \sigma_{ij} d\Omega \tag{3}$$

$$\hat{\varepsilon}_{ij} = \frac{1}{\Omega}\int_{\Omega} \varepsilon_{ij} d\Omega \tag{4}$$

In this study, the transverse shear elastic modulus ($\hat{G}_{23}$) and the transverse shear strength ($\hat{S}_{23}$) have been predicted. The transverse shear elastic modulus ($\hat{G}_{23}$) is defined as the ratio of the homogenised shear stress ($\hat{\sigma}_{23}$) to the homogenised shear strain ($\hat{\varepsilon}_{23}$) in the elastic region of the shear stress-strain plot. The transverse shear strength ($\hat{S}_{23}$) is measured as the maximum homogenised shear stress ($\hat{\sigma}_{23}$) that the RUC can support before failure.

2.4. Model validation

Model validation has been performed by comparing the transverse shear elastic modulus $\hat{G}_{23}$ and the transverse shear strength $\hat{S}_{23}$ predicted using the 2D RUC against data available in the literature [6,7]. The predicted values are in excellent agreement with the ones available in the literature, as shown in Table 3.

Table 3. Predicted transverse shear modulus and shear strength compared against Yang [6,7].

	RUC	Yang [6,7]	Relative variation (%)
$\hat{G}_{23}$ (GPa)	4.21	4.67 ± 0.07	-10
$\hat{S}_{23}$ (MPa)	60.77	62.19 ± 1.52	-2

3. Results and Discussion

In this section the lamina transverse shear stiffness, lamina transverse shear strength, and normalised von Mises matrix stresses (*i.e.,* per unit MPa of macro transverse shear, with and without matrix plasticity) for different secondary fibre stiffness to the primary fibre (E-glass) stiffness ratio (β_E) are investigated.

3.1. Lamina properties

Table 4 presents the predicted transverse shear modulus and transverse shear strength for various fibre-hybrid E-glass/secondary/epoxy unidirectional composite laminae using the developed 2D RUCs. The stiffness ratio β_E *i.e.*, E_{fS}/E_{fG} , the secondary fibre stiffness to the primary fibre (E-glass) are used: 5, 1, 0.1 and 0.02. The transverse shear stiffness is significantly affected by the stiffness of the secondary fibre volume fraction, especially when the secondary fibre stiffness is comparable or lower than the one of the matrix. The lamina transverse shear strength has been predicted by determining the maximum transverse shear stress that the lamina can bear before failure. The transverse shear strength has been shown to be highly dependent on the matrix properties and not affected by the fibre type used, while the stiffness highly depends on the material properties of the fibres.

Table 4. Predicted transverse shear modulus and transverse shear strength for different β_E (*i.e.*, E_{fS}/E_{fG}).

$\beta_E = E_{fS}/E_{fG}$	5	1	0.1	0.02
$\hat{G}_{23}$ (GPa)	4.45	4.21	2.73	1.26
$\hat{S}_{23}$ (MPa)	60.77	60.77	60.74	60.59

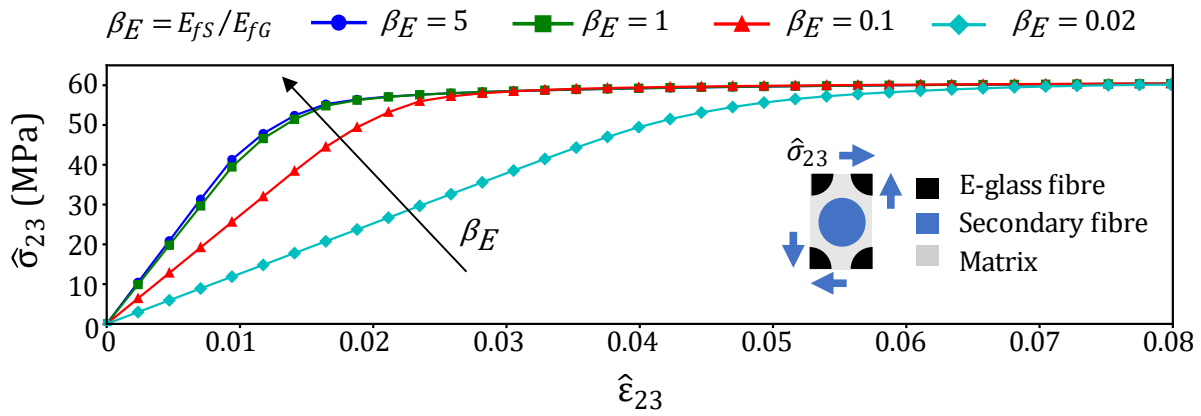

Figure 3. The transverse shear-strain curve for different β_E (*i.e.*, E_{fS}/E_{fG} , the secondary fibre stiffness to the primary fibre (E-glass) stiffness ratio: (**a**) β_E = 5, (**b**) β_E = 1, (**c**) β_E = 0.1, and (**d**) β_E = 0.02.

3.2. Matrix stress-fields

The von Mises matrix stress has been normalised first in the elastic regions using a unit MPa of macro-transverse shear (*i.e.*, $\hat{\sigma}_{23} = 1$ MPa), Figure 4 (a-d). This normalization has been used to understand where plasticity is most likely to initiate. To investigate the effect of matrix plasticity on the normalised von-Mises matrix micro stress distribution, a macro-transverse shear stress of 50 MPa (*i.e.*, $\hat{\sigma}_{23} = 50$ MPa) has been used, as shown in Figure 4 (e-h). This macro-stress state is enough high to introduce significant plastic deformation within the matrix. The maximum normalised von Mises matrix micro-stress occurs in the regions where the inter-fibre distance is minimal and the fibres are aligned with the loading direction [11]. The maximum stress is not significantly altered when the secondary fibre is 5 times stiffer and 10 times less stiff than the primary E-glass fibre, while when the secondary fibre is softer than the matrix, the normalised von Mises matrix micro-stress is significantly altered and a larger volume of the matrix is subjected to higher stress compared to the case when only E-glass fibres are used, as shown in Figure 4 (c).

The matrix plasticity is significantly affecting the matrix von Mises micro-stress fields and the position of the maximum normalised von Mises matrix micro-stress, as shown in Figure 4 (e-h). Moreover, the matrix plasticity is reducing the normalised stress within the matrix when β_E = 0.02. The asymmetrical stress distribution during matrix plastic deformation is due to the differing matrix strengths under compression and tension. Now, the maximum stress is located in the matrix region which goes under compression state. Moreover, matrix plastic deformation seems to be beneficial when the secondary fibre is soft (*i.e.*, β_E = 0.1 and 0.02), by reducing the matrix stress amplification significantly in proximity of the soft secondary fibre. Then having a secondary soft fibre opens the door for a solution to benign the matrix micro stress fields.

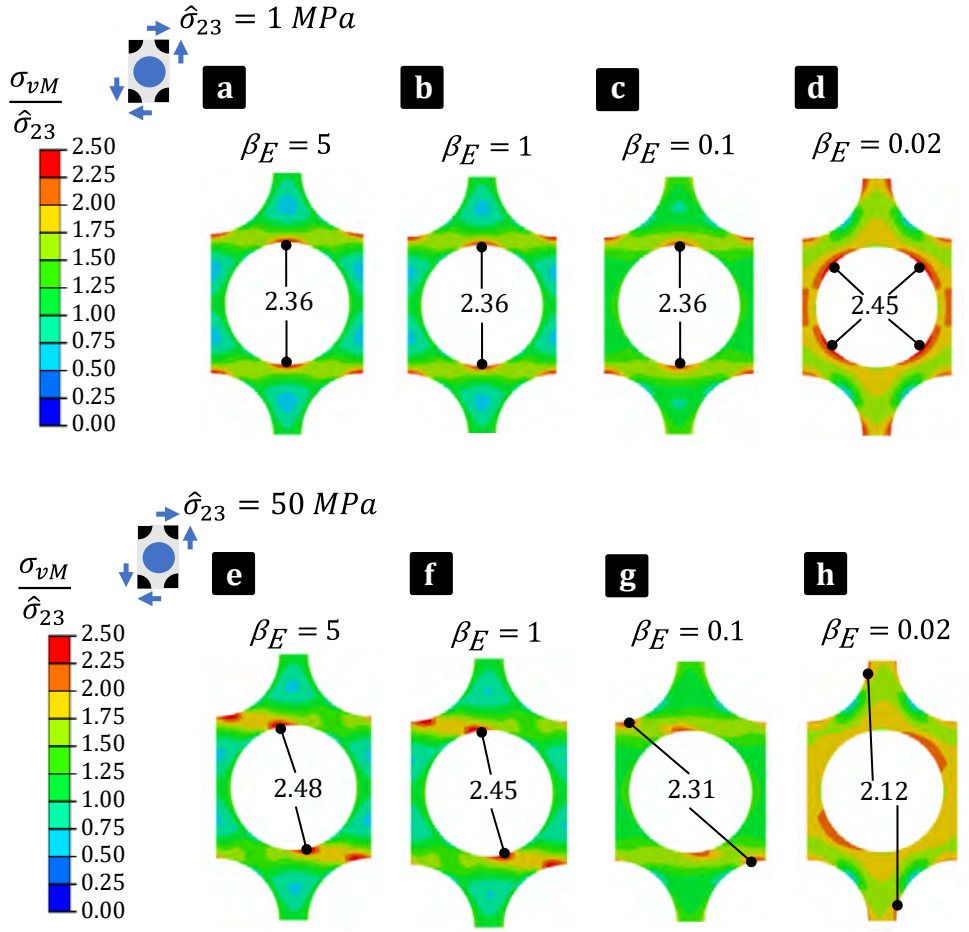

Figure 4. The normalised von Mises matrix micro-stress fields ($\sigma_{vm}/\hat{\sigma}_{23}$) per unit macro shear ($\hat{\sigma}_{23} = 1$ MPa) for different β_E (*i.e.*, E_{fS}/E_{fG} , the secondary fibre stiffness to the primary fibre (E-glass) stiffness ratio: (**a**) β_E = 5, (**b**) β_E = 1, (**c**) β_E = 0.1, and (**d**) β_E = 0.02; and for ($\hat{\sigma}_{23} = 50$ MPa), for (**e**) β_E = 5, (**f**) β_E = 1, (**g**) β_E = 0.1, and (**h**) β_E = 0.02

3.3. Fibre-matrix interfacial stresses

The normalised interfacial normal and shear stresses ($\sigma_n/\hat{\sigma}_{23}$, and $\tau_{nt}/\hat{\sigma}_{23}$) measured counterclockwise for the bottom left corner fibre and the middle fibre are given in Figure 5.Only a quarter of the fibres is studied because of symmetry in stress distribution. Figures 5 (a) and (b) reports the normalised Interfacial stresses for $\hat{\sigma}_{23} = 1$ MPa, while Figures 5 (c) and (d) report the normalised interfacial stresses for $\hat{\sigma}_{23} = 50$ MPa. The maximum normalized normal stress ($\sigma_n/\hat{\sigma}_{23}$) is at the minimum inter-fibre distance and aligned with the loading direction, *i.e.*, $\theta = 60°$, when the fibres are stiffer than the matrix [11]. On the other hand, when the secondary fibre is less stiff than the matrix, the peak $\sigma_n/\hat{\sigma}_{23}$ location changes, as illustrated in Figure 4 (a). Matrix plasticity is not affecting the normalised interfacial normal and normalised shear stresses for the E-glass corner fibres, Figures 4 (a) and (c), and the normalised shear stresses for the middle fibres (d). On the other hand, matrix plasticity is altering the $\sigma_n/\hat{\sigma}_{23}$ for the middle secondary fibre, when the secondary fibre stiffness is significantly lower than the E-glass fibre and even lower than the matrix stiffness (*i.e.*, $\beta_E = 0.02$), Figures 4 (b). The secondary fibres exhibit a compressive $\sigma_n/\hat{\sigma}_{23}$ at $\theta = 0°$, which could hinder and delay fibre-matrix interface debonding.

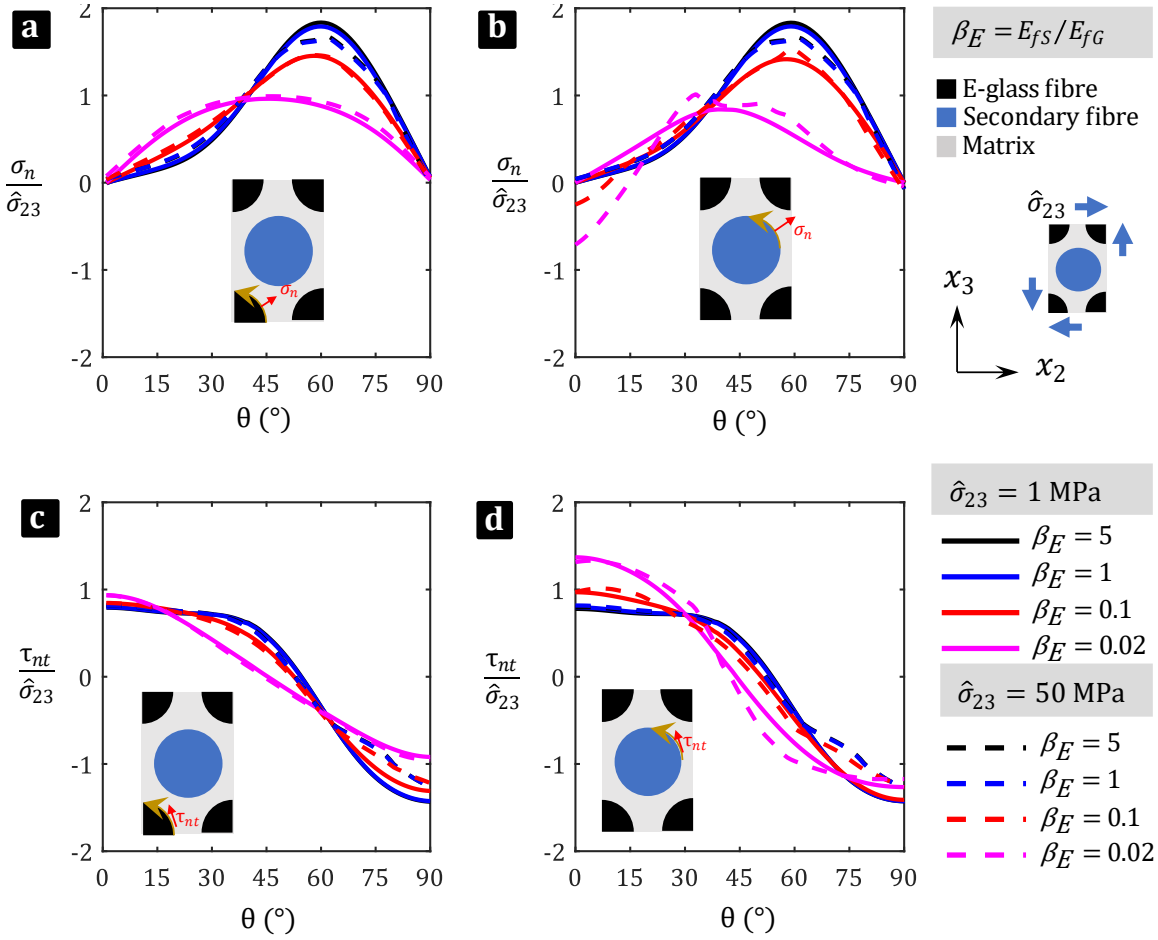

Figure 5. The normalised interfacial normal stresses ($\sigma_n/\hat{\sigma}_{23}$, and $\tau_{nt}/\hat{\sigma}_{23}$) for $\hat{\sigma}_{23} = 1$ MPa and $\hat{\sigma}_{23} = 50$ MPa for different β_E (*i.e.*, E_{fS}/E_{fG} , the secondary fibre stiffness to the primary fibre (E-glass) stiffness ratio: normalised interfacial normal stresses for **(a)** bottom left corner fibre and (**b**) middle fibre; normalised interfacial shear stresses for **(c)** bottom left corner fibre and **(d)** middle fibre

4. Conclusions

This study investigated the transverse shear behaviour of fibre-hybrid unidirectional thermosetting composite laminae with primary (E-glass) fibres combined with secondary fibres in an E-glass/secondary/epoxy fibre-hybrid system using 2D hexagonal fibre packing. The micromechanical analysis led to the following conclusions:

- The transverse shear stiffness $\hat{G}_{23}$ is highly depending on the stiffness on the secondary fibres, while the transverse shear lamina strength $\hat{S}_{23}$ is not affected and depends mainly on the matrix properties.
- Matrix plasticity significantly alters matrix micro-stress fields, especially when the secondary fibre stiffness is comparable to or lower than that of the matrix.
- The effect of matrix plasticity on interfacial stress is negligible, except for the normalised interfacial normal stress component for the secondary fibre when its stiffness is lower than that of the matrix.

Thus, matrix plasticity and fibre properties play a significant role on the transverse shear behaviour and failure of the fibre-hybrid unidirectional composite laminae. Future studies should investigate the effect of matrix plasticity on other independent and combined loading cases. Additionally, the effect of fibre-matrix interface debonding should be examined to predict the nine engineering constants and all strength components for different fibre-hybrid composite laminae.

Keywords: cycle jump technique, fatigue damage modelling, cohesive zone models

Abstract
For high cycle fatigue simulations, cyclic loads are often replaced by constant envelope loads using a cycle jump technique. However, this simplification cannot be used under general loading conditions where the local stress ratios can substantially deviate from global load ratios. The local stress ratios have to be determined for every material point individually by periodically performing a full loading-unloading cycle. Usually, commercial finite element (FE) solvers use time integration methods that are not energy-conserving, so that the simulation of such a loading-unloading cycle produces a numerical energy error. In this contribution, a new cycle jump and load application technique for high cycle fatigue simulations under general loading conditions is presented. It combines the simulation of full load cycles to determine local stress ratios with cycle jumps to save computational costs. The new technique is characterized by its energy-conserving behavior which is reached by a complete unloading of the FE model after each cycle jump and a modified formulation of the element residual vectors. By using user-defined elements, this modified formulation can also be used with commercial FE solvers.

1. Introduction

The importance of structural components made of fiber-reinforced composites is continuously increasing in several engineering disciplines like aircraft or automotive. Composite structures usually experience cyclic loadings with variable load characteristics during their service life causing various damage modes like matrix cracking or delamination [1]. In Addition to knowledge of possible damage mechanisms, the use of accurate and reliable fatigue damage models (FDM) must be ensured during the design process of safety-relevant composite structures [2].

A well-established method for the numerical simulation of cyclic delamination growth is the use of so-called cohesive zone models (CZM), where a damage growth rate $\partial D/\partial N$ is used to describe the cyclic degradation of the interface stiffness. This damage rate can be a function of several fatigue-relevant parameters like the mixed mode ratio and the stress ratio [3].

In a numerical high-cycle fatigue analysis, it is computationally inefficient to simulate each load cycle individually. Instead, cycle jump techniques are used. The most common technique is to replace cyclic loads with a constant envelope load, which is equal to the maximum load F_{max} of the represented cyclic load (Figure 1a). It has to be assumed that the local stress ratio at every material point is equal to the global load ratio given as an input to the model, which may not be true if a complex inhomogeneous stress field prevails in the structure [4]. A simple method to determine the local stress ratios is the “Min-

Max Load" approach by Raimondo and Bisagni [5], in which a finite element (FE) analysis is conducted with two models of the component in parallel. A constant maximum load F_{max} is applied to one model, while a constant minimum load F_{min} is applied to the other model (Figure 1b). By sharing information about the local stress states, the local stress ratios can be determined. However, the Min-Max Load approach is limited to components experiencing only cyclic loads that are in phase. Under general loading conditions, various dephased cyclic loads as well as static loads can act on a structural component. The "In-Situ" approach by Nojavan et al. [6] uses a global load profile with a full loading-unloading cycle, followed by a cycle jump ΔN, as plotted in Figure 1c. The stress states at every material point have to be saved during the simulation of a full loading cycle so that the local stress ratios can be subsequently determined. Joosten et al. [7] took up this approach and defined a stress ratio and an effective mixed mode ratio for a CZM under general loading conditions with a 3D stress state.

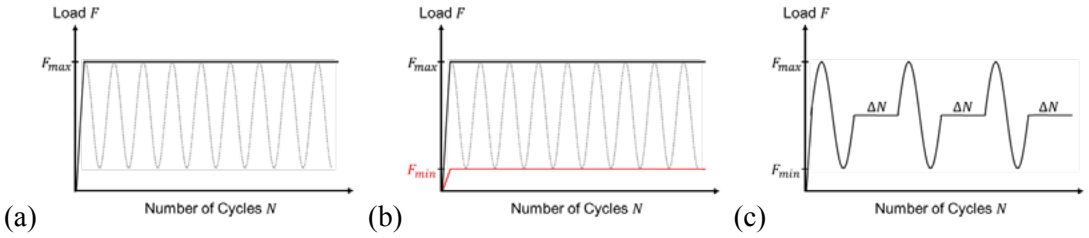

Figure 1. Three approaches to apply a cyclic load in a FE analysis: (a) Envelope Load, (b) Min-Max Load [5], (c) In-Situ Analysis [6]

A nonlinear FE solver is required for the numerical simulation of delamination using a CZM. Common commercial FE solvers use time integration schemes for nonlinear analyses that are not energy-conserving. Thus, the simulation of a full load cycle inevitably produces a numerical energy error, which is accumulated if a loading profile with several full load cycles as plotted in Figure 1c is simulated.

In this paper, a cycle jump technique with a new global load profile is presented allowing the simulation of any number of full load cycles without producing numerical energy errors. In Section 2, the global load profile and the implementation into commercial FE solver ABAQUS/Standard are explained. The energy-conserving property of the new technique is demonstrated by means of a simple one-element test in Section 3. In Section 4, concluding remarks and an outlook to future works are given.

2. Cycle Jump and Load Application Technique

2.1. Global Load Profile

The global load profile is plotted in Figure 2. The applied load F, which can be either a force or a displacement, represents a cyclic load with a maximum load of F_{max} and a minimum load of $F_{min} > 0$. One cycle consists of five steps illustrated by the circled numbers in Figure 2.

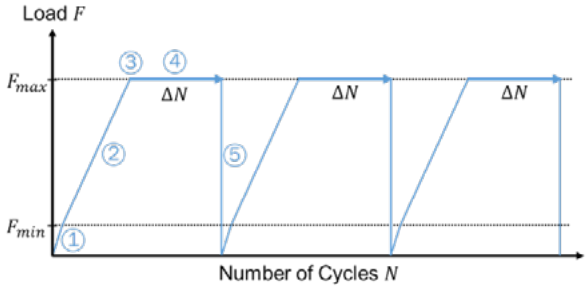

Figure 2. Illustration of global load profile

Starting from an unloaded state, the load is incrementally increased up to F_{min} in the first step. In the second step, the load is further increased up to F_{max} while the stress values are recorded. The local stress ratios R_s are determined from the recorded stress values in the third step. After that, the cycle jump ΔN can be performed. In the fifth step, the model is completely unloaded. It is worth mentioning that in the load profile shown in Figure 2, only the loading phase of the represented cyclic load is covered in the second step. It is assumed, that during the unloading phase, the same stress states occur. If multiple dephased loads or loads with various cycle lengths act on a component, step 2 has to cover a full loading-unloading cycle of that load with the longest cycle length in order to record all stress states occurring during the cycle.

2.2. Energy Conservation

In a nonlinear FE analysis, the displacement field is computed iteratively. The displacement field for the next iteration $\boldsymbol{u}^{(n+1)}$ is updated from the displacement field of the current iteration $\boldsymbol{u}^{(n)}$ by

$$\boldsymbol{u}^{(n+1)} = \boldsymbol{u}^{(n)} + \Delta\boldsymbol{u}. \tag{1}$$

The displacement increment $\Delta\boldsymbol{u}$ can be calculated by

$$\Delta\boldsymbol{u} = \boldsymbol{A}^{-1}\boldsymbol{r}, \tag{2}$$

where **A** is the tangential matrix and **r** is the residual vector. If a non-energy-conserving time integration scheme like the explicit or implicit Euler scheme is used, the simulation of a full loading-unloading cycle leads to a hysteresis curve, because the linearization of the loading and unloading path are not equal. If however, the residual vector $\boldsymbol{r}$ is set to

$$\boldsymbol{r} = -\boldsymbol{A}\boldsymbol{u}^{(n)}, \tag{3}$$

the new displacement field will be $\boldsymbol{u}^{(n+1)} = \boldsymbol{0}$ which is equal to the unloaded initial state. Equation (3) is thus used in step 5 of the previously described load profile to set the whole system back to its initial state without producing or dissipating energy.

2.3. Implementation into ABAQUS

The load profile described in section 2.1. is implemented in a Fortran module. The module is used by the ABAQUS subroutines UEL and UAMP (user-defined amplitude) for exchanging information, as illustrated in Figure 3. The UAMP is linked to the boundary condition where the load is applied to the FE models. It gets all relevant input properties like the maximum load F_{max}, the load ratio R_L or the total number of cycles N_{tot} via the input file and transfers it to the cycle jump module, from where it gets back the amplitude value.

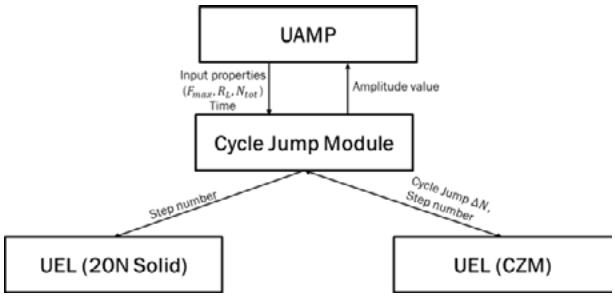

Figure 3: Exchange of information between different subroutines

In order to use equation (3), the whole FE model has to consist of user-defined elements (UEL). The solid user elements need information about the step number of the load profile, so that equation (3) can be used only in step 5. The CZM is also implemented in user elements exchanging information on the step number and the value of the cycle jump ΔN with the cycle jump module.

3. One-Element Test

The energy conservation of the new load application method is demonstrated in a simple one-element test in ABAQUS. The FE model consists of a single cubic 20-node solid (user) element with an edge length of 1mm, as illustrated in Figure 4. One side of the cube is clamped while the opposite side is loaded with a periodic cosine-shaped displacement with a load ratio $R_L = 0.1$ (
Figure *5*a). The presence of middle nodes in a 20-node element enables a constriction of the cube under tensional loading constituting a geometric nonlinearity. A transversally isotropic linear elastic material model is assigned to the cube. The "fiber direction" corresponds to the load direction. Deliberately, no kind of damage model was used here in order to not mix the energy dissipating effect of the damage model with possible numerical energy errors.

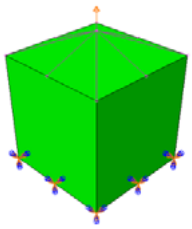

Figure 4: *One element test*

As plotted in Figure 5b, the reaction force caused by the periodic cosine-shaped displacement load is linearly increasing over the number of cycles, which means an unphysical production of energy. If however, the cosine-shaped displacement load is replaced by a periodic displacement load with the load profile presented in section 2.1, the maximum reaction force remains constant, as plotted in Figure 6. The deformation behavior is energy-conserving here.

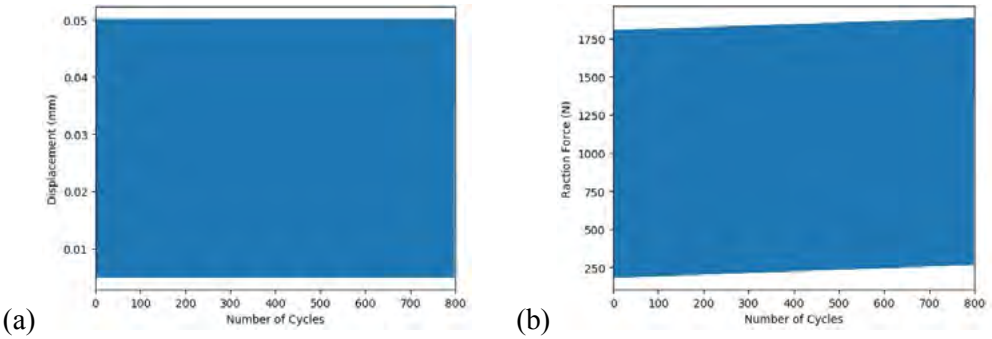

Figure 5: Non energy conserving behaviour of the cube loaded by a cosine shaped displacement (a) with an increasing reaction force (b)

4. Conclusion and Outlook

A new cycle jump and load application technique for high cycle fatigue simulations under general loading conditions based on the in-situ approach by Nojavan et al. [6] was presented. The in-situ" approach enables the determination of local stress ratios under general loading conditions, which have an important impact on the fatigue damage rate of a CZM. However, using this approach in a commercial FE solver causes a numerical energy error.

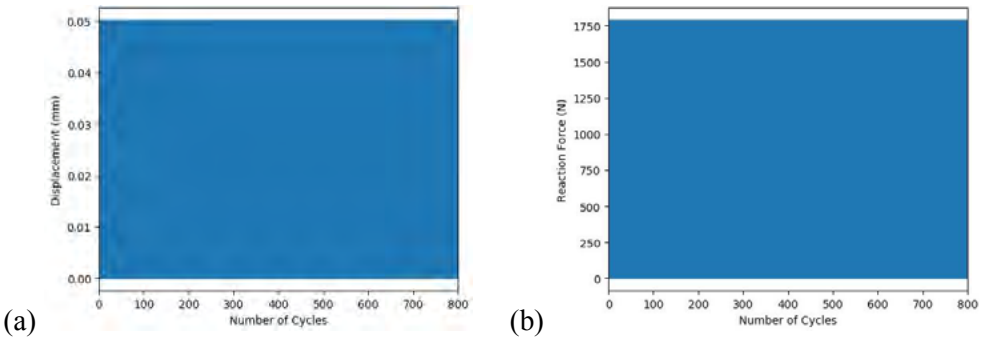

Figure 6: Energy conserving behaviour of the cube loaded by the newly developed load profile (a) with a constant reaction force

It was shown in a simple one-element test, that the energy produced by the simulation of a loading-unloading cycle accumulates with the number of simulated cycles and can no longer be neglected after comparatively few cycles. To overcome this, an additional step was added to the load profile, where the FE model is completely unloaded to its initial state. This is realized by modifying the formulation of the element residual vectors. This modified element formulation requires the exclusive use of user-defined elements and is limited to elastic material behavior.

For future works, the numerical simulation of microcracked-induced delamination (MCID) under cyclic loading can be a possible application example, where the use of the newly developed energy-conserving cycle jump and load application technique is required. Previous studies by the authors showed a variable mixed ratio during the process of delamination propagation under static loading [8]. It is assumed, that under cyclic loading, also the stress ratios will change and significantly deviate from the global load ratio, especially if the global load ratio is negative.

Keywords: Composite stiffened panels, Damage identification, Machine learning, Structural strain responses

Abstract
Damage identification in composite structures is both a focal point and a challenge in the field of structural health monitoring. This study presented a data-driven method for damage identification in composite stiffened panels based on structural strain responses under load. Damage-inclusive models with various types and locations of damage were established using finite element methods to generate the original damage-strain dataset. Five machine learning models with different strain input processing methods were developed and trained, including Graph Neural Network (GNN), Decision Tree (DT), Random Forest (RF), Artificial Neural Network (ANN), and K-Nearest Neighbors (KNN). Comparative analysis of their predicitons revealed that the GNN model, which incorporated the structure's geometric characteristics through graph-based strain input, performed best. The capability of GNN model to handle missing strain data was further analyzed, and the results validated the accuracy and robustness of the proposed data-driven method.

1. Introduction

Composite materials, with high specific properties and exceptional design flexibility, are ideally suited to lightweight applications such as aerospace. In particular, composite stiffened panels with superb load-bearing capacity and excellent post-buckling characteristics [1], are widely used in aircraft structures. However, during the entire lifecycle of production, processing, and cyclic loading in aircraft structures, composite materials often incur damages such as low-velocity impact-induced dents, delamination, and debonding [2]. These damages are not only difficult to detect visually but also significantly impair the structural strength and stiffness. Therefore, there is an urgent need to develop an efficient and reliable damage identification technology for composite stiffened panels to assess structural integrity and prevent catastrophic failures.

Non-destructive testing (NDT) techniques are currently the most widely used methods for assessing the safety and integrity of aircraft structures. Common techniques include visual inspection, acoustic emission, infrared thermography, optical interferometry, ultrasonic testing, radiography, and vibration/modal analysis [3]. However, these NDT techniques have limitations due to their inherent characteristics, and most require operators to possess considerable experience and expertise [4]. In this context, strain-based damage detection methods have garnered attention due to the ease of signal acquisition, high sensitivity to local damage, and low operational costs [5]. This approach involves deploying strain sensors on structures to collect raw strain data, which is then analyzed to extract features indicative of structural damage. To accurately identify structural damage from strain responses, it is crucial to select appropriate computational methods to extract damage features from the collected strain signals.

Recently, machine learning (ML) algorithms have demonstrated unique advantages in establishing mappings between structural responses and damage characteristics. These efficient and adaptable methods have been progressively applied in advanced research fields, including composites damage identification [6]. For example, Song et al. [7] developed an artificial neural network (ANN) to elucidate the relationship between the electrical resistance and strain in carbon fiber-reinforced composites, facilitating real-time monitoring of damage under simple loading conditions. Almeida et al. [8] employed a supervised learning model based on the K-Nearest Neighbors (KNN) algorithm to process acoustic emission signals collected during tests, investigating the correlation between these signals and composite material damage. Pham V T et al. [9] developed a highly robust damage identification model by establishing a nonlinear mapping between the vibration data features of composite cables and structural damage using a Multi-Layer Perceptron (MLP) and Graph Neural Networks (GNN). The integration and application of emerging ML technologies in the field of composite damage identification have received increasing attention. However, most prior studies have focused on specific structures or components, with insufficient research on damage identification in typical structures such as composite stiffened panels. Moreover, previous research often relied on specific ML algorithms, and the variations in training outcomes due to different algorithms and data processing techniques have not been sufficiently explored.

This study utilizes data-driven methods to analyze the strain response of composite stiffened panels for structural damage identification, aiming to explore the differences in training outcomes attributable to various ML algorithms and data processing approaches. Initially, the finite element method is employed to construct the stiffened panel models featuring skin-stiffener debonding and stiffener damage, from which strain response data at monitoring points under compressive load are extracted and processed to compile the damage-strain response dataset. Subsequently, GNN, Decision Tree (DT), Random Forest (RF), ANN, and KNN models are established and trained using strain responses processed in various ways as inputs to predict the type and location of structural damage, followed by the assessment and comparison of prediction accuracy of each model. Finally, the performance of GNN model is further evaluated, particularly its capability to handle missing strain data, thereby validating the model's robustness.

2. Model Establishment

2.1. Damage-inclusive finite element model

A finite element model of a stiffened panel with three stiffeners was constructed, featuring a panel size of 300mm*300mm and incorporating three T-shaped stiffeners. The adhesive layer between the panel and stiffeners has material properties of E = 250 GPa, $G_1 = G_2 = 100$ GPa, and the panel and stiffeners are made of X850, with its mechanical properties detailed in Table 1. Fixed boundary conditions were implemented via coupling constraint, while compressive loads were applied at the loading end in the direction of the stiffeners via the RP-1 reference point. Strain gauges were strategically placed at intervals of 50mm along one side of the T-shaped stiffeners and on the external side of the web, totaling 36 monitoring points as depicted in Figure 1 (a).

Two types of damage were preset in the stiffened panel: debonding of the panel and stiffeners, and impact damage to the web of the stiffeners, achieved by applying a stiffness reduction method [10]. Considering the randomness of damage locations in practical engineering applications, the stiffened panel structure was divided into zones. The specific location of identified damage is characterized by the corresponding area, with the damaged areas schematically shown in Figure 1 (b). Two sets of varying magnitudes of compressive loads were applied to models with different types of damage (including undamaged case), to expand the dataset.

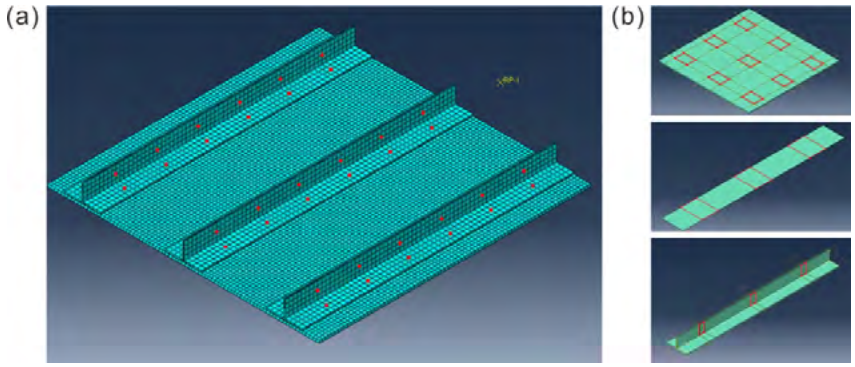

Figure 1. (a) Layout of strain-monitoring points. (b) Schematic diagram of the damaged area.

2.2. Data processing

Data augmentation can rapidly generate sufficient and efficient datasets from a limited original dataset, which is critical for enhancing the performance of data-driven models. By adding noise to the strain data, this study simulates engineering strain gauge data errors and the variability in strain values due to differing damage locations within the same zone. The random method from the numpy library was employed to augment the data, ultimately generating 5700 training datasets. Cross-validation was utilized to divide the obtained dataset into three subsets: training, validation, and test, with a ratio of 7:2:1. The strain data were standardized using the min-max normalization method to analyze the relative magnitudes of structural responses, thereby reflecting information on the damage. The dimensions and magnitudes of the features were standardized to effectively enhance the convergence speed and learning stability of the ML models.

Labels for the dataset were encoded using one-hot encoding, mapping nine types of debonding damage models, nine types of rib damage models, and one undamaged model into discrete 19-bit binary-coded categories. This digital representation eliminates ordinal relationships among labels and converts categorical features into binary vector representations, thus enhancing the sparsity of the feature vector and enabling the models to process and interpret these features more effectively.

2.3. Machine learning model

This study examines the damage identification performance of five machine learning models. For the GNN, the input data are normalized strain measurements transformed into a graph structure, where relationships between nodes represent spatial information inherent in the structure itself. In contrast, the DT, RF, ANN, and KNN models use raw one-dimensional data with 36 components as input. All five models use structural strain responses as inputs to produce outputs of 19-component one-hot encoded damage labels.

A key feature of GNN is its ability to incorporate original topological information through graph-structured data inputs, thereby integrating the spatial relative positions of strain measurement points into the original graph features. Initially, the input graph features are passed through a 1*1 convolutional layer that transforms dimensions while preserving spatial information, converting the channel count of input features to the dimensions of hidden layer. Following a nonlinear transformation by the activation function, the conv2 layer converts the dimensions of the hidden layer to the number of output categories,

which is then passed to the next layer's activation function. Subsequently, information is transmitted from source nodes to target nodes and aggregated via maxpooling from adjacent nodes. Considering both training performance and computational cost, the selected model configuration was set with hidden_size=16, learning_rate=0.01, lr_decay=0.3, and num_epochs=50, using a combination of Leaky_ReLU and Linear activation functions, with learning rate decay applied every 10 epochs. The other four models were developed using the scikit-learn package, with the ANN model structured as 36-64 (ReLU)-32 (Tanh)-19 (Softmax); key parameters for each network are provided in Table 2.

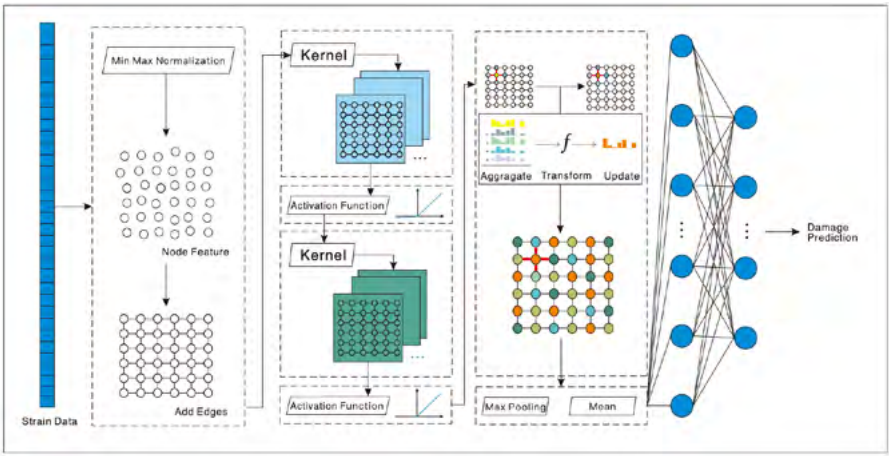

Figure 2. Framework of proposed GNN model.

Table 2. Critical parameters of ML models.

ML model	Critical parameters
Decision Tree	Max_depth=10
Random Forest	N_estimators=50, mini_samples_split=10, mini_samples_leaf=5
ANN	lr=0.1, optimizer=Adam, loss=categorical_crossentropy, epochs=50
K_Neighbors	N_neighbors=2, weights='uniform' , metric='manhatan' , p=2

3. Results and discussions

3.1. Comparison of predicted results across different models

This section explores the optimal method for processing structural strain response data in machine learning by comparing the predicted outcomes resulting from different data processing approaches. Specifically, the GNN processes graph-structured strain data considering inter-node relationships, DT and RF make decisions through feature splitting and selection, ANN establish nonlinear relationships by learning weights and biases from raw feature data, and KNN calculates feature similarity using appropriate distance metrics.

Accuracy is initially used to assess the proportion of correctly predicted samples by the classifiers, with the comparative predictive accuracies of the five models presented in Table 3 following cross-validation. The results indicate that the GNN model achieves optimal prediction on the training, validation and test sets. The DT model, constrained by the complexity of its network structure, showed the lowest predictive accuracy. The RF model, which adds complexity to the DT framework, achieved a training accuracy of 94.94% but performed poorly on the validation and test sets. The ANN model, after appropriate optimization of network structure and parameters, exceeded 90% accuracy across all datasets, with minimal variation among them. The KNN model, second only to the GNN in predictive precision, achieved an accuracy of 95.26% on the training set, likely due to the algorithm's consideration of sample

similarity. The core challenge in damage identification based on structural strain responses is how to process raw strain inputs to adequately extract damage information contained within the strain responses. Unlike the other four models, which use raw strain inputs, the GNN introduces physical information of original structure, establishing strain nodes graph which representing the geometric spatial relationships among the measurement points. This approach significantly enhances the predictive performance of the damage identification model.

Table 3. Comparison of prediction accuracy of five ML models.

	Training Accuracy	Validation Accuracy	Testing Accuracy
Decision Tree	86.17%	78.25%	77.37%
Random Forest	94.94%	86.67%	88.95%
ANN	92.03%	91.75%	92.81%
K_Neighbors	95.26%	92.19%	93.51%
GNN	97.59%	94.56%	95.61%

To further compare the predictive efficiency of five ML models for three types of damage: debonding, stringer damage, and undamaged. The prediction results for each model across varying types and locations of damage were aggregated and represented in grouped box plots as shown in Figure 3. The debonding and stringer damage consist of nine damage zones each, whereas the undamaged model shows no variation in damage location, hence is represented by a single horizontal form line in the box plots. Comparing the predictive performances of the five models, the DT model exhibits poor predictive performance in the undamaged cases and low accuracy rates for both debonding and stringer damage, with notable variability. The RF model shows some improvement overall, yet it still achieves less than 70% accuracy for the undamaged cases and displays considerable variability in the accuracy for debonding. Compared to these, the ANN model improves the dispersion of accuracy for debonding damage, but the average predictive accuracies, especially for the undamaged model, remain low. The KNN model achieves high accuracy for debonding and stringer damage but shows two outliers in its predictions for the nine stringer damage scenarios and achieves less than 90% accuracy for undamaged cases. The GNN model demonstrates the best overall predictive performance, with an impressive 94% accuracy for the undamaged model and the highest accuracy and lowest variability for both debonding and stringer damage. Accurately identifying whether a structure is damaged is crucial for structural health monitoring. The GNN model significantly enhances its predictive performance by analyzing the relative magnitude and spatial relationships between data, effectively accomplishing the task of binary classification.

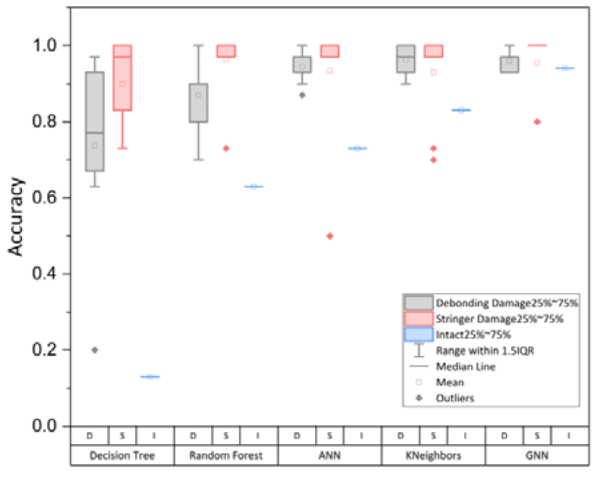

Figure 3. Grouped box plots of the results of the five model predictions.

3.2. Robustness analysis of GNN model

This section further evaluates the the proposed GNN model, which demonstrated the best predictive outcomes. The model's prediction accuracy and the learning curves of the loss function are shown in Figure 4. Both the training and validation loss curves exhibited a smooth decline until convergence, their similar trends indicating that there is no overfitting in the training process. Furthermore, in practical engineering applications of composite stiffened panels, strain data are often acquired from strain gauges mounted on the structure's surface. Due to various factors such as environmental conditions and human error, strain gauges may exhibit inaccurate readings or even become damaged, affecting structural health monitoring. Therefore, the model's ability to correctly predict damage when strain gauges are impaired is a critical metric for assessing its performance. This subsection considers two scenarios of strain gauge impairment: 1) random damage occurring in 0, 1, or 2 out of 36 strain gauges; 2) random damage occurring in 1 of 36 strain gauges. Datasets for both scenarios were generated by assigning zero values to the affected strain gauges in the test set using random numbers, and instances where more than one strain gauge is damaged are typically preventable with timely maintenance, thus these scenarios adequately represent realistic conditions. The model's prediction accuracy results, as shown in Table 4, indicate that under both scenarios of strain gauge damage, the model achieved approximately 80% accuracy in predicting various damages, demonstrating its stability in handling noisy inputs. Figure 5 further assesses the prediction results through a normalized confusion matrix. The confusion matrix, in table form, uses predicted and actual values as its axes, with each cell's normalized value representing the proportion of predictions corresponding to the true labels.

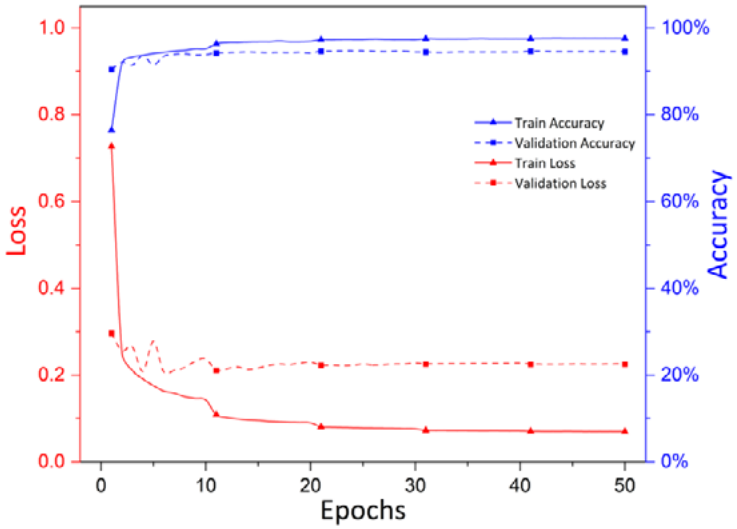

Figure 4. Learning curves of model accuracy and loss function.

Table 4. Model training effect considering strain gage damage scenario.

	Accuracy	Debonding Accuracy	Stringer Accuracy	Intact Accuracy
Case 1	84.74%	90.00%	80.00%	80.00%
Case 2	82.81%	85.93%	79.63%	83.33%

The confusion matrix clearly shows that, despite data loss, the model still maintains a high prediction accuracy for debonding damage, with 90% and 85.93% for the two cases. However, for stringer damage and undamaged scenarios, data loss significantly reduces prediction accuracy. This occurs because the GNN model distinctly extracts structural strain response features for these scenarios: undamaged cases show a uniform strain distribution, whereas regions near stringer damage exhibit significant differences compared to other areas. Consequently, missing data values set to zero result in strain inputs that do not

match the learned damage features, thus reducing prediction accuracy. Furthermore, it is notable that under conditions of data loss, the model's prediction accuracy significantly decreases for label 10 and 12, 16 and 18, which involve stringer damage. An analysis of the model's geometric structural features reveals that these groups correspond to four types of damage located near the vertices on both sides of the stiffened panel. The similarity in spatial structures among these damage scenarios results in similar strain response datasets, complicating the machine learning model's ability to accurately map strain responses to damage conditions, especially in cases of data loss. This underscores the importance of considering geometric spatial features in addressing related challenges. Overall, the model demonstrates strong robustness and maintains stability in the presence of data loss, noise, or other disturbances, exhibiting excellent generalizability.

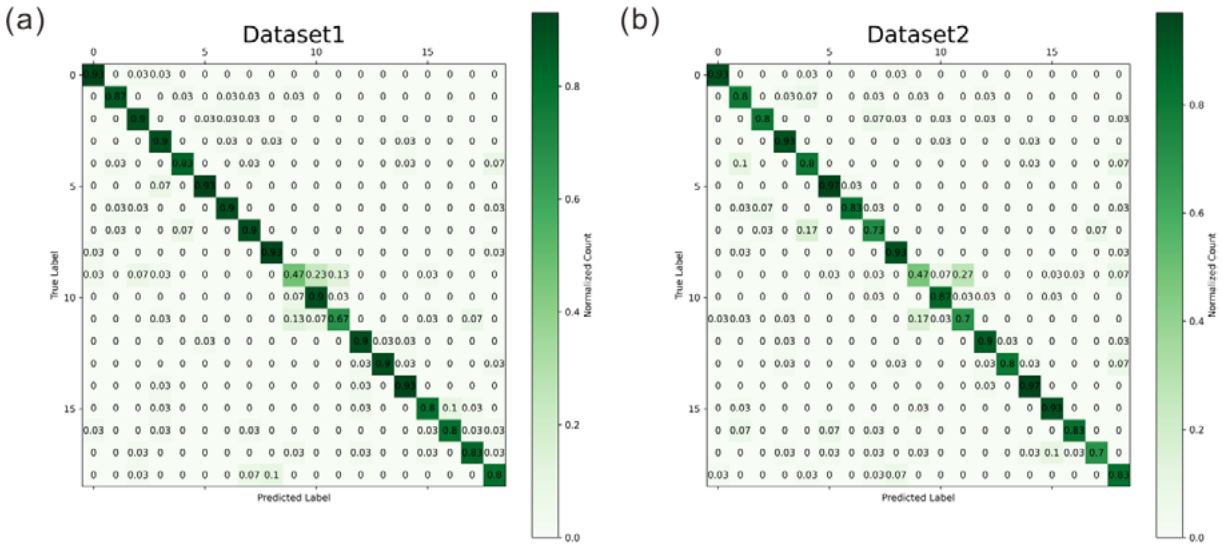

Figure 5. Confusion matrix of model predictions with impaired strain gages. (a) Case 1. (b) Case 2.

4. Conclusions

This study employs five machine learning models to identify damage in composite stiffened panels with debonding between the panel and stiffeners, and stiffener damage. A finite element model of the damaged composite stiffened panels was developed, incorporating different types of damage across nine zones. Thirty-six strain response monitoring points were placed on three ribs of the stiffened panel structure to capture and process the strain responses under compressive loads, thereby creating a damage-strain dataset. Five data-driven models were developed, including GNN, DT, RF, ANN, and KNN, using strain responses obtained via the finite element method as inputs to predict the types and locations of damages in the stiffened panels. The predictive results from the five models indicate that the GNN, utilizing graph-structured strain responses as inputs, achieves the highest accuracy and lowest variability in predicting debonding and stiffener damage. Notably, it exhibits a significant performance advantage, especially in predicting the presence of damage, over the other four models that input strain data as one-dimensional vectors. Furthermore, the GNN model's accurate predictions for datasets with missing strain data validate its high noise resistance and robustness.

Abstract

This paper introduces a geometrical grading technique aimed at enhancing joint performance through a novel joint interface design. The implementation and demonstration of this technique are discussed. The design aspects of various fused deposition modelling (FDM) printed single lap joints (SLJs) were analyzed to understand their strengths and failure mechanisms. The study focuses on evaluating the failure behavior dissimilar FDM printed SLJs, using two commonly used thermoplastics, polylactic acid (PLA) and polyamide (PA), through numerical and experimental methods. Computational damage modeling, incorporating cohesive zone modeling (CZM) and ductile damage, has been utilized to investigate the failure load and failure mechanisms of polymer joints. Experimental studies have been carried out to validate these computational models confirming very good match. The research delves into understanding failure initiation and damage progression, specifically evaluating how geometric grading parameters and bonding substrates influence the failure load. The optimized toothed-shaped interface in dissimilar PLA-PA single lap joints (SLJs) shows a substantial improvement, with enhancements in strength and failure strain of approximately 46% and 480%, respectively, compared to the baseline PLA-PA SLJs.

1. Introduction

The presence of joints in structures is common as it is challenging to construct any structure without joints. The size of print beds and budgetary constraints prevent contemporary manufacturing techniques, such as additive manufacturing, from producing entire structures [1]. Hence, design requirement of joint is imperative to ensure a structure's overall strength and durability.

Single-lap adhesive joint (SLJ) are easiest and dependable technique for joining similar and dissimilar adherends. However, sudden material mis-match and eccentricity of applied load in SLJs causes peak stress to originate at the bond-layer and decreases the load bearing capacity, causing premature failure of SLJs [2]. Hence, it is a common practice to geometrically grade adherend or adhesive based on stress transfer mechanism complexity. Fused deposition modelling (FDM) [3] allows to achieve intricate geometries at a lower fabrication cost. These meticulously designed optimized adherends, can then be joined together using adhesive joining processes.

A thorough examination of the strength and failure analysis of different SLJs that include adherends made by 3D printing is presented in this paper. The analysis involves evaluating the strength of joints and identifying the reasons for their failure. It also involves developing new joints using knowledge gained from traditional SLJs and confirming their effectiveness through computer simulations and experiments. In addition, a thorough study is performed to examine the failures of the innovative interface-tailored SLJs. This analysis specifically focuses on assessing how the geometrically graded

tooth characteristics affect the load at which failure occurs and the resulting strain. This study presents computational simulations that incorporate cohesive zone and ductile damage modeling to evaluate the initiation and spread of failure. The objective of the research is to improve the maximum load capacity and deformation properties, prolong the time it takes for damage to start and advance, and get a more profound comprehension of design factors in dissimilar 3D-printed SLJs.

A notable deficiency in the existing literature is the lack of comprehensive analysis of failure causes in dissimilar SLJs using 3D printed adherends. Current research predominantly emphasizes stress analysis rather than going into the complexities of failure analysis. Furthermore, the primary emphasis in this area of study has been on the connection of different materials, such as metal-to-metal or metal-to-composite surfaces. As a result, there is a lack of knowledge regarding the fundamental reasons for failure in 3D printed SLJs. The absence of understanding has impeded the enhancement of 3D printing skills to effectively tackle these modes of failure. In order to fully utilize the potential of 3D printing technology in improving joint strength, it is crucial to thoroughly comprehend the capabilities and failure analysis of FDM printed adherends. This is especially important for adherends that have geometrically graded interfaces combined with adhesive bonding.

The paper presents a detailed examination into the failure mechanisms and root causes of different SLJs made of FDM-printed Polylactic acid (PLA) and Polyamide (PA) that are bonded using adhesive bonding. The discrepancy in modulus between PA and PLA is substantial, validating the selection of these two materials to exemplify the difficulties associated with differing adherends. The decreased flexural rigidity of the PA adherend led to significant tensile stress, resulting in noticeable deformation in the bond-layer close to the left free edges [4,5]. The insufficient strength of the adhesive, along with significant peeling and shearing stress, resulted in a cohesive breakdown in the non-customized SLJ. An asymmetrical stress distribution was caused by the difference in stiffness between the adherends, resulting in increased stress concentration on the adherend with lower stiffness. These observations support the need to apply geometric grading to the different adherends in order to reduce the risk of premature SLJ failure and improve the strength of the joint [6,7]. The second and third structures of the SLJ unique showcase customized interfaces that incorporate an innovative toothed design. The second SLJ structure, known as "*P/PA-A-N/PLA*", incorporates positive interlocking teeth on the PA adherend and negative interlocking teeth on the PLA adherend (Figure 1). The third SLJs, also known as *"P/PLA-A-N/PA*," consist of interlocking teeth that are oriented in opposite directions. The PLA adherend has positive interlocking teeth, while the PA adherend has negative interlocking teeth.

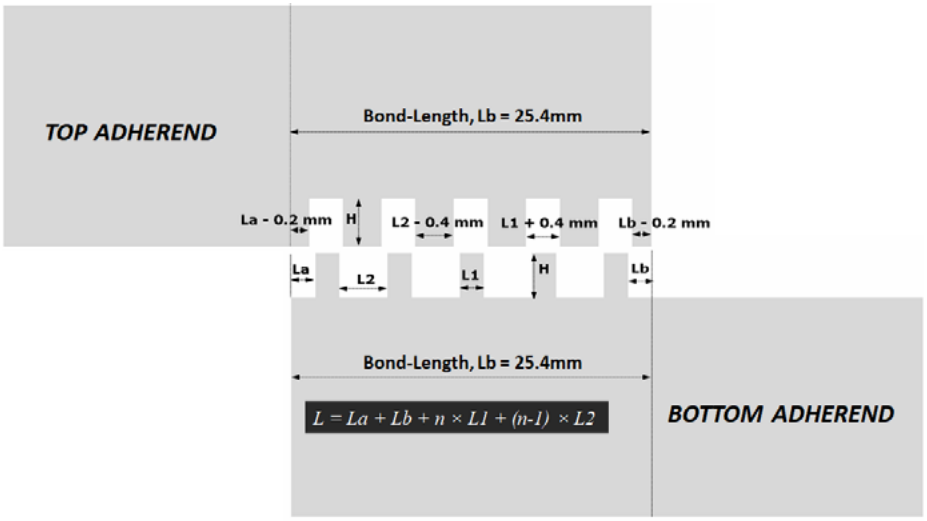

Figure 1: Represntative image of positive and negative interlocking teeth graded on bond-layer interface.

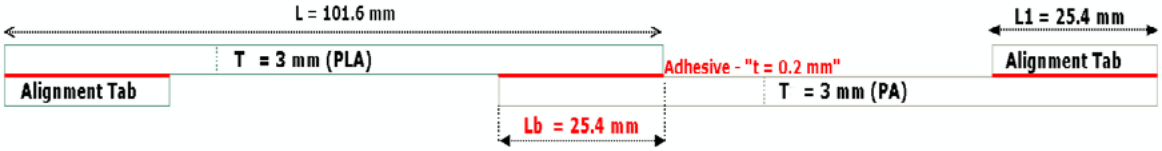
CONTENTS

2. Materials and Methods

Commonly used thermoplastic filaments; freshly extruded Polyamide (PA) and Polylactic acid (PLA) were used for this study.

Specimens were 3D printed using line infill, which had a density of 100%. The fused material lines were deposited primarily in a parallel manner in this configuration, resulting in the formation of successive stacked layers that ultimately constitute the final specimen. CURA software was utilized to process the 3D model of the adherend, ensuring the correct printing method. The 3D-printed adherends were given sufficient time to cool down after the printing process before being removed from the print bed. The introduction of an MK2a heat bed in the printer has significantly contributed to reducing the occurrence of warping in the specimens. A glass cage was used to prevent moisture absorption during the printing of specimens on the FDM printer. Open-source Creality CR-10 3D printer was used for the printing. The printing parameters used for the test samples are listed in table 1.

Table 1: FDM Printing Parameters.



Printing Parameters	**Neat PLA**	**Neat PA**
Infill Density	100%	100%
Infill Pattern	Line	Line
Nozzle Diameter (mm)	0.4	0.4
Nozzle Extrusion Temperature (ºC)	210º	240º
Raster Orientation	0º	0º
Bed Temperature (ºC)	60º	80º
Deposition Layer Height (mm)	0.1	0.1
Printing Speed (mm/s)	20	20

Initially, the uniaxial tensile parameters, such as Young's modulus, elongation at break, and ultimate tensile strength, were determined by experimental means from the tensile test results. Tensile tests are repeated three times for each SLJ configuration using servo-hydraulic tensile testing equipment (Instron 3365) equipped with a 5 kN load cell. The obtained material properties for PLA and PA are listed in table 2.

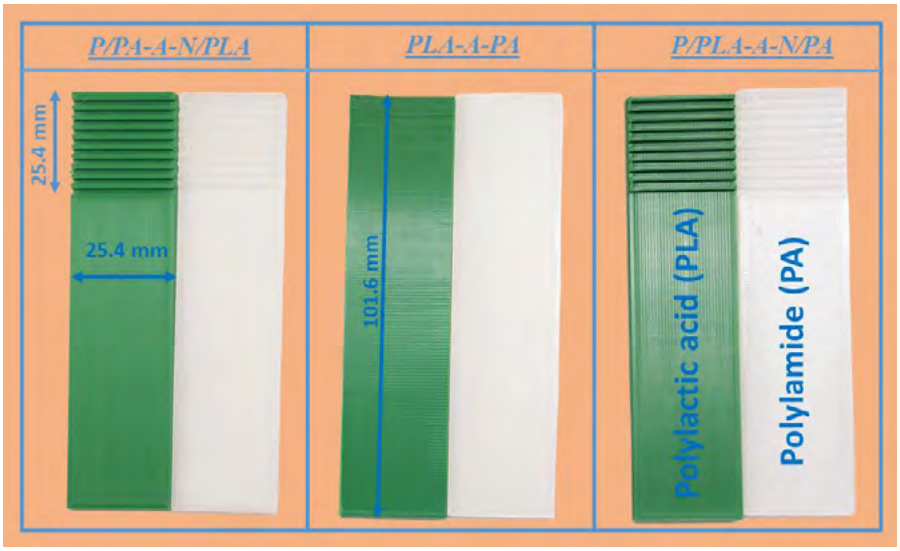


Table 2: Extracted material property of FDM printed PLA and PA from uniaxial tensile test.

Material Property	**FDM printed PLA**	**FDM printed PA**
Young’s Modulus (MPa)	1778.68 ± 63.21	293.27 ± 9.46
Ultimate Tensile Strength (MPa)	65.5 ± 9.84	42.76 ± 1.60
Fracture Strain (%)	7.54 ± 0.46	326.01 ± 47.51

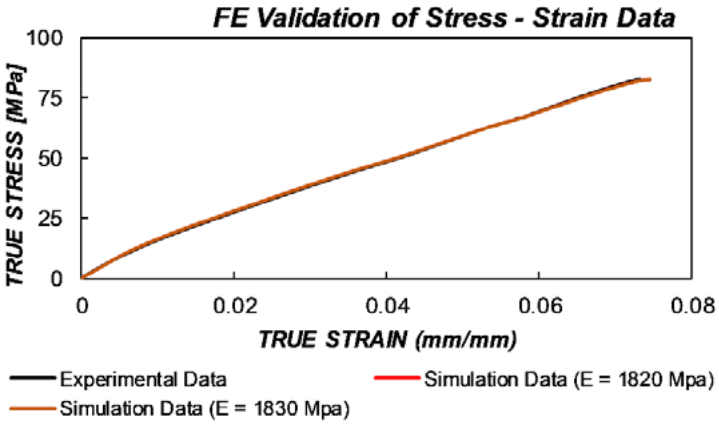
Subsequently, adherends and SLJs were fabricated. The dimension of SLJs manufacture by FDM are depicted in Figure 2. The width of the SLJs is 25.4 mm. The ASTM D638-14 Type V, which is the established standard for assessing the tensile strength of polymers, was chosen because there are no special standards available for thermoplastics.

(a)

(b)

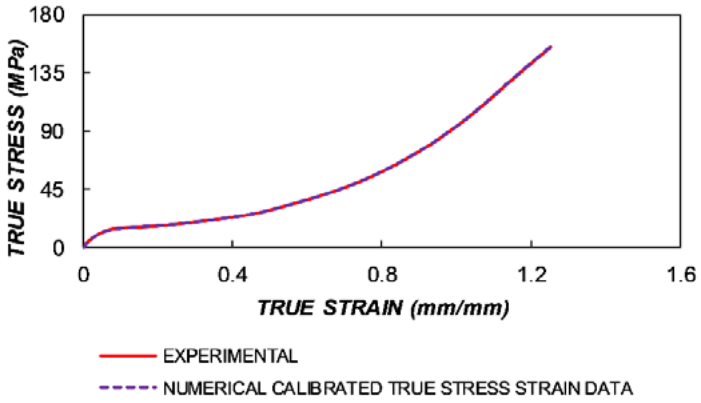
Figure 2: (a) Dimensions of SLJs (b) FDM printed SLJs for experimental validation.

The adhesive "*Momentive RTV 106*" is utilized to attach adherend due to its ductility and excellent temperature resistance [8]. This is a single-component, pre-mixed silicone rubber adhesive sealant that offers strong bonding to plastics, ceramics, and glass surfaces.



3. Numerical Approach

Abaqus CAE 6.21 [9] was used to create two-dimensional finite element (FE) models for all SLJ configurations. The purpose of these computer models is to forecast the point at which a system or structure will fail and determine the specific way in which it will fail. Finite Element Analysis (FEA) was used to analyze the impact of geometric parameters related to positive and negative interlocking teeth on enhancing the strength of *"P/PA-A-N/PLA*" and *"P/PLA-A-N/PA*" SLJs.



The failure of the adhesive material is simulated using cohesive zone modeling (CZM) with element-based criteria. The governing principle of CZM involves the application of cohesive elements or a surface approach, where cohesive forces exist between the failure surface to accurately model the start and propagation of damage [10]. CZM with a mixed-mode formulation was employed, which had a triangular shape.The adhesive was composed of a uniform layer of cohesive components that extended throughout its entire thickness. A four-node two-dimensional (COH2D4) element was employed to create a mesh for the adhesive layer. The cohesive properties for the finite element simulation of the "Momentive RTV 106" adhesive were obtained from the literature [11].

The behavior of 3D printed PLA and PA was simulated using multi-linear elasto-plastic data that included a ductile damage criterion. The ductile damage criterion is both computationally stable and very easy to implement. Thermoplastics, like PLA and PA, can display either brittle or ductile characteristics depending on how they are processed. FDM-printed thermoplastics such as PLA, PA, and others often exhibit elasto-plastic characteristics (Figure 3). The ductile damage criterion facilitates

a seamless shift from elastic to plastic behavior.The materials PLA and PA were simulated using four-node planar strain elements (CP4ER). The mesh was adequately adjusted with 16 elements over the thickness of the adherend in order to decrease the size of the elements in areas with significant stress gradients.

(a)

(b)

Figure 3: Computational vs experimental validation of obtained elasto-plastic dataset for (a) 3D printed polylactic acid (PLA) and (c) 3D printed polyamide (PA).

The lower adherend's right vertical end moved to the right, but the upper adherend's left vertical end did not move horizontally in the X-direction ($U_X = 0$). In order to preserve grip-related boundary conditions, the lateral displacement in the Y-direction ($U_Y = 0$) for the upper and lower adherends was restricted to 25.4 mm. The boundary conditions used in this study closely resemble those used in experimental tensile testing.

4. Results and Discussion

The primary investigation was on a specific type of SLJ that had an uncustomized interface, known as *PLA-A-PA* SLJ. The PA adherend had substantial longitudinal deformation in comparison to PLA. The decreased flexural rigidity of the PA adherend led to significant tensile stress, resulting in noticeable deformation in the bond-layer near the left free margins. The insufficient strength of the adhesive, along with significant peeling and shearing stress, resulted in a cohesive failure in the *PLA-A-PA SLJ* under normal conditions. The variation in stiffness between the adherends resulted in an uneven distribution of stress along the bond-layer, with the lower stiffness adherend experiencing higher levels of stress. These observations support the need to apply geometric grading to the different adherends in order to reduce the risk of premature SLJ failure and improve the strength of the joint.

The correlation between the strength of the "*P/PA-A-N/PLA*" joint and various geometric parameters is determined. The customized SLJs exhibited intricate failure modes, showcasing several interacting damage modes that varied based on the geometric parameters' values. The ideal joint configuration, determined by adjusting the tooth geometric parameter to achieve the highest load, includes the following coefficients: The values are as follows: *H = 1.4 mm, L1 = 1 mm, L2 = 1.4 mm, La = 0.6 mm, and n = 10.* (Figure 4)

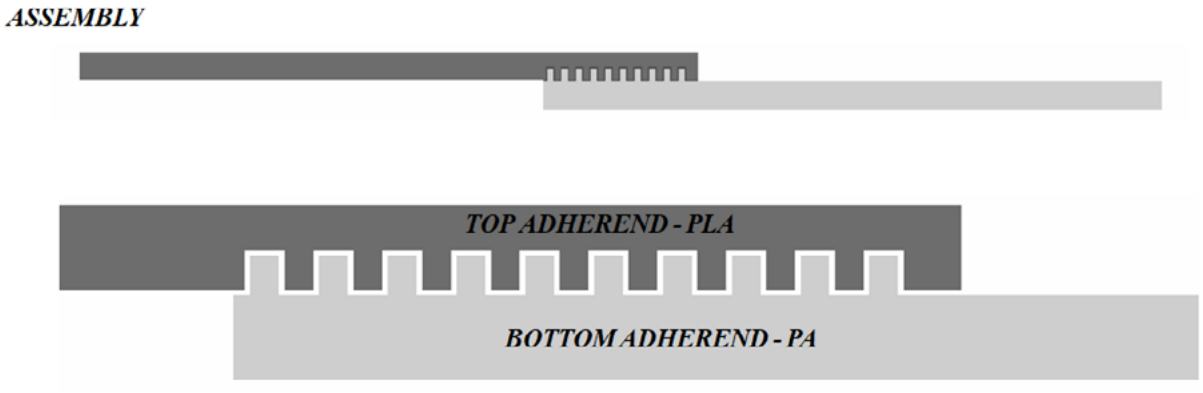


Figure 4: Optimal tooth coefficients obtained after calibrating tooth parameters for strength

The modification of tooth geometry parameters in the "*P/PLA-A-N/PA*" SLJ exhibits a more pronounced deviation in failure load in comparison to the "*P/PA-A-N/PLA*" SLJ. The incorporation of positive interlocking teeth on the PLA adherend enhances the failure load in comparison to the baseline "*PLA-A-PA*" SLJ (Figure 5). Nevertheless, the enhancement in the strength of the joint is greater when positive interlocking teeth are incorporated into the adherend made of PA. The differential in stiffness between PLA and PA is the main reason for this divergence. Introducing interlocking teeth to PLA, which is already a hard material, often enhances its stiffness. On the other hand, removing material from the PA adherend reduces its stiffness.

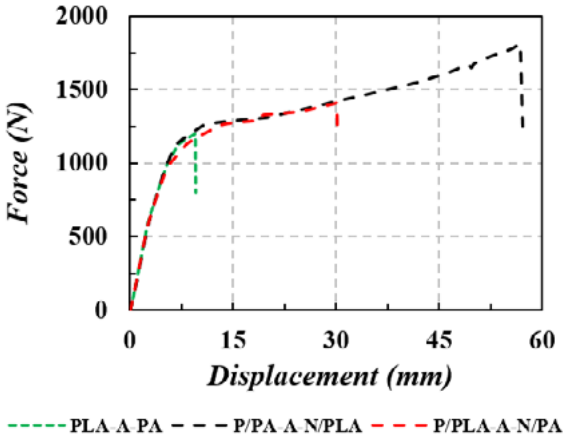

Figure 5: Computation load vs displacement curve for all the three realized SLJs configuration

The addition of interlocking teeth on the PA adherend is efficient in increasing the bending stiffness of the PA adherend, therefore improving the overall global rigidity. In contrast, the act of removing material from the adherend made of PA decreases the rigidity of the adherend, which is already less rigid. The observed augmentation in failure load and strain in the "*P/PLA-A-N/PA*" configuration is attributed to a synergistic effect of the geometrical interlocking mechanism and adhesive bonding. The importance of geometric tooth characteristics in enhancing interfacial stiffness is evident in both

customized setups. Moreover, it is important to mention that the most efficient arrangement, obtained by modifying tooth geometric characteristics, remained consistent for both customized setups.

The customized SLJs exhibit exceptional durability due to a gradual deterioration process, which is made possible by the inventive tooth-interface design utilized. This design approach enables the creation of localized tensile and compressive stresses along certain tooth edges, substantially reducing the concentration of maximum peel and shear stresses inside the adhesive layer. The failure originates in the bond layer located close to the unfixed border of the flexible PA adherend. The main reason for this phenomenon is the significant uniaxial straining that the PA adherend undergoes, which is in contrast to the stronger PLA adherend. Afterwards, the damage slowly advances towards the center of the bond layer, finally extending to the interlocking teeth, indicating a combined failure of the tooth-interface joint. The occurrence of many sequential failures significantly prolongs the time it takes for the joint to completely fail, leading to significant enhancements in total strength.

In all three situations, the finite element analysis overestimated the failure loads in comparison to the experimental data (Figure 6). For the numerical simulations, it is assumed that the adherend is isotropic. The parameters of the 0° raster orientation were used as input. FDM printed plastics exhibit anisotropy, which poses challenges in managing print orientations for intricate designs. In customized joints, teeth were printed at a right angle to the direction of applied force. In addition, the use of FDM printing for PA materials can result in various issues such as warping and delamination, which can have a detrimental impact on the overall strength of the printed object. In addition, Momentive RTV106 exhibited reduced adherence to PA. Furthermore, it is recognized that triangle cohesive laws tend to overestimate the failure load, especially for extremely flexible adhesives like Momentive RTV106 [12].

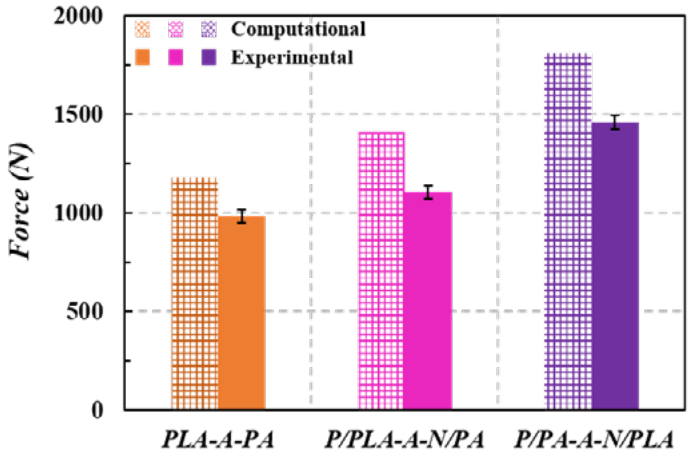

Figure 6: Experimental vs numerical comparison of failure load for all the three realized SLJs

The experimental findings and numerical modeling of the baseline *PLA-A-PA* SLJ demonstrate cohesive failure processes. Examination of the failure surface of *PLA-Adhesive-PA* SLJ reveals that certain adhesive material remains partially connected to the interface of the bond layer. The examination of the compromised surface of the "*P/PA-A-N/PLA* and *P/PLA-A-N/PA*" reveals a combined failure that impacts both the adhesive layer and the interfacial teeth. There are visible signs of the adhesive partially clinging to the interface between the bonded layers. These signs are accompanied by an uneven surface at the interface, which is generated by the breaking of interfacial teeth. This failure mode allows for the simultaneous utilization of adhesive bonding and geometrically interlocked joint technologies, resulting in the development of more reliable SLJs. Both numerical and experimental findings indicate that the failure of PA teeth in customized designs is attributed to the lower strength of PA compared to PLA.

5. Conclusions

This work presents a novel geometrically graded interface for connecting dissimilar parts that have been printed using FDM technology. The primary objective is to enhance the durability of SLJs by postponing

the onset and advancement of failure. This was accomplished by integrating adhesive bonding with mechanical interlocking teeth in a hybrid joint configuration. The study assesses the influence of positive and negative interlocking teeth on the adherends in relation to failure load and mechanism. The following conclusion can be drawn from the study:

- Untailored *PLA-A-PA* SLJs exhibit the lowest load capacity because the PA adherend experiences significant longitudinal deformation induced by its lower bending rigidity.
- The strength of tailored *P/PA-A-N/PLA* and *P/PLA-A-N/PA* SLJs was higher compared to non-tailored SLJs. Remarkably, the inclusion of favorable interlocking teeth on the PA adherend substantially enhanced the strength of the joint in comparison to their placement on the PLA adherend.
- The ideal combination of joint settings, achieved by adjusting the tooth's geometric parameters, consists of the following values: H = 1.4 mm, L1 = 1 mm, L2 = 1.4 mm, La = 0.6 mm, and n = 10.
- The improved "*P/PA-A-N/PLA*" SLJ exhibited a significant 58.5% enhancement in average strength when compared to the baseline.
- The failure modes in the three numerical SLJ setups correspond to those found numerically.

Keywords: Fracture, Sandwich, Cohesive law, Shear web, Building block approach

Abstract
This manuscript presents the overview of the multi-scale level approach applied to the evaluation of disbond damage observed in the transition region of a large wind turbine blade. In particular in the bonded joint between the 3rd shear-web and the trailing edge sandwich panel. This work applies the Building Block Approach, adopted from the aircraft industry in the wind energy industry. It consists of performing a set of physical tests and virtual FEA simulations of increasing complexity to properly understand the fracture mechanism and its implications for the joint's integrity. Results from the experimental test campaign suggest that quasi-static and fatigue crack propagation are dominated by large fibre bridging. As a result, non-linear numerical models based on Cohesive Zone Modelling are been proposed at three different scale levels to analyze quasi-static and fatigue crack propagation in the adhesive interface. Correlation between experimental and numerical results seems promising although further improvements in the formulation and calibration of the fatigue model are still a matter of development.

1. Introduction

In wind turbines, a blade is a major structural/aerodynamic component with the primary function of transforming part of the kinetic energy of the incoming wind into rotatory kinetic energy in the turbine shaft. This is done by transferring the aerodynamic shear, bending and torsional loads along the blade to the center hub. A wind turbine's blade comprises two outer aerodynamic shells (upwind and downwind shells), spar caps to increase the blade's flexural stiffness and shear webs (typically two) which are bonded to the shells at the leading and trailing edges. Shear webs usually run almost the entire length of the blade from the transition zone (denoted by the shear web fish mouth). The cross-section of a typical blade is depicted in Figure 2.

Due to the increasing global demand for clean and sustainable energy, wind turbines have become more prevalent over the past few decades. This surge in interest has driven manufacturers to develop larger wind turbines that are more efficient and cost-effective than their smaller counterparts. However, the continuous increase in size has resulted in higher loads, which require additional strengthening. This challenge is addressed by adding a third shear web to the blades. Unfortunately, this leads to a failure phenomenon known as shear web disbonding, where cracks in the adhesive interface between the shear web footing and spar cap propagate due to large deflections in the aerodynamic skins near the third shear web. If the crack grows too large this could compromise the integrity of the blade, eventually causing the wind turbine to collapse. A detailed discussion of the type of loads and structural response that trigger shear web disbond in wind turbine blades can be found in (Jensen et al., 2023)

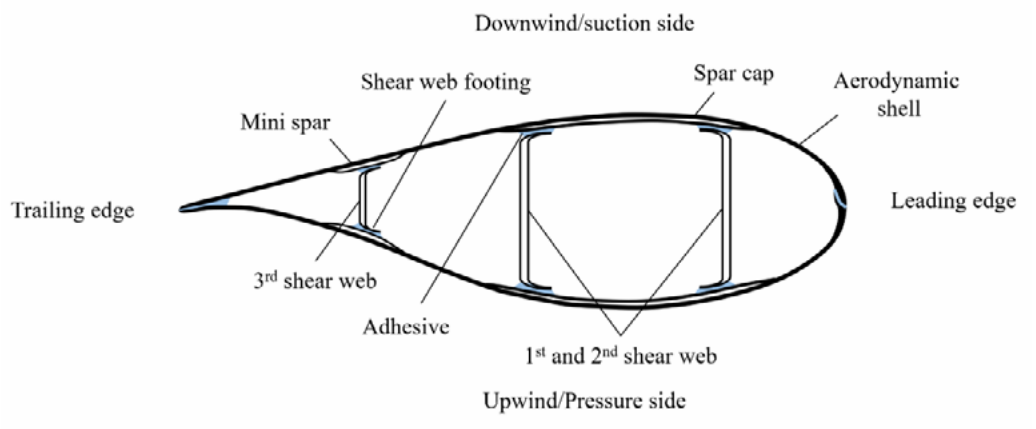

Figure 1. Example of a wind turbine blade section

To address this issue, Bladena has partnered with wind turbine owners and operators, The Technical University of Denmark (DTU) and Aalborg University, to initiate the CORTIR-II project, which aims to investigate shear web disbond in large wind turbine blades. The project is divided into four stages to investigate the issue in detail. It starts with characterisation and moves on to sub-component testing with more detail, before finally conducting large-scale testing. The current manuscript focused on the first three stages but further details and partial results about the large-scale testing can be found in (Waldbjørn et al., 2023).

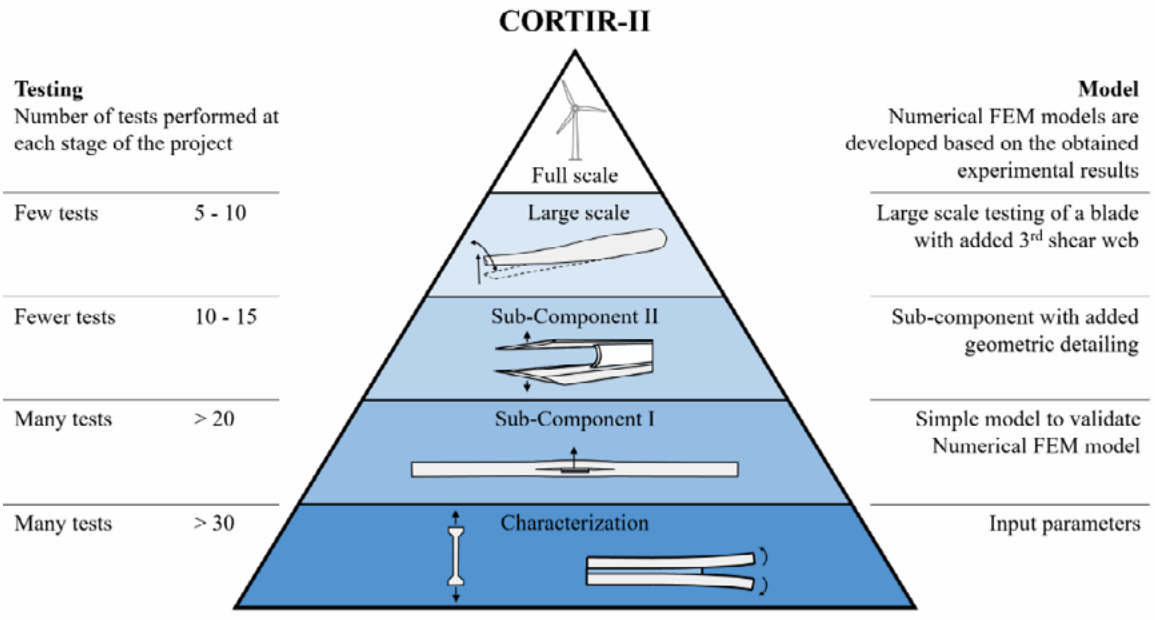

Figure 2. Building block approach applied to CORTIR-II project

2. Fiber bridging at different scale levels

The joint interface studied here is the same as in the real 3rd shear web for the 34 m balde (laminate materials and thickness and stacking sequence are the same). The top laminate is made from a triaxial/biaxial E-glass fabric with the following stacking sequence 8[45/0/-45/ ±45] and an average cured thickness of 10 mm. The bottom laminate is made from biaxial E-glass fabric with a stacking sequence of 10[±45] and an average cured thickness of 6.8 mm.

Quasi-static and fatigue fracture testing of the joint interface has been carried out at three different scale levels. At the most fundamental level, fracture characterization has been carried out using the

Double Cantilever Beam with Uneven Bending Moments (DCB-UBM) method, which is a novel test method for mixed-mode fracture. The DCB-UBM test, as introduced by (Sørensen, 2022), involves the application of uneven bending moments to the crack flanks' tips in the specimen (Figure 3.a.). By adjusting the ratio of these applied moments, crack propagation can occur under different fracture modes, ranging from pure mode I to pure mode II. Since the load applied to the specimen solely originates from bending moments, both the energy release rate and the mode-mixity angle remain unaffected by the crack length. Another advantage of employing pure bending moments for loading, particularly in cases involving large process zones, is that the applied load remains constant throughout the entire process zone.

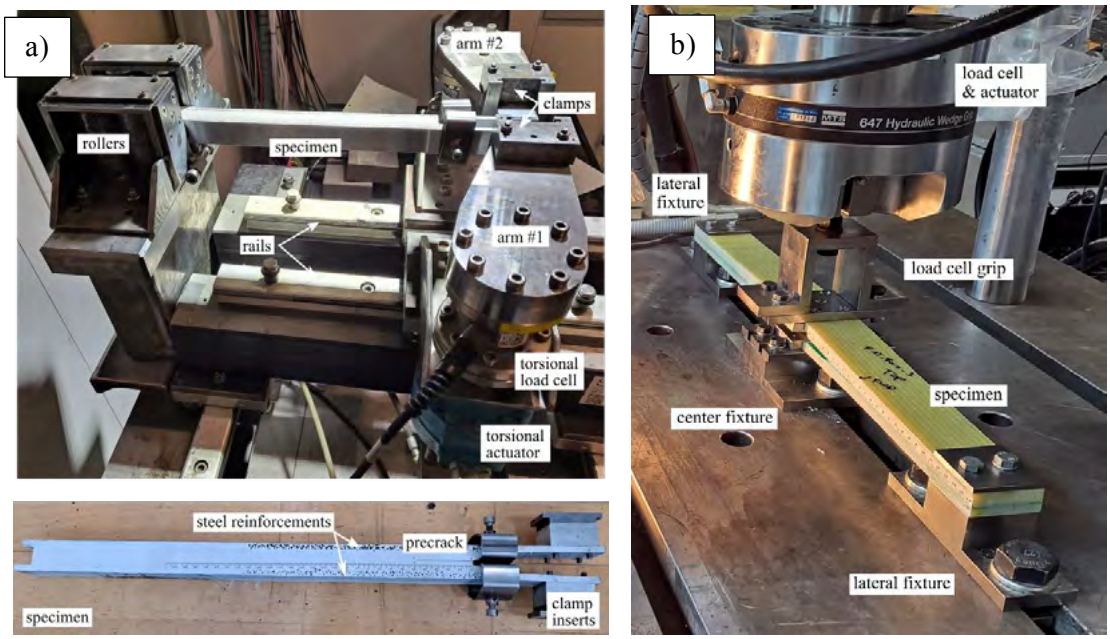

Figure 3. Test set-up. a) DCB-UBM, b) MTT

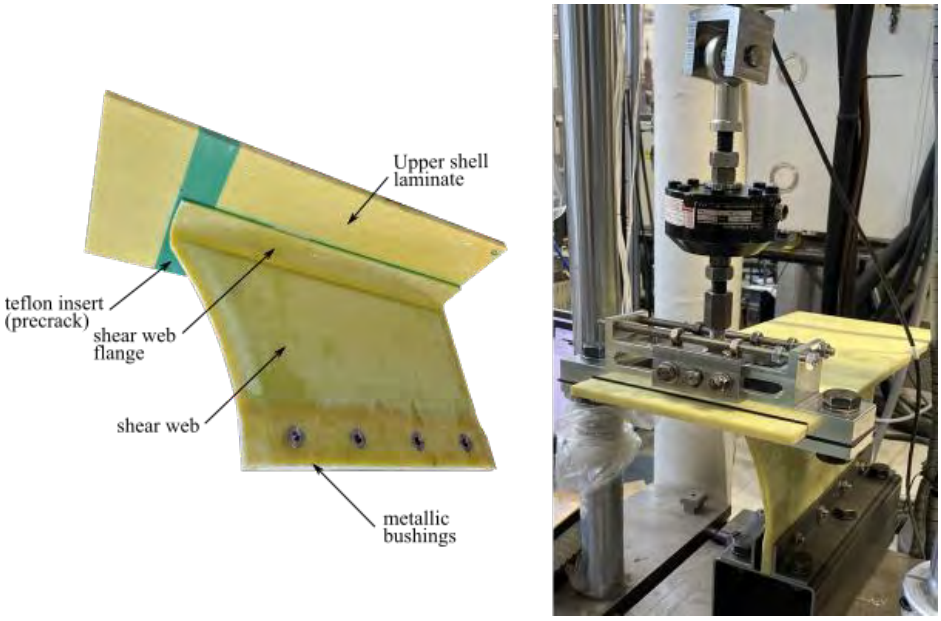
Subsequently, two subcomponent scale levels have been carried out to study. The first, using a Modified Tear Test (MTT) with simplified geometry and loading in which the variation of fracture mode mixites is accounted during the crack propagation process. The Modified Tear Test (MTT) is derived from the Sandwich Tear Test (STT) method in which the upper laminate is pulled upwards, so the in-plane membrane forces escalate significantly as the test proceeds (Figure 3.b). This escalation leads to an increase in the mode-mixity angle, transitioning from an initial pure mode I opening condition to mixed fracture modes (opening and shear). Finally, the second subcomponent test or Shear Web Disbond Test (SWDT) is based on a more complex geometry and loading conditions which replicates a simplified portion of a real 3rd shear web paying particular attention to the bonded interface between the shear web flange and the blade outer shell. The top laminate and shear web flange have the same composite layup as those used in level-I and level-II tests.



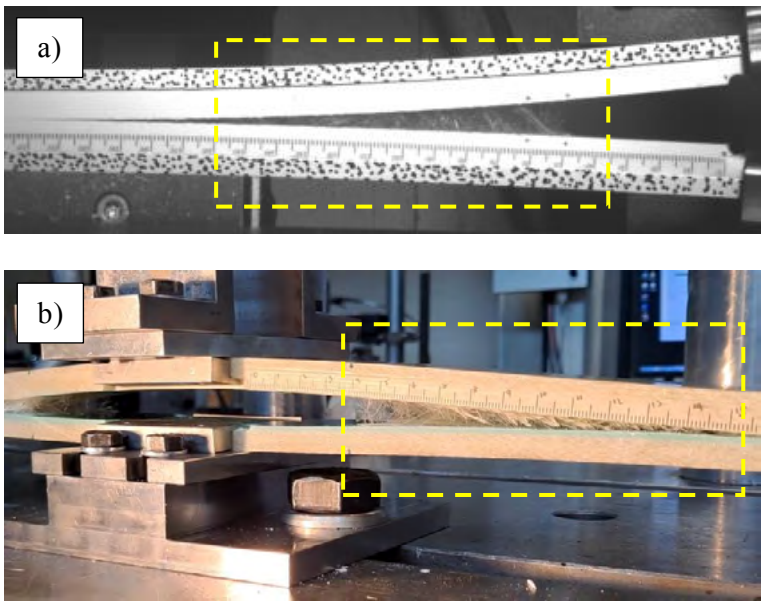


Figure 4. SWDT experimental set-up

Tests at all different scale levels for quasi-static and fatigue crack growth show the presence of large fibre bridging zones which dominate the fracture process. In short, the fibre bridging phenomenon occurs when the fibres in neighbouring laminate plies bridge the debonding plane, serving as crack arrestors. As a result of fibre bridging, the debonding resistance, inter-laminar fracture toughness and fatigue crack growth are enhanced.

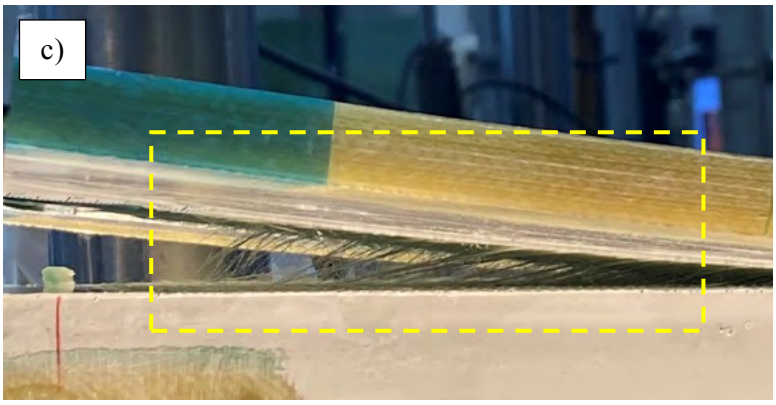

Figure 5. Fiber bridging at different scale level tests.
a) DCB-UBM, b) MTT, c) SWDT

3. Modelling fiber bridging with the cohesive zone approach

The non-linear nature of the fiber bridging phenomena can be addressed by Cohesive Zone Modeling (CZM). In this approach, the fracture process zone (FPZ) is substituted with a cohesive region, where the exchange of stress between the two artificial crack surfaces is defined using a relationship between the traction and separation of the FPZ. This relationship is then incorporated into the non-linear constitutive behaviour of the material. In practical FEA analysis, the cohesive zone model is commonly applied by a single layer of cohesive elements, which are placed along the expected path of crack propagation. It is generally agreed that the key parameters of traction-separation law can be obtained from direct experimental testing (Sørensen, 2022) although some other studies have used calibration methods based on trial-and-error search methods (Barbero et al., 2013) or a combination of both.

An extension of this quasi-static method is to consider the degradation of the traction-separation response due to fatigue cycles. This degradation as proposed by (Khoramishad et al., 2010) follows a predefined power law such that coefficients must be calibrated against experiments.

For the DCB-UBM and MTT cases, two-dimensional FEA models were generated in Abaqus 2021. The laminates and adhesive layer are modelled as separate geometric bodies joined at the interface using a tie constraint. The laminates are modelled as orthotropic materials while the adhesive material and the material for the doubler stiffeners an isotropic materials. Quasi-static tests are run using the standard/linear solver while the fatigue test uses an explicit solver. For the fatigue model, the damage criteria are described in section 2.2. was implemented in a VUSDFLD Fortran subroutine and computational time is accelerated by applying the cycle jump technique (Moslemian et al., 2011) within the subroutine. An example of the good correlation that can be achieved between experimental and FEA model results is presented in Figure 6.b. for a DCB-UBM test.

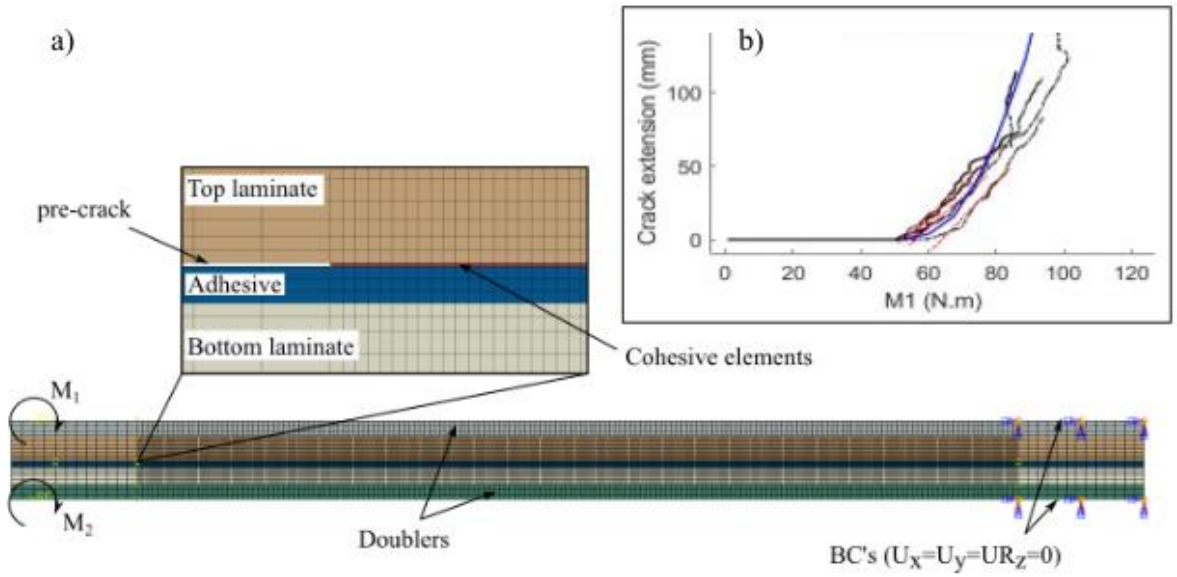

Figure 6. a) FEA model for DCB-UBM test using the CZM, b) Comparison between FEA model and test results for a quasi-static DCB-UBM test. Experimental (black), FEA (blue). a) MR = -1.2

In the case of the SWDT a fully detailed 3D FEA model was implemented in Abaqus to study the behaviour of the shear web specimen and the fracture behaviour at the bondline in both quasi-static and fatigue loading conditions. A detailed 3D CAD model was initially prepared in SolidWorks which includes the most important geometrical features of the specimens (e.g. shear web flange, local reinforcements, core-laminate transition, laminate drop-offs, insert holes). Each part was imported independently in Abaqus as a 3D solid and modelled with 8-node linear brick elements with reduced integration (C3D8R). Contact interactions and tie constraints were applied between interacting bodies as required. The bondline is modelled using cohesive elements using the same traction separation in the same way as in the previous scale levels a 3D FEA model is adopted due to the level of detail required to reproduce the geometry and load pattern. A more extensive description of the results and limitations of the current implementation can be found in (Gomez & Berggreen, 2023).

Conclusions

A building block methodology has been implemented to study crack initiation and propagation in bonded joints of glass fibre laminates and epoxy adhesives, typically encountered in shear webs in wind turbine blades. The phenomena have been studied from an experimental and numerical perspective at three different levels of complexity. Tests show that the crack propagation behaviour is dominated by a large fibre bridging zone in the bondline which acts as a toughening mechanism, particularly at small mode mixites phase angles (mode I opening-dominated fracture). It was also possible to obtain the traction-separation law directly from the experiments for a range of phase angles by measuring crack tip displacements and applying a data reduction method. The proposed 2D FEA models capture with accuracy the crack onset and crack propagation observed in experimental testing. A novel approach to model fatigue crack growth in the bondline was successfully implemented through a material user subroutine in which a fatigue damage law is coupled with the cycle jump technique. The same 2D FEA model was used to calibrate the fatigue damage law parameters using trial-and-error search methods. However, it was not possible to find a combination of material parameters that fully validate the experimental data. Implementation of the CZM into a full 3D method is still an active subject of research with promising applications for detailed component analysis.

Keywords: Hydrostatic buckling, Carbon fiber reinforced plastic (CFRP) composites, Sandwich structure, Corrugated core, Finite element analysis (FEA)

Abstract
In this study, buckling behaviors of composite cylinder and sandwich structure with corrugated core (SSCC) were investigated through finite element analysis (FEA). The composite cylinder and sandwich structure skins were composed of twill woven carbon fiber reinforced plastic (CFRP) composites and cores of sandwich structure were composed of 3D printed CFRP composites with continuous carbon fiber filament. In the case of SSCC, corrugated cores could be split according to their length, and split cores were rotated by 18 degrees. To derive critical buckling pressure, FEA simulation was conducted for composite cylinder and sandwich structures. As a result, the SSCC showed higher critical buckling pressure than that of the composite cylinder. Furthermore, different buckling behaviors were observed with number of cores. Critical pressure was improved with more split cores. Especially, sandwich structure with maximum multiple cores showed about 2 times higher critical buckling pressure compared to the sandwich structure with single core.

1. Introduction

Underwater vehicles are designed with cylindrical structures that have relatively small external diameters than length to operate smoothly in underwater environments. These cylindrical structures are vulnerable to external loads due to their geometry, and buckling can occur at lower strength than the material's strength [1,2,3]. Therefore, buckling analysis under hydrostatic pressure should be considered to design underwater vehicle.

Various studies have been conducted to apply carbon fiber reinforced plastic (CFRP) composites to hulls such as ships and underwater vehicles (UVW) in the marine field due to their advantages such as high mechanical properties with light weight and corrosion resistance etc. [4,5,6]. C. J. et al., investigated effect on winding angle of CFRP composites, so they anlayzed buckling characteristics and failure of thick-walled filament wound CF/epoxy cylinders under external hydrostatic [7]. Lee et al. studied optimization of composite sandwich cylinders to increase the design load considering buckling and material failure [8].

In our previous study, energy storage-corrugated lattice core sandwich structures were designed to not only protect battery but also achieve superior mechanical properties [9]. Moving forward, the buckling behaviors of composite cylinders and sandwich structures with corrugated cores were analyzed for application in underwater vehicles. To anlayze buckling behavior of composite cylinder, linear buckling analysis was referenced in our study under samd boundary and load conditions [5]. Additionally, buckling behaviors of sandwich structures with corrugated lattice core was analyzed according to core length under hydrostatic pressure through FEA.

2. Finite Element Analysis

2.1. Buckling simulation

To analyze buckling of structure, finite element analysis was performed using the commercial program ABAQUS for two structures: single composite cylinder (SCC) structure and sandwich structures with corrugated core (SSCC). The SCC structure was designed with thickness of 1.5 mm, external diameter of 210 mm and length of 450 mm. The SSCC are divided into two skins and core parts, which had thickness of 1.5 mm and 2 mm, repectively. It was modeled with the same external diameter of 210 mm and length of 450 mm. The core of sandwich structure was designed in our previous study [9] (shown in Fig 1.(a)) and it can be split along its length. In this study, while maintaing the same overall length, the core was divided into several segments of equal legnth. Each divided core segment was placed with rotation angle of 18 degrees in the sandwich structure. The core number by length is noted such as C1, C2. The geometry of single core was presented in Fig 1.(b) and separated cores rotated by 18 degrees also in Fig 1.(c).

Figure 1. Geometrical model of (a) corrugated core (cross section), (b) single core of C1, and (c) separated cores of C2.

The SCC and skins of SSCC were characterized by the properties of CF/epoxy twill prepreg (CPF-3327, 353 gsm; TB Carbon, Korea), and the corrugated cores by the properties of continuous carbon fiber (CCF) filament (Markforged, USA) provided by the manufactures (Table 1). To calculate eigenvalue in FEA, both structures were modeled using continuum shell elements (SC8R), and end cover was modeled using shell model (S4R). The boundary conditions were set such that one end was fixed while the other end allowed only axial displacement. The pressure applied to the external face contacted with water such as outer skin and end cover (Fig 2.).

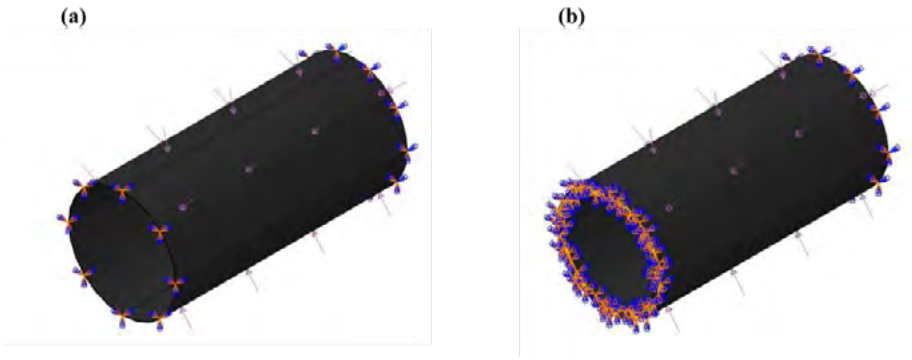

Figure 2. Simulation conditions of (a) composite cylinder structure and (b) sandwich structure with corrugated core.

Table 1. Material properties provided by manufacturer.

Properties	Symbol	CF/epoxy twill	CCF filament
Elastic modulus [GPa]	E_1	56.0	60.0
	E_2	56.0	22.4
Shear modulus [MPa]	G_{12}	4.6	5.0
	G_{13}	4.6	5.0
	G_{23}	2.3	2.5
Poisson's ratio	ν_{12}	0.3	0.33
Tensile strength [MPa]	X^T	430	726
	Y^T	430	115
Compressive strength [MPa]	X^C	340	320
	Y^C	340	131

3. Result and Discussion

3.1. Linear buckling of cylindrical composite

As a results of the linear buckling analysis for a SCC made with twill woven fabric, buckling deformation occured in the cylinder's overall shape. The Fig 3. shows displacement magnitude of the composite cylinder buckling with scale factor of 20. The red region showed significant deformation, while the blue region showed relatively less deformation, displaying a four-lobed shape in the first mode (Fig 3.). The critical buckling pressure derived from the linear analysis was 0.3 MPa. Furthermore, large mode shape has more

3.2. Buckling analysis of sandwich structure with corrugated core

The buckling analysis of the sandwich structure showed more complex buckling shapes compared to a composites cylinder due to the support by the core. Because the internal core supporting the skin enhanced buckling load, SSCC have critical load more than 10 times that of the composite cylinder. The Fig 4. presents the critical load of the first buckling mode of the sandwich structure according to core length, and it also shows first buckling mode shape. In Fig 4., a sandwich structure with a single core (C1) showed buckling across the entire skin similar to composite cylinder (SCC). However, as the number of separated and rotated cores increased, localized buckling behavior was observed. Furthermore, as the number of cores increased, there was a significant increase in the critical buckling load. The sandwich structure with the most separated cores at a core length of 50 mm (C9) showed more than 1.7 times increase in critical bucking strength compared to the structure with a single core (C1).

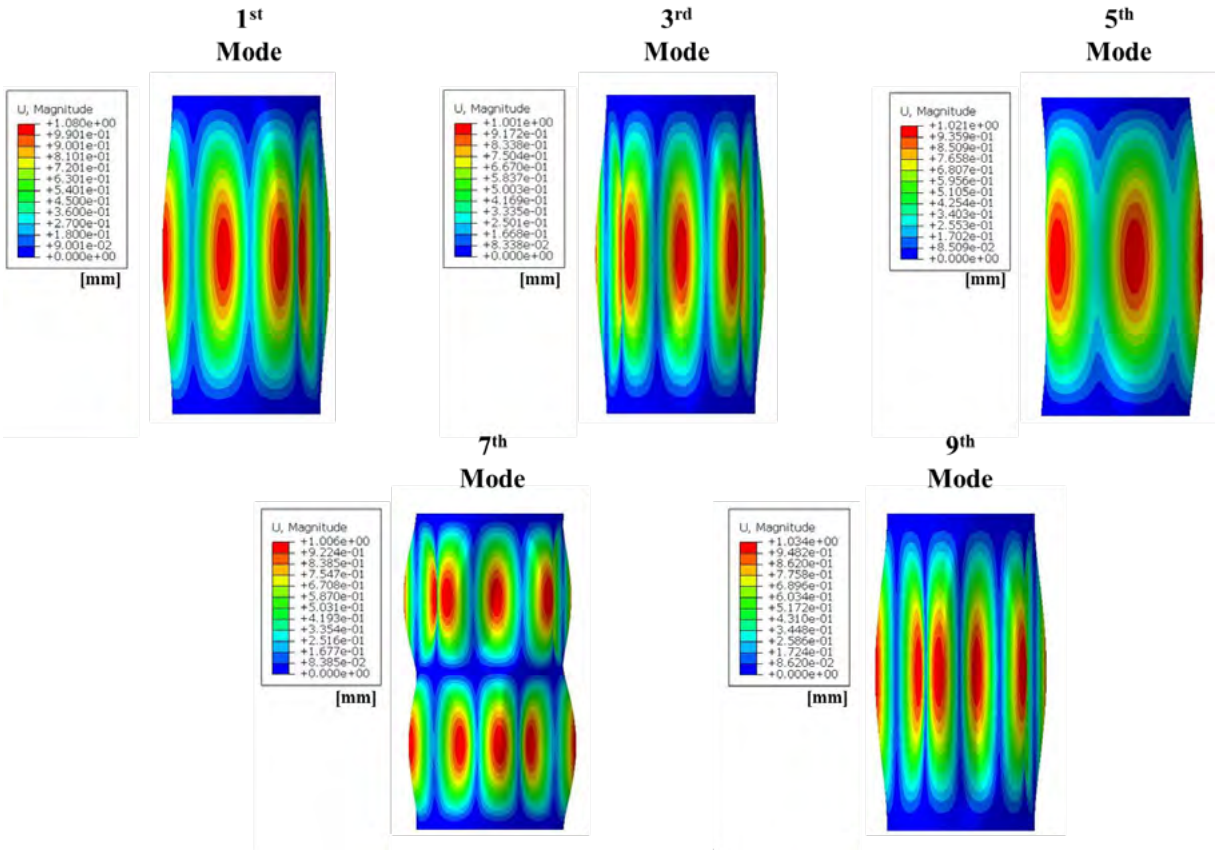

Figure 3. Linear buckling mode shape of cylindrical composite

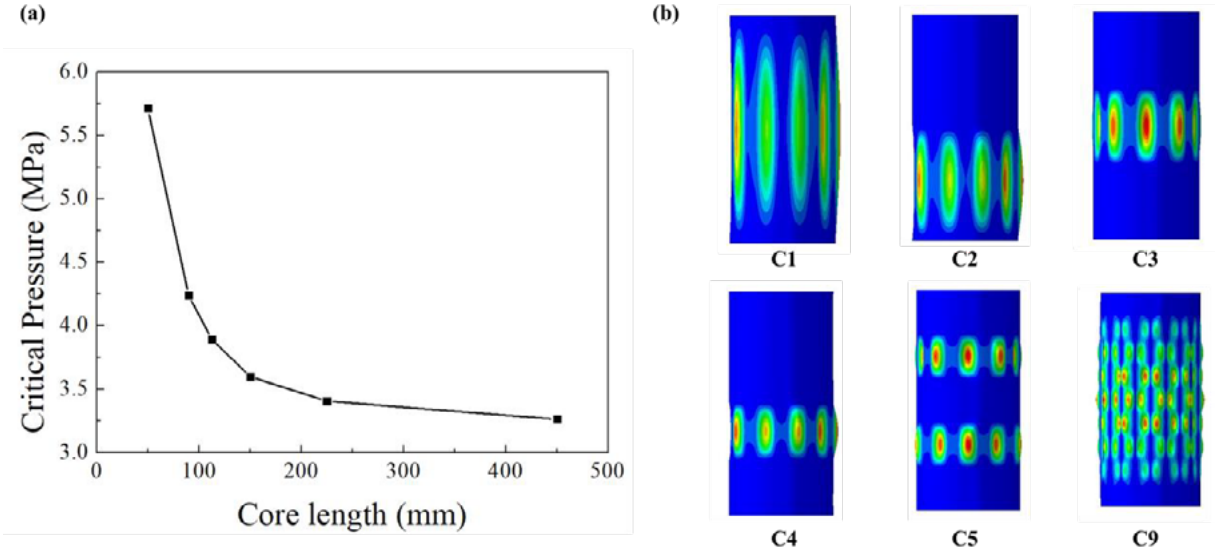

Figure 4. Linear buckling simulation results of sandwich structure according to core length: (a) critical pressure, and (b) first mode shape.

4. Conclusion

In this work, a sandwich structure which was designed with corrugated core was applied to underwater vehicle, and a buckling analysis under hydrostatic pressure was conducted using FEA. For cylinders composed with twill woven CFRP composites, the buckling load was around 0.3 MPa. On the other hand, buckling load of SSCC was enhanced more than 10 times that of the composite cylinder due to the internal core supporting the skin enhanced. Moreover, the critical buckling pressure increased as having more split cores. However, in the case of buckling failure, the actual buckling occurs at a lower pressure than the linear buckling pressure due to the nonlinearity in the manufacturing process such as imperfection. Additionally, to analyze failure of SSCCs under hydrostatic pressure, the relationship between buckling and material failure should be considered. Therefore, it will be anlyzed and verified in nonlinear analysis of composite cylinder and sandwich structures to predict the actual buckling pressure with experiment in next step.

Abstract
As the demand for high-performance composite structures increases, the manufacturing of composite materials continues to be a very active research field, seeking to attend to such demand by improving the quality of manufactured components with reduced costs. One of the research topics involves manufacturing process control. Controlling such processes can be challenging due to the difficulty of placing sensors at the required locations, so a technique known as virtual sensing is preferred. This technique implyes having a detailed model of the process, and such model requires running in real time along the process itself. Depending on the process complexity, the model cannot run in real time, so alternative methods must be researched. In this work, a soft computing approach is presented based on artificial neural networks trained using physics equations. The goal is to determine the temperature distribution along a composite material inside a mould. This approach also includes a framework to define an adimentional set of geometry and the thermal properties of the materials involved.

1. Introduction

Before a composite process begins to produce structures, some studies are performed to determine the optimal manufacturing conditions. A recently developed strategy to address such topics is the Virtual Testing [1, 2, 3]. It has been developed as an approach that employs simulation tools for analyzing composite structures, beginning with conceptualization and, more recently, throughout the production process.

During the conceptualization part, researchers develop advanced numerical simulations [4], not only for design purposes but also to determine appropriate manufacturing process conditions to attend to the strict design requirements of high-performance structures.

Once those conditions are determined, the next step is to produce the structure. Typically, the manufacturing process conditions won't change once the process starts. This is due to the difficulty of placing sensors to monitor its progress, which allows a system to compute control actions by closing a control loop, which increases the probability of producing a structure that does not meet the required performance.

To close the control loop, a typical strategy consists of using a state estimator. The state estimator uses the gathered information about the process input variables and boundary variables to estimate its state. To achieve that goal, this strategy requires a model to simulate the process in real time, which can be challenging to implement.

This work explores a framework for a state estimation strategy using Physics-Informed Neural Networks (PINN). Recently, PINNs have been implemented to solve problems by fast computing system predictions [5, 6, 7]. It bases its predictions on the initial state of a process and its interactions with its bounds by proposing a Neural Network as the solution to the differential equation that describes the process. As a demonstration, it is used in the heating stage of a Resin Transfer Mould process.

2. Physics-Informed Neural Networks

To understand the working strategy of a PINN, it is recommended to first understand the formulation of an artificial neural network.

2.1. Artificial Neural Networks

Artificial Neural Networks have been developed since the 1950's inspired by rats cortex functioning [8, 9]. A Neural Network is a set of simple computational units, perceptrons, Fig. 1a, where a set of inputs is multiplied by weights and its sum with a bias is sent to an activation function.

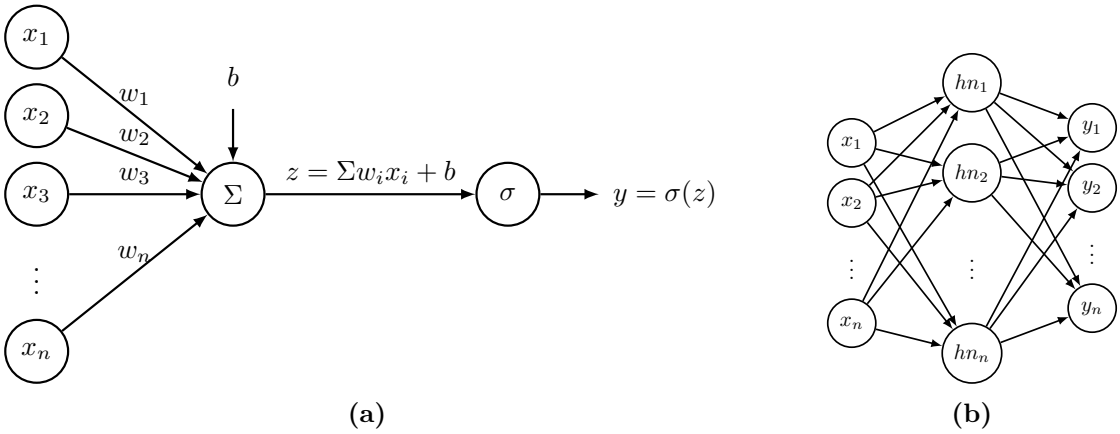

Figure 1: Graphical representation of a Perceptron (1a), and a Neural Network (1b)

In Neural Network a set of inputs can feed a set of perceptrons, forming a layer, and an entire neural network is composed of multiple of those layers, Fig 1b.

For the training process for the neural network, it is generally required to have a set of data with real inputs and real results from such input data over the real system. Then, weights w_n are initialized with a random number. The input data x_n is evaluated to obtain a result y_n. Such result is compared with the real result that such input is supposed to obtain. The difference between those values are used by an optimization algorithm to compute a net set of weights w_n

to reduce such gap. The process is repeated until that gap is zero or lower than a tolerance value.

2.2. Physics-Informed Neural Networks

The concept of a PINN is similar to that of a regular neural network. A PINN was first suggested in 1998 as an alternative to solving differential equations [10]. The training stage is the main difference between a regular neural network and a PINN. For a PINN, the training data does not have the output values; instead, the network has to solve a differential equation that is forced to be zero. For the PINN strategy, the neural network is suggested as a solution for the differential equation shown in Eq. 1; the solution is of the form of $f(x) = \mathcal{N}(X, w, b)$.

$$\frac{\partial f(x)}{\partial x} - g(x) = 0 \tag{1}$$

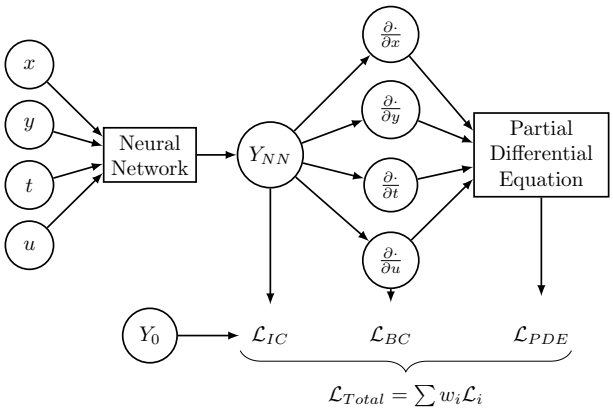

Figure 2: Physics-Informed Neural Network graphical representation

The differential equation is evaluated by deriving the found solution $f\mathcal{N}(X, w, b)$ with respect to the input variables, evaluating the input data values, and then checking the error generated by evaluating the differential equation. This derivative is possible by applying the chain rule or, more recently, by using an automatic differentiation algorithm [11].

3. Methods and materials

In this section, we present the details of the problem used to test the proposed methodology, which aims to utilise a dimensionless model compatible with neural networks.

3.1. Framework

Let's suppose a two-dimensional heat transfer problem, whose general equation is presented in Eq. 2.

$$\frac{\partial T}{\partial t} = \frac{k}{\rho\, c_p}\frac{\partial^2 T}{\partial x^2} + \frac{k}{\rho\, c_p}\frac{\partial^2 T}{\partial y^2}, \tag{2}$$

where T is the temperature of the material, t is the time, k is the thermal conductivity, ρ is the material density, and c_p stands for the specific heat capacity.

Let's suppose that the problem is a rectangle in which x direction has a length of L and the

y direction has a length of H, where $L > H$. The goal is to use the x direction length as a reference, so the following variables change are proposed: Eq. 3 and Eq. 4.

$$x = \chi\, L \tag{3}$$

$$y = \psi\, H \tag{4}$$

where $H = a \cdot L$, and a is a proportioonal constant, and χ and ψ are dimensionless variables in the following range $[0, 1]$. On the other hand, for the time variable change, as it has to maintain the dimensionless nature of the main equation, the proposed variable change is expressed in Eq. 5.

$$\frac{\rho \cdot c_p \cdot L^2}{k}\tau, \tag{5}$$

where τ is the temporal dimensioless variable in the range $[0, \infty)$. The last variable change is related to the temperature, where a dimensionless temperature variable in the range of $[0, 1]$ is proposed as shown in Eq. 6.

$$\theta = \frac{T - T_o}{T_m - T_o} \tag{6}$$

where θ is the dimensionless temperature, T is the temperature at a specific location, T_m is the maximum expected temperature, and T_o is the minimum temperature. Replacing Eq. 3, Eq. 4, Eq. 6 and Eq. 5 into Eq. 2 and making all the variable manipulation, we can obtain the dimensioless expression presented in Eq. 7.

$$\frac{\partial \theta}{\partial \tau} = \frac{\partial^2 \theta}{\partial \chi^2} + \frac{1}{a^2}\frac{\partial^2 \theta}{\partial \psi^2}, \tag{7}$$

where the coefficient a^2 stands to correct the geometrical difference between the x and y directions.

3.2. Case of study

Resin Transfer Moulding is a composite manufacturing process that consists of injecting resin into a mould filled with a type of reinforcement. In some cases, the mould needs to be at a certain temperature for the process to take place. Let's consider a section at the interface between the mould and the composite material as presented in Fig. 3. We would apply the framework presented in Section 3.1 for the material 1.

For material 2, as it is a composite, it is expected that the thermal properties, specifically the thermal conductivity, will be different for the x and y directions. The same framework is applied, according to the thermal and physical properties of material 2 presented in Table 1.

When working with a composite material, the framework has to be applied to both materials, always referencing material 1 for the properties and the length along the x direction. For this case, the differential equations to be solved by the PINN strategy for material 1 and material 2 are Eq.8 and Eq. 9 respectively.

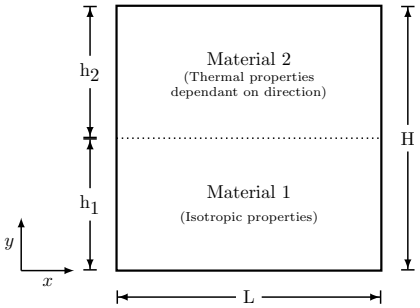

Figure 3: Schematic of the interface mould-composite

Table 1: Material's properties

Property	**Material 1**	**Material 2**
Thermal conductivity	1.0	10.0 (x direction)
		0.01 (y direction)
Specific heat	1.0	15.0
Density	1.0	5.0

$$\frac{\partial \theta}{\partial \tau} = \frac{\partial^2 \theta}{\partial \chi^2} + 400\,\frac{\partial^2 \theta}{\partial \psi^2} \tag{8}$$

$$\frac{\partial \theta}{\partial \tau} = 0.13\,\frac{\partial^2 \theta}{\partial \chi^2} + 0.053\,\frac{\partial^2 \theta}{\partial \psi^2}, \tag{9}$$

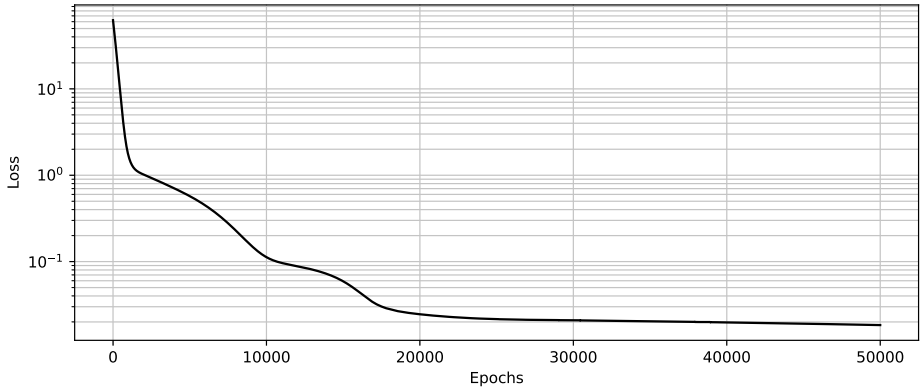
where the geometrical factor is reflected as the coefficient of the second term in Eq. 8, the coefficient of the first term of Eq. 9 stands for the property correction, and a combination of geometrical and property coefficients is present at the second term of the same equation.

For demonstration purposes, the boundary conditions in this case will be defined as follows:

- The initial condition will be set to a uniform temperature of 0.2
- The right-hand side of the domain will be adiabatic, as well as the left-hand side od the domain
- The bottom surface will be set at a constant temperature of 0.6
- The upper surface will be set at a constant temperature of 0.2

4. Results

The neural network architecture used consists of 4 inputs, 3 hidden layers of 15 neurons each, and one output. The inputs are: x coordinate, y coordinate, t time step, and the initial temperature T_0 for each pair of coordinates x, y. A set of 121 collocation points was selected, dividing the x direction into 11 parts as well as the y direction and 301 time steps. 50000 epochs were used to train the entire model. Fig. 4 shows the loss evolution along the training stage of the neural network.



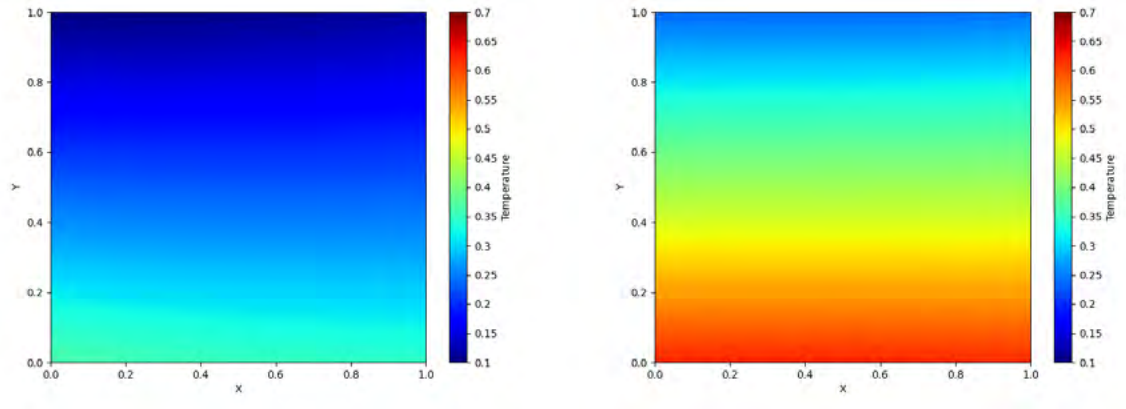


Figure 4: Train loss along the 50000 epochs

(a) **(b)**

Figure 5: Temperature distibution for the initial conditions (5a). Temperature distibution for the final conditions (5b)

The results presented in Fig. 5a show the temperature distribution at the initial conditions. The non-uniformization of data can be attributed to the randomness of the initialization of the neural network.

Fig. 5b shows the temperature distribution after a simulation of 1.5 τ. It is visible that the lower half of the domain has a higher and more consistent temperature compared to the upper half, due to the difference between the thermal conductivities of both materials.

5. Conclusions

In this work, a neural network was trained using the proposed framework. This framework allows us to address the orthotopic nature of composite materials, referring to their thermal properties, to handle the physics of the problem.

The framework allows the inputs of the resulting neural network to be on the same scale, guaranteeing the numerical stability of the method.

This framework can be scalable to any geometry in a two-dimensional plane, allowing its implementation to solve similar problems. On the other hand, as the framework does not depend on

units, it can be used to comprare two similar systems with different dimensions.

Keywords: fatigue, notch effect, fading notch sensitivity, stress ratio, analytical model

Abstract
Constant amplitude fatigue tests are performed on notched specimens of a woven fabric carbon/epoxy laminate for different notch sizes and stress ratios, respectively, and the effects of these factors on the notched fatigue behavior are examined. A new model applicable to the notched fatigue of compsoites is developed which can predict the notched S-N relationship for any notch size and stress ratio by means of the unnotched S-N relationship for the same value of stress ratio. The capability of the model to predict the notch sensitive and insensitive bounds of fatigue life for a given composite with help of the unnotched fatigue bahavior is highlighted. It is shown that the proposed method can successfully predict the notched fatigue life of the woven CFRP laminate for different notch sizes and stress ratios.

1. Introduction

Structural components in engineering applications often contain notches or holes. Because of stress concentration caused by those stress risers, the local failure in machines and structures during service is apt to initiate at the edges or in the vicinity of the notches or holes involved. The degree of reduction in strength of a carbon fiber-reinforced plastic (CFRP) laminate due to a notch is governed by the intensity of stress concentration in the vicinity of the notch that is affected not only by the inherent elastic anisotropy but also by the multiple non self-similar cracking in the composite laminate. This suggests that a CFRP laminate exhibits a notch sensitivity within the notch sensitive and insensitive bounds, depending on stacking configuration as well as on damage in the vicinity of notch tips. A more important suggestion in the present context is that the notch sensitivity of a CFRP laminate may not be constant but it may be changed during service depending on the accumulation of damage at notch tips as well as in the ligaments that controls the progressive dissipation of local strain energy.

The notch effect in fatigue of CFRP laminates is practically very important for accurate evaluation of their fatigue lives [1]. Notched fatigue of composites is considered to be affected by the stress ratio of fatigue loading, since the difference in load waveform has a significant influence on the fatigue strength in their unnotched configuration [2, 3]. The change in notch sensitivity during fatigue loading, however, has not quantitatively been examined for carbon fiber composites subjected to different *R*-ratio loadings. In order to fully understand and quantify the wear-in and wear-out behaviors of notched CFRP laminates [4], we need more systematic studies on their notched fatigue behaviors from both experimental and modeling points of view.

In the present study, fatigue tests are performed on unnotched and notched woven fabric carbon/epoxy laminate specimens for different notch sizes as well as for different stress ratios, respectively, including tension-tension (T-T), tension-compression (T-C) and compression-compression (C-C) waveforms, at room temperature. Experimental results show a gradual decrease in sensitivity to a notch during fatigue

loading, regardless of stress ratio. A measure of fatigue notch sensitivity is defined, and it is successfully used to quantify the transient notch effect on fatigue by contrasting the observed unnotched and notched S-N relationships for each of different R-ratios. A simple and effective model is developed to predict the notched fatigue life of a given composite for any notch size as well as for any stress ratio. A further development into a more general version is attempted that allows describing the gradual decrease in fatigue notch sensitivity with cyclic loading. It is also demonstrated that the general notched fatigue life prediction model can describe the wear-in behavior of residual notch strength of the woven composite taking into account the effect of R-ratio.

2. Specimen and experimental procedure

2.1. Material

Carbon fiber plain weave roving fabric laminates were used. The woven prepreg cloths were made of carbon fibers T300 (Toray) and thermosetting epoxy resin #2500 with the curing temperature of 130°C. A woven CFRP laminate consists of 12 sheets of prepregs aligned in the same orientation and molded using an autoclave.

Central circular-hole specimens were employed. The length and width of the circular hole specimens are identical to those of the unnotched specimens (L = 10 mm, W = 10 mm). The circular holes were machined using a drill with a special jig. The relative notch sizes D/W, which are the ratios of the diameter D of the circular hole to the specimen width W, were set to D/W = 0.1, 0.2, and 0.4 for static tests and to D/W = 0.1 and 0.4 for fatigue tests.

2.2. Testing

Constant amplitude fatigue tests were performed under load control at room temperature with a sinusoidal waveform at a constant frequency of f = 10 Hz. To examine the effect of stress ratio (fatigue waveform) on S-N behavior, constant-amplitude fatigue tests were performed for different constant values of stress ratio R, which is equal to the ratio of minimum stress to maximum stress $\sigma_{min}/\sigma_{max}$, respectively. Fatigue tests on unnotched specimens were performed at R = 0.5, 0.1, -0.5, -0.7, -1, -2, 10, 2, and $\chi_0 = \sigma_0^C/\sigma_0^T$, respectively, and on notched specimens at R = 0.1, -0.5, $\chi_N = \sigma_N^C/\sigma_N^T$, -2, and 10, respectively. The stress ratios indicated by χ represent the critical stress ratios [5] which is equal to the ratio of compressive strength to tensile strength of the unnotched and notched specimens, respectively.

3. Experimental results and discussions

The notched fatigue behavior of the woven CFRP is gentle. The notched S-N relationships are close to those obtained by the parallel shift of the unnotched S-N relationship to their lower stress sides by the difference between the unnotched and notched strengths, regardless of stress ratio and notch size.

To observe the effect of stress ratio on the notched fatigue behavior, the notched S-N data are normalized using the associated static notched strength (ψ_N), and the results for D/W = 0.1 are shown in Fig. 1. We can see that the slope of the notched S-N relationship is the largest for the fatigue loading at the notched critical stress ratio, irrespective of notch size. This observation reveals that the concept of critical stress ratio [5], which was confirmed for the unnotched fatigue of the woven CFRP laminate, also holds true for the notched fatigue of the composite tested.

The difference in the shape of the S-N relationship between the unnotched and notched specimens is examined. For this purpose, the S-N data are normalized using their associated static strength. For the unnotched specimens, the fatigue stress is normalized using the unnotched strength (ψ_0). For the notched specimens, the normalization with respect to the static notched strength (ψ_N) and the normalization with respect to the notch insensitive strength (ψ_{NI}) are considered. The comparisons of the normalized notched and unnotched S-N data for R = 0.1 and 10 are shown in Fig. 2 and Fig. 3, respectively.

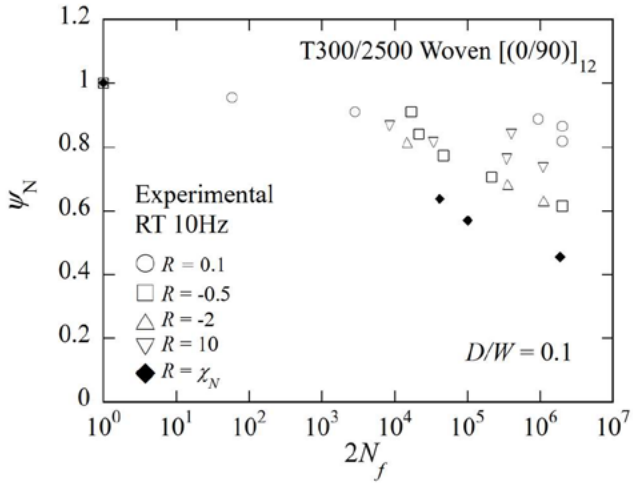

Figure 1. Comparison of notched S-N data for different stress ratios.

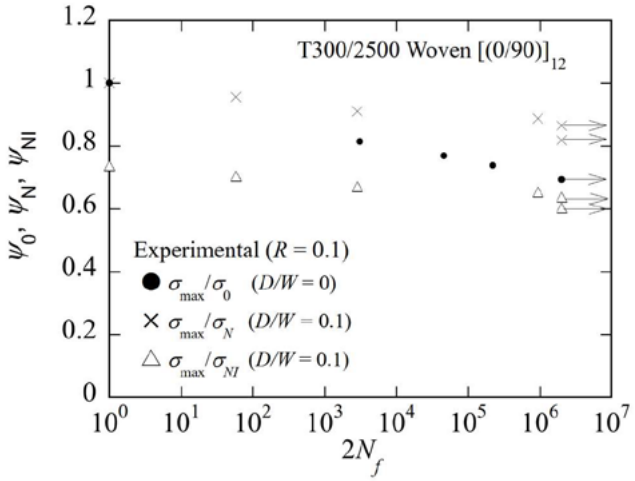

Figure 2. Notch effect on tensile fatigue for $R = 0.1$.

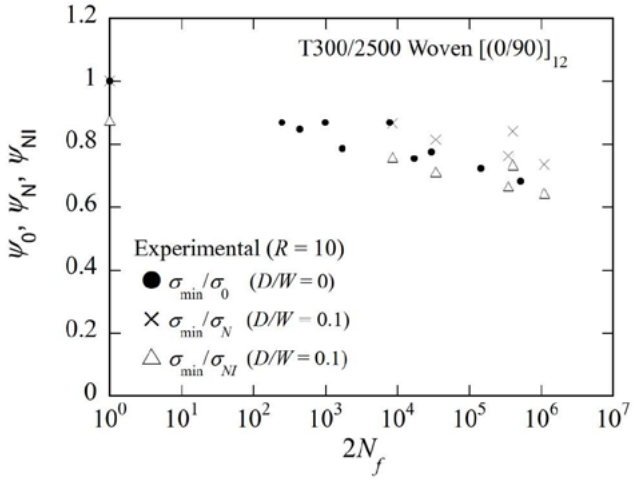

Figure 3. Notch effect on compressive fatigue for $R = 10$.

Compare the plots for the tensile fatigue at R = 0.1. The normalized S-N plots using ψ_{NI}, in which the fatigue stress is divided by the notch insensitive strength, start from the value of fatigue strength ratio smaller than 1 on the vertical axis since the notch insensitive strength is larger than the actual notched strength. In the range of low cycle fatigue, therefore, they are distributed away from the normalized S-N plots for unnotched specimens using ψ_0 to the lower side. As the number of cycles to fatigue failure increases, however, we can see that the normalized S-N plots using ψ_{NI} gradually approach the normalized S-N plots for the unnotched specimens. The latter observation suggests that the notched fatigue at R = 0.1 turns to be dominated by the unnotched fatigue of the ligaments in the high cycle range. In other words, the initial notch effect is fading and the notched fatigue behavior is changing to be notch insensitive.

Looking at the normalized S-N plots for the notched specimens using ψ_N for the tensile fatigue loading at R = 0.1, we can see that they start from the value of 1, since the fatigue stress is divided by the actual notched strength, along with the normalized S-N plots for the unnotched specimens using ψ_0. In contrast to the S-N plots using ψ_{NI} observed above, the normalized S-N plots using ψ_N gradually deviate from the normalized S-N plots for the unnotched specimens using ψ_0 to the upper side as the fatigue life increases. This observation means that the slope of the notched S-N relationship is smaller than that of the unnotched S-N relationship. Thus, the notched fatigue strength relative to the static strength at the onset of fatigue loading is larger than the unnotched fatigue strength. In other words, the fatigue notch sensitivity is lower than the static notch sensitivity for the tensile fatigue loading at R = 0.1.

The compressive notched fatigue behavior for R = 10 is complicated. In the case of the notch size D/W = 0.1, it is seen that the notched S-N data normalized using the notched strength and the notch insensitive strength (ψ_N and ψ_{NI}) are both distributed close to the normalized S-N data (ψ_0) for the unnotched specimens. A bit closer observation reveals that the normalized S-N data (ψ_N) with respect to the notched strength tend to be distributed slightly above the normalized S-N data (ψ_0) with respect to the unnotched strength in the range of high cycle fatigue. Conversely, the normalized S-N relationship with respect to the notch insensitive strength (ψ_{NI}) tends to be slightly below the normalized S-N relationship for the unnotched specimens in the high-cycle range. However, the difference in normalized stress in the high-cycle range is small in both cases using ψ_N and ψ_{NI}. This prompts us to consider that the notch effect may have substantially disappeared in the high cycle range.

Observing the results for D/W = 0.4, we can see the normalized S-N data using the notched strength are distributed slightly above the normalized S-N data for the unnotched specimens, similar to the case for D/W = 0.1. As for the normalized S-N plots with respect to the notch insensitive strength, we can see they are clearly away from the normalized S-N plots for the unnotched specimens to the lower side, and they seem to be almost parallel to each other up to the high cycle range. The latter observation suggests that the normalized S-N relationship using the notch insensitive strength does not fully approach the normalized S-N relationship of the unnotched specimens even in the high cycle range. This feature observed in the notched fatigue for D/W = 0.4 implies that the decrease in notch sensitivitywith fatigue is small and thus the notched fatigue behavior is moderately notch sensitive even in the high-cycle range. In another compression-dominated notched fatigue at the stress ratio R = -2, we observed similar effect of notch on fatigue behavior as well. The compressive notched fatigue behavior thus suggests an influence of notch size.

4. Modeling of notched fatigue behavior

4.1. Fatigue notch factor

In order to establish a quantitative relationship between the unnotched and notched S-N relationships for loading at the same stress ratio, the fatigue notch factor is defined as

$$K_{f(net)}(N_f) = \frac{\sigma^0_{\max}(N_f)}{\sigma^N_{\max(net)}(N_f)} \tag{1}$$

The fatigue notch factor expresses the extent to which the presence of a notch reduces the fatigue strength of a notched specimen from the fatigue strength of a unnotched specimen. It is an important quantitative measure of the effect of notch on fatigue. Note that the variables with the subscript of *net* are on the net-section basis.

4.2. Equivalent notched fatigue strength ratio

Normalizing the unnotched and notched fatigue stresses in Eq. 1 using the associated static strengths, we can obtain the relationship between the fatigue strength ratios for unnotched and notched specimens;

$$\psi_N(N_f) = \frac{1}{K_f^*(N_f)}\psi_0(N_f) \tag{2}$$

where

$$\psi_N = \frac{\sigma_{\max}^N}{\sigma_N} \tag{3}$$

$$\psi_0 = \frac{\sigma_{\max}^0}{\sigma_0} \tag{4}$$

$$K_f^*(N_f) = K_{f(net)}(N_f)\frac{\sigma_{N(net)}}{\sigma_0} \tag{5}$$

The modified fatigue notch factor defined by Eq. 5 has an important role to play, because it can be interpreted as a transformation that relates the normalized S-N relationship for notched fatigue to the normalized S-N relationship for unnotched fatigue;

$$K_f^*(N_f)\psi_N(N_f) = \psi_0(N_f) \tag{6}$$

Defining the left-hand side of Eq. 6 as

$$\psi_N^*(N_f) = K_f^*(N_f)\psi_N(N_f) \tag{7}$$

we can express Eq. 6 as

$$\psi_N^*(N_f) = \psi_0(N_f) \tag{8}$$

Eq. 8 explains that the modified notched fatigue strength ratio defined by Eq. 7 is equivalent to the unnotched fatigue strength ratio for loading at the same stress ratio. Therefore, the modified notched fatigue strength ratio defined by Eq. 7 may be called the equivalent notched fatigue strength ratio.

4.3. Notched S-N relationship

As observed above, the notched fatigue behavior can be identified with the equivalent unnotched fatigue behavior with the help of the equivalent notched fatigue strength ratio. For fatigue loading at a constant stress ratio R, the S-N relationship for unnotched specimens is expressed as

$$2N_f = f_R(\psi_0) \tag{9}$$

Making use of the concept of equivalent plain material given by Eq. 8, we can express the notched S-N relationship as

$$2N_f = f_R(\psi_N^*) \tag{10}$$

4.4. Specific forms

The S-N relationship of unnotched composites for fatigue loading at a constant stress ratio R can be well described by means of the following fatigue function [6]:

$$2N_f = f_R(\psi_0) = \frac{2}{(1+k)K}\frac{1}{\psi_0^{\,n}}\frac{\langle 1-\psi_0\rangle^a}{\langle \psi_0 - \psi_{0W}\rangle^b} \tag{11}$$

where the coefficients $(1+k)K$, a, b, n, and ψ_{0W} are determined by fitting to the unnotched S-N data for a stress ratio of interest. Using the equivalent notched fatigue strength ratio and the unnotched S-N function, we can express the notched S-N relationship as

$$2N_f = f_R(\psi_N^*) = \frac{2}{(1+k)K}\frac{1}{\psi_N^{*\,n}}\frac{\langle 1-\psi_N^*\rangle^a}{\langle \psi_N^* - \psi_{0W}\rangle^b} \tag{12}$$

for fatigue loading at R.

4.4.1. Notch sensitive S-N behavior

In the case of notch-sensitive fatigue, the equivalent notched fatigue strength ratio may be considered as the notch sensitive fatigue strength ratio; $\psi_N^*(N_f) = \psi_N(N_f)$. Accordingly, the notch-sensitive S-N relationship can be expressed as

$$2N_f = \frac{2}{(1+k)K}\frac{1}{\psi_N^{\,n}}\frac{\langle 1-\psi_N\rangle^a}{\langle \psi_N - \psi_{0W}\rangle^b} \tag{13}$$

4.4.2. Notch insensitive S-N behavior

For a notch insensitive fatigue behavior, the equivalent notched fatigue strength is given as $\psi_N^*(N_f) = \psi_{NI}(N_f)$. The baseline strength at the onset of fatigue of notched specimens is the static notched strength. Taking into account this initial condition, we can express the notch insensitive S-N relationship as

$$2N_f = \frac{2}{(1+k)K}\frac{1}{\psi_{NI}^{\,n}}\frac{\langle 1-\psi_N\rangle^a}{\langle \psi_{NI} - \psi_{0W}\rangle^b} \tag{14}$$

The notch insensitive S-N model may be identified with the vanishing notch sensitivity model [7].

4.5. Comparison with experimental results

The notch-sensitive and notch-insensitive S-N relationships provide the lower and upper bounds of notched fatigue life. The predicted notch-sensitive and notch-insensitive S-N relationships for the woven CFRP laminate are compared with the experimental results in Fig. 4 and Fig.5 for R = 0.1 and 10, respectively. We can see that the measured notched S-N data are distributed between the notch-sensitive and notch-insensitive S-N relationships, regardless of stress ratio.

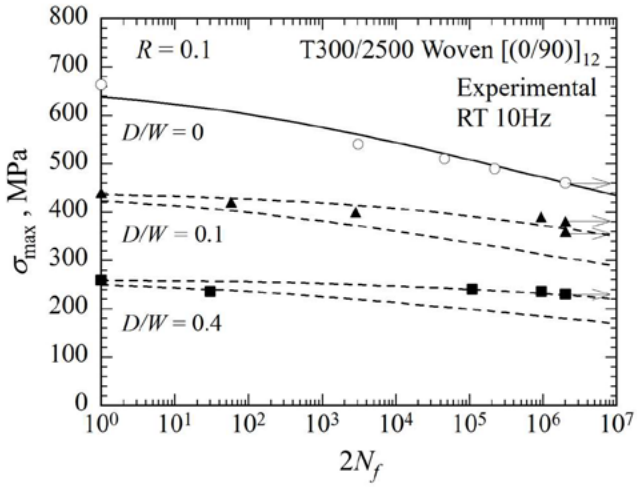

Figure 4. Notch sensitive and insensitive S-N relathionships for $R = 0.1$.

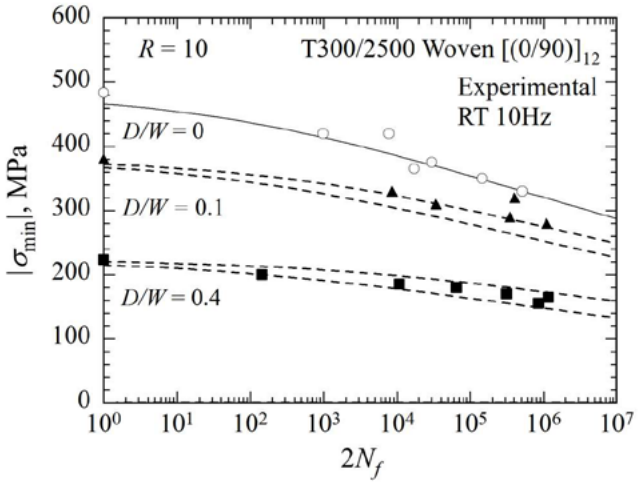

Figure 5. Notch sensitive and insensitive S-N relathionships for $R = 10$.

The notch-sensitive S-N relationship can be easily predicted utilizing the unnotched S-N relationship and the static notched strength. The notch sensitive S-N relationship represents the lower bound of notched fatigue life, and thus the use of it allows a conservative prediction of notched fatigue life, regardless of stress ratio. In case of no knowledge of the transition of fatigue notch sensitivity, therefore, the notch-sensitive S-N relationship is a safe choice. For compressive fatigue loading, as seen in Fig. 5, it is a good choice as well because the prediction is moderately conservative, not too much, and the degree of accuracy of prediction is acceptable. For tensile fatigue loading, however, the transition to notch insensitivity is rapid as seen in Fig. 4, so the use of the notch-sensitive S-N relationship for the actual notched fatigue behavior is too conservative while it is on the safe side. The latter observation suggests a need for developing a notched fatigue model that takes into account a stress-ratio dependent transition of fatigue notch sensitivity.

5. Conclusions

The effects of stress ratio and notch size on the fatigue behavior (S-N relationship) of plain weave roving fabric CFRP laminate were investigated in detail by experiments. Based on the comparison of the S-N relationships of unnotched and notched specimens for the same stress ratio, the fatigue notch factor was

defined, and the dependence on stress ratio and notch size was quantitatively elucidated. A method was developed to predict the S-N relationships of notched specimens for different constant values of stress ratio by means of the S-N relationships of unnotched specimens for the same stress ratios and the static notched strengths. It was shown that the notch insensitive and notch sensitive S-N relationships, which correspond to the upper and lower bounds of notched fatigue life, respectively, can be predicted easily using the unnotched S-N relationship and static notched strength and they actually bound the measured S-N data for notched specimens.

Further development into a more general methodology will be presented in which a gradually decreasing fatigue notch sensitivity is modelled taking into account the continuous reduction of notch sensitivity due to fatigue as well as its dependence on stress ratio. It allows to formulate a general notched fatigue life prediction method. The general notched fatigue life prediction method is applied to predict the S-N relationships corresponding to the experiments for different stress ratios, and they are evaluated by comparing with the experimental results. A capability of the gradually fading fatigue notch sensitivity model to predict the wear-in behavior of residual notch strength during fatigue loading is also demonstrated.

Keywords: moisture absorption, swelling, CFRP, modeling

Abstract
Water or moisture absorption causes swelling and plasticization of polymers and polymer matrices. The swelling of composite structures is a dominant factor in deteriorating the observational accuracy of space telescopes. Prediction of long-term deformation behavior for stable composite structures is essential for feasibility studies of advanced space missions. This work developed a rational model of nonlinear and hysteretic deformation behavior during moisture absorption and desorption processes using a modified two-phase diffusion theory. The model was based on the findings of water-polymer interactions. The mechanism of water transport was identified by gravimetric analysis and molecular-scale analysis using NMR. Furthermore, macroscopic strain behavior measured by fiber optics sensing resulted from swelling responses induced by anti-plasticization and plasticization effects. The strain model was formulated using a piecewise linear function with respect to the moisture concentration of bound water, which responded to shrinkage due to anti-plasticization and swelling due to plasticization. Consequently, a model for nonlinear and hysteretic deformation behavior in CFRP was successfully developed.

1. Introduction

Carbon fiber reinforced polymer (CFRP) is used in precise structures for space optics due to its excellent material properties (e.g., high specific stiffness, high specific strength, and low thermal expansion). A stable composite structure is crucial for advanced observation missions that demand large optical systems for high pointing accuracy. The development of a model for the evaluation and prediction of the long-term deformation behavior of composite structures is essential for the feasibility studies of such missions. Polymers and polymer-based composites absorb water or moisture, causing physical swelling and plasticization, which can deteriorate the pointing accuracy of observation satellites [1–3]. The nonlinear, hysteretic, and irreversible deformation behaviors observed in polymers during moisture absorption and desorption cycles make predicting these behaviors challenging [1,4–6]. The mechanisms of water transport, swelling, and plasticization due to moisture absorption in the polymers have been experimentally studied [7,8]. Absorbed water in epoxy is categorized into bound water, which interacts with hydrophilic group sites through hydrogen bonding, and free water, which does not form such bonds and is stored in free volume. Advanced techniques such as Fourier transform infrared (FTIR) spectroscopy, nuclear magnetic resonance (NMR), and positron annihilation lifetime spectroscopy (PALS) have been used to investigate water-polymer interactions at the molecular scale [7,8]. Although such findings have partially advanced understanding of the mechanisms, there is no physics-based model that can explain the deformation behavior in connection with molecular-scale mechanisms during the entire process from moisture absorption to desorption.

This study focuses on the development of a rational model based on the physics for the nonlinear, hysteretic, and irreversible deformation behavior during moisture absorption and desorption in epoxy-based CFRP. The model employs a modified two-phase diffusion theory based on findings from analyses of water-polymer interactions at the molecular scale. Specifically, we identify the mechanisms of water transport and swelling through NMR and macroscopic strain measurements. The two-phase diffusion theory, which accounts for water-polymer interactions within a material, is modified based on NMR for water-transport modeling. The strain behavior, measured by optical fiber sensing, is modeled based on the modified two-phase diffusion theory. Lastly, the moisture-induced deformation behavior is evaluated to validate the model.

2. Material testing

The water-polymer interaction and macroscopic strain behavior are evaluated during moisture absorption and desorption in epoxy-based CFRP. Specifically, the state of absorbed water within the polymer is identified by NMR and the moisture-induced strain is measured using optical fiber sensing.

2.1. Sample preparation and moisture test conditions

CFRP samples for material testing were made using unidirectional carbon fiber/epoxy prepregs (T700S/2592, Toray) and were manufactured by a typical autoclave process. All samples were thoroughly dried in a vacuum oven at 100°C until their weight stabilized. For moisture absorption tests, the samples were placed in a constant temperature and humidity chamber at 40°C and 93%RH. For subsequent desorption tests, the samples were placed in a vacuum chamber set at 40°C. The sample's weights were measured using an electronic balance (BP211D, Sartorius). Moisture content $M(t)$ was determined from the gravimetric analysis according to Eq. (1).

$$M(t) = \frac{W(t) - W_{ini}}{W_{ini}} \times 100 \tag{1}$$

where $W(t)$ is the weight of the specimen at time t, and W_{ini} is the initial weight in the dry-out state.

2.2. Methods

Time-domain NMR (TD-NMR) was used to evaluate the mobility of water molecules in moisture-absorbed CFRP. The T_2 relaxation behavior of proton nuclei ^1H in CFRP samples was measured using the Bruker Minispec mq20 (Observation nuclei: ^1H, Resonance frequency: 20 MHz) by the solid echo method. The free induction decay (FID) was interpreted as a superposition of three components: the Hard component, which has extremely low mobility and derives from protons inherently present in the polymer matrix network; the Soft component, which has high mobility and derives from protons in free water; and the Middle component, which represents intermediate mobility and derives from protons in bound water. The moisture uptake of the sample was assumed to be the sum of that of the Middle and Soft components. The moisture content of each component is calculated as the product of its compositional proportion determined through NMR, and the moisture content of the sample is determined through gravimetric analysis. The moisture contents of bound water $M_{bound}(i)$ and free water $M_{free}(i)$ were estimated using Eq. (2), respectively.

$$\begin{aligned} &Bound\ (or\ free)\ water\ content\ M_{bound\ or\ free}(i) \\ &= \frac{Middle\ fraction\ (or\ soft\ fraction)(i)}{Middle\ fraction(i) + \ soft\ fraction(i)} \times Moisture\ content\ M(i) \end{aligned} \tag{2}$$

where i represents the sample number corresponding to different degrees of moisture absorption. Six levels of CFRP specimens (50 mm in length x 50 mm in width x 0.56 mm in thickness, 4 plies) were prepared. Strain measurements by optical fiber sensing were used to evaluate the swelling behavior of moisture-absorbed CFRP [1]. The moisture-induced strain in CFRP samples embedded with polyimide-coated fiber Bragg grating (FBG) sensors (coating diameter: 150 μm, grating length: 1 mm, Technica SA) was measured using an interrogator (sm125, Micron Optics). Two types of specimens (100 mm in length x 25 mm in width x 1 mm in thickness, 8 plies) were prepared for measuring the strain in the fiber and transverse directions.

2.3. Results and discussion

Figure 1 shows the moisture content as a function of the square root of time over the specimen's thickness. As shown in Figure 1(a), an initial increase in bound water is followed by a gradual rise in free water during moisture absorption. The bound water increased proportionately to the square root of time and reached saturation. The Fick-like behavior suggests that the diffusion in bound water is preferential in the water-transport kinetics during absorption. The desorption curve in Figure 1(b) indicates that the initial desorption rate is rapid, then gradually slows, and finally reaches an equilibrium moisture content of approximately 0.05 wt%. The TD-NMR results indicated that free water was rapidly desorbed and eventually completely removed, while bound water was gradually desorbed and remained even at desorption equilibrium. The observation suggests that the diffusion in free water is preferential in the water-transport kinetics during desorption.

Figure 2 shows the moisture-induced strain in the fiber and transverse directions as functions of moisture content. The strain varied nonlinearly with moisture content. During absorption, strain in the fiber direction increased slowly until moisture content exceeded 0.25 wt%, then rose significantly in proportion to moisture content up to 0.55 wt%, and the increase became more gradual above 0.55 wt%. Conversely, during desorption, the reduction in strain was small until 0.55 wt%, and thereafter, the strain decreased significantly in proportion to the moisture content. Similar to the TD-NMR results, desorption equilibrium was reached at a moisture content of approximately 0.05 wt%. The shrinkage strain was observed at the desorption equilibrium. Therefore, during absorption and desorption cycle, nonlinear, hysteretic, and irreversible strain behavior relative to moisture content were observed. The strain behavior in the transverse direction was similar to that in the fiber direction. Since swelling increases significantly at intermediate moisture content, where TD-NMR results show an increase in bound water, the swelling is attributed to this bound water. Conversely, since the change in swelling is small at high moisture content, where free water is dominant, free water does not induce swelling. In addition, since the residual water in desorption is identified as bound water (Figure 1(b)), the shrinkage can also be attributed to the bound water. It suggests that a low concentration of bound water, corresponding to residual water, can induce shrinkage. Other studies report that the shrinkage is an anti-plasticization effect, which enhances the mechanical properties by forming a secondary cross-linking network through interactions at multiple hydrophilic sites with a small amount of water [9,10].

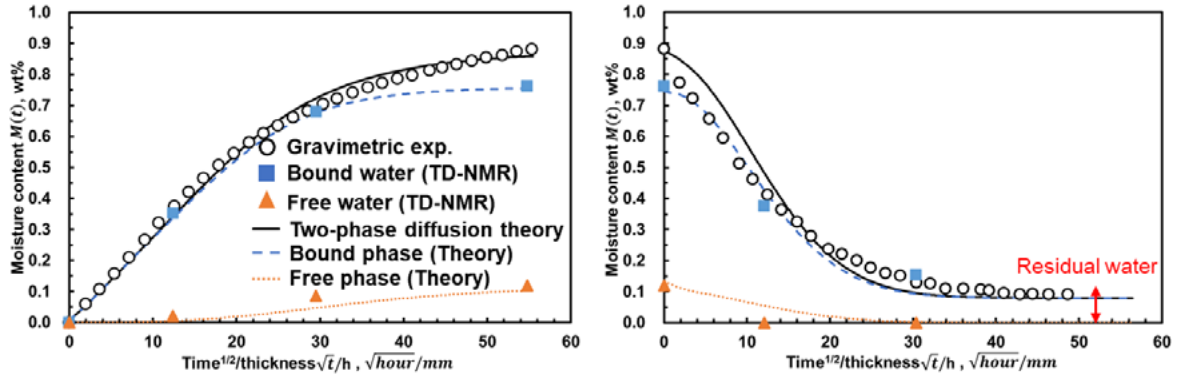

Figure 1. Bound and free water as a function of (a) moisture absorption and (b) desorption times. The white symbols indicate the moisture content determined by gravimetric analysis using Eq. (1), while the blue and orange symbols denote the moisture content of bound and free water, respectively, as determined by TD-NMR results using Eq. (2).

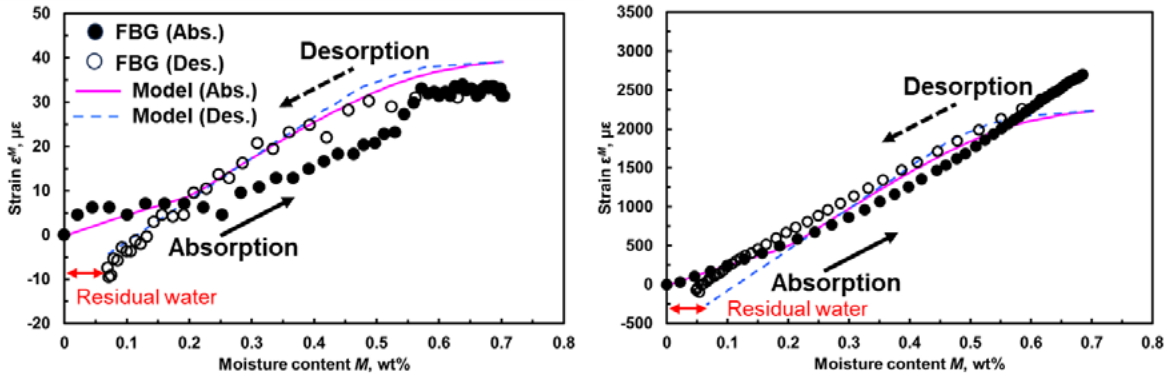

Figure 2 Moisture-induced strain as a function of moisture content in unidirectional composites. (a) Strain in the fiber direction and (b) in the transverse direction. Closed and open symbols correspond to the strain during moisture absorption and desorption, respectively.

3. Modelling

The mechanisms of water transport and swelling during moisture adsorption and desorption are strongly associated with the interactions between water molecules and polymers.

3.1. Water transport

The two-phase diffusion theory serves as a model for water transport that accounts for water-polymer interactions within a material during moisture absorption [11,12]. In this study, the water-transport model was conducted based on the two-phase diffusion theory (as interpreted by Popineau et al. [11]). The one-dimensional diffusion equation during absorption is described by Eq. (3).

$$D_{z,n}\frac{\partial^2 n}{\partial z^2} = \frac{\partial n}{\partial t} + \frac{\partial N}{\partial t}$$
$$\frac{\partial N}{\partial t} = bn - aN \tag{3}$$

where n and N represent the water concentration of bound and free water in the material, respectively. $D_{z,n}$ is the constant diffusion coefficient of bound water in the z (through-the-thickness) direction, b is a probability per unit time to become free water from bound water, a is a probability per unit time to become bound water from free water, t is time; z is the location in the through-the-thickness direction of the material. Next, the water-transport model during desorption must reflect that free water diffuses preferentially, while bound water reaches desorption equilibrium with a small amount of water remaining. Therefore, the two-phase diffusion model was modified during desorption as described in the following Eq. (4).

$$D_{z,N}\frac{\partial^2 N}{\partial z^2} = \frac{\partial N}{\partial t} + \frac{\partial (n - R_w)}{\partial t}$$
$$\frac{\partial (n - R_w)}{\partial t} = aN - b(n - R_w) \tag{4}$$

where $D_{z,N}$ is the constant diffusion coefficient of free water in the z direction, and R_w is residual water.

These differential equations were solved using the partial differential equations (PDE) function in a commercial finite element analysis software (COMSOL Multiphysics 6.2). The diffusion coefficients and the probability parameters (as described in Table 1) were determined using a nonlinear least squares method to fit the two-phase diffusion models (Eqs. (3), (4)) to the experimental data obtained from gravimetric analysis and TD-NMR. The theoretical curves are shown in Figure 1. Figure 1 shows that

the moisture contents in total, bound, and free water agree well with the results of gravimetric analysis and TD-NMR. during absorption and desorption.

Table 1. Parameters for two-phase diffusion model.

Process	Diffusion coefficient D_z, $\times 10^{-13}$ m^2/s	a, $\times 10^{-7}$ 1/s	b, $\times 10^{-7}$ 1/s	Equilibrium moisture content M_∞, wt%
Absorption	2.5	0.9	1.0	1.0
Desorption	30.6	2.6	6.7	0.05

3.2. Swelling

Modeling the swelling behavior during moisture absorption and desorption was conducted based on the two-phase diffusion models, which were applied to water transport in the previous section. It is assumed that only the epoxy matrix absorbs moisture, and that the moisture-induced strain solely responds to the bound water $n(z,t)$ of the two-phase diffusion models. Specifically, a piecewise linear function was used for a simplified modeling, in which the coefficient of moisture expansion (CME) $\beta_m(n)$ for the epoxy matrix varies at a specific threshold C_T of moisture concentration in the bound water as described in Eq. (5). Therefore, the moisture-induced strain response model was expressed as shrinkage due to anti-plasticization at moisture concentrations C_T or below and expansion due to plasticization at moisture concentrations above C_T.

$$\begin{gathered}\beta_m(n) = \beta_{m,ap} \quad if\ n \le C_T \\ \beta_m(n) = \beta_{m,p} \quad if\ n > C_T \\ \text{where,}\quad \beta_{m,ap} \le 0,\quad \beta_{m,p} \ge 0\end{gathered} \tag{5}$$

The CMEs ($\beta_{c,0}(n)$ and $\beta_{c,90}(n)$) of CFRP in the fiber and transverse directions when the moisture absorption of carbon fiber is negligible are expressed by the following Eq. (6) [13].

$$\begin{gathered}\beta_{c,0}(n) = \frac{V_m E_m \beta_m(n)}{\left(V_f E_f + V_m E_m\right) V_m s_m} s_c \\ \beta_{c,90}(n) = \frac{V_m \beta_m(n)(1+\nu_m)}{V_m s_m} s_c - \left(\nu_f V_f + \nu_m V_m\right)\beta_{c,0}(n) \\ s_c = s_f V_f + s_m V_m\end{gathered} \tag{6}$$

where, V is the volume fraction, E is the elastic modulus, ν is Poisson's ratio, and s is the specific gravity. Subscripts c, f, and m denote the CFRP, fiber, and matrix, respectively. The parameters (C_T, $\beta_{m,ap}$, and $\beta_{m,p}$) of the moisture-induced strain response model, as shown in Table 2, are determined using classical lamination theory so that the strains (ε_0^M and ε_{90}^M) in each direction of the laminated plates fit the material test results of unidirectional CFRP as described in Section 2. The curves in Figure 3 represent the moisture-induced strain response model. The developed model agrees well with the nonlinear, hysteretic, and irreversible strain behavior observed in experiments.

Table 2. Parameters for strain response model.

C_T, wt%	$\beta_{m,ap}$, $\times 10^{-6}$/wt%	$\beta_{m,p}$, $\times 10^{-6}$/wt%
0.05	-3800	3000

4. Conclusions

This study developed a rational model that can explain the nonlinear, hysteretic, and irreversible deformation behavior during moisture absorption and desorption in CFRP. The model modifies the two-phase diffusion theory based on findings from the analysis of water-polymer interactions at the molecular scale. The mechanisms of water transport and swelling were clarified through gravimetric and NMR analyses. The analysis shows bound water diffuses preferentially during absorption, whereas free water does during desorption, with some remaining strongly bound after long-term desorption. The strain model employed a piecewise linear function to respond to shrinkage due to anti-plasticization and

swelling due to plasticization, based on the water concentration of bound water. Consequently, we have successfully developed a model that reproduces nonlinear, hysteretic, and irreversible deformation behavior.

Keywords: Ceramic Matrix Composites, sandwich, instrumented test, parametric analysis, manufacturing defects

Abstract
A liner made of Ceramic Matrix Composites (CMC) and monolithic ceramic is currently being studied for a potential use in the micro-tunnels of a radioactive waste geological disposal facility. Proof of concept and representative specimens have been manufactured and mechanically tested. In parallel, a numerical model is being developed with the objective of designing an optimum liner in regards to the manufacturing constraints and the in-service load evolving over time.

1. Introduction

The French project called Cigéo [1], led by Andra (the French National Agency for Radioactive Waste Management), aims at creating and managing a deep geological disposal facility for intermediate-level long-lived (ILW-LL) and high-level (HLW) radioactive waste. The high-level waste (HLW) will be placed in horizontal micro-tunnels, known as cells, excavated deep (at ~ 500 m) in a clay layer. A liner will be inserted in the cells to facilitate the placing of the waste packages and allow their retrieval (if needed) during the Cigéo facility operation time (~100 years). To further increase the safety margins above the expected levels presented in the Cigéo licensing application file [2], the current carbon steel liners could be replaced by a ceramic liner. This substitution would limit the amount of $H_{2(g)}$ production that comes from steel corrosion under anoxic conditions. However, no monolithic ceramic can sustain the loading due to the rock convergence. Therefore, the use of Ceramic Matrix Composites (CMC) was proposed. Yet, to sustain the load, the required thickness of CMC makes the solution economically prohibitive.

An innovative solution, combining CMC and monolithic ceramic materials, has then been invented by the authors [3]. This sandwich solution consists of a thin outer skin made of CMC, a core made of several sections of a dense ceramic material, and a thicker inner skin in CMC. Two Proofs of Concept (PoC), shown in Figure 1, have been manufactured and mechanically tested. Different materials, manufacturing processes and dimensional tolerances were considered. Both PoC had a core made of alumina. The skins were either made of Carbon/Geopolymer (PyroKarb) or Oxide/Geopolymer (PyroXide), both materials being developed and commercialised by Pyromeral. Filament winding and hand lay-up fabrication methods have been investigated.

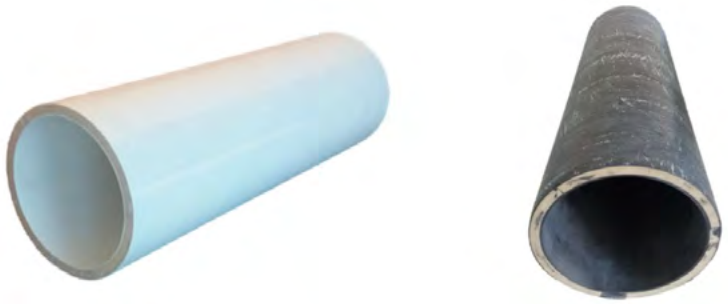

Figure 1. Proof of Concept made of PyroXide/alumina/PyroXide (left) and PyroKarb/alumina/PyroKarb (right)

The liner would be subjected to a non-uniformly distributed pressure applied to its external surface by the geological envrironment. The magnitude and the distribution of the pressure are governed by the motion of the rock around the liner that is strongly dependent on the mechanical response of the liner itself. Thus, two types of tests were considered to evaluate the response of the PoC in conditions aiming at approaching the in-service ones:

- a confinement test consisting in applying a uniformly distributed pressure on the external surface of the PoC,
- a compression test representing a severe anisotropic loading.

The in-service conditions would actually consist of the combination of both tests with a ratio between the two types of loading evolving with time.

Both tests were performed on the PoC, starting with the confinement test followed by the compression test. This latter enables a rich instrumentation set up, including Digital Image Correlation (DIC) as shown in Figure 2. DIC was used to identify the damage such as cracks in the ceramic core and debonding between the core and the skins. For instance, a discontinuity in the displacement field, due to a crack in the ceramic core, was observed in the superior part of the specimen (see Figure 2). Despite the damage, both PoC maintained their structural integrity after the two subsequent tests, which suggests a high technical potential of this sandwich architecture.

Figure 2. Compression test with digital image correlation (DIC) – test setting (left) and measured displacements (right).

Within the project, new PoC will be designed, manufactured then placed in Andra's Underground Research Laboratory (URL) for in-situ testing. The objective is to acquire data on the load generated by the rock convergence. The design of the POC must be optimised so that this latter sustains the load without any catastrophic failure occuring. The deformation of the PoC will provide essential information on the relationship between the rock convergence and the PoC stiffness that is needed for further design optimisation of the liner. Furthermore, designing composite structure must account for the manufacturing process, as technical constraints and fabrication defects will affect the mechanical performance. To tackle this issue, studies combining Finite Element Analysis (FEA) and experiments on representative samples are currently carried out and provide fundamental information on the influence of design parameters – such as dimensions or material orientation – and manufacturing tolerances and defects – such as skin/core bond quality.

2. Design and preliminary analysis of the representative annular technological specimen

Following the analysis of the PoC, a representative annular technological specimen (RATS) was considered to perform a deeper analysis of the mechanical behaviour of the sandwich structure. Design examples are presented in Figure 3. A numerical analysis was perfomed to evaluate the impact of the design parameters such as the skins thickness or the number of core sections. In addition, dimentionnal tolerances and manufacturing defects were considered.

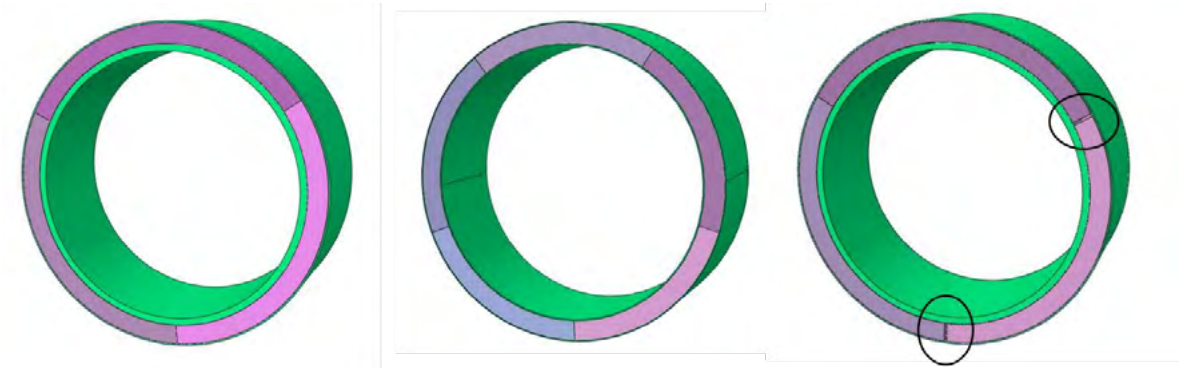

Figure 3. Example of 3 designs with a thick internal skin and 3 core sections (left), with a thin internal skin and 5 core sections (centre) and with 2 manufacturing defects (gaps between sections) (right)

The preliminary analyses highlight the influential parameters and phenomena that need to be investigated further. For instance, a combination of a thin internal skin and a ceramic core divided into 5 sections creates a compliant structure that tolerates a larger deflection; indeed, the core sections may slide along each other in this case. However, the stress in the skins may locally reach high levels, eventually leading to the failure of the composite. Figure 4 shows the displacement and stress fields in such a structure. The deformed shape is shown with a scale factor of 10 to underscore the critical areas. The highest levels of stress in the skins can be observed near the junctions between the ceramic sections. The tensile stress in the ceramic remains below the tensile strength estimated at 280 MPa by the ceramic manufacturer. On the other hand, a thick internal skin combined with a reduced number of core sections would be stiffer and the relative sliding of the core sections would be limited. Thus, the local stress in the skins would be reduced, but the bending load applied to the ceramic core would generate a higher risk of cracks occurring in the ceramic. Figure 5 shows a different deformed shape as the one seen in the previous example. The stresses, plotted with the same scale as in Figure 4, are lower in the internal skin but higher in the ceramic core compared to those obtained with the previous 5-section RATS. Although cracks in the ceramic core are not critical as the core is contained within the skins, these cracks lead to a reduction of the structure's stiffness and a change in the mechanical response of the 3-section structure that will ressemble the one of the 5-section RATS.

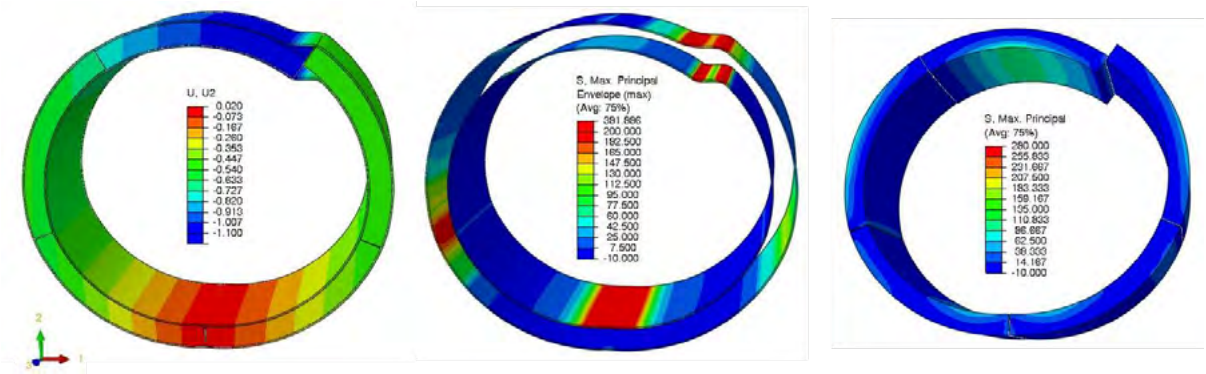

Figure 4. FEA of RATS with a thin internal skin and 5 core sections – predictions of displacement in mm (left), tensile stress in MPa in the skins (centre) and in the core (right) – scale factor = 10

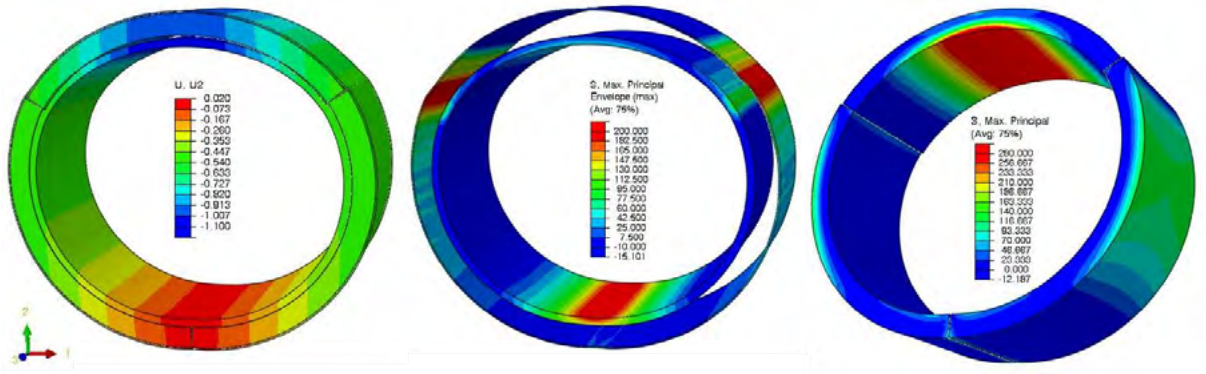

Figure 5. FEA of RATS with a thick internal skin and 3 core sections – predictions of displacement in mm (left), tensile stress in MPa in the skins (centre) and in the core (right) – scale factor = 10

The mechanical response of the structure would also be affected by the manufacturing defects. For instance, a weak bond – or an initial debonding – between the core and one of the skins would disrupt the load transfer. On the other hand, the debonding would provide more compliance to the system, as the displacement of its different parts would be facilitated in this case (see Figure 6).

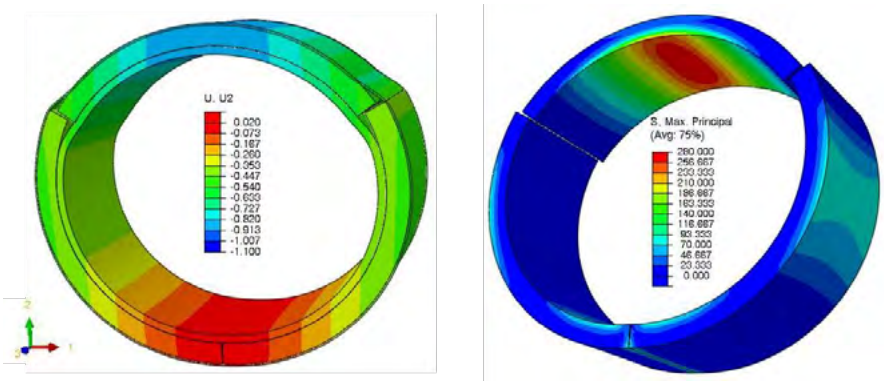

Figure 6. FEA of RATS with a thick internal skin, 3 core sections and an initial debonding between one of the sections and the internal skin – predictions of displacement in mm (left) and tensile stress in MPa in the core (right) – scale factor = 10

Table 1 summarises the design parameters and the potential manufacturing defects that were considered in the parametric study. The trends identified with the numerical model need to be confirmed by experiments.

Table 1. Design parameters and potential manufacturing defects that may influence the mechanical response of the RATS

	Design parameters	Manufacturing defects	Influence
Internal face	Internal diameter Internal skin thickness and lay-up		Global stiffness, stress in both skins and likelihood of damage in core or skin; thicker laminate can compensate for defects in core or in core/skin bond
		Initial debonding between core and internal skin	Disruption of load transfer between core and internal skin and higher levels of stress in the skins
	Number of core sections		Global stiffness and number of critical areas in the skins
		Junction with gaps between core sections	Disruption of load transfer between core and skin and higher levels of stress in the skins
	Core thickness		Global stiffness and load carrying capacity
		Bond between core and external skin	Disruption of load transfer between core and internal skin and higher levels of stress in both skins
External face	External skin thickness and lay-up		Thicker laminate can compensate for defects in core or in core/skin bond

3. Manufacturing process

The RATS were made of PyroKarb/Alumina/PyroKarb and manufactured in 4 steps as illustrated in Figure 7:

1. The elaboration of the internal skin by filament winding.
2. The positioning of the ceramic sections on the internal skin.
3. The elaboration of the external skin by filament winding.
4. The final processing stage (Pyromeral's Intellectual Property) including the separation of the RATS

Multiple RATS were manufactured with different skin thicknesses and lay-ups and variable dimensions of the core sections. As the skins were made by filament winding, the dimensions and material orientation were precisely controlled. On the contrary, the manufacturing process of the ceramic parts is not controlled as accurately. The geometrical tolerances then lead to variable adjustments of the core sections and a variable quality of bond between the core sections and the skins. These variabilities were observed on the final structure. Micro-computed tomography (μCT) was used to both identify and quantify the initial defects. An example is shown in Figure 8. The manufacturing process is under development and the quality of the RATS could be improved. However, the need for improvement will be determined by evaluating the required structural properties; the manufacturing tolerances will be then defined accordingly.

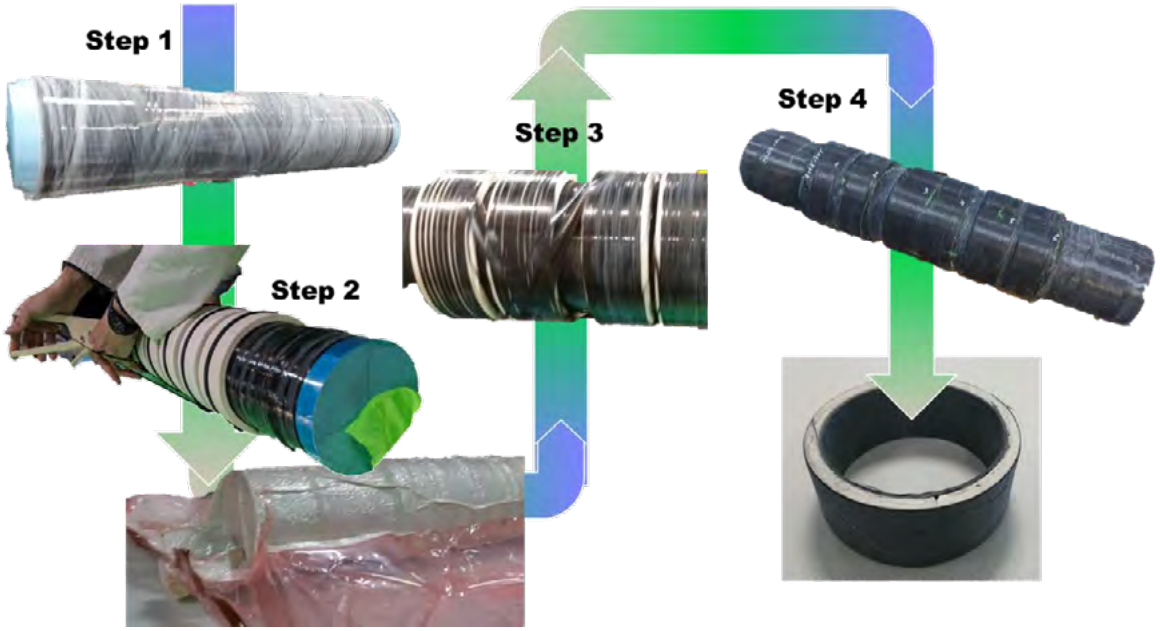

Figure 7. Manufacturing process of the RATS

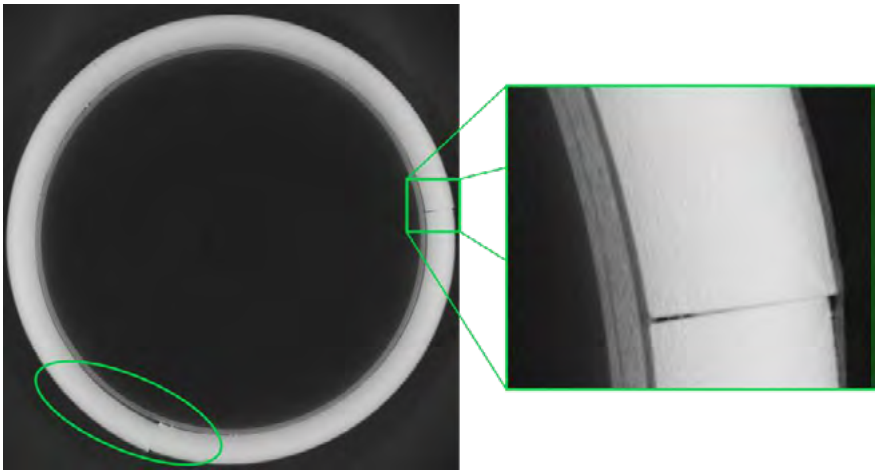

Figure 8. Observation by µCT of a RATS where defects including internal skin/core debonding and variable thickness of core section leading to gaps are readily visible

4. Experimental study

A compression test was specifically developed to characterise the mechanical response of the sandwich structure, analyse the influence of the design parameters and evaluate the impact of the manufacturing defects. Figure 9 shows the set-up with the relevant instrumentation including cameras to perform Digital Image Correlation (DIC) analysis, a microphone to capture Acoustic Emission (AE) and a Linear Variable Differential Transformer (LVDT) to measure the cylinder ovalisation.

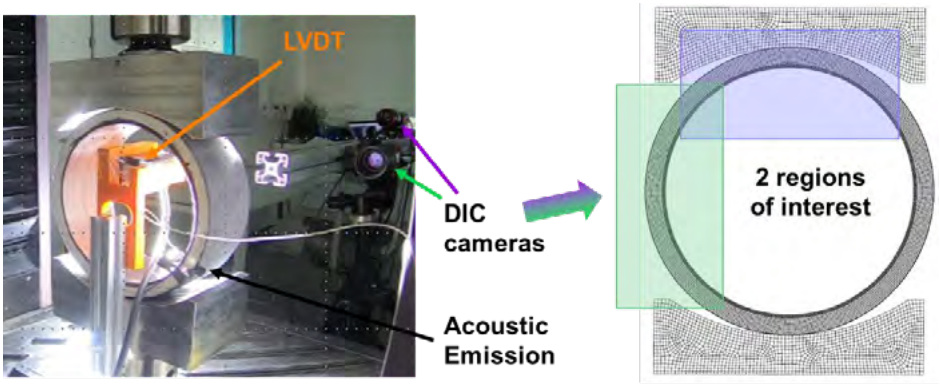

Figure 9. Compression test on RATS with dedicated instrumentation (LVDT, DIC, AE)

A cyclic compressive loading was applied to the RATS. The displacement was imposed at a rate of 0.2 mm/min until 2 mm, then at 0.5 mm/min until 4 mm. Unloadings were set at regular intervals of 0.2 mm until 2 mm, then at 0.5 mm between 2.5 mm and 4 mm. The force was measured by a 50 kN load cell. As shown in Figure 10, during this test, a sudden event was captured by the AE and corresponds to a drop in the Force/Displacement curve. The DIC analysis allowed the identification of this event: a crack occurred in the top section of the ceramic core that was loaded in bending. The crack triggered a debonding between the core section and the internal skin. The DIC residuals highlight the crack (see lower right-hand side image in Figure 10). The test continued and a new event occurred (after ~66 minutes), indicating additional damage that yet remains to be identified. A decrease in global stiffness is observed on the Force/Displacement curve. In particular, if we compare the initial slope at the beginning of the test (purple curve) with the slope at the beginning of the new cycles in black, the residual stiffness is about half of the initial one. However, the structure could still carry the load. The test was stopped to analyse the damage in the RATS. Further tests will be performed on the same specimen until complete failure.

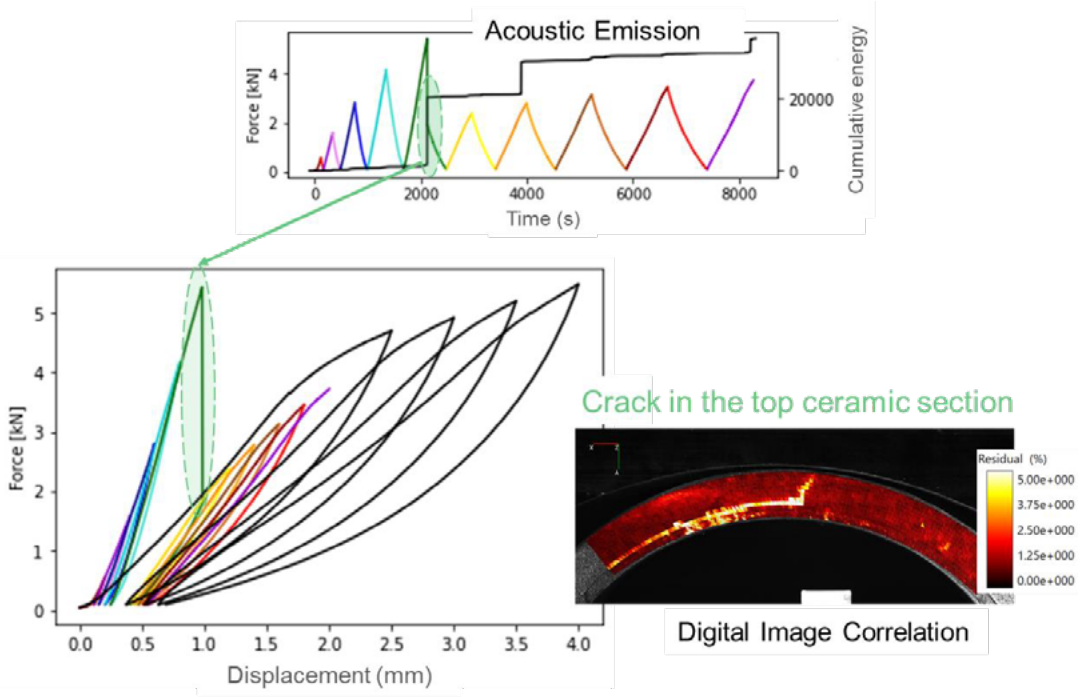

Figure 10. Compression test on RATS with instrumentation (LVDT, DIC, AE)

5. Conclusion

A sandwich tube was created to be evaluated as a potential liner for a micro-tunnel in a deep radioactive waste disposal facility. Two PoC were manufactured and mechanically tested under severe conditions: they exhibit a high technical potential, as both maintained their overall integrity. Subsequently, a smaller representative annular technological specimen was designed to perform further systematic and parametric studies and improve the understanding of the mechanical response of the sandwich structure. These RATS' skins were made of Carbon/Geopolymer and the core was made of alumina. Multiple RATS were manufactured. A comprehensive analysis based on µCT observations, FE simulations and experimental tests is in progress. The objective is to evaluate the influence of the various design parameters and the impact of the manufacturing tolerances and defects on the mechanical performance of the sandwich structure. A predictive model will then be proposed to help and design a liner that would be a compromise between the optimum design for a given load, the expected quality of the manufactured product and the evolving in-service load over time. New PoC will then be manufactured and placed in Andra's Underground Research Laboratory for in-situ testing to assess that this innovative component fulfil the safety requirements associated with the Cigéo project.

Abstract

The solution of Eshelby's inhomogeneity problem in the second form of Mindlin's first strain gradient elasticity theory is developed to predict the effective elastic properties of micro or nanocomposites. Thanks to the Green's function technique, the local strain is expressed, in terms of an integral equation, for an ellipsoidal inhomogeneity embedded in an infinite homogeneous elastic medium subjected to non-homogeneous boundary conditions. The expression of the mean strain inside a spherical inhomogeneity with isotropic elastic behavior is acquired and depends on two characteristic length scale parameters and five elastic gradient constants introduced by the Mindlin's strain gradient elasticity theory. The effective bulk and shear moduli are predicted through Mori-Tanaka homogenization scheme for a two-phase composite, considering some simplified versions of the strain gradient elasticity theories: simplified strain gradient elasticity theory, reduced strain gradient elasticity theory and couple-stress theory. These predictions are then compared with those proposed by some investigations on the same topic.

Keywords

Heterogeneous materials, strain gradient elasticity theory, Eshelby's inhomogeneity problem, integral equation, Mori-Tanaka scheme.

1. Introduction

The prediction of the elastic behavior of heterogeneous materials based on the properties of their constituents and their microstructures is one of the interests of mechanics of materials. Eshelby's inclusion [1] and inhomogeneity models [2] provide a valuable tool for the development of micromechanical models for the prediction of the effective elastic properties through the chosen homogenization schemes. Classical models failed to account for the size effects of inhomogeneities on the effective elastic behavior of heterogeneous materials and high-order micromechanical theories such as strain gradient elasticity theories are investigated to this end. Recently, Bonfoh and Sabar [3] developed a new method based on the Eshelby's inhomogeneity issue, within the simplified strain gradient elasticity theory. This method is developed within a simplified version of Mindlin's first strain gradient elasticity theory with a unique material's characteristic length scale parameter. Sidhardh and Ray [4,5], solved the Eshelby's inclusion problem within Mindlin's first strain gradient elasticity theory with three characteristic's length scale parameters and suggested the necessity of multiple characteristics

length scale parameter for a relevant prediction of the size effects at different length scales for crystals, polymers and micro and nanocomposites. Mindlin's first strain gradient elasticity theory introduces five gradient constants and appears as the general and complete version to address these issues. In the present study, an Eshelby's inhomogeneity model is developed within a complete version of Mindlin's first strain gradient elasticity theory. Through Mori-Tanaka scheme, a relevant estimation of the size-dependent effective elastic moduli of micro or nanosized composites is provided for some simplified theories and compared with those issued from some investigations.

2. Eshelby's inhomogeneity problem within Mindlin's first strain gradient elasticity theory

2.1. Integral equation

Let us consider an elastic heterogeneous medium with a volume V and outer boundary ∂V. Its local linear elastic behavior is described by the elastic moduli tensors $\boldsymbol{C}(\boldsymbol{r})$ and $\boldsymbol{D}(\boldsymbol{r})$ at an arbitrary vector position $\boldsymbol{r}(x_1, x_2, x_3)$. The corresponding representative volume element (RVE) is subjected to non-homogeneous boundary conditions [6]: uniform strain $\boldsymbol{\varepsilon^0}$ and strain gradient $\boldsymbol{\kappa^0}$ prescribed at ∂V :

$$u_i(\boldsymbol{r}) = \varepsilon^0_{ij}\, x_j + \kappa^0_{ijq}\, x_j\, x_q \;\; ; \text{ for } \boldsymbol{r} \in \partial V \tag{1}$$

Considering the general Eshelby's equivalent inclusion method as suggested by [1], and based on the Green's function technique, an integral equation for an isotropic infinitely elastic RVE subjected to non-homogeneous conditions within the Mindlin's first strain gradient elasticity theory is obtained:

$$\begin{aligned} u_m(\boldsymbol{r}) &= u^0_i(\boldsymbol{r}) - \int_{V'} G^0_{km,l'}(\boldsymbol{r}-\boldsymbol{r}')\, \delta C_{klij}(\boldsymbol{r}')\, \varepsilon_{ij}(\boldsymbol{r}')\, dV' \\ &- \int_{V'} G^0_{km,l'n'}(\boldsymbol{r}-\boldsymbol{r}')\, \delta D_{klnijp}(\boldsymbol{r}')\, \kappa_{ijp}(\boldsymbol{r}')dV' \\ &+ \int_{\partial V'} \left\{ G^0_{km}(\boldsymbol{r}-\boldsymbol{r}')\, t^d_k(\boldsymbol{r}') + G^0_{km,q'}(\boldsymbol{r}-\boldsymbol{r}')\, q^d_k(\boldsymbol{r}')\, N_q \right\} dS' \\ &- \int_{\partial V'} \left\{ T^0_{im}(\boldsymbol{r}-\boldsymbol{r}')\, u^d_i(\boldsymbol{r}') + Q^0_{im}(\boldsymbol{r}-\boldsymbol{r}')\, u^d_{i,q'}(\boldsymbol{r}')\, N_q \right\} dS' \end{aligned} \tag{2}$$

where $\boldsymbol{N}$ stands for the outward unit normal vector to ∂V, $\boldsymbol{G^0_{km}}$ the Green's function tensor of the homogeneous reference medium (HRM) with elastic moduli tensors $\boldsymbol{C}^0$ and $\boldsymbol{D}^0$, $\delta\boldsymbol{C}(\boldsymbol{r}) = \boldsymbol{C}(\boldsymbol{r}) - \boldsymbol{C}^0$, $\delta\boldsymbol{D}(\boldsymbol{r}) = \boldsymbol{D}(\boldsymbol{r}) - \boldsymbol{D}^0$, the fluctuating moduli tensors.

The local displacements field is decomposed as:

$$u_i(\boldsymbol{r}) = u^0_i(\boldsymbol{r}) + u^d_i(\boldsymbol{r}) \tag{3}$$

and $\boldsymbol{u^d}$, $\boldsymbol{t^d}$ and $\boldsymbol{q^d}$, are respectively the fluctuating of displacements, Cauchy stress traction, double stress traction vectors, defined by:

$$t_i = \sigma_{ij}\, N_j - \left(\mu_{ijk}\, N_k\right)_{,j} + \left(\mu_{ijk}\, N_k\, N_l\right)_{,l} N_j \;\text{ and }\; q_i = \mu_{ijk}\, N_j\, N_k \tag{4}$$

with:

$$\tau_{ij} = C_{ijkl}\,\varepsilon_{ij} \;\;,\;\; \mu_{ijq} = D_{ijqklp}\kappa_{klp} \;\text{ and }\; \sigma_{ij} = \tau_{ij} - \mu_{ijq,q} \tag{5}$$

Moreover, the transformed traction tensors, $\boldsymbol{T^0}(\boldsymbol{r}-\boldsymbol{r'})$ and $\boldsymbol{Q^0}(\boldsymbol{r}-\boldsymbol{r'})$ are defined by:

$$\begin{aligned} T^0_{im}(\boldsymbol{r}-\boldsymbol{r'}) &= C^0_{klij}\,G^0_{km,l'}(\boldsymbol{r}-\boldsymbol{r'})\,N_j - D^0_{klnijp}\,G^0_{km,l'n'p'}(\boldsymbol{r}-\boldsymbol{r'})\,N_j \\ &- D^0_{klnijp}\,G^0_{km,l'n'j'}(\boldsymbol{r}-\boldsymbol{r'})\,N_p + D^0_{klnijp}\,G^0_{km,l'n'q'}(\boldsymbol{r}-\boldsymbol{r'})\,N_p\,N_q\,N_j \\ &+ D^0_{klnijp}\,G^0_{km,l'n'}(\boldsymbol{r}-\boldsymbol{r'})\left\{N_{p,q'}\,N_q\,N_j + N_p\,N_{q,q'}\,N_j - N_{p,j'}\right\} \end{aligned} \tag{6}$$

$$\text{and } Q^0_{im}(\boldsymbol{r}-\boldsymbol{r'}) = D^0_{klnijp}\,G_{km,l'n'}\,(\boldsymbol{r}-\boldsymbol{r'})\,N_p\,N_j$$

The topology of the considered Eshelby's inhomogeneity model consists of an ellipsoidal inhomogeneity (denoted by index I) with a volume V_I embedded in an infinitely homogeneous reference medium (denoted by index 0). The fluctuating tensors are defined as: $\delta\boldsymbol{C}(\boldsymbol{r}) = \Delta\boldsymbol{C^{I/0}}\,\theta^I(\boldsymbol{r})$ and $\delta\boldsymbol{D}(\boldsymbol{r}) = \Delta\boldsymbol{D^{I/0}}\theta^I(\boldsymbol{r})$ where $\theta^I(\boldsymbol{r}) = \begin{cases}1 & \text{if } \boldsymbol{r}\in V_I \\ 0 & \boldsymbol{r}\notin V_I\end{cases}$, is the Heaviside function of the inhomogeneity volume V_I.

In the absence of the double stress traction $\boldsymbol{q^d}$ at the boundary ∂V, the Green's tensor $\boldsymbol{G^0}$, the displacements field $\boldsymbol{u^d}$ and its gradients vanished at the infinite boundary ∂V. Eq.(2) therefore leads to:

$$\begin{aligned} \varepsilon_{mn}(\boldsymbol{r}) &= \varepsilon^0_{mn} + \left(\kappa^0_{mnl} + \kappa^0_{mln}\right)x_l - \int_{V_I'}\Gamma^0_{mnkl}(\boldsymbol{r}-\boldsymbol{r'})\,\Delta C^{I/0}_{klij}\,\varepsilon_{ij}(\boldsymbol{r'})\,dV' \\ &- \int_{V_I'}\Gamma^0_{mnkl,p'}(\boldsymbol{r}-\boldsymbol{r'})\,\Delta D^{I/0}_{klpijq}\,\kappa_{ijq}(\boldsymbol{r'})\,dV' \;\text{ and} \\ \kappa_{mnr}(\boldsymbol{r}) &= \kappa^0_{mnr} + \kappa^0_{mrn} - \int_{V_I'}\Gamma^0_{mnkl,r}(\boldsymbol{r}-\boldsymbol{r'})\,\Delta C^{I/0}_{klij}\,\varepsilon_{ij}(\boldsymbol{r'})\,dV' \\ &- \int_{V_I'}\Gamma^0_{mnkl,p'r}(\boldsymbol{r}-\boldsymbol{r'})\,\Delta\mathcal{D}^{I/0}_{klpijq}\,\kappa_{ijq}(\boldsymbol{r'})\,dV' \end{aligned} \tag{7}$$

where $\boldsymbol{\Gamma^0}$ is the modified Green's tensor, defined by:

$$\Gamma^0_{mnkl}(\boldsymbol{r}-\boldsymbol{r'}) = -\frac{1}{2}\left[G^0_{mk,nl}(\boldsymbol{r}-\boldsymbol{r'}) + G^0_{nk,ml}(\boldsymbol{r}-\boldsymbol{r'})\right] \tag{8}$$

In what follows, we are interested in the prediction of the first-order elastic properties of a heterogeneous material within Mindlin's first strain gradient elasticity theory. To this end, a remote uniform strain tensor $\boldsymbol{\varepsilon^0}$ $(\boldsymbol{\kappa}=0)$ is prescribed at the boundary of the RVE.

Within the present investigation, the Green's tensor $\boldsymbol{G^0}$ is decomposed as suggested by [7] :

$$G^0_{mk}(\boldsymbol{r}-\boldsymbol{r}') = G^c_{mk}(\boldsymbol{r}-\boldsymbol{r}') + G^G_{mk}(\boldsymbol{r}-\boldsymbol{r}') \tag{9}$$

Consequently, the uniform classical part $\boldsymbol{T^C}$ and the gradient part $\boldsymbol{T^G}$ of the Hill's polarization tensor $\boldsymbol{T}$ inside V_I read as:

$$\int_{V_I} \Gamma^C_{mnkl}(\boldsymbol{r}-\boldsymbol{r}')\, dV = T^C_{mnkl} \quad \text{and} \quad \int_{V_I} \Gamma^G_{mnkl}(\boldsymbol{r}-\boldsymbol{r}')\, dV = T^G_{mnkl}(\boldsymbol{r}') \quad \text{for} \quad \boldsymbol{r}' \in V_I \tag{10}$$

Assuming a constant elastic behavior per local phase and uniform characteristic length scale parameters (l_1 and l_2) inside the heterogeneous material, the volume average $\bar{\boldsymbol{\varepsilon}}^{\boldsymbol{I}}$ of the strain inside inhomogeneity volume V_I can be considered:

$$\begin{aligned}\bar{\varepsilon}^I_{mn} = \varepsilon^0_{mn} - T^C_{mnkl}\, \Delta C^{I/0}_{klij}\, \bar{\varepsilon}^I_{ij} - \frac{1}{V_I}\int_{S_I} T^G_{mnkl,p}(\boldsymbol{r})\, \Delta D^{I/0}_{klpijq}\, \varepsilon_{ij}(\boldsymbol{r})\, n_q\, dS \\ - \frac{1}{V_I}\int_{S_I}\left[T^G_{mnkl}(\boldsymbol{r})\, \Delta C^{I/0}_{klij} - T^G_{mnkl,pq}(\boldsymbol{r})\, \Delta D^{I/0}_{klpijq}\right] u_i(\boldsymbol{r})\, n_j\, dS\end{aligned} \tag{11}$$

The main difficulty of the complete expression of the volume average $\bar{\boldsymbol{\varepsilon}}^{\boldsymbol{I}}$ arises from the analytical evaluation of the surface integrals of Eq.(11), since the local fields $\boldsymbol{u}(\boldsymbol{r})$, $\boldsymbol{\varepsilon}(\boldsymbol{r})$ and $\boldsymbol{T^G}(\boldsymbol{r})$ are non-uniform inside the inhomogeneity.

2.2. Exact analytical solution for spherical Eshelby's inhomogeneity problem

We considered a spherical inhomogeneity with radius a. Thanks to Green's function [7], the components of Hill's polarization tensors for a HRM with an isotropic elastic behavior read as:

$$\begin{aligned}T^C_{mnkl} &= \frac{1}{30\mu_0(1-\nu_0)}\left[(8-10\nu_0)\, I_{mnkl} - \delta_{mn}\, \delta_{kl}\right] \quad \text{and} \\ T^G_{mnkl}(\boldsymbol{r}) &= -\alpha_0\, {l_1}^2[\varphi^I(r) - \Lambda^1(r)]_{,mnkl} + \frac{{l_2}^2}{\mu^0}[\varphi^I(r) - \Lambda^2(r)]_{,mnkl} \\ &+ \frac{1}{2\mu_0}\left[\Lambda^2_{nl}(r)\, \delta_{mk} + \Lambda^2_{ml}(r)\, \delta_{nk}\right]\end{aligned} \tag{12}$$

where $\alpha_0 = (1-2\nu_0)/2\mu_0(1-\nu_0)$; μ_0 and ν_0 are shear modulus and Poisson's ratio of the HRM, respectively. $I_{mnkl} = (\delta_{mk}\, \delta_{nl} + \delta_{nk}\, \delta_{ml})/2$ are the components of the four-order identity tensor, $\varphi^I(\boldsymbol{r})$ and $\Lambda^i(\boldsymbol{r})$ for $i = 1,2$, respectively Newtonian and Yukawa potential functions related to the characteristic length scale parameter l_i (l_1 and l_2) [3]:

$$\varphi^I(\boldsymbol{r}) = \frac{1}{4\pi}\int_{V_I'} \frac{1}{|\boldsymbol{r}-\boldsymbol{r}'|}\,dV' \quad \text{and} \quad \Lambda^i(\boldsymbol{r}) = \frac{1}{4\pi}\int_{V_I'} \frac{e^{-|\boldsymbol{r}-\boldsymbol{r}'|/l_i}}{|\boldsymbol{r}-\boldsymbol{r}'|}\,dV' \quad \text{for} \quad \boldsymbol{r} \in V_I \tag{13}$$

For a spherical inhomogeneity, these potential functions are expressed as [3]:

$$\varphi^I(\boldsymbol{r}) = -\frac{1}{6}(r^2 - 3a^2) \quad \text{and} \quad \Lambda^i(\boldsymbol{r}) = {l_i}^2 - {l_i}^2\,(l_i + a)e^{-\frac{a}{l_i}}\frac{\sinh(\boldsymbol{r}/l_i)}{\boldsymbol{r}} \quad \text{for} \quad \boldsymbol{r} \in V_I \tag{14}$$

Considering Eqs. (12)-(14), Eq. (11) becomes:

$$\begin{aligned}\bar{\varepsilon}^I_{mn} = {}& \varepsilon^0_{mn} - T^C_{mnkl}\,\Delta C^{I/0}_{klij}\,\bar{\varepsilon}^I_{ij} \\ & - \alpha_0\left[\left(\Delta a_1^{I/0} + 2\Delta a_2^{I/0}\right)R^1_{mn} + \left(\Delta a_1^{I/0} + 2\Delta a_3^{I/0}\right)R^2_{mn}\right. \\ & \left. + \left(2\Delta a_4^{I/0} + 2\Delta a_5^{I/0}\right)R^3_{mn} + \left(\Delta\lambda^{I/0} - \frac{\Delta a_1^{I/0} + 2\Delta a_2^{I/0}}{{l_1}^2}\right)(R^4_{mn} - R^5_{mn})\right] \\ & - \frac{1}{\mu_0}\left[\left(2\Delta a_4^{I/0} + 2\Delta a_5^{I/0}\right)(R^6_{mn} - R^7_{mn}) + \left(2\Delta\mu^{I/0} - \frac{2\Delta a_4^{I/0}}{{l_2}^2}\right)(R^8_{mn}\right. \\ & \left. - R^9_{mn})\right]\end{aligned} \tag{15}$$

where $\Delta a_i^{I/0} = a_i^I - a_i^0$, (for $i = 1,2,\dots,5$), $\Delta\mu^{I/0} = \mu_I - \mu_0$ and $\Delta\lambda^{I/0} = \lambda_I - \lambda_0$. The second-order tensors $\boldsymbol{R}^p$ (for $p = 1,2,\dots,9$) are introduced as:

$$\begin{aligned} R^1_{mn} &= \frac{1}{V_I}\int_{S_I} \Lambda^1_{mnp}(\boldsymbol{r})\,\varepsilon_{qq}(\boldsymbol{r})n_p\,dS \;;\; R^2_{mn} = \frac{1}{V_I}\int_{S_I} \Lambda^1_{mnl}(\boldsymbol{r})\,\varepsilon_{pl}(\boldsymbol{r})\,n_p\,dS\,; \\ R^3_{mn} &= \frac{{l_1}^2}{V_I}\int_{S_I} \Lambda^1_{mnklp}(\boldsymbol{r})\,\varepsilon_{kl}(\boldsymbol{r})\,n_p\,dS \;;\; R^5_{mn} = \frac{{l_1}^2}{V_I}\int_{S_I} \Lambda^1_{mnlp}(\boldsymbol{r})\,u_l(\boldsymbol{r})\,n_p\,dS\,; \\ R^6_{mn} &= \frac{1}{2V_I}\int_{S_I} \left[\Lambda^2_{mlp}(\boldsymbol{r})\,\varepsilon_{nl}(\boldsymbol{r}) + \Lambda^2_{nlp}(\boldsymbol{r})\,\varepsilon_{ml}(\boldsymbol{r})\right]n_p\,dS\,; \\ R^7_{mn} &= \frac{{l_2}^2}{V_I}\int_{S_I} \Lambda^2_{mnklp}(\boldsymbol{r})\,\varepsilon_{kl}(\boldsymbol{r})\,n_p\,dS\,; \\ R^8_{mn} &= \frac{1}{2V_I}\int_{S_I} \left[\Lambda^2_{ml}(\boldsymbol{r})\,u_l(\boldsymbol{r})\,n_n + \Lambda^2_{nl}(\boldsymbol{r})\,u_l(\boldsymbol{r})\,n_m\right]dS\,; R^9_{mn} = \frac{{l_2}^2}{V_I}\int_{S_I} \Lambda^2_{mnlp}(\boldsymbol{r})\,u_l(\boldsymbol{r})\,n_p\,dS \end{aligned} \tag{16}$$

2.3. Spherical and deviatoric parts of strain inside spherical inhomogeneity

Within an isotropic elastic behavior of spherical inhomogeneity, the mean strain tensor $\bar{\boldsymbol{\varepsilon}}^{\boldsymbol{I}}$ and the remote uniform strain tensor $\boldsymbol{\varepsilon}^0$ can be decomposed into spherical $\bar{\varepsilon}_s = \bar{\varepsilon}_{pp}/3$ and deviatoric $\bar{\boldsymbol{e}}$ parts as:

$$\bar{\varepsilon}_s = \frac{1+\alpha_0\,\eta_1\,\xi}{1+\alpha_0\,\eta_1\,\xi+\alpha_0\,\Delta\kappa^{I/0}\left(1+3\bar{D}_1+\alpha_0\,\xi\,(3{l_1}^2+\eta_1)\right)}\,\varepsilon_s^0 \quad \text{and}$$

$$\begin{aligned}\bar{e}^I_{mn} = e^0_{mn} &- \frac{(8-10\nu_0)\Delta\mu^{I/0}}{15\mu_0(1-\nu_0)}\,\bar{e}^I_{mn}\\ &- \alpha_0\left\{\left(\Delta a_1^{I/0}+2\Delta a_2^{I/0}\right)R^{1d}_{mn}+\left(\Delta a_1^{I/0}+2\Delta a_3^{I/0}\right)R^{2d}_{mn}\right.\\ &\left.+\left(2\Delta a_4^{I/0}+2\Delta a_5^{I/0}\right)R^{3d}_{mn}+\left(\Delta\lambda^{I/0}-\frac{\Delta a_1^{I/0}+2\Delta a_2^{I/0}}{{l_1}^2}\right)\left(R^{4d}_{mn}-R^{5d}_{mn}\right)\right\}\\ &-\frac{1}{\mu_0}\left\{\left(2\Delta a_4^{I/0}+2\Delta a_5^{I/0}\right)\left(R^{6d}_{mn}-R^{7d}_{mn}\right)\right.\\ &\left.+\left(2\Delta\mu^{I/0}-\frac{2\Delta a_4^{I/0}}{{l_2}^2}\right)\left(R^{8d}_{mn}-R^{9d}_{mn}\right)\right\}\end{aligned} \tag{17}$$

$\boldsymbol{R^{pd}}$ is the deviatoric part of the tensors $\boldsymbol{R^p}$, $\eta_1 = -\,l_1(a^2+3a\,l_1+3l_1^2)/(l_1+a)$, $\xi = a^2\,\bar{D}_3\left(\Delta\lambda^{I/0}+2\Delta\mu^{I/0}\right)+\left(5\Delta\lambda^{I/0}+10\Delta\mu^{I/0}-\frac{2(2\Delta a_4^{I/0}+2\Delta a_5^{I/0})}{{l_1}^2}\right)\bar{D}_2$ and

$$\begin{aligned}\bar{D}_1(r) &= \frac{1}{r}\frac{\partial\Lambda^1(r)}{\partial r}\bigg|_{r=a}\;;\quad \bar{D}_2(r)=\frac{1}{r^2}\left\{\frac{\partial^2\Lambda^1(r)}{\partial r^2}-\frac{1}{r}\frac{\partial\Lambda^1(r)}{\partial r}\right\}\bigg|_{r=a}\;;\quad \bar{D}_3(r)\\ &= \frac{1}{r^3}\left\{\frac{\partial^3\Lambda^1(r)}{\partial r^3}-\frac{3}{r}\frac{\partial^2\Lambda^1(r)}{\partial r^2}+\frac{3}{r^2}\frac{\partial\Lambda^1(r)}{\partial r}\right\}\bigg|_{r=a}\end{aligned} \tag{18}$$

3. Simplified theories

In the following, some simplified theories are investigated, to provide particular solution.

3.1. Simplified strain gradient elasticity theory (SSGET)

Initially promoted by Atlan and Aifantis [8], the SSGET is obtained by putting material's constants a_i of the gradient elastic moduli tensor $\boldsymbol{D}$ as: $a_1 = a_3 = a_5 = 0\;;\quad a_2 = \frac{\lambda}{2}\,l^2\;;\; a_4 = \mu\,l^2\;;\; l_1 = l_2 = l.$

3.2. Reduced strain gradient elasticity theory (RSGET)

Suggested by Lazar [9] to investigate straight dislocations problems, the RSGET is a generalization of the SSGET by putting: $a_1 = a_3 = a_5 = 0\;;\; a_2 = \frac{\lambda+2\mu}{2}\,{l_1}^2 - \mu\,{l_2}^2\;;\; a_4 = \mu\,{l_2}^2.$

3.3. Couple stress theory (CST)

Following Yury Solyaev et *al*. [10], the couple-stress theory can be deduced by putting: $a_1 = 4\mu\,\gamma\,l^2$; $a_2 = a_3 = -2\mu\,\gamma\,l^2$; $a_4 = -a_5 = 2\mu\,l^2\,(\gamma+1)$; $l_1 = 0$; $l_2 = l$ with $-1 < \gamma < 1$ for the positive definiteness of the strain density energy.

4. Comparisons with other models

Through Mori-Tanaka homogenization scheme, the solution of Eshelby's inhomogeneity problem is implemented to predict the effective properties of a heterogeneous materials. These predictions are then compared with those issued from uniform eigenstrain-based models suggested by Ma and Gao [11], SSGET and the recent model within SSGET developed by [3]. As depicted by Figures 1 and 2, the predicted elastic bulk and shear moduli are strongly depended on the inhomogeneity size a/l_i for $i = 1; 2$. Some significant deviations are noticed between results predicted by considered simplified models.

The predicted normalized effectives properties κ_{eff}/κ_M and μ_{eff}/μ_M tends asymptotically to the classical elasticity theory predictions when the ratio a/l_i tends to the infinity. As shown by Figures 1 and 2, for a Young's modulus ratio $E_I/E_M = 20$, Poisson's ratio $\nu_I = \nu_M = 0.3$ and $a/l_1 = 2$; $a/l_2 = 2$, these properties are enhanced by the volume fraction f of inhomogeneities, whatever the simplified theory.

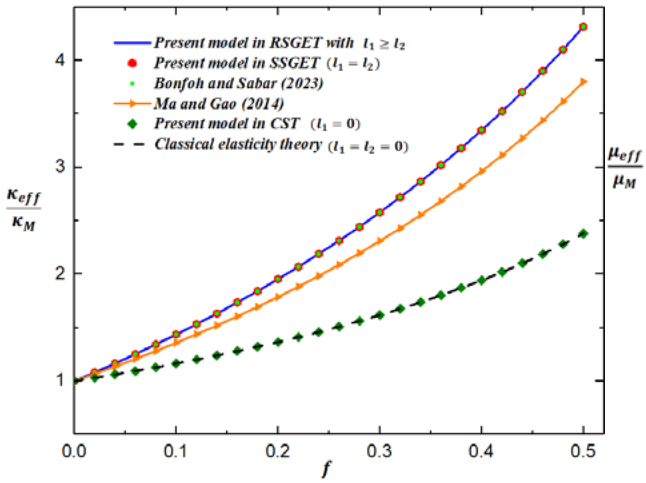

Figure 2: Normalized effective bulk modulus as a function of inhomogeneity volume fraction f $a/l_1(a/l_2 \text{ for } CST) = 2$.

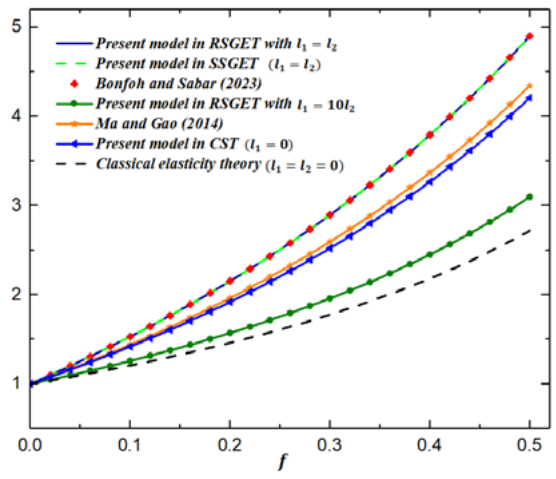

Figure 2: Normalized effective shear modulus as function of inhomogeneity volume fraction f $a/l_1(a/l_2 \text{ for } CST) = 2$.

5. Conclusion

The present micromechanics model provides an exact solution of Eshelby's inhomogeneity problem for a spherical inhomogeneity with an isotropic elastic behavior within the second form of Mindlin's first strain gradient elasticity theory. Some predictions of the present model within simplified versions of the theory, through Mori-Tanaka homogenization scheme, revealed the gradient effects on the effective bulk and shear moduli of two-phase composite. Within the simplified strain gradient elasticity theory, the predictions of Bonfoh and Sabar [3] are retrieved and significant deviations are noticed with other theories. The present micromechanical model can be extended to cylindrical or the ellipsoidal

inhomogeneities and also to an anisotropic elastic behavior per phase. Moreover, elastic mechanical problems such as: chiral materials, quantum dots or void materials can also be investigated.

Keywords: Hydrogen storage, Cork agglomerates, Energy absorption, Thermal insulation, Mechanical characterization, Finite element analysis (FEA), Numerical modelling

Abstract
Since hydrogen presents more supply chain challenges than conventional fossil fuels, the project aims to investigate the safety of type I pressurized hydrogen storage tanks using composite materials based on cork agglomerates, particularly in accidents, fires, or explosions, as well as the relationship between their mechanical and thermal properties and their density. The samples underwent dynamic impact compression and thermal tests to assess thermal conductivity, diffusivity, volumetric specific heat, and fire behaviour. A numerical model was created using Finite Element Analysis (FEA) to confirm the mechanical results, indicating that agglomerated cork composite materials are suitable for coating type I hydrogen storage tanks. The numerical model validates that lower densities increase the energy absorption capacity during dynamic events because of the shear rate. Thermal diffusivity and volumetric-specific heat significantly impact fire behaviour more than thermal conductivity. To illustrate how agglomerated cork composite materials can be applied to hydrogen storage tanks and support a secure energy transition without jeopardizing the Sustainable Development Goals (SDGs) or the European Green Deal, a demonstrative prototype was developed. The coatings are practical and safe for the environment.

1. Introduction

The global population's rapid growth is exacerbating the scarcity of natural resources, and the high levels of greenhouse gas (GHG) and CO_2 emissions necessitate funding sustainable development and renewable energy sources. Hydrogen, the energy of the future, is highly regarded due to its energy efficiency and zero emissions. However, production, storage, transport, and usage safety conditions are less established than in conventional fuels. This study aims to develop materials and methods to make hydrogen storage reservoirs safer without compromising Sustainable Development Goals or the European Green Deal.

Hydrogen, the most abundant element in the universe, is the first and simplest atom, with only one proton and one electron. It is highly reactive and can be found in various inorganic and organic chemical substances, with water being the most common [8]. Hydrogen can be produced and stored in large quantities for long periods, making it a viable alternative to fossil fuels [2]. Its high specific energies make it an energy-efficient and relatively harmless element. However, its low density (0.089 kg/m^3) makes it challenging to develop mobile hydrogen tanks. Despite its low density, handling hydrogen

requires extreme caution due to its properties [12]. Hydrogen gas storage under pressure is the most established method due to its low density and high-pressure requirements [6]. Type I tanks, made of carbon or low-alloy steel, are used in industrial and commercial operations and operate between 200 and 300 bar. However, lighter composite materials have been developed due to weight requirements [1]. Hydrogen can cause explosions when it reacts with oxidizing substances like oxygen or chlorine, especially in enclosed spaces. Air-powered low-energy ignition sources initiate the burning of hydrogen, which diffuses four times faster than natural gas. This means that if a leak occurs, hydrogen will evaporate into thin air in seconds. The hydrogen flame is almost invisible during the day, increasing the fire risk. Safety mechanisms in hydrogen storage tanks mainly consist of pressure relief valves and temperature sensors to gradually release hydrogen into the atmosphere. However, these mechanisms have limitations in efficiency and size [9]. It is crucial to consider alternatives that can enhance the safety of hydrogen tanks and prolong their exposure to fire without causing damage. In a fire, it is difficult for operators of type I tanks to open the valve without jeopardizing their physical safety.

Cork is a natural substance that has been suggested for its potential to improve safety regulations for hydrogen storage tanks. Its mechanical and thermal properties make it an ideal material for insulating tanks, reducing the risk of explosions and slowing flame spread during fires. Cork's unique chemical composition, derived from its low polysaccharide content, provides exceptional thermal stability and is impermeable to gases and liquids [5]. Its moisture resistance and low solid fraction make it a suitable material for sealing. Additionaly, cork has inferior heat transfer properties due to its low solid fraction, low conductivity of gas, tiny cells that prevent gas convection, and radiation reduction from repeated absorption and reflection at the multiple cell walls [7]. Therefore, cork agglomerates, created by triturating leftover cork planks and combining them with a polymer binder, offer excellent options for coating type I hydrogen storage tanks due to their remarkable mechanical properties under compression and energy absorption [3,4,10]. This makes cork a promising material for improving safety regulations in type I hydrogen storage tanks.

In the academic sense, there has yet to be prior use of composites made of agglomerated cork to protect hydrogen storage tanks. The main goal of this project is to research and evaluate a composite material composed of cork agglomerates that may be applied to hydrogen storage type I tanks to increase their safety. Specifically, it is anticipated that the suggested composite will offer enhanced thermal insulation, function as a flame retardant, and possess a substantial energy absorption capability in case of an explosion.

2. Materials and Methods

2.1. Type I Tank

In order to characterize the tank that will be used in the project in terms of its physical, thermal, and chemical properties, two type I tanks were purchased from Luxfer Gas Cylinders (Luxfer, Nottingham). Technical characteristics for the two P3338N tanks are as follows: type 25E connection, 200 bar operating pressure, 660 mm height, 176 mm outer diameter, 12.91 kg net weight, 10 l water volume, and compliance with Directive 2010/35/EU. Luxfer claims that the building material is a unique 6061 aluminium alloy they created independently.

2.2. Design of Experimens (DOE)

Amorim Cork Composites (ACC, Mozelos) supplied materials for this research. The three types of materials that ACC made available will hereafter be referred to as kinds A, B, and C since they are products that ACC offers for sale and makes available on the market and for reasons of confidentiality. The most essential details and attributes of each material group are shown in **Table 1**.

Table 1. Design of experiments of the samples.

Material	**Density** [kg/m^3]	**Grain size** [mm]	**Binder**	**Binder** wt.%
A	210	2-4		15
B	300	2-5	PU Rigid	13
C	400	2-4		10

2.3. Dynamic Impact Compression Tests

The state-of-the-art drop tower Instron 9440 was used for impact testing. The impactor was raised to a height of roughly 750 mm and had an overall mass of 8.15 kg for experiments employing 60 J of impact energy. The cork samples were squares of 50 mm with a thickness of 25 mm. A 45 kN load cell and a position encoder incorporated into the machine were used to collect the load, position, and time data to create the time acceleration history, forced displacement, and stress-strain curves for each sample. A second impact of the same magnitude was made 30 to 40 seconds following the first impact. The objective of this effort is to ascertain how the density of the composites affects the mechanical response of cork agglomerates under dynamic loading. Since the absorbed energy is equal to the area under the stress-strain curve, the energy density (E_v), or the amount of energy absorbed per unit volume, may be calculated by integrating the following equation (Eq. 1):

$$E_v = \int_{\varepsilon_1}^{\varepsilon_2} \sigma(\varepsilon) d\varepsilon \tag{1}$$

where ε_1 and ε_2 are the lower and higher limits of integration and $\sigma(\varepsilon)$ is the equation for the stress-strain curve.

2.4. Thermal Tests

The method used to determine the samples' thermal conductivity and diffusivity was the transient plane heat source (hot disc) method. Materials with uniaxial structures that are homogenous, isotropic, or anisotropic can all be tested using this method. A sample with a tiny hot-disc probe placed in it can reach equilibrium at a specific temperature. The probe produces a dynamic temperature field inside the object. The temperature rise of the probe is measured as a function of time. The probe doubles as a self-heating heat source and temperature sensor. Next, the response is analysed using the model developed for that specific probe and the assumed boundary conditions. The Hot Disk software provides some suggested settings for each material class's heating power and heating duration, but it is up to the user to calibrate those values.

2.5. Fire Behaviour and Retardancy Tests

It is significant for one to understand that there are two different kinds of fire tests: fire behaviour tests and fire heat conduction tests. The fire behaviour testing aimed to evaluate the burned area and mass loss. The fire-related heat conduction tests aimed to evaluate the samples' thermal behaviour. The cork samples were 200 mm square, 15 mm thick for experiments on fire behaviour, and 10 mm thick for tests on heat conduction. No instrumentation was used in the first kind of test. The blowtorch was the only tool used and operated at maximum power. The distance between the samples and the flame was adjusted. It took two minutes for each test. At maximum power, tests were conducted at three distinct torch-to-sample distances: 200 mm (450 °C), 175 mm (580 °C), and 150 mm (700 °C). Due to a lack of infrastructure and technical conditions and the high cost required by companies specializing in this kind of testing, it was decided to conduct fire heat conduction tests following GTR-13 and NHTSA standards using a simple and basic setup. A surface temperature cycle was carried out after the distance between the material and the flame apparatus where adjusted: 0 to 1 minute: 200 mm and 415 °C; 1 to 3 minutes: 175 mm and 535 °C; 3 to 10 minutes: 150 mm and 650 °C; Over 10 minutes: cool down at

room temperature. **Figure 1** (a) shows a schematic illustration of the experimental setup, whereas **Figure 1** (b) shows the actual experimental setup.

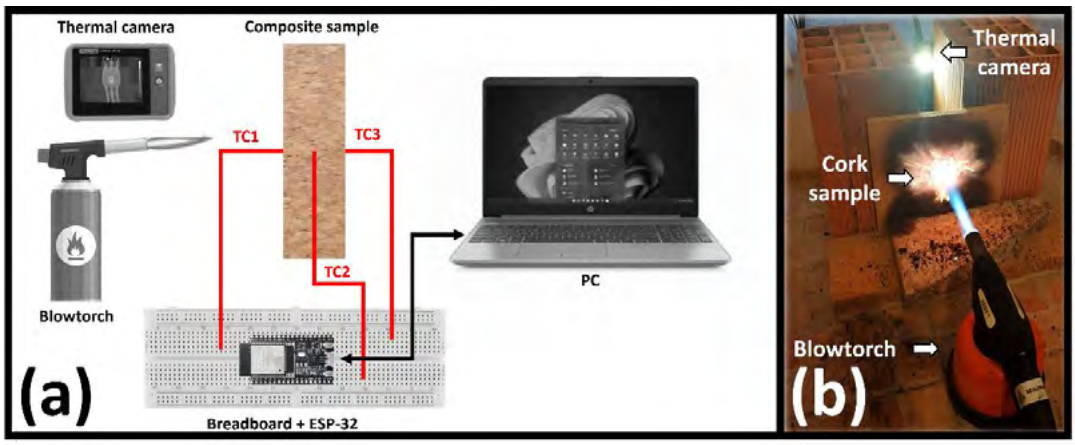

Figure 1. (a) Fire test schematic setup (TC stands for thermocouple) **(b)** Fire test experimental setup.

2.6. Numerical Model

This study uses the Hyperfoam model from the ABAQUS material library to study agglomerated cork as a hyperelastic material. This established nonlinear isotropic model explains the hyperelastic behaviour of elastomeric foams. The Mullins effect model is used with the Hyperfoam material model to expand the isotropic elastomeric foam model and accurately reflect the long-term energy dissipation and stress-softening effects in agglomerated cork. The stress softening phenomenon is replicated in the ABAQUS Mullins effect material model. The experimental testing allowed the conclusion that there is virtually minimal lateral deformation; hence, a negligible Poisson coefficient was considered [11]. Simulations of impacts were performed using the ABAQUS FE program's Explicit solver and large deformation option. To navigate the hourglass phenomenon, the sample was represented as an eight-node linear brick element with reduced integration (ABAQUS' C3D8R element).

3. Results and Discussion

3.1. Dynamic Impact Compression Tests and Numerical Comparision

Figure 2 suggests that the stress-strain curve becomes more “open” as sample density increases, resulting in more considerable stresses for more minor strains. **Table 2** shows impact testing mean parameters and associated standard deviations (SD), supporting the previous finding (Acc. stands for acceleration). Four isocurves have been constructed for dynamic impact testing at 200, 400, 600, and 800 kJ/m^3 energy densities. Given the nature of isocurves, it is reasonable to assume that they are roughly equivalent to straight lines. All four isocurves have a negative slope. As absorbed energy increases, the slope decreases. The energy densities of the samples decrease as their densities increase.

The outcomes of the simulation and the experiments were compared. The entire stress-strain curve (loading and unloading) is shown in **Figure 3** for both experimental and numerical methods. Overall, the FEA results are equivalent to those obtained experimentally despite the numerical results indicating slightly higher stresses and strains.

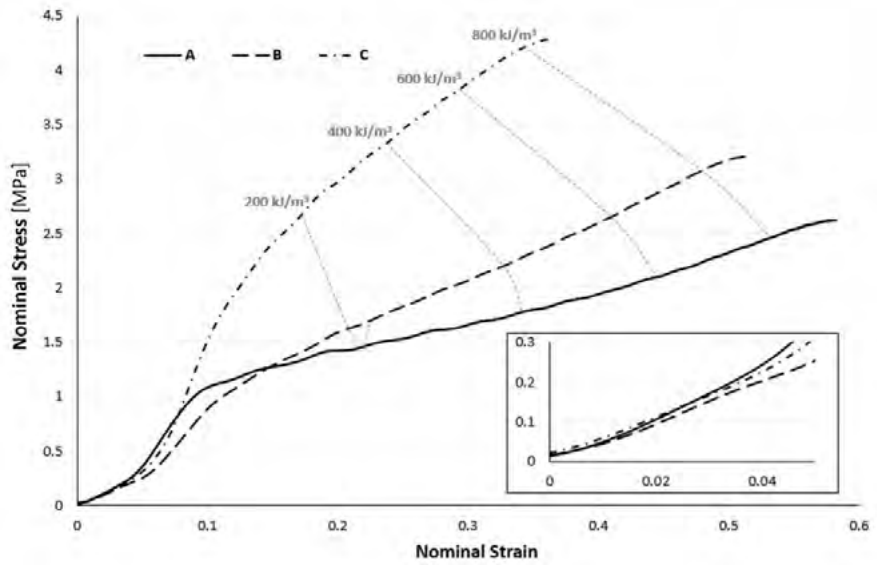

Figure 2. Nominal impact stress-strain curve for the three samples and four different energy levels.

Table 2. Data on the samples impact test that were performed.

Material	Density [kg/m³]	Peak Force [N]	SD Force	Peak Acc. [g]	SD Acc.	Peak Strain	SD Strain
Type A	210	6549.0	9.3	81.9	0.1	0.58	0.0034
Type B	300	8022.2	101.1	100.4	1.3	0.52	0.0053
Type C	400	10717.2	386.8	134.1	4.8	0.37	0.0058

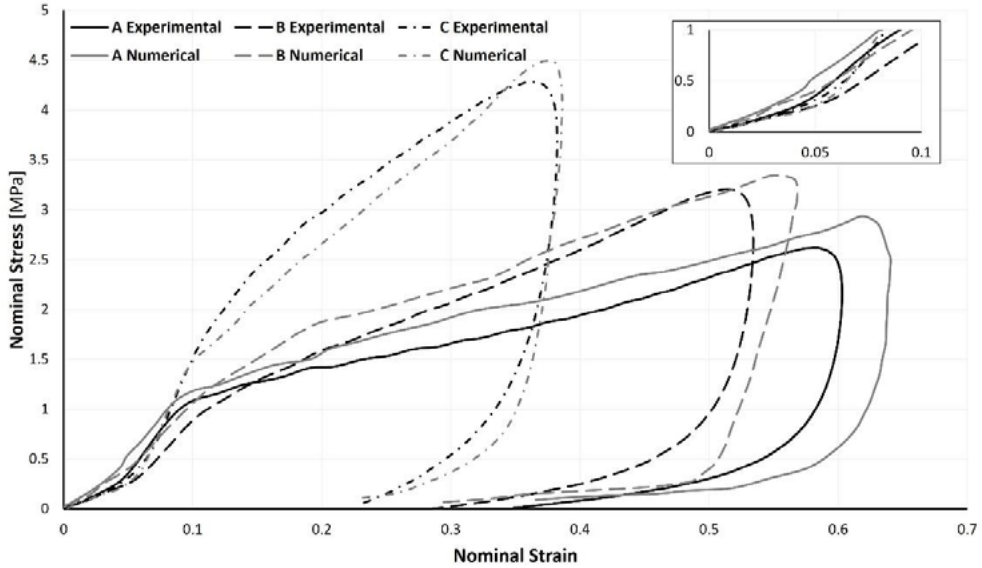

Figure 3. Comparison between experimental and numerical stress-strain curves (full impact test).

3.2. Thermal Tests

As predicted, it can be inferred from **Table 3** that thermal conductivity rises as density does. Although thermal conductivity rises with density, thermal diffusivity falls because the difference in densities in the samples is more significant than in thermal conductivity. Thermal diffusivity is reliant on both thermal conductivity and density. The sample with a density of 400 kg/m³ has a lower thermal diffusivity. Finally, it is found that an increase in density causes an increase in specific heat, or more precisely, volumetric heat capacity. This is particularly relevant since more heat will be required to raise the substance's temperature.

Table 3. Thermal properties of the samples.

Material	Thermal Conductivity [MW/m³·K]	Thermal Diffusivity [mm²/s]	Specific Heat [MJ/m³·K]
Type A	0.060	0.43	0.1393
Type B	0.066	0.23	0.2879
Type C	0.077	0.14	0.5668

3.3. Fire Retardancy Tests

3.3.1. Fire Behaviour Tests

Figure 4 shows that, as expected, bringing the torch closer to the sample results in a larger burned area. More importantly, it has been shown that improved fire behaviour, or a reduced burned area, is correlated with larger sample densities. A higher density leads to a lesser burned area. For example, a 400 kg/m^3 sample has a burned area equivalent to 39.8% and 53.3% of samples A and B's burned areas, respectively. However, as the distance from the blowtorch decreases, the relationship between the burned areas of samples C, A, and B increases. This leads us to the conclusion that the greater the distance from the torch, the more significant the difference between the burned areas of samples with different densities.

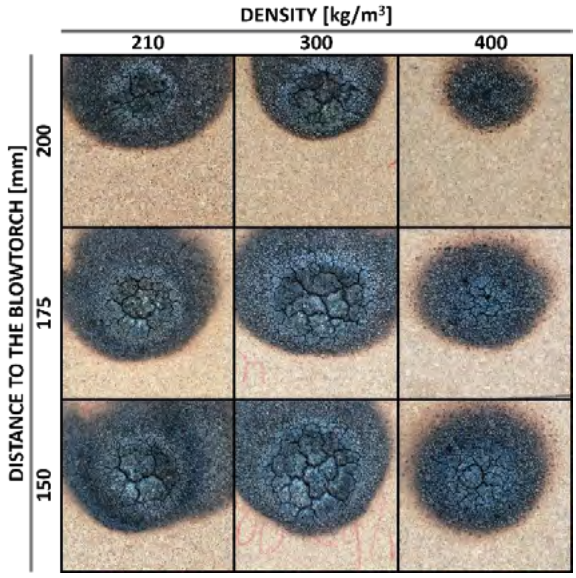

Figure 4. Samples' burnt area as a function of density and blowtorch distance.

A higher density also leads to less mass loss or more structural stability when a structure is exposed to fire. It is interesting to note that mass loss is decreased when the flame is positioned closer to the sample for the same density. There is less mass loss because the burned area grows as the flame gets closer to the sample. This indicates that the heat is dispersed more evenly throughout the sample rather than focused in one spot. It should be mentioned that a polyurethane-based binder, which makes up most of the mass burned by fire, has a melting point far lower than the temperature at which cork grains burn—roughly 100 °C.

3.3.2. Fire Heat Conduction Tests

Since the flame broke through the plate in Type A and Type B samples, the test had to be terminated after 355 and 310 seconds, respectively, and they could not withstand the entire fire test. It is still possible to get some intriguing findings. The examination of **Figure 5** and **Figure 6** indicates that a higher density results in better thermal insulation or lower temperatures on the interior surface. After 310 seconds of testing, samples A, B, and C each displayed an inner surface temperature of 271.8, 230.1, and 124.1 °C. This observation is exciting because sample C should have a greater inner surface temperature than the other samples. After all, it is supposed to have superior thermal conductivity and

is denser than the other samples. This discovery leads one to the intriguing conclusion that thermal conductivity has minimal bearing on the thermal behaviour of the burning samples. Consequently, this behaviour can be explained by thermal diffusivity and volumetric specific heat rather than thermal conductivity.

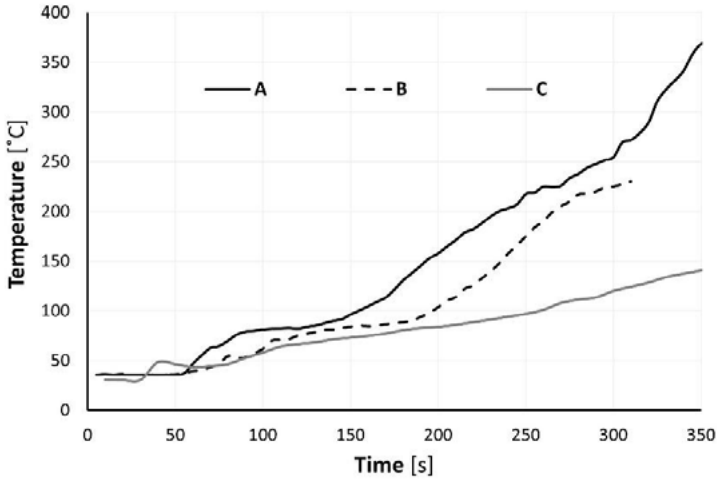

Figure 5. Density influence on the back surface temperature evolution.

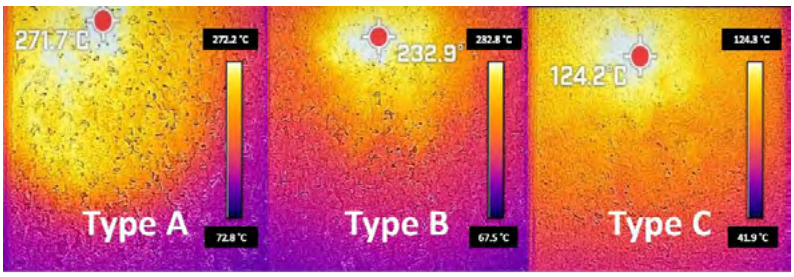

Figure 6. Back surface temperature after 310 seconds for all samples (recorded with Flir One).

Fire experiments were conducted for type C samples with thicknesses of 10, 15, 20, and 25 mm under the previously described conditions since sample C, with a density of 400 kg/m^3, shows the best thermal behaviour in a fire. **Figure 7** shows that a thinner thickness leads to higher interior surface temperatures. It is also evident that the temperature takes longer to reach its maximum as thickness increases. Samples with 10, 15, 20, and 25 mm thicknesses have maximum temperatures of 183.4, 123.5, 100.6, and 66.5 ºC, respectively. This graph only serves as a recommendation for temperature values on an experimental basis. A red line has also been added to show the maximum temperature the hydrogen storage tank can reach without jeopardizing its safety. This suggests that a covering thicker than 15 mm is required.

4. Conclusions and Prototype

The research was successful, in a very clear-cut and objective sense, because it validated using composite materials based on cork agglomerates for hydrogen tank linings to boost their safety. This investigation revealed that type C samples, which have a density of 400 kg/m3, are the best for composite materials because they simultaneously provide strong mechanical and thermal properties. Samples with this density exhibit significantly more intriguing thermal features, especially concerning thermal behaviour and fire resistance, even though they have a slightly lower energy absorption capacity and worse mechanical performance than other samples with lower densities.

More density has been shown to enhance heat conductivity, which has implications for thermal behaviour and fire resistance. Higher density, on the other hand, results in a lower thermal diffusivity. More density enhances fire resistance since it reduces mass loss and the burned area in terms of fire behaviour.

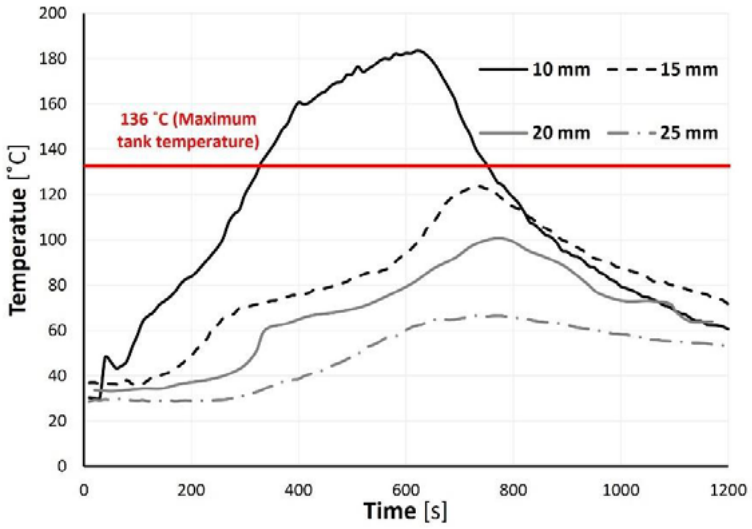

Figure 7. Thickness influence on the back surface temperature evolution of type C samples.

Further evidence that thermal conductivity has minimal bearing on the sample's response to fire comes from the finding that larger densities lead to lower inner surface temperatures. More important impacts are caused by specific heat and thermal diffusivity. The requirement for a coating thicker than 15 mm was also established. From a mechanical perspective, peak forces and acceleration increase with density. Lower density favours a better energy absorption capacity. It was found that a higher density causes a shorter dimensional recovery period during the rebound phase. Conversely, the almost immediate recovery from deformation is decreased with increasing density. The research was successful numerically because it was possible to improve and optimize an already-existing model for impact simulations. The current model can simulate the hit, recovery period, and second impact with remarkable accuracy. On the other hand, the numerical results indicate values that are marginally greater than those from the experimental campaign. Still, other numerical models encounter the same problem.

Coatings and their adhesion can be produced by various processes and technologies. The prototype type I hydrogen storage tank was covered using the most practical and affordable approach: folding and adhering plates. The SOUDAL 22A adhesive, specifically formulated for bonding composites comprised of cork agglomerates, was used in this instance. Notably, the coating was applied in sections to facilitate the appropriate curing of the coating. **Figure 8** shows the final prototype's 3D CAD model as well as the actual prototype, which is presently undergoing development and optimisation.

Figure 8. Real prototype currently in development and CAD 3D model of the prototype.

Abstract
To understand the overall behaviour of fabrics in depth, it is necessary to study the behaviour of the fiber yarn (the basic unit) under different mechanical paths. Due to the limitations of experimentation, simulation becomes an effective tool to study the behaviour of fiber bundles under different stress conditions. The goal of this study is to create simulation tools to understand and model the behaviour of a fiber yarn in microstructure to build a constitutive law of the yarn. This work creates numerical fiber bundle based on tomography and combines micro-compaction experiments with 40 polyester fibers (15mm length, 0.5mm diameter). The initial numerical fiber bundle geometry is extracted with MATLAB and input into ABAQUS® to simulate the mechanical load as the experiments. The compaction behaviour curve and the microstructure of fiber bundle of simulation and experiment are compared after last compaction step. (i) From the compaction curves, the experimental and simulation results are approximate. (ii) In addition, in the final compaction step, the error of three fiber bundle samples between simulation and experiment is optimistic, with mean values of 27.95%, 14.07% and 19.6%, and standard deviations of 10.56 %, 7.89% and 11.6% with respect to the fiber diameter, respectively.

1. introduction

Composite materials are used for different industrial applications like transports. Among the most widespread, one can find composite materials based on fibrous reinforcements. But, the proper functioning of processes now results from know-how and experience resulting from an empirical approach, much more than from a complete mastery of the physical phenomena involved. The RTM (Resin Transfer Molding) manufacturing of composite parts starts usually by the preforming of dry or pre-impregnated fabrics according to a defined mold, sometimes complex, before the resin is injected. The mechanical behavior of the fabric is therefore crucial during the preforming process because it influences the next steps of the manufacturing process. However, a fibrous reinforcement is a complex structure since it results from the weaving of thousands of yarns, themselves made up of the assembly of tens of thousands of fibers of few microns diameter. Thus, the mechanical behavior of the reinforcements is obtained by a sum of responses obtained experimentally to specific loading path (compression, tension, bending, shear, etc.) [1]. These mechanical responses are subsequently modeled

by equations whose form is obtained by hypotheses on the most influent parameters [2, 3, 4], without a truly rigorous approach of the complex physics involved (large number of fibers, variability, undulation of fibers, sizing, etc.). This is particularly the case for compression behavior in which a direct relationship is assumed between the compression stiffness and the fibers volume fraction according to an empirical law. If this law works correctly, it requires an identification for each new type of yarn and does not allow to highlight the structural parameters, which can improve the structure performances and to anticipate the mechanical behavior of fabrics without having to create and test it.

The goal of this paper is therefore to be able to tackle this lack by studying the mechanical behavior of an assembly of quasi-parallel fibers which represent the fibrous structures most used for technical applications. In order to achieve this goal, several solutions exist; an experimental approach couldn't be sufficient as it requires a very important number of experiences, because there are many loading paths and an important number of undulations exist. It is therefore necessary to be able to use effective numerical approaches allowing a parametric study, i.e. carrying out many tests in a short time. The chosen strategy is therefore to be able to create a virtual estimator of the behavior of a fibrous assembly and to validate it by experiments. One of the most important difficulties to study the behavior of fiber assembly is undoubtedly the size of the fibers (a few micrometers) which make them very difficult to handle and observe individually. As the goal of this study is to understand the strain phenomenology of fibrous assemblies, a model of fibers is done at larger scale (500 microns) as a first approach; in a second time, simulations with fibers at a "real" scale are performed. To achieve this goal, many steps should by carried-out successfully. The first is to develop a numerical strategy to efficiently simulate, at the fiber scale, the strain of the architecture under various solicitation. The second step is to define experimental validations to ensure the reliability of this virtual estimator by comparing its results with experimental results. The third step aims to define indicators of the microstructure that allow to analyze the results. Finally, it is necessary to use this strategy to create any type of architecture with a defined parameters and apply different paths of loadings to analyze the mechanical response of the structure. A first numerical approach was established by the thesis of Oussama HAJI [5]. This approach allowed to highlight the feasibility of the first and the second step of the strategy, but it is now necessary to be able to improve them and especially to carry out the last two steps as well as to operate the entire strategy to carry out parametric studies and conclude on their influence on the mechanical behavior. The aim of this paper is to improve the accuracy of existing virtual numerical estimators from experimentation to post-processing, as well as numerical strategies. The developed accurate model approach allows understanding and modeling the mechanical behavior, to build a constitutive law of the yarn.

2.Experiment and simulation strategy

2.1. Tomography combines micro-compaction experiment

Two fiber bundle samples consisting of 40 dry polyester fibers, without matrix or sizing, were manually prepared, where a single fiber length is approximately 14-14.5 mm, with diameter of 0.5mm, density of 1.38e-09 T/mm^3, Young's modulus of 6 GPa and Poisson's ratio of 0.25 as shown in Fig.1(a). The sample contained only 40 fibers since considering that (i) the numerical virtual estimator is still in the validated stage, a large number of numerical simulations are required, with a reasonable number of fibers to control the simulation time; (ii) the fiber samples are prepared manually, so it is difficult to prepare a large number of fiber samples. The sample is placed in a transparent support of PMMA (Poly methyl methacrylate) as shown in Fig.1(a).

This study used an X-ray tomography system (model EasyTom Nano 160, Fig.1(b)) to scan the samples. The micro-compaction machine (Deben, Fig.1(c)) is equipped with two compaction plates, upper and lower. The upper compaction plate is always fixed, while the lower one is movable and connected to a piezoelectric linear motor installed at the bottom of the compaction machine. The sample is compressed vertically in the "scan channel". The sensor is located in the upper part of the machine Deben, and the sensor of 500N was used. To avoid the influence of inertial effects on the fiber rearrangement, it was crucial to maintain quasi-static compression. The speed of compaction was fixed to $V_{compaction}$=1 mm/min. The tomography scan sample at each compaction step (Fig.1 (d, e)), with the spatial resolution of 9 μm, tube tension of 60 KV and tube intensity of 100 μA. The slices (cross-sections) of the fiber bundle were obtained by three-dimensional reconstruction of the tomography data processing by using the software “Xact”.

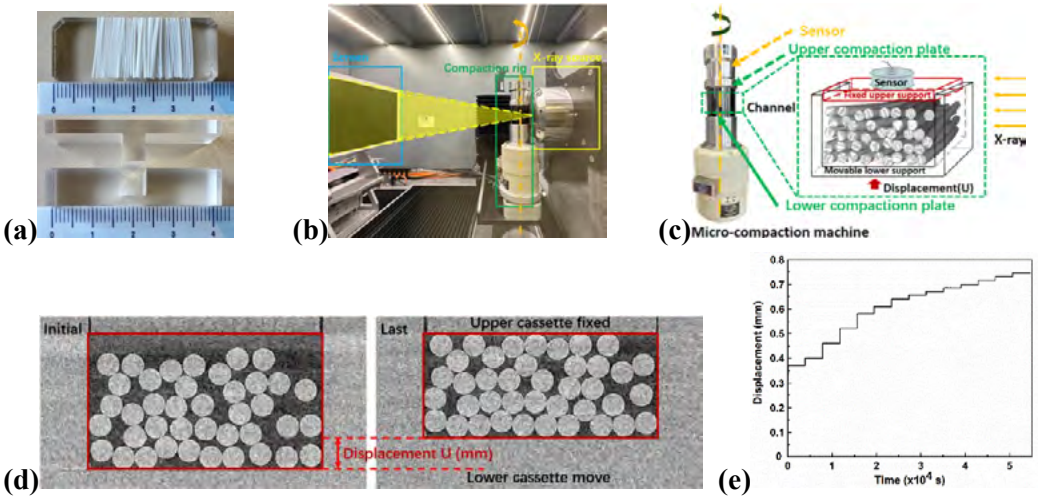

Figure 1. Tomography combines micro-compaction experiment. (a) The fiber bundle sample with cassette/compaction channel/ transparent support of compaction. (b)X-ray tomography system, (c) micro-compaction machine (Deben). (d, e) Compact path imposed by displacement.

2.2 Reconstruction fiber bundle with virtual numerical estimator

As mentioned above, the fiber bundle virtual numerical estimator was developed by O. Haji [5, 6], and includes two parts: reconstruction of numerical fiber bundle geometry and simulation compaction test with ABAQUS®.

The reconstruction step of numerical fiber bundle geometry consists of two steps: (i) tomography slices post-treatment and (ii) create fiber bundle centerline with MATLAB.

(i) Tomography slices post-treatment:

Firstly, the flow chart for post-treatment tomography slices of fiber bundle shown in Fig.2(a). According to the tomography slices of fiber section (horizontal, vertical), the shape of fiber vertical section could be considered ideal regular circle, then extract the fiber centerline to reconstruct the numerical fiber geometry. In order to improve the accurate of reconstruction step, it’s important to remove another part except fiber section, the 3 steps were performed for fiber bundle: (a) separation, the X-ray CT scan image manifest as an aggregation of pixel points. It can be seen that fibers and pores are composed of these distinct pixel points, and each one is characterized by varying the grayscale values. Therefore, by setting a grayscale threshold to make the separation between voids and fibers (only black and white exists). (b) elimination of compaction channel, here, the cassette and fibers both are white, this step

cloud avoid the influence of compaction channel during extract fiber centerline. (c) remove noise, this step plays the same role of avoiding the effects of noise in slices on the extracted fibers. Secondly, the fiber bundle centerline is extracted by detecting the center of the fiber cross-section based on the FIJI preprocessed image, and then connecting the center points of the same fiber.

(ii) Create fiber bundle centerline with MATLAB:

The fiber cross-section in each X-ray tomography slice can be approximated as a circle, and the center of this circle can be a pixel point coordinate. Therefore, the radius and the center of each circle can be defined by the "Imfindcircles" function in MATLAB. The principle used in this function for definition of the circle is the “Circle Hoff Transform (CHT)”, as shown in Fig.2 (b1). The detected section (circle) projected on the initial slice shown in Fig.2 (b2). The coordinates of the center point and the radius of each fiber cross-section are obtained by the CHT algorithm, but MATLAB cannot automatically determine which circles of different slices belong to the same fiber. Therefore, the determination method is shown in Fig.2 (b3, b4), for center point $\boldsymbol{C_{ij}}$ in slice $\boldsymbol{j}$ and the center point $\boldsymbol{C_{ij+1}}$ in slice $\boldsymbol{j+1}$ belonging to the same fiber **i**, the distance between the projection of $\boldsymbol{C_{ij}}$ and $\boldsymbol{C_{ij+1}}$ should be less than the diameter of fiber:$\left|\boldsymbol{C_{ij+1}} - \boldsymbol{C_{ij}}\right| < \emptyset$. In this study, the distance between the two slices was $d = 9$ µm, which is enough small compared to the fiber’s diameter $\emptyset = 500$ µm.

As mentioned earlier, the tomography images are composed of thousands of pixel points. As shown in Fig.2 (b5), when defining a circle, the position of the center coordinates in the slice calculated using the CHT algorithm can be divided into two cases: Case 1, the center of the circle is not on the pixel point and the actual center point is offset to the nearest pixel point when defining the center of the circle; Case 2, the center of the circle is on the pixel point and no offset occurs.

Therefore, when the center coordinates of fibers are connected, the form of the “folded” line (extracted line) in Fig.2 ((b5)-right) and Fig.2 (b6)) (before smooth centerline) is obtained, which does not correspond to the actual fiber morphology due to the uncertainty of 1 pixel on the center position. The oscillations amplitude depicted Fig.2 (b6)) are, indeed verified to be lower than 1 pixel. A smoothing step has then to be performed on them to obtain the consistent trajectory Fig.2 (b6)).

2.2.2 Numerical strategy

This study develops and enhances an existing simulation strategy [5, 6]. The simulation strategy, which is executed in ABAQUS®/EXPLICIT, shows that Explicit method can be used for quasi-static dynamics simulations under many contact conditions and that selection of appropriate simulation parameters can

optimize the computational time. The beam element used in the present strategy are B31 as they are more stable than B32, and the material damping coefficient $\alpha = 10^5$ and a compaction loading speed of $v = 10^3$ mm/min, can optimize the calculation time and avoid the inertia effect of the fibers [5,6] . In addition, for this simulation, other parameters were chosen: (i) the tangential contact was modeled by the Coulomb's friction law, where the friction coefficient was used with an average value of $\mu = 0.2$ according to Gassara [7]; (ii) the adhesion coefficient was assumed to be equal to the coefficient of friction; and (iii) the diameter of the beam elements of the single fibers was the same (0.5mm) and constant [5,6].

In order to improve even more the numerical simulation estimator, the selection of the size of the mesh elements of the fibers and the compaction channels (sample cassettes), the correction of initial penetration between the fiber bundles was set in next part.

When the mesh size is small enough, the accuracy of the calculation does not change significantly as the mesh continues to decrease, after the calculation of 3 beams compaction test, the sensitivity analysis the good range the for the mesh sizes is defined and will then be used for the compaction calculations. When the element size of the fibers is L_b=0.3 (a single beam contains 50 elements), the reaction force of compaction planes stabilizes and reaches a critical value for the mesh sensitivity. Since, the discrete rigid solid will have to be considered for the real compaction case, the mesh sensitivity of the discrete rigid is tested with a beam with a mesh size of 0.3mm and the same case. The reaction force results are basically the same as the reference with analytical rigid part when the mesh size of the discrete rigid part is 0.2mm. The considered Polyester fibers (Poisson's ratio = 0.25 [5]) for the validation experiments have a diameter of 500 µm and a density of 1.38×10^{-09} T/mm^3. In order to optimize the mechanical properties of the fibers as accurately as possible, mechanical tests were carried out. The tensile experiment was performed for single fiber, the resulted average Young's modulus is 6 ± 0.2 Gpa, and the average value of this parameter will be used in the simulation. In addition, the initial penetration (Fig.3) and contact control are manually proposed in the "*.inp*" file for the contact pairs between fibers [8].

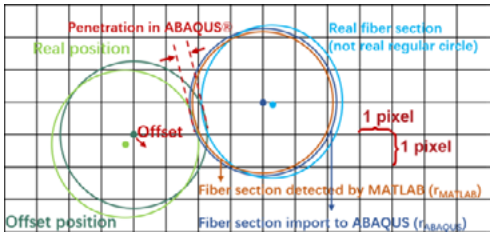

Figure 3. Penetration principle between fibers in ABAQUS®.

3.Indiacotor tools

Fiber Position Deviation Diameter Ratio (FPDDR) and Fiber Position Deviation Displacement Ratio (FPDUR) are the ratio of the average of the fiber position distance relative to the fiber diameter and displacement of compaction step in the experiments and simulations, respectively. Fig.4 shows FPDDR and FPDUR error proposed indicators to quantify the fiber position between simulation and experiment:

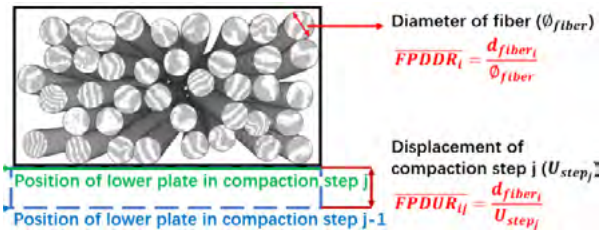

Figure 4. Indicators used to represent fiber position errors in experimental and simulation results.

4.Discussion

4.1 Imposing gravity simulation to the initial geometry

As mentioned before, the fiber's section is composed with thousands of pixel points, when reconstruct the fibers with MATLB, the fiber's centerline is not exactly coinciding with real one (Fig.2 (b5, b6)), where the deviation less than 1 pixel. Indeed, the initial fiber's section penetrated a little before calculation or miss the point of contact that exists in the real bundle geometry. After the introducing of the gravity force, the fibers move towards each other until their contact are each an equilibrium, the centerline before and after imposing gravity shown in the Fig.5, and the fiber position errors shown in the Tab.1 ($\boldsymbol{d_{fiber_i}}$: the distance between simulation and experiment for fiber $\boldsymbol{i}$). This clearly shows the influence of the voxel size but also that the initial modeling obtained for sample 1 and 2 is accurate since very small changes and the indicators are observed.

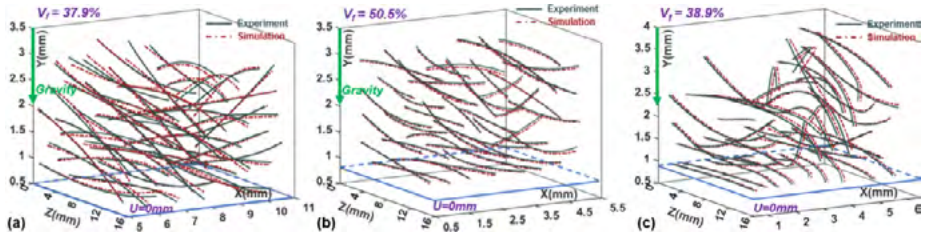

Figure 5. The centerline of fiber bundle after imposing the gravity field. (a) Sample 0 (Dr. Haji's sample), (b) Sample 1, (c) Sample 2.

Table 1. The position errors of fibers between experiment and simulation after imposing gravity.

	Sample 0		Sample 1		Sample 2	
Spatial resolution (μm)	15		9		9	
FPDDR (%)	μ =15.83	σ =5.50	μ =5.20	σ =1.20	μ =8.30	σ =2.45

4.2 Compaction simulation

The compaction simulation of sample 0, 1 and 2 were performed here, volume fraction in the function of compaction pressure the shown in Fig.6 (a1-c1), form the compaction curve, the consistency between the simulated and experimental values is interesting and acceptable. In addition, the 3D rendering fiber bundle of simulation and 3D reconstrued geometry of experiment of last compaction step were performed. The morphology of fibers in simulation and experiment are closely related.

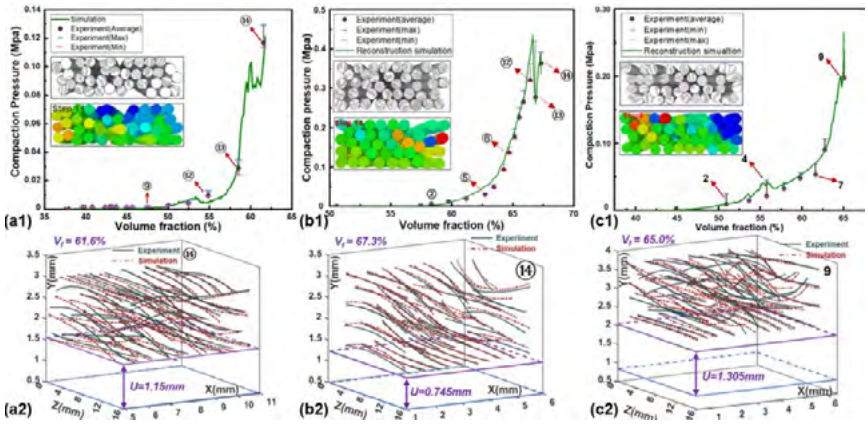

Figure 6. Compaction simulation for the 3 samples.

Furthermore, the centerline position for the last step shown in the Fig.6 (a2-c2). Even if the sample 2 results are not as accurate as for the sample 1, experimental and simulated results is good remains in good agreement which enables to confirm the potential of the strategy to model consistently the deformation of a fiber bundle during compaction. By introducing a gravity field into the three fiber samples, the contact between the fibers of Sample 1 is more stable. The more stable contact state results in the less error accumulation between the simulated and experimental fiber positions in the last compaction simulation. It is important to notice and confirm here that the initial errors of the reconstructed microstructure from the experimental one is of a main importance for the general consistency which is definitely a very good thing for the use of the strategy as a virtual estimator because this step does not exist for such simulations.

Table 2. The position errors of fibers between experiment and simulation of 3 samples for last compaction step.

Indicators (%)	Sample 0		Sample 1		Sample 2	
	μ	σ	μ	σ	μ	σ
FPDDR	27.95	10.56	14.07	7.89	19.60	11.60
FPDUR	12.15	2.59	9.44	5.40	7.51	4.45

5. Conclusion

Compaction experiments and simulations were carried out on three samples using the simulation strategy described above, with an initial volume fraction of 37.9%, 50.5%, 38.9%. The accuracy of the initial model was verified by imposing a gravity simulation. The contact position detected by post-treatment strategy could be verified by imposing the gravity filed to the fiber bundle geometry: the fibers move until the static equilibrium and the differences consequently point out the uncertainties of the reconstruction process. The average error (FPDDR: the error according to the fiber diameter) of the fiber position under imposing gravity simulation and the one extracted by tomography experiment for the three samples was 16%, 5%, and 8% of the fiber diameter, respectively. As expected the increase in the XCT resolution enables obtain a more accurate initial consistency which is very promising for the proposed strategy. This means that the initial contact introduced by the post-treatment strategy achieve the goal, with a very satisfying accuracy even if the errors couldn't be completely eliminated due to the necessary simplification of the modeling.

Even though, there is potential for improvement, the comparison between the simulated and experimental, in terms of macroscopic compaction behavior, and the position of the fibers after compaction is interesting and promising and enables to validate that the virtual numerical estimator, as well as the developed microstructural analysis tools are effective for the current work.

Keywords: delamination, fibre bridging, design, damage tolerance

Abstract
Composite structures can fail by delamination. For some composite materials, denoted damage tolerant materials, the fracture resistance increases with crack length (R-curve behavior). We consider three design approaches: Level 1 is a traditional linear elastic fracture mechanics design approach where the applied J integral value, J, should be kept below J_0, so that no crack growth occurs, and cyclic crack growth is assessed by the Paris-Erdogan relation of an unbridged crack. Level 2 is restricted to steady-state problems for which the J integral is independent of crack length, so that under monotonic loading unstable cracking will not occur unless J reaches J_{ss}. The design can be made using analytical models. Level 3 is design using cohesive laws. Level 3 is more general, but also more demanding; the cohesive laws must be known, and a numerical model must be used. We illustrate the Level 1 and Level 2 approaches by analyzing delamination crack growth from a ply-drop under static and cyclic loading. The Level 2 design stresses for both static and cyclic crack growth were significantly higher than that for Level 1. Finally, we discuss the implications regarding safety factors and the limitations of the proposed approaches.

1. Introduction

Failure of composite structures often involves delamination, which is crack growth between layers. Some composites have a relative brittle interface between layers, while others, denoted damage tolerant materials, demonstrate an increasing fracture resistance with crack extension (R-curve behaviour). A physical mechanism that can generate rising fracture resistance is large-scale bridging by fibres that cross over the crack and create tractions along the crack faces opposing the crack opening. The fracture resistance, characterized in terms of the J integral [1], rises from an initial value, J_0, (a sharp, unbridged crack) to a significantly higher steady-state value, J_{ss} (fully developed bridging zone) under monotonic loading [2]. Under cyclic loading, the crack growth rate is fastest in the beginning (sharp, unbridged crack) and decreases as the bridging zone becomes larger and reaches a

significantly slower growth rate as the bridging zone is fully evolved [3]. From an engineering standpoint, such material behaviours are highly desirable, since the increasing fracture resistance provides an additional intrinsic safety margin. However, current design approaches based on linear elastic fracture mechanics do not utilize these behaviours. This paper proposes a design approach to utilize the advantageous properties of damage tolerant composites, shifting from a "no crack growth" to a "controlled crack growth" philosophy, allowing for stable, but not unstable crack growth.

The paper is organised as follows. First, in Section 2, we describe in more details the fracture mechanics properties of damage tolerant materials that exhibit large-scale bridging. Next, in Section 3, we discuss how these properties can be utilized in engineering design and presents two novel design approaches. Section 4 includes a case study, delamination from a ply drop. Section 5 includes some considerations and suggestions for future work and Section 6 presents the main conclusions.

2. Design with damage tolerant materials

2.1. Utilization of R-curve

In this paper, we will make a sharp distinction between brittle materials and damage tolerant materials. By "brittle materials" we refer to those that follow linear elastic fracture mechanics (LEFM). Conversely, "damage tolerant materials" are characterized by R-curve behavior, i.e., the fracture resistance expressed in terms of the J integral, rises as the crack tip advances. Fig. 1 shows a schematic of R-curve behavior. In Fig. 1, the fracture resistance, J_R, is shown as a function of the end-opening, δ_n^* , the opening of the original crack tip. Crack growth starts when the value of the applied J integral reaches the value, J_0. With increasing loading, J_R rises, eventually reaching a steady-state value, J_{ss}, denoted the steady-state fracture resistance. Fig. 2 provides a visual representation of the mechanism of crack bridging that underpins the rising fracture resistance. The bridging zone spans the distance from the initial crack tip to the current crack tip. The fracture resistance J_R increases as the end-opening increases. Eventually, the bridging starts failing at the original crack tip, and now the bridging zone extends along with the crack tip at a constant, steady-state fracture resistance, J_{ss}.

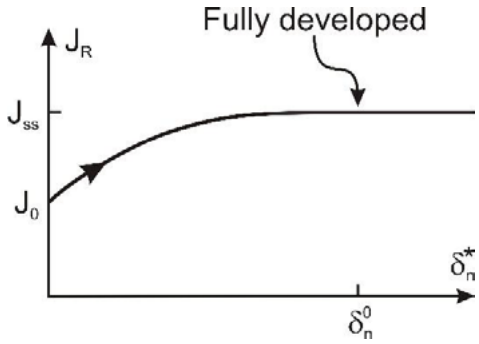

Figure 1. Schematic of R-curve behavior: The fracture resistance, J_R, starts from an initiation value, J_0, rises with crack opening, eventually reaching a constant, steady-state fracture resistance, J_{ss} as the bridging zone is full developed.

Fig. 3 shows the crack growth behavior for a crack in a damage tolerant material subjected to cyclic loading between fixed maximum and minimum J integral values, J_{max} and J_{min}, respectively. Initially, the crack starts growing as a sharp, non-bridged crack. As the crack tip advances and the bridging zone developed between the original crack tip and the current crack tip, the crack growth rate da/dN decreases (here, a is the crack length and N is the number of load cycles). In steady-state specimens (see Section 2.3 below) the crack growth rate attains a constant crack growth rate once the bridging zone is fully-evolved and the crack tip and bridging zone translate along the specimen in a self-similar manner. The crack growth rate at the onset of cyclic crack growth is denoted as da/dN_{nb} (subscript nb indicates "non-bridged") and crack growth rate of the fully-developed bridging zone is denoted as

da/dN_{fd} (subscript fd indicates "fully developed"). The crack extension corresponding to the onset of the fully-developed crack growth is denoted by Δa_{fd} and the associated number of cycles to reach the fully-developed bridging zone under cyclic loading is denoted N_{fd}. In general we expect theses parameters to be material constants but for mixed mode cracking they will depend on the mode mix.

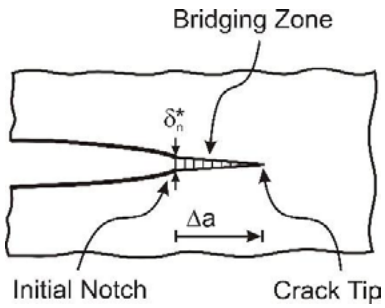

Figure 2. Schematics of a crack tip with a bridging zone. The bridging zone spans the distance from the original to the current crack tip position.

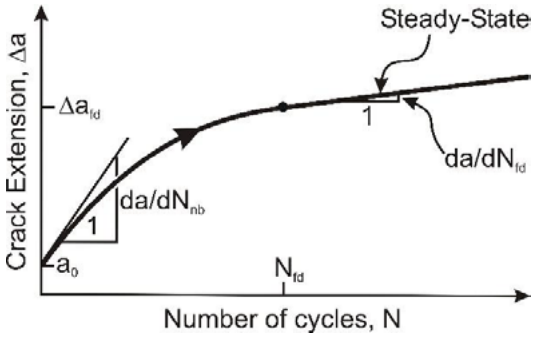

Figure 3. Schematic of cyclic crack growth with large-scale bridging in a steady-state specimen. The crack growth rate starts from an initial value, da/dN_{nb} (corresponding to an un-bridged crack), decreasing to a lower, constant growth rate, da/dN_{fd}, as the bridging zone becomes full developed.

It is clear that the presence of fibre bridging is beneficial from the perspective of engineering design: The rising fracture resistance can lead to crack arrest, or in the case of cyclic loading, substantially reduce the crack growth rate. The goal of this paper is to develop robust design guidelines that fully exploit the fracture mechanics of damage-tolerant materials, ensuring safety and reliability.

In the following, we will formulate design criteria for static loading corresponding to the maximum allowed applied load (avoiding unstable crack growth) and design criteria for the number of cycles between inspection intervals to ensure that unstable crack growth does not happen under cyclic loading. Our approach is categorized into three distinct levels of design methodology: Level 1, Level 2, and Level 3. These design approaches are described in the following sub-sections.

2.2. Level 1 design approach: Traditional LEFM

Level 1 is a traditional design where under static loading, the applied J integral value, J should be kept below J_0, so that no crack growth occurs. Crack growth under cyclic loading is assessed by the Paris-Erdogan relation [4] for unbridged crack, i.e., using Paris-Erdogan parameters fitted to da/dN_{nb}-data.

While the Level 1 design approach is universally applicable and inherently safe, it is also notably conservative for damage-tolerant materials. This conservatism stems from its failure to utilize the

potential benefits of increased fracture resistance and the deceleration of crack growth observed in cyclic loading of such materials.

2.3. Level 2 design approach: Steady-state specimens

The Level 2 design approach is restricted to a class of problems we call steady-state problems for which the J integral remains constant regardless of crack length. The concept of steady-state specimens was introduced by Suo *et al*. [2, 5]. For a steady-state specimen subjected to a monotonic increasing loading, the crack front will advance stably when J exceeds J_0 until the load is so high that the value of the applied J reaches J_{ss}. When J exceeds J_{ss}, the crack grows unstably. Consequently, for steady-state specimens, J_{ss} can be used as the critical value for the applied load in the prediction of the load-carrying capacity. Under cyclic loading, the crack growth in steady-state specimens will include both the initial region where the crack growth rate slows down and the fully-developed (steady-state) cyclic crack growth rate, da/dN_{fd}. Assuming the maximum permissible crack length is a_{max} (an example will be given in Section 3), and the initial unbridged crack length is a_0. Then, the total number of cycles required for the crack to extend from a_0 to a_{max} can be estimated by taking into account the effects of crack bridging:

$$N_i = N_{fd} + \frac{a_{max} - a_0 - \Delta a_{fd}}{da/dN_{fd}} \tag{1}$$

2.4. Level 3 design approach: Design using cohesive zone modelling

The Level 3 design approach involves numerical modelling with cohesive laws for the prediction of the load-carrying capacity of composite structures. The design approach is general, it is not restricted to steady-state specimens. Thus, it can provide precise predictions for structures that may fail under loads where the bridging zone has not yet fully developed. However, the development of cohesive laws based on experimental data - especially those pertaining to mixed-mode loading conditions - is still an emerging discipline. Similarly, modelling cyclic crack growth with cyclic cohesive laws has yet to reach a level of maturity suitable for standard engineering practice. Thus, although Level 3 design is expected to be more accurate and general than the Level 1 and Level 2 design approaches, it is not yet sufficiently mature to be used in engineering analysis of large-scale crack bridging problems. Consequently, we will not employ the Level 3 design approach in the analyses presented within this paper.

3. Case story: Delamination from a ply-drop

To demonstrate the practical application of the Level 2 design approach, we present a case study focusing on delamination crack growth originating from a ply-drop. A ply-drop is a common feature in composite structures designed to achieve targeted variations in thickness; this is typically accomplished by terminating a layer of the composite, known as "dropping" a ply. The geometry at the site of the ply-drop can lead to stress concentrations or even stress singularities upon loading, which in turn may initiate a delamination crack. This crack can then propagate along the interface between the terminated ply and the main laminate. We wish to analyse the delamination crack growth under both static and cyclic loading.

3.1. Problem description

An idealized situation of a delamination from a ply-drop is depicted in Fig. 4. The applied stress in the main laminate is $\bar{\sigma}$, the initial crack length is a_0, the thickness of the delaminated layer is h_1, the thickness of the main laminate is $h_2/2$, the width of the laminate is B and the Young's modulus of the laminate in the longitudinal direction (the x_1-direction in Fig. 4) is denoted E_{11}. Furthermore, the spacing to the next ply-drop is L. This implies that before the crack tip reaches the next ply drop, the

thickness of the delaminated part equals one ply thickness, $h_1 = t$, where t is the thickness of a single ply. Once the crack tip has advanced by the next ply-drop, the delaminated layer will include two plies, i.e., $h_1 = 2t$.

The problem (Fig. 4) has been analysed by fracture mechanics [6]. The model is actually a symmetric model with two delamination cracks propagating simultaneously, so that the specimen does not undergo bending. Still, the analytical model has been shown to give results that deviate only about 4 % from a J integral calculation obtained using an accurate finite element model of the ply-drop problem with one delamination crack (i.e., not assuming symmetry) [7]. The J integral evaluated along a path along the external boundaries gives:

$$J_{ext} = \frac{\bar{\sigma}^2 h_1}{2E_{11}} \frac{h_2}{(2h_1 + h_2)} \tag{2}$$

Note that the J integral result is independent of crack length and that the J integral value scales with the layer thickness h_1. For thick laminates ($h_2 \gg h_1$), J_{ext} scales linearly with h_1.

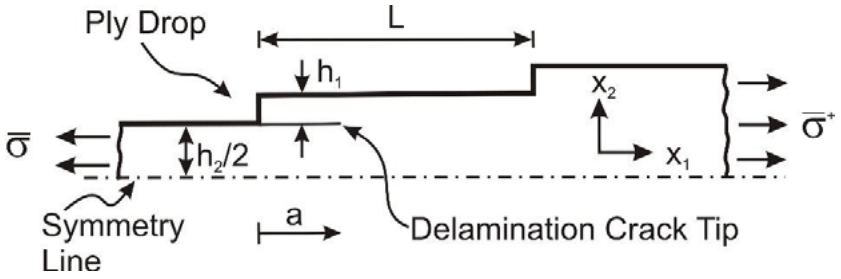

Figure 4. The idealized ply-drop problem with a delamination crack extending between along the interface between a surface layer and a main laminate. The thicknesses of the surface layer and the main laminate are h_1 and $h_2/2$ respectively, and the spacing to the next ply-drop is L.

For the present case, we will assume the following parameters: $h_1 = 1.5$ mm, $h_2 = 6.0$ mm, $B = 12.5$ mm, $L = 850$ mm and $E_{11} = 45$ GPa, corresponding to a unidirectional glass fibre/polyester polymer matrix composite. Additional fracture mechanics parameters will be taken from the literature. The static properties will be taken from Sørensen and Jacobsen [8] and the cyclic properties will be obtained from Holmes *et al*. [3].

The task is, for each design approach, to predict a maximum allowable stress for static loading and the number of cycles between inspection intervals assuming that the non-destructive inspection method can detect delamination cracks larger than the size, a_0. Thus, for the cyclic loading, we will calculate the number of cycles it takes for a crack to propagate from crack length a_0 to $a_{max} = L$. The logics is, that when the crack tip advances past the ply drop, $h_1 = 2t$, so that J_{ext} will increase significantly (nearly doubled, see eq. (2)), resulting in a much faster crack growth under cyclic loading.

3.2. Design using Level 1 design approach

For the prediction of the static strength, we rewrite (2) as follows:

$$\bar{\sigma}_i = \sqrt{\frac{2(2h_1 + h_2)}{h_2} \frac{J_0 E_{11}}{h_1}}, \tag{3}$$

where subscript *i* has been added to indicate the stress value that corresponds to the initiation of crack growth and we have set the J integral value equal to J_0. Moreover, we take the LEFM mode mixity, ψ,

for the delamination crack to be 50°. We obtain the value of J_0 for $\psi = 50°$ from Fig. 10 in Sørensen and Jacobsen [8] to be 250 J/m^2. Inserting values into (3) gives $\bar{\sigma}_i = 150$ MPa.

For cyclic loading, we use the experimental data of Holmes *et al*. [3] for J_{max} = 402 J/m^2 and a moment ratio $M_1/M_2 = 0.1$. Then from Fig. 11 in Holmes *et al*. [3] we find $da/dN_{nb} = 67$ x 10^{-4} mm/cycle. The number of cycles to grow the delamination crack from an initial length a_0 to the critical length, a_{max}, is

$$N_i = \frac{a_{max} - a_0}{da/dN_{nb}}. \tag{4}$$

Setting $a_{max} = L$ and (for simplicity) $a_0 = 0$, gives

$$N_i = \frac{L}{da/dN_{nb}}. \tag{5}$$

Inserting values gives $N_i = 127$ x 10^3 cycles = 0.123 x 10^6 cycles.

3.3. Design using Level 2 design approach

The J integral result (2) is valid also for the large-scale bridging situation. For the static analysis, we now set $J_{ext} = J_{ss}$. Then (2) can be rewritten as:

$$\bar{\sigma}_{fd} = \sqrt{\frac{2(2h_1 + h_2)}{h_2}\frac{J_{ss}E_{11}}{h_1}}, \tag{6}$$

where we have used the subscript fd to indicate that the bridging zone is assumed to be full developed. From Fig. 12 in Sørensen and Jacobsen [8] we find $J_{ss} = 2400$ J/m^2 for a tangential separation, δ_t, of 2 mm. Inserting values into (6) gives $\bar{\sigma}_{fd} = 460$ MPa.

For the cyclic loading, we find from Fig. 11 in Holmes *et al*. [3] that $da/dN_{fd} = 3.4$ x 10^{-4} mm/ cycle (i.e., only about 5 % of da/dN_{nb}), $N_{fd} = 100.000$ cycles, and $\Delta a_{fd} = 100$ mm. Furthermore, setting $a_{max} = L$ and (for simplicity) $a_0 = 0$, eq. (1) becomes

$$N_i = N_{fd} + \frac{L - \Delta a_{fd}}{da/dN_{fd}}. \tag{7}$$

Inserting values gives $N_i = 2.21$ x 10^6 cycles.

3.4. Safety factors and allowable design value

The DNV standard for composite components [9] can be used to determine allowable design values for both static and cyclic loading. This standard allows for designing structures or components with different safety requirements based on their assigned safety class, which is determined by the consequences of failures at the ultimate limit state (ULS). Structural reliability is maintained through the use of partial safety factors specified in the standard, which are adjusted to achieve specific reliability levels. Table 1 summarizes the assumptions from [9] and the main results for static loading. The maximum allowable design stress of the Level 2 design approach (fully utilizing the fracture resistance due to fibre bridging) for static loading is more than 2.5 times the design stress for the Level 1 design approach.

Table 1 Allowable design stresses for static loading obtained using partial safety factors from [9]

	Level 1	**Level 2**
Safety class	Normal	Normal
Failure type	Ductile	Brittle
Number of test repetitions	10	10
COV	15%	15%
k-factor for characteristic value	2.5	2.8
Partial resistance factor, γ_m	1.49	1.83
$J_{0\ mean}$ for Level 1 or $J_{ss\ mean}$ for Level 2	250 J/m^2	2400 J/m^2
$J_{0\ char}$ for Level 1 or $J_{ss\ mean}$ for Level 2	156 J/m^2	1392 J/m^2
$J_{0\ allowable}$ for Level 1 or $J_{ss\ allowable}$ for Level 2	105 J/m^2	761 J/m^2
Maximum allowable design stress	97 MPa	262 MPa

Table 2 presents the assumptions from [9] and the main results for cycling loading. Safety class, failure type and number of test repetitions are assumed identical to those of Level 1. The inspection interval of the Level 2 design approach is more than 20 times that associated with the Level 1 design approach.

Table 2 Inspection intervals for cyclic loading obtained using partial safety factors from [9]

	Level 1	**Level 2**
COV	5%	5%
k-factor for characteristic S-N curve	3.9	3.9
Partial fatigue safety factor, γ_{fat}	30	30
da/dN_{mean}	$67 \cdot 10^{-4}$ mm/cycle	$3.4 \cdot 10^{-4}$ mm/cycle
da/dN_{char}	$80.1 \cdot 10^{-4}$ mm/cycle	$4.06 \cdot 10^{-4}$ mm/cycle
Calculated number of cycles	$106 \cdot 10^3$	$2.09 \cdot 10^6$
Allowed number of cycles between inspections	$3.53 \cdot 10^3$	$69.7 \cdot 10^3$

4. Discussion

For the Level 1 design approach, the maximum allowable stress under static monotonic loading is determined based on the condition that there is no crack growth in a non-bridged crack, following traditional LEFM principles. The number of cycles until the crack reaches the next ply drop is calculated using the growth rate characteristic of a non-bridged crack. While these estimates are precise for brittle interface fractures, they tend to be overly conservative for damage-tolerant materials that display significant R-curve behavior.

Conversely, the Level 2 design approach sets the maximum stress under monotonic loading at the point where the bridging zone in damage-tolerant materials is fully developed. This approach is expected to yield a more accurate estimate of the structure's load-carrying capacity. Similarly, the prediction of the number of cycles between inspection intervals under cyclic loading is anticipated to be more precise. It is important to note that the Level 2 design stress and the number of cycles between inspection intervals are substantially higher than those suggested by the Level 1 approach, highlighting the conservative nature of the latter. However, the Level 2 results are finely balanced; a slight excess in the maximum allowable stress can lead to unstable crack growth, and if the actual number of load cycles surpasses the estimated threshold, the crack may extend beyond the next ply drop and propagate more rapidly. Therefore, the safety factors for design stress and number of cycles between inspections in the Level 2 approach should be selected with greater caution than those for Level 1.

An additional perspective to consider is the advancement of more damage-tolerant materials, such as composites that exhibit enhanced fibre bridging during delamination. The development of such

materials is particularly advantageous for large-scale composite structures like wind turbine rotor blades, which are manufactured in large sections and cannot be entirely free from manufacturing defects. The importance of creating composite materials with improved damage tolerance cannot be overstated. In parallel, design methodologies like the one outlined here must evolve to ensure that the benefits of increased fracture resistance can be fully utilized.

Future research should explore incorporating cohesive laws into a probabilistic load-resistance design format (LRDF) similar to DNV-ST-C501, and the facilitating the application of a Level 3 design approach.

5. Conclusions

The study has demonstrated that fibre bridging in damage-tolerant composite materials can markedly enhance fracture resistance during static loading, as evidenced by R-curve behavior, and can significantly decrease the crack growth rate under cyclic loading. The traditional design approach, referred to as Level 1 in this paper, does not incorporate these advantageous material properties during the design phase. However, an alternative design methodology, named Level 2, has been shown to fully exploit the characteristics of damage-tolerant materials.

Our case study, which examined delamination crack growth originating from a ply drop, revealed that the maximum allowable design stress for static loading in the Level 2 design approach is more than double that of the Level 1 approach. Similarly, the inspection interval for cyclic loading under the Level 2 approach can be extended to over ten times that of the Level 1 approach. The substantial benefits observed with the Level 2 approach suggest that it offers a compelling advantage and warrants further development and maturation for practical engineering applications.

Keywords: buckling resistance, wind turbine blades, stability analysis

Abstract
The latest design standards and guidelines for wind turbine rotor blades encourage model validation through sub-component testing, offering the incentive of lower material reduction factors. Structural stability, i.e., the buckling resistance, stands out among the critical design parameters. This aspect is crucial for the large, aerodynamic shell-like areas constructed from lightweight sandwich materials. In support of this model validation, our research introduces a novel test load frame designed to assess the stability of composite sandwich plates under quasi-static compressive loads. The load frame accommodates relatively thick plates with adjustable aspect ratios and aims to: (i) provide simply supported boundaries on all four edges, (ii) enable rapid installation of the specimen while accurately aligning the plate to the load axis, and (iii) allow for easy mounting in a standard universal testing machine. We successfully conducted a proof-of-concept test. For this purpose, a sandwich configuration consisting of glass, epoxy, and balsa wood was manufactured. It was tested quasi-statically to failure, while strains and out-of-plane deflections were monitored using a digital image correlation system. The critical buckling load was predicted using both an analytical orthotropic plate model and a finite element model, with the theoretical results overestimating the experimental values by 1.3% to 5.7%.

1. Introduction

Wind turbine blades are typically constructed from thin-walled cylindrical and airfoil-shaped shells, primarily composed of fiber-reinforced polymers (FRPs). These shells, susceptible to buckling [[1]-[2]], are designed with sandwich panels for enhanced stability, incorporating thin FRP skins and core materials like balsa wood, polyvinyl chloride (PVC), or polyurethane (PU) foam for lightweight purposes. Resin-filled grooves and holes in the core material aid resin infusion during manufacturing and accommodate the curvature of the shells. In [3], the importance of realistically representing core materials, considering resin uptake in sandwich constructions for wind turbine blades, was emphasized. Reducing resin uptake offers notable benefits to the specific flexural strength of the core [4]. However, the challenge lies in the complex experimental validation required to assess the impact of resin uptake on buckling resistance, particularly in adherence to the new design standard for blade structures [5][6]. This advocates for experimental validation to minimize partial material safety factors during the design process.

In response to this need, our research introduces a novel load frame designed for characterizing the buckling resistance of thick sandwich constructions [7]. This unique test frame accommodates simply supported flat plates with variable aspect ratios. The load frame can be mounted in standard universal testing machines. Moreover, we describe the proof of concept test and validate numerical and analytical predictions of the critical buckling resistance with the experimental results.

2. Methods

2.1 Experiment

2.1.1 Load frame design

The sandwich plate width and thickness can be adjusted at the lateral, as well as at the upper and lower boundaries, to accommodate variable plate dimensions. The frame can host spanning dimensions of 1.2m in height, 0.3m to 1.2m in width, and up to 0.05m in thickness. Its segmented, articulated roller bearing supports allow the plate edges to twist non-uniformly out of the plane at the load application and load reception positions. The tested plate is simply supported, with modular roller bearings for the horizontal edges and 'knife edges' for the vertical boundaries. The frame is optimized for compatibility with standard universal uniaxial testing machines, having clamping heads with flat bearing surfaces.

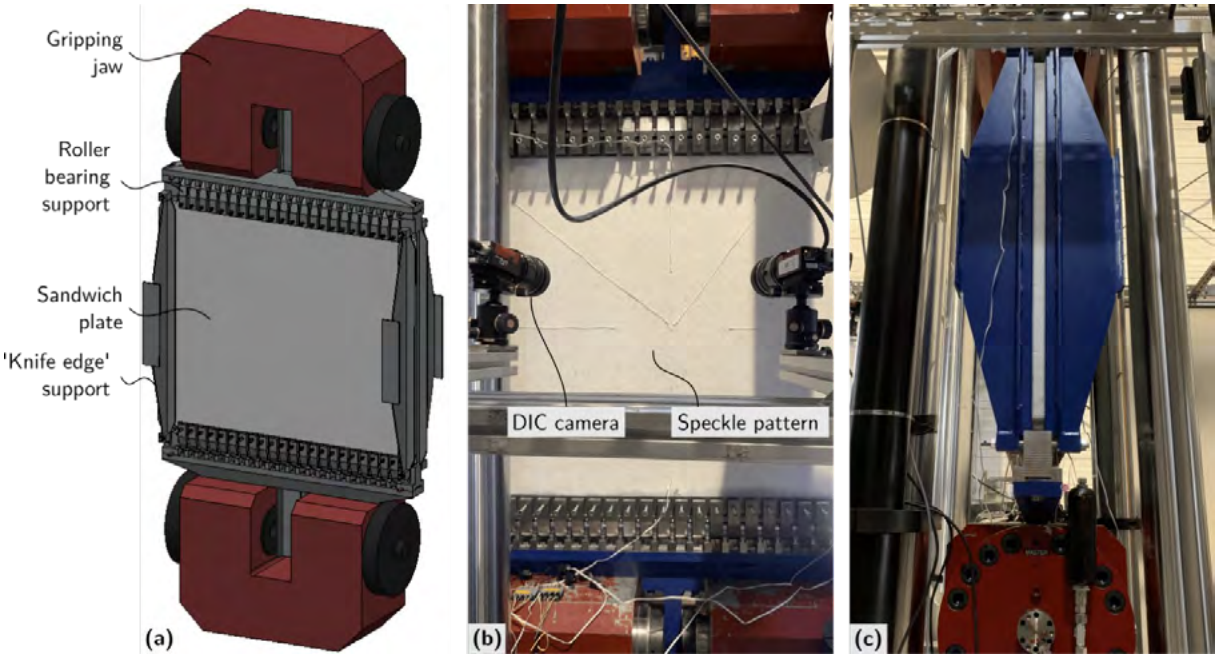

Figure 1. Load frame design: a. overview, b. front view (side B), and c. side view.

2.1.2 Manufacture of specimen

A sandwich panel of 1.2 m in width and 1.2 m in height was manufactured with Vacuum Assisted Resin Infusion Molding (VARIM) using E-glass fabrics of type SAERTEX X-E-778g/m^2 infused with epoxy resin of type Westlake EPIKOTE™ Resin MGS® RIMR035c with EPIKURE™ Agent MGS® RIMH037 for the skins and a balsa wood core of type BALTEK SB.100 with a nominal density of 148kg/m^3. The total thickness of the sandwich was measured to be 27.82 ± 0.42 mm around the plate edges (**Figure 2a)**. Additionally, the average thickness of the balsa wood, measured along the plate edges, was 24.86 mm, resulting in an average thickness of 0.74 mm per [±45$_2$] ply.

The layup was built symmetrically, i.e., [±45$_2$/Balsa/±45$_2$], with the last two biaxial plies rotated by 90° in the roll direction. During the infusion, a table was heated to 40°C. After the infusion, the sandwich was cured for 12 hours at 40°C.

About 25 mm balsa wood was removed from the load-introducing plate edges (**Figure 2b**) and replaced with short-glass-fiber-filled epoxy adhesive to enhance a smoother load transition in the sandwich structure, reducing the risk of local core crushing due to the low strength of the balsa wood. Afterwards, the panel was post-cured at 80°C for 7 hours.

2.1.3 Measurement instrumentation

A Digital Image Correlation (DIC) system was used to monitor the global displacement field from side B of the panel, where a fine black speckle pattern was applied over white ground paint (**Figure 1b**). Moreover, five pairs of axial Strain Gauges (SG) were mounted back-to-back on both sides of the plate (**Figure 2c**). SG1, SG2, and SG5 were aligned with the load axis (x-direction) while SG3, SG4, and

SG6 were applied at 90° to it. SG5 and SG6 were installed at the center of the plate, while all others were symmetrically placed around it, on a virtual circle with a radius of 150 mm.

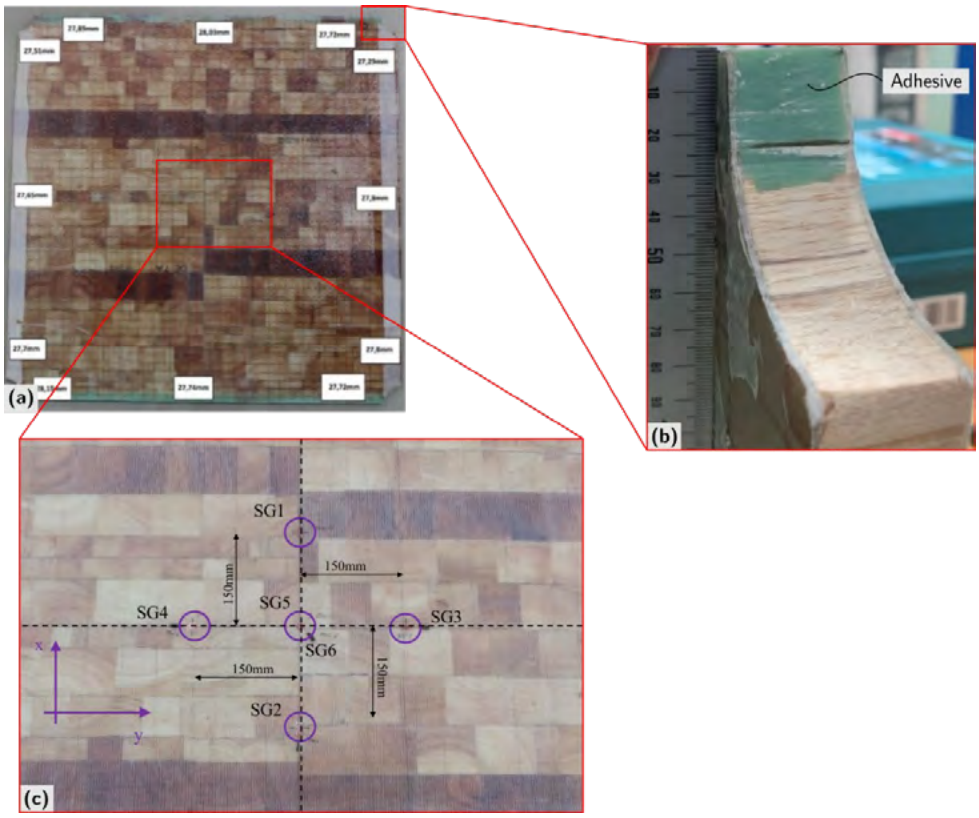

Figure 2. a. Sandwich plate thickness measurements at the edges, b. adhesive at edge, and c. strain gauge positions measured from the center of the sandwich plate.

2.1.4 Experimental determination of buckling resistance

The critical buckling load F_{cr}, i.e., the buckling resistance, was determined using two methods. The first method involves analyzing the experimentally recorded load versus in-plane displacement diagram of the plate. Although there is no drop in load, just a reduction in the stiffness of the plate as suggested by Zaal [12], the buckling load is identified at the ordinate of the intersection point between the tangents of the pre- and post-buckling gradients (**Figure 3a**). In the second method, as described by Schuette [13], the buckling load is defined as the level at which the compressive strain on the convex side of the buckle crest stops increasing and begins to decrease, a method known as strain reversal (**Figure 3b**).

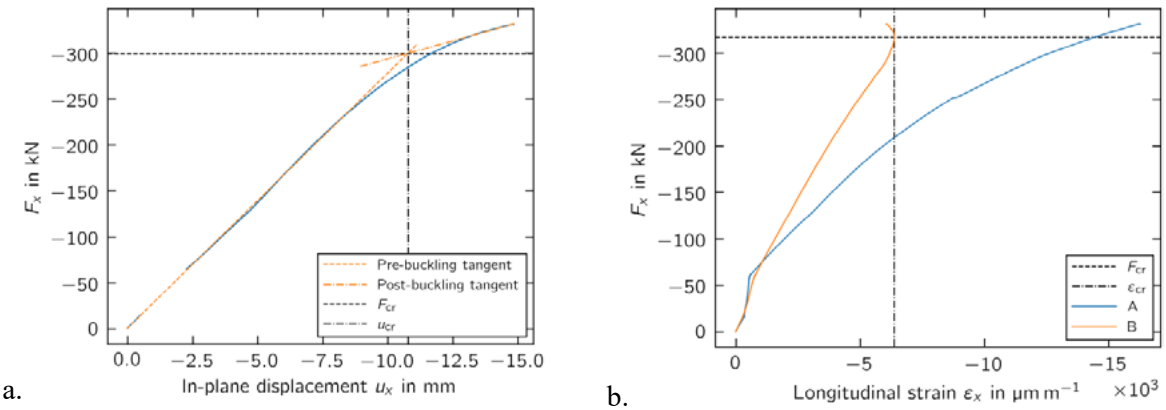

Figure 3. Experimental buckling loads: a. tangent method, b. strain reversal method.

2.2 Theoretical analyses

2.2.1 Material properties

The raw material properties listed in **Table 1** were used to calculate the lamina properties of the sandwich skin using a micro-mechanical approach, as introduced in [8]. Based on the thickness measurements, the skins were estimated to have a fiber volume fraction of 40%. The laminate properties (**Table 2**) were then calculated using Classical Laminated Plate Theory (CLPT). The raw material properties of the infusion resin and the adhesive were mechanically tested at Fraunhofer IWES according to international test standards. The glass fiber properties were sourced from the literature [8]. The balsa wood properties were derived from an experimental database using a curve-fitting approach that linearly correlates the material properties with the corresponding wood density [9].

2.2.2 Analytical sandwich plate model

The critical buckling resistance was estimated for a simply supported plate considering an orthotropic model according to Wiedemann [10], as described in [3]. The materials used and the coordinate system are illustrated in **Figure 4**.

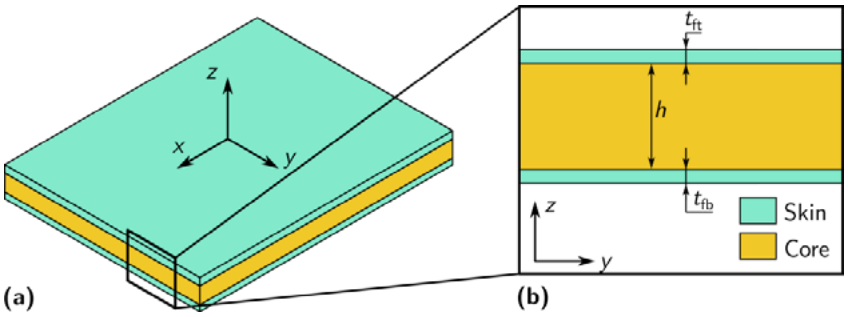

Figure 4. Sandwich plate model parameters; based on [3].

The critical buckling value k is defined as

$$k = \frac{p_{xcr} b^2}{\sqrt{B_x B_y}\pi^2} = \frac{1}{\Phi_x} + a_{wm}^2 \left(\frac{1}{\Phi_y} - \frac{H_1 + H_2 - 2(v + \hat{v})}{(H_1 H_2 - (v + \hat{v})^2)\Phi_x \Phi_y} \right) \quad (1)$$

where p_{xcr} is the critical buckling resistance and b the width of the sandwich plate. The help functions H_1 and H_2 are defined as

$$H_1 = \frac{\Phi_y\left(1+\frac{\hat{v}}{a_{wm}^2}\right)+1}{\Phi_x} \tag{2}$$

and

$$H_2 = \frac{\Phi_x(1+\hat{v}a_{wm}^2)+a_{wm}^2}{\Phi_y} \tag{3}$$

The buckling ratio a_{wm} is given by

$$a_{wm} = \frac{a}{mb}\sqrt[4]{\frac{B_y}{B_x}} \tag{4}$$

where a is the length of the sandwich plate and m the number of buckling half waves. Poisson's ratio is determined as

$$v = \frac{D_{12}}{\sqrt{B_y B_x}} \tag{5}$$

and the drill stiffness number as

$$\hat{v} = \frac{D_{66}}{\sqrt{B_y B_x}} \tag{6}$$

where D_{ij} represents the terms of the bending stiffness matrix of the sandwich as described in [11], which can be determined using Classical Laminated Plate Theory (CLPT). B_x and B_y denote the matrix elements D_{11} and D_{22}, respectively. The core number in each plane direction is defined as

$$\Phi_y = \frac{\pi^2 B_y}{K_y b^2} \tag{7}$$

and

$$\Phi_x = \frac{\pi^2\sqrt{B_y B_x}}{K_x b^2} \tag{8}$$

where the shear stiffness is defined as

$$K = \frac{G_c d^2}{h} \tag{9}$$

where G_c is the through-the-thickness core shear stiffness (G_{13} and G_{23} in **Table 1**) and d is defined as

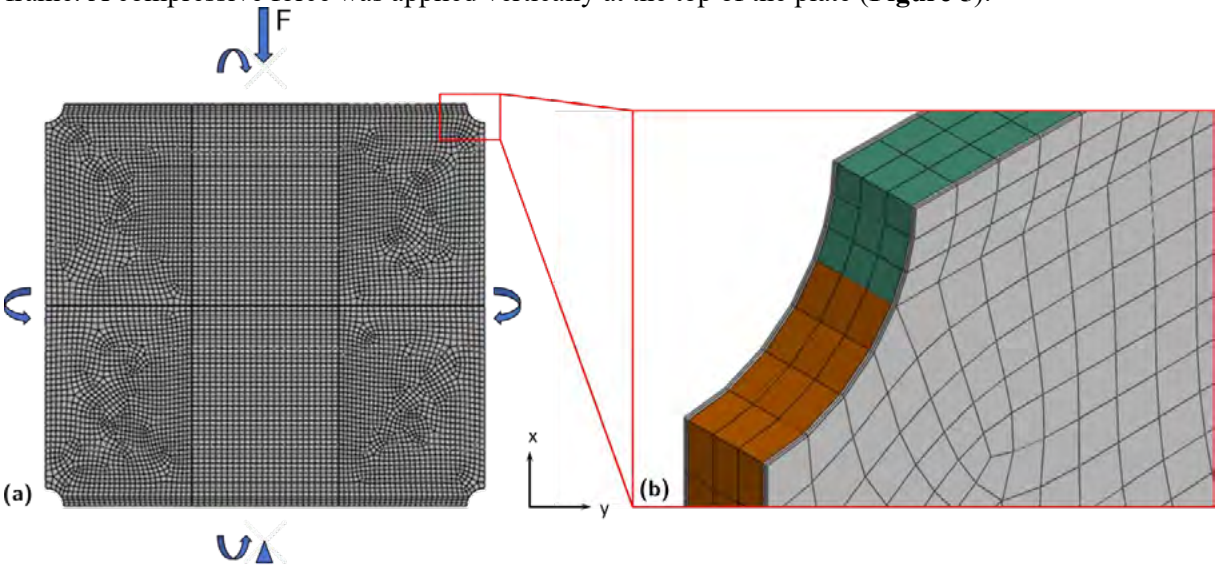
$$d = h + \bar{t_f} \tag{10}$$

with $\bar{t_f}$ as the arithmetic mean thickness of the two skins t_{ft} and t_{fb}. h denotes the thickness of the core.

2.2.3 Finite element model

A three-dimensional finite element model was developed in ANSYS to predict the bifurcation load, i.e., the buckling resistance, of the sandwich plate. The material properties used are detailed in **Table 1** and **Table 2**. Each skin layer of the model was represented by a single element in the thickness direction. The adhesive at the top and bottom of the test plate at the load introduction points was also modeled. In

total, 68,375 eight-node brick elements of type SOLID185 were utilized. At the virtual panel edges, the rotational degrees of freedom were left free, simulating the degrees of freedom provided by the test load frame. A compressive force was applied vertically at the top of the plate (**Figure 5**).



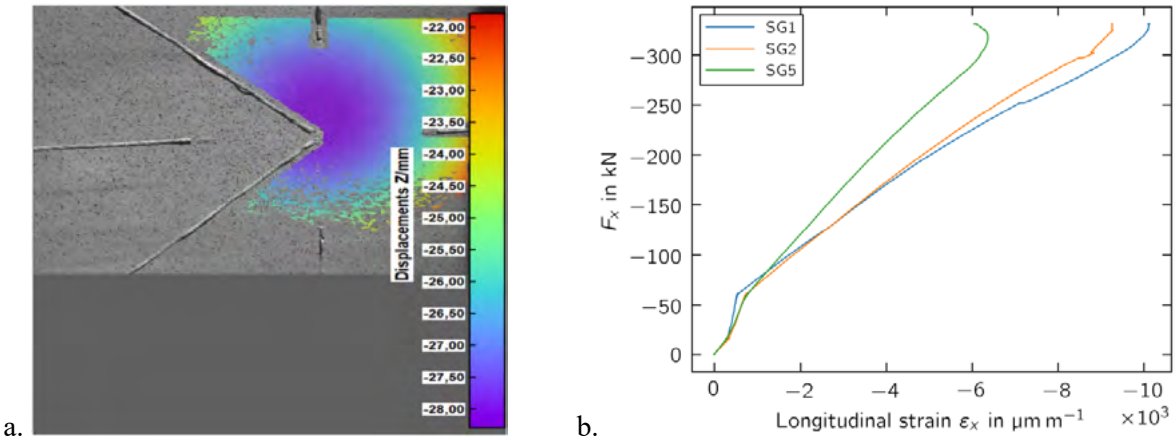


Figure 5. Finite element model of the plate: a. boundaries and mesh, b. zoom-in of corner.

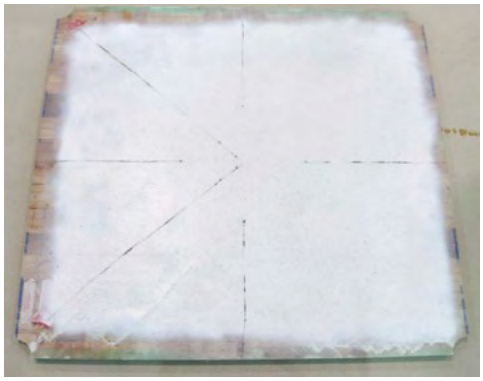
3. Results and discussion

From the DIC displacement recordings, it is clear that the plate was deforming according to the first buckling eigenmode (**Figure 6a**). The negative displacement indicates that the monitored surface (side B) was deflecting out-of-plane towards the viewer. This observation is corroborated by the strain gauge measurements along the load axis. The diminishing recordings suggest that, although the plate was under compression, the developed dimple caused side B to bend out-of-plane, adding positive deformation to the overall negative displacement. This phenomenon explains the strain reversal that occured at the buckling load, as defined in Chapter 2.1.4., before the final collapse (**Figure 6b**).

Based on the force-displacement diagram shown in **Figure 3a**, it is evident that the panel exhibits limited post-buckling performance in terms of displacement. After a slight drop in stiffness, the plate failed, as illustrated in **Figure 7**. Delaminations were observed at the lower right edge of the plate at side A, and cracks along the lower edge of side B, which ultimately led to the final failure.

a. b.

Figure 6. Side B: a. out-of-plane displ., b. strain-gauges along load axis



a.  b. 

Figure 7. Post-mortem specimen: a. Side A, b. Side B

The theoretical buckling load predictions are presented in Table 3, alongside the experimentally determined buckling loads.

Table 3. Summary of theoretical and experimental buckling loads

	Tangent of pre- & post buckling (Exp.)	Strain reversal (Exp.)	Analytical model	Linear bifurcation analysis (FE)
F_{cr} in kN	299	310	314	316

The theoretically determined buckling loads overestimate the experimentally determined buckling loads by 1.3% to 5.7%. The tangent method yields a more conservative buckling load than the strain reversal method. Both the analytical and numerical predictions are in good agreement with each other, differing by only 0.6%.
The lower experimental values could be a result of imperfections in the plate geometry, structure, and load introduction. The analytical and numerical models do not account for these imperfections, hence they predict higher buckling loads. However, it is noteworthy that in this proof-of-concept case, the discrepancy was relatively small.

4. Conclusions

A novel test load frame was introduced to enhance the experimental design validation of the critical buckling load of thick composite sandwich plates, as found in wind turbine blades. A proof-of-concept test was successfully conducted, confirming the expected performance and validating both analytical and numerical predictions. The compressed sandwich panel deformed in the anticipated first buckling eigenmode, as recorded by a DIC (Digital Image Correlation) system. Moreover, the theoretically determined buckling loads overestimated the experimentally determined buckling loads by 1.3% to 5.7%, while the analytical and numerical predictions were in good agreement with each other.
Future finite element analyses should consider geometric imperfections to further reduce the remaining discrepancy between the model and experiment.

Abstract
The development of linerless liquid hydrogen composite tanks is a major challenge for improving the performance, lightweight and cost of Hydrogen-powered commercial aircraft. Since the tightness must be provided by the composite itself, an in-depth understanding of the damage mechanisms of laminated composites at cryogenic temperatures is desired. The aim of the present study is to propose a micromechanical numerical approach in order to analyze the effect of matrix type on the development of transverse cracks in various ply thicknesses under cryogenic thermomechanical loading. Experimental results have shown that the decrease in ply thickness leads not only to the delay of the transverse crack initiation thresholds, but also to a transition to a more diffuse and progressive cracking, particularly in the case of the thermoplastic matrix. Numerical results indicate that even at cryogenic temperature, the elasto-plastic behavior of the matrix plays a significant role on both the magnitude of thermal residual stresses and the resulting transverse crack initiation thresholds and propagation.

1. Introduction

Airbus aims to lead the decarbonization of the aviation sector by building the world's first Hydrogen-powered commercial aircraft. The use of liquid hydrogen as a fuel is very promising thanks to its high energy density and renewable production potential. The development of linerless liquid hydrogen composite tanks is a major challenge for improving the performance of low-carbon commercial aircraft. Since the tightness must be provided by the composite itself, an in-depth understanding of the damage mechanisms and resulting permeability of laminated composites at cryogenic temperatures is desired. Indeed, it has been shown that under thermomechanical loading, the main types of damage are transverse cracking and micro-delamination [1]. This leads to the creation of crack networks which, if they coalesce in the thickness, constitute leak paths [2]. Experimental results have shown so far that at ambient temperature, the decrease in ply thickness leads not only to the delay of the transverse crack initiation thresholds, but also to a transition from an almost instantaneous crack propagation though the thickness of the ply to a more diffuse and progressive cracking initiated by fibre/matrix decohesions [3], [4]. The reduction in ply thickness implies a greater importance of microstructure morphology on the laminate's mechanical behaviour and damage. Scale separation is thus harder, and it becomes necessary to explicitly represent the microstructure across the various constituents in the modelling [5], [6]. However, these experimental and numerical studies were carried out at room temperature, and mostly on epoxy-type thermosetting resin composite systems [5], [6], [7]. The present study therefore proposes an evaluation of this type of behavior and modeling in the context of two laminated composites, composed either of a thermoset or a thermoplastic resin. In both materials, ply thicknesses of 70µm, 140µm and

280µm will be considered, and measurements will be performed at cold and cryogenic temperatures (-130°C, -196°C). First, the studied materials, experimental protocols and main results will be presented. Then, a micromechanical finite element model developed will be introduced to help understand the effect of ply thickness but especially the micro-constituent properties on transverse cracking mechanisms.

2. Materials and experimental observations

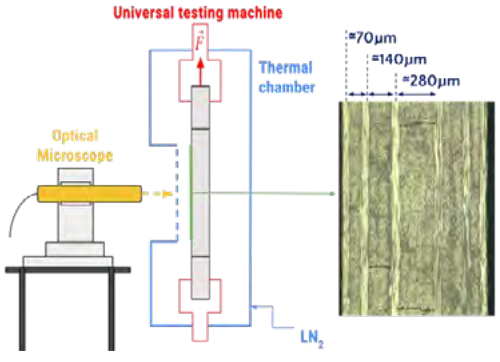
Two carbon fibre (CF) composites with thermoset (CF/TS) and thermoplastic (CF/TP) matrices are considered in this study. For the CF/TS material, tensile test specimens were extracted from plates obtained from unidirectional prepreg material followed by autoclave curing. Plates of CF/TP material were manufactured using an Automated Fibre Placement (AFP) process, followed by heated press consolidation. Materials were chosen so as to have a thin unit ply thickness similar between the two of them: approximately 70µm. The samples manufactured were all checked by C-Scan and microscopic observations to guarantee the quality of their initial state and cutting directions. All specimens to be tested were dried in a silica gel desiccator prior to testing.

2.1 Transverse cracking tests

Tensile tests with microscopic monitoring of the cracking process under thermomechanical loading were set up to study the evolution of transverse cracks at cryogenic temperatures (-196°C and -130°C). They consist of successive incremental loading steps in tension, all at cryogenic temperature. After each thermomechanical loading step, damage within the sample is monitored by observing the sample's polished edge with an optical microscope (see Figure 1) [8], [9]. The stacking sequence $[0/90/0/90_2/0/90_2]_s$ enables three different ply thicknesses to be studied: thin (90 alone), intermediate (90_2) and thick (90_4) (see Figure 1). Each test is stopped before reaching failure of the sample. The polished edge monitored during the test is then subjected to an abrasion and polishing cycle to remove a surface layer containing damages that initiated due to edge effects and did not propagate through the material. This is particularly relevant for thin plies, which have shown to exhibit a higher tendency of developing this type of damage [3], [7], [10], [11]. Accounting for those edge effects would lead to a significant overestimation of the damage effectively developing in the thinner plies, as well as an underestimation of the transverse crack initiation threshold. Damage in each ply and material at a given longitudinal strain ε_x is quantified through the use of the reduced crack density $\bar{\rho}$ $[-]$:

$$\bar{\rho} = \sum_n \frac{L_c^n}{h_{ply}^n} \cdot \frac{h_{ply}}{L_{obs}} \tag{1}$$

Where L_c^n is the crack n's length, normalized by the local ply thickness h_{ply}^n. This allows to account for partial cracks that do not fully propagate across the ply thickness (see Figure 3). The sum of all partial crack's relative lengths is then divided by the total observed length L_{obs} multiplied by the average ply thickness h_{ply} to obtain a non-dimensional number. Only the cracks that are present within the bulk of the material, after final polishing are counted.



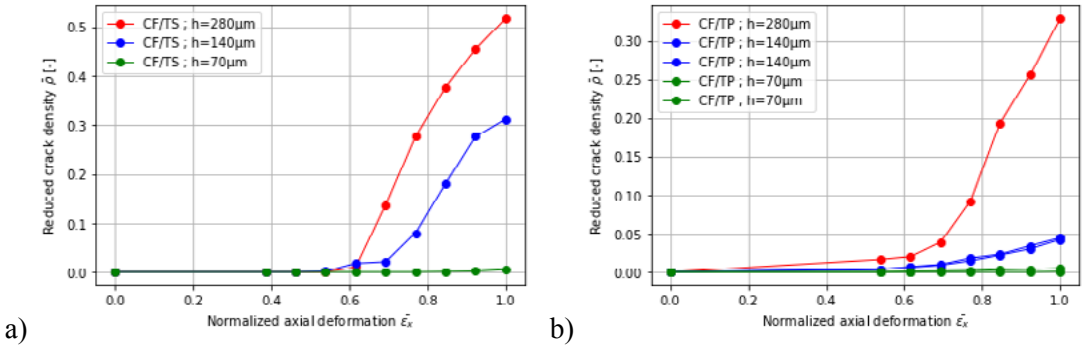


Figure 1. Diagram of the experimental setup used for transverse cracking tests at -130°C and -196°C

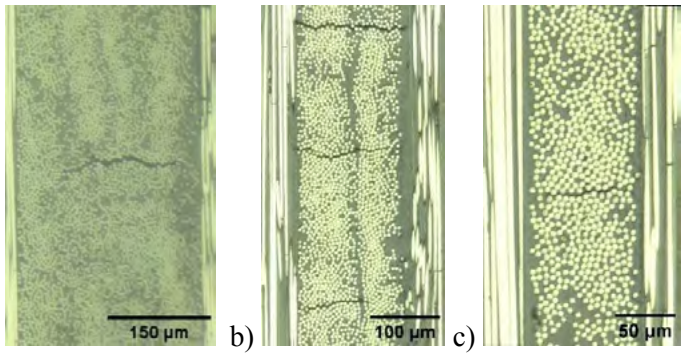

Results show that temperature, ply thickness and matrix type play a significant role in the initiation and propagation of transverse cracks. Indeed, little to no transverse cracks were observed at -130°C up to deformations close to the sample failure, while numerous of them develop in both materials in both thick (280µm) and intermediate (140µm) plies at -196°C. Very few cracks were observed in the thin (70µm) plies (see Figure 2). Transverse cracking does not initiate with the thermal loading alone. Figure 2 shows that the reduction in ply thickness shifts crack density curves towards higher loading levels, delaying transverse cracking thresholds and reducing cracking rates for both materials.

a) b)

Figure 2. Reduced crack density as a function of normalized axial strains applied to the laminate for the three ply thicknesses considered, at -196°C for the CF/TS (a) and CF/TP (b) materials. The normalization is identical for each figure.

An interesting observation is that the CF/TP material not only presents a smaller crack density than the CF/TS material (Figure 2), but also a transition from a majority of fully developed cracks in the thick ply, to partial ones that do not propagate through the entirety of the intermediate and thin plies' thickness, as shown in Figure 3. Damages initiated by fibre/matrix decohesions no-longer propagate quasi-instantaneously, but progressively extend during loading. Such partial cracks were indeed observed in other studies, yet for thin plies (<100µm) and only at ambient temperatures [3], [4], unlike in the present study under cryogenic conditions.

Figure 3. Microscopic observations of partial cracks observed in the bulk of CF/TP samples after transverse cracking tests: thick 280µm ply at -130°C (a); intermediate 140µm ply (b) and thin 70µm ply (c) at -196°C.

2.2 Elastic and elasto-plastic mechanical testing properties

To feed numerical models, tension tests up to failure were performed on composite samples (250x25mm² equipped with tabs) of both materials to determine the mechanical properties at three temperatures (20°C, -130°C and -196°C) on lamination specimens $[0]_{16}$, $[90]_{16}$ and $[\pm45]_{4s}$ enabling longitudinal, transverse and shear moduli to be determined.

Tension tests were also performed on neat TP resin samples according to ISO 527-2, at four different temperatures (T_{hot}, 20°C, -130°C and -196°C). T_{hot} being a temperature comprised between the TP material's T_g and consolidation temperature.
All tests were carried out at a constant crosshead speed of 0.5 mm/min. Two samples were tested for each configuration. Strain and temperature were measured using strain gauges and thermocouples respectively. At 20°C and T_{hot}, strains were also measured using an extensometer, allowing to reach deformations up to 25%, after which the test was stopped if failure was not reached.
Some of the experimental results for both neat TP resin samples and CF/TP $[90]_{16}$ tensile tests are presented in Figure 5.

3. Computational micromechanics strategy

In this study, a 2D micro-mechanical finite element (FE) model was developed, consisting in a representative volume element (RVE) of a thin 90° ply surrounded by two homogenized 0° plies (Figure 4a). Each of the three ply thicknesses tested experimentally can be represented numerically, namely $h_{ply} \in \{70; 140; 280\}\mu m$. The RVE is rectangular with length $L_{RVE} = 2 \cdot h_{ply}$, and the adjacent ply thickness is kept at $h_{ply} = 70\mu m$ similarly as in experiments.

The adjacent plies are assumed to be homogenous with transversally isotropic thermo-elastic properties. The temperature-dependent elastic properties of adjacent plies were measured experimentally as described in the previous section. The thermal expansion coefficients (CTEs) are determined either from documentation available from the manufacturer or experimental measurements that were performed. The interface with the 90° ply is assumed perfect, as no micro-delaminations were observed experimentally.
Fibres are distributed randomly within the RVE, while respecting a prescribed fibre volume fraction V_f and constraints on the minimum distance between two fibres' external surface and with the matrix's edges ($> 0.05R$). The fibre radius R is constant. The transversally isotropic thermo-elastic properties of the carbon fibres were taken from the literature, and are considered independent from temperature.
The matrix behavior was modelled using a pressure-dependent hyperbolic Drucker-Prager model with regularized damage [7], [12] and associated flow. Properties in function of temperature are considered rate independent and are either based on tensile tests performed on neat TP specimens or from literature, as well from UD composite tensile tests. Numerous studies propose to extend the stress/strain curves measured experimentally until a perfectly plastic behavior is reached (horizontal tangent) [5], [7], [13]. This is motivated by notable size-effects observed in neat resin mechanical tests [14], [15], [16], and by the fact that at micrometric scales, much higher strains are encountered than those conventionally observed in thick specimen testing. Whether this is still the case at cryogenic temperatures is yet to be verified, and will be discussed in the next sections.
Nevertheless, the way in which the tests are extended has a strong influence on the levels of plastic stress and strain achieved. Kohler [7] suggests using a second-order polynomial fit. A more conventional approach is Voce's law [13], [17], where true stresses σ_t asymptotically tend towards a plastic plateau as true strains ε_t increase, following an exponential law:

$$\sigma_t = A(T) \cdot \left(1 - e^{-B(T) \cdot \varepsilon_t}\right) \tag{2}$$

Where $A(T)$ and $B(T)$ are temperature-dependent parameters to be determined experimentally. They govern the initial linear elastic $E \approx A(T) \cdot B(T)$ and final plastic plateau $A(T)$ of the curve. This empirical law has proved to be the most consistent with the tension tests performed on our TP neat resin samples, and will be kept in the present study.
Once the ultimate strain ε_u^m and stress σ_u^m are reached, an exponential softening, energy based regularized damage model reduces the stiffness of the matrix elements.

The brittle behavior of the fibre–matrix interface [6], [18] was modelled using the linear softening, energy based, cohesive model. The interface is first linear elastic with a stiffness of $K = 10^8$ [MPa/mm]

that ensures displacement continuity between the fibre and the matrix. The onset of damage is dictated by a quadratic stress criterion. The shear strength τ_s was assumed to be equal to 3/2 of the normal strength τ_n, based on the experimental results obtained by Ogihara and Koyanagi at ambient temperatures [19]. Once the damage begins, the interface stiffness is progressively degraded following a damage variable d whose rate is controlled by the mixed-mode critical energy release rate of the cohesive element according to the Benzeggagh-Kenan (BK) law [20]. Mode I and Mode II fracture energies are complex to measure experimentally and are generally set using an inverse identification between experimental measurements and numerical models [18]. Regarding mode II, as contact is present, the friction dissipates some energy and can generate plastic deformations within the matrix due to contact stresses. These additional dissipation mechanisms corroborate the assumption of a larger mode II fracture energy. Various ratios can be found across literature [5], [7], [18], yet for simplicity a ratio of 1.5 will be kept in the present study.

Abaqus Finite Element code is used. Adjacent plies are meshed using linear quadrilateral generalized plane strain elements CPEG4R. For higher mesh quality, triangular linear elements CPEG3 are used to discretize the matrix. Finally, fibres are meshed using quadratic quadrilateral elements CPE8R allowing for a better approximation of their curved geometry (Figure 4a). Typical element size of 1µm are used in the fibres, 0.5µm in the matrix. Element size gradually increases from the interface to the free edges in the adjacent plies.

In order to represent the behavior in the bulk of the material, while maintaining reasonable calculation times, a 2D Generalized Plane Strain modeling strategy was chosen. Periodic boundary conditions are applied on the RVE's lateral edges (Figure 4a) and the top and bottom surfaces are kept free, similarly as in experiments. The model was implemented using Abaqus/Standard with an implicit dynamic resolution scheme. Geometric non-linearities (i.e. large deformation assumptions) are considered due to large strains encountered. Each simulation consists in a first thermal step between the stress-free temperature T_0 down to the considered temperature. During that first step, the RVE remains unconstrained to allow for thermal contraction. This is followed by a mechanical displacement-controlled loading step along the $\vec{x}$ direction (Figure 4a), until the desired macroscopic strains ε_{max} are reached.

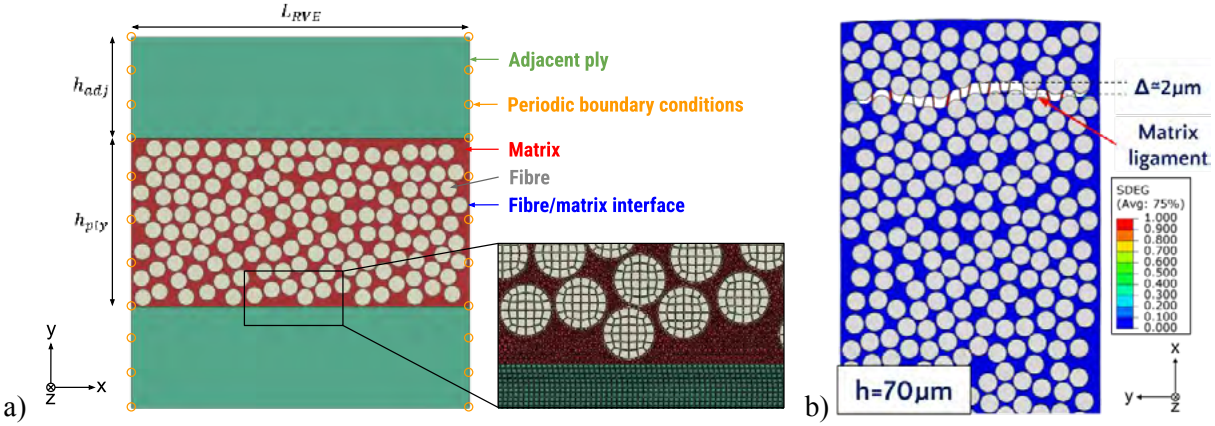

Figure 4. (a) RVE of the composite laminate with stacking sequence $[0/90_n]_s$ and associated length and boundary conditions. Detail of the finite element discretization.
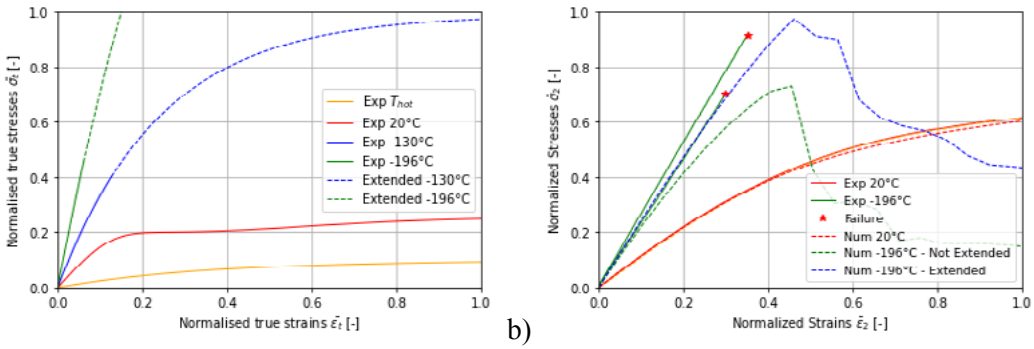
(b) Numerical result at -196°C close the sample failure of a thin ply (70µm) subject to axial loading along the $\vec{x}$ direction (vertical). Matrix ligaments subject to large deformations are visible, along with their corresponding damage variable (SDEG). Adjacent plies are not represented.



4. Numerical results and discussion

The consideration of a thermoplastic matrix at cryogenic temperatures underlines and amplifies certain difficulties and limitations associated with this type of numerical approach. First, the vast majority of micromechanical models presented in literature consider epoxy-type resins, whose properties are very often set to those obtained by Fiedler et al. [14]. Thermo-elastic properties are considered as independent

of temperature (moduli and CTE) and the stress-free temperature T_0 is set to that of the glass-transition temperature T_g [5], [6], [7]. This approximation is acceptable as long as properties do not vary significantly across the studied temperature range. On the contrary, thermoplastics can exhibit higher CTEs than those conventionally found in epoxy-type polymers and increased ductility at high temperatures. This is particularly the case for semi-crystalline thermoplastics where T_0 is no longer equal to the T_g but is often considered to be equal to the peak crystallization temperature $T_c > T_g$ [21], [22]. In order not to over-estimate thermal residual stresses, the present model needs thus to account for the variation of the thermo-elasto-plastic properties of the considered polymers from the rubbery state after manufacturing, down to the rigid glassy state at cryogenic temperature.
A second limitation is related to the matrix energy release rates G_m. For un-toughened epoxy resins, G_m is typically in the range of $10^0 - 10^2 [J/m^2]$ [7], [23], [24]. Authors generally study the effect of various energy release rates, yet never to magnitudes of $[kJ/m^2]$ that are typically encountered in thermoplastics [25], [26], [27]. Whether such high values are still encountered at cryogenic temperatures has yet to be evaluated.

4.1 Extension of the resin elasto-plastic curves

Whether the elasto-plastic curves of the resin should be extended or not as proposed by other studies, even at cryogenic temperatures, can be evaluated by modeling the tensile tests performed at various temperatures on unidirectional $[90]_{16}$ laminated composites. The model used here is the one described in the previous section yet without the presence of adjacent plies, and will be referred to as the UD90 model. It has been noted that, provided the RVE is sufficiently large, little effect of the RVE size was observed on the macroscopic behavior of the system before damage onset and localization. A model with dimensions of 100x50µm² was therefore used.
Figure 5a presents the normalized experimental tensile curves of the neat TP resin samples performed at T_{hot}, 20°C, -130°C and -196°C. The proposed extension of the experimental curves at cryogenic temperature based on Voce's law (eq.2) is presented alongside. As one can see at cryogenic temperatures, the plastic plateau is reached at very high stresses (not fully shown at -196°C) that seem unlikely to be encountered in a real microstructure. In addition, the extrapolation is performed on a very small part of the fully extended curve, making uncertainty about the latter all the more significant.
Figure 5b) presents experimental tensile curves at 20°C and -196°C of the CF/TP unidirectional $[90]_{16}$ laminated composite samples along with numerical results. In this configuration, the 90° ply is free to contract in all directions due to thermal expansion coefficients. From a macroscopic point of view, one could say that no stresses should build. Nevertheless, at microscopic scales, significant stresses are reached. So much that, at cryogenic temperatures and when the elasto-plastic curves of the neat TP resin are taken "as is" (i.e. not extended and damage initiates at the experimentally determined ultimate stresses) from experimental measurements, tensile tests of UD plies cannot be reproduced numerically with high fidelity. Indeed, the micro-stresses within the matrix rapidly reach the limit stresses observed on the macroscopic resin samples, and premature plasticity is obtained. This leads to an overly non-linear macroscopic behavior of the system at cryogenic temperature (see Figure 5b for the "non-extended" properties), even when parameters of the Drucker Prager model are adjusted. This behavior is observed regardless of the properties of the cohesive zones selected and independently of the stress-free temperature T_0. This excessive softening behavior can be suppressed when the elasto-plastic properties of the TP matrix are extended at cryogenic temperatures, as seen in Figure 5b. In this case, the initial thermal loading and parameters of the plasticity model affect only slightly the macroscopic behavior of the system at 77K. Indeed, stresses reached after thermal loading remain well below the matrix extended ultimate stresses, and the overall system behaves rather elastically with a brittle failure controlled by the cohesive zones, as observed experimentally.
This suggests that properties of the matrix should be extended as proposed by other authors [5], [7], [14], even at cryogenic temperatures. The way to extend these properties at cryogenic temperatures remains an open issue.

a) b)

Figure 5. Normalized stress-strain curves of neat TP resin samples (a) and CF/TP UD $[90]_{16}$ tensile tests (b) at different temperatures. T_{hot} is comprised between material's T_g and consolidation temperature. In (a), experimental results (full line) are extended (dashed lines) at cryogenic temperature using Voce's law (eq.2). In (b), numerical results are presented in dashed lines, with the extended matrix properties (green) or not (blue).

4.2 Polymer fracture toughness

Before diving into the modeling of transverse cracks within constrained 90° plies, it is important to study the capability of the present approach to solve the crack initiation and propagation, based on the input matrix fracture energy. As said before, the matrix's mode I fracture toughness G_m is provided as an input parameter. In order to decrease mesh dependencies in the damage localization, Bažant and Oh's crack band model [28] stipulate that under mode I loading, the area under the stress-strain curve once damage initiates should be equal to G_m/l_e^m where l_e^m is the characteristic element length in the direction along the crack path. In common FEM softwares, it is defined as a function of the element's volume V_e^m in 3D and cross-sectional area A_e^m in 2D: $l_e^m = \sqrt[3]{V_e^m}\big|_{3D} = \sqrt{A_e^m}\big|_{2D}$. Elements should thus have an aspect ratio as close to 1 as possible. Assuming a linear damage softening law, the strain at which an element is fully damaged (i.e. damage variable $d = 1$) when subject to a unidirectional tensile load is: $\varepsilon_f^m = \frac{2G_m}{l_e^m \sigma_u^m} + \varepsilon_u^m$, where ε_u^m is the strain at which damage onsets [29]. Using properties classically used in literature for thermosets at ambient temperatures ($G_m = 0.1\,N/mm$, $\sigma_u^m = 100\,MPa$ and $l_e^m = 1\mu m$), it is common to obtain failure strains up to $\varepsilon_f^m = 2$. The corresponding length of the ligament upon full damage depends whether geometrical non-linearities are accounted for or not, i.e. whether the small or finite deformations theory is used. When considering small deformations, the length becomes $\Delta L_f^{eng} = l_e^m \varepsilon_f^m \approx 2\mu m$, which is large yet reasonable when considering classical crack opening displacements that are in the same order of magnitude (see Figure 4b). It is no longer acceptable when true strains (i.e. finite deformations) are used: $\Delta L_f^{true} = l_e^m \cdot \left(e^{\varepsilon_f^m} - 1\right) \approx 6.4\mu m$.

This explains the presence of matrix ligaments (see Figure 4b) that require large crack openings in order to be fully damaged, and thus to dissipate the desired energy. This issue is further enhanced when mesh size (i.e. l_e^m) decreases and matrix fracture toughness increases to values expected for thermoplastics. Here, it is almost impossible to completely damage matrix ligaments, no matter whether geometrical non-linearities are accounted for or not. The model thus does not dissipate the desired damage energy, making comparisons of various matrix fracture toughness impractical.

The present approach thus appears incapable of describing the brittle fracture of highly energetic dissipative processes, as the characteristic length scales required for the damage process to occur are larger than the crack openings observed experimentally.

4.3 Thermal residual stresses and matrix plasticity model

In spite of the limitations presented above, a qualitative analysis of the transverse cracking mechanisms at various temperatures and ply thicknesses can be performed. Here, the properties of the resin are fully extended, and the matrix energy release rate G_m will be kept to a small value typically used in literature, namely 0.12N/mm in order for the matrix elements to reach full damage and dissipate the entire input

fracture energy. The model will be the one described in the section 3, consisting of a 90° ply surrounded by homogenized adjacent plies (Figure 4a).
As pointed out by Kohler et al. [30], the implementation of thermal residual stresses is not trivial and their magnitude can generate significant stresses leading to the formation of transverse cracks in the 90° ply during the thermal step. The magnitude of those stresses is directly driven by the stress-free temperature T_0, the CTEs of the micro-constituents, the elasto-plastic properties of the matrix (and thus the extension or not of the experimental curves) and the ultimate stress at which damage onsets in the CZMs (τ_{CZM}) and in the matrix (σ_u^m). The energy release rates of both the CZM (G_{CZM}) and the matrix (G_m) does not have a significant impact on the thermal residual stresses. The ply thickness has also little impact on them. Surprisingly, even at cryogenic temperatures, the plasticity model used significantly affects the average thermal residual stresses built during the thermal step, leading to an important effect on the transverse crack initiation threshold. More specifically, for the same model parameters, changing from a pressure-independent plastic model with isotropic hardening based on Von-Mises' yield criterion to a pressure-dependent hyperbolic Drucker-Prager plastic model can lead to a 15% decrease in average thermal residual stresses, and a transverse crack initiation threshold increased by a factor 3. This is observed even when the matrix properties have been extended, where the plasticity model showed no impact on the behavior of the UD90 model. This underlines the need for precise knowledge of the elasto-plastic and thermal behavior of components over the entire temperature range, from T_0 and even down to cryogenic temperatures. Complementary tests (DMA, CTE, compression) therefore seem necessary to restrict the range of uncertainties.
Whether non-linear geometry is accounted for or not does not influence the thermal residual stresses. It was nevertheless observed that considering small deformations leads to a decrease of the transverse crack initiation thresholds by approximately $\Delta\varepsilon = 0.05\%$. It also leads to the formation of non-physical deformation in certain highly deformed elements, supporting the idea that finite deformations theory should be used.

5. Conclusion and perspectives

The present study aims at improving the understanding of transverse cracking of thin plies in cryogenic environments, and to investigate the influence of the damageable elasto-plastic properties of the polymer resin. Experimental tests at -130°C and -196° on two carbon fiber composites with thermoset (CF/TS) and thermoplastic (CF/TP) matrices demonstrated the significant influence of temperature and ply thickness on transverse cracking mechanisms. In particular, the appearance of partial cracks was noted in the case of intermediate and thin (<140µm) plies of the CF/TP composite, whose initiation is driven by microstructural variability. A micromechanical finite element numerical model has been developed, allowing to model the initiation and propagation of transverse cracks without presupposing their path, and to study the influence of the matrix. It was noted that, even at cryogenic temperatures, experimentally measured resin properties need to be extended to higher strain levels, and that the plasticity model chosen has a significant influence on both the level of thermal residual stress reached at -196°C and the resulting transverse cracking threshold. However, further experimental measurements are required to narrow down the range of possible values defining the micro-constituents (matrix and interfaces).
This type of approach has nevertheless a number of limitations, which were highlighted by the study of a thermoplastic matrix composite at cryogenic temperature. First, this type of approach has a strong dependence on interfacial properties modeled by cohesive zones. It is very difficult to identify these numerically and experimentally, especially under cryogenic conditions. In addition, due to large element elongations required for the damage process to occur in the matrix, the small crack opening displacements ($\propto 1\mu m$) encountered in thin plies do not allow for the damage process to fully develop, and thus dissipate the entire input matrix fracture toughness. This modeling approach therefore appears incapable of describing the brittle fracture of highly energetic dissipative processes that are encountered in some thermoplastic resins.
It would thus be interesting to compare the present approach with other ones such as the Finite Fracture Mechanics (FFM), where a double criteria governs the initiation and propagation of damage, without the need to spread the damage over a certain characteristic length for it to be fully completed.

Abstract
Aramid honeycomb cores are widely used in combination with composite face sheets for various sandwich structure applications due to their exceptional stiffness-to-weight ratio. Although numerical simulation techniques for the material and failure behavior of composite skins are well-established, modeling the honeycomb core continues to present a challenge. The honeycomb core is often modelled at meso-scale using shell elements, with geometry and material properties evaluated through a combination of tests and assumptions. However, this approach becomes computationally expensive for simulating large structures. In this study, a new method is presented where the honeycomb core is homogenized using orthotropic solid elements, incorporating an advanced material and failure model. The effective core material properties used in the model were determined for an aramid honeycomb core by tension, compression, and shear testing on coupon level. Furthermore, effective material values obtained from analytical calculations were compared with the experimental results to assess the accuracy of the analytical methods. The new developed model was finally validated by four-point-bending testing. This method aims to replace current expensive simulation involving shell elements for the core with a more computationally efficient solution using orthotropic solid elements.

1. Introduction

In various load bearing applications across aerospace, automotive, marine, and civil engineering, the utilization of honeycomb sandwich structures is prevalent [1]. Main reasons for this are their exceptional stiffness-to-weight ratio and weight specific bending strength. When confronted with high requirements for lightweight design, impregnated aramid papers are commonly chosen for the honeycomb core material, owing to their outstanding stiffness-to-weight ratio. This was also the case in the Ba-varian-funded project BayLu25-BLANCA, which is a collaborative effort on opti-mizing load introductions in sandwich structures, involving the University of the Bun-deswehr Munich (UniBw M), the testing facility GMA, the small and medium-sized enterprise GERG, and the aircraft manufacturer Boeing This work presents the inves-tigations on sandwich structures within the projects scope.

Aramid honeycomb cores exhibit orthotropic structural behavior [2], which is caused by both the inherent nature of the aramid paper material [3] and the manu-facturing process of the honeycomb core. Manufacturing of aramid cores is com-monly done using the expansion process, illustrated in Fig. 1. In a first step, an adhe-sive is applied to the aramid paper sheets, which are subsequently laminated into a stack. After curing, the stack is expanded to achieve the specified cell configuration. Various cell shapes are available for honeycomb cores, with the most common ge-ometry being the hexagonal cell. Subsequent to shaping, the honeycomb structure is immersed multiple times in a resin bath until the desired density is reached, followed by curing in an oven. Notably, the walls where the aramid papers are bonded together have a higher thickness than the single paper cell walls. This causes a pronounced orthotropic structural behavior with higher mechanical properties in the L-direction.

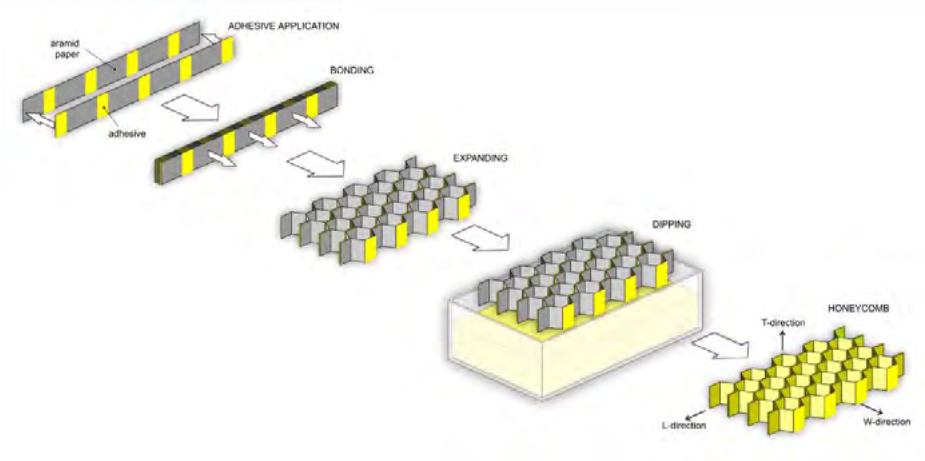

Figure 1. Manufacturing process of aramid honeycomb cores

For simulating a honeycomb core there are two main approaches. One method is to simulate the honeycomb core at meso-scale using shell elements [3,4]. This approach requires detailed modeling and fine discretization of the cell walls to accurately pre-dict the structural behavior. A high computational effort is therefore needed, which can become problematic, particularly for simulating large structures. This drawback can be mitigated by homogenizing the honeycomb structure to a 3D-continuum, integrating an appropriate material and failure model. This approach allows for a significantly coarser discretization, thereby reducing computational time. In addition, the homogenization approach requires fewer material data input as for detailed me-so-scale modeling. To describe the honeycomb structure behavior with 3D-solid ele-ments, the input depicted in Fig. 2 is needed.

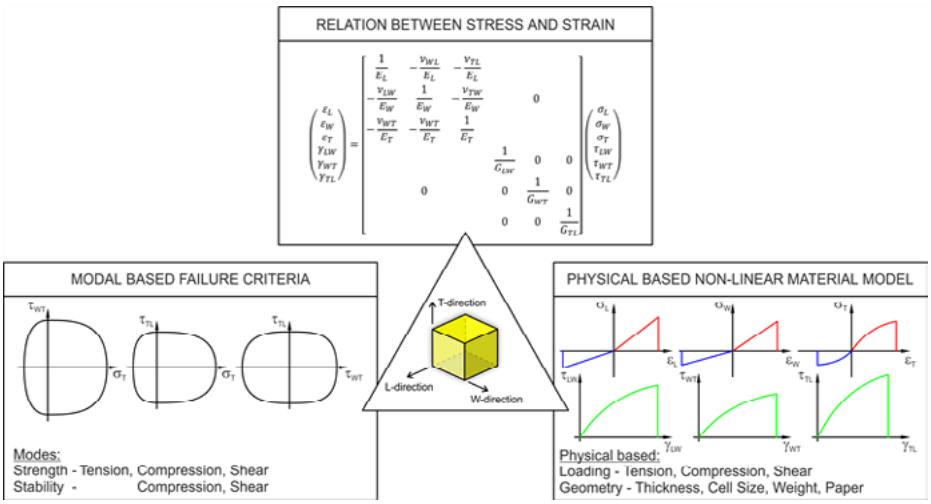

Figure 2. Input for homogenized honeycomb core model

The effective orthotropic properties of the honeycomb core must be determined to describe the stress-strain relation. This can be done by experiments [3,4], analytical models [5-7] or numerical homogenization [8,9]. Moreover, a failure criterion is need-ed to predict the honeycomb core failure modes as well as a non-linear material model to describe the elastoplastic behavior.
In this study, the homogenization approach was used for modeling the honey-comb structure since it allows highly efficient simulation. The effective orthotropic properties of a honeycomb core were determined by experimental testing and com-pared to analytical solutions. Furthermore, a material- and failure model was devel-oped for the homogenized honeycomb core. The models were then validated by four-point testing.

2. Honeycomb Core Testing

In honeycomb core datasheets, typically only the stiffness and strength values for out-of-plane compression and shear are provided [10,11]. These are the most im-portant properties for dimensioning honeycomb cores in sandwich structures [3]. However, there are also applications where the in-plane properties are relevant. An example is the core-forming process, in which the honeycomb core is largely de-formed to complex shapes, such as for airframe sandwich panels [12]. To compre-hensively describe the honeycomb behavior, both out-of-plane and in-plane proper-ties were considered in this work. Testing was conducted by the project partner GMA, utilizing universal testing machines (Zwick Z010, Z330) under nominal environmen-tal conditions. In addition, digital image correlation measurements were performed by the UniBw M for the non-standard tests. A hexagonal para-aramid (Twaron®) /phenolic honeycomb core was used in this work, with a cell size of 3.2 mm, density of 40 kg/m3 and a thickness of 10 mm. The experimental results are presented in the following sections.

2.1. Out-of-Plane Testing

For characterizing the out-of-plane behavior, tensile and compression tests were con-ducted in T-direction of the honeycomb core, while shear tests were performed for the LT- and WT-directions. The standard ASTM C297 [13] was used for the tensile tests in T-direction and ASTM C365 [14] was utilized for the compression tests. In both load cases, the honeycomb core was tested with face sheets (“stabilized”). Further-more, the machine displacement was used for calculating the strains. To ensure accu-racy, the measured displacements were corrected by the hinge tolerances in the test fixture. The resulting stress-strain curves are depicted in Fig. 3.

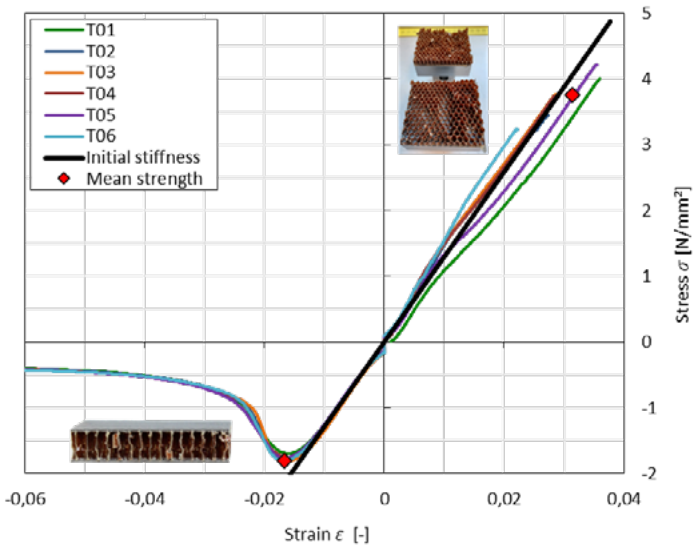

Figure 3. Stress-strain curves of the out-of-plane tensile and compression tests in T-direction

Under tensile loading, the honeycomb structure exhibits linear elastic behavior until reaching a brittle failure of the core cell walls. Core rupture failure also occurs in compression, but here subsequently leading to a nearly constant stress plateau due to the formation of plastic hinges [5]. Comparing both load cases showed that the initial stiffnesses are similar, whereas the tensile strength is approximately twice as high compared to compression.
The shear behavior in LT- and WT-directions was investigated following ASTM C273 [15]. In both directions, the stress-strain curves can be approximated by a bilinear curve, as depicted in Fig. 4. The initial linear part ends with a stability failure onset [16]. This was also observed by finite element analysis of the honeycomb cell walls. It is further evident that stability failure in LT-direction occurs at lower stress levels than in WT-direction. However, the shear strength and the initial stiffness are higher in LT-direction due to the increased cell wall thickness in L-direction. Notably, the evaluated out-of-plane core properties are within a similar range to the effective properties given in comparable core datasheets [10,11].

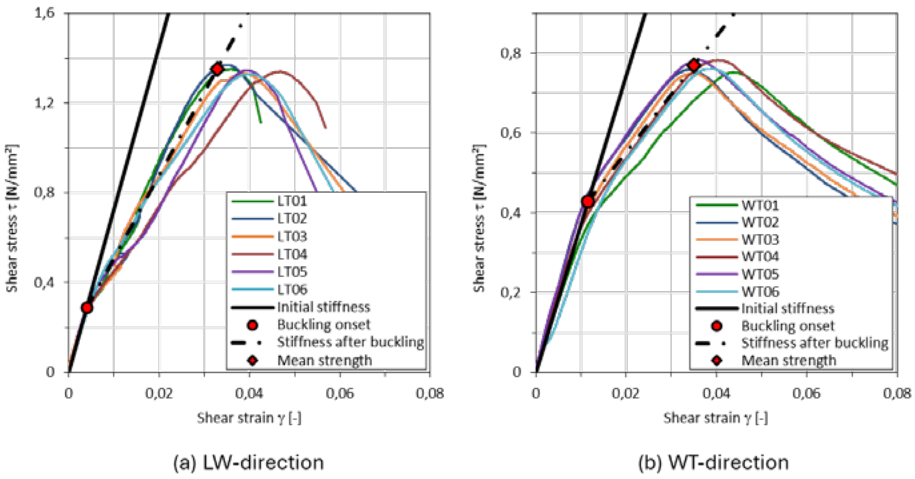

Figure 4. Stress-strain curves of the out-of-plane shear tests in LT- and WT-direction

2.2. In-Plane Testing

The in-plane behavior was investigated by tensile and compression loading in L- and W-direction, as well as by in-plane shear tests in LW-direction. The tests in L- and W-directions were conducted based on ASTM C363 [17]. According to this standard, pins are used for constraining the core specimens in the test fixture. In case of the tensile tests, it was necessary to adhesively bond the pins to the cell walls to prevent failure at the clamping area. The tensile and compression test setups and the resulting stress-strain curves are depicted in Fig. 5.

In tension, failure was caused in both L- and W-directions by bond rupture between the cell wall nodes. Contrary, for compression no rupture occurred in W-direction since the honeycomb core is compressed to the initial stacked aramid paper configuration. The initial stiffness and failure load in W-direction were found to be about three times lower than in L-direction. This was observed for both tensile and compression loading. Furthermore, comparing both load cases showed that the initial stiffnesses are nearly the same, while the compression strength is approximately half that of the tensile strength.

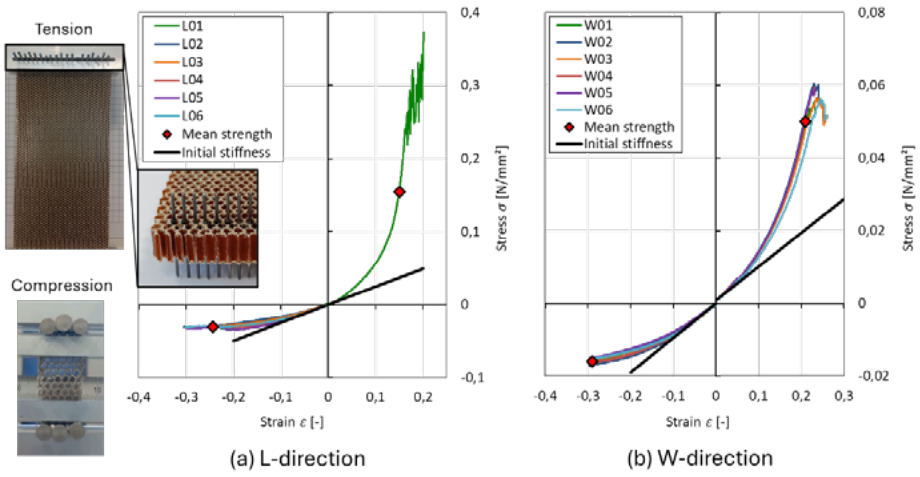

Figure 5. Stress-strain curves of the in-plane tests in L- and W-direction

For investigating the in-plane shear behavior no standard is currently available. Therefore, a new picture frame setup explicitly tailored for testing honeycomb cores was developed in this study. The specimen is mounted in the test fixture using pin rows positioned on all four sides (Fig. 6). In these areas a potting material (Neukasil SN 2907, Altropol Kunststoff GmbH) is used to clamp the specimen.

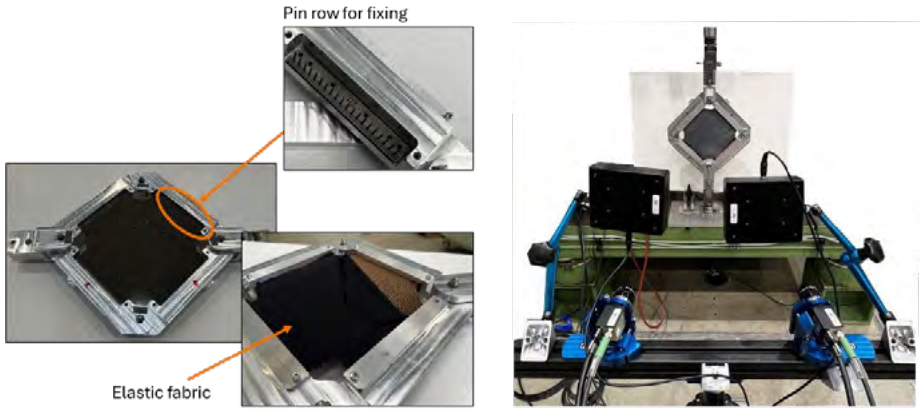

Figure 6. Picture frame test setup for in-plane shear testing

To assess the uniformity of the shear strain distribution, a digital image correlation (DIC) system (Q400D, Limess GmbH) was used. DIC requires a surface on which it can monitor deformations. Therefore, an elastic fabric, consisting of a cotton-elastane mix, was bonded on the honeycomb surface using a spray adhesive. Moreover, a white speckle pattern was sprayed on the fabrics surface for the DIC-measurement. Two 12-megapixel cameras equipped with standard lenses were utilized for this purpose. The resulting in-plane shear strain field is exemplary shown for the linear elastic region in Fig. 7.

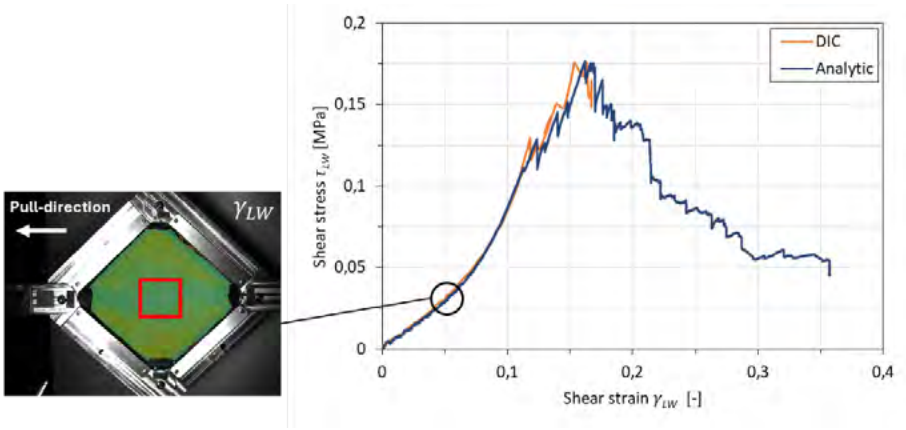

Figure 7. Stress-strain curves of the in-plane shear tests in LW-direction measured with DIC and compared to an analytical solution

At the border areas the shear strain is as expected higher, while the middle region shows a nearly homogeneous strain condition. This uniform region was selected for evaluating the shear strain. An alternative to obtain the shear strain is through analytical calculation. By using the machine displacement δ_f as an input and considering the kinematics of the picture frame, the shear strain and stress can be calculated with Eqs. (1) and (2) [18]. Comparing the analytic solution with the DIC results showed a very good agreement, thereby validating the accuracy of the conducted measurements.

$$\gamma_{LW} = \frac{\pi}{2} - 2cos^{-1}\left[\frac{1}{\sqrt{2}} + \frac{\delta_f}{2L_f}\right] \tag{1}$$

$$\tau_{LW} = \frac{F_f}{\left(\sqrt{2} + \frac{\delta_f}{L_f}\right) L_e t_h} \tag{2}$$

3. Analytical Models for Effective Core Properties

To reduce the number of tests, analytical models can be used to predict the effective orthotropic core properties. Numerous approaches have been developed for this in literature. In the present work, three widely used models are considered, namely Gibson and Ashby [5], Malek and Gibson [6] and Sorohan [7]. The models in [6,7] are based on the work by Gibson and Ashby [5] and consider further influences and corrections. As an input, the core cell geometry and the solid cell wall material data are used. For regular hexagonal honeycomb cores, the models assume that the cell walls containing two bonded papers (aligned in L-direction) have double thickness and that the cell angle Θ equals to 30° [5-7] (Fig. 8). Upon comparison, the analytical results derived from these assumptions did not align well with the observed test results. Therefore, the real thickness and the cell angle Θ of the investigated honeycomb core were measured.

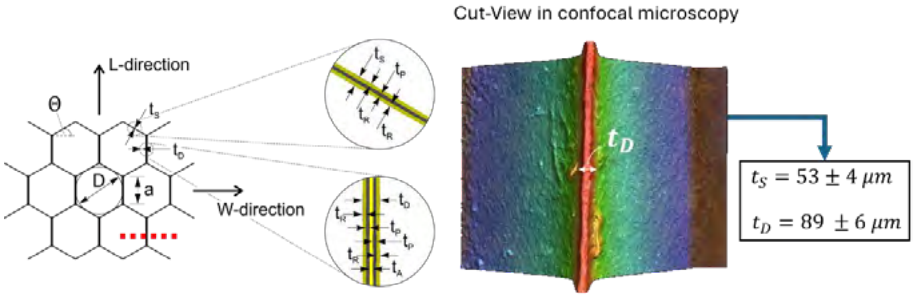

Figure 8. Thickness measurement of the single and double paper cell walls of the honeycomb core

For the thickness measurement, the core was cut along its height and analyzed by confocal laser scanning microscopy (CLSM), as depicted in Fig. 8. Evaluating the single and double wall areas revealed that the thickness of the cell walls aligned in L-direction is only around 70% higher than that of the single paper walls. Furthermore, measuring the cell angle Θ with a microscope indicated an angle of 37.5°. The real cell angle can also be determined by analytical calculation of stiffness ratios for different cell angles and subsequent comparison with the test results. This is exemplary shown in Fig. 9 for the stiffness ratios E_L/E_W and G_{LT}/G_{WT}, calculated with the model proposed by Gibson and Ashby [5].

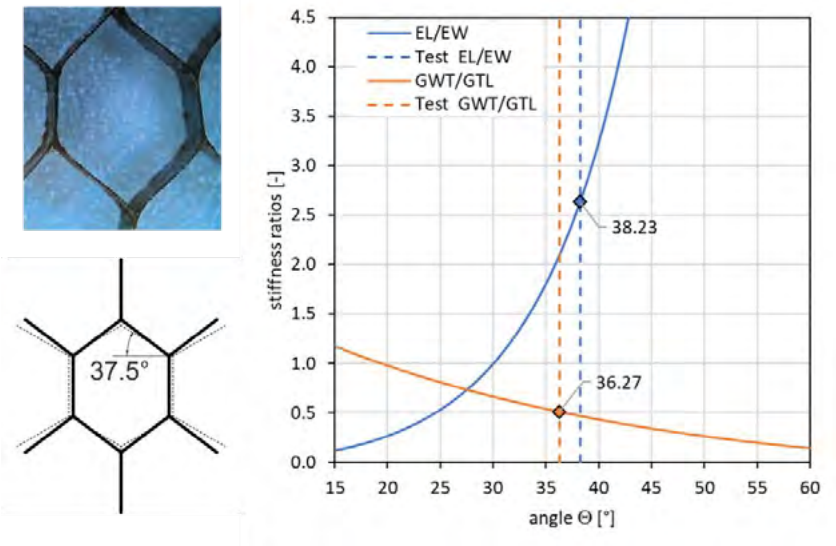

Figure 9. Determination of the cell angle Θ by optical measurement and analytical calculation

Considering the measured thicknesses and cell angle Θ, the effective Young's moduli were calculated with the analytical models for all directions and compared with the test results (Fig. 10). For directions where both tension and compression tests were conducted, the mean stiffness values are given in the following charts.

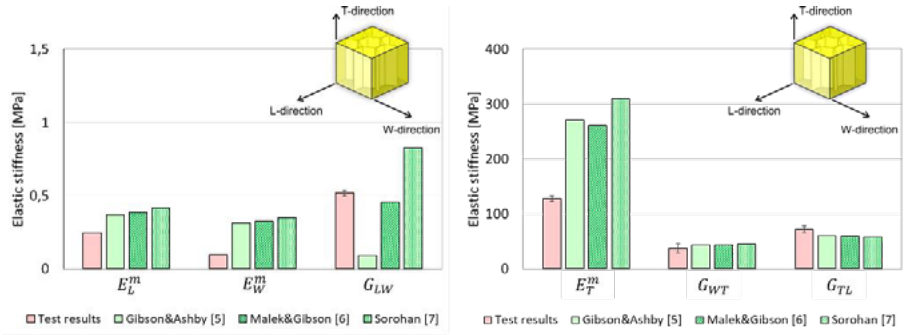

Figure 20. Comparison of effective Young's moduli between test results and analytical models

Using the models in [5-7] resulted in similar stiffness values in most cases. However, for the in-plane shear stiffness G_{LW} and the out-of-plane stiffness E_T, the analytical formulae suggested by Malek and Gibson [6] provides a better prediction. Furthermore, comparing the analytical solutions with the test results showed an overall good agreement. A larger deviation is present for E_T, which needs to be further investigated.

Based on the presented results, a method was developed for honeycomb core testing and analysis (Fig. 11). The approach suggests to only conduct the standard out-of-plane tests and additionally to measure the cell wall thicknesses. With this input, the real cell angle Θ can be determined by calculating the stiffness ratios and comparing it with corresponding analytical solutions, such as in [6]. The analytic model can then be used to calculate all remaining effective elastic properties of the honeycomb core. Afterwards, the effective properties can be utilized for numerical analysis of the honeycomb core. The developed material- and failure model for the numerical analysis is presented in the following chapter.

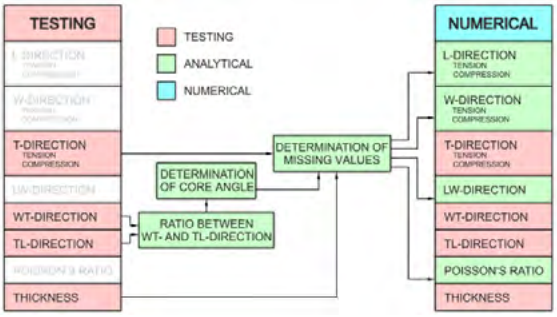

Figure 31. Method for honeycomb core testing and analysis

4. Non-Linear Material Model and Failure Criterion

4.1. Non-Linear Material Model

For modeling the elastoplastic behavior, the Bold non-linear material model for unidirectional and woven composite materials [19] was used. A significant advantage of this model is that it only requires measurable physical properties as input. These are initial stiffness E^{in}, failure stress R^{fr} and elongation at failure ε^{fr}. Unlike many other elastoplastic models, such as Ramberg and Osgood [20], no tuning parameter is needed here. The base form of the material model is shown in Eq. (3).

$$\sigma(\varepsilon) = E^{in}\varepsilon\left(\frac{R^{fr}}{E^{in}\varepsilon^{fr}}\right)^{\frac{\varepsilon}{\varepsilon^{fr}}} \tag{3}$$

This model was applied for all loading types and directions except for the out-of-plane shear loading cases. Regarding the shear behavior in LT- and WT-direction, the following bilinear model was used, here exemplary shown for LT.

$$\tau_{31} \leq R_{TL}: \qquad \tau_{31} = G_{TL}^{in}\gamma_{31} \tag{4}$$

$$R_{TL} < \tau_{31} \leq R_{TL}^{res}: \qquad \tau_{31} = R_{TL} + G_{TL}^{res}\left(\gamma_{31} - \gamma_{31}^{fr}\right) \tag{5}$$

Applying the material model for the investigated honeycomb core showed a good agreement with the experimental stress-strain-curves. This is illustrated in Fig. 12 for tensile and compression loading in L-, W-, T-direction, and in Fig. 13 for the shear behavior.

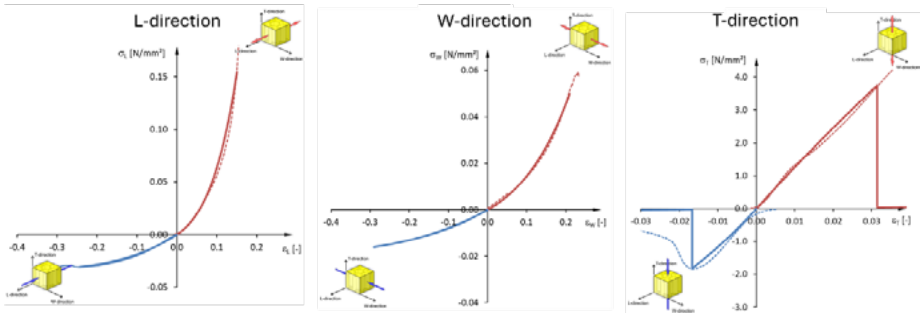

Figure 42. Bold non-linear material model applied to tensile and compression loading in L-, W-, T-direction

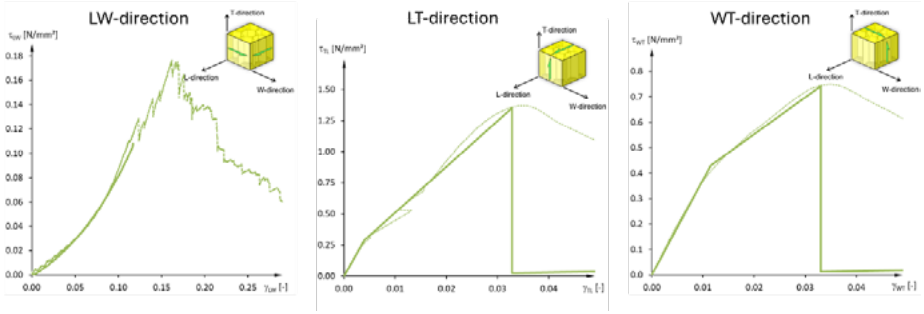

Figure 53. Bold non-linear material model applied to shear loading in LW-, LT-, WT-direction

4.2. Failure Criterion

To model the failure modes of an aramid honeycomb core, it's crucial to account for its orthotropic behavior. A new failure criterion was therefore developed, based on the Cuntze failure criterion for woven materials [21]. This modal-based failure criterion was adapted by considering the most relevant failure modes of honeycomb cores in a sandwich structure. These are failure due to out-of-plane tension (CTF1), compression (CTF2) and two for shear (CSF1 and CSF2). In-plane failure was neglected, given that the core's deformation within a sandwich structure is constrained by the stiff face sheets. Moreover, the friction parameters in the Cuntze-model were set to 0, considering the absence of a matrix in this application. With that, efforts were calculated for the out-of-plane failure modes using Eqs. (6-9).

CTF1: $\sigma_3 \geq 0$ $$Eff^{TF1} = \frac{\sigma_3}{R_T^t} \quad (6)$$

CTF2: $\sigma_3 < 0$ $$Eff^{TF2} = \frac{|\sigma_3|}{R_T^c} \quad (7)$$

CSF1: $$Eff^{SF1} = \frac{|\tau_{31}|}{R_{TL}} \quad (8)$$

CSF2: $$Eff^{SF2} = \frac{|\tau_{23}|}{R_{WT}} \quad (9)$$

The efforts are then combined in the failure criterion, by using the parameter m, which describes the interaction between the failure modes (Eq. (10)). Based on applications in [19, 21], the m value was set to 2 for this study.

$$Eff^m = (Eff^{TF1})^m + (Eff^{TF2})^m + (Eff^{SF1})^m + (Eff^{SF2})^m \leq 1 \quad (10)$$

It should be noted that for other applications the in-plane failure modes could also be considered in the same manner as it was done here for the out-of-plane failure modes.

4.3. Validation

The developed material- and failure model for hexagonal aramid honeycomb cores was validated by four-point-bending-testing (4PB) of sandwich plates. The woven CFRP system Teijin - Q110-2/2TW-285-38-10/HTS40-6k was utilized for the face sheets, with different layups for lamination. This resulted in a total face sheet thickness of 0.915 mm. Moreover, testing was conducted based on ASTM C393 [22].

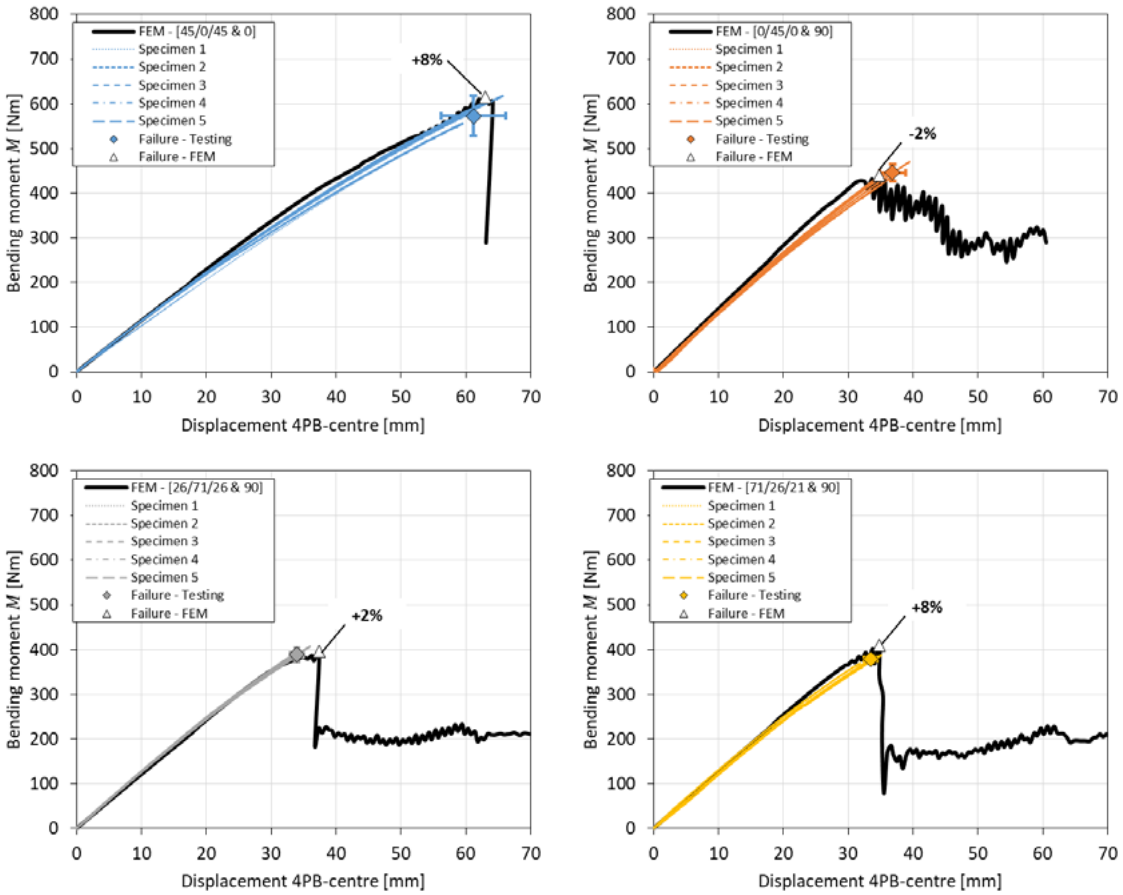

Figure 64. Bending moment-displacement test results of 4PB-experiments compared with FE-simulation

Comparing the bending moment-displacement curves between FE-simulation and 4PB-tests at the middle position demonstrated a good alignment (Fig. 14). Furthermore, the FE simulation accurately identified the failure mode at the expected location, which in this instance was core shear failure. This is illustrated in Fig. 15 by overlaying FE-simulation and experiment using the failure index.

Figure 75. Comparison between FE-simulation and experiment using numerical failure index plot

5. Conclusion and Outlook

The out-of-plane and in-plane behavior of a hexagonal aramid core was investigated by experimental testing. The obtained effective orthotropic core properties were sub-sequently used for modeling a homogenized core. Moreover, a comparison of the test results with existing analytical models was conducted to assess the model accuracy to predict the effective core properties. It was found that only after considering the real cell wall thicknesses and cell angles, the models allow a generally good prediction of the effective elastic properties. Based on these results, a method was developed for core testing and analysis. The proposed approach recommends to only conduct the standard out-of-plane tests alongside measurements of the cell wall thicknesses. With this input, the real cell angle can be calculated, enabling the use of analytical models to predict the unknown elastic in-plane properties. The core properties can then be used for an orthotropic material- and failure criterion. In this study, the Bold non-linear material [19] and the Cuntze modal based failure criterion for woven material [21] were adapted for honeycomb cores. The validity of the developed simulation approach was confirmed through four-point-bending-testing. In future investigations, the developed method will be validated for other honeycomb core configurations. In addition, the analytical models will be further improved to also predict stability and strength failure.

Acknowledgments

This study is part of the research project BLANCA, which is funded by the Bavarian Ministry of Economic affairs, Regional development and Energy (StMWi) within the program BayLu-25. The authors thank Teijin Aramid and Teijin Carbon Europe for providing honeycomb core and prepreg materials free of charge.

Abstract

The implementation of in-situ integrity monitoring of wind turbine blade structures used in the marine environment requires an understanding of the strucure damage kinetics. These structures mainly elaborated with sandwich composite materials.This study focuses on the influence of water aging of sandwich structures immersed in seawater heated to 40°C on their mechanical behavior and the evolution of various types of damage. The 4-point bending behavior of structures samples after aging was analyzed. Monotonic and repeated progressive loading tests were carried out. Damage initiation and propagation were monitored by acoustic wave recording. Water absorption monitoring on the test specimens showed that the water content equilibrium is reach after 15 weeks. After 15 weeks, begin the second phase of hydric aging. The two stages were identify in water aging influence on sandwich behaviour. The water content equilibrium time apprears to be the threshold. The K-means classification method was used to obtain the acoustic wave average parameters signatures of the 5 damage mechanisms : matrix cracking, fiber/matrix decohesion, skin/shell decohesion, delamination and fiber breakage. During the first phase, the structure absorbs water. This phase is characterized by an initial change in the structure behavior, with an increase in dissipated energy and in the average amplitudes of the damage classes. After water content has stabilized, the mechanical behavior of the structures is characterized by a decrease in energy and average amplitudes with aging. The study also shows that aging accelerates material failure under load.

1. Introduction

The law on energy transition [1], passed on August 17, 2015 voted by the French National Assembly, aims to boost the share of green energy in France's energy mix [2]. With this in mind, the wind power sector (marine and terrestrial) is therefore aiming to produce 10 GigaWatts of electricity by 2050. As a result, innovative projects such as COSPHI are developped. The COPSHI project, supported by LABEX EMC3 (https ://www.labex-emc3-gsmes.fr/labex-emc3/), aims to work on a in-situ method to monitor offshore wind blade turbine integrity in service. When in service, these blades are subjected to coupled mechanical and environmental stresses, leading to damage and aging of the structures. Understanding sandwich structure behavior and damage are essential to optimize the service life of wind turbine structures.

Sandwich panels mechanical properties is characterized by bending tests. The stiffness values of the sandwich structure depend essentially on the stiffness of the skins and the mechanical properties of the core [3, 4, 5, 6]. Studies on the mechanical behavior under static and dynamic 4-point bending loading of sandwich structures with glass composite skins in a polyester matrix with a PVC core were carried out [7]. The main goal is to characterize the stiffness, energy dissipation and damping of this sandwich structure, and at the same time to monitor the evolution of damage by acoustic emission. Indeed, the use of acoustic emission enables a better understanding and monitoring of damage on composite sandwich structures [8]. A classification of the various damage classes is made using the K-means method [9, 10, 11, 12]. This method consists in segmenting the data (acoustic waves bursts) collected by the sensors into classes using "moving center" classification algorithms. These algorithms perform iterations of data partitioning, minimizing the distance variance intra non overlaping clusters. At the same time, post-mortem microscopic observation of the samples tested and advanced knowledge of damage patterns enabled to associate a damage mechanism with each class obtained [13, 14, 15]. In general, most of the damage observed and identified by acoustic emission on the composite samples tested was matrix cracking, decohesion between the fibers and the polymer resin matrix, delamination and fiber breakage. Fiber breakage is considered to be the most energetic form of damage, occurring mainly just before structural failure. This is in contrast to matrix cracks, which are diffuse in time and very low in energy [13, 14, 15]. In sandwich structures, the same types of damage can be found, plus decohesion between the skins and the core. These interfaces, which are sometimes glued together, represent an additional source of fragility for the structure.

The aim of this article is to understand to what extent the hydric ageing of sandwich structures with glass/polyester composite skins in seawater at 40°C affects the overall mechanical behaviour of these structures. and the evolution of damage mechanisms.

2. Structure and Methodology

2.1. Sandwich structure

Despite the wind turbine blade structural complexity, the work focus on a representative sandwich structure panel. The skins are unidirectional fiberglass laminates with an isophthalic unsaturated polyester resin suitable for marine environment. The reinforcement weight ratio was set at 35%. The density of the glass/polyester composite skins is 1550 kg/m^3. The core is a closed-cell rigid foam of SAN (styrene acrylonitrile) polymer, suitable for the marine environment, with a density of 85 kg/m^3. The sandwich plates were processed by under vaccum contact molding at a pressure of 1 bar at room temperature for 24 h. After demolding, the sheets were post-cured for 1 hour at 130°C to achieve complet cross-linking of the resin.

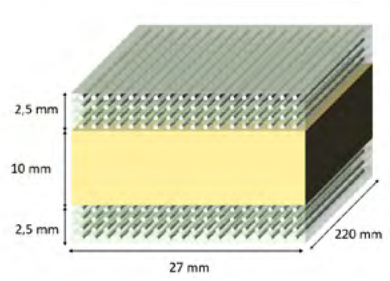

Fig. 1. – Sandwich structure used in this study

2.2. Mechanical testing

An experimental behavior characterization protocol has been set up to reproduce some of the stresses experienced by a wind turbine blade in service. The sandwich structures were subjected to 4-point bending tests in accordance with ISO standard NFT54-606 on a servo-hydraulic machine equiped with a 100kN force cell. The experimental data base is composed of monotonic loading controlled at 2 mm/min and repeated progressive loading (RPL). The dimensions used for the sandwich samples, in line with the standard, are : length 220 mm, width 27 mm, total thickness 15 mm, core thickness 10 mm. The span of the sandwich specimens tested was 190 mm, and the distance between the two upper supports was 100 mm.

2.3. Acoustic emission

Bending tests are coupled with acoustic emission recording to monitor damage mechanisms. Two piezoelectric transducers, 20 mm in diameter and with a bandwidth of 20 kHz to 1 MHz, are placed on the tension skins of the sandwich specimens. These sensors convert the mechanical waves generated by the damage into acoustic waves. The acoustic signals are pre-amplified with a gain of 40 dB before acquisition on a PC running Noesis software. Acoustic signals were classified using a K-means method, enabling the acquired data to be partitioned into K groups. A maximum number of iterations of 1000 was used as an additional stopping criterion. The 5 most commonly accepted descriptors in the literature are used, namely amplitude (dB), rise time (µs), duration (µs), number of strokes and energy of acoustic signals (aJ). This method was applied to classify the signals into 5 classes associated with 5 damage mechanisms in sandwich structures, in order of severity : matrix cracking, fiber/matrix decohesion, core/skin decohesion, delamination and fiber breakage.

2.4. Damage and energy dissipation parameters of the sandwich structure

Using normal stress curves in the skin under tension and deflection under support, we were able to determine the evolution of quantities associated with the mechanical behavior of structures as a function of water aging time. As the behavior is non-linear, the evolution of the variables is analyzed as a function of the residual deflection after unloading.

2.4.1. Damage rate "d"

Damage is classically defined by the decrease in stiffness obtained during the unloads of a RPL test (Eq. 1).

$$d(f) = 1 - \frac{Z(f)}{Z_0} \quad \text{(Eq. 1)}$$

With :

- d(f) : damage rate
- Z(f) : specific unloading stiffness module (MPa/mm)
- f : permanent displacement (mm)
- Z_0 : modulus of initial specific rigidity (MPa/mm)

The specific stiffness modulus Z(f) is determined by calculating the slope at unload of the RPL loops of the normal stress curve in the skin in tension as a function of permanent deflection. The start of unload is assumed to be a linear elastic zone. The damage rate d(f) varies between 0, representing the initial state, and 1, representing complete failure of the sandwich structure at the end of the test.

2.4.2. Cumulative surface energy dissipated

During a bending test on a sandwich specimen, the foam core of the structure contributes to energy dissipation [16]. The dissipated cumulative surface energy, E_{diss}, quantifies this energy dissipation. This energy quantifies all dissipative phenomena such as plastic phenomena, viscoelastic deformations and the progression of damage. This energy is determine by calculation of the cumulative difference between the area under the loads and unloads (Eq. 2). This calculation allow to measure the structure's capacity to dissipate energy following the evolution of mechanical damage. This dissipation may be linked to elasto-plastic or visco-elastic phenomena, or to damage to the sandwich structure.

$$E_{diss} = E_{def} - E_{res} \quad \text{(Eq. 2)}$$

With :

- E_{diss} : cumulative surface energy dissipated (mJ/m^2)
- E_{def} : surface energy of deformation (mJ/m^2)
- E_{res} : surface energy restored (mJ/m^2)

3. Results and discussion

3.1. Hydric aging

After immersion in distilled water maintained at 20°C, regular monitoring of the mass of sandwich specimens shows that the time required to reach water saturation is 2500 hours (15 weeks) (Fig.2). To sum up, the immersion of sandwich structures in water first causes an absorption phenomenon through the diffusion of water in the pores of the foam and in the pores of the skin. The equilibrium is reached after 15 weeks and the maximal water weight content is 9 %.

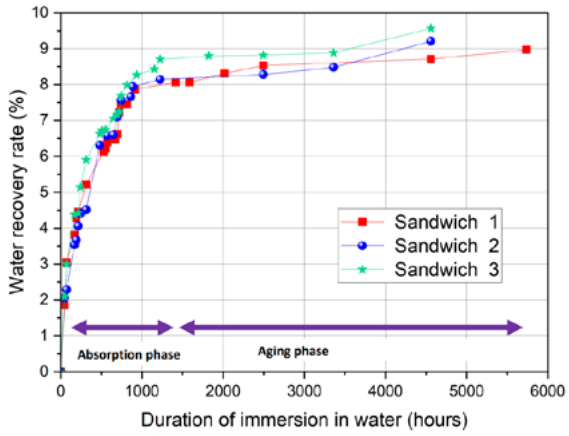

Fig. 2. – Water uptake curves for sandwich samples at 20°C

The sandwich specimens used to characterize flexural behaviour are immersed in seawater at 40°C to accelerate aging. According to the literature, the mineral salts present in seawater do not change the maximum water content, even if they modify absorption through accelerated diffusion by ions [17, 18]. Nevertheless, diffusion phenomena are accelerated by temperature [18, 19]. Consequently, the first sandwich structure characterization occurs after 16 weeks of immersion.

3.2. Study of dissipated energy and damage

The curves in Fig. 3 show the evolution of the cumulative dissipated surface energy of sandwich specimens under 4-point repeated progressive bending loading for aging periods ranging from 0 to 88 weeks. Firstly, the energy dissipation by the structure during the water absorption phase is studied, and secondly the study focuses on the aging phase from 16 to 88 weeks.
The study showed a 3-stage evolution. During the absorption phase (<16weeks), for all deflections, the aging causes a diminution of cumulative energy. In contrario, a aging time longer than 16 weeks tends to decrease the energy whatever the deflection. Between 60 and 88 weeks, a final major change is observed, with a significant increase in dissipated energy close to structural failure. Aging shows that under bending loads, dissipation close to sandwich failure accelerates.
The curves in Fig. 4 show the evolution of the damage rate of sandwich specimens under 4-point bending repeated progressive loading for aging periods ranging from 0 to 88 weeks. The study of the influence of water aging on the damage rate is divided into two parts. The first is carried out during the first 16 weeks, during which the immersed sandwich structure absorbs water, and the second is carried out between 16 and 88 weeks.
Over the first 16 weeks, the damage rate curves remained virtually unchanged. At the start of the test, damage to the sandwich structure increased significantly, with a permanent deflection, i.e. a rate of over 0.2. Damage continues to growth slower until the end of the test. Between 16 and 88 weeks of water aging, the damage rate curves also remain virtually unchanged. In short, water aging has few influence on the kinetics of damage evolution during the absorption phase and for longer aging periods.

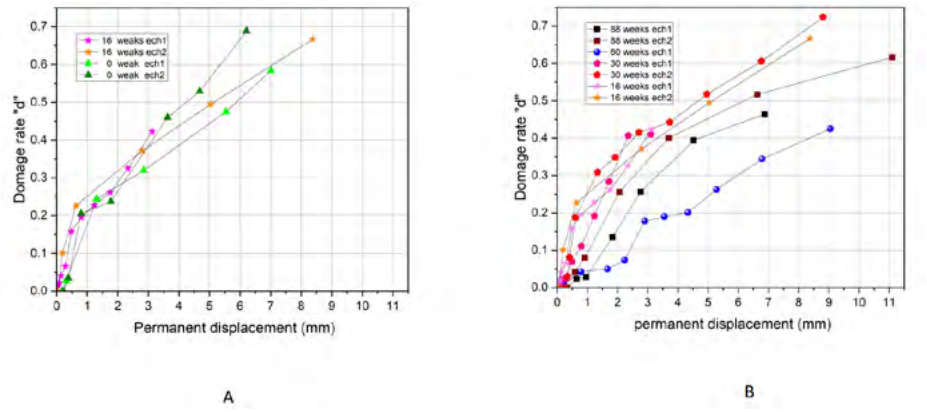

Fig. 4. – Evolution of the damage rate during a RPL bending test of sandwich structures as a function of water aging. A : absorption phase, B : aging phase

3.3. Damage monitoring by acoustic emission

The damage evolution is monitoring using acoustic wave emission during flexural tests. The 5 parameters previously mentioned, namely amplitude (dB), rise time (µs), duration (µs), number of hits and energy (aJ), were used by applying the unsupervised K-means classification method. Fig. 5 to Fig. 9 are average acoustic signatures of damage clusters associated with a type of damage. For each damage mechanism, the evolutions of the acoustic signatures are first observed during the water absorption phase (between 0 and 16 weeks) and during the aging phase from 16 to 88 weeks.

Polyester resin cracking and glass fiber breaks in composite skins are considered to be volume damage. Decohesion between glass fibers and polyester resin, decohesion between composite skins and foam core, and delamination are thus considered to be interfacial damage. The descriptor most affected is sound intensity. Observations are in line with those observed for dissipated energy.Two distinct phases are observed, with sound intensity increasing during the absorption phase (<16 weeks) then decreases until 88 weeks for all damage classes.

Fig. 5. – Evolution of acoustic signatures associated with polyester matrix cracking as a function of water ageing

Between 16 and 60 weeks, the intensity of the sound remains unchanged, but decreases sharply thereafter. Between 16 and 88 weeks of ageing, there is a small variation in wave energy, characterized by a slight increase with ageing (Fig. 5).

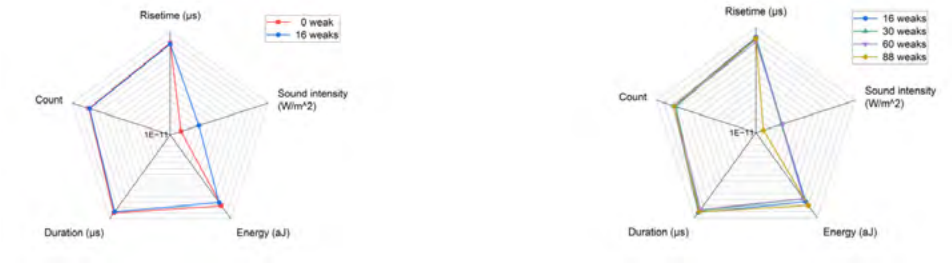

Fig. 6. – Evolution of acoustic signatures associated with decohesion between glass fibres and polyester matrix as a function of water ageing

During the aging phase up to 88 weeks, signal energy decreases slightly. Between 16 and 60 weeks, the intensity decreases slightly, and beyond that it decreases sharply. Between 16 and 88 weeks of aging, wave energy remains unchanged (Fig. 6).

Fig. 7. – Evolution of acoustic signatures associated with decohesion between glass/polyester UD skins and SAN foam core as a function of water ageing

During the aging phase up to 88 weeks, signal energy remains unchanged. Between 16 and 60 weeks, the intensity decreases progressively, and beyond that it decreases sharply. Between 16 and 88 weeks of aging, wave energy decreases slightly (Fig. 7).

Fig. 8. – Evolution of acoustic signatures associated with delamination in UD glass/polyester skins as a function of water ageing

During the aging phase up to 88 weeks, signal energy remains unchanged. Between 16 and 60 weeks, the intensity decreases progressively, and beyond that it decreases sharply. Between 16 and 88 weeks of aging, wave energy decreases slightly (Fig. 8).

Fig. 9. – Evolution of acoustic signatures associated with glass fiber breakage as a function of water aging

During the aging phase up to 88 weeks, signal energy remains unchanged. Between 16 and 60 weeks, the intensity of the sound remains unchanged, but decreases significantly thereafter. Between 16 and 88 weeks of aging, there is a small variation in burst energy, characterized by a slight increase with aging (Fig. 9).
During the absorption phase, continuous water absorption in the pores of the sandwich structure changes the acoustic impedance of structure, thereby modifying the propagation of acoustic waves resulting from mechanical damage. The sandwich structure itself

remains unaffected, which explains why, under 4-point bending loading, the damage propagation is low. This non-degradation of the sandwich structure at this stage of aging explains why the evolutions between surface and interface damages are the same. Between 16 and 88 weeks, the 9 % water weigth ratio content of the sandwich structure causes degradation at the interlaminar, intralaminar and skin-core interfaces. Water aging induces plasticization of the polyester matrix and hydrolysis of the polyester chains, leading to long-term depolymerization. Plasticization of the matrix is seen in the drop of its glass transition temperature T_G [17]. Experimental measurements of the evolution the value of T_G according aging time confirm this observation (not showing here).This embrittlement of the polyester resin accelerates the phenomena of decohesion between the glass fibers and the matrix, and interlaminar decohesion. Since glass fibers are inert, this explains why water aging has few influence on the development of glass fractures. Water absorption causes differential hygroscopic expansion between the glass/polyester composite skins and the foam core, which in turn causes differential swelling responsible for brittleness at these interfaces. As a result, water aging degrades the interfaces between skin and core. The embrittlement of all these interfaces is accompanied by a small increase in energy dissipation and a small increase in damage. The energy stored in the interfacial bonds once broken leads to an increase in the energy dissipated [20]. The hypothesis that the evolution of decohesions is guided by an energy criterion can be posed.

4. Summary

The aim was to study the influence of hydric aging on the behaviour and evolution of structural damage in sandwiches. The sandwich structure, which is representative of wind turbine blade structures on a laboratory scale, is made up of unidirectional laminated composite skins of glass fibers in an isophthalic polyester resin, and a rigid SAN (styrene acrylonitrile) polymer foam core. The sandwich structure was water-aged by immersion in seawater at 40°C. Through 4-point bending tests with monotonic loading and progressive repeated loading, damage parameters and dissipated energy were assessed. Acoustic emission is used to monitor the evolution of damage mechanisms. Water absoption test point out the water content equilibrium is reached after 15 weeks. Water aging increases energy dissipation during the absorption phase, with few change between 16 and 60 weeks, and a significant increase beyond 60 weeks. Experimental characterization shows a sudden increase of cumulative energy close to structure final failure. The kinetics of damage evolution remained unchanged throughout the hydric aging of the sandwich structure. Acoustic emission, using the non-overlapping K-means classification method, revealed the presence of 5 clusters of acoustic waves in the sandwich structure. These clusters are associated to the following damage mechanisms : matrix cracking, fiber/matrix decohesion, skin/shell decohesion, delamination and fiber breakage. No new damage mechanisms appear with water ageing, although variations in the waves parameters were observed. The descriptor most affected is sound intensity and, to a lesser extent, the energy of acoustic signals. During the absorption phase, there is a significant increase in sound intensity for all damage mechanisms. Between 16 and 60 weeks, for surface damage, i.e. polymer matrix cracking and glass fiber breakage, sound intensity remains unchanged. For interfacial damage, i.e. both types of decohesion and delamination, sound intensity decreases progressively. Acoustic signal energy either decreases slightly or remains unchanged for all damage mechanisms. Beyond 60 weeks, sound intensity decreases sharply for all types of damage, while waves energy either decreases slightly or remains unchanged.
The results show that the 88 weeks hydric aging of sandwich samples in 40°C seawater mainly degraded the interfaces of the structure. This degradation of the interfaces was accompanied by an increase in energy dissipation [20]. The causes of this interface degradation during water ageing can be multiple, such as plasticization and hydrolysis of the polyester matrix chains [17]. Differential swelling between the skins and the core due to differential expansion is at the root of decohesions between skins and core.

Keywords: natural-fiber composites, hybrid composites, crashworthiness, energy absorption, tubular structures

Abstract
Natural fibers are pivotal in the development of green composites, offering lightweight and sustainable solutions. However, their mechanical performance often falls short of synthetic counterparts. The combination of natural and synthetic fibers in hybrids balances performance with environmental impact, resulting in improved sustainability and properties such as lightweight and crashworthiness. This study focuses on the crashworthiness of chamfer-triggered circular tubes made from flax/epoxy and hybrid carbon-flax/epoxy, highlighting the potential of natural fibers compared to carbon in energy-absorbing composite structures during axial crushing. The energy-absorbing capabilities of these composite tubes are investigated through both experimental and numerical methods. Performance results under quasi-static and dynamic loading conditions are compared. Starting from the mechanical characterization of composite materials, a finite element model of these structures is developed to simulate their crushing behavior using LS-DYNA. The numerical and experimental results are compared to validate the effectiveness of the designed models, showing a high consistency of results indicating good model predictability. Concurrently, an optimization procedure is conducted using LS-OPT to identify optimal material parameters to accurately predict experimental responses and damage mechanisms.

1. Introduction

The recent adoption of natural fiber composites (NFCs) as a sustainable alternative to synthetic ones has garnered significant attention from research and various industries, including the automotive sector [1]. This interest stems from their notable specific strength, energy absorption capability, and design flexibility, alongside their improved sustainability compared to conventional materials. The diminished environmental impact ensured by substituting synthetic fibers with natural ones yields benefits for pollution issues like waste reduction, landfill management, toxicity mitigation, and the reduction of greenhouse gas emissions. When evaluating their eco-friendliness it is crucial to consider the entire lifecycle from raw material extraction and fiber processing to textile and apparel manufacturing, distribution, consumer use, and end-of-life disposal. In this regard, the life cycle assessment (LCA) is essential to evaluate the products environmental impact across their entire life span, from raw materials extraction to end-of-life, providing insight into its environmental performance [2]. First, the extraction of raw materials for reinforcements of NFCs is simpler and more environmentally friendly than petroleum-based fibers. Moreover, natural fibers are biodegradable, being able to decompose naturally over time through biological processes. Despite the advantages of incorporating natural fibers, their exclusive application in high-performance composites is hindered by challenges, such as limited thermal stability, sensitivity to humidity, inferior durability compared to synthetic counterparts, along with

inadequate adhesion with different types of matrices due to their hydrophilic nature. All these aspects lead to a reduction in the final mechanical properties of the composite. To overcome these issues, researchers proposed several solutions like the hybridization of plant fibers with synthetics, the application of polymer coatings, and the use of advanced manufacturing techniques [3].
In the automotive industry, among natural reinforcements, bast fibers such as flax, hemp, jute, and kenaf are the most commonly used. Several prominent car manufacturers incorporate NFCs into body panels (door and window frames, columns, ceilings, seat backs, trunk liners, etc.) [4]. However, the use of purely reinforced natural fiber composites in structural applications, such as crash-boxes, side impact, and pillar structures, is still not entirely feasible and remains a future challenge due to poorer mechanical performance compared to synthetic. Therefore, the hybridization of natural and synthetic fibers is one of the most promising strategy to obtain improved mechanical properties, such as strength, stiffness, toughness, and impact resistance, while also offering other benefits such as reduced weight, cost-effectiveness, and environmental sustainability. Components designed to withstand axial or lateral crushing are commonly thin-walled structures, such as tubes, cones, truncated cones, square frusta, and grooved or un-grooved pyramids. Circular and square sections are the most common adopted for composites striking a balance between performance and ease of manufacturing [5]. The present study concentrates on investigating structures with circular cross-sections, considering both axial dynamic and quasi-static loading scenarios. Furthermore, a finite element (FE) modeling of these composites is designed to simulate the crushing behavior of tested samples through LS-DYNA [6]. Material properties are determined from experimental mechanical characterization. The aim is to establish a robust correlation between experimental and numerical results, validating the efficiency and predictability of models. In this regard, an optimization tool (LS-OPT) [7], is used to determine the best unknown parameters required by the material card, performing a surrogate-model (Kriging) based strategy, i.e., Efficient Global Optmization (EGO) [8].

2. Materials And Experimental Methods

The crashworthiness performance of circular tubes made from flax (F), carbon (C), and hybrid (H) reinforced toughened epoxy resin was evaluated under both quasi-static and dynamic conditions. The experiments aimed to investigate the behavior of tubular structures reinforced with flax fibers during axial crushing. The primary objective was to understand how composites containing flax fibers respond during crushing compared to tubes made exclusively with carbon reinforcements. This involved conducting quasi-static compression tests to assess the effectiveness of natural fibers in crashworthiness applications, studying their failure mechanisms and energy absorption capability, as well as comparing their performance under dynamic loading conditions.
Laminated tubes were produced by HP Composites SpA using a Prepreg composed of flax and carbon balanced woven fabric (weight distribution: 50% warp and 50% weft) with a toughened epoxy resin. They consist of five, six, and four layers for flax, carbon, and hybrid reinforcements (CF_2C and FC_2F), respectively. Different numbers of layers were used to achieve comparable wall thicknesses for flax and carbon fiber cases, as well as for the two hybrid configurations. Specifically, technical features of the used composites are detailed in Table 1.

Table 1. Features of material laminates for the used Prepregs.

Fiber	Grammage [g/m^2]	Resin Content	Average layer thickness [mm]
Flax	350	52 %	0.56
Carbon	384	38 %	0.45

The curing cycle was performed in autoclave at 135 °C for 90 min under 6 bar, with a vacuum bag on the components. A gradual thermal process was employed, characterized by low heating (3 °C/min) and cooling (4 °C/min) rates, ensuring a uniform temperature distribution aiming at preventing deformations of the specimens.
In particular, four material configurations of laminated circular tubes were investigated. Materials differ in reinforcement type, comprising flax, carbon, and hybrid fibers. In the hybrid case, the variation also encompasses different stacking sequences. For the dynamic experiments, each configuration included

two samples tested for each energy level, while three specimens were tested under quasi-static compression. The tubular specimens had a length (L) of 100 mm and an internal diameter (D) of 70 mm. Additionally, to initiate failure and thereby prevent catastrophic crushing, all tubular samples were triggered with a single 45° external chamfer (bevel) at the top, as outlined in Figure 1. Additional details on the geometry and stacking sequence of tubes are reported in Table 2.

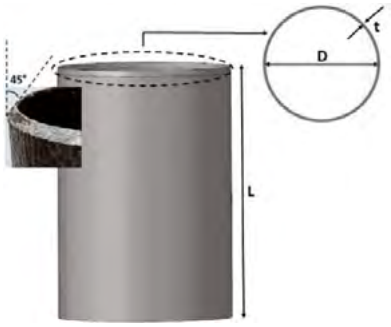

Figure 1. Geometry of tubes under axial crushing. L: length, D: internal diameter, t: thickness.

Table 2. Tested tubes under dynamic (D-) and static (S-) axial crushing. F: flax, C: carbon, H: hybrid. From H1 to H6, the reinforcement sequence is CF_2C, from H7 to H10 is FC_2F.

Specimens	Number of layers	Stacking sequence

D-H7, D-H8, D-H9, D-H10; S-H7, S-H8, S-H9	4	$[0°/45°]_S$

2.1 Mechanical characterization

Firstly, PrePreg comprising flax and carbon woven fabric with a toughened epoxy resin were mechanically characterized through tensile and compression tests, using a Zwick Z100 electromechanical machine. The aim was to acquire input data for simulating composite structure behavior and validating the reliability of numerical material models. Tensile tests were conducted on 8-layers tabbed standard rectangular specimens following ASTM Standard D3039. These experiments, with the warp direction aligned either parallel (0°) or perpendicular (90°) to the test direction, provided data on modulus, ultimate strength, yield stress, and strain in both warp and weft directions. In contrast, in accordance with ASTM Standard D3518, samples with the fiber aligned at 45° to the test direction, determined shear properties of materials. Compression tests according to the ASTM Standard D6641 allowed to complete the mechanical characterization necessary to model the material card. The material properties of the carbon and flax composites, obtained from these tests, are reported in Table 3.

Table 3. Experimental tensile properties of carbon (C) and flax (F) laminates. E_T: tensile modulus; σ_T: tensile strength; ε_T: ultimate tensile strain; E_C: compression modulus; σ_T: compression strength; ε_C: ultimate compression strain; G: shear modulus; τ: shear strength; ε_T: ultimate shear strain.

	E_T [GPa]	σ_T [MPa]	ε_T	E_C [GPa]	σ_C [MPa]	ε_C	G [GPa]	τ [MPa]	ε_S
C	59.4±2.9	993±9	0.016	57.4±2.5	468 ±15	0.009	3.3±0.1	58	0.050
F	9.9±0.6	138±14	0.018	9.0 ±0.2	99±8	0.077	1.7± 0.1	40±1	0.085

2.2 Quasi-static axial crushing

The quasi-static axial crushing tests were conducted using a 200 kN dynamometer GALDABINI machine. The average test speed was 15 mm/min for a set maximum displacement of 80 mm. The load applied and the displacement over time of the cross-head were monitored and recorded using an automated data acquisition system. To prevent the sliding of samples, each one was constrained on the bottom end (10 mm length) during the test using a support fixture.

2.3 Dynamic axial crushing

The dynamic experimental tests were performed using a Drop Tower Machine (Instron 9450), equipped with a total mass of 59.128 kg. The recorded initial velocities were 5.82 m/s, 6.88 m/s, and 7.80 m/s, for impact energies of 1000 J, 1400 J, and 1800 J respectively. The maximum energy level is applied exclusively to carbon and hybrid tubes externally reinforced with carbon, as they are capable of withstanding higher loads compared to the others. The remaining tubes had already reached a displacement of half the tube length with the previous impact energy. Each sample was supported at the bottom end, as in the quasi-static scenario.

3.Crashworthiness

Crashworthiness of a component is defined as the ability of absorbing energy, typically converting kinetic energy mainly into internal one, during an impact event. The standard load-displacement response of a composite under axial crushing can be divided into: (1) the pre-crushing zone, extending from the origin to the peak load, (2) the crushing zone, defined by the average crush load, and (3) the post- crushing zone, representing compaction or failure. The crashworthiness performance of the tested tubes is evaluated here through parameters, that can be defined from the load-displacement curve.

- The peak load (P_{max}) is the maximum load, at least excluding a possible compaction zone.
- The total absorbed crush energy (AE) is the amount of energy absorbed during the impact event: $AE = \int_0^{\Delta x_{max}} P\, d\Delta x$, where Δx_{max} is the maximum displacement, and P represents the load.
- The specific absorbed energy (SEA) is the ratio of AE and the mass of crushed specimen (m), measured as $m=\rho\, A\, \Delta x_{max}$, where ρ is the material density, and A is the cross-sectional area: $SEA = \frac{AE}{m}$.
- The average crush load (P_{avg}) is the ratio of the absorbed energy (AE_{post}) in the crushing zone and the related displacement (Δx_{post}): $P_{avg} = \frac{AE_{post}}{\Delta x_{post}}$.
- The crush force efficiency (CFE) is the measure of variation of P_{avg} from P_{max}, $CFE = \frac{P_{avg}}{P_{max}}$.

The higher the SEA, the better the energy absorption capability. Conversely, it is important to limit the magnitude of P_{max} to minimize the deceleration experienced by the crushed structure. Specifically, a CFE value close to unity indicates a reduction in deceleration changes. This aspect is crucial in automotive applications for protecting vehicle passengers.

4. Numerical modeling

The Finite Element (FE) models (see Figure 2) created in Altair HyperMesh were simulated using the commercial solver LS-DYNA. The tube was modeled using two (for flax and hybrid) and three (for carbon) cylindrical shell layers. To define composite numerical model, the PART COMPOSITE card was used, so that the laminate thickness was defined by the sum of each individual layer. Two rigid walls were designed to model the plate load test and ground floor, respectively - one planar and the other rigid. To the moving rigid wall the same constant velocity was assigned as in the experimental test, as well as the mass in case of dynamic loading conditions. The specified boundary conditions required constraining nodes in the lower part of the tube, as in the physical test. This involved constraining translational degrees of freedom. The design of the single 45° external chamfer followed the scheme proposed in [9], as shown in Figure 2. Moreover, a wavy mesh was employed for the entire length of the tube (except for the short trigger zone), extending to the lower band constrained by the fixture, where a flat mesh is used. This mesh design characterized as a tailored approach to capture the experimental

trend aiming at reaching a greater load-displacement response stability. All elements were defined as fully integrated quadrilater shell elements (ELFORM=16).
The LS-DYNA material card MAT54/55 (MAT ENHANCED COMPOSITE DAMAGE) was used for modeling all composite materials. MAT54/55 is the most commonly used material model in crash simulations among those directly avaliable in LS-DYNA for describing composites.This model is specifically designed for orthotropic unidirectional fiber composite material, exhibiting linear behavior until fracture. On the other hand, due to the fewer parameters to be set compared to other more complex models, it is successfully used here to model flax/epoxy composites as well. This adopted simplified method should provide a reasonable compromise between accuracy and computational cost, especially when an optimization strategy must be performed. The CRIT material card parameter was set equal to 54, referring to in the failure criterion of the Chang-Chang model [10].
The CONTACT_AUTOMATIC SURFACE_TO_SURFACE TIE-BREAK (OPTION=8) was used to replicate the bonding between each pair of adjacent plies, considering both normal and shear forces on the interface surfaceAdditionally, to avoid the interpenetration of the inner and outer layers during the splaying, the CONTACT_SINGLE_SURFACE (OPTION=8) was implemented.

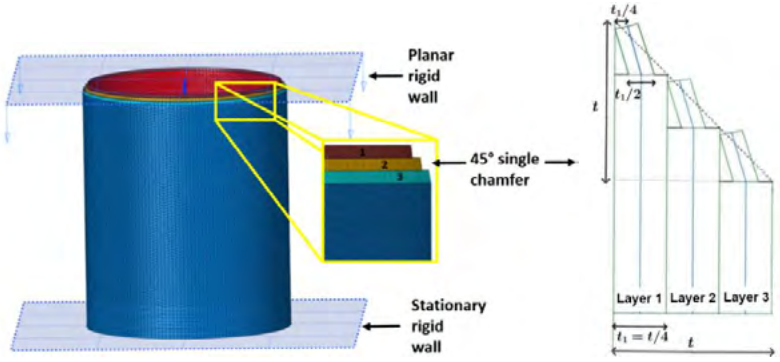

Figure 2. Shell finite element model for axial crushing of a 45° chamfered-tube (carbon fiber case).

5. Material card optimization

Most of the parameters of the material cards were experimentally determined (see Table 3). However, some of them require an optimization strategy for tuning to achieve an accurate reproduction of crushing behavior. A manual calibration process through a trial-and-error approach would be inefficient and finding a global optimum challenging. Hence, an EGO approach was pursued to precisely identify optimal material parameters for the considered composite materials. The parameters DFAILT and DFAILC, i.e., the maximum strain for fiber tension and compression respectively, and DFAILS, i.e., the maximum shear strain, were selected to be optimized, resulting as the most influential from a preliminary sensitivity analysis. The EGO algorithm based on Kriging model, as surrogate model, and expectation improvement (EI) criteria, as acquisition function. The LS-OPT software is used to perform the optimization procedure. It was performed in two steps, as shown in Figure 3.

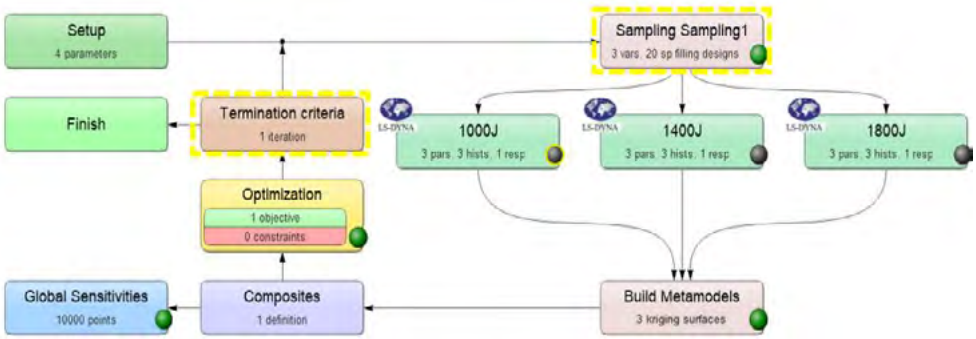

Figure 3. LS-OPT flowchart for the EGO strategy (1st step). The 2st step differs for yellow blocks.

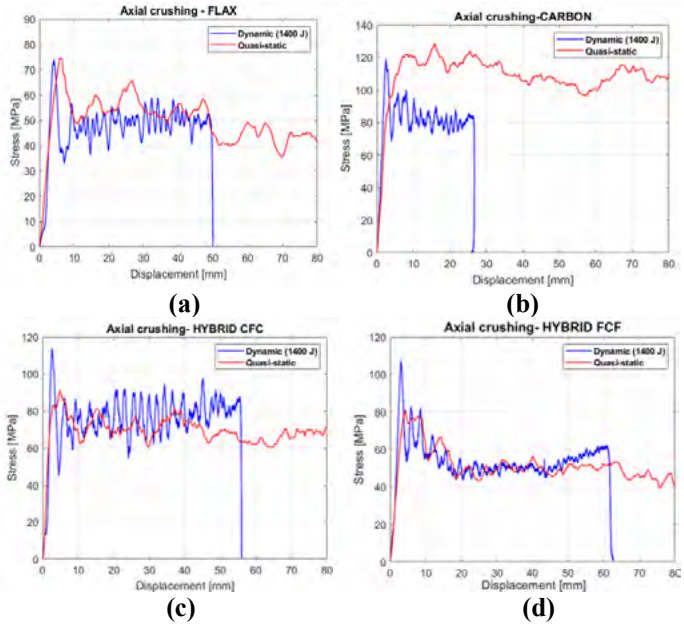
The initial step consisted of a single iteration, which entailed sampling the design space to generate a set of training points for assessing the objective function. A space-filling design approach was used to locate 20 sample points within a four-dimensional search space, adhering to the following variables bounds: $0.01 \leq DFAILT \leq 0.15$, $-0.8 \leq DFAILC \leq 0$, $0.01 \leq DFAILS \leq 0.15$. The training data with the observed responses were then used by a Kriging model to predict the value of the objective function at each point of the search domain. Hence, the EI function was built over the same domain and its optimization provided the infill point to be evaluated through FEM simulation. Step 2 consists of 100 iterations, with one function evaluation per iteration. An infill point was added at each iteration and the best design is updated only if the simulated infill point had a better objective function value than the previous best design. In either case, the new data was used to update the Kriging approximation model. The infill procedure was repeated until it met the termination criterion [11].

6. Results and discussion

The stress-displacement curves from experimental tests are illustrated in Figure 4. Across all materials, a consistent trend emerged between quasi-static and dynamic responses, except for carbon fiber. Notably, carbon fiber exhibited strain-rate sensitivity [12], resulting in a higher loading capacity in the quasi-static scenario. Consequently, there was a 15% decrease in SEA compared to the quasi-static value, attributed to larger delaminations leading to folding observed in the dynamic tests. All tubular samples crushed in a progressive manner. In particular, they presented similar crushing modes, with the main energy absorption mechanisms given by splaying.



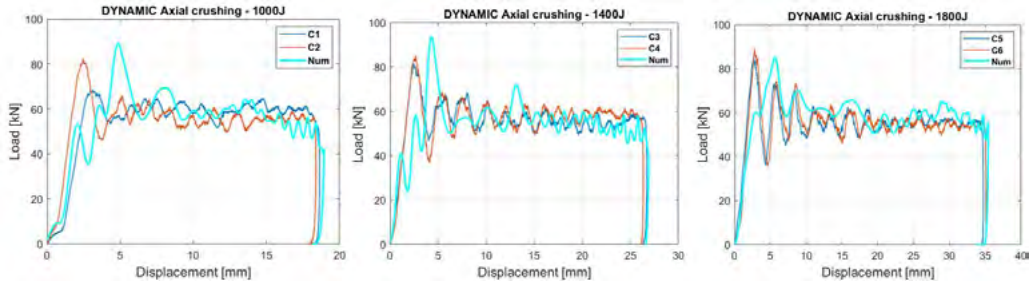


Figure 4. Comparison of stress-displacement curves of quasi-static (red) and dynamic (blue), at 1400 J, axial crushing tests: (a) flax, (b) carbon, hybrid (c) CFC, (d) FCF.

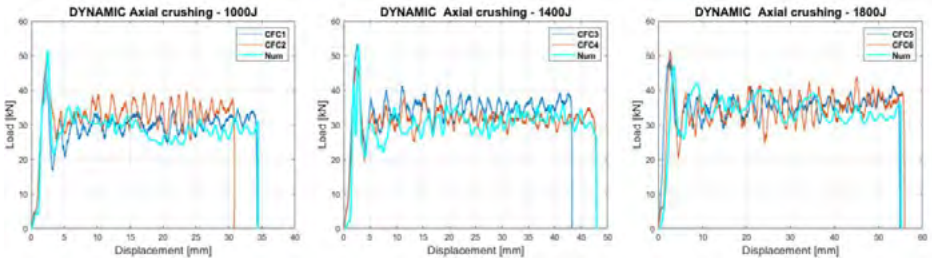

For the sake of brevity, numerical results only for dynamic tests are presented here and compared with the experimental outcomes to evaluate the accuracy of the designed models coupled with the optimization strategy. Load-displacement reponses from experiments and numerical outcomes are depicted in Figures 5-7.

From a quantitative point of view, SEA and CFE values were evaluated to analyze the energy absorption performance of structures and efficiency during crushing. Notably, numerical simulations exhibited SEA and CFE values that closely matched the experimental ones, as shown in Table 5. The designed FE models effectively captured the experimental trends and can thus be considered effective tools for predicting the behavior of composite materials under axial crushing.

Figure 7. Experimental and numerical load-displacement curves of dynamic axial crushing: flax samples impacted at (a) 1000 J, (b) 1400 J, and hybrid FCF at (c) 1000 J, (d) 1400 J.

Table 5. Comparison of numerical and experimental dynamic results.

	1000 J		1400 J		1800 J		
Fiber	**SEA [J/g]**	**CFE**	**SEA [J/g]**	**CFE**	**SEA [J/g]**	**CFE**	
Carbon	63.2	0.8	64.0	0.7	62.1	0.7	*Experimental*
	64.3	0.7	67.5	0.7	65.7	0.7	*Numerical*
Flax	32.7	0.6	38.0	0.7			*Experimental*
	30.8	0.6	36.5	0.6			*Numerical*
CFC	53.1	0.7	55.8	0.7	55.4	0.7	*Experimental*
	54.3	0.6	53.6	0.6	53.3	0.7	*Numerical*
FCF	40.1	0.5	39.7	0.5			*Experimental*
	40.9	0.5	35.7	0.4			*Numerical*

Moreover, numerical results demonstrated the ability of the designed models to replicate tube crushing behavior and associated damage mechanisms for both flax and carbon fiber, as illustrated in Figure 8. Specifically, the simulations successfully captured the splaying mode, reproducing the outward and inward splaying of composite fronds.

(a) (b)

Figure 8. Experimental and numerical damage progression of (a) flax and (b) carbon tubes impacted at 1400 J.

3. Conclusions

A comparative analysis of carbon, flax, FCF, and CFC tubes regarding their load-displacement responses and crashworthiness performance, evaluated in terms of SEA and CFE values, has been conducted from both experimental and numerical perspectives. It emerged that the two hybrid solutions perform better compared to the pure flax case, with CFC emerging as the superior configuration, exhibiting results closely aligned with carbon. Finally, the integration of numerical simulations with the EGO strategy enabled an accurate reproduction of the crushing behavior of tested samples, ensuring both qualitative and quantitative accuracy.

Keywords: Structural health monitoring, Mechanochromic, Hybrid Composites

Abstract
The present paper reports an overview of mechanochromic self-reporting thin-ply hybrid composite sensors, which are designed to visually indicate overload in structures. These sensors, made from combinations of high-strain and low-strain materials, change appearance earlier than the final fracture, providing a clear visual cue of damage like delamination or strain overload. They can be used for various applications, for example, overload monitoring, and to detect barely visible impact damage in composites.

1. Introduction

The development of mechanochromic composites for structural health monitoring (SHM) presents a novel and efficient approach to improving the safety and performance of various structures in industries like aerospace, civil, and automotive. These are based on self-reporting polymer composites which provide a light-weight sensor with an easy-to-read visual cue. These composites can sense their state of health, such as damage or deformation, through changes in colour or appearance, and do not require external data acquisition systems. They offer a user-friendly, cost-effective, and environmentally sustainable solution for SHM, with the potential for significant technological and economic benefits [1].
As summarised in figure 1, the mechanochromic composites are categorized into two primary groups: chemical-based and physical-based colors. Chemical-based colors involve the use of pigments or dyes that change color upon mechanical excitation, often through the rupture of micro-capsules or fibers containing dyes. These can be used in various composites and coatings for metals and concrete, providing a visible response to mechanical stimuli [2]. Physical-based colors, on the other hand, arise from the interaction of light with the material's structure, as seen in phenomena like the iridescent colors of butterfly wings or peacock feathers. These structural color materials can change color under different stimuli like electricity, heat, light, and strain, offering an eco-friendly alternative to traditional pigments and dyes [3].

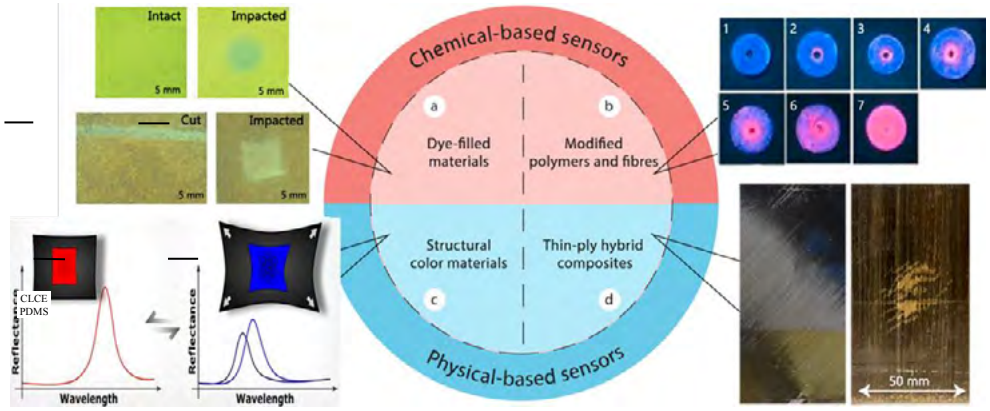

Figure 1. Examples of different mechanochromic approaches for SHM applications: a) characterisation of impact damage and cuts in polymer composites prepared with microcapsules [4], b) color changing process in composites under compression, increasing from left to right, indicating the fluorescent activation [5], c) a structural color patterns that are either always visible or reversibly revealed or concealed upon

mechanical deformation [6], d) comparison of the visual damage detection in a structure with (right) and without (left) hybrid composite sensors under the same impact loading condition [7].
The present paper reports a critical overview of mechanochromic self-reporting thin-ply hybrid composite sensors, which are designed to communicate visual information for SHM purposes. These sensors, made from combinations of high-strain and low-strain materials, change appearance earlier than the final fracture, providing a clear visual cue of damage like delamination or strain overload. They can be used for various applications, for example, overload monitoring [3], and to detect barely visible impact damage in composites [8].

2. Mechanochromism based on Glass/Carbon Hybridisation

Thin-ply hybrid composite sensors have been developed as an easly-implementable approach for visual indication of overload. These sensors are made using commercial prepregs and the sensing mechanism is activated via fracture. Different types of failure in a three-layer uni-directional hybrid laminate made from high-strain-material and low-strain-material are shown in figure 2. Damage and failure mechanisms lead to a visual indication of strain overload, where delamination is suppressed and several low strain fractures occur, followed by stable localised pull-out. This is achieved by choosing appropriate material properties, relative low-strain-material to high-strain-material thicknesses and absolute thickness of the low-strain-material [9].

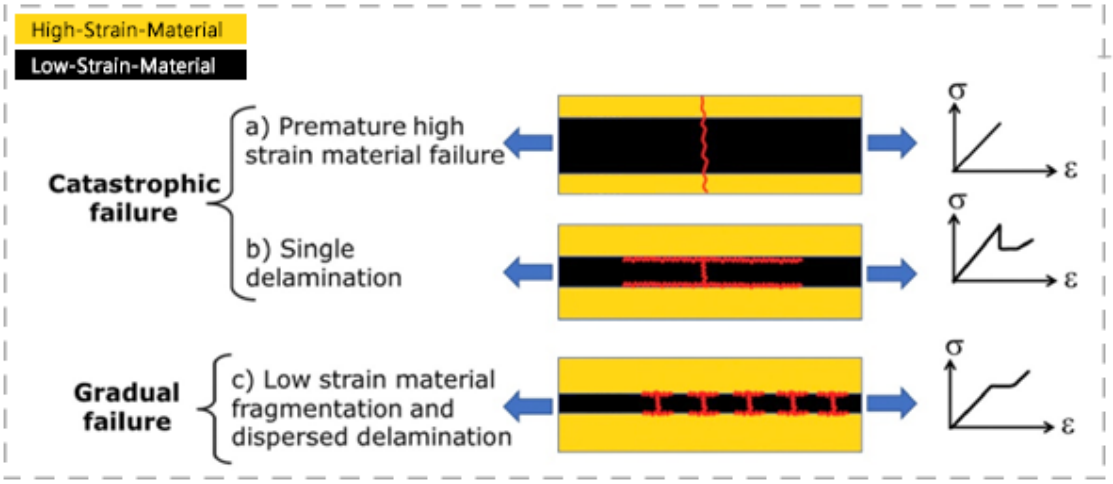

Figure 2. Different failure mechanisms in a three layer uni-directional hybrid composed of high-strain-material and low-strain-material (red lines indicate fracture) (a) single crack through the whole specimen, (b) single crack in the low-strain-material followed by instantaneous delamination, and (c) multiple fracture and localised stable pull-out of the low-strain-material [10]

Figure 3 shows two different designs of the uni-directional hybrid composite sensors, where the visual change is achieved by a purpose-designed, thin interlayer of glass/carbon-epoxy hybrid composite loaded by a predefined strain value. Light passes through the translucent glass layer and is absorbed by the intact carbon layer, creating a dark appearance. Figure 3(a) shows fragmentation of the low strain material followed by gradual, dispersed delamination [11]. The incident light is reflected from the locally damaged glass/carbon interface around the carbon layer fractures, creating light stripes. Figure 3(b) shows another type of failure in thicker carbon layers: a single fracture of the low-strain-material is followed by sudden delamination [12]. Both can act as good overload indicators since it is easy to visually monitor the delamination through the translucent glass layer.
Hybrid sensors can also be used for fatigue life monitoring, where an increase in the delamination area can be correlated to the number of cycles, as shown in Figure 4 [13].

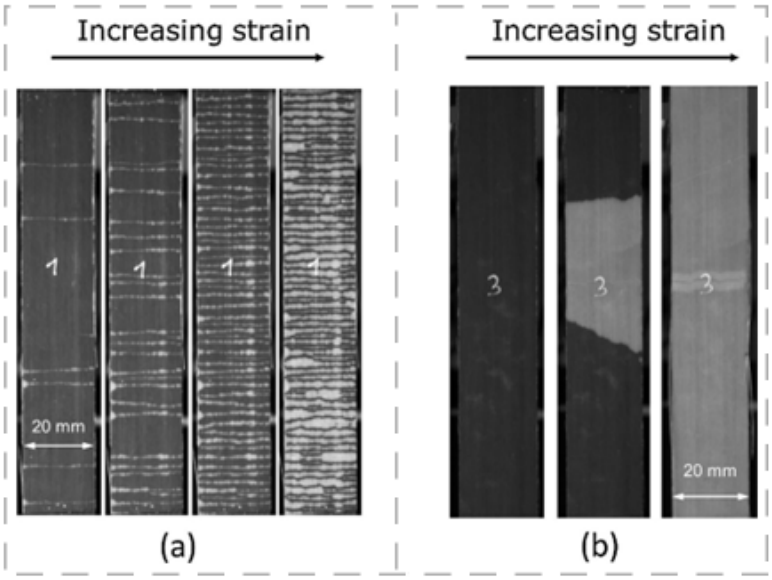

Figure 3. Visual indication of damage in thin-ply glass/carbon hybrids: (a) carbon layer fragmentation followed by stable, dispersed delamination [11], (b) carbon layer fracture followed by sudden delamination [12].

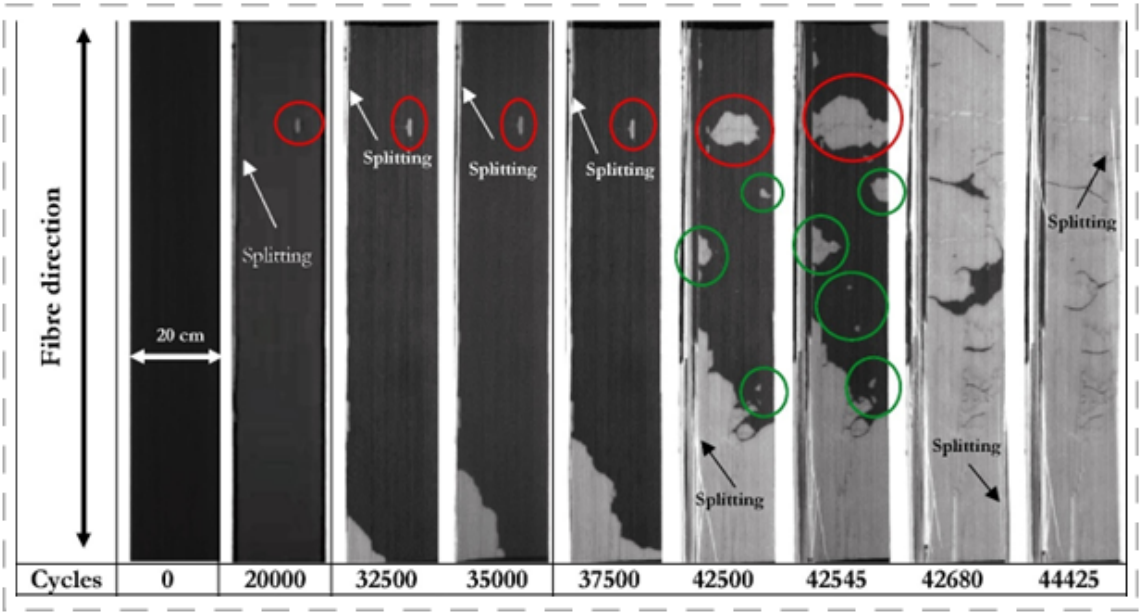

Figure 4. Fatigue life monitoring in a uni-directional thin-ply glass/carbon hybrid composite at 90% stress level of the carbon fragmentation initiation [13].

Multidirectional pseudo-ductile thin-ply hybrid laminates with improved ductility and notch insensitivity have also been developed [10,14]. These multidirectional laminates showed similar damage mechanisms to the uni-directional laminates but have the advantage of being able to monitor damage evolution, as the damage can be observed around the notches before any catastrophic failure occurs, as shown in Figure 5. Typically, hybrid composite sensors are either bonded directly onto the structures' surface or they are incorporated into the structure as a sensing layer (see Figure 6). By combining different sensing materials activated by different strains, they can provide a more detailed picture of the overload. Also, by designing an array of sensors orientated in different directions, the overload direction can be monitored. A sensor mounted on a component is subjected to the same strains as the material below. Carbon and glass layers serve as the 'sensing' and 'outermost' layers in this case.

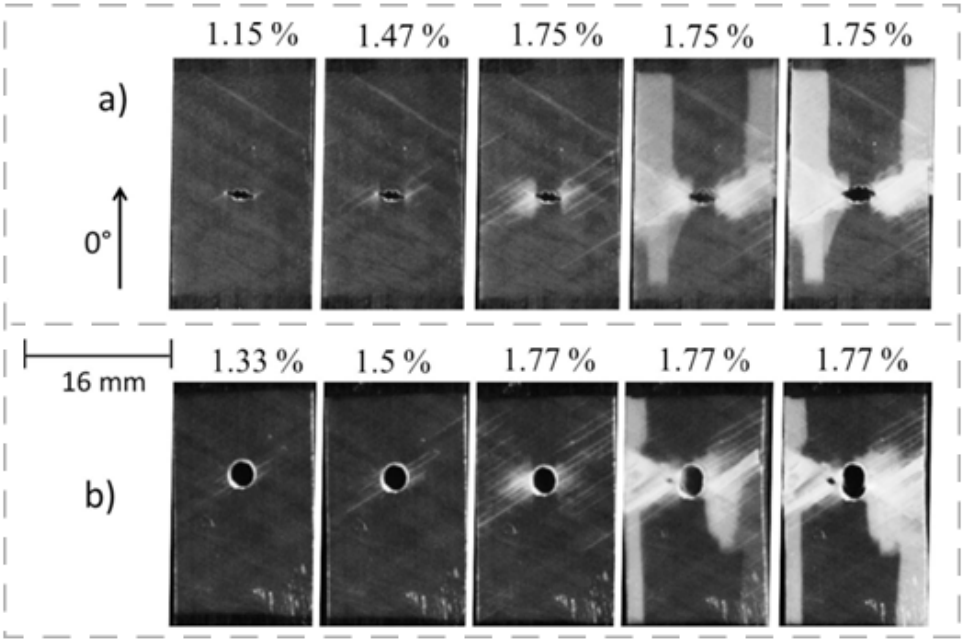

Figure 5. Visual indication of damage in (a) sharp notched and (b) open-hole ±60QI/Hexcel laminates, at different strains in tensile test [14].

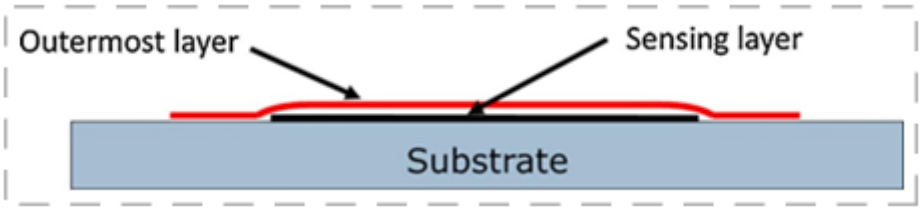

Figure 6. Schematic of a hybrid composite strain overload sensor attached to a substrate material [3].

Unlike other mechanochromic systems reviewed in previous sections the simplicity and practicality of glass/carbon hybrid sensors has led to their relatively rapid use in SHM. For example, a set of short and long sensors made of single ply XN80/EPOXY were applied on some commercially available CFRP bike handlebars, and both handlebar structures with and without sensors were tested under a three-point bending load. Figure 7 shows the force-displacement response of the tested structures, here the activation point for long sensors is between 1500 N and 2000 N. The graph also shows the load (1000 N) prescribed for testing Racing Bicycle handlebars according to the European Standard (EN14781) [15]. Results of this test suggested that sensors did not induce any noticeable increase in stiffness.

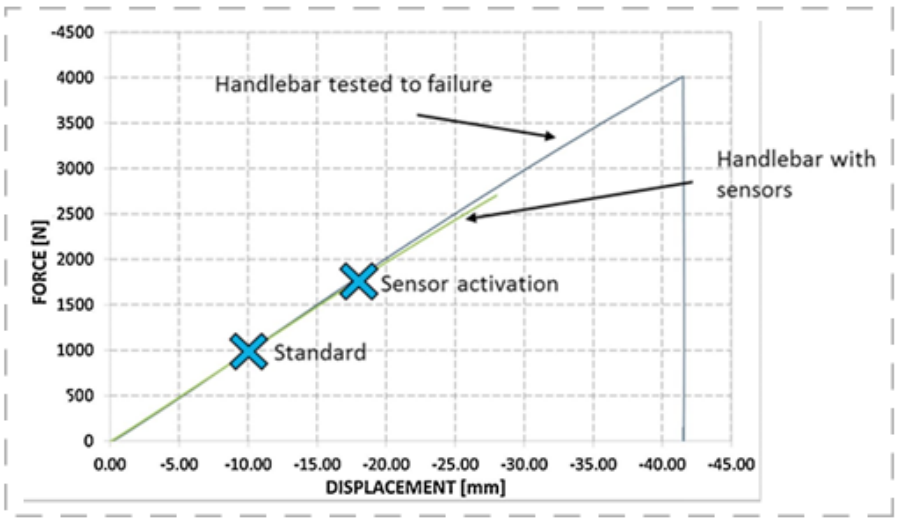

Figure 7. Force-displacement response of the tested CFRP bike handlebars [3].

Figure 8 illustrates a handlebar equipped with both short and long sensors. Here the first fracture of the long sensor was observed at 1750 N. The self-reporting concept could be successfully achieved by using long sensors, providing a warning to the user that a critical loading condition had occurred.

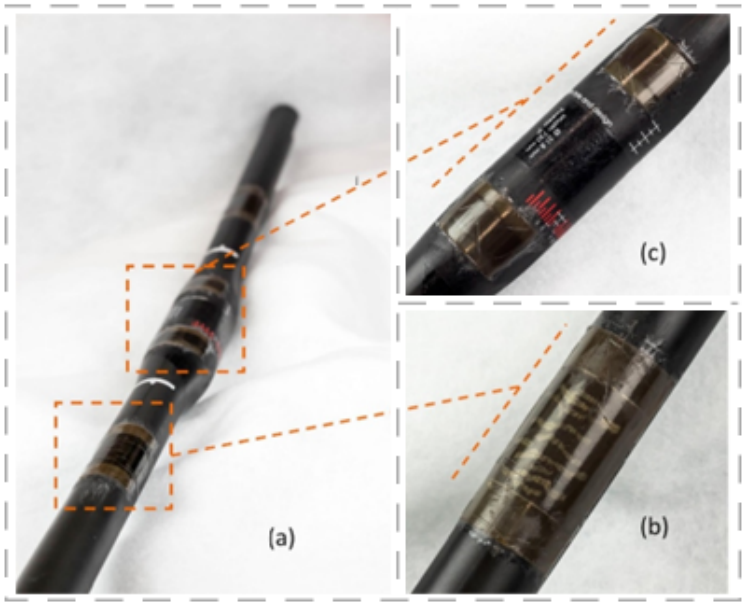

Figure 8. Bike handlebar eqipped with hybrid composite sensors: (a) MTB Racing flat handlebar, fitted with (b) long (c) short sensors [3].

A bonded composite patch is one method used to repair cracks in aluminium panels used in aerospace structures. However, in the case of standard repair techniques, damage beneath the repair patch cannot be detected by simple visual inspection alone. Therefore, hybrid composite sensors can be used as a composite repair patch which can self-report critical situations, e.g. an overload or crack extension in the substrate. As discussed earlier, these sensors are designed such that they do not change the local strain distribution. Nevertheless, in case of a repair patch, it is necessary to have enough stiffness so that the load in the substrate damaged area is reduced and carried instead by the patch. The practicality of the concept was investigated by applying a hybrid composite sensor on an aluminium panel with a 20mm initial crack length (see Figure 9).

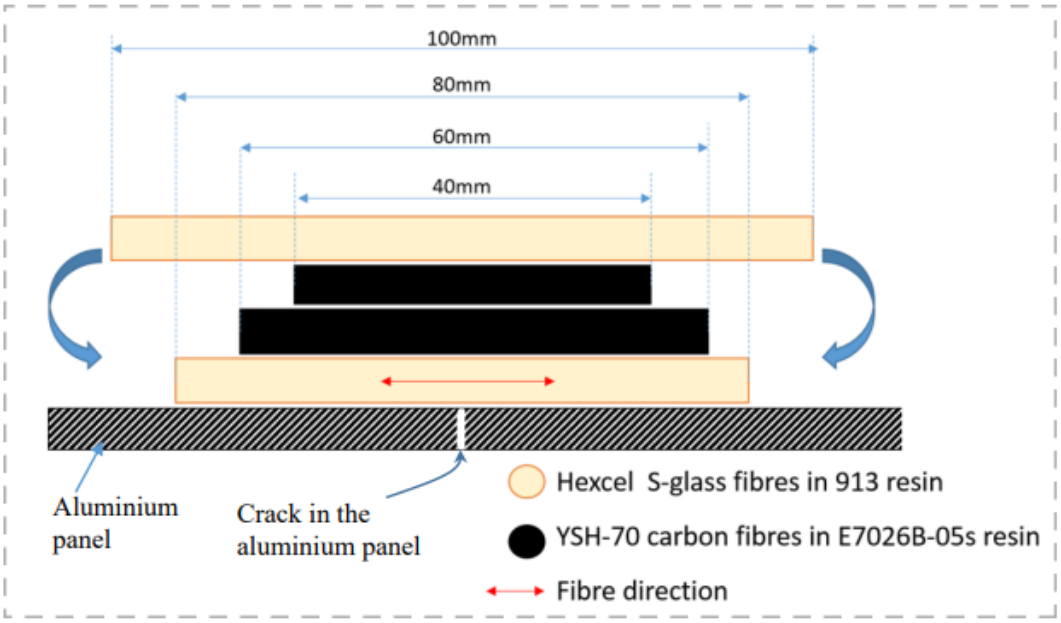

Figure 9. Schematic of hybrid composite repair patch [16].

During the quasi-static tensile test, changes in appearance were evident above the threshold load in the repaired specimen (see Figure 10). By overloading the specimen, crack propagation began beneath the repair patch. Figure 10 shows a change of appearance due to delamination, induced by fractured carbon at the centre of the specimen (above the crack), demonstrating the self-warning ability of the repair patch.

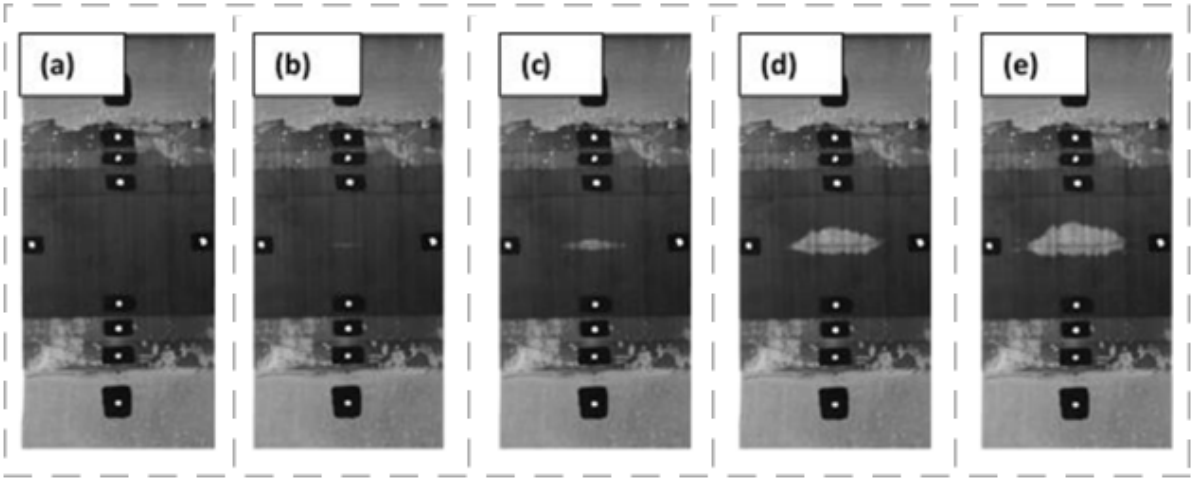

Figure 10. Self-reporting hybrid composite sensors subjected to increasing loads: (a) 195 MPa; (b) 197 MPa; (c) 304 MPa; (d) 336 MPa; (e) 340 MPa (99% failure load) [16].

A hybrid sensor was also used to detect BVID, which can have a noticeable influence on the mechanical performance of laminates, especially the compressive strength which may decrease by up to 60% compared with an undamaged laminate [17]. A hybrid composite layer composed of a unidirectional ultra-high modulus carbon (YS-90)/epoxy and a S-glass/epoxy material was used. It was applied to detect BVID in a quasi-isotropic $[45/0/90/-45]_{4S}$ laminate fabricated from unidirectional T800 carbon/MTM49-3 epoxy prepreg. Figure 11 shows an example of the impacted-face-, back-face and c-scans for samples subjected to a 12-Joule drop tower test. The c-scan reveals significant delamination damage for all samples, and the delamination size is slightly higher in the original sample compared to the sensor integrated sample. However, there is no change in the appearance of the original sample on either the front or back faces. In contrast, for the sample with the sensor, a visible colour change is observable on both faces. As discussed, these colour changes are due to damage induced in the hybrid sensors. The size of the visible damage area on the front face corresponds to the level of the impact energy.

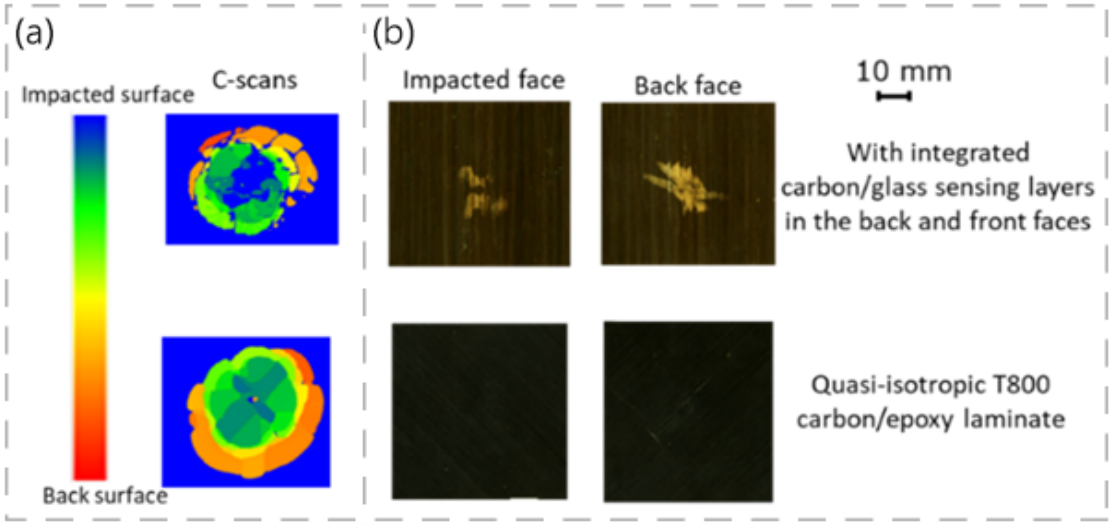

Figure 11. A carbon/epoxy composite (substrate) with integrated impact detector hybrid composite. a) Schematic 3D view, and b) impacted and back faces of specimens with (up) and without (bottom) sensors [18].

A hybrid composite composed of a layer of unidirectional S-glass/epoxy and another layer of unidirectional ultra-high modulus (UHM) carbon/epoxy was used for improving the performance of damaged concrete beams post-retrofitting, to showcase the practical use of mechanochromic composite for both strengthening and structural health monitoring purposes. As depicted in figure 12, when subjected to a strain beyond the strain to failure of the UHM carbon layer, the mechanochromic composite changes its appearance, indicating an overload of the structure.

Figure 12. Colour change in the composite of the retrofitted sample, showing the location and size of the developed underneath cracks [19].

3. Conclusions

The results demonstrated that mechanochromic composites serve as both reinforcement and passively activated, visually readable sensors. The dynamic color change phenomenon provides valuable insights into structural performance, acting as a passive indicator of stress accumulation and potential failure. These glass/carbon hybrid sensors are simple and easy to implement, making them attractive for use in SHM. Practical applications were discussed, including damage monitoring of a bike handlebar and repair of a damaged aluminum panel and a concrete beam. Currently, hybrid composite sensors are developed only for static overload sensing, are not reversible, and are limited to specific strain ranges due to the low strain of carbon fiber. They cannot be fabricated using conventional hand layup or liquid infusion methods because of the thin ply requirement of the sensing layer. Future studies should investigate the performance of purposely pre-damaged sensors in BVID detection to determine precise thresholds for different damage modes, such as delamination and fiber breakage. Additionally, hybrid composite sensors should be tested under various environmental conditions to develop high-performance, function-oriented sensors.

Keywords: Flax fibre, Polymer-matrix composites, Moisture sorption, Durability

Abstract
This study investigates the changes in the transverse flexural properties of flax fibre composites induced by accelerated and natural ageing methods. The reductions in flexural strength and modulus of composites, ranging from 14% – 48% and 6% – 57%, respectively or even an increase in flexural properties after the cyclic ageing test, show the diverse effects of the tests on flax composites. Moreover, the water immersion test seems to be predictive of the long-term durability of flax composites in natural conditions. The simplicity of water immersion makes it a suitable method for evaluating the baseline durability of these materials in outdoor environments. Overall, the results suggest that uncoated flax composites can withstand extreme humidity changes, but perhaps not in applications wherein composites come in contact with liquid water for long periods.

1. Introduction

In natural fibre composites (NFCs), moisture exposure enables water sorption by the hydrophilic fibres, potentially disrupting fibre/matrix interfacial adhesion [1]. Moisture sorption of NFCs affects them by swelling of the reinforcing fibres, leading to a microcrack formation at the interface and thus compromising the mechanical properties of the composites [1–2]. The degradation of the fibre/matrix interface is a primary failure mode in NFCs following water ageing tests [3–4].

Several researchers have studied NFCs moisture durability through water immersion, cyclic exposure to high and low humidity environments and natural ageing tests. Despite extensive research on NFCs durability, there is still a lack of understanding on how these different test results relate to each other. There is a lack of comprehensive data concerning the ageing damage and degradation mechanisms suffered by NFCs subjected to the different ageing tests. Therefore, this study aims to compare the changes in flexural properties of flax fibre composites caused by accelerated and natural ageing methods and to determine each method's similarity with the other ageing protocols. It would help choose the best durability study to be used for NFCs.

2. Experimental procedure

Untreated unidirectional (UD) flax fibre (Flax Tape 200, Lineo) was used in this study. Before composite manufacturing, the fibres underwent conditioning at 80% relative humidity (RH), resulting in 10% moisture content, to assess the impacts of utilising non-dry fibres on the ageing behaviour of the composites. The matrices used were unsaturated polyester resin ((Synolite 1967-N-1, DSM), peroxide curing agent (Butanox M-50, Nouryon), inhibitor (NLC-10, Nouryon) and cobalt-free accelerator (Nouryact CF-32, Nouryon)) and epoxy resin ((Epikote 828 LV), hardener (Vestamin® IPD, Evonik)). The polyester matrix was prepared using 1 wt% curing agent, 1 wt% accelerator, and 0.6 wt% inhibitor. The epoxy matrix was formulated with a resin-to-hardener weight ratio of 100:23, according to the

manufacturer's specifications. The UD flax fibre-reinforced polyester and epoxy composite laminates with dimensions of 300 mm x 300 mm and a thickness of 2 mm were fabricated using a vacuum-assisted resin infusion technique. During the infusion process, a vacuum pressure of 0.6 bar was applied for both composites. The flax/polyester composites were cured at room temperature for 24 hours, followed by post-curing at 70°C for 12 hours in an oven. The flax/epoxy composites were cured at 70°C for 4 hours on a hot plate and post-cured at 150°C for 1 hour in a hot press under a pressure of 15 bar to prevent the evaporation of sorbed moisture from the non-dry fibres.

The moisture durability tests used in the study were long-term moisture cycling (CYC), water immersion (IMM), natural ageing under the shade (SHA) and natural ageing exposed to sunlight (NAT) tests (Figure 1). The long-term moisture cycling was performed over 40 weeks using 20 cycles of "wet-dry" conditions in an oven with potassium nitrate and potassium fluoride salt solutions. The wet/humid condition held the temperature at 40°C and used 89% RH. The dry condition maintained 40°C and 23% RH. The IMM test was conducted by immersing samples in distilled water at 20 ± 1°C for 30 days.

An outdoor ageing test was conducted in Leuven, Belgium, from September 2019 to June 2020. The test included a shaded ageing (SHA) component, where samples were kept shaded, and a natural ageing test (NAT) component, where samples were unshaded. The SHA and NAT used similar experimental setups, with the SHA test eliminating direct solar radiation effects for comparison to the NAT test and accelerated tests, which only examine temperature and moisture influences. This way, it was possible to evaluate the influences of solar radiation, temperature, and moisture, including water immersion, on the aged samples.

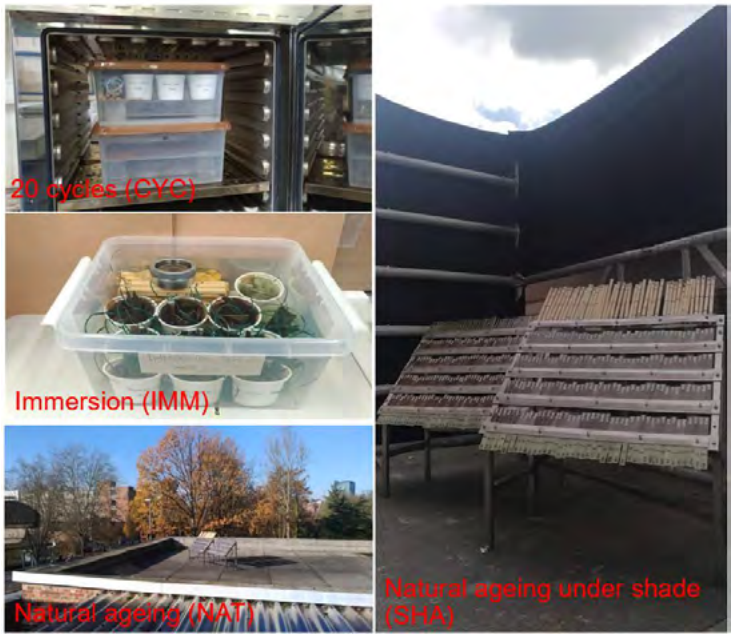

Figure 1. Ageing test setups: long-term moisture cycling (CYC), water immersion (IMM), natural ageing under the shade (SHA) and natural ageing exposed to sunlight (NAT), of uncoated samples.

3. Results

The transverse flexural properties of the composites after ageing tests are presented in Figure 2. Similar results were obtained for samples which were prepared with fibres that were dried before composite manufacture, albeit with lower mechanical properties, due to the initial damage resulting from fibre swelling [5]. Composites manufactured using non-dry fibres exhibited superior flexural performance compared to those made with dried fibres, a trend observed consistently across both flax/polyester and flax/epoxy composite systems. This enhancement in flexural properties can be attributed to the reduced swelling and shrinkage of composites reinforced with non-dry fibres during the different ageing tests.

©2024 | 3_LU_Maria Morissa_9XW3W.pdf:2

It is apparent that there are differences among the ageing tests for both the flexural strength and modulus of the composites. The IMM samples exhibited flexural properties similar to those of NAT-exposed samples. This suggests that the water immersion protocol, although accelerated, induced a degree of degradation representative of natural ageing exposure.

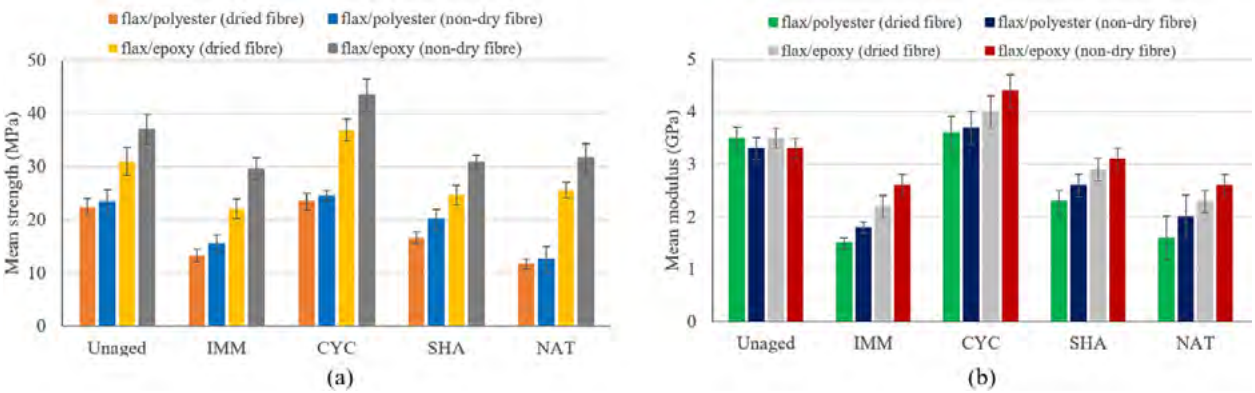

Figure 2. Transverse flexural properties of composites made of dried and non-dry fibres after the ageing tests: (a) mean flexural strength and (b) mean flexural modulus of composites.

Unexpectedly, as discussed in the literature [5], the CYC test did not reduce the transverse flexural properties of the composites after 20 cycles. Instead, the test increased both the mean strength and modulus, especially for flax/epoxy composites compared to unaged samples, likely due to some hornification mechanism in the fibres and/or post-curing of the resin. Because similar results were obtained for pre-cycled fibres, which were then converted into composite and tested for ageing, the main strengthening/stiffening effect seems to be within the fibres [5].

The transverse strength and modulus of SHA samples were similar to those of NAT samples, especially for flax/epoxy composites. Despite a 47% decrease in the strength of aged epoxy resin after NAT testing (Figure 3), exposure to solar radiation did not significantly reduce the transverse flexural properties of the composites.

The flax/epoxy composite exhibited higher transverse flexural strength across all ageing conditions compared to the flax/polyester composite. This can be attributed to the inherently higher strength of the neat epoxy resin versus the polyester resin, as shown in Figure 3. The epoxy matrix also likely formed a stronger interfacial bond with the flax fibres than for polyester. An increase in resin modulus was observed during the CYC, SHA, and NAT tests (see Figure 3), which could be explained by post-curing effects [6–7].

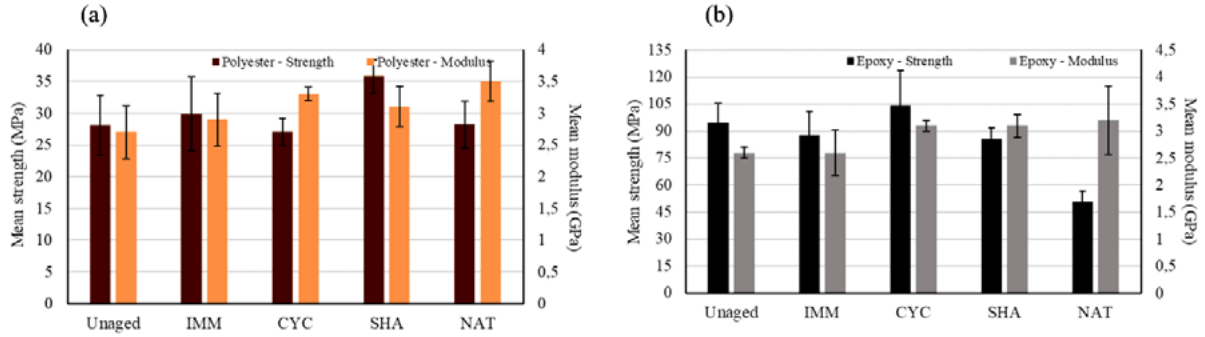

Figure 3. Flexural behaviour of reference materials after the different ageing tests: (a) neat polyester resin and (b) neat epoxy resin.

Visual observation revealed colour fading in aged composites (Figure 4). After 20 cycles, the CYC test produced only slight colour changes in all composites compared to SHA and NAT samples. After ten months of NAT testing, the flax/epoxy composites appeared darker yellow than the flax/polyester composites. This suggests that direct sunlight radiation during the NAT test caused colour changes to a dark yellow in the epoxy composites. In contrast, the ageing under the SHA test induces a light yellow colour for flax/epoxy composites. The yellowing of the composites during NAT testing correlates directly with the severe yellowing of the resins, especially the epoxy resin, as shown in Figure 4.

The significant colour change of the epoxy resin after the NAT test supports the decreased flexural strength observed for NAT-tested epoxy samples compared to those without direct sun exposure (SHA test). These results clearly demonstrate that solar radiation exposure causes reduced strength in the used epoxy resin.

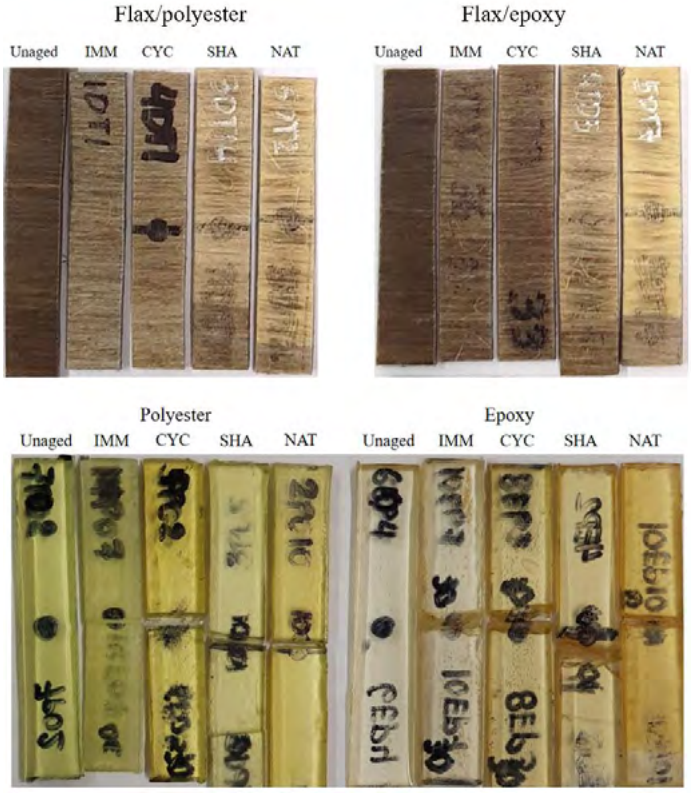

Figure 4. Comparison of the change in appearance of the composites and resins after the different ageing tests.

Figure 5 presents the SEM images showing the microstructure of unaged and aged composite samples. The images include aged flax/polyester and flax/epoxy samples from the IMM and NAT tests. SEM images of composites aged under the SHA test are not shown, as the surface microstructures were comparable to those resulting from the IMM and NAT tests. This similarity in the surface microstructure following IMM, SHA, and NAT testing aligns with the declining flexural properties exhibited across all three ageing methods, as presented in Figure 2.

The ageing tests revealed notable differences in the microstructure properties of the composites. As seen in Figure 5, the unaged samples of both composites displayed generally good fibre/matrix bonding. However, the two ageing methods, IMM and NAT, substantially increased the damage in the composites. The flax/polyester samples showed more extensive cracking and degradation than the flax/epoxy samples after both ageing tests. These microstructural defects accounted for the reductions

in flexural properties, with the flax/polyester composite exhibiting a sharper decline in flexural properties relative to the flax/epoxy composite. The greater susceptibility of the flax/polyester composite to ageing damage indicates inferior durability compared to the flax/epoxy composite under these testing conditions.

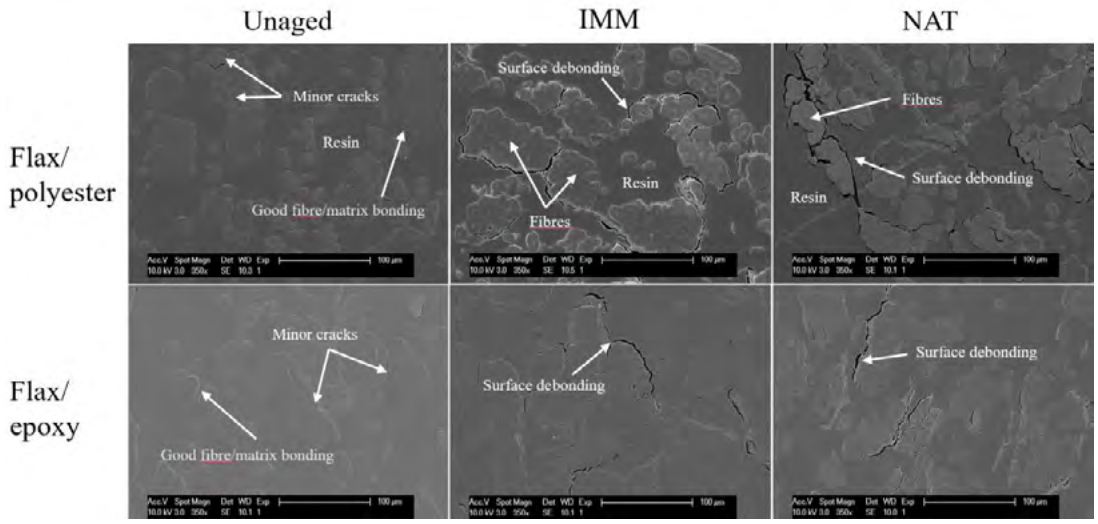

Figure 5. SEM images of flax/polyester and flax/epoxy composites' cross-sections before and after the immersion (IMM) and natural ageing (NAT) tests.

3. Conclusions

Across ageing methods, flax/epoxy composites outperformed flax/polyester, aligning with their superior starting mechanical properties. Microstructure analysis confirmed interfacial debonding as the key failure mode, arising from moisture-driven swelling differences between fibre and matrix. Overall, uncoated flax fibre composites demonstrate the potential to be used in environmental conditions even with extremely varying humidity values but are less suitable in applications wherein composites come in contact with liquid water for long periods. In the latter case, the use of water barrier coatings should certainly be considered.

The composite durability tests performed in this study offer insights toward optimising flax fibre composites for enhanced durability under long-term, real-world service conditions. The diverse effects of various ageing tests on the flax fibre composites highlight the importance of selecting appropriate testing protocols that suitably replicate application-specific exposure scenarios of composites.

The immersion test as accelerated test method, appeared to give the best prediction of real outdoor testing conditions for the uncoated samples. Cyclic moisture loading surprisingly lead to improved composite properties after 20 cycles of loading. This effect may be related to a "hornification" of the fibres and is currently topic of further research.

Keywords: Cured-In-Place Pipe (CIPP), tensile test, three-point bending test, ring stiffness test, modulus of elasticity

Abstract

This study focuses on the mechanical properties of installed cured-in-place pipe (CIPP) liners as determined by various tests. The experimental methods used include tensile tests on longitudinal specimens, three-point bending tests on hoop curved specimens and ring stiffness tests on whole pipe segments. The variability of the mechanical properties can be caused by defects, different strain rates during tests, anisotropic properties and specimen geometry. Finite element (FE) simulations of the three-point bending test on curved specimens and the ring stiffness test were performed in Abaqus to evaluate the influence of specimen geometry. The longitudinal, flexural and ring moduli of synthetic felt and GRP CIPP specimens cut from pipes with different nominal diameters and wall thicknesses were determined experimentally. There is good agreement between the experimental results and the theoretical relationships. Since the ring stiffness method is a simple method and the cut pipe segment is approximately the same as for curved specimens, the ring modulus can be considered a reliable parameter for hoop performance.

1. Introduction

The cured-in-place pipes (CIPP) have been used as a trenchless (“no dig”) rehabilitation method for water and sewer pipelines since the 1970’s. This technology is often used to address issues such as leaks, corrosion, and structural damage to concrete pipelines. A thermoset resin-saturated liner (flexible tube) is inserted into the damaged pipe by mechanical pulling or inversion. The liner is inflated to the inner surface of the pipe by air or water pressure and then cured by heat or ultraviolet (UV) light to obtain a hardened liner inside. The heat curing method is a traditional, low-cost curing method with a significant carbon footprint and energy consumption. The UV curing method, on the other hand, is characterized by fast curing, a lower carbon footprint and higher costs. The liner serves as a resin carrier and can be a synthetic fiber needle felt liner or GRP (glass reinforced polymer) liner. The fiber reinforcement reduces the thickness of the inner pipe and at the same time increases its mechanical properties. Resin systems mostly used are styrene-free Vinylester or styrenated Polyester. Laboratory tests are performed on specimens taken from full-length liners to verify that the installed liner fulfils the performance

requirements. The modulus of elasticity serves as an indicator of the load-bearing capability. To accurately characterize the mechanical performance of CIPP, various test methods are used, including tensile, three-point bending and ring stiffness tests [1] [2]. The expressions used to calculate the longitudinal, flexural and ring moduli are valid if linear elastic behavior and small deflections are assumed. Each test method includes a specific specimen geometry and test conditions such as strain rate. For example, the three-point bending tests can be performed on curved specimens cut in the circumferential (hoop) direction or on flat longitudinal specimens. Current quality control methods are predominantly based on hoop performance [3]. The apparent values of the flexural modulus determined on curved specimens are converted to the flexural modulus that would be obtained on an equivalent flat specimen using a theoretical correction factor. In practice, the modulus values obtained from different tests differ, although ideally they should be the same for a homogeneous, isotropic material. The variability of mechanical properties can be caused by common installation defects such as cracks and impregnation imperfections [4], different strain rates, anisotropic properties and specimen geometry [5]. In this study, the longitudinal, flexural and ring moduli of synthetic felt CIPP specimens cut from pipes with different nominal diameters and wall thicknesses were experimentally determined. The three-point bending tests were also carried out on GRP CIPP specimens. The specimens were not produced in the laboratory but were taken on site and represent realistic mechanical properties of installed CIPP. The resin system used was polyester and the reinforcement consisted of E-glass fibers. Finite element (FE) simulations of the three-point bending test on curved specimens and the ring stiffness test were performed in Abaqus to evaluate the influence of the specimen geometry. The aim of this study is to provide an understanding of the mechanical properties of CIPP as determined by various tests related to the effects of specimen geometry, test conditions and liner material.

2. Experimental setup, procedure and data

2.1. Tensile test

The tensile tests were performed on parallel-sided specimens cut in the longitudinal direction of the pipe in accordance with EN 1393 [6]. The tests were carried out in the tensile zone of the Zwick/Roell universal static machine using an extensometer (Figure 1, left). The speed of the tests was 5 mm/min. Eight series of synthetic felt CIPP specimens were prepared from pipes with different nominal diameters (d_n) and wall thicknesses (h). The composite thickness is then determined by subtracting the known thickness of the membrane layer ($e_1 = 0.5$ mm). The length and width of the specimens were $l = 300$ mm and $b = 25$ mm respectively. The gauge length was set at $l_G = 100$ mm. The number of specimens in each series was five. The average values of the measured dimensions of the width b and the composite thickness $e_{c,m}$ were used to determine the tensile stresses and strains. The modulus of elasticity was determined as the slope of the stress/strain curve (Figure 1, right) in the strain interval between $\varepsilon_1 = 0.05\%$ and $\varepsilon_2 = 0.25\%$.

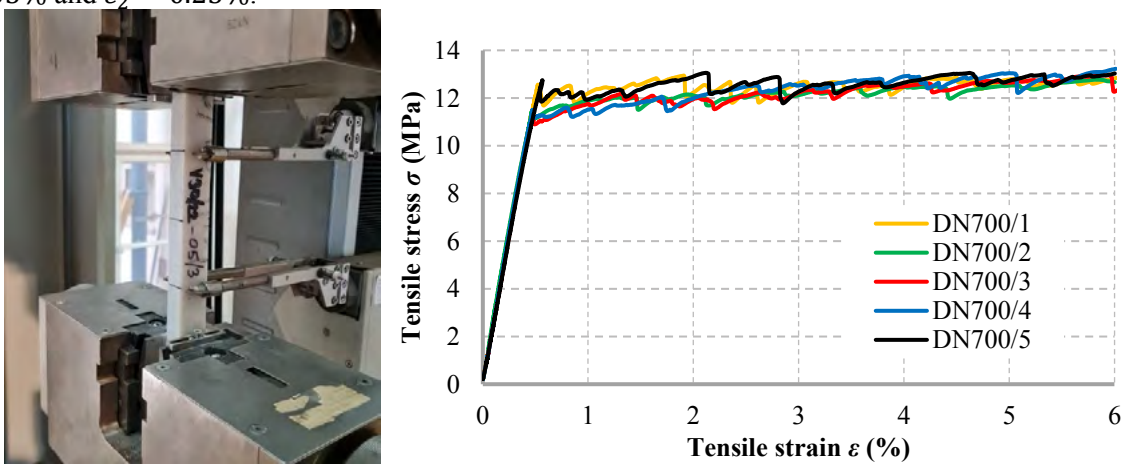

Figure 1. Tensile test on CIPP specimen (DN700/15): test setup (left) and stress/strain curves (right)

2.2. Three-point bending test

The three-point bending tests were performed on curved specimens (Figure 2, left) in accordance with EN ISO 178 [7] and EN ISO 11296–4 [8]. The tests were carried out in the compression zone of the Zwick/Roell universal static machine. An HBM LVDT WA 50 mm was used to measure the displacement in the middle of the span. The speed of the tests was 10 mm/min. Eight series of CIPP specimens made of synthetic felt were cut from the circumferential direction of pipes with the same nominal diameters and wall thicknesses as in the tensile tests. The specimens were taken from the same locations as the specimens for the tensile tests. The same synthetic felt liner material was used for the bending and tensile specimens. The number of specimens in each series was five.

The nominal distance L between supports was set at 16 times the composite thickness $e_{c,m}$ to minimize the influence of shear strain on deflection (less than 1.2 %). L_2 is the true span of the curved specimen and R_2 is the radius of curvature of the specimen calculated at the mid-thickness of the composite. The width b of the curved specimens is generally set at 50 mm. The total chord length of the specimen L_3 is equal to 20 times the total thickness. Both supports and the loading edge have a cylindrical shape with a radius of 5 mm.

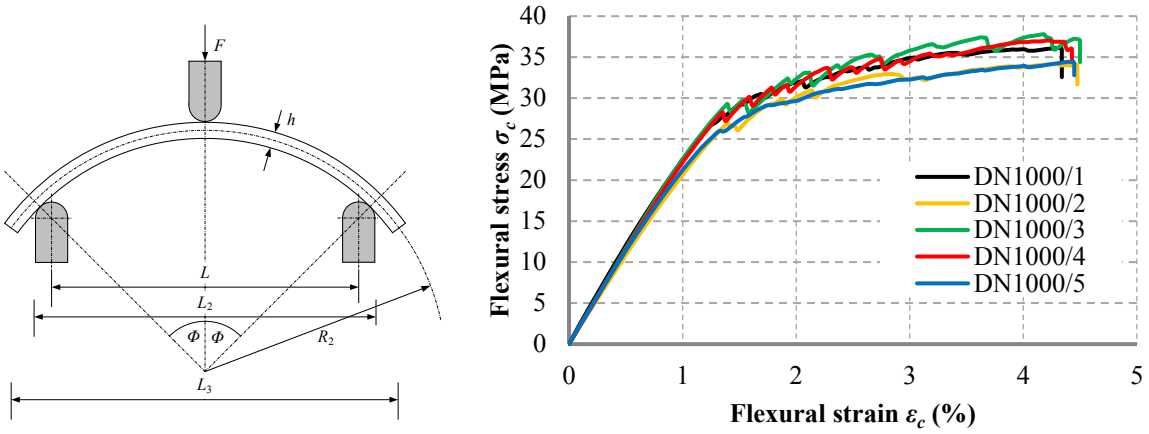

Figure 2. Three-point bending test setup for curved specimens (left) and stress/strain curve for DN1000/21 (right).

For the range of typical values of the diameter to thickness ratio for CIPP from 40 to 80 [5], the apparent flexural stress σ_c and strain ε_c are calculated as for flat specimens as follows

$$\sigma_c = \frac{3FL_2}{2be_{c,m}^2} \tag{1}$$

$$\varepsilon_c = \frac{6se_{c,m}}{L_2^2}. \tag{2}$$

F is the applied force and s is the deflection in the middle of the span. The apparent flexural modulus E_c is determined as the slope of the flexural stress/strain curve (Figure 2, right) in the strain interval between $\varepsilon_1 = 0.05\%$ and $\varepsilon_2 = 0.25\%$.

In 1998, a correction factor C_E was introduced by Niemann that corrects the apparent modulus obtained from a curved specimen E_c and gives the apparent modulus obtained from an equivalent flat specimen E_f. This factor can be found in the standard in the following form [8]

$$C_E = \frac{E_c}{E_f} = \frac{(L_2/d_m)^3 \cos^2 \phi}{1{,}5[\phi - (L_2/d_m)\cos \phi]}. \quad (3)$$

The mean pipe diameter is equal to $d_m = 2R_2$. The half angle ϕ, as defined in Figure 2 (left) and calculated from the formula $\sin \phi = L_2/d_m$, should not exceed 45° according to the standard. This corresponds to an upper limit for the true span to mean diameter ratio L_2/d_m of 0.71 and an underestimated value of the modulus before correction for curvature $E_c = 0.41E_f$.
A correction factor C_σ that corrects the apparent stress obtained from a curved specimen σ_c to the equivalent for a flat specimen, σ_f is given in the following form

$$C_\sigma = \frac{\sigma_c}{\sigma_f} = \left[1 + \frac{e_{c,m}}{3d_m}\right] / \cos \phi. \quad (4)$$

A further five series of curved GRP CIPP specimens were also tested in a three-point bending test. As the liner material is reinforced with glass fibers, the wall thicknesses are reduced compared to synthetic felt CIPP. The influence of curvature is less pronounced, as the values of the mean diameter to composite thickness ratio $d_m/e_{c,m}$ are closer to and above 100 and the values of the half angle ϕ are up to 10°.

2.3. Ring stiffness test

The initial specific ring stiffness of CIPP was determined in accordance with EN 1228 [9] using the same Zwick/Roell machine. A pipe segment of 300 mm length (L) is compressed over its entire length to achieve a change in mean diameter of 3% (Figure 3, left). The load was applied under displacement control so that a change in the mean diameter of 3% is reached in 60 seconds. The test is carried out two more times on the same specimen, which is rotated by 60° (a, b and c). The specimen must be allowed to recover between the individual tests. The ring stiffness is calculated using the following expression

$$S = \left(0.0186 + 0.025\frac{y}{d_m}\right) \cdot \frac{F}{L \cdot y}. \quad (5)$$

F is the applied force and y is the deflection of the pipe. The average of the three values represents the initial specific ring stiffness of the specimen. The force/deflection curve for a synthetic felt CIPP specimen DN300-1/6 is shown in Figure 3 (right). Two pipe segments with the same diameter and thickness were taken from the same location and tested for ring stiffness. A pipe segment with the same nominal diameter and thickness was taken from the same location, cut into five curved specimens and tested in a three-point bending test.

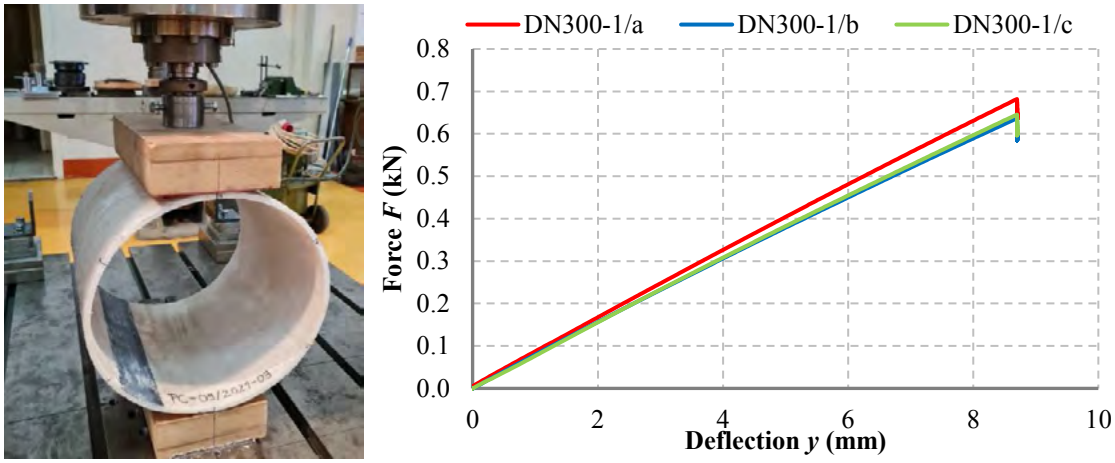

Figure 3. Test setup (left) and force/deflection curve (right) in the ring stiffness test.

The apparent modulus of elasticity can also be calculated based on the initial ring stiffness as follows

$$E_r = \frac{S \cdot d_m^3}{I} = \frac{12 \cdot S \cdot d_m^3}{e^3}. \quad (6)$$

3. Finite element analysis

Finite element (FE) simulations of the three-point bending test on curved specimens and the ring stiffness test were performed to compare different test methods for determining the modulus of elasticity of CIPP specimens. The analytical expressions (Eqs. 1, 2 and 6) used in both methods to calculate the modulus of elasticity are valid if an isotropic linear elastic material is assumed. Therefore, the synthetic felt CIPP material was modelled in FE models as an isotropic, linear elastic material with $E = 2500$ MPa and $\nu = 0.25$. The aim was to evaluate the influence of the specimen geometry.
Two different pipe segments (DN200 and DN1000) were modeled considering a typical span-to-diameter ratio of synthetic felt CIPP specimens in practice. The dimensions of the curved segments and the distances between the supports are given in Table 1. The FE simulations of the ring stiffness test were carried out for pipes with the same diameters and wall thicknesses from Table 1 and a length of 300 mm.

Table 1. Geometry of the curved segments in a three-point bending simulation.

Pipe segment	b (mm)	h (mm)	R_2 (mm)	L (mm)	L_2 (mm)	L_2/d_m	$C_E = \frac{E_c}{E_f}$
DN200	15	5.9	97.0	90.3	98.4	0.51	0.68
DN1000	50	21	490	329.2	340	0.35	0.84

Numerical models were created using Abaqus/Standard. The CIPP segments were meshed with 8-node linear bricks labeled C3D8R. All other instances apart from CIPP were modelled as analytical rigid surfaces in all simulations. The contact between the supports and the curved instance was modelled as frictionless. Due to the symmetry, the ring stiffness simulations were performed using one eighth of the pipe. In the simulations of the three-point bending test, the supports were fixed and a displacement was defined at the loading nose. In the simulations of the ring stiffness test, a displacement was defined on the upper plate. The numerical models of the three-point bending test and the ring stiffness test are shown in Figures 4 and 5.

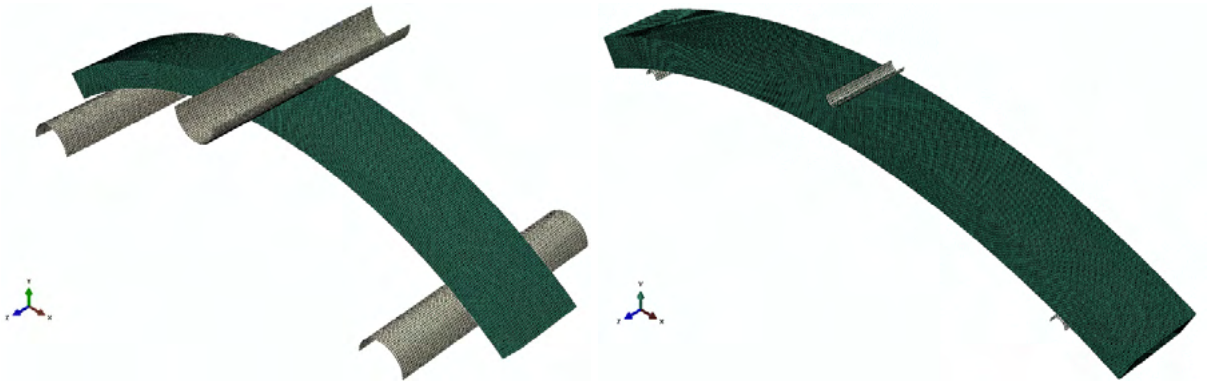

Figure 4. Numerical models of the three-point bending test for DN200 (left) and DN1000 (right).

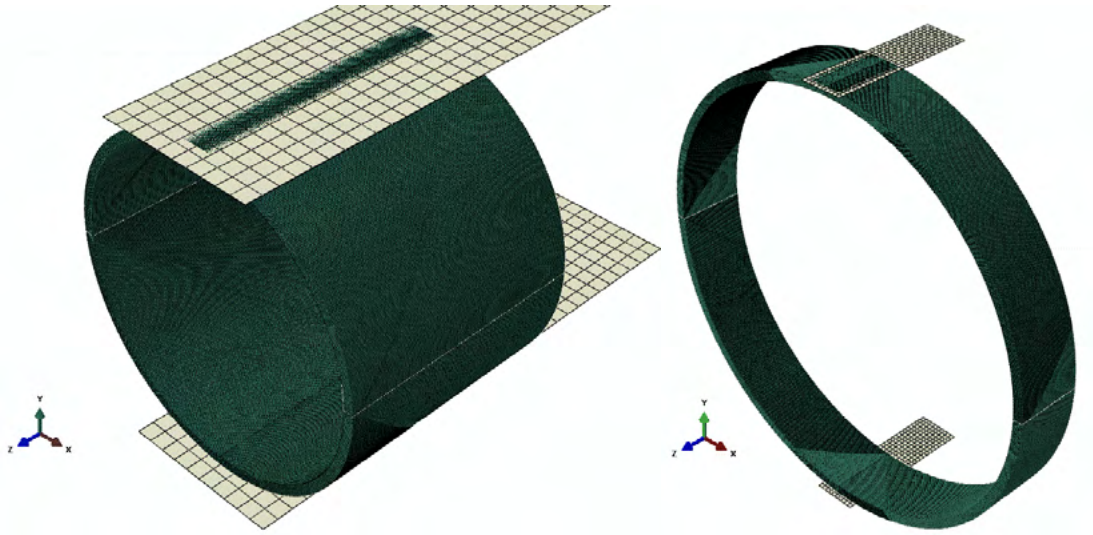

Figure 5. Numerical models of the ring stiffness test for DN200 (left) and DN1000 (right).

The theoretical relationship between the flexural moduli obtained from curved and flat specimens with regard to the ratio L_2/d_m is shown graphically in Figure 6. The correction factors for DN200 and DN1000 calculated according to Eq. 3 are given in Table 1. The results of the finite element analysis (FEA), i.e. the values of the displacement and the reaction force of the moving analytical rigid surface in the three-point bending test simulations, were used to calculate the flexural stress and strain according to Eqs. 1 and 2. The numerical flexural modulus was determined as the slope of the flexural stress/strain curve. For both values of the true span-to-mean diameter ratio L_2/d_m, the underestimation of the value $E = 2500$ MPa corresponds to the values in Table 1. The theoretical correction factor accurately takes into account the geometry of the curved specimen (Figure 6).

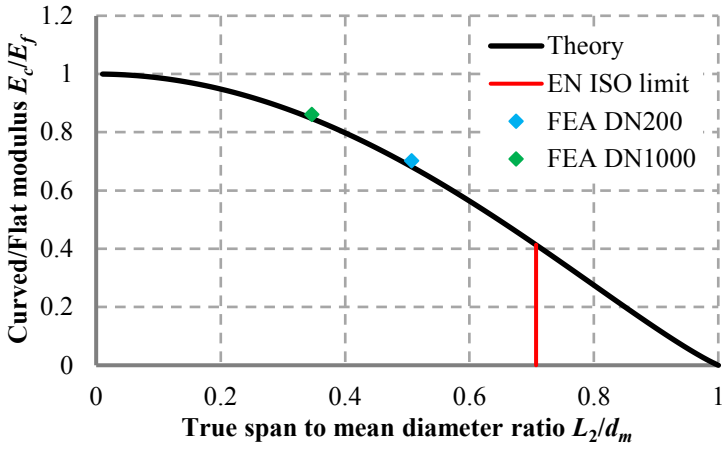

Figure 6. Comparison of apparent flexural moduli obtained from three-point bending tests on curved and flat specimens.

The values of displacement and reaction force from the moving analytical rigid surface in the ring stiffness test simulations were used to calculate the ring stiffness according to Eq. 5. The values of the modulus of elasticity calculated on the basis of the ring stiffness according to Eq. 6 deviate from the value $E = 2500$ MPa by approx. 2%. The correction factor E_c/E_f can also serve as a theoretical relationship between the flexural modulus obtained from a curved specimen and the modulus obtained from the ring stiffness test.

4. Experimental results and discussion

The apparent values of the flexural modulus determined from the three-point bending test on curved specimens are listed in Table 2. These values were corrected for curvature using a correction factor from Eq. 3. The corrected values of the flexural modulus E_f, obtained from an equivalent flat specimen are compared with the apparent longitudinal modulus E_L, obtained by tensile tests. Ideally, they should be the same for a homogeneous, isotropic material. Considering the variability of the CIPP material due to defects and anisotropic properties as well as different strain rates during the tests, there is a good agreement between the flexural and longitudinal modulus. The curved and longitudinal specimens taken from the DN500 pipe segment obviously do not represent the same material, even though they were taken from the same location.

Table 2. Results of the three-point bending and tensile tests (synthetic felt CIPP).

Pipe segment	h_n (mm)	L_2/d_m	$C_E = \frac{E_c}{E_f}$	E_c (MPa)	E_f (MPa)	E_L (MPa)	$\frac{E_f}{E_L} - 1$
DN500	10.5	0.34	0.853	3560	4180	2450	71%
DN1000	21	0.35	0.844	2320	2730	3130	-13%
DN600	12	0.37	0.826	3590	4360	3530	24%
DN800	18	0.38	0.817	2290	2810	2670	5%
DN400	9	0.39	0.808	3300	4100	4120	0%
DN700	15	0.43	0.768	2530	3280	2600	26%
DN300	6	0.46	0.736	2350	3200	3330	-4%
DN200	4.5	0.51	0.678	1680	2460	2650	-7%

The apparent values of the flexural modulus obtained from the three-point bending tests on curved and equivalent flat GRP CIPP specimens are given in Table 3. The influence of curvature is practically eliminated as the values of the correction factor are very close to 1.

Table 3. Results of the three-point bending tests (GRP CIPP).

Pipe segment	h_n (mm)	$d_m/e_{c,m}$	L_2/d_m	$C_E = \frac{E_c}{E_f}$	E_c (MPa)	E_f (MPa)
DN400	3.0	94	0.18	0.96	9600	10100
DN500-1	4.2	95	0.17	0.96	12300	12800
DN500-2	4.2	99	0.17	0.96	12900	13300
DN1000	6.3	140	0.11	0.98	15200	15500
DN1200	7.0	151	0.11	0.98	15100	15300

The apparent value of the flexural modulus E_f, obtained from an equivalent flat specimen is in good agreement with the apparent ring modulus E_r, obtained by ring stiffness tests (Table 4).

Table 4. Results of the three-point bending and ring stiffness tests (synthetic felt CIPP).

Pipe segment	h_{nom} (mm)	L_2/d_m	$C_E = \frac{E_c}{E_f}$	E_c (MPa)	E_f (MPa)	E_r (MPa)	$\frac{E_r}{E_f} - 1$
DN300-1	6	0.38	0.817	2920	3580	3640	+2%
DN300-2						3450	-4%

5. Conclusions

In this study, the mechanical properties of installed cured-in-place pipe (CIPP) liners are evaluated as determined by various tests. The experimental methods used include tensile tests on longitudinal specimens, three-point bending tests on hoop curved specimens and ring stiffness tests on whole pipe segments. The specimens tested in this study were taken on site and represent realistic mechanical properties of installed CIPP. The experimental results are in good agreement with the theoretical relationships. The question arises as to whether the flexural modulus of GRP CIPP should be corrected for curvature in the test reports. Which method provides the most reliable value of the modulus of elasticity in the context of quality control varies from country to country. The current quality control methods in Croatia are based on three-point bending tests on curved specimens. The ring stiffness test is performed on whole pipe segments and is a mandatory quality control test for thermoplastic pipes in Croatia. Since it is a simple test method and the cut pipe segment is approximately the same as for curved specimens, the ring modulus can be considered a reliable parameter for hoop performance.

Keywords: Delamination, Buckling, Cohesive Zone Model, Finite Element Method

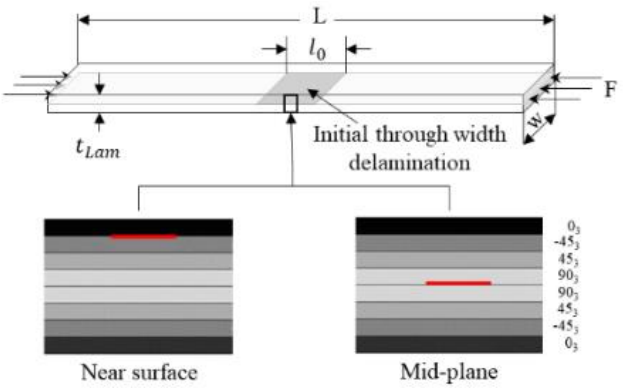
Abstract
The integrity of wind and aerospace structures encounter significant challenges due to various damage mechanisms, including delaminations. Delaminations pose critical threat to safety and reliability of the structure due to challenges in detecting them and the severe detriment they cause to mechanical performance, especially under compressive loads. As delamination advances under service loads like impact or fatigue, the vulnerability of the structure to buckling failure increases, due to possibility of its critical buckling load falling below the encountered service load. This work elucidates the phenomenon on a classic case of column buckling with the aid of a quasi-static 'Effect of Defect' study. A serie of finite element analyses have been carried out which involved maintaining a constant applied load while progressively increasing the delamination sizes in the models. The investigation systematically evaluates the influence of through thickness position of the delamination on the laminate behaviour. It was observed that near surface delamination induces local buckling initially, followed by mixed local/global buckling failure. On the other hand midplane delamination tends to global buckling. Also owing to initial thin sublaminate buckling, the near surface configurations exhibit axial stiffness reductions and are prone to unstable growth, even for smaller delamination sizes. The study also outlines how the observed results provide a foundation for future investigations into analyzing delaminated laminates under fatigue loading conditions.

1. Introduction

Fiber reinforced composites, owing to their exceptional specific stiffness and strength, have found a wide range of applications, particularly in aerospace and wind energy sectors. Their excellent in-plane properties are however not matched by their through-thickness properties, making them prone to delaminations, which continues to be a major concern for designers [1]. Delaminations may occur due to impact loads or develop under static/fatigue loads, due to factors such as matrix cracks, free edge effects or the propagation of interfacial defects introduced during manufacturing [2, 3]. These delaminations can significantly decrease the stiffness and load-carrying capacity of composite structures, especially under compression loads, by potentially instigating sublaminate buckling and subsequent delamination propagation [2, 4]. A number of numerical works have investigated the influence of through-width delaminations on buckling and post-buckling behavior of composite laminates and they are well documented in literature [2, 4, 5, 6, 7]. Apart from nonlinear finite element (FE) analysis [2, 4, 6, 7], other approach like layerwise B-spline finite strip method (FSM) [5] has also gained attention over the years. For the simulation of delamination propagation techniques such as virtual crack closure technique (VCCT) [5, 6] and cohesive zone model (CZM) [2, 4, 7] have been utilized.

Wang et al. [5] employed B-spline FSM for deformation analysis and VCCT to compute the energy release rate along the delamination front. By comparing local laminate surface strains with experiments

conducted by Kutlu et al. [8], they demonstrated that their method yields a good prediction of buckling loads corresponding to thin and thick sublaminate. Similarly Liu et al. [6] used VCCT approach to compute energy relase rate for crack propagation in a geometric nonlinear FE analysis and made a comparison of their prediction with the results in [5]. Although VCCT has shown good agreements for these simple 3D cases and 2D plane strain (geometry and loading invariant along the width) problems, they still have difficult propagating cracks when the crack front is not aligned with the mesh and require additional techniques such automated and robust remeshing procedures [9] or gradual release of forces [10]. Finally, such linear elastic fracture mechanics (LEFM) techniques cannot predict crack nucleation and needs an initial crack in the model.



Alternatively, in few studies [2, 4, 7], researchers have used CZM within a geometrically nonlinear FE framework to simulate delamination propagation, employing a fracture mode-dependent traction-separation law for CZM. In one such studies, Mekonnen et al. [2] demonstrated that the through-thickness location of delamination can influence the buckling mode. It was also reported that the sequence of events involving thick sublaminate buckling and delamination propagation can vary based on delamination length and through-thickness location (for upto intermediate locations). In another study Nikrad et al. [7] has shown that off-centre delamination can produce asymmetric instability configuration and may also trigger asymmetric delamination growth. Though accurate energy dissipation in CZM requires multiple elements in fracture process zone [11], CZM does not require adaptive remeshing procedures for capturing different fracture modes and can predict crack initiation as well as propagation [4].

Although previous studies provide a thorough understanding of numerical modeling for the discussed problem, their focus has primarily been on determining the critical buckling load associated with the given delamination configurations. However, during the operational lifespan of a composite structure it is generally the known design limit load (DLL) that sets the requirement for critical buckling load [12]. Under the action of service loads which usually do not exceed the DLL the delaminations can grow in length and reach a critical length when their buckling load falls below the DLL. In this context an Effect of Defect study has been carried out, involving a series of analyses with a constant applied load and increasing delamination lengths in the models. The significance of this study lies in its departure from the conventional way in which the critical buckling load is predicted for a given delamination length. Instead, the focus is on predicting the critical delamination length for a given load, thereby paving the way towards the concept of slow-growth damage tolerance, which has been largely unexplored until now [12]. A nonlinear FE framwork, coupled with CZM has been employed in this work to analyse the buckling evolution and delamination propagation. In Section 2 the methodology has been discussed which comprises the general aspects of the study and the modelling framework. The subsequent section (section 3) presents and discusses the results. The paper ends with a section on conclusions along with the outlook in section 4.

2. Methodology

2.1. General Aspects of Parameteric Study

This study examined the evolution of buckling in composite laminates as the length of delamination was increased in the models under a constant applied load. The Figure 1 depicts the details such as layup, geometry, applied load and locations of delaminations examined in this study. The selection of delamination locations represents two extreme cases: the near-surface delamination results in two sublaminates with most asymmetric bending stiffness, while the midplane delamination results in sublaminates with symmetric bending stiffness.

2.2. Modelling Framework

The FE modelling was conducted employing a commercially available software package, ABAQUS 2023. Figure 2 illustrates the schematic representation of the steps followed in the analysis. The first step involved setting up of the FE model. The deformed configuration of a FE model with an initial delamination has been depicted in Figure 3.

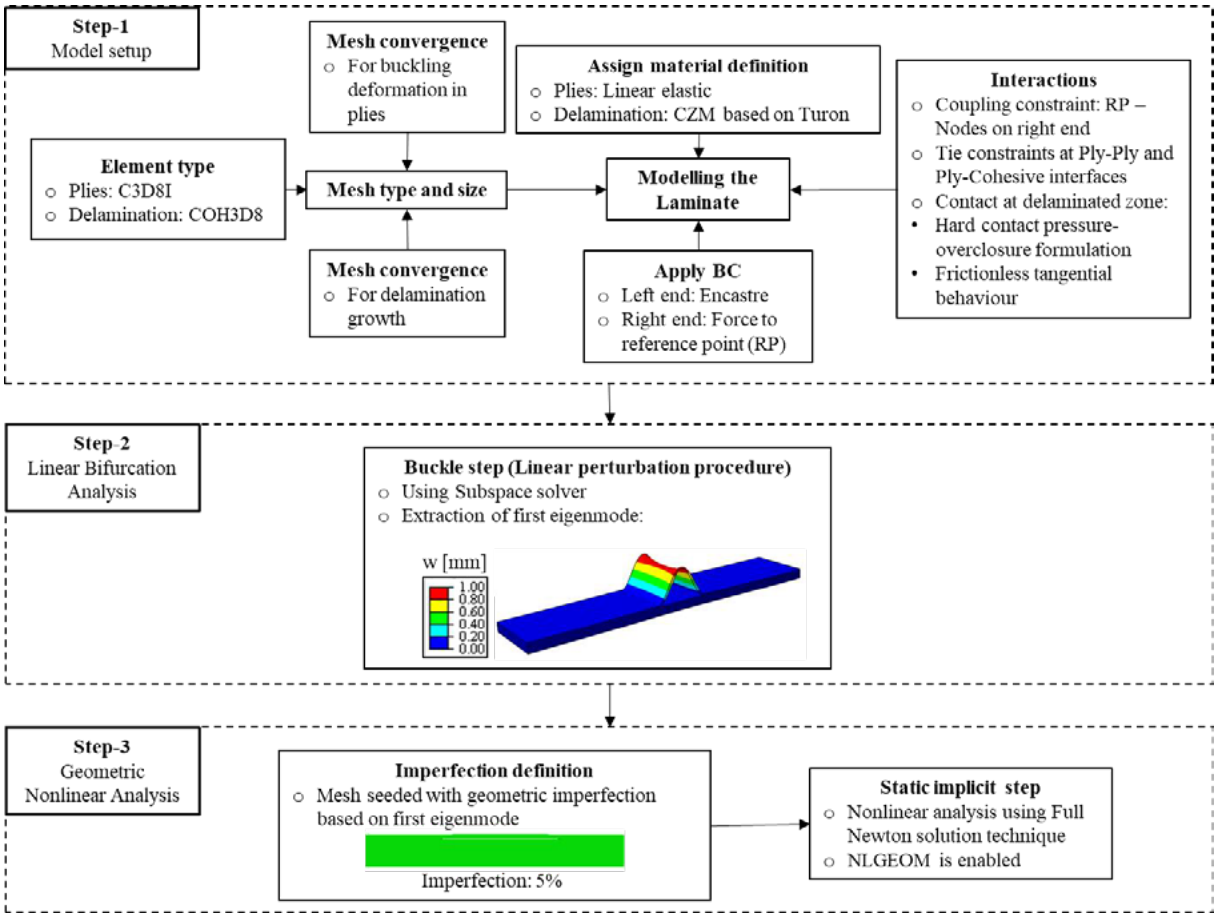

Figure 2. Flowchart of the FE framework

The laminate was modeled using the eight-noded incompatible mode solid element (C3D8I), chosen for its capacity to alleviate shear locking during bending [13]. To simulate delamination growth, zero-thickness eight-noded cohesive elements (COH3D8) were placed in the plane along the initial

delamination. The plies were modeled as linearly elastic and transversely isotropic. To accurately model the fracture mode dependent delamination growth, a static CZM based on Turon et al. [14] was used. This damage model was chosen for its accuracy in predicting the mixed mode delamination growth in composite laminates [14]. The computational algorithm of the damage model was implemented as a user-defined material subroutine (UMAT) in Abaqus/Implicit, tailored for the COH3D8 elements. The mesh sizes for solid and cohesive elements were selected based on mesh convergence studies focusing on buckling deformation and delamination growth, respectively. The first convergence study showed that modelling each three ply sublaminate (e.g. 0_3) using a single element through the thickness and in-plane mesh size of 0.5 mm was sufficient to produce converged buckling results. To conduct accurate delamination analysis the mesh size must be sufficiently fine to ensure that enough interface elements exist within the fully developed prozess zone length near the crack tip [15]. The mesh size was determined through a convergence study conducted on the mode I double cantilever beam (DCB) test, as this mode typically governs the minimum mesh density requirement [11]. Finally the converged mesh size of 0.1 mm along the propagation direction and 0.5 mm along the width direction was utilized in the fine mesh region in the model. The model's interactions and boundary conditions (BC) have also been detailed in Figure 2 and depicted in Figure 3.

In the nonlinear analysis, laminate buckling is only initiated through geometric or loading imperfections [2]. A geometric imperfection was defined based on the linear bifurcation analysis as illustrated in the second step of Figure 2. Due to its plausible shape and lowest eigenvalue, only the first mode was selected for defining the geometric imperfection. In line with the study by Mohammadi et al. [4], 5% of the calculated deformation of the first eigenmode was applied to the mesh for nonlinear analysis. The final third step involved performing the geometric nonlinear analysis as detailed in Figure 2.

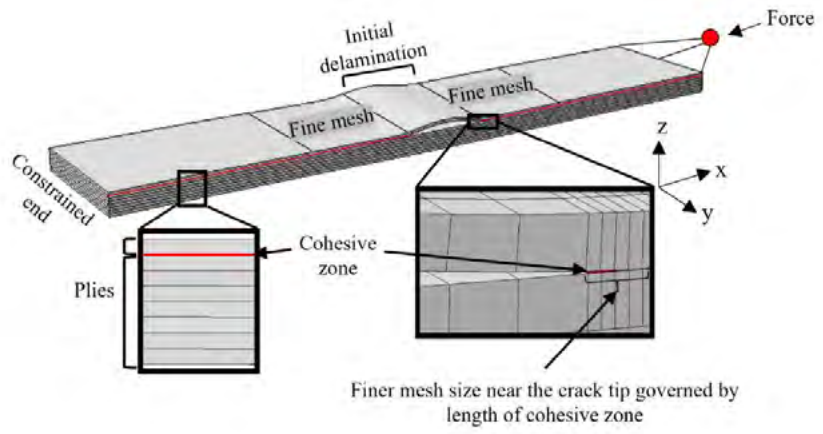

Figure 3. FE model depicting the mesh and the boundary conditions

3. Results and Discussion

Following the methodology outlined in the previous section, the FE analyses were carried out, and a comprehensive discussion of the obtained results is presented in this section.

3.1. Near Surface Delamination

For near surface delamination, in Figure 4 a) the evolution of out-of-plane displacement, *w* is depicted in relation to delamination lengths, while Figure 4 b) displays delamination growth using the damage variable, *d* across various delamination lengths. Figure 5 illustrates axial stiffness change with the normalized delamination length. In these figures, the delamination length has been normalized with respect to the laminate length.

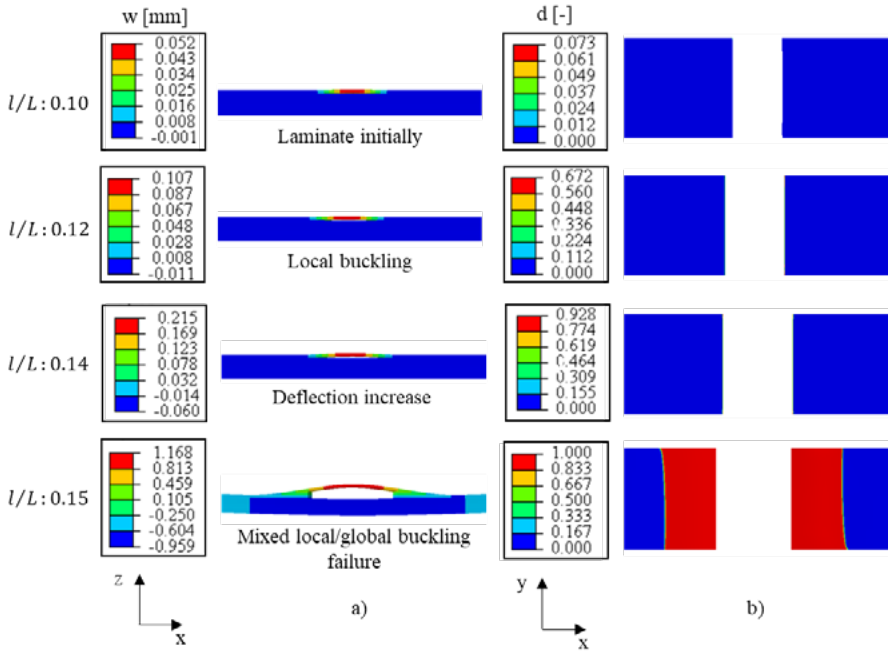

Figure 4 a) Evolution of out-of-plane displacement, *w* with the delamination length and b) Damage variable, *d* showing delamination growth for different delamination length. The delamination length is normalized with respect to length of the laminate

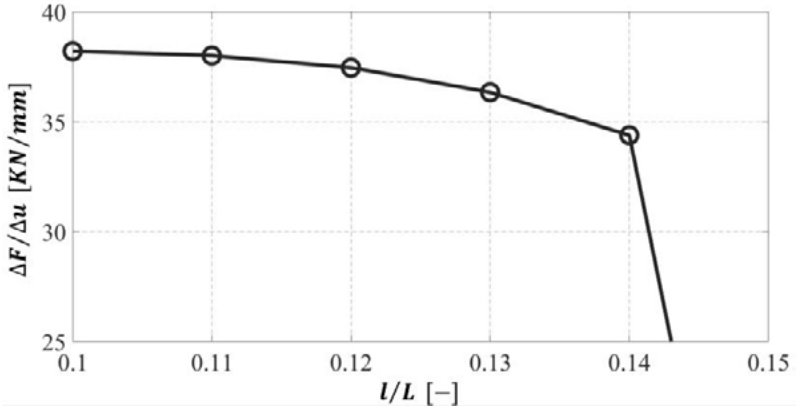

Figure 5 Axial stiffness drop with the normalized delamination length

Near-surface delamination results in two sublaminates: an upper thin sublaminate with lower bending stiffness and a lower thick sublaminate with higher bending stiffness. Due to its lower bending stiffness and presence of geometric imperfection (as illustrated in Figure 2), bending is induced in the upper sublaminate, even at the lowest normalized delamination length of 0.10. This is confirmed by out-of-plane displacement value of the upper sublaminate of 0.052 mm (Figure 4 a). Subsequently as the delamination length is increased, the upper sublaminate undergoes local buckling. Figure 4 a) illustrates that local buckling occurs at a normalized delamination length of 0.12, with the upper sublaminate displaying an out-of-plane displacement of 0.107 mm, exceeding 25% of its thickness (that is 0.393 mm). However, it should be noted that determining the precise point of local buckling is challenging due to the presence of geometric imperfection. Future research will explore this further, aiming to determine whether a discrete bifurcation point corresponding to local buckling can be identified for lower magnitudes of imperfection.

With the further increase in delamination length it is noticed that out-of-plane displacement of upper sublaminate continues to increase beyond the point of local buckling. At a normalized length of 0.14, out-of-plane displacement of upper sublaminate increases to a value of 0.215 mm and that of lower sublaminate also increases marginally to 0.056 mm. The impact of the increased out-of-plane displacement is clearly evident in the reduction of axial stiffness by around 10.5% as the normalized length increases from 0.10 to 0.14 (Figure 5). At a normalized length of 0.15, the delamination extends on both ends by 11 mm (Figure 4 b)) , causing the out-of-plane displacement in lower sublaminate also to increase significantly. At this point, the laminate is considered to have undergone mixed local/global buckling failure. In the Figure 5 this is indicated by the sudden drop in the value of axial stiffness. It should be noted that for normalized delamination lengths below 0.15, damage is only seen at the corners of the delamination tip (not clearly visible), as indicated by the values in the legend (Figure 4 b)).

From the results, it can be concluded that in this scenario of near-surface delamination, the laminate experiences local buckling initially as the delamination length increases. Following local buckling the out-of-plane displacement continues to increase with the delamination length. This trend persists until a critical length is reached and beyond this length, the laminate experiences significant delamination growth, leading to what is termed as mixed local/global buckling failure of the laminate.

3.1. Midplane Delamination

For midplane delamination, in Figure 6, evolution of out-of-plane displacement, *w* has been shown in relation to normalized delamination length. Figure 7 illustrates axial stiffness change with the normalized delamination length. The midplane delamination divides the laminate into two sublaminates with identical bending stiffnesses. Consequently, the laminate does not demonstrate local buckling, as seen in the previous configuration. Instead, both sublaminates deform in the same direction, as illustrated in Figure 6. This suggests that for this configuration the laminate is prone to undergo what is known as the global buckling failure. The Figure 6 also shows that the mode shape changes as the normalized delamination length increases from 0.10 to 0.20. At a normalized length of 0.20, the laminate shows an S-shaped deflection, and beyond that the magnitude of out-of-plane displacment continues to increase following the same deformation pattern as the delamination length increases.

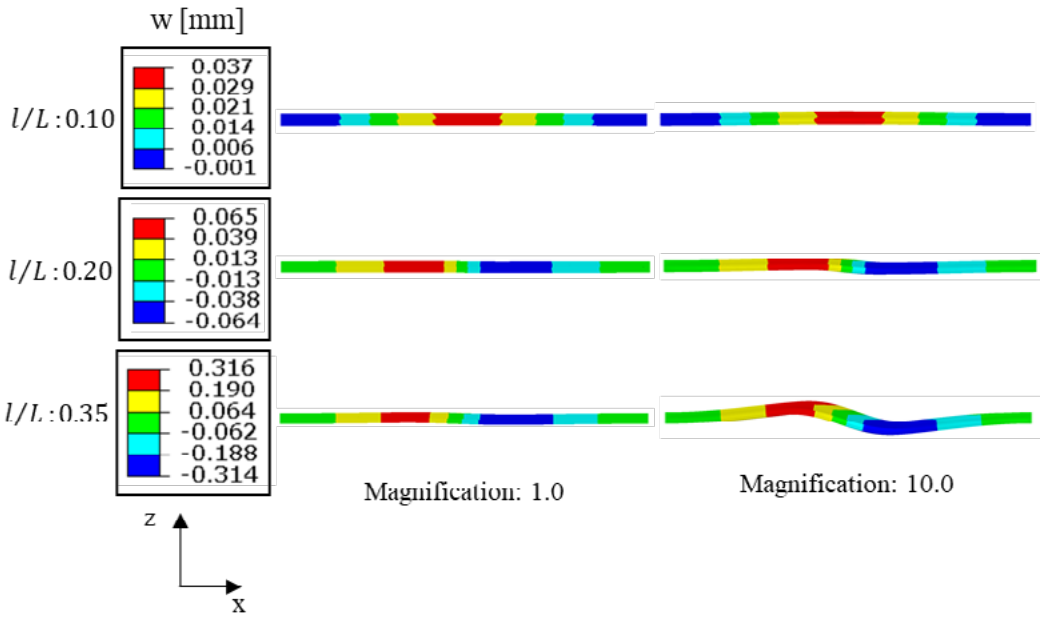

Figure 6. Evolution of out-of-plane displacement (w) with the normalized delamination length. The plots compare two levels of magnification for improved visualization.

The Figure 7 indicates that increasing the normalized delamination length from 0.10 to 0.15 does not show any visible change in its axial stiffness, unlike the near surface case where the laminate failed when the delamination was increased to same length. This shows that the mode of buckling has a significant influence on the behaviour of the laminate. Even beyond the normalized delamination length of 0.15, the drop in axial stiffness occurs gradually with the delamination length and at a normalized length of 0.35, only the delamination tip displays some damage, without significant extension of the delamination to cause a sudden drop in axial stiffness.

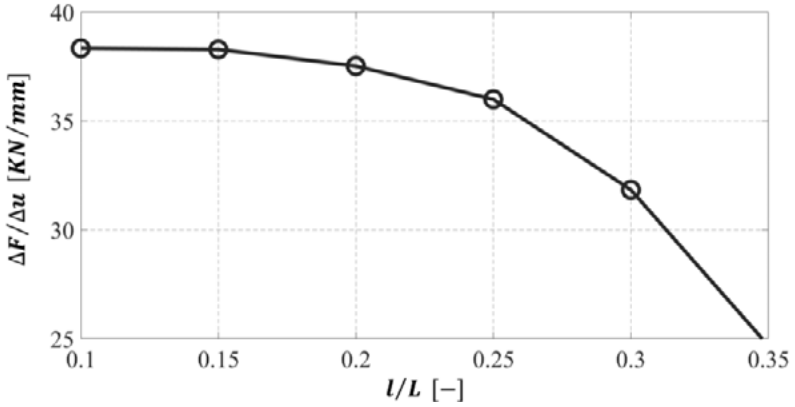

Figure 7. Axial stiffness drop with the normalized delamination length

4. Conclusions

The conclusions from the current study are summarized below:

- For the near-surface delamination, the laminate initially experiences local buckling as the delamination length increases. The out-of-plane displacement continues to grow with the delamination length until reaching a critical size. Subsequently, significant delamination growth occurs, leading to a mixed local/global buckling failure of the laminate.Due to local buckling the delamination growth and, consequently, laminate failure occurs at shorter delamination lengths compared to midplane delamination configuration.
- In the case of midplane delamination, where the two sublaminates have identical bending stiffnesses, the laminate does not demonstrate local buckling but rather tends toward global buckling. The global mode was found to be less critical, as unlike near-surface delamination, there's no substantial reduction in laminate axial stiffness for shorter delamination lengths. With further increases in length, there's a gradual decline in laminate stiffness, yet for the considered load no significant delamination growth was observed even at larger delamination lengths.

These findings are useful for the subsequent investigation on the impact of delamination defects under fatigue loading. In this future study, the near surface delamination scenario is considered relevant due to its tendency for local buckling, which acts as the main mechanism for driving delamination growth. Other areas of investigation include examining the impact of intermediate delamination, conducting a study on imperfection sensitivity and studying the influence of a stiffer lower sublaminate in the context of near-surface delamination.

Keywords: Residual strength, Fatigue, Temperature dependency, Composite vessel, Filament winding

Abstract
A temperature dependency of a stiffness degradation during fatigue of a carbon fiber reinforced plastics manufactured by filament winding and the residual mechanical property after fatigue was experimentally studied. A coupon specimen was made with a towprepreg and prepared using a plate-type mandrel for filament winding. The stacking sequence of the laminate was $[45/-45]_{2s}$ in order to focus on the matrix resin cracks and interface fracture between fiber and matrix resin as major dominants of intralaminar fracture. Fatigue test was performed under the temperature of -40 ℃, +85 ℃ and room temperature (RT) using a three-point bending test. The residual property was evaluated by a tensile test at RT. The stiffness degradation during fatigue at -40℃ was more likely to occur than at RT and showed more brittle characteristics. On the other hand, the fatigue stiffness degradation at +85 ℃ was less likely to decrease than at RT and showed more toughness. The residual strength at the same residual stiffness after fatigue at -40 ℃ and +85 ℃ decreased in comparison with that at RT. This suggested that the temperature dependency of the mechanical properties of the matrix resin influenced the damage propagation during fatigue of the composite laminate.

1. Introduction

A type-IV high-pressure vessel is becoming a mainstream for a hydrogen storage system of automotive application in order to achieve both of a pressure resistance and weight reduction. The reinforcement shell of the vessel is made of carbon fiber reinforced plastics (CFRP) manufactured by filament winding. The performance requirement of the composite high-pressure vessel is characterized by low-cycled fatigue due to high ratio of residual burst strength after durability to initial one. In order to achieve further weight reduction of CFRP, it is required that building an analytical method that can predict precisely not only initial burst strength but also residual one after durability. In addition, in order to verify a certification test and to ensure an end-of-life performance of high-pressure vessel by numerical analysis, it will become necessary to take into account for the effect of environment temperature and loading sequence on fatigue damage inside CFRP.

We have studied a residual strength after fatigue for CFRP in in-plane share direction, which is strongly related with matrix resin cracks and interface fracture between fiber and matrix resin as major dominants of intralaminar fracture shown in the reference [1] and [2]. Characterization of stiffness degradation of filament-wounded CFRP during fatigue using three-point bending test and residual strength after fatigue damage were investigated experimentally. And we have also reported a possibility of numerical prediction of residual mechanical property after fatigue using the finite element analysis with material damage models, which were based on Ladevèze model for static analysis and dd/dN model for fatigue analysis.

In this study, fundamental efforts to realize the extension of the numerical analysis method of fatigue stiffness reduction and residual strength to temperature dependency was described. A coupon specimen with layup of $[45/-45]_{2s}$ were made with a towprepreg and filament winding using a flat

plate mandrel. Fatigue stiffness degradation under the temperature condition of -45 ℃ and +85 ℃ using a three-point bending test was understood experimentally and compared with that at room temperature. In addition, the residual strength in the case of the same stiffness degradation rate after fatigue at each temperature was evaluated using a tensile test at room temperature, and the effect of the environment temperature during fatigue on the residual strength was investigated.

2. Materials and experimental method

2.1. Materials and specimen preparation by filament winding

Figure 1 shows the method for producing a laminated flat plate of CFRP by filament winding to obtain a coupon specimen. The towprepreg, which was carbon fiber (T720SC-36000-50C, Toray Co., Ltd.) pre-impregnated with uncured epoxy resin, was used. The glass transition temperature of the cured epoxy resin was about 120 ℃. The towprepreg was supplied to a filament winding machine and wound onto a steel flat mandrel (380 mm in length and width, 10 mm thickness) alternately in the 0 degree and 90-degree direction to obtain the layup of $[0/90]_{2s}$. The filament-wounded mandrel was lapped in a bagging film and cured at 110 ℃ for 8 hours. Then, the laminated flat plate was removed from the mandrel and the coupon specimen with the layup of $[45/-45]_{2s}$ was cut out from the laminated plate by adjusting the cutting angle. The dimensions of specimen were 250 mm in length and 25 mm in width, The thickness was approximately 2.4 mm after molded.

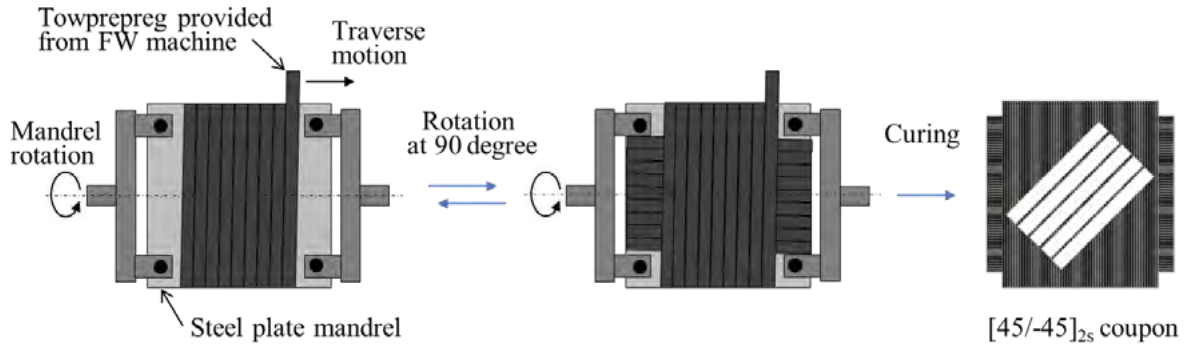

Figure 1. Preparation of coupon specimens manufactured by filament winding.

2.2. Characterization of stiffness degradation due to fatigue damage

Fatigue test was performed at room temperature, -40 ℃ and +85 ℃ using a three-point bending method. The stress conditions for fatigue test were set based on the strength of static three-point bending test shown in Table 1. Cyclic loading was applied using a sine wave with a stress ratio of 0.1 and a frequency of 2 Hz until failure occurred. The radius of the indenter and support point for the three-point bending test was 5 mm, and the indenter position was at the longitudinal center of the coupon specimen. The distance between the supports was 96 mm, and the distance between the indenter and the support was 48 mm. The maximum and minimum values of the applied load and the indenter stroke were measured for each cycle of the fatigue test, and the slope of the load amount with respect to the stroke amount of each cycle was defined as the bending stiffness of that cycle. The residual stiffness obtained by normalizing the bending stiffness of each cycle by the initial bending stiffness was plotted against the number of cycles and this was taken as the stiffness reduction characteristic.

2.3. Evaluation of residual strength after fatigue damage

The residual strength after fatigue was evaluated by a tensile test after adjusting the ratio of the residual stiffness to 0.8 by a pre-fatigue bending test under the conditions shown in Table 2. The strain in the tensile direction at the center of the specimen during the tensile test was measured using an extensometer with the gauge length of 25 mm, and the test speed was 1.5 mm/min.

Table 1. Static bending strength of filament wound CFRP coupon with $[45/-45]_{2s}$ layup.

	Temperature		
	-40 ℃	RT	+85 ℃
Bending strength (MPa)	232.5	193.7	126.5

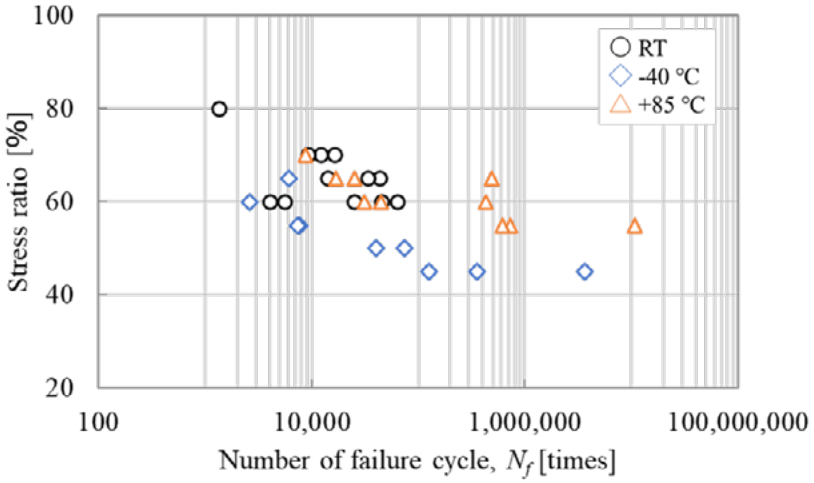
Table 2. The conditions of pre-fatigue bending test.

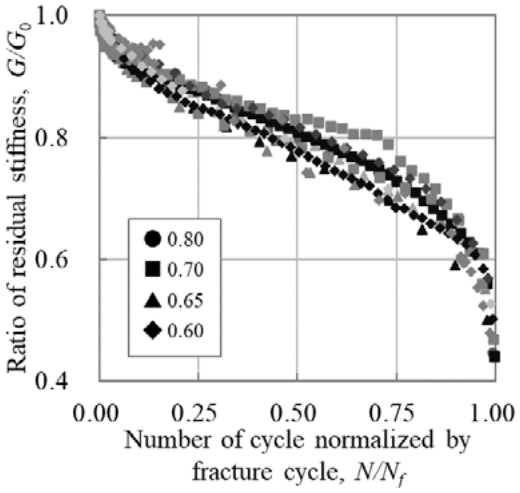
	Temperature		
	-40 ℃	RT	+85 ℃
Fatigue stress (MPa)	116.3	116.2	75.9
Stress ratio for static strength	0.50	0.60	0.60
Target ratio of residual stiffness after fatigue	0.80	0.80	0.80

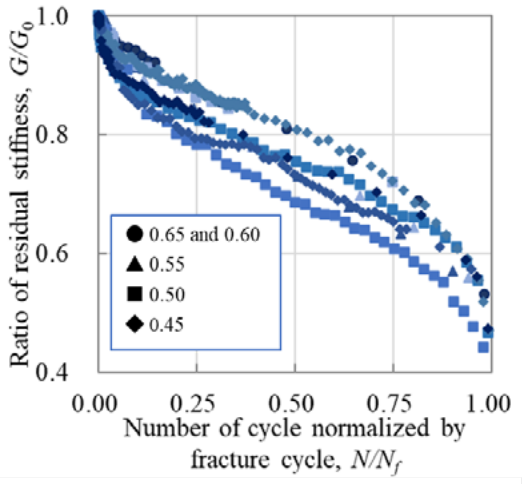
3. Results and discussion

3.1. Effect of temperature on stiffness degradation of CFRP due to fatigue damage

Figure 2 shows a stress-failure number diagram of filament wound CFRP when performing the three-point bending fatigue test at RT, -40℃ and +85℃. The vertical axis is the fatigue stress ratio relative to the static strength, and the horizontal axis is the number of the cycle which the fracture occurred. There is a large variation in the fracture cycle at each temperature, but this is thought to be caused by fiber gaps, voids and interlaminar defects that generated in the specimens due to filament winding process. At a low temperature of -40 ℃, fatigue failure tended to occur at a lower fatigue stress level than at RT. On the other hand, the number of the failure cycle at of 85℃ tended to be longer that at RT. Figure 3 shows the stiffness degradation characteristics due to fatigue damage at (a) RT, (b) -40 ℃ and (c) +85 ℃. The vertical axis means the ratio of the residual stiffness G/G_0 obtained by normalizing the bending stiffness of each cycle by the initial stiffness, and the horizontal axis means the number of fatigue cycles normalized by the fracture cycle N/N_f. At RT, there was a rapid decrease in stiffness of about 5 to 10 % at the beginning of the fatigue cycle up to N/N_f of 0.1. During N/N_f was from 0.2 to 0.9, the stiffness showed a constant and gradual decrease. After N/N_f was 0.9, at which the residual stiffness reached to 0.65, the stiffness decreased sharply again, leading to failure. Then, the behavior of the stiffness degradation characteristics until fracture was consistent regardless of the ratio of fatigue stress. At a low temperature of -40 ℃, a greater decrease in stiffness than at RT was observed at the beginning of the cycle until N/N_f reached 0.1. Although the subsequent stiffness reduction behavior matched the trend at RT, there was a large variation in stiffness reduction. On the other hand, at a high temperature of +85 ℃, the rapid stiffness degradation at the beginning of the cycle was alleviated, and the subsequent stiffness reduction until N/N_f reached to 0.9 also showed a gradual tendency compared to RT. In-plane share damage progression involves matrix resin cracking and fiber-resin interface failure, both of which are influenced by the mechanical properties of the matrix resin. The glass transition temperature of the matrix resin used in this study was about 120 ℃, and at -40 ℃ it has a higher elastic modulus and strength but more brittle behavior, whereas at +85 ℃, it has a lower elastic modulus and strength but more ductile behavior. It is thought that this temperature effect on the mechanical properties of the matrix resin contributes to the stiffness degradation characteristics due to fatigue damage observed in this experiment.







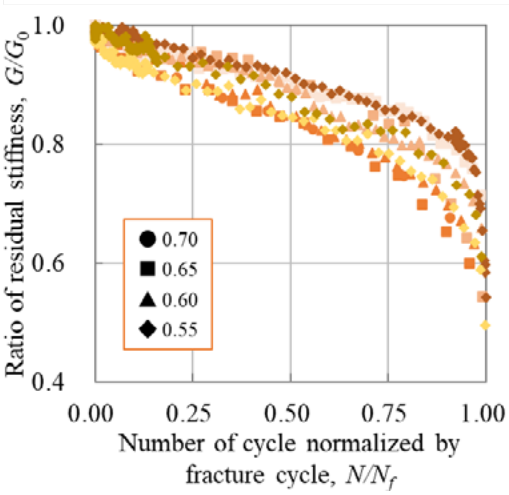


Figure 2. Fatigue life diagram of filament wound CFRP coupon with $[45/-45]_{2s}$ layup.

(a) RT

(b) -40 °C

(c) +85 °C

Figure 3. Stiffness degradation curves of filament wound CFRP coupon with $[45/-45]_{2s}$ layup.

3.2. Comparison of residual strength after fatigue damage at each temperature

Table 3 shows the residual tensile strength of CFRP coupon with $[45/-45]_{2s}$ layup after the bending fatigue test under the conditions shown in Table 2.

In all three temperature conditions, the residual strength after fatigue damage decreased compared to the initial strength. However, the ratio of the residual strength showed different values depending on each fatigue temperature, which was 87 % at RT, 73 % at -40 ℃ and 70 % at +85 ℃ respectively. Observation of the cross-section of the coupon near the indenter after fatigue damage revealed that the amount of resin cracking on the tension side directly below the indenter was small at -40 ℃ and the amount of the plastic deformation was extremely small. In contrast, at 85 ℃, the number of resin cracking near the indenter was greater than at -40 ℃, and the amount of plastic deformation after fatigue was also very large. From the above, it was confirmed that even if the residual stiffness after fatigue is the same, the state of fatigue damage and plastic deformation differs depending on the temperature of the fatigue test environment, and this affects the residual strength.

Table 3. Residual tensile strength of CFRP with $[45/-45]_{2s}$ layup after bending fatigue test.

	Initial	Temperature during fatigue		
		-40 ℃	RT	+85 ℃
Residual strength (MPa)	79.8	69.6	58.2	55.5
Remaining ratio with respect to initial strength (%)	-	87	73	70

4. Conclusions

The effect of environmental temperature on the stiffness degradation due to fatigue damage was experimentally investigated using CFRP coupon with $[45/-45]_{2s}$ layup manufactured by filament winding and three-point bending test. At a low temperature of -40 ℃, the stiffness degradation at the initial stage of fatigue was greater than that at room temperature, but the behavior of stiffness reduction during steady stage was the same as room temperature. On the other hand, at a high temperature of +85 ℃, the stiffness degradation at the initial stage and subsequent steady stage tended to be more alleviated and gradual than at room temperature.

After conducting preliminary fatigue test at each temperature until the residual stiffness reached 0.8, the residual strength was evaluated. As a result, the residual strength decreased from the initial strength at all temperatures, and the ratio of residual strength differ depending on the environmental temperature. From the cross-sectional observation of the post-fatigue coupons, it was confirmed that the state of fatigue damage and plastic deformation differs depending on the temperature of the fatigue test environment, and that this affects the residual strength.

Keywords: Ceramic matrix composites, Fatigure-creep coupling, Trapezoidal-wave fatigue

Abstract

In this study, the fatigue-creep interaction behavior of 2.5D ceramic matrix composites (CMCs) under anaerobic environment at 1100℃ was carried out. The influence of creep loading on fatigue properties of CMCs was studied by comparing fatigue life, hysteresis loop shape, hysteresis dissipation energy accumulation rate and fracture micromorphology of fatigue specimens under sine-wave and trapezoidal-wave fatigue loading. The results show that the fatigue-creep coupling damage has a great influence on the fatigue life of 2.5D CMCs. In addition to the hysteretic dissipation energy caused by friction during sine-wave fatigue loading, the damage accumulated during load holding is the main factor affecting the fatigue life of CMCs.

1. Introduction

Ceramic matrix composite (CMCs) has the characteristics of low density (approximately 1/3 of traditional superalloy), high temperature resistance and oxidation resistance. The application of CMCs is expected to bring a higher turbine inlet temperature. Therefore, CMCs is regarded as the ideal high temperature material for hot sections of aeroengines[1-3]. In the mid-1990s, GE, Safran, Rolls-Royce[4-9] and other companies have invested a lot in the development of CMCs components. GE applied CMC chambers, high-pressure turbine guide blades and high-pressure turbine outer rings to the GE9X engine,which saves $1 million in fuel costs per aircraft every 10 years and the rotor blades, mixer and center cone components prepared by Safran were tested on the CFM56 engine on the ground, and the nozzle were also tested on the A320, A380 and other aircraft.

As one of the most important hot-end components, turbine rotor blades are mainly subjected to centrifugal load and high service temperature during operation, which may result in complex failure modes of the blade due to fatigue or creep damage [10,11]. Under such complex working conditions, the failure mechanism of CMCs is significantly different from that of metals, and there is a lack of effective fatigue life prediction methods, which impedes the application of CMCs on rotor blades. Therefore, it is important to study the fatigue-creep failure mechanism of CMCs and establish the corresponding fatigue life prediction methods.

By far, scholars have conducted a lot of studies on the fatigue behavior and failure mechanism of CMCs[12-16], the results show that CMCs mainly includes several basic damage forms, such as matrix cracking, interface debonding, interface wear and fiber fracture. In addition, some scholars further studied the effects of loading frequency and load holding time on the fatigue life of CMCs[17-20]. The above studies usually focus on single factors such as fatigue or creep, and the studies on the fatigue-creep coupling failure of CMCs under complex working conditions are extremely lacking. Based on the above research background, the failure mechanism of 2.5D CMCs under fatigue-creep coupling load at high temperature and anaerobic environment is studied in this paper.

2. Material and experimental procedures

2.1. Test material and technology

The 2.5D CMCs used in this paper is composed of silicon carbide fiber, silicon carbide matrix and boron nitride interface. The general preparation steps are as follows: Firstly, the plate preform was processed by 2.5D twill weaving process. The boron nitride interface was then deposited on the fiber surface of the preform by Chemical Vapor Infiltration (CVI), and the silicon carbide substrate was deposited on the boron nitride interface. Finally, a plate-like specimen with the thickness of 3 mm was prepared by surface machining.

The size of the specimen used in this paper was based on the existing design standards, considering the internal size of the high temperature furnace and the vacuum environment chamber. The total length of the specimen is 200mm, the length of the test section is 80mm, the width of the clamping end is 12mm, and the width of the test section is 6mm. The 2.5D CMCs plate specimen was shown in Figure 2.1.

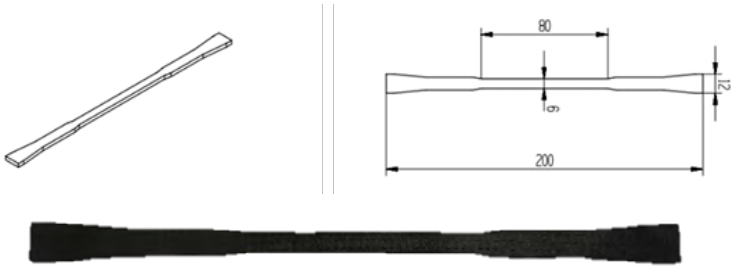

Figure 2.1 2.5D CMCs fatigue specimen

2.2. High temperature anaerobic fatigue test platform

In order to carry out high temperature anaerobic fatigue test of 2.5D CMCs, a set of high temperature anaerobic environment test system was built as shown in Figure 2.2. This test system mainly includes high temperature furnace, empty chamber, vacuum pump, temperature control chamber, water cooling, high purity argon filling device and fatigue loading system.

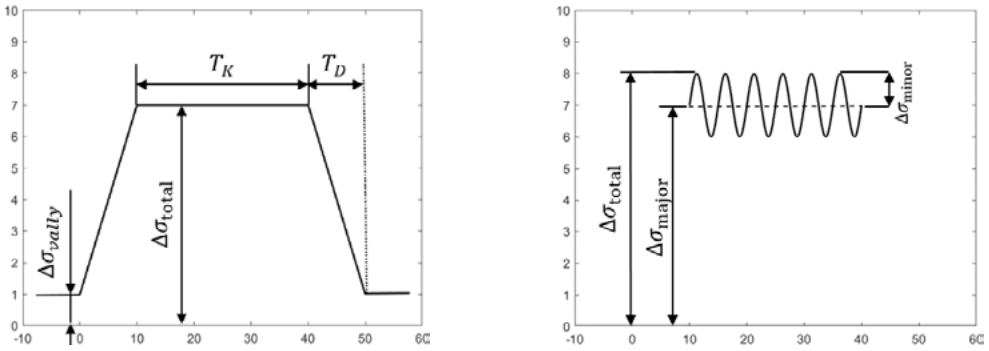

Figure 2.2 High temperature anaerobic fatigue test system

2.3. Load conditions

In order to investigate the effects of fatigue-creep interaction of CMCs, the fatigue tests carried out in this paper were divided into sine-wave and trapezoidal-wave fatigue tests. The fatigue life and failure modes resulting from the two loading waves were compared in this study to clarify the effects of load holding on fatigue life of CMCs at high temperature.

Figure 2.3(a) shows the diagram of the sine-wave fatigue load.It is mainly defined by five characteristic parameters, namely the median value of fatigue load $\Delta\sigma_{major}$, the amplitude of fatigue load $\Delta\sigma_{minor}$,the loading frequency f (cyclic load period T=1/f),the peak value of fatigue load is defined as $\Delta\sigma_{total}$=$\Delta\sigma_{major}$+$\Delta\sigma_{minor}$ and the stress ratio is defined as $R = (\Delta\sigma_{major}\text{-}\Delta\sigma_{minor})/(\Delta\sigma_{major}+\Delta\sigma_{minor})$.

Figure 2.3 (b) is a schematic diagram of the trapezoidal-wave fatigue load, which is mainly defined by four characteristic parameters, including the peak fatigue load $\Delta\sigma_{total}$, the valley fatigue load $\Delta\sigma_{vally}$, the load holding time T_K, the load loading (unloading) time T_D and the stress ratio defined as $R_T = \Delta\sigma_{vally}/\Delta\sigma_{total}$.

（a）Trapezoidal wave　　（b）Sinusoidal wave

Figure 2.3 Fatigue load spectra with different waveforms

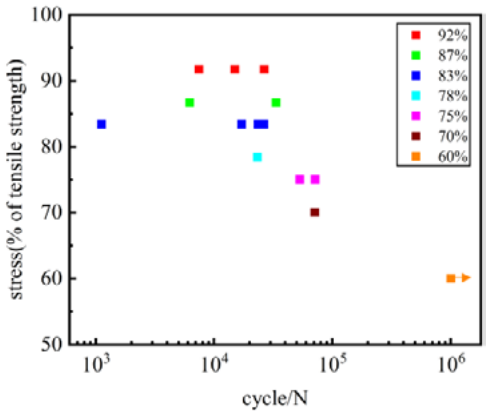
Based on the above definition, the sine-wave and trapezoidal-wave fatigue tests under anaerobic environment at 1100℃ was carried out in, in which the $\Delta\sigma_{total}$ of sine-wave fatigue load was 60%-92% of the tensile strength of CMCs, with the f and R being set as 10Hz and 0.1 respectively. Based on the results of sine-wave fatigue test, the $\Delta\sigma_{total}$ of trapezoidal wave was set as 75% of the tensile strength of CMCs,in which the effect of fatigue-creep coupling on the material can be clearly shown .The T_K was set as 30s or 60s. The T_D was set as 0.1s and the R_T was set as 0.1. The complete load parameters of the two waveform fatigue tests are shown in Table 2.1.

Table 2. 1 Loading parameters of fatigue test with different waveforms

Test waveform	sine wave	trapezoidal wave
Hold time (loading frequency)	10Hz	30s/60s
Fatigue peak load	60%-92% tensile strength	75% tensile strength
Stress ratio	0.1	0.1
Number of specimens	14	2/2

3. Results

The S-N curve of anaerobic sine-wave fatigue of 2.5D CMCs at 1100℃ was shown in Figure 3.1. It can be seen from the figure that the fatigue limit (corresponding to 10^6 cycles) of the material under anaerobic conditions at 1100℃ is between 60% and 70% of the tensile strength. It can also be seen that the fatigue life of CMCs is less affected by the change of load, as the fatigue peak load decreases from 75% to 60% of the tensile strength, the fatigue life of the specimen is only increased by one order of magnitude. The fatigue life of most specimens is in the order of 10^4 to 10^5.



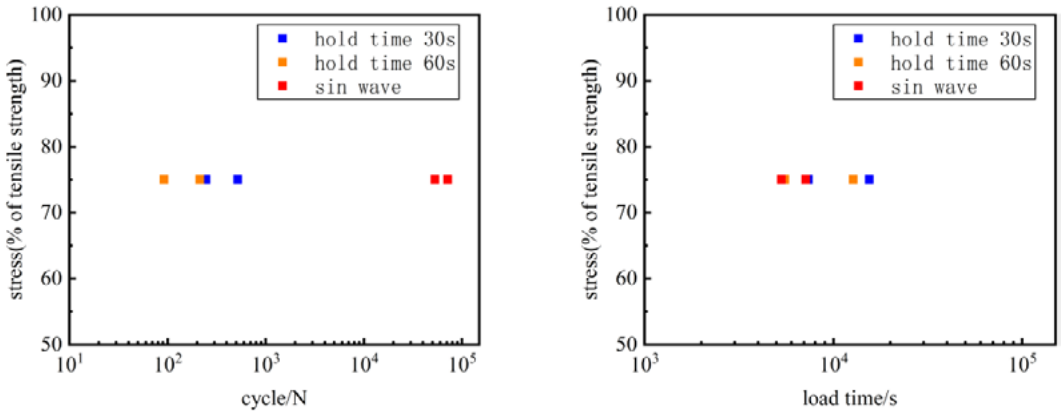


Figure 3.1 S-N curve under sine wave at 1100℃

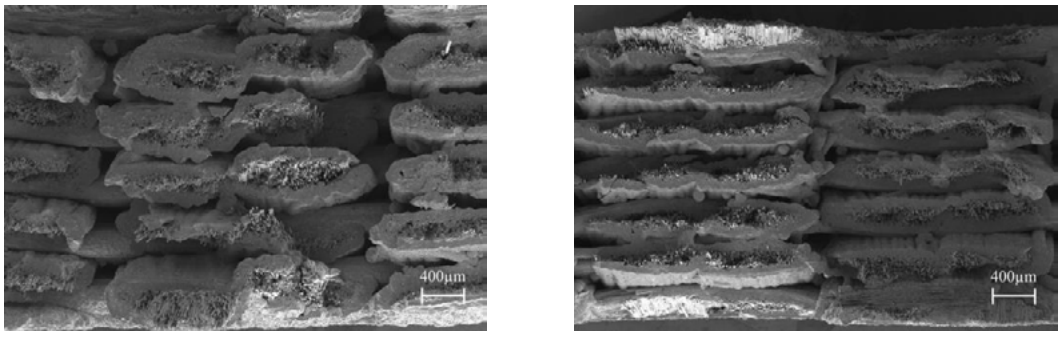
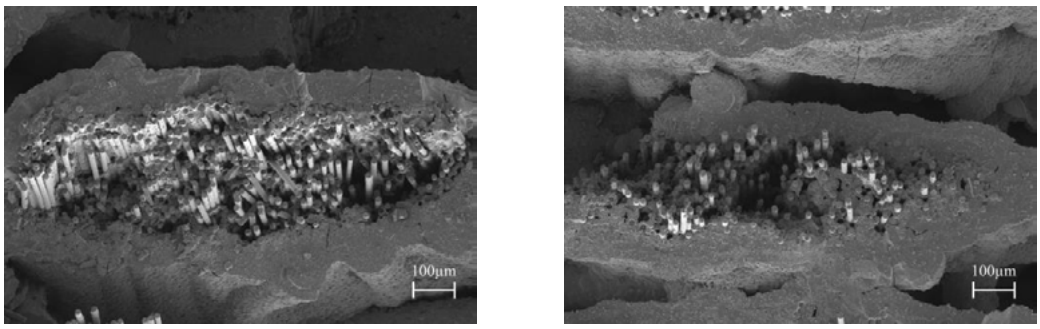
Figure 3.2(a) summarizes the fatigue life test data of CMCs under trapezoidal-wave loading and 10Hz sine-wave loading (same peak load) under anaerobic environment at 1100℃. As can be seen from the figure, the dispersion of fatigue life cycles of CMCs under trapezoidal-wave loading is less than 4 times (same load holding time). In addition, it can be seen that the fatigue life cycles resulting from 30s holding time is about twice that with 60s. Compared with the fatigue life of sine-wave loading under the same peak load, the sine-wave fatigue life cycles is about 100~1000 times that of the trapezoid-wave loading condition. However, if the number of fatigue cycles is converted into loading time (unit:s), the trapezoidal-wave loading (including 60s and 30s load retention) shows a good consistency with the 10Hz sine-wave loading condition, as shown in Figure 3.2 (b).



（a）S-N curve　　（b）S-T curve

Figure 3.2 2.5D CMCs trapezoidal wave and sine wave fatigue life curve

In order to study the difference of fatigue failure mechanism between trapezoidal wave loading and sine wave loading, the fracture characteristics of the two fatigue loading specimens were compared and analyzed in this paper, as shown in Figure 3.3. As can be seen from the figure, no clear difference in the overall morphology of fatigue failure fractures under the two waveforms can be found, with no obvious

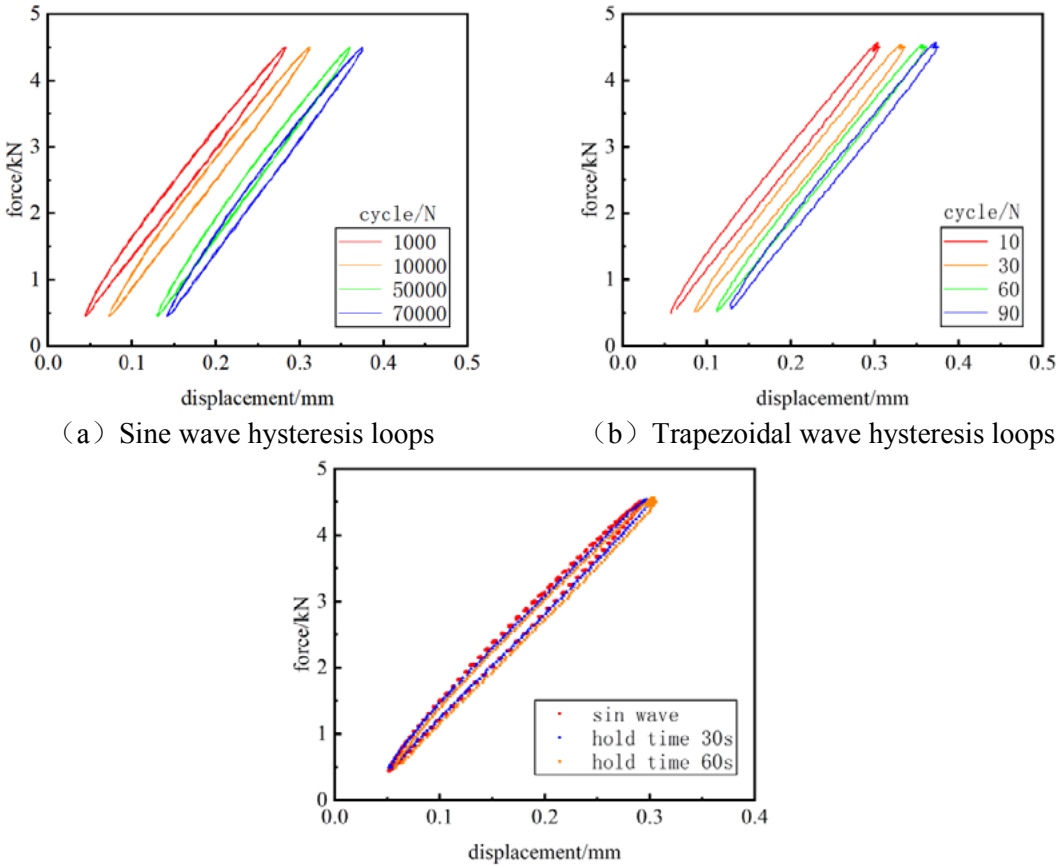


transverse tearing of weft yarns. The main fracture locations are between two adjacent weft yarns, and the fracture of warp yarns is the main failure mode.

（a）Sine wave （b）Trapezoidal wave

Figure 3.3 Overall appearance of fatigue failure fracture with different waveforms

Figure 3.4 compares the fracture surface morphology of warp yarns between the sine-wave and trapezoidal-wave fatigue loading specimens.It can be seen that the trapezoidal-wave loading and unloading with fewer times produces the fiber pulling out with the same length as the sine-wave loading. It can also be seen that under the condition of the same temperature and load amplitude, trapezoidal-wave load retention can also promote the damage of CMCs.



（a）Sine wave （b）Trapezoidal wave

Figure 3.4 Local appearance of fatigue failure fracture with different waveforms

Figure 3.5 further compares the force-displacement hysteresis curves of 2.5D CMCs under sine-wave and trapezoidal-wave fatigue loading. As can be seen from the figure, 2.5D CMCs exhibit similar fatigue hysteresis laws under different fatigue load waveforms. Further analysis shows that under the same loading time, although the number of cycles of trapezoidal-wave loading is less than that of sine-wave loading, the accumulated residual deformations of specimens under these two loading conditions remain consistent, about 0.1mm. For instance, Figure 3.5 (c) compares the hysteresis shapes of different loading waveforms at the same loading time (300s). It can be seen that the hysteresis loops of different waveforms coincide well, and that the trapezoidal-wave load retention does not significantly affect the shape of the hysteresis loop, with a limited deformation (about 0.001mm) resulting from load retention occurring at the maximum load.

In summary, trapezoidal-wave load retention has no effect on the hysteresis loop of CMCs. Therefore, the difference in cycle number of fatigue test between the two waveforms may be caused by creep damage，and the influence of this factor should be considered for more accurate fatigue life prediction.

（a）Sine wave hysteresis loops （b）Trapezoidal wave hysteresis loops

（c）Hysteresis loops with different waveforms at the same loading time

Figure 3. 5 Hysteresis loops of different waveforms

4. Conclusion

In conclusion, the number of fatigue life cycles of CMCs under trapezoidal-wave loading decreases by 10^2-10^3 orders of magnitude compared with that under sine-wave loading. Although the characteristics reflected on the fracture surface of CMCs under different loading waveforms are similar, it can be inferred that the load-holding process in trapezoid-wave loading tends to significantly promote the damage accumulation in CMCs, showing a non-negligible fatigue-creep interaction effects. However, the traditional law of hysteretic dissipation energy accumulation based on the number of loading cycles can only reflect the energy dissipation caused by friction during fatigue loading, and cannot consider the damage of CMCs caused by load retention. It is found that if the number of fatigue life cycles is equivalently converted to the loading time, the hysterical dissipation energy accumulation law and stiffness attenuation law of CMCs during fatigue loading have good consistency under different load conditions, which is promising in providing a method of quantifying equivalent damage of different fatigue loading waveforms.

Abstract
Consideration of material degradation is important when designing structural polymeric components exposed to outdoor environmental conditions. This is necessary to be able to guarantee safe and reliable performance of these components over their intended lifespan. Thus, a systematic approach is required to generate relevant mechanical property degradation data and model it in a way that can be implemented in design analysis simulations. In this study, aging effects have been assessed using nanoindentation measurements throughout the cross-section of a PC/PBT (polycarbonate-polybutylene terephthalate) material plate. Accelerated artificial weathering with State-of-the-Art Xenon arc lamps has been used to age the material according to ISO 4892-2 standard. The variation of the elastic modulus through-the-thickness of the plate has been evaluated showing a significant increase at the exposed side of the plate compared to the unexposed one. A modeling framework is presented to capture the degradation of mechanical properties through-the-thickness of the plate. A gradient is defined to represent the degradation of the modulus through the material thickness using a user subroutine (USDFLD) in Abaqus, where the definition of the material properties is dependent on a field variable via a predefined function. The results show that the model prediction is dependent on element size and therefore, a sensitivity analysis was carried out. A defined load case, i.e. cooling from room temperature (RT) to -40°C is analyzed using a virgin homogenized material definition for the plate versus a functionally graded material model.

1. Introduction

Functionally graded materials (FGM) are composite materials that exhibit innovative characteristics, featuring a gradual variation in material properties along specified dimensions [1]. In general, these materials are designed to combine strengths of multiple materials to statisfy a functional requirement [1–3]. The main advantage of FGM is the seamless transition of properties from one material to another, resulting in the elimination of stress singularities at the interfaces between different materials which are commonly found in composites, especially in ultra-high temperature environments [1, 4, 5]. Bhavar et

al. [2] described the different types of FGM and their manufacturing methods. On the other hand, several studies have focused on the characterization, modeling and analysis of parts with respect to various aspects, including testing, manufacturing, homogenization of particulate FGM, issues with heat transfer, residual stresses and fracture [3, 4, 6]. Exponential and power-law functions are commonly used to describe the varying material properties of FGMs [7–12]. Similarly, surface aging causes variation of material properties throughout the depth of designed polymeric parts [13, 14]. Polymers exhibit sensitivity to various types of radiation, including ultraviolet and gamma rays [13, 14]. Typically, these external stimuli have a greater impact on the surface of the polymer than on its bulk; however, this can have a significant impact on the overall performance of these materials depending on the application and its use-environment. A comprehensive evaluation of these aging consequences necessitates the assessment of the variation in chemical and morphological modifications in conjunction with the corresponding physical properties, enabling the determination of a characterization profile from surface to bulk [13].

In contrast to metals and ceramics, nanoindentation (NI) has not been widely used to measure the mechanical properties of polymeric materials because the viscoelastic behavior of these materials during deformation causes difficulties [13]. Nevertheless, NI is a powerful and versatile technique for polymer surface characterization [15, 16]. NI has been adapted to detect and analyze early changes in mechanical properties induced by aging mechanisms for polymers [17], as long as macrostructural factors such as cracks are not present [16, 18]. Christöfl et al. [19, 20] have shown that NI can be a reliable method to reproduce the viscoelatic properties of semi-crystalline thermoplastics, such as polyoxymethylene (POM), as well as amorphous thermoplastics, such as poly(methyl metacrylate) (PMMA).

In this paper, NI measurements are used to determine the Young's modulus profile through the thickness of an artificially weathered polycarbonate-polybutylene terephthalate (PC/PBT) material plate. A simulation approach, inspired by FGM modeling techniques, is implemented in a commercial finite element (FE) simulation software to describe the varying modulus through the thickness of the material plate.

2. Materials and Methods

2.1. Material Preparation

The virgin material used in this study is an unreinforced, UV stabilized resin. It is an impact modified PC/PBT flame retardant injection moldable grade blend. Common applications for this material include switches, housings, and coils in the electrical industry.

Tensile test specimens were injection molded standard dogbone type (1A) specimens in accordance with ISO 527-2. Tests were performed under standard laboratory conditions of 23 °C and 50 % relative humidity at a loading rate of 1 mm/min for Young's modulus evaluation, followed by a test rate of 50 mm/min. Strain measurements were acquired and analyzed using the Digital Image Correlation (DIC) technique with an ARAMIS 4M system developed by GOM.

Thermal expansion measurements were performed using a Dantec Q400 TCT (Dantec Dynamics, Ulm, Germany) DIC system. For these measurements, 30 × 30 × 3 mm^3 specimens were cut from injection molded plates. The test program had a defined temperature range of -40 °C to 140 °C at a heating rate of 1 °K/min.

For the nanoindentation (NI) tests, samples were prepared from a 3 mm thick injection molded plates. These plates were aged using an ATLAS Xenontester 440 according to the ISO 4892-2 standard settings summarized in (Table 1) for a total of 3000 hours. After cutting the samples from the aged plates as shown in (Figure 1a), they were embedded in Technovit epoxy resin. The prepared embedded sample was then ground with silicon carbide up to a grain size of 4000 and polished with 1 µm diamond polishing paste. NI measurements were performed on the polished surface using an Anton Paar UNHT^3 nanoindenter according to the measurement scheme presented in (Figure 1b). The measurements were performed under standard laboratory conditions of 23 °C and 50 % relative humidity at a loading rate of 20 mN/min and 30 s holding phase using a sphero-conical diamond indenter tip with a diameter of 10 µm.

Table 1. Accelerated aging conditions as per ISO 4892-2 standard.

Exposure period	Relative humidity (%)	Black-standard temperature (°C)	Chamber temperature (°C)	Irradiance	
				Broadband (W/m^2)	Narrowband (W/(m^2 nm))
102 min dry	50 ± 10	65 ± 3	38 ± 3	60 ± 2	0.51 ± 0.02
18 min water spray	-	-	-	60 ± 2	0.51 ± 0.02

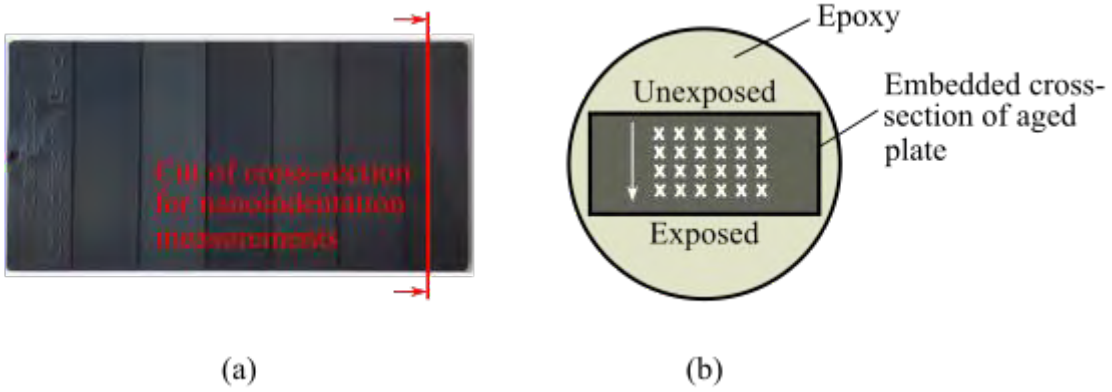

Figure 1. a) Top view of PC/PBT material plate. b) Schematic diagram for the embedded cross-section of PC/PBT sample with exemplary indents marked as "x".

2.2. Tensile test results

The virgin material properties obtained from these tests are presented in (Table 2).

Table 2. PC/PBT blend virgin material properties.

Elastic modulus (MPa)	Poisson's Ratio (-)
2102	0.3911

2.3. Coefficient of thermal expansion (CTE) results

The results of the CTE measurements on the virgin material are presented in (Figure 2).

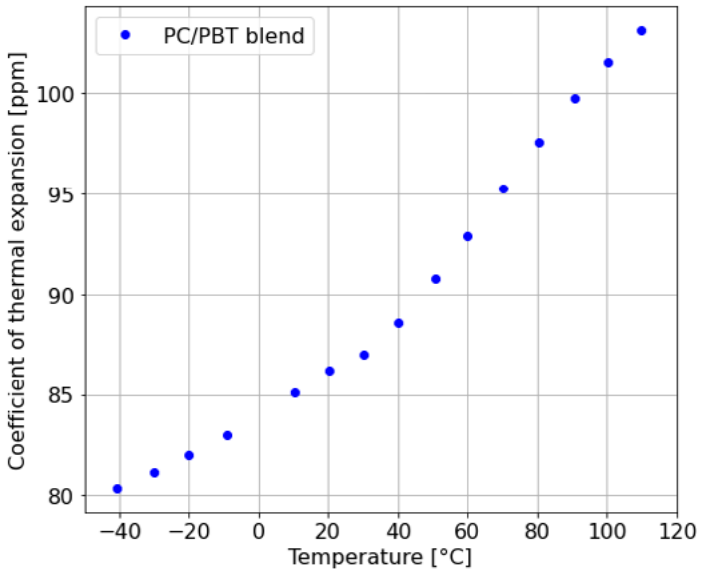

Figure 2. Coefficient of thermal expansion (CTE) measurements for PC/PBT material.

2.4. Nanoindentation results

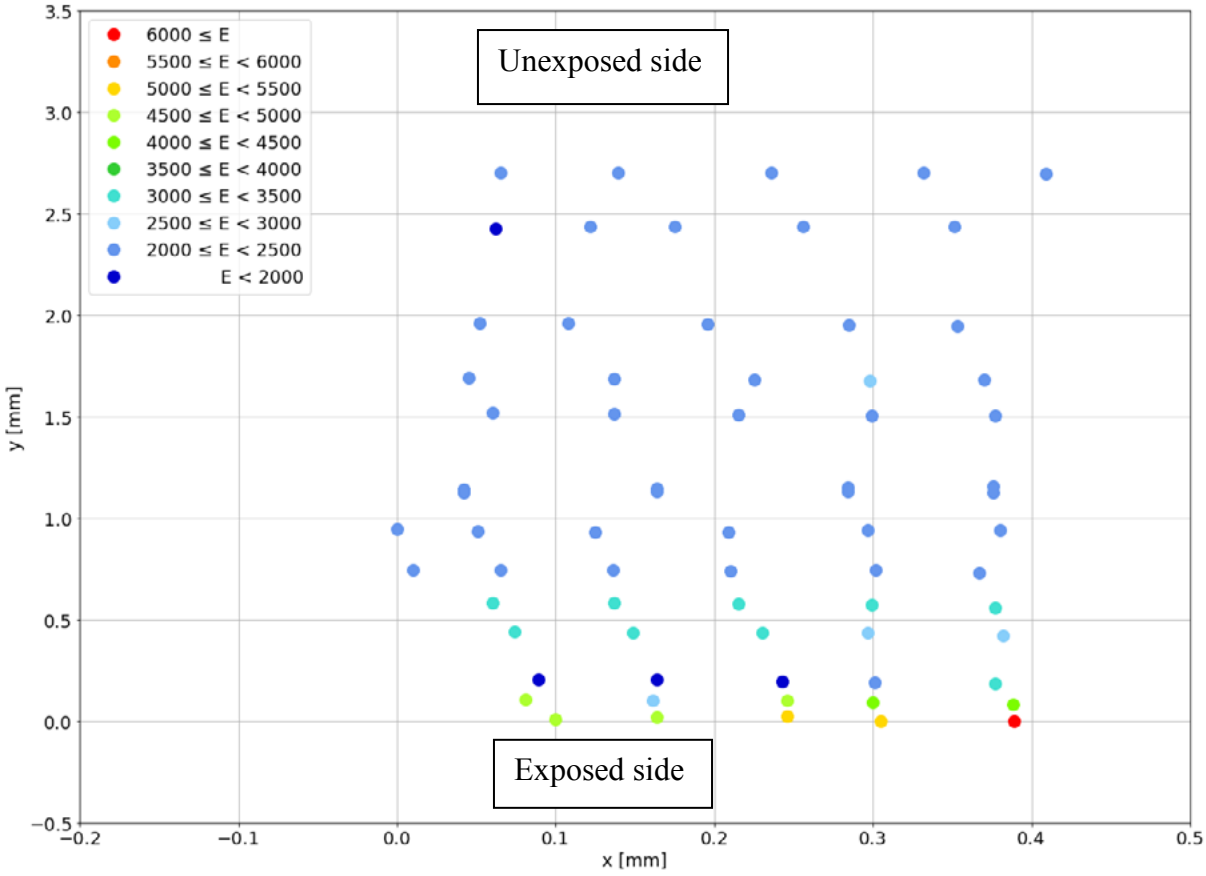

Figure 3. Nanoindentation results of the aged sample: Young's modulus variation through-the-thickness in MPa.

NI curves were evaluated using the method of Oliver and Pharr [21], where the reduced elastic modulus E_r in N/mm^2 is calculated using the following equation (Eq. 1),

$$E_r = \frac{\sqrt{\pi}}{2\beta}\frac{S}{\sqrt{A_p(h_{max})}} \quad (1)$$

where, S is the contact stiffness of the upper portion of the unloading curve at the maximum indentation depth in N/mm, A_p (h_{max}) is the contact area of the indenter tip in mm^2 as a function of h_{max} , which is the contact depth of the indenter at the maximum force in mm, and β is a dimensionless geometry factor equal to 1 for a sphero-conical tip. The method used assumes that unloading is purely elastic, which is not the case for viscoelastic polymers. As clarified in our previous work [20], the Oliver and Pharr approach with a longer hold phase is good enough for a quatitative analysis as in this work. For more sophisticated modulus evaluation, other methods such as the creep method or dynamic methods would be appropriate. This was not possible in this work due to time and equipment limitations.
The evaluated measurements for the elastic modulus are shown in (Figure 3). A gradient throughout the thickness of the plate can be observed, indicating material surface embrittlement at the UV exposed side of the plate compared to the unexposed side.

3. Simulations

In this section, a modeling framework is presented to capture the degradation of mechanical properties through-the-thickness of a PC/PBT plate.

3.1. Model setup

The setup for the finite element model (FEM) is presented as a global model in (Figure 4). In order to reduce computational effort, symmetric boundary conditions are assumed and therefore, only a quarter of the model is analyzed. The dimensions of the quartered plate are 30 × 30 × 3 mm^3. The mounting of the global model is represented by a fixed boundary condition at the edges of the plate, as illustrated in (Figure 4). 8-node linear brick elements, with reduced integration, and hourglass control are used in this model.

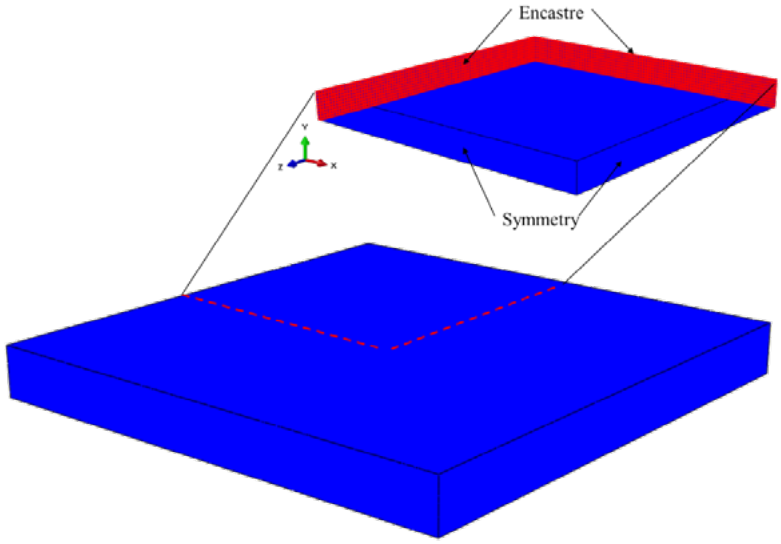

Figure 4. FE model setup and definition of boundary conditions.

3.2. Material modeling

The evaluated nanoindentation measurements at each depth are used to calculate a representative, averaged value for the Young's modulus, as depicted in (Figure 5). An optimization scheme using Genetic Algorithm (GA) is implemented to find a least squares fitting function to represent the material

degradation profile of the elastic modulus evaluated through the thickness of the plate. The function takes an exponential form, see (Eq.2). The fitted coefficients are given in (Table 3).

$$E(y) = ae^{by} + ce^{dy} + k \tag{2}$$

where, y is the position of the material point within the plate thickness, a, b, c, d and k are fitting parameters.

Table 3. Fitting parameters for the functionally graded material: PC/PBT blend

a	b	c	d	k
2435.42	-2.71	783.98	-3834.19	2241.92

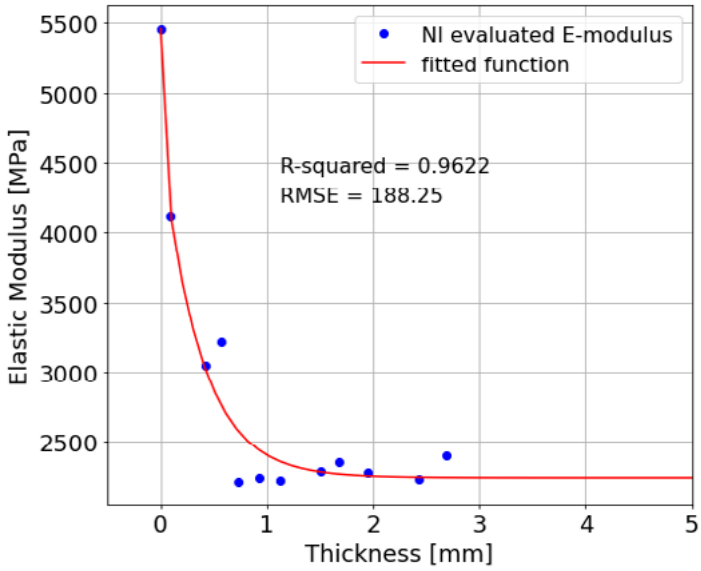

Figure 5. Fitting function for the Young's modulus variation through the thickness of the plate.

A gradient is defined to represent the degradation of the modulus through the material thickness using a user subroutine (USDFLD) in Abaqus 2019. Here, the definition of the Young's modulus in the through thickness dimension is dependent on a field variable, which is calculated using the fitted function presented in (Eq.2) and (Figure 5).

3.3. Loading conditions

The load case is defined by applying a thermal profile to cool the plate from room temperature (RT) to -40 °C. The load case is analyzed using a virgin homogenized material definition for the plate as described in (Table 2) versus a functionally graded material model.

3.4. Numerical results

The numerical results of five models with refined meshes are compared below, see (Figure 6). The element sizes and corresponding number of elements are listed in (Table 4). The model prediction shows element size dependency and therefore, a mesh sensitivity analysis is carried out. The results are found to be accurate enough at an element size of h = 0.125 mm.

Table 4. Mesh information summary for the analyzed models.

Model	Element size, h (mm)	Number of elements, N
1	0.5	21600
2	0.35	66564
3	0.25	172800
4	0.125	1382400
5	0.1	2700000

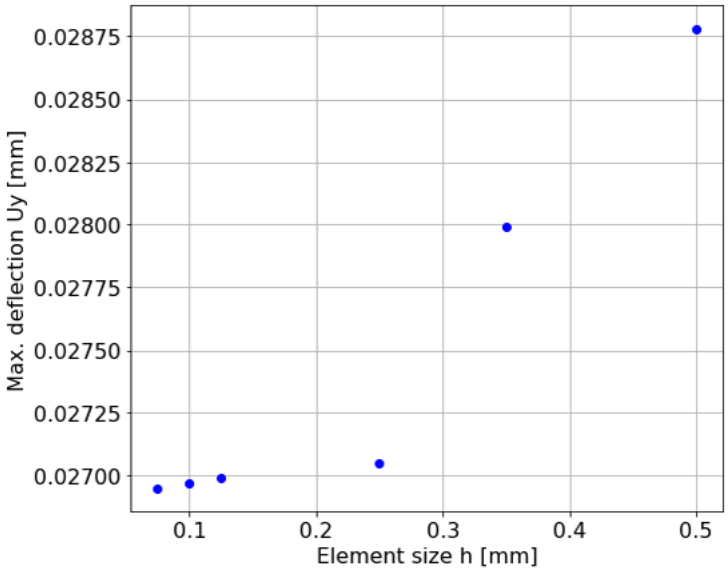

Figure 6. Max. deflection obtained from different mesh sizes.

(Figure 7) shows a contour plot of the deformation results for a homogeneous plate with virgin, non-degraded material properties (see, Table 2) and a functionally graded material plate (material model see Section 3.2). In the case of the homogeneous plate, the deformations are symmetrical, as expected. However, in the case of the functionally graded material plate, non-symmetrical deformations are observed due to the increase in Young's modulus closer to the UV-exposed surface. To further illustrate this deflection asymmetry in the case of the FGM plate vs. the homogeneous virgin material, the deflection through the thickness of the plate in both cases is plotted against the nodal coordinate in the thickness direction, as shown in (Figure 8). In the case of the homogeneous virgin material, zero deflection is observed at the line of symmetry, which is exactly the mid-plane of the plate (at y =1.5 mm), while in the case of the FGM plate, the plane of zero deflection is shifted toward the exposed side of the plate by 0.2163 mm.

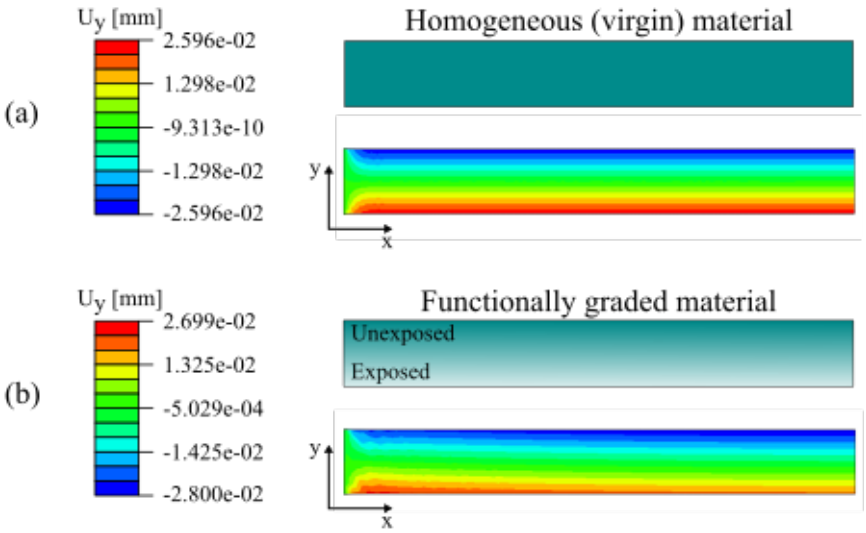

Figure 7. Deformation results when cooling from room temperature to -40 °C: (a) Homogeneous (virgin) material properties, (b) Aged material, modelled as functionally graded material.

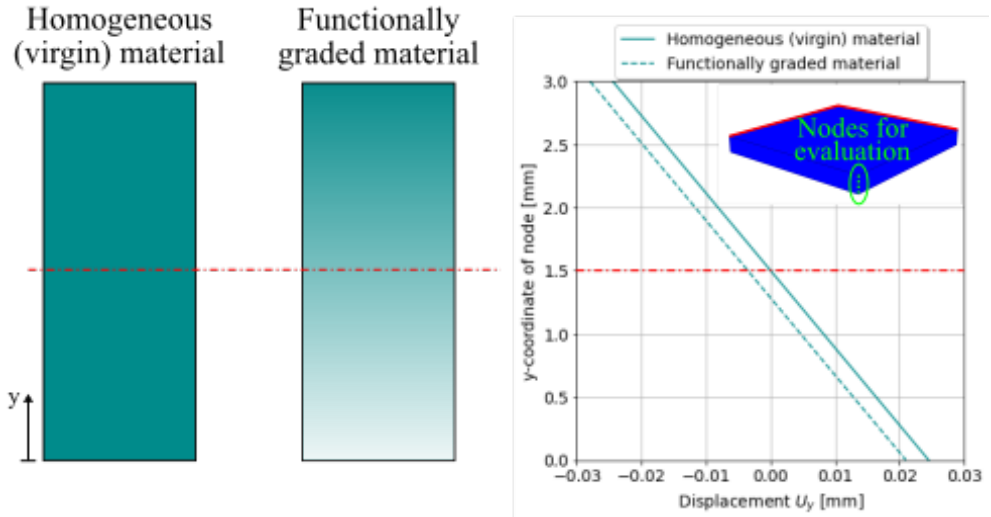

Figure 8. Deflection through the thickness of the plate: Homogeneous (virgin) material vs. Functionally graded material (FGM).

4. Conclusions and Outlook

Surface aging effects are determined using through-thickness nanoindentation measurements of a polymer plate. These effects are captured in numerical simulations using the FGM modeling approach in a thermo-mechanical simulation, where, non-symmetric deformations are observed in the case of the FGM plate compared to the results for the virgin material. This indicates that it is necessary to consider material degradation in order to assess the lifetime of the designed part. However, the methodology used has been shown to be highly dependent on the element size and therefore the computational effort for complex geometries is expected to be significant. The effect of the element type and formulation used on the simulation results obtained would be further investigated in the future, as well as the effect of aging on the thermal properties of the material, i.e., CTE measurements and its inclusion in the material model.

Abstract
Short-fiber reinforced composites are used in lightweight construction due to their numerous advantages: they have a high strength-to-weight ratio together with a low specific density and can be manufactured cost efficiently in complex geometries. Standard manufacturing technologies like injection-molding can be used. In this contribution, the material uncertainty of a short fiber reinforced composite material is investigated by mechanical characterization and multiscale simulations based thereon. The objective is to assess the propagation of uncertainties across the scales. Uncertainties in short-fiber reinforced composites can be caused by a scatter in the material properties but especially by a local variation in the fiber orientation and fiber density.
Experimental results of mechanical testing showed a scatter of the mechanical properties inside a plate and between different plates. This scattering is mainly caused by the scattering of the fiber orientation. Microstructure generation and simulation enable the investigation of the local microstructure influence.

1. Introduction

The material investigated has a heterogeneous microstructure consisting of a phenolic-resin polymer matrix reinforced with short glass fibers. The material compounding and manufacturing was done in a thermoset injection-molding process at Fraunhofer ICT, Pfinztal, Germany [1]. Due to the material flow in the manufacturing process, this composite has an uncertainty in the fiber orientation distribution. This leads to an uncertainty in the mechanical properties. The material is characterized experimentally on plates manufactured under constant conditions to investigate the scatter of the material behavior. Additionally plates with different fiber volume contents are manufactured. The characterization of the uncertainty of the mechanical properties is done by experiments on different levels of structural hierarchy. Large scale tensile, compression and shear tests are performed on different plates to investigate the scatter between different plates. Small scale tensile tests are performed to investigate the scatter of the mechanical properties inside a plate [2]. Additionally microscale tensile tests are performed to investigate the debonding between fiber and matrix at the fiber-matrix interface.
The experimental microstructure is rebuilt for numerical simulations. Finite element simulations of the microstructure are performed to investigate the influence of the scattering of the fiber orientation distribution and the fiber volume content. The microstructure simulations require different material models for fibers, matrix and the intermediate fiber-matrix interface. The fiber-matrix interface is modeled by a cohesive zone model. The microstructure simulations form the basis for multiscale simulations with a consideration of the uncertainty of the fiber orientation and fiber volume content.
Microstructure motivated representative volume element (RVE) simulations can be utilized to study the effect of the fiber orientation on the macroscale (see e.g. [4],[5]). The term statistical volume element

(SVE) is often used for microstructures that are not individually representative of a material because they are too small. Only the sum of all SVEs is in turn representative of a material. [6] However, the scattering of the material behavior can be investigated with SVE simulations.
In this work, experimental tensile test results on a short fiber reinforced polymer on two different scales are shown. In a second step, microstructure simulations using the finite element method (FEM) are performed to further investigate the material scattering. They form the basis for a microstructurally motivated investigation of the scattering of material properties.

2. Experimental investigation

2.1. Material

The material under investigation is a short fiber reinforced polymer consisting of glass fibers and a phenolic resin matrix. The manufacturing was done by a thermoset injection molding process [1]. The material was characterized on rectangular plates of size 480 x 190 mm² and thicknesses of 2 and 3 mm. The plates possess a fiber mass content of 37.5 wt%.

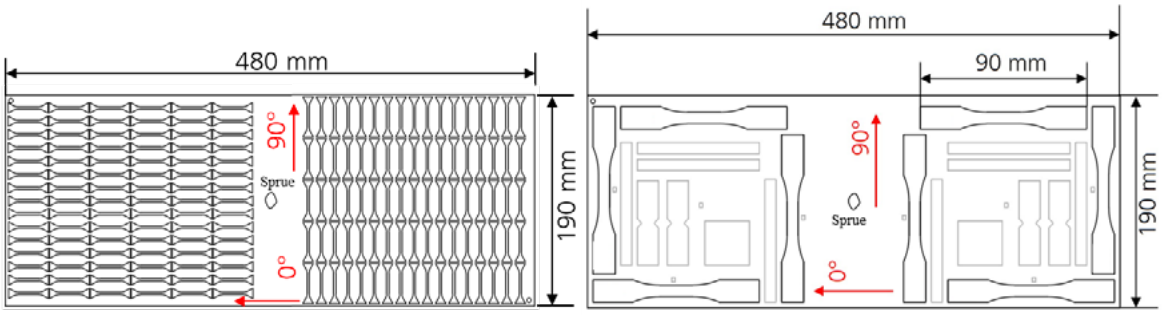

Figure 1. Sample plan with sprue in the middle of the plates.

2.2. Experiments and evaluation

Two sizes of tensile test specimens were taken from the plates. Miniature samples of a cross-section of 2 x 2 mm² and a length of 36 mm and shortened ISO size samples (3 x 10 mm² and 90 mm length). The sample plan is shown in Figure 1. The miniature samples were taken from two half plates of 2 mm thickness to investigate the material scatter inside a plate. 90 miniature samples were taken in 0° and 85 in 90°. The shortened ISO size samples were taken from seven different plates to investigate the scatter between different plates. From every plate were taken four 0° samples and four 90° samples. A total of 28 0° ISO samples and 28 90° ISO samples were tested. The samples were cut out by water jet cutting.

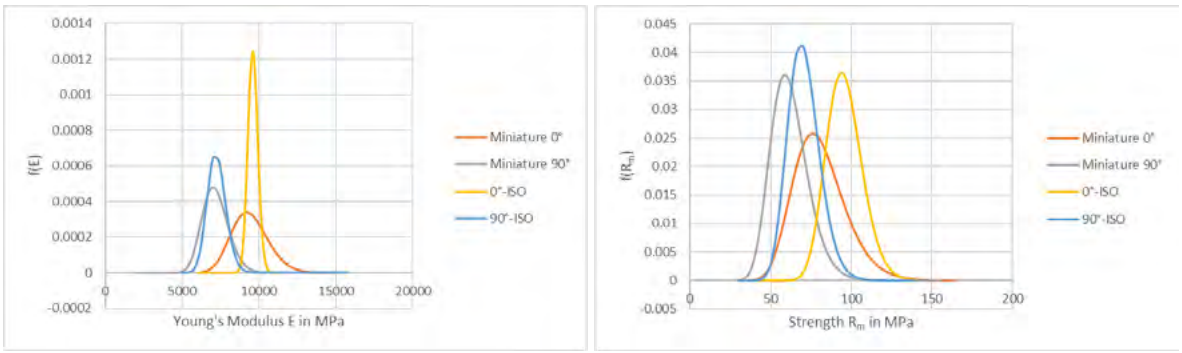

Figure 2. Experimental data.

A statistic evaluation of the experimental tensile test results is given in Figure 2. The distribution functions of the Young's modulus and strength are shown. A Log-normal distribution is used for every distribution. More details of the experimental results are given in [2]. Both sizes of tested samples show higher Young's modulus and strength values in 0° direction which coincides with the flow direction of the material. The tests on the miniature samples show a larger scatter than the tests of the ISO size samples. Compared to the ISO specimen tests, the 0° tests on the miniature specimens show a slightly lower stiffness. This could be due to the fact that the 0° ISO specimens were only taken at the edges of the plate and not in the middle. In addition, the tests of the miniature samples showed a lower strength. As the material is brittle, edge effects from the sampling could play a greater role.

3. Simulation investigation

3.1. Microstructure simulation

Microstructures with fibers and matrix are used as the basis for FEM-simulations. Short fiber microstructures with given fiber volume content and fiber orientation distribution are generated using the sequential addition and migration method of Schneider [3]. The generated microstructures are used as geometry for FEM simulations in Abaqus. Material models for fibers (linear elastic), matrix (elastic-plastic with damage) and interface (cohesive zone contacts) are used in the simulation.
Microstructures are generated on a representative volume element (RVE) scale. To include a scatter of the mechanical properties, the evaluation of the RVEs is done on a statistical volume element (SVE) subscale. An example microstructure of the size 0.6 x 0.6 x 0.1 mm³ is shown in Figure 3 with the separation in SVEs for the evaluation. The SVEs are only representatives of the material as a whole.

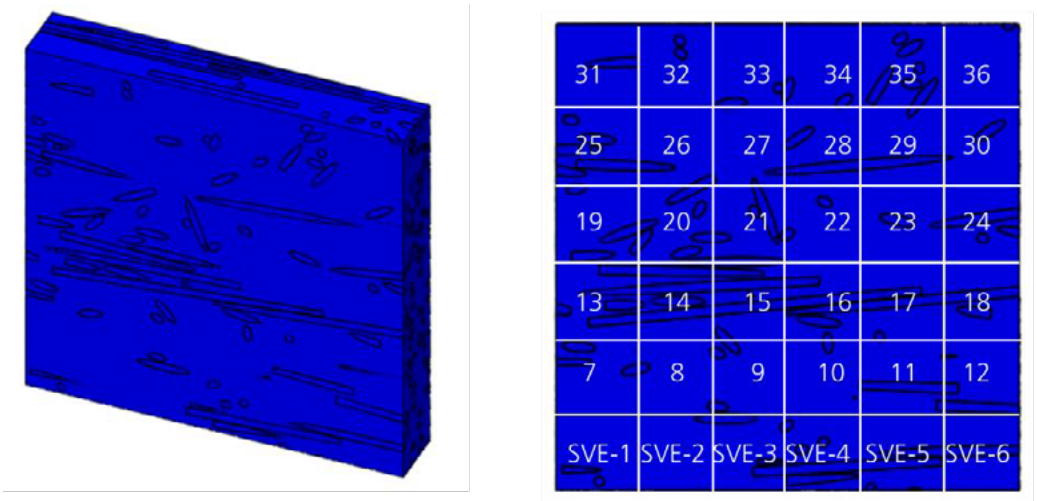

Figure 3. Microstructural RVE, separated in SVEs for evaluation.

The RVE is loaded in tension and shear directions as shown in Figure 4. Most fibers are arranged in xx-direction, which is the flow direction in the manufacturing process. Additionally, the stress-strain curves for all SVEs are given. Stresses and strains of every SVE are determined by averaging over the individual elements. The ij-th component of the stress tensor is determined by

$$\bar{\sigma}_{ij} = \frac{1}{V_{\mathrm{SVE}}} \int_{V_{\mathrm{SVE}}} \sigma_{ij} \, \mathrm{d}V \cong \frac{1}{V_{\mathrm{SVE}}} \sum_{k=1}^{n_{\mathrm{SVE}}} \sigma_{ij}^{(k)} V^{(k)} \tag{3}$$

with n_{SVE} as the number of elements in the SVE and V_{SVE} as the volume of the SVE. The strain is determined in the same way.

$$\bar{\varepsilon}_{ij} = \frac{1}{V_{\mathrm{SVE}}} \int_{V_{\mathrm{SVE}}} \varepsilon_{ij} \, \mathrm{d}V \cong \frac{1}{V_{\mathrm{SVE}}} \sum_{k=1}^{n_{\mathrm{SVE}}} \varepsilon_{ij}^{(k)} V^{(k)}. \tag{3}$$

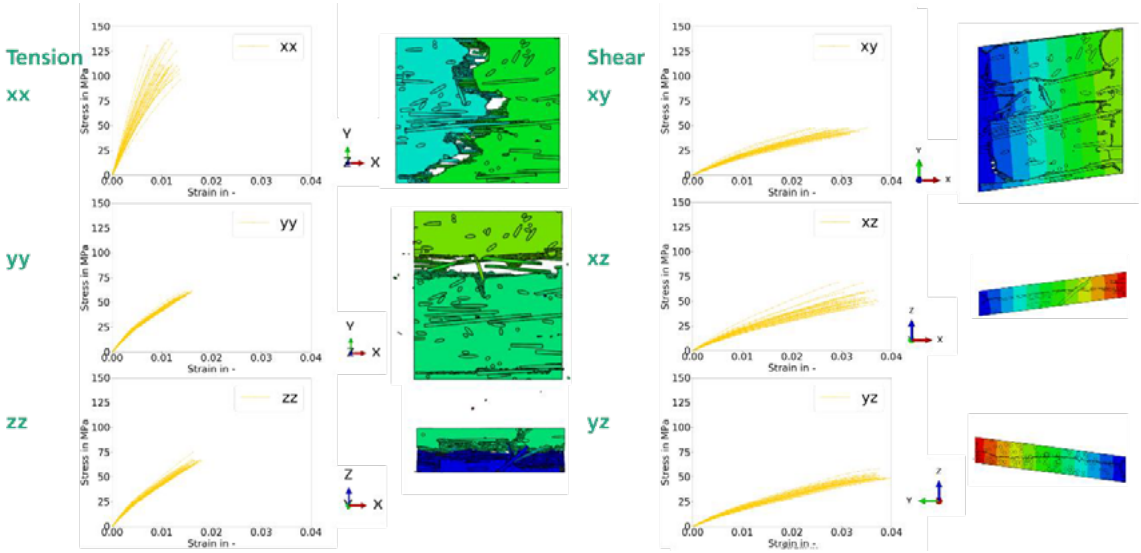

Figure 4. Tension and shear loading evaluations of SVEs with RVE from Figure 3.

4. Discussion

The experimental results show a higher scatter for the mechanical properties of the miniature samples than for the ISO size samples. This means the flow-induced variation of the fiber orientation inside a plate is larger than the variation between the same positions of different plates.

The evaluation of the microstructure simulation on the SVE scale enables the consideration of the scattering of the mechanical properties. The SVE evaluation shows a high scattering of the stress-strain curves in the xx-direction (flow direction) of the material. This can be explained by the fact that the fibers in the flow direction have the largest reinforcing effect and deviations therefore also have a greater influence. The scatter of the shear loading is relatively similar. Slightly higher scatter in the shear load in the xz- and yz-directions can be caused by the stronger influence of the boundary conditions, because the geometry is thinner in the z-direction. Also the correlation between fiber orientation and mechanical properties can be investigated in detail.

5. Conclusions

For short fiber reinforced composites, microstructure simulations provide a way of predicting the production-related scattering of material properties. They thus form a basis for probabilistic multiscale simulations in virtual process chains.

Keywords: press fit, fibre reinforced polymer, centrifugal force

Abstract *(max 200 words)*
This paper proposes an analytical method for the efficient prediction of the effective joint pressure in interference fits of metal/fibre reinforced polymer (FRP) joints. The approach can be used by engineers to efficiently estimate key design parameters such as laminate structure or wall thickness. A simplified model for describing joints with anisotropic material behavior is developed using analytical models of press-fitted isotropic cylinders known from DIN 7190 for interference fits, among others. The model is based on various assumptions about the structural behavior of the FRP component. The presented calculation method enables the calculation of joint pressure curves that are dependent on circumferential speed with minimal computational effort. These curves can be used to draw conclusions about functionality and load transferability within a defined speed range by comparing them with the loads that need to be transferred. To ensure accuracy, the analytical calculation approach is checked against the results of a corresponding numerical simulation. This paper presents practical design recommendations for metal/FRP interference fits with high circumferential speeds. The recommendations are derived based on a parameter variation analysis. The aim is to facilitate the time and computationally efficient design of hybrid press-fitted shaft-hub connections in metal-FRP designs considering the deformation induced by centrifugal force during operation.

1. Introduction

Fibre reinforced polymer (FRP) structural components have the potential to achieve high circumferential speeds due to their high density-related mechanical properties, such as strength and stiffness, which reduce centrifugal forces and induced stresses. These materials are particularly suitable for use in rotating components, as future demands will require higher circumferential speeds and reduced rotating mass or moment of inertia to meet technical and economic criteria.

Interference fits, also known as press-fits, represent an attractive solution for lightweight design, as they connect without the need for additional fasteners or connection elements that would otherwise require significant design space. Furthermore, the load can be applied to a defined area of the FRP, which is advantageous as stress peaks are avoided. This reduces system mass and centrifugal forces, leading to reduced energy consumption and stresses during operation.

However, the use of hybrid interference fit connections in metal/FRP designs presents challenges due to the anisotropic behaviour of FRP materials. Existing analytical approaches do not consider this issue [1-3] or have other disadvantages, such as high computational effort or the inability to consider

the influence of rotation [4-8]. Moreover, at high circumferential speeds, the outer part experiences radial deformation, resulting in a decrease in the effective joint pressure. This can cause the outer part to slip or even lift off [3]. The subsequent discussion explores a simplified analytical approach that considers these effects for anisotropic hybrid metal/FRP interference-fitted connections.

2. Hybrid Interference fits with high circumferential speed.

2.1 Hybrid interference fits

The force transmission in a press-fit connection is achieved through surface friction between the connection partners. The transmittable force F_T is determined by Coulomb's law for static friction $F_T = \mu_{sf} \cdot F_N$ with the static friction coefficient μ_{sf}. The contact pressure F_N is a result of the interference between the inner and outer parts, which is specifically set during the joint process [3].

This paper investigates Type A connections (cf. Figure 1) since it is assumed that they reach the highest circumferential speeds. The induced stresses in the tangential direction are limiting, especially for the metal part. Therefore, Type A is chosen because the induced stresses in solid shafts are much lower than in hollow shafts according to Type B and Type C. This is justified by simple calculations of rotating circular disks [9].

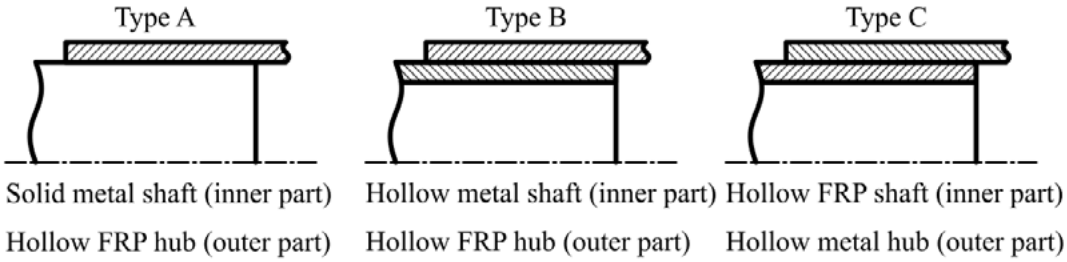

Figure 1. Different designs for hybrid metal-FRP-interference fits

2.2. Interference fits with isotropic components

The analytical calculation of interference fits for isotropic connection parts of the same material, whether solid or hollow, is a well-established practice described in DIN 7190. However, the calculation under the influence of centrifugal forces is limited to designs where the inner part I and the outer part A have the same modulus of elasticity, Poisson ratio, and density, i.e $E_I = E_A$, $\nu_I = \nu_A$ and $\rho_I = \rho_A$ [1]. Additional literature sources [2,3] offer an analytical approach to the isotropic properties of both the inner and outer parts.

Consideration based on the joint pressure, as described in [2]:
The minimum joint pressure $p_{\min}$ required to transmit the axial force F_{ax} and the torsional moment M_t can be calculated from equation

$$p_{\min} = \frac{1}{\mu_{sf} \cdot \pi \cdot D_F \cdot L_F} \sqrt{F_{ax}^2 + \frac{4 \cdot M_t^2}{D_F^2}} \tag{1}$$

where D_F is the diameter and L_F is the length of the interference fit. The calculation of the angular velocity for lift-off ω_{ab} with the outer diameter of the outer part D_{aA} is given by:

$$\omega_{ab} = \frac{4}{D_{aA}} \sqrt{\frac{E_A \cdot \xi}{K \cdot \rho_A}}. \tag{2}$$

That requires the determination of the relative stiffness factor ξ and the support factor K:

$$\xi = \frac{1}{E_A}\left[\left[\frac{E_A}{E_I}\left(\frac{1+Q_I^2}{1-Q_I^2} - \nu_I\right) + \frac{1+Q_A^2}{1-Q_A^2} + \nu_A\right] p_{min} + \frac{K \cdot D_F^2 \cdot \omega^2 \cdot \rho_A}{16 \cdot Q_A^2}\right], \tag{3}$$

$$K = 3 + \nu_A + (1-\nu_A)\cdot Q_A^2 - \frac{E_A \cdot \rho_I}{E_I \cdot \rho_A} \cdot Q_A^2 \cdot [1 - \nu_I + (3+\nu_I)\cdot Q_I^2], \tag{4}$$

$$Q_A = \frac{D_F}{D_{aA}} \text{ with } Q_I = 0\,. \tag{5}$$

The following equation enables the calculation of the joint pressure at standstill p_{still} using $p_\omega = p_{min}$:

$$p_\omega = p \cdot \left[1 - \left(\frac{\omega}{\omega_{ab}}\right)^2\right]. \tag{6}$$

Additionally, it facilitates the determination of the joint pressure at any arbitrary angular velocities ω.

Consideration based on the interference, as described in [3]:
The effective interference is calculated based on the expansions and constrictions of the inner and outer parts, separately, according to the influencing factors: joint pressure ($\Delta D_{aI,p}$ and $\Delta D_{iA,p}$), centrifugal force ($\Delta D_{aI,rot}$ and $\Delta D_{iA,rot}$) and temperature ($\Delta D_{aI,T}$ and $\Delta D_{iA,T}$). The equations used are as follows:

$$\Delta D_{aI,p} = -\frac{p}{E_I} \cdot D_F \cdot \left(\frac{1+Q_I^2}{1-Q_I^2} - \nu_I\right), \tag{7}$$

$$\Delta D_{iA,p} = \frac{p}{E_A} \cdot D_F \cdot \left(\frac{1+Q_A^2}{1-Q_A^2} + \nu_A\right), \tag{8}$$

$$\Delta D_{aI,rot} = \frac{\rho_I \cdot \omega^2}{2 \cdot E_I} \cdot \left(\frac{D_F}{2}\right)^3 \cdot (1-\nu_I), \tag{9}$$

$$\Delta D_{iA,rot} = \frac{\rho_A \cdot \omega^2 \cdot D_F}{E_A} \cdot \left[2 \cdot c_1 \cdot \left(\frac{D_{aA}}{2}\right)^2 + (c_1 - c_2) \cdot \left(\frac{D_F}{2}\right)^2\right], \tag{10}$$

$$\Delta D_{aI,T} = D_F \cdot \alpha_A \cdot \Delta\theta_A\,, \tag{11}$$

$$\Delta D_{iA,T} = D_F \cdot \alpha_I \cdot \Delta\theta_I \text{ with} \tag{12}$$

$$c_1 = \frac{3+\nu_A}{8} \text{ and } c_2 = \frac{1+3\cdot\nu_A}{8}. \tag{13}$$

When considering influencing factors, it is important to note that joint pressure can be reduced by the centrifugal force of the outer part, but can also be increased by the thermal expansion of the inner part. The effective interference during operation is determined by the superposition of these effects. The following equation allows the recalculation from the effective interference $P(n,T)$ at a specific rotational speed n and temperature T back to the joint pressure $p(n,T)$:

$$p(n,T) = \frac{P(n,T)}{D_F \cdot \left[\frac{1}{E_A} \cdot \left(\frac{1+Q_A^2}{1-Q_A^2} + \nu_A\right) + \frac{1}{E_I} \cdot \left(\frac{1+Q_I^2}{1-Q_I^2} - \nu_I\right)\right]}. \quad (14)$$

The temperature difference required to join the interference fit $\Delta\theta_F$ (cooling of the inner part) can be calculated from the required interference at standstill with the isotropic temperature expansion coefficient of the inner part α_I as follows [5]:

$$\Delta\theta_F = -\frac{\Delta D_{aI,p} + \Delta D_{iA,p}}{D_F \cdot \alpha_I}. \quad (15)$$

2.3. Interference fits with orthotropic components

The literature provides calculation methods and design recommendations, although their practical applicability is often limited due to underlying assumptions and simplifications. For instance, [4] presents an analytical method for calculating torsionally loaded interference fits, which enables the determination of stresses in finitely extended, orthotropic connection partners. Various assumptions are necessary due to the complexity of the differential equation systems involved. These assumptions limit the use of the calculation method to preliminary design applications. Further details on this calculation approach can be found in [5], which does not provide consideration of rotational stresses.

Other calculation approaches pose similar challenges for engineers, as they are often only applicable to specific use cases or involve significant simplifications. For instance, the calculation of radial and tangential stresses in cylinders under internal pressure can be performed assuming a unidirectional laminate, as described in [7]. Another method for calculating pressed anisotropic laminates is presented in [8], wich requires a significantly higher calculation effort. These models describe cylinders with infinite expansion, making it impossible to consider the axial stress distribution curves.

In order to take into account the influence of temperature, [6] proposes a method for the calculation of stresses in thick-walled, anisotropic cylinders. The calculation includes the effects of axial force, torsional moment, internal and external pressure, and centrifugal force. However, solving the differential equations results in systems of equations that are difficult to solve analytically [4].

This paper focuses solely on the force transmission of the interference fit and not on the strength analysis of the part. Therefore, the stress distribution in the laminate and resulting failure indices are not considered. Simply the elastic properties of the connecting parts are used to determine the force transmission. The presented analytical calculation approach requires the determination of the laminate engineering constants of the FRP part. The ABD-matrix describes the stiffness of a multiaxial laminate made up of several unidirectional layers. It allows the calculation of the averaged engineering constants for the laminate [10].

3. Results

3.1 Analytical calculation of the joint pressure considering the centrifugal force

The presented analytical model combines the advantages of low computational effort and ease of design studies in the early stages of the development process, based on state-of-the-art methods for calculating interference fits.

The following assumptions have been made:

I. Both connection partners are considered to be infinitely extended, isotropic cylinders.
II. The FRP connection partner is described by the engineering constants of the multilayer composite in the circumferential direction.

III. Both connection partners are subjected to purely elastic deformation.
IV. The reduction in joint pressure due to relaxation of the matrix is neglected.
V. In the case of longitudinal compression joints, the influence of the compression process is neglected.
VI. The leveling of roughness (smoothing) is neglected.

The calculation procedure is based on the calculation of isotropic interference fits. An estimation of the properties through the engineering constants of the laminate in the tangential direction t with $E_A = E_t$ and $\nu_A = \nu_t$ is used to consider the anisotropic behavior. This is based on the assumption that the properties in the tangential direction determine the behavior of the interference fit and its load transferability. The calculation procedure can be summarized as follows:

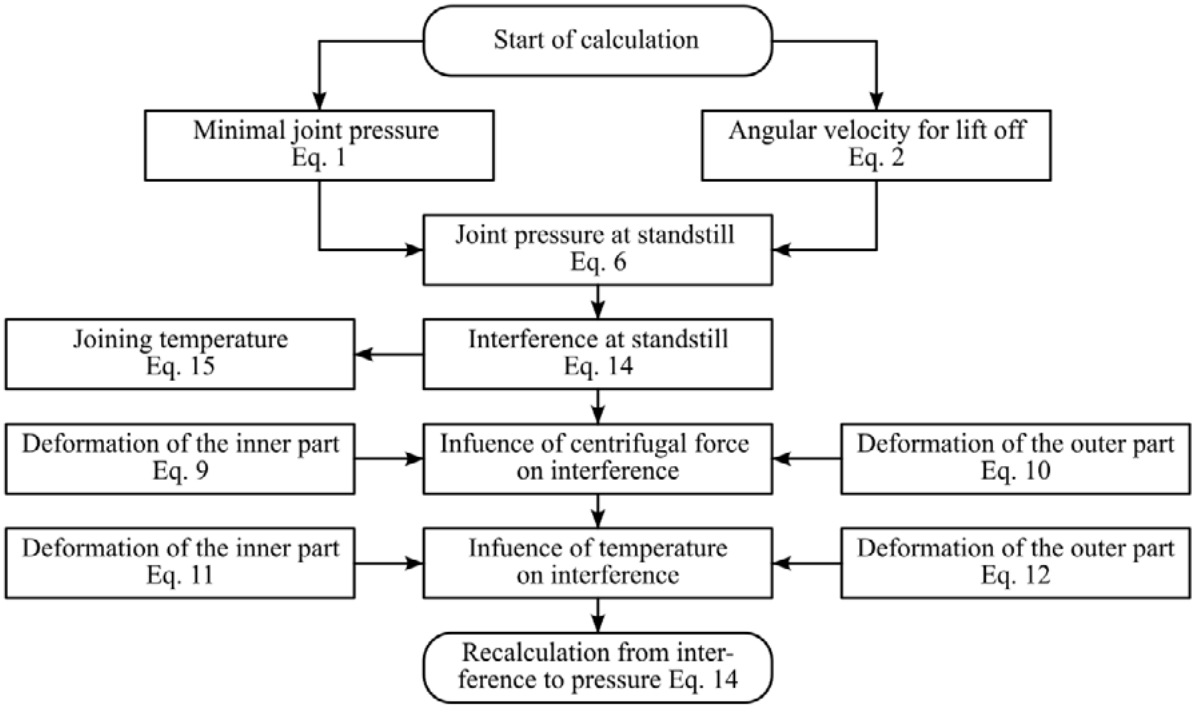

Figure 2. Calculation procedure for hybrid metal-FRP interference-fitted connections with high circumferential speed

3.2 Numerical Model

To verify the analytical approach, an FE model of interference-fitted cylinders was created (cf. Figure 3). Simplifications III to VI also apply, while simplifications I and II are no longer valid due to the modeled joint length and direction-dependent properties of the FRP.

In the first load step, the joint interference is eliminated by the contact definition, and the circumferential speed is increased to the analytically calculated lift-off speed in five subsequent load steps. An outer shaft edge is subject to a boundary condition that restricts the axial and tangential degrees of freedom in a cylindrical coordinate system. The shaft is modelled with a length of $3 \cdot L_F$ to minimize the impact of the boundary condition on the compressed area.

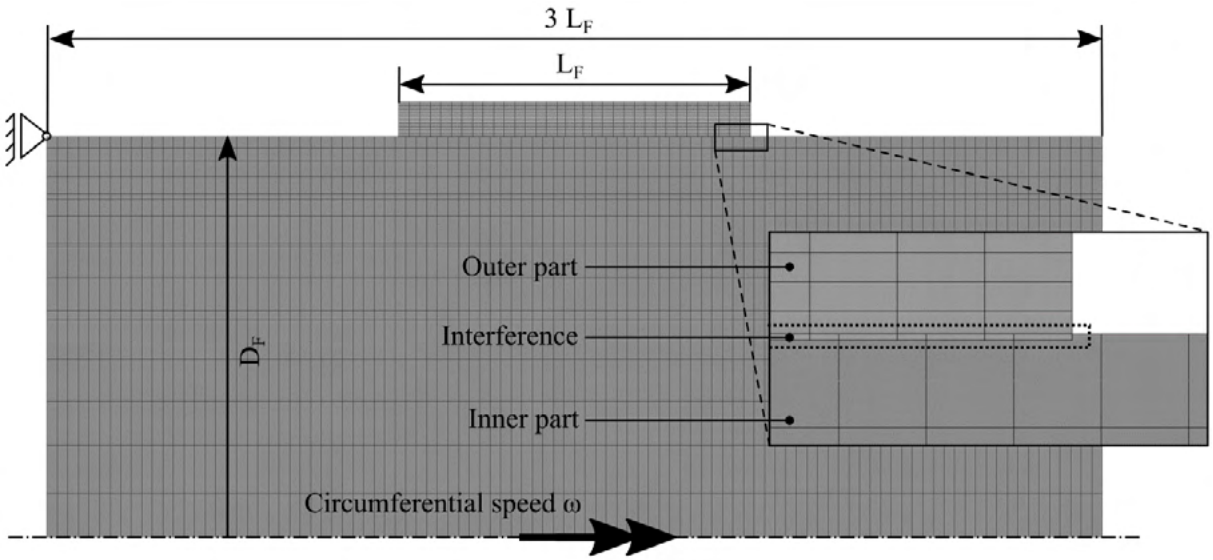

Figure 3. Section cut of the numerical model

3.3 Comparison of analytical and numerical results and investigation of different designs

To evaluate whether the assumption II can be used as an approximation, several compression joints are simulated by varying stiffness-relevant parameters. Starting from a reference Design 1, the fibre type (Design 2), laminate structure with 90° for the tangential orientiation and 0° for the axial direction (Design 3) and wall thickness of the laminate (Design 4) are varied according to Table 1.

Table 1. Parameter study for different designs.

	Stiffness relevant parameters			E_t [GPa]	P [mm]
	Fibre	Laminate	Thickness [mm]		
Design 1	UMS45	$[90_4/0]_S$	10	197,9	0,241
Design 2	IMS65	$[90_4/0]_S$	10	136,0	0,431
Design 3	UMS45	$[90_5/0_3/\pm45]_S$	10	137,5	0,411
Design 4	UMS45	$[90_4/0]_S$	10	198,9	0,168

Figure 4 illustrates the comparison between the analytical and numerical results of the circumferential speed-joint pressure curves. The dimensioning speed describes the highest angular velocity that provides enough pressure to transfer the loads according to equation (1).

Designs 1, 2 and 3 exhibit good correlation. However, Design 3 shows discrepancies of 3% up to 11% between the analytical and numerical calculations at low speeds and standstill. A similar observation was made in [5] regarding the analytical model for determining the joint pressure from [4] (without considering centrifugal forces). The cause of this discrepancy lies in the neglect of the radial strain of the laminate. The calculation approach used in this paper also does not provide a physically correct description of the radial strain. This is because the modulus of elasticity in the laminate thickness direction is overestimated with the assumption II $E_A = E_t$, which leads to an overestimation of the joint pressure.

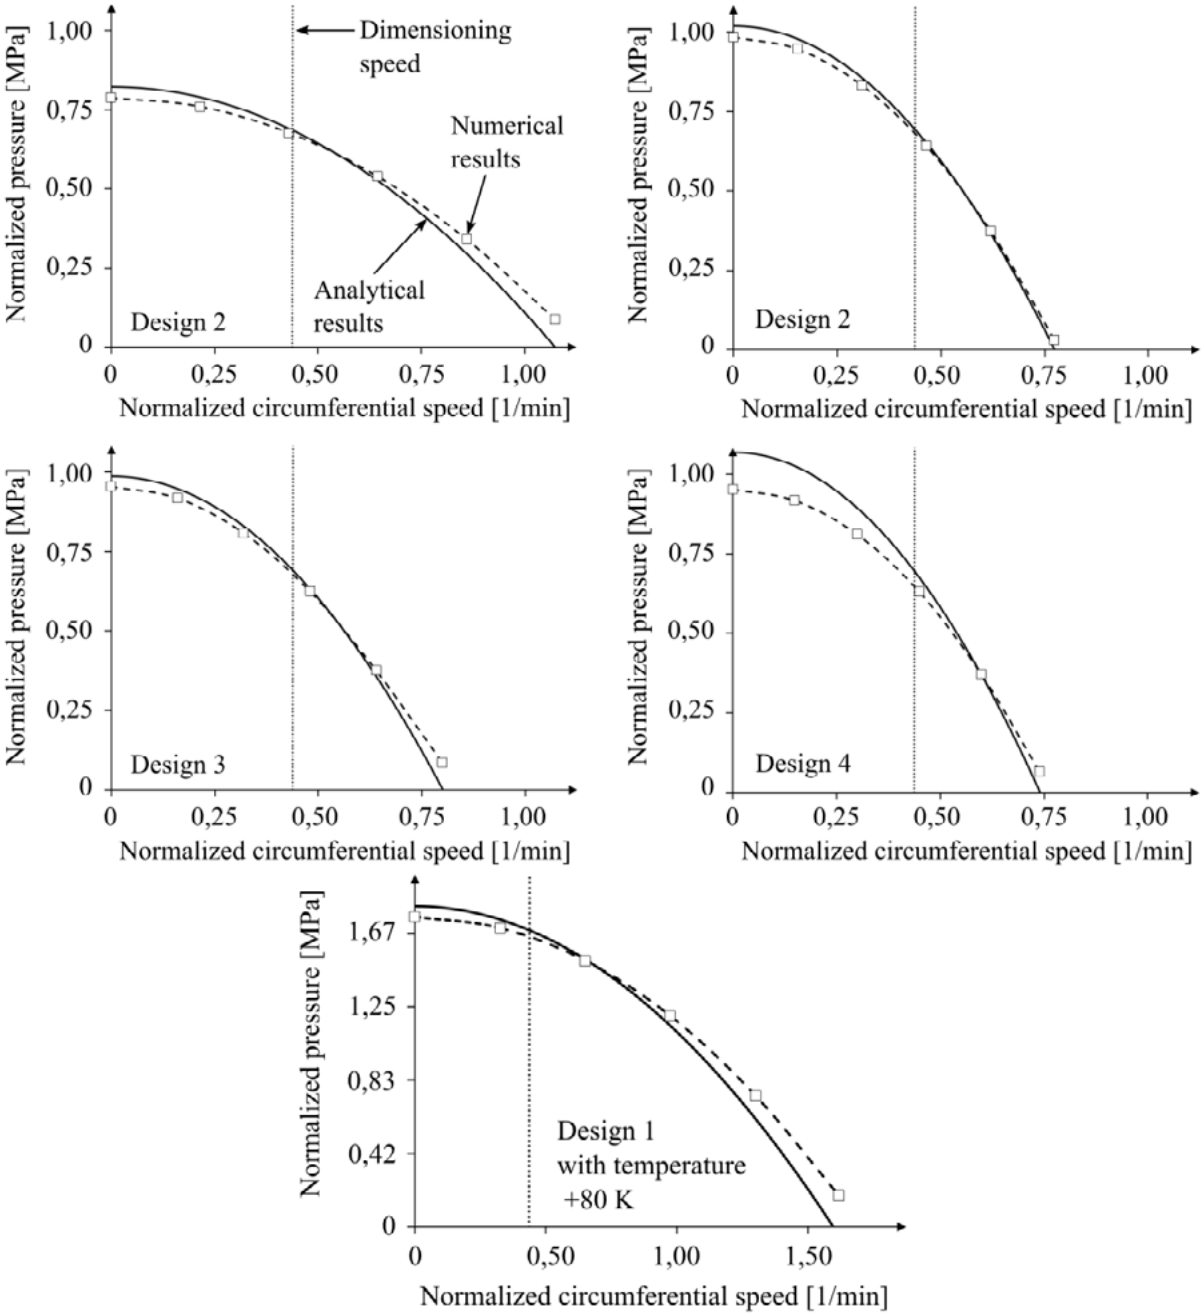

Figure 4. Analytically and numerically determined joint pressure curves of steel-CFRP press fits over the speed with variation of stiffness-relevant parameters.

4. Design recommendations for high circumferential speeds

Based on the presented results, the following observations can be made (comparisons with Design 1):

- When joining fibre types of lower stiffness, a higher joint pressure is required due to the steeper drop in joint pressure that occurs when the speed is increased (cf. Figure 3, Design 2). As a result, the interference to be set also increases (cf. Table 1).
- Laminate structures with a lower proportion of 90° layers require a higher joint pressure at standstill. This is because there is a steeper drop in joint pressure when the speed is increased, (cf. Figure 3, Design 3). The interference to be set also increases (cf. Table 1).

- Increasing the wall thickness results in a higher required joint pressure during joining. This is due to the steeper drop in joint pressure when the speed is increased (cf. Figure 3, Design 4). The interference to be set is reduced accordingly (cf. Table 1).
- The rise in operating temperature causes an increase in joint pressure across all speeds, resulting in a higher lift-off speed (cf. Figure 4, Design 1) with temperature +80 K.

Design recommendations for metal/FRP interference fitted connections with high circumferential speed under the influence of temperature are as follows:

- The use of high-stiffness fibre types is recommended for FRP joint partners as it leads to a smaller reduction of joint pressure at high circumferential speeds. However, the decreasing strength of high-stiffness fibre types should be considered.
- The use of laminates with a high proportion of 90° layers results in less reduction of joint pressure at high circumferential speeds. When developing a laminate structure, it is important to consider additional loads such as axial forces and torsional moments.
- Increasing the wall thickness of the hub laminate is a suitable measure for reducing the necessary interference during manufacturing. It is important to note that an increase in speed results in a steeper decrease in joint pressure.
- The properties of the interference fit are influenced by the operating temperature due to the different thermal expansions of the connection partners. This can be used to adjust the properties of the joint without design adaptation. For example, high speed ranges may only be approached at defined operating temperatures.

5. Conclusion

This paper addresses the challenge of designing efficient connections for rotating components using fibre-reinforced polymer materials, which offer high strength and stiffness. Interference fits, which connect parts without additional fasteners, are explored for their potential to reduce mass and energy consumption. However, designing hybrid metal/FRP interference fits is complex due to the anisotropic nature of FRP and the influence of high circumferential speeds on joint pressure.

The study focuses on hybrid connections with solid metal shafts and hollow FRP-hubs, assuming they reach the high circumferential speeds according to the stress distribution. Analytical approaches for isotropic and orthotropic components are discussed, highlighting existing limitations in practical applicability. The paper proposes a simplified analytical model considering centrifugal forces and anisotropic behavior to calculate joint pressure.

Numerical models validate the analytical approach, revealing discrepancies primarily due to neglected radial strain in the laminate. Design recommendations emphasize factors influencing joint pressure, such as fibre type, laminate structure, and wall thickness. For high-speed applications, using high-stiffness fibre types, incorporating more tangential layers in laminates, and decreasing wall thickness of the FRP-hub are suggested. Additionally, considering operating temperature effects on joint properties offers optimization opportunities.

In conclusion, the paper provides insights into efficiently dimensioning hybrid metal-FRP interference-fitted connections for high circumferential speeds, offering practical design recommendations to meet technical and economic criteria.

Keywords: Bolted joints, Low-velocity impact, Tensile test, Low-temperature, Damage mechanism

Abstract

Jointed structures become inevitable due to high-strength requirements and the need for assembly, especially in large parts. Industrial applications often highlight the significance of multi-bonded joints, leading to the development of stronger and more durable structures. The exploration of jointed structures becomes even more critical in understanding their behavior under various conditions. In this study, carbon fiber-reinforced thermoset composites manufactured via the automated fiber placement process with a cross-ply ($[0/90°]_{4s}$) lay-up are employed. The study focuses on a multi-bolted joint, employing two bolts symmetrically positioned. Specifically, a 10J impact energy and a temperature of -55°C are chosen to simulate transverse impact and low-temperature conditions, respectively. The mechanical performance of the jointed composite laminates is investigated through a tensile test. The results are then compared with reference jointed composite laminates to assess the effect of impact and operating temperature on the structural integrity and performance of the composites. To gain insights into the damage mechanisms and propagation during the tensile test, in-situ acoustic emission analysis is performed at both room and low temperatures. It is shown that the joint strength is significantly influenced by the operating temperature and the joint's load-bearing capacity is less enhanced when impacted transversely at low temperature, compared to the enhancement observed solely due to low temperature condition. The mentioned effects are further explained and verified by damage mechanism evaluation using acoustic emission.

1. Introduction

Joints have found wide-ranging application in the assembly of substantial components in aerospace applications, primarily as a consequence of the constraints due to design, cost and maintenance associated with the manufacturing of oversized parts [1]. On the other hand, the use of jointed materials become more preferrable to achieve the high strength. The composite material with the advantage of high strength and lightweight become the main source to apply the joints . However, the joining process leads to discontinuity and reduced mechanical performance compared to a single-piece component. The discontinuity offered by joints makes them vulnerable points in terms of damage initiation and failure

of the structure [2]. Each joining methodology offer advantages and drawback, for the case of bolted joints, the drilled holes perform as stress concentration points and weaken the structure due to damages induced by the opening a hole [3]. Moreover, enhanced load-bearing capacity is attainable through multi joints commonly employed in practical applications. Multi joints distribute loads across multiple paths, leading to altered load distribution and diverse failure modes. Typical failure modes in multi-bolt joints encompass net-section failure, shear-out, and bearing failure. While net-section failure and shear-out can result in abrupt and catastrophic failures, bearing failure is preferred in structural applications, underscoring the critical need for accurate prediction of failure modes [4]. On the other hand, composite structures exhibit susceptibility to impact events and are often subjected to fluctuating temperatures during their operational lifespan. The impact-induced damage can be further compounded by exposure to varying operating temperatures, leading to altered damage mechanism and failure modes [5]. This phenomenon becomes particularly significant in cases involving structures with potential stress concentration areas, such as multi-jointed structures. Several studies investigate the effect of temperature on joints strength [6,7]. Ulus studied the temperature dependent behavior of hybrid, bolted and bonded BFRP composites from room temperature to 150°C, comparing tensile strength with DMA results for SLJ composites. Adhesive bonded joints had higher strength below Tg, while bolted joints performed better above Tg up to 50°C; hybrid joints prevented sudden failure by transferring load from adhesive to bolt [8]. The effect of impact and the combined effect with temperature are investigated in studies mostly focused on adhesively bonded joints [9–18]. Sayman et al. studied single lap joints bonded with adhesive using glass fiber-epoxy composites under varied conditions (surface type, temperatures, impact energies). They found that load-carrying capacities decrease at low and high temperatures and with lower impact energies (5 J, 10 J, 15 J), but increase at 20 J due to adhesive perforation, with rough surfaces showing higher capacities than smooth surfaces [11]. In another study done by Sayman et al. investigated adhesively bonded joints post-axial impacts at -20°C to 80°C and impact levels ranging 10J to 25 J, finding high-energy impacts beyond specific temperature limits cause immediate failure. Deviations from room temperature negatively affect tensile strength, particularly at lower temperatures, reducing load carrying capacities [12]. Akderya et al. investigated thermal aging effects on adhesively bonded glass fiber/epoxy composite joints at -18°C, 25°C, and 70°C, observing increased load capacity at -18°C but decreased capacity with impact application (5-30 J). Tensile tests at different temperatures revealed reduced load capacity with higher impact energies, particularly at 18°C and 70°C, compared to room temperature [13]. Considering all the studies available in literature, the combined effect of impact, temperature of laminates on mechanical performance of composites with multi bolted joints remain still unclear. This study investigates the impact of transverse impacts and low-temperature conditions (-50°C) on the residual tensile strength of multi-bolted CFRP composite laminates. Specifically, cross-ply laminates arranged in jointed configurations undergo impact testing at room temperature (RT), followed by subsequent tensile strength assessment at both RT and low temperature (LT). The study employs acoustic emission analysis to explore damage mechanisms and conduct failure analysis comprehensively.

2. Experimental Methodology

2.1. Manufacturing of Laminates and Joint preparation

HexPly 8552 carbon/epoxy unidirectional prepreg spool fiber tapes were employed to fabricate composite laminates. The lay-up process was conducted utilizing an advanced Coriolis automated fiber placement (AFP) robot. Each laminate layer comprised 8 tows per course, with a tow preg width of 6.35 mm and a feeding rate set at 0.1 m/s. The resulting 16-layer laminates were arranged in a cross-ply (CP) configuration with a lay-up sequence of $[0/90°]_{4s}$, ensuring varied fiber orientations, and subjected to 1 atm pressure using vacuum bagging for 24 hours at room temperature, followed by autoclave curing according to the prepreg manufacturer's instructions. The cured thermoset composite laminates attained final dimensions of 900 mm × 600 mm, with an average thickness measured at 3 mm at three different points on the laminate. Subsequently, the laminated composites were cut into 100 mm x 150 mm sizes using a Kuka KR16 robot equipped with a high-performance water jet for precise composite specimen

cutting, intended for impact testing, and further trimmed to dimensions of 36 mm × 150 mm to serve as the adherends of single lap joints (SLJs). The geometric characteristics of multi-bolted joints are depicted in Figure 1. The holes are drilled utilizing a DMG Mori Seiki Lasertec 65 3D Hybrid Process Machine, operating at a cutting speed of 90 m/min and a feed rate of 0.005 mm/rev. Assembly of the adherends, sized at 150 mm × 36 mm × 3 mm, involved the utilization of an M6 stainless steel bolt, nut, and two washers with a 6 mm internal diameter and 18 mm external diameter. The bolted joints were torque tightened to a level of 15 N × m using a torque control wrench.

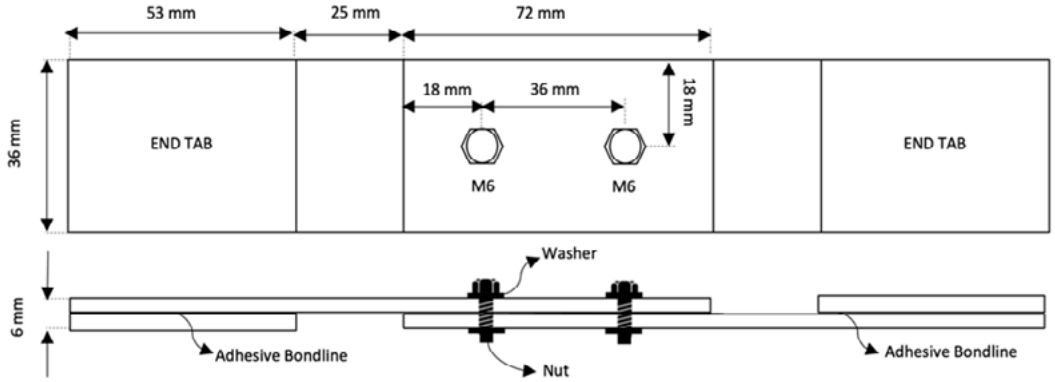

Figure 1. Schematics of front and top view of SLJ specimen

2.2. Impact Testing and Tensile-after-Impact Testing

Barely visible low-velocity impact tests at 10 J are conducted using a hemispherical steel impactor (16 mm diameter and 2.5 kg mass) with 2.83 m/s velocity and 40.7 mm height, tests followed ASTM D7136 with 3 repetitions for OB joint types. Following impact testing, tensile tests were conducted to evaluate residual mechanical properties. Specimens were tested using an Instron universal testing machine at a constant crosshead speed of 1 mm/min, following ASTM D3039 standards. Load-displacement curves were recorded to analyze the residual strength and stiffness of the laminates after impact. Three specimens were tested for each joint type.

2.3. Acoustic Emission Monitoring

Damage mechanisms in tensile after impact tests, for both impacted and non-impacted specimens, relied on AE. Mistras PCI-2 AE system with PICO-200–750 kHz sensors captured AE data continuously. The Physical Acoustics 0/2/4 voltage preamplifier enhanced signal detection by 20 dB. AE sensors' sensitivity was evaluated per ASTM E976-10. Digital conversion used an 18-bit A/D converter. System parameters included a 45 dB threshold, 50 µs PDT, 150 µs HDT, and 200 µs HLT, with a 2 MHz data collection rate per sensor. Post-experiment analysis involved noise elimination, Bessel bandpass filtering (from 20 kHz to 800 kHz), and MATLAB for pattern recognition based on features like weighted peak frequency and amplitude. Clustering, using the unsupervised k-means algorithm and Calinski-Harabasz criteria, performed as three clusters for OB joints.

3. Results and Discussion

The maximum load carried by multi bolted SLJ with cross-ply laminates is represented in Figure 2(a). For intact joints the maximum load at RT is 23940 which increases up to 26875 as it is exposed to LT. this can be explained by the effect of LT on matrix shrinkage, the shrinkage tightens the bond between matrix and fiber and strengthen the interface region. Thus, the maximum load capacity increases by 12%. The same scenario is valid for impacted laminates as exposed to LT the load carrying capacity of the joint increases by 9%. It can be understood that, although the 10J impact considered as low velocity impact with barely visible damage, the damage induced by 10J to interface region reduce the load

bearing capacity by 3% when exposed to LT. This happens when the 10J impact at RT reduces the maximum load by only 0.4%. Figure 2(b) depicts the maximum displacement or the displacement at failure. The maximum displacement decreases by 13.9% and 12.5% for impacted joints at RT and LT respectively. However, the effect of impact and operating temperature reduce the displacement decrease rate to 10.5%. In other words, the LT increases the stiffness and load bearing capacity for both intact and impacted joints while the displacement decreases due to brittle behavior at LT.

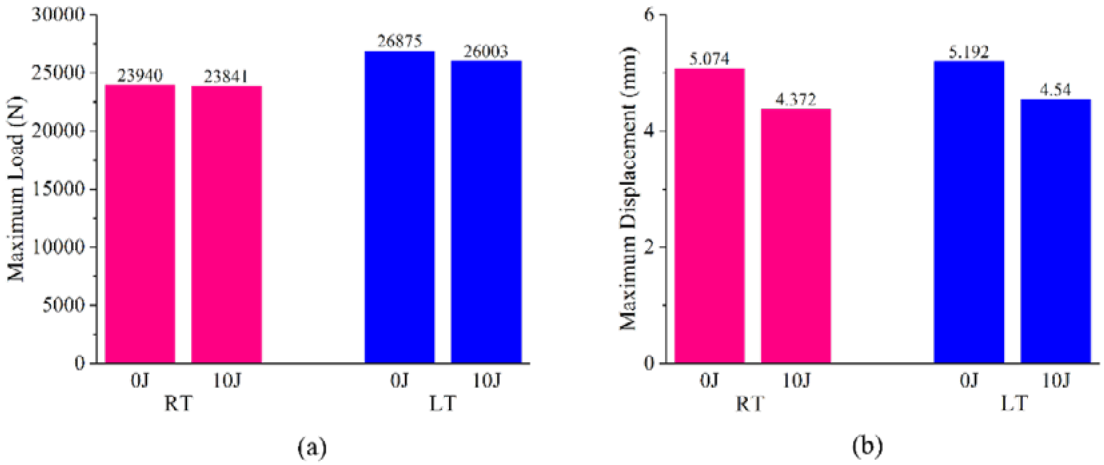

Figure 2. The maximum load bearing capacity (a) and maximum displacement (b) of multi-bolted SLJ for intact and 10J impacted joints at RT and LT.

Figure 3 presents the damage classification of SLJs based on peak frequency and amplitude under different conditions: RT with 0J impact (a), RT with 10J impact (b), LT with 0J impact (c), LT with 10J impact (d). In RT conditions, non-impacted joints exhibit higher amplitudes (reaching a maximum of 120 dB) compared to the 10J impacted joints (maximum amplitude around 90). This difference is due to pre-existing damage between the bolts in impacted joints, allowing for lower amplitude hits before failure point during AE monitoring. Under LT conditions, the maximum amplitudes for non-impacted and 10J impacted joints are almost the same, both around 120. This indicates that the rigidity of the material in cold conditions leads to consistent amplitude levels for AE signals, regardless of low velocity impact energy. The observed behavior suggests that even when impacted in cold conditions, the multi-jointed laminate remains relatively rigid, resulting in consistent AE signal amplitudes reflecting the internal damage mechanisms. Figure 4 illustrates the distribution hit fractions of each cluster for RT-0J (a), RT-10J (b), LT-0J (c), LT-10J (d). The graph indicates that fiber failure is the predominant type of failure observed in both non-impacted and 10J impacted joints under RT and LT conditions, owing to the alignment of fibers with the applied load. Since the load is mainly bearing with reinforcing fibers, the total AE hits related to matrix and interfacial failure are lower compared to fiber failure. In non-impacted joints (Figure 4(a) and (b)), there is a transition to matrix-related failure events under LT conditions due to the increased sensitivity of the matrix to crack initiation, stemming from its molecular composition. Moreover, differences in the coefficients of thermal expansion between the matrix and fibers result in thermally induced residual stresses, facilitating damage initiation and progression [8]. Conversely, there is no significant change observed between RT-10J and LT-10J joints, attributed to pre-existing damage in the matrix and interface influenced by the applied impact energy.

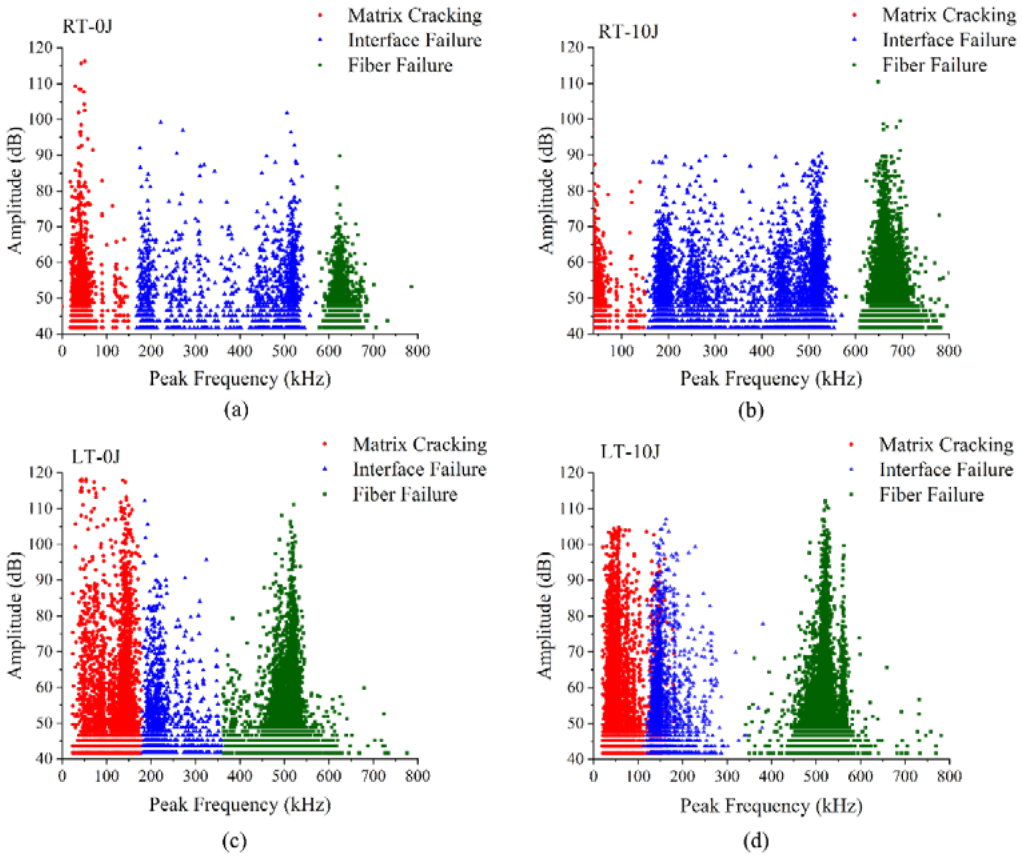

Figure 3. Peak Frequency vs Amplitude based failure classification of SLJ specimens.

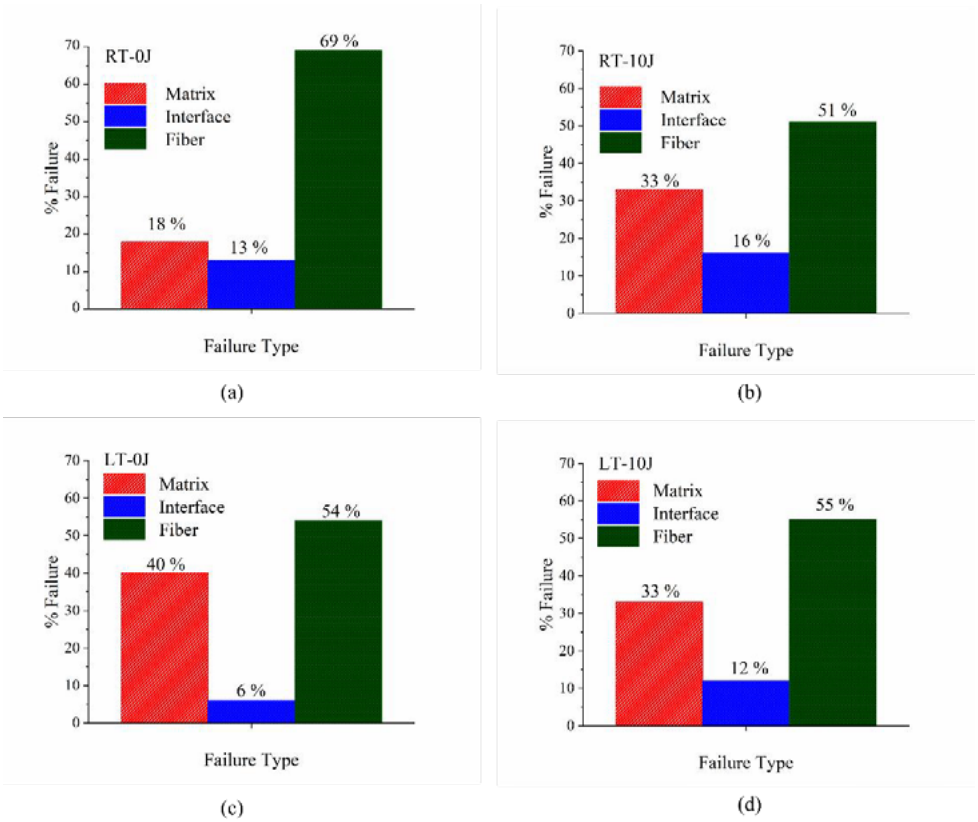

Figure 4. Average hit fractions of all three classified failure types of SLJ specimens.

4. Conclusions

In conclusion, this study focuses on the effect of impact loading and operating temperature on multi bolted joints. The residual strength of intact and 10J impacted joints are evaluated at both RT and LT. Furthermore, the failure analysis is conducted by using acoustic emission evaluation. The conclusion is as following:

- In multi-bolted joints, the influence of impact loading on the joint's maximum load-bearing capability is negligible at room temperature (RT) but becomes significant at low temperature (LT). This implies the importance of barely visible damage induced to the jointed structures at low operating temperatures. This assertion is confirmed through a separate comparison between intact and impacted joints exposed to LT. Moreover, the combined effect of impact load and temperature results in a reduced enhancement of load-bearing capacity compared to the effect of temperature alone.
- The assessment of damage mechanisms involved comparing the acoustic emission hits collected from three distinct clusters representing matrix cracking, interface failure, and fiber-related failure. The combined effect of impact and temperature results in the increase for matrix cracking and reduction in interface and fiber related failure.
- It is noteworthy that the effect of impact in LT is more pronounced with higher interface related failure, and leads to less enhancement in load bearing capacity compared to intact joints at LT.
- The introduction of impact loading decreases the displacement at failure in both Rt and LT. However, the combined effect of impact and low temperature weakens the effect of impact loading by less reduction in failure displacement, a phenomenon explained by evaluating damage mechanism. The impacted joints at LT experience less interface related failure compared to the same impacted joints at RT.

Keywords: Mode I loading, Thick adhesive joints, Drucker-Prager plasticity, Thermal residual stresses, Pre-cracking

Abstract

Wind turbine blades are manufactured by molding them in two halves and joining them using thick adhesive joints. The failure of these adhesive joints, particularly in the trailing edge of the blades, compromises the structural integrity of the wind turbine. Therefore, comprehending the mechanisms of failure in adhesive joints is critical to designing wind turbine blades efficiently. For this purpose, the present study proposes a novel approach that integrates computational and experimental methods to enhance the overall understanding of the factors that influence the failure of thick adhesive joints. The experimental specimens consist of two cross-ply glass fibre composite laminates bonded with a ~10 mm thick layer of an epoxy-based adhesive. The specimens are cured at 70°C. After curing, a pre-crack is generated within the adhesive layers of each specimen. The specimen is subjected to Double Cantilever Beam (DCB) tests at room temperature to induce mode I failure. The load-displacement curves of the DCB specimens are obtained. The strain in the adhesive layer is determined using the Digital Image Correlation (DIC). Finite Element (FE) models of the DCB specimens having virtually generated pre-cracks are created to predict the experimental load-displacement curves. So far, most researchers have employed the cohesive zone model for the adhesive in such numerical studies. However, epoxy-based adhesives typically exhibit plastic deformation. Hence, the Drucker-Prager plasticity criteria are utilised to model the mechanical response of the adhesive. Also, it is crucial to assess the influence of thermal residual stresses that arise from the thermal mismatch between composites and adhesives, an aspect that has not been adequately addressed in the literature. Thus, appropriate thermal expansion coefficients are assigned to both composites and adhesives. Furthermore, a cool-down is simulated before mechanical loads to mimic the temperature transition from curing to room temperature. A very good agreement is observed between the experimental and numerical results. A satisfying correlation is also observed between the FE analysis and the DIC, further verifying the effectiveness of the proposed modelling strategy.

1. Introduction

Thick adhesive joints are used to create bonds between the two halves of the wind turbine blades [1]. Adhesive bonding offers remarkable durability, resilience to fatigue, and the ability to distribute stress evenly in the joined area, but it also meets the requirement for lightweight blades. [2]. Despite these advantages, the failure of the thick adhesive joints in the trailing edge of the wind turbine blade compromises the structural integrity of wind turbines [3–6]. Understanding the mechanisms of mode I failure in adhesive joints is crucial for efficiently designing wind turbine blades [7,8]. Therefore, the current research uses a combined computational and experimental approach to investigate the mode I failure behaviour of the thick adhesive joints.

In this context, the elastoplastic mechanical properties of the adhesives, T-stresses and the existence of residual stresses influence the failure behaviour of adhesive joints [9,10]. The non-linear mechanical behaviour of commercial-grade adhesives can be ascribed to their epoxy content, which is well-known for its elastoplastic characteristics [11]. The residual stresses are primarily caused by the thermal expansion/contraction caused by the prevalent mismatch in the thermal expansion coefficients of the adherends and the adhesive during the post-curing cool-down [12–17]. The T-stress, which refers to the stress acting parallel to the crack plane in an adhesive layer that connects two adherends, significantly affects the directional stability of the crack path. Therefore, it is essential to evaluate the T-stress accurately to comprehend the crack propagation in thick adhesive joints. [18–20].

Finally, researchers usually create pre-crack in the thick adhesive joint specimens for the DCB tests [10,19,21]. To the best of the authors' knowledge, the current literature has not addressed the potential influence of pre-crack generation on the mode I behaviour of the thick adhesive joints. Therefore, the influence of the aforementioned factor was incorporated by creating virtual pre-cracks through Finite Element (FE) modelling. Subsequently, virtual DCB tests were performed on the aforesaid FE models. The FE results were thoroughly compared with experimental results to evaluate the accuracy of the modelling approach. The experimental campaign involved the Double Cantilever Beam (DCB) tests on Glass Fibre Reinforced Polymer (GFRP) composites bonded using an epoxy-based adhesive layer, which was pre-cracked in the middle. The computational results were extensively verified against the experimental results. The results obtained, as well as the insights from the findings, are presented below.

2. Experiments

2.1. Characterisation of materials

2.1.1 Adhesive

Tensile and compressive tests were performed on the bulk adhesive specimen to determine the material properties of the Sika power®-830 adhesive. The adhesive is categorised as epoxy-based. The compressive tests were conducted following the ASTM D695 standard. The tensile tests adhered to the ASTM D638-22 standard [10].

2.1.2 Composite

The adherends used in the current research were cross-ply ($[90/0]_{7s}$) GFRP Composite laminates. The UD glass fabric with an aerial weight of 425 g/m^2 was used as reinforcement. The infusion process utilised EPIKOTE Resin MGS RIMR 135 epoxy resin in conjunction with EPIKURE MGS RIMH 137 as the curing agent. The manufactured composite laminates had a fibre volume fraction of 50.8%. Experiments, as well as FE-based homogenisation, were carried out to obtain the elastic properties of the cross-ply GFRP composite laminate. In addition, Table 1 and Table 2 display the properties of the adhesive and composite.

2.2. Double Cantilever Beam tests

The samples consisted of two composite adherends joined together by the adhesive layer (Figure 1a). The specimen was heated to 70 °C and maintained at that temperature for four hours for curing. More details regarding the manufacturing method can be found in the study by Fan et al. [10]. Figure 1b shows the experimental setup. The adhesive layers in each specimen had a pre-crack. The pre-crack length a_0 varied from 24 mm to 52 mm. Also, all the pre-cracks had a thickness of ~1 mm. The crack length (a_0) for each specimen were: 24 mm for specimen-1, 29 mm for specimen-2, 34 mm for specimen-3, 39 mm for specimen-4, 48.5 mm for specimen-5, and 52 mm for specimen-6. The rest of the dimensions remained the same.

3. Computational simulations approach

The Finite Element (FE) models of the DCB specimens were meshed with 8-noded hexahedral elements with reduced integration (C3D8R). The dimensions of the FE models were the same as the experimental specimens. As shown in Figure 2, the X-direction is the direction parallel to the crack plane. The Z-direction is along the thickness of the DCB FE models. Finally, the Y-direction is along the width. Note that six FE models were created from the aforesaid model through the virtual pre-crack generation, each corresponding to specimens 1 to 6.

The adhesive and composite sections of the model were assigned appropriate material models. The adhesive was assigned with the built-in Abaqus Drucker-Prager plasticity model and the ductile damage criterion in combination. The details of the above models are given in [22]The built-in isotropic thermal expansion model was used to compute the thermal stresses in the adhesive. The composite was assigned a linear elastic and orthotropic material model. In addition, the orthotropic thermal expansion model was used to compute the thermal stresses in the composite. In the devised simulations approach, the model was first exposed to a thermal load representing the specimen's cooling down process.

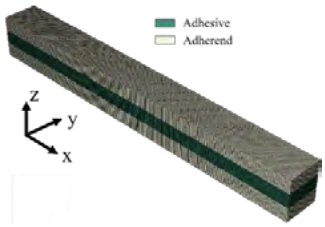

Figure 2. Finite element model for the DCB specimen.

Then, a pre-crack was created by eliminating the relevant elements from the adhesive layer. Finally, mechanical forces were applied to trigger mode I failure. Thus, the simulations were performed in three stages: i) application of thermal load, ii) creation of a virtual pre-crack, and iii) mechanical load application. The first two stages of the simulations were carried out in Abaqus/standard module. Subsequently, the results from the end of the pre-crack generation stage were imported into Abaqus/explicit. The mechanical loads were applied using the Multiple Point Constraint available in Abaqus. The mass scaling factor 0f 1000 was utilised in this step. The ratio between kinetic and internal energy in the third step needed to be low to maintain the quasi-static nature of the FE simulations. The aforementioned ratio was significantly below the recommended allowable limit of 10% [23], ranging from 1-4% for all the numerical results presented in this paper. The boundary conditions of each step are highlighted in Figure 3. The following sections describe the results relevant to each step.

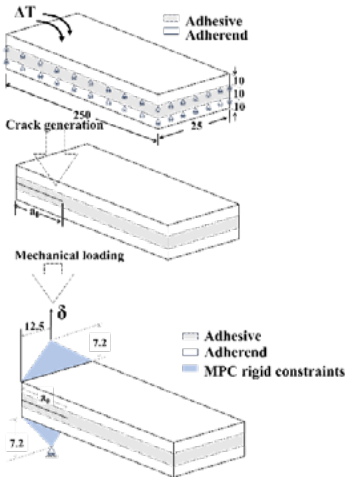

Figure 3. Description of the applied boundary conditions on the DCB FE model

4. Results and discussion

4.1 Effect of thermal loading

The FE model was subjected to a temperature difference of -50 °C. Due to thermal loading, the composite experienced a thermal strain of -747 με (THE_{XX}), while that in the adhesive layer was -391 με. Also, the thermal strain observed in the through-thickness direction (THE_{ZZ}) was -1900 με. The aforesaid thermal strain contours are highlighted in Figure 4.

a) b)

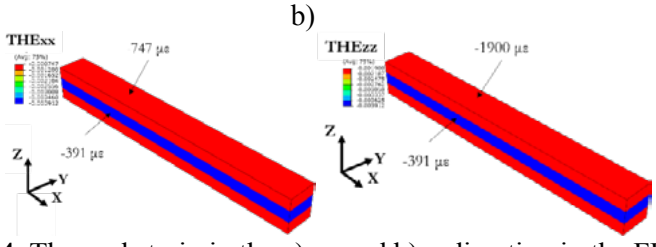

Figure 4. Thermal strain in the a) x- and b) z-direction in the FE model

4.2 Effect of pre-cracking

The thickness of the pre-crack was set at 1 mm, which corresponded to the thickness of the saw employed to produce the pre-crack in the experimental samples. Furthermore, the element size in the adhesive layer of the FE models was set at 1 mm. Therefore, after removing the elements at the location of the pre-crack, the resulting virtual pre-crack had a thickness of 1 mm. Figure 5 highlights the subsequent stages of the virtual pre-crack generation. The stress contours shown belong to the surface Y=0. The through-thickness stresses in the middle of the adhesive layer were approximately 7-12 MPa when the virtual pre-crack was first formed. The virtual pre-crack generation led to unbalanced forces. As a result, the adhesive surfaces on either side of the crack tried to move closer together. The stress values mentioned earlier became negative, approximately -2.5 MPa, due to stress redistribution. The crack closure continued until the mechanical equilibrium was reinstated. At the end of the virtual pre-crack generation, the compressive through-thickness stresses reached -17 MPa (Figure 5).

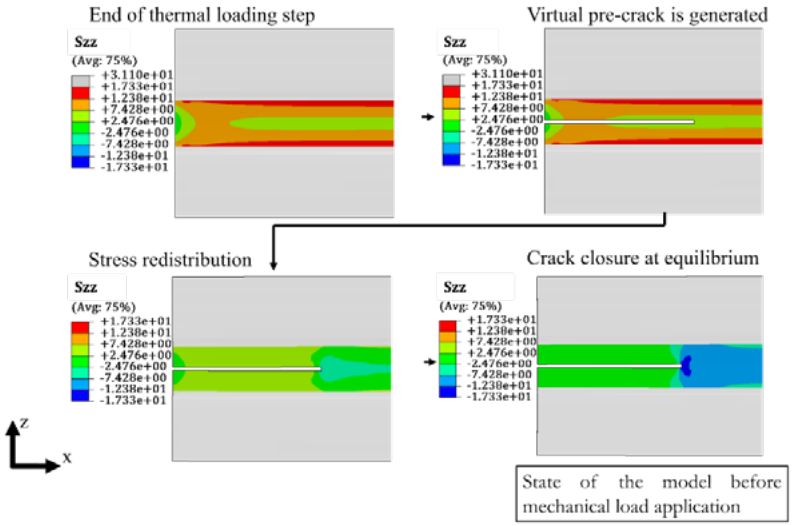

Figure 5. Effect of the virtual pre-crack generation on stresses at the crack tip

4.3 Load-displacement curves

The load-displacement curves for the FE simulations were created by plotting the vertical reaction force of the loading point against the relative displacement between the loading point and the bottom fixed point (refer to Figure 3) for each crack length.

To emphasise the influence of the adhesive's plasticity on the overall mode I behaviour, Figure 6a displays the plastic strains at different increments of the FE simulation of specimen-1. According to the figure, the plastic strain reached its highest value at the crack tip. Once the plastic strain near the crack tip reached a value of 0.0118, the same as the adhesive's plastic strain at failure, the damage to the elements near the crack tip began. Due to a very low fracture energy of 0.001 N/mm, the damage at the crack-tip element quickly evolved, resulting in the continuous removal of the adjacent elements at the crack-tip. During the loading process, the plastic strain of the adjacent elements along the line parallel to the crack tip consistently reached the point of failure strain. As a result, these elements were continuously removed, resembling the propagation of a crack. Figure 6a clearly shows that the crack extended through the centre of the adhesive layer (refer to 'crack propagation' in Figure 6a).

Figure 6b compares experimental and numerical load versus displacement curves. The FE simulations predicted load-displacement curves that matched the experimental results, and the crack length influenced the slope of the numerical load-displacement response. Thus, Figure 6b shows that the FE results correlate well with the experimental specimen behaviour.

a) b)

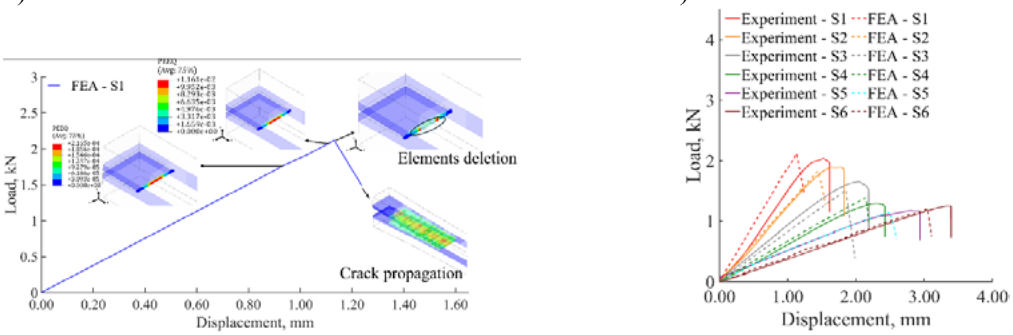

Figure 6. Finite Element Analysis (FEA) and experimental results: a) Evolution of the plastic strain around the crack tip; b) FEA versus Experimental load-displacement curves

4.4 Comparison with DIC

The displacement contours were extracted for specimen-3 for the load step at which the maximum load occurs during the experiment (i.e., peak-load step). Three linear trajectories were established in the experimental sample and FE model of specimen-3 [Figure 7 (a, b)]. Subsequently, the vertical displacements along the top trajectory (V^{top}) and the bottom trajectory (V^{bottom}) were extracted using DIC. The relative displacement (V^{top} - V^{bottom}) was calculated and plotted against the horizontal distance (in the X-direction) from the crack tip in the specimen. Relative displacement was favoured over absolute displacement to avoid the influence of rigid body movements during the experiments. Later, the abovementioned process was repeated for the FE model.

a) b)

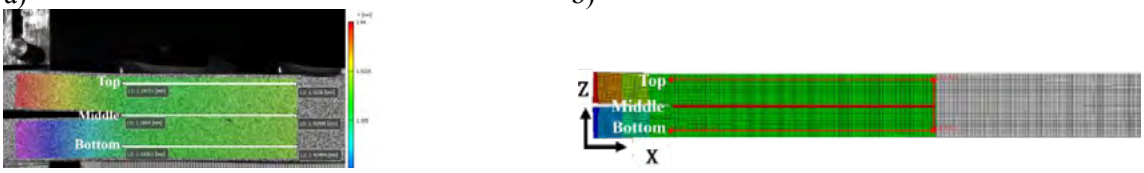

Figure 7. Description of trajectories for a) an experimental specimen and b) an FE model

The comparison between Finite Element Analysis (FEA) and DIC highlighted a significant discrepancy (Figure 8a). In the abovementioned scenario, the FE simulations were once again carried out, and the deformations resulting from thermal loads and the subsequent stress redistribution were neglected, similar to the DIC analysis. This was accomplished by deactivating the result update while importing the FE results into the Abaqus/explicit [24]. Figure 8b shows that upon removing the influence of the factors above, the relative displacements obtained from the FE model were consistent with those obtained from DIC.

a) b)

Figure 8. Relative displacement versus distance from crack tip plot a) FEA with the influence of thermal load and pre-cracking b) FEA without the influence of thermal load and pre-cracking around the crack tip

5. Conclusion

The present computational approach is unique for its capability to simulate thermal loading and generate virtual pre-cracks. The generation of virtual pre-cracks caused the adhesive surfaces to close, resulting in stress redistribution. Due to the virtual pre-cracking, the tensile opening stresses at the crack tip were transformed into compressive stresses. A notable difference between the FEA- and DIC-based results was observed. However, ignoring the influence of thermal loads and virtual pre-crack generation in an FE simulation yielded numerical results that matched the results provided by the DIC. Additionally, the FE models accurately predicted experimental load-displacement curves. The crack length significantly influenced the slope of both experimental and numerical curves, with longer cracks resulting in decreased slopes. Moreover, crack propagation was governed by the adhesive's plastic deformation. The strong correlation between the experimental and computational results confirms the effectiveness of the proposed modelling strategy.

Abstract

The tensile properties and resulting damage mechanisms observed in three-dimensional four-directional (3D4d), three-dimensional five-directional (3D5d) and three-dimensional six-directional (3D6d) braided composites have been studied experimentally and numerically. Finite element (FE) models have also been established using a continuous damage mechanics methodology, with user-defined subroutines being developed to define the damage criteria and the associated stiffness degradation in the yarns and matrix. The bridging and Chamis models are used to define the mechanical properties of yarns. The proposed method is then used to predict the tensile properties and damage development in these novel 3D braided composites. The FE models are subsequently validated by comparing the results of the simulations with experimental data. It has been shown that the maximum longitudinal tensile strength is associated with the 3D4d braided composites, whereas the maximum longitudinal tensile modulus is exhibited by the 3D5d braided composites. In contrast, the 3D6d braided composites exhibit the lowest values for each of these test parameters. It has been shown that the 3D4d braided composites tend to fracture along the braiding angle, whereas axial splitting occurs in the 3D5d braided composites and transverse failure predominates in the 3D6d braided composites.

1. Introduction

Three-dimensional (3D) braided composites are currently attracting significant attention in both the academic and industrial sectors due to their high specific strength and modulus, exceptional impact resistance, and design versatility [1-4]. However, their complex meso-structure frequently results in a mechanical behavior that is challenging to predict [5]. Therefore, it is necessary to study the mechanical properties and damage mechanisms of such composites in order to guide their design and use in load-bearing applications.

Recently, a number of studies have been undertaken to experimentally investigate the mechanical properties of 3D braided composites [6-8]. In addition to investigating the quasi-static mechanical properties of three-dimensionally braided composites [9-11], their response to complex loading and environmental conditions has also been studied in the past [12-14]. In addition, the damage mechanisms occurring in 3D braided composites has been analyzed using acoustic emission (AE), computed tomography (CT), scanning electron microscope (SEM) and other advanced tools [15-17]. Measuring the mechanical properties and subsequent internal failure processes in braided composites is both expensive and challenging. Additionally, these properties are known to vary with changes in the braiding

angle and fiber volume fraction [18, 19]. As a result of their high accuracy and cost-efficient nature, finite element (FE) models are regularly used to study the mechanical behavior of 3D braided composites [20-23]. For example, Du et al. [24] developed a parametric FE model for a 3D6d braided composite. Their investigations highlighted a reduction in the longitudinal mechanical properties of such composites with increasing braiding angle. In contrast, increasing the fiber volume fraction resulted in an increase in these properties. Li et al. [25] found that decreasing the braiding angle and increasing the fiber volume fractions lead to notable enhancements in the strength and modulus of the 3DR5d braided composites. In summary, the previously-mentioned studies mainly focus on the variation of mechanical properties with void content, fiber volume fraction and braiding angle. However, the effect of modifying the braiding architecture on the mechanical properties of 3D braided composites is also likely to be significant and should be studied.

This paper describes the development of FE models for 3D4d, 3D5d, and 3D6d braided composites, with the aim to investigate the effect of varying braiding architecture on mechanical response. The FE models are used to predict the mechanical properties and damage behavior of these three braided composites under longitudinal tensile loading, and the models are then validated against experimental data. Differences in the tensile properties and resulting damage mechanisms observed in the different braiding architectures are investigated in detail.

2. Materials and geometric structure

2.1. Materials

In the present study, 3D braided composites, with a theoretical internal braiding angle of 20° are investigated. These braided composites are designated as 3D4d-20°, 3D5d-20° and 3D6d-20°. The 3D braided fabrics were prepared using T700-3K carbon fiber yarns (Toray®, Tokyo, Japan) through the 4-step 1×1 procedure [26]. The preforms were then impregnated using with a TDE86 resin matrix (Jingdong®, Tianjin, China) [27] the resin transfer molding (RTM) technique.

These 3D braided composites comprise of fiber bundles and a matrix, which can be considered to be transversely-isotropic and isotropic, respectively. Tables 1 and 2 present the mechanical properties of the carbon fibers and epoxy resin investigated here. The impregnated fiber bundle is composed of fibers and matrix and its mechanical properties can be calculated using the bridging model [28] and Chamis model [29].

2.2. Geometric structure

As a result of the periodic nature of 3D braided composites, it is possible to predict their mechanical properties by selecting a representative volume element (RVE), and in doing so, greatly improve the calculation efficiency. The geometric relationships between the yarns in the RVE are shown in Fig. 1.

It is evident that differences in three braiding architectures are associated with the presence of axial yarns or warp yarns. The braiding yarns 1, 2 ,3 ,4 signify that the braiding yarns have four different distribution patterns in a 3D space. Considering the extrusion deformation of the yarns, several assumptions are applied to model the geometrical configurations in this study, as proposed by Li [25]. The braiding yarns are assumed to have hexagonal cross-sectional shapes, the axial yarns are presumed to be square and the warp yarns are assumed to have a quadrilateral configuration.

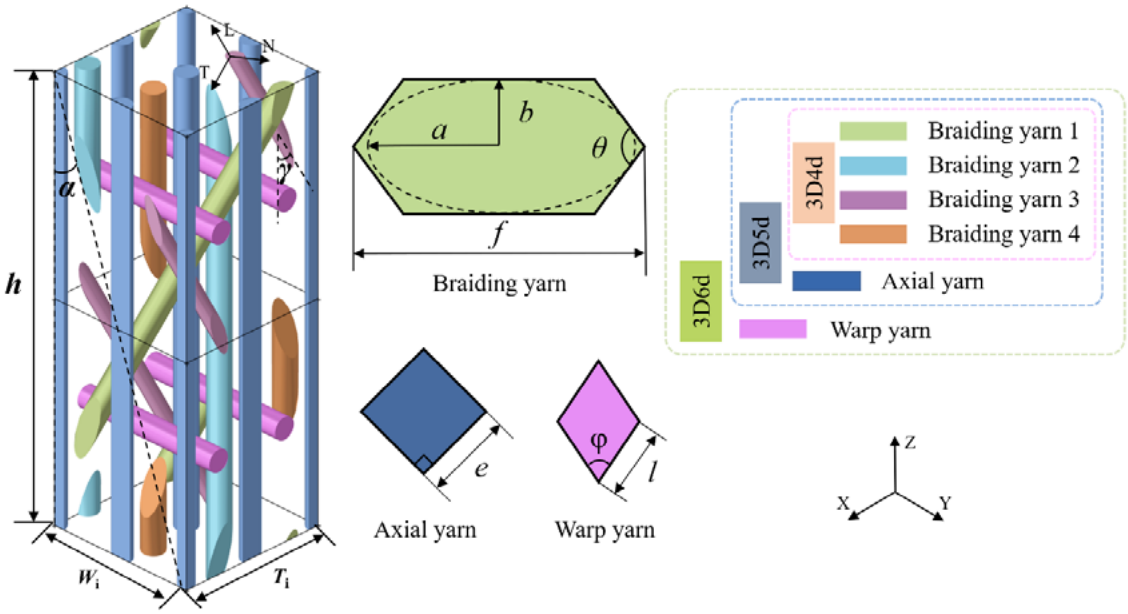

Fig. 1. RVE structure of the braided composites

Parameters, such as the width (W_i), thickness (T_i), height (h) and internal braiding angle (γ), are used to define the size of the RVE. The relationships between these parameters are given in Eqs. (1) - (3).

$$W_i = T_i = 2\sqrt{2}(2+r)b \tag{1}$$

$$\tan\gamma = \frac{\sqrt{2}W_i}{h} \tag{2}$$

$$\tan\alpha = \frac{\sqrt{2}}{2}\tan\gamma \tag{3}$$

where r represents the section factor of the axial yarn, which should be zero in the 3D4d composite model; b is the short half-axis of the cut ellipse in the braided yarn section. The geometrical relationships of the yarns can be inferred as follows.

$$a = b\sqrt{r^2+4r+3}\cos\gamma \tag{4}$$

$$\theta = 2\arcsin\left(\frac{1}{\sqrt{1+\cos^2\gamma}}\right) \tag{5}$$

$$f = 2b\cos\gamma \tag{6}$$

$$e = rb \tag{7}$$

$$l = \frac{1}{2\sin\alpha}\left(\frac{W_i}{2} - \frac{a\sin\theta}{\cos\alpha}\right) \tag{8}$$

$$\varphi = 2\alpha \tag{9}$$

where a is long half-axis of the cut ellipse in the braided yarn section; θ and f are the incline angle and side length of the hexagon; e and l are the side length of the axial and warp yarns.

Based on the equations outlined above, the parameterized RVE of each of the 3D braided composites can be created using SolidWorks software. Periodic meshing is required, as periodic boundary conditions need to be imposed on the established RVE models. The 3D four-node tetrahedral (C3D4) element is chosen to mesh the RVE models using the Hypermesh software to generate the periodic meshes.

3. Numerical Model Implementation

3.1. Failure criteria

The stress states in the fiber bundles and the matrix in different regions are unequal since the meso-structure of a 3D braided composite is complex, but they are closely related to each other, which determines the complexity of the damage process in the 3D braided composites. Therefore, a suitable damage criterion is required to accurately predict damage initiation based on the mechanical properties of the composites. In the current study, the Hashin criterion [30, 31] was used to predict tensile damage in the fiber bundles in the L-direction. This approach has been used with great success in previous studies. For the T and N-directions, the Hou failure criteria [32] are adopted. The matrix was modelled using Christensen's criterion [33], which can be used to predict damage and yielding in isotropic materials subjected to various stress states. And a bilinear constitutive relation was determined to describe the constitutive responses before and after failure in the composites. Then, the progressive damage model was implemented through a user-defined subroutine (UMAT) coded in Fortran within the commercial software ABAQUS 2021 [34].

3.2. Boundary conditions

In order to accurately analyze the mechanical properties of three-dimensional braided composites, it is necessary to establish the exact boundary conditions of the RVE. Based on the symmetry of the material microstructure, Li et al. [35, 36] proposed periodic boundary conditions, which ensure that the unit cell satisfies stress continuity and deformation coordination at the same time. In this paper, the nodal displacement constraint relationships for symmetric nodes on parallel faces were imposed using a Python script within ABAQUS 2021 [34]. Finally, the average stress and strain were determined through the following equations.

$$\begin{aligned} \bar{\sigma}_{ij} &= \frac{1}{V}\int_V \sigma_{ij}\mathrm{d}V \\ \bar{\varepsilon}_{ij} &= \frac{1}{V}\int_V \varepsilon_{ij}\mathrm{d}V \end{aligned} \tag{10}$$

where V is the volume of RVE.

3. Results and Discussion

3.1. Mechanical properties

The predicted longitudinal tensile responses of the three different braiding architectures were compared with the experimental data to validate the proposed FE models, in Table 3 and Fig 2. It is evident that the predicted stress-strain curves initially exhibit linear growth with increasing strain, followed by a

rapid drop at the peak stress. The model clearly predicts that the three composites fail in a brittle fracture manner, which is consistent with the experimental observations. It is worth pointing out that the greatest error between the FE simulation and the experimental results remains less than 5 %.

Table 3. Comparison of the predicted results with the experimental data

Test	Strength (MPa)			Modulus (GPa)		
	FE	Exp	Relative error	FE	Exp	Relative error
3D4d-20°	1123.95	1079.35	4.13 %	112.17	117.42	-4.47 %
3D5d-20°	951.65	960.66	-0.94 %	114.41	120.13	-4.76 %
3D6d-20°	787.76	754.34	4.43 %	94.78	98.44	-3.72 %

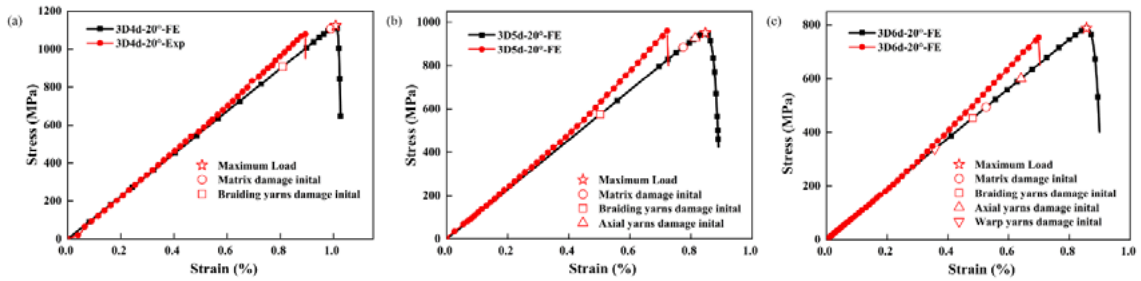

Fig. 2. Comparison of the predicted results with the experimental data (a) 3D4d-20°, (b) 3D5d-20° and (c) 3D6d-20°

The mean and variance of longitudinal tensile properties of the three types of 3D braided composite are compared in Fig. 3. An examination of the figure shows that the highest tensile strength is associated with the 3D4d-20° composite, whilst the 3D5d-20° exhibits the highest tensile modulus. The tensile strength of the 3D5d-20° composite is only 3%lower than the 3D4d-20° composite, whereas its tensile modulus is almost 14% greater. This evidence suggests that the axial yarns exert only a minimal influence on the longitudinal tensile strength, but have a much greater effect on the longitudinal tensile stiffness of these 3D braided composites. The tensile strength and modulus values of the 3D6d-20° composite are the lowest of those measured here, being approximately 21 %, 12 % lower than its 3D5d-20° counterpart, respectively. This suggests that the warp yarns reduce the tensile properties of these 3D braided composites.

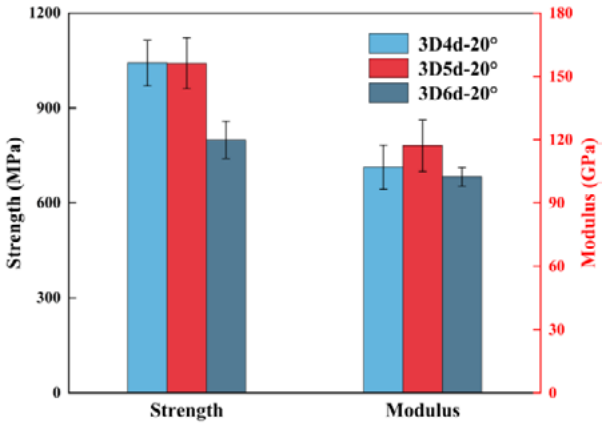

Fig. 3. The longitudinal tensile strength and modulus of the 3D braided composites

3.2. Damage mechanisms

Figs. 4 (a)-(c) present the external damage morphologies in the three braided composites under tensile loading. Here, the predominant tensile failure modes in the 3D4d-20° braided composite are fiber fracture perpendicular to the loading direction and tension-shear failure roughly parallel to the internal braiding angle. The effect of the braiding yarn on the failure mode is readily apparent. For the 3D5d-20° braided composite, the damage mode is mainly fiber fracture perpendicular to the loading direction and splitting along the longitudinal direction, suggesting that the axial yarns play a major role. For the 3D6d-20° braided composite, the warp yarns prevent crack propagation in the longitudinal direction, so that transverse fiber fracture occurs. Figs. 4(d)-(e) show the predicted damage patterns, which agree well with the experimental results. These findings suggest that the proposed FE models are capable of accurately predicting the mechanical behavior of these 3D braided composites under longitudinal tensile loading.

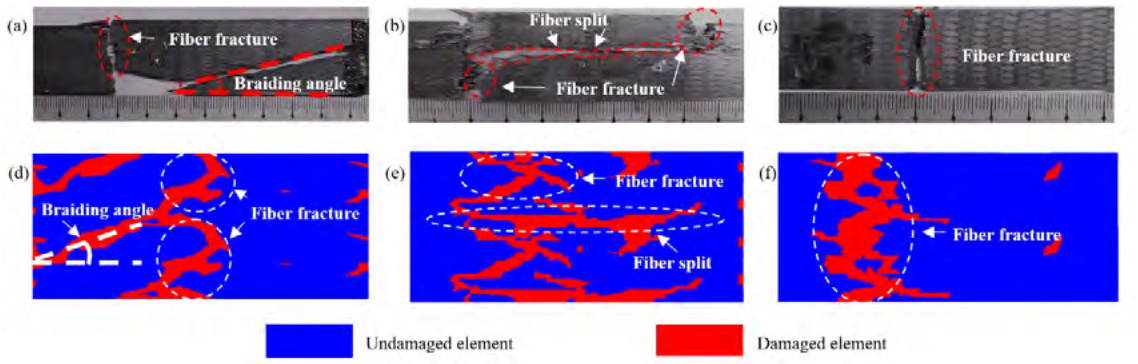

Fig. 4. Longitudinal tensile fracture morphology (a) 3D4d-20° (Exp), (b) 3D5d-20° (Exp), (c) 3D6d-20° (Exp), (d) 3D4d-20° (FE), (e) 3D5d-20° (FE), (f) 3D6d-20° (FE)

4. Conclusions

The longitudinal tensile responses of three types of braided composite have been studied both experimentally and numerically. Finite element models have been developed and validated against the corresponding experimental results and the damage mechanisms occurring in the composites have been highlighted. It has been shown that the tensile strength of the 3D4d-20° braided composite and the tensile modulus of 3D5d-20° braided composites are the highest among the three composites, whereas the 3D6d-20° braided composite exhibits the lowest strength and modulus. The difference between the tensile strength of the 3D5d-20° and 3D4d-20° composites is less than 3%. This suggests that the axial yarns enhance the longitudinal tensile stiffness of 3D braided composites, but the warp yarns weaken the longitudinal tensile mechanical properties.

The tensile damage mechanisms differ between the three braided composites, due to the presence of the axial and warp yarns. In the 3D4d composites, the braiding yarns play a major role in determining the tensile response. The observed damage modes are therefore fiber fracture perpendicular to the loading direction and tension-shear failure along the braiding angle. The failure patterns observed in the 3D5d composites are dominated by fiber fracture perpendicular to the loading direction and longitudinal cracking. This is attributed to the influence of the axial yarns, which direct the evolution of damage along them. In contrast, the failure modes observed in the 3D6d composite are characterized by fiber fracture along the transverse direction, primarily due to the abrupt failure of the warp yarns during initial loading.

Abstract
For strengthening or rehabilitation of existing structures, patches of fiber-reinforced polymers (FRP) materials are being adhesively bonded to the existing metallic structures. So far, Carbon FRP (CFRP) are the main composite materials industrially implemented for metal structural reinforcement, due to their reliability and high mechanical performances. However, multiple researchers have highlighted the negative environmental impact of synthetic composite materials, and interest is shifting towards the use and development of bio-based composite materials. This paper presents an FE numerical investigation of the use of Hybrid Carbon/Flax FRP as an alternative solution for structural reinforcement of steel plates under flexural loading. Four different configurations of patches are studied to be bonded to steel rectangular plates, and three point bending tests are numerically modelled to simulate the flexural behaviour of the assemblies. Compared to the unreinforced steel plate baseline, reinforcements C5, F5, CFFFC, and FFFCC exhibited improvements of 149%, 120%, 137%, and 145% in bending stiffness, respectively.

1. Introduction

Advanced composite materials have been employed in the civil engineering industry for many years [1]. One of the most popular use of composites in the civil engineering field is the repair and upgrading of beams in bridges and buildings. Although not as widespread as the upgrading of reinforced concrete structures, carbon fiber reinforced polymer (CFRP) is becoming a very attractive solution for the retrofitting of metallic beams, especially for cases where there are severe access constraints, or associated high costs with installation time [2]. Various research findings have established the effectiveness of strengthening metallic structures by bonding CFRP strips and proved that the load-carrying capacity and post-yielding flexural stiffness of steel beams can be significantly improved [2,3,4]. Design guidance documents have been published regarding the use of CFRP for the rehabilitation and upgrading of metallic civil engineering structures by CIRIA [5] and ICE [6].

©2024 | 3_TAZI_Mohamed Amine_2MIF4.pdf

Nevertheless, researchers have lately highlighted the important negative environmental impact of synthetic composite materials, and interest is shifting towards the use and development of natural-based composites [7]. Flax fiber has attracted increasing attention as a reinforcement material because of its low environmental impact, weight and cost compared to traditional carbon or glass fiber. The main drawbacks of flax fibers, like many other natural fibers, are their lower mechanical properties (elastic module, strength, etc.), and poor hygrothermal behavior. Natural fiber reinforced polymers (NFRP) are therefore limited to sub-structural applications such as interior automotive or aircraft parts, sports, music instruments, among others [8].

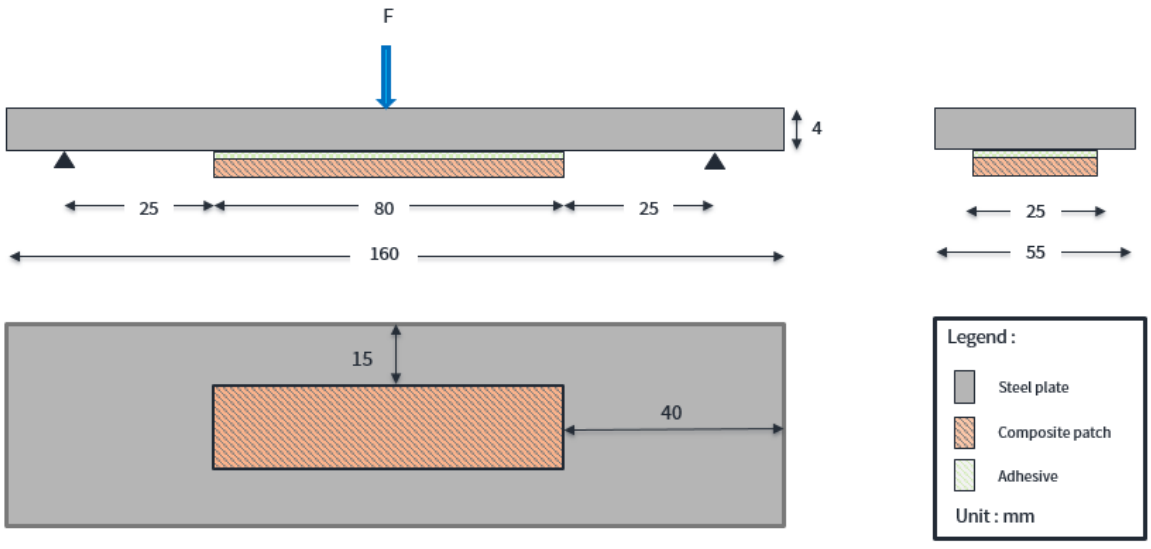
Hybridizing flax and carbon fibers is considered an interesting and effective method to overcome the mechanical shortcomings of flax fibers. By investigating the right hybrid modes and stacking sequences, hybridization technique may combine the advantages of both flax fibers (environmental friendliness, low cost) and carbon fibers (higher mechanical properties and hygrothermal resistance).

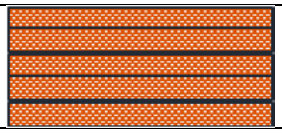
In this paper, a 3D solid FE model was built, to investigate the flexural behavior of a steel rectangular plate, reinforced by bonding a composite patch on its tension flange. Four different patch configuration consisting of CFRP, FFRP and hybrid Carbon/Flax composites are studied. Three point bending tests are numerically simulated to assess and compare the flexural stiffness values of the modelled specimens.

2. FE Modelling

2.1. Model description

A 3D solid model is designed to investigate the flexural behaviour of a steel rectangular plate, reinforced by bonding a smaller rectangular composite patch to its tension flange. Three point bending tests are modelled to assess the flexural gain of the assemblies and compare them to those of a non-reinforced reference steel plate. Figure.1 presents the geometries of the designed specimens and their dimensions. Four different composite configurations are studied, and consist of either carbon fiber reinforced epoxy (CFRP), flax fiber reinforced epoxy (FFRP), or hybrid carbon-flax reinforced epoxy. All modelled composite patches contain five plies. According to a previous work from the authors [9], and a study by Wang et al. [10], CFRP and FFRP plies are chosen to be 0.3mm and 0.5mm thick, respectively. Table.1 presents relevant details of the used configurations.





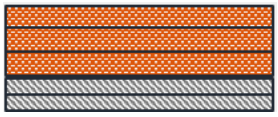


Figure 1. Schematic of a composite-strengthened steel plate.

Table 1. Composite patch configurations.

Configuration name	Representation	Nominal thickness [mm]	CFRP relative thickness	Number of CFRP plies	Number of FFRP plies
C5		1.5	1.5	5	0
F5		2.5	0	0	5
CFFFC		2.1	0.6	2	3
FFFCC		2.1	0.6	2	3

2.2. Material properties

2.2.1. Steel

A36 steel is a very commonly used material in bridge construction, and is chosen as the metallic substrate to be reinforced. Since the purpose of the study is to assess flexural gain, its behaviour is approximated with a simple bilinear elastic-plastic law, in accordance with material properties provided by the American Society of Testing and Materials (ASTM A36 Steel) [11]. Figure.2 displays the stress-strain behaviour and table.2 summarizes the used steel mechanical properties for FE modelling.

Figure 2. Stress-Strain bilinear law for A36 Steel.

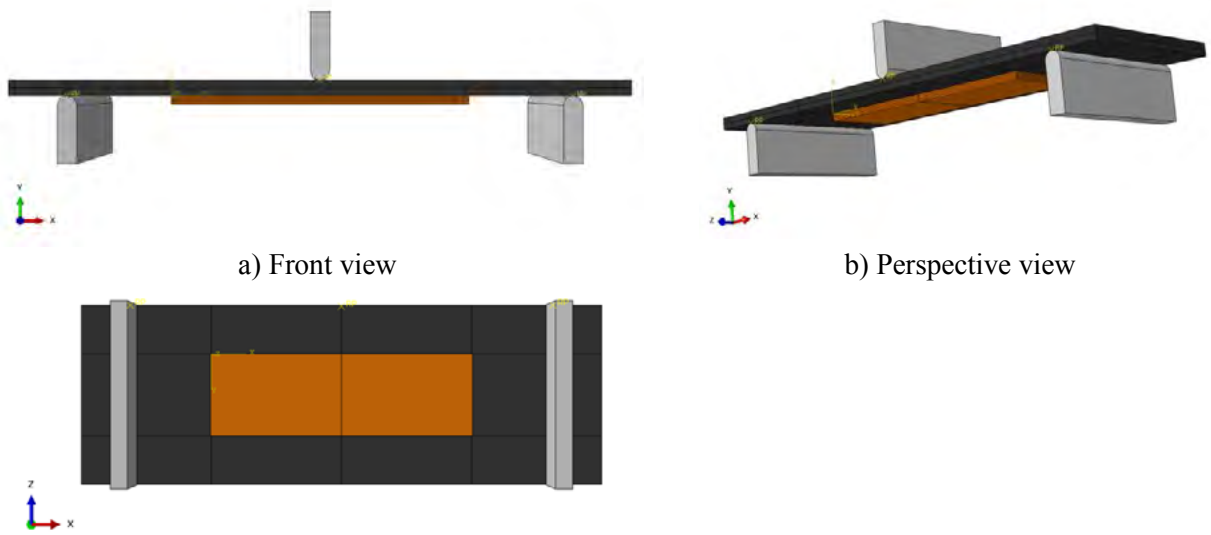
Table 2. Mechanical properties of A36 Steel and adekit a-140 adhesive.

Mechanical properties	Value	
	A36 Steel	Adekit a-140
Young's Modulus [GPa]	200	2.5
Poisson Ratio	0.26	-
Yield Tensile Strength [MPa]	250	-
Ultimate Tensile Strength [MPa]	450	30

2.2.2. Composite patch

Unidirectional carbon fibers and bidirectional flax fibers with an epoxy matrix are used as reinforcement materials for the steel substrate. Table.3 summarizes their mechanical elastic properties, which were experimentally characterized in previous studies [12], [13]. We note that all laminates have 0° ply orientation relative to the longitudinal axis of the steel plate.

Table 3. Mechanical properties of composite materials.



Mechanical properties	Symbol	Values	
		CFRP	FFRP
Elastic tensile Modules [GPa]	E_1	105.5	13.81
	E_2	7.2	13.81
	E_3	7.2	5.32
Shear Modules [GPa]	G_{12}	3.4	1.58
	G_{13}	3.4	1.64
	G_{23}	2.52	1.64
Poisson ratios	ν_{12}	0.34	0.144
	ν_{13}	0.34	0.51
	ν_{23}	0.378	0.51

2.2.3. Adhesive (cohesive contact)

A cohesive contact interaction has been created between the top surface of the composite patch and the bottom surface of the steel substrate, to simulate the bond behaviour which would result from using the epoxy adhesive adekit a-140. Table.2 gives relevant mechanical properties of the adhesive. The cohesive zone was modelled as an elastic non-damageable interaction, because we are exclusively interested in assessing the flexural gain prior to debonding in this study. Traction-separation stiffness coefficients were all taken equal to the young's modulus of the adhesive, in accordance with the values provided by the supplier data sheet [14], $K_{nn} = K_{ss} = k_{tt} = 2500$ MPa.

2.3. Three point bending test

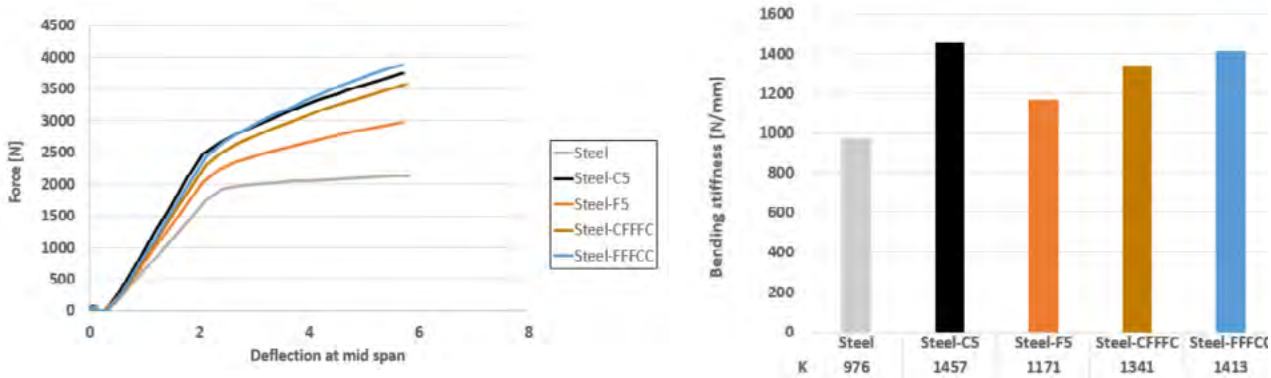
Three point bending test set up is designed to assess the flexural behavior of the reinforced steel plates. Figure.3 gives a visual representation of the CAE model. Fixtures were designed as rigid body parts. Contact interactions were created between the fixtures and the steel plate, and consist of a normal "hard" contact behavior and tangential friction behavior, with a friction coefficient equal to 0.15, as advised from literature for steel-steel contact [15]. 6mm displacement loads are imposed for all studied configurations.

a) Front view

b) Perspective view

c) Bottom view

Figure 3. Visual representation of the CAE model.



3. Numerical results and discussion

3.1. Force-deflection results

Figure.4.a) represents the force-deflection curves numerically obtained. In order to compare the flexural gain due to the bonding of the composite patches, we calculate the bending stiffness K within the elastic domain (between 0.5 – 2mm of deflection) with the following equation:

$$K = \frac{p}{w} \tag{1}$$

Where p is the applied load measured at the reference point of the moving fixture, and w is the deflection at mid span of the composite plate.
The bending stiffness values, depicted in Figure 4.b), highlight significant enhancements for steel plates reinforced with used configurations. Specifically, compared to the unreinforced steel plate baseline, reinforcements C5, F5, CFFFC, and FFFCC exhibit improvements of 149%, 120%, 137%, and 145% in bending stiffness, respectively. We note that the higher flax fiber ply thickness, acts like a geometrical compensation for their lower mechanical properties compared to carbon fiber plies.

a) Force-deflection curves

b) Bending stiffness for each configuration

Figure 4. Force-deflection simulation results.

3.2. Evaluation of zone of maximal stress

Figure.5 shows the longitudinal stresses S_{11}, along the thickness of the composite patches, at the end of the load history, for the four tested configurations. We notice that the patches are exclusively loaded in tension, which is due to the higher traction forces of the steel bottom flange compared to the compression of the composite patch top surface because of the curvature. From figure.5, we can also perceive that the highest stresses in the patches are contained in their bottom surfaces. This explains the high values of bending stiffness increase obtained with the CFFFC and FFFCC configurations.

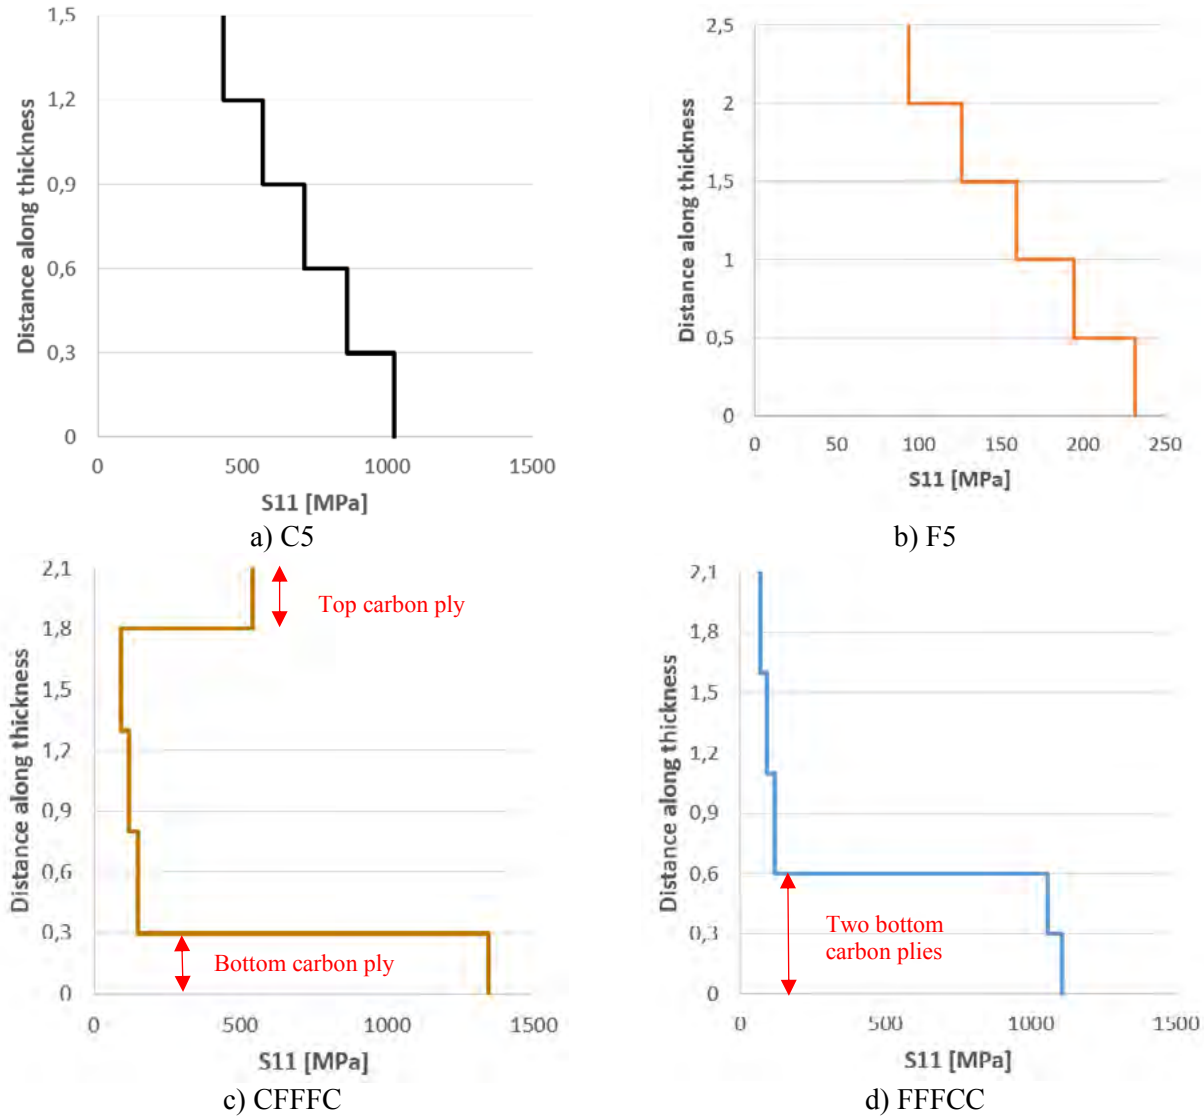


Figure 5. Distance along the thickness of the composite patches vs longitudinal stresses at mid-span

4. Conclusion

The aim of this work is to establish a finite element model to investigate the flexural stiffness gain of a steel plate reinforced by bonding a composite patch to its tension flange. Four different patch configurations consisting of CFRP and FFRP have been used, namely C5, F5, CFFFC and FFFCC. From the analysis of the obtained results, the following conclusions are drawn:

- Compared to the unreinforced steel plate baseline, reinforcements C5, F5, CFFFC, and FFFCC exhibit improvements of 149%, 120%, 137%, and 145% in bending stiffness, respectively. It is of interest to note that we achieve relatively close flexural stiffness gain with hybrid carbon/flax configuration compared to C5, while substituting 60% of carbon fibers with flax fibers.
- For various composite manufacturing processes, the choice of number of used fiber plies is the main design parameter. This study highlights the fact that natural fibers usually achieve a higher thickness per ply compared to synthetic composites, which is an interesting way of geometrically compensate their lower mechanical properties in flexural loading.
- FFFCC configuration showed the best mechanical performances after C5. Indeed, since both carbon plies are place at the bottom surface where maximal stresses evolve. Moreover, Flax fibers are the ones in contact with the steel interface, which limits risks of galvanic corrosion caused by carbon-steel contact.

Keywords: composite, fber reinforced, epoxy, flexibilizer, fracture toughness

Abstract
The goal of this work is to modify glassfiber-reinforced plastics (GFRP) with a procedure which has already increased the fracture toughness in tests with pure resin, while the glass transition temperature Tg was not decreased. To increase the fracture toughness, a flexibilizer is used. But instead of simply adding it to the resin and hardener, a procedure with a two-step synthesis is used. A prereaction of resin and flexibilizer leads to the formation of partially reacted substructures (PRS), which are fully crosslinked in the next step by adding resin and hardener, so that the PRS form as domains in the composite. By vary curing temperature, curing degree and weight portions of the PRS the best possible combination can be chosen. Dynamic mechanical thermal analysis (DMTA), SEM, and Double Cantilever Beam (DCB) analyses provide information on T_g, PRS size and interlaminar toughness G_{Ic}. The interlaminar toughness reaches a value of 490,05 ± 40,91 J/m^2, which is an increase of 38% compared to the reference of homogeniously distributed flexibilizer and 118% compared to specimens without any flexibilizer. T_g can be increased by 7% compared to the reference of homogeniously distributed flexibilizer.

1. Introduction

The fracture toughness as a characteristic value depends on the molecular structure. In contrast to elastomers and thermoplastics, thermosets have a dense polymer network. The dense cross-linking prevents plastic deformation during crack propagation, which is why thermosets are brittle and have a lower fracture toughness. One advantage, however, is their high adaptability to specific load cases. The fracture toughness can be increased through the use of flexibilizers. These react chemically in a similar way to normal hardeners, but are characterized by longer-chain molecules that expand the polymer network and lead to greater mobility. However, the increase in fracture toughness is accompanied by a reduction in thermal resistance and thus the glass transition temperature. As a reduction in important mechanical properties such as strength or stiffness occurs in this area, a high value for the glass transition temperature is important for the safe use of the component.

Sharifi et al [1] have developed a two-stage synthesis that eliminates this contradictory dependency and prevents a reduction in the glass transition temperature. Instead of mixing all components - resin, hardener and flexibilizer - directly with each other and allowing them to crosslink, pre-crosslinking of resin and flexibilizer takes place. Partially reacted substructures (PRS) are formed during pre-crosslinking. An intermediate step in the production process causes the resin and flexibilizer to pre-crosslink and form partially reacted substructures (PRS). In the composite, the PRS are then locally concentrated in spherical form, as can be seen in Figure 1.

(a) Statistically distributed flexibilizer units. **(b)** Locally concentrated flexibilizer units in domains.

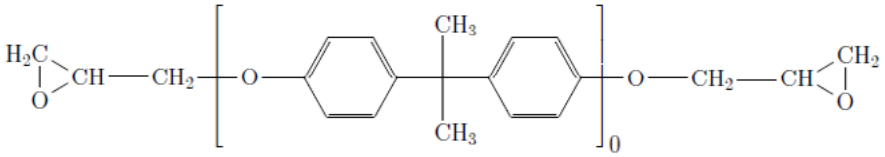

Fig. 1: Comparison of the schematic polymer networks of a (a) reference sample to the (b) Sample with formation of PRS domains based on [1].

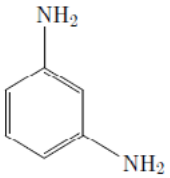
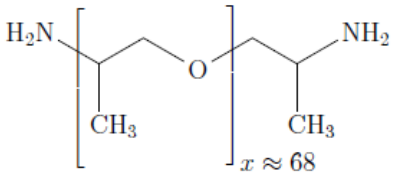
These are mixed with resin and hardener and fully cross-linked. This intermediate step in the production process causes domains of locally concentrated flexibilizer units to form in the composite. The aim of this work is to transfer and test this principle of two-stage synthesis to a composite with glass fibers. For this purpose, the formation of the PRS in the pure resin is first examined in two preliminary test series as a function of the previously selected influencing factors - crosslinking temperature, crosslinking time or degree of crosslinking, weight proportion of the PRS in the composite -. The most suitable combination of these parameters is produced as a glass fiber composite in the main series of tests and examined with regard to domain formation and the resulting characteristic values for fracture toughness and glass transition temperature.



2. Experimental approach

2.1. Materials



The resin used in this study is EPON 162 from HEXION, which belongs to the group of bisphenol A diglycidyl ethers (DGEBA).

The hardener used, DETDA 80 from Lonzacure, belongs to the group of diamine hardeners, which differ in the position of the amino groups. The mixture consists of approx. 80 % 3,5-diethyltoluene-2,4-diamine and approx. 20 % 3,5-diethyltoluene-2,6-diamine. In DETDA 80, the two amino groups are meta-positioned.

In addition, the flexibilizer JD-4000 from Huntsman is used. The repeating segments, which form no cross-links, create a flexibilizing effect.

For the main tests, glass filament fabrics from Interglas Porcher Industries are used for the reinforcement. The unidirectional fabric (Interglas 92145, Aero, FK 144, LW, UD) has a area weight of 220 g/m^2 and a warp thread in the 90° direction.

2.2. Processing

In the first series of preliminary tests, samples are prepared for combinations of crosslinking temperature, degree of crosslinking and a fixed weight proportion of the PRS.
First, the degree of crosslinking of the resin and flexibilizer is determined over time using the Netzsch Kinetics Neo software [2] in order to remove the pre-crosslinked PRS from the oven accordingly.

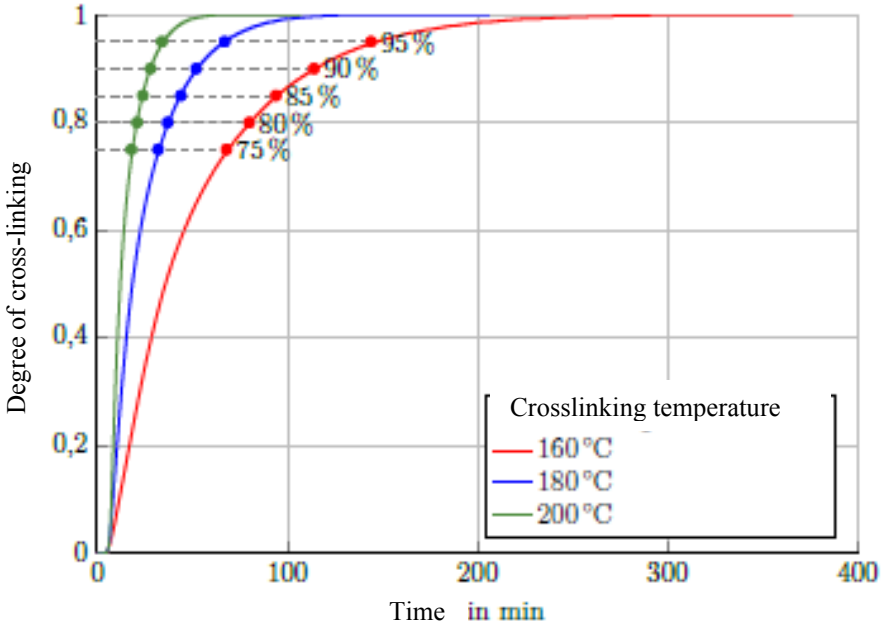


Fig. 2: Degree of crosslinking of the PRS of EPON 162 and JD-4000 simulated in Kinetics Neo at different crosslinking temperatures as a function of time.

The two components are mixed together superstoichiometrically (0.344 : 1) and mixed in a speed mixer at 3500 rpm for 2 min. For pre-crosslinking, the PRS are placed in an aluminum crucible in the oven, whereby three different crosslinking temperatures of 160 °C, 180 °C and 200 °C must be observed. The aluminum crucibles are removed from the oven at the predetermined times at the corresponding crosslinking levels of 75 %, 80 %, 85 %, 90 % and 95 % and cooled at room temperature. The PRS are then mixed with appropriate quantities of resin and hardener. Care must be taken to compensate for the over-stoichiometric proportion of the resin in order to achieve a stoichiometric mixture.
For the main series of tests, sheets of glass fiber reinforced plastic (GRP) with a unidirectional layer structure of $[0_{16}]$ are manufactured. The individual steps are illustrated in Figure 3. The individual matrix components are initially mixed as in the preliminary test series. However, the finished uncrosslinked mixtures are applied to the rollers of an impregnating roller mill in order to wet the individual glass fiber fabrics. The impregnating roller mill is made by EXAKT and is operated at room temperature with a gap width of 240 µm. The continuous rolling process removes air inclusions from the mixture. After

complete wetting, the fabrics are placed by hand on a Teflon foil covered metal plate and applied in the direction of the fibers using a roller. The metal plate ensures an even distribution of pressure and vacuum in the autoclave. After every four layers, an intermediate vacuum is applied for 7 minutes in order to achieve uniform consolidation and a reduction in air inclusions (debulking). In addition, after the eighth layer, two cut Teflon foils are inserted into the laminate, which later serve as artificial cracks in the tests. After the plates have been fully cross-linked in the autoclave and demolded, they are machined to the samples sizes needed.

Fig. 3: Sequence for manual lamination with (a) impregnation using a rolling process, (b) manual unrolling, (c) pulling intermediate vacuum, (d) vacuum bag for autoclave, (e) autoclave.

The samples are named according to the selected parameters. They are named in the following order: crosslinking temperature - degree of precrosslinking - weight percentage of PRS. Examples of sample naming are shown in Table 1.

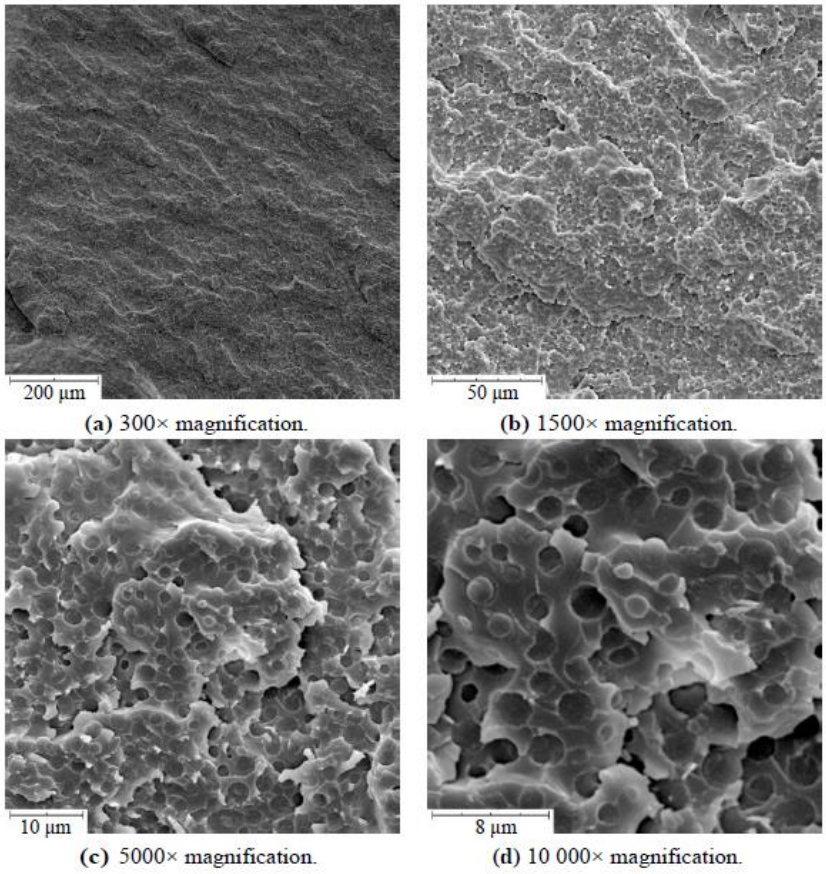

Table 1: Nomenclature of the samples used.

Sample name	Cross-linking temperature in °C	Degree of cross-linking in %	Weight percentage of PRS in wt%
160-75-20	160	75	20
180-80-10	180	80	10
200-95-20	200	95	20

In addition to the samples with PRS, references are also produced. The proportion of flexibilizer in these is the same as that contained in the samples with PRS. With a weight proportion of 30 wt%, the designations are accordingly Ref 30 or Ref 00 for samples without any flexibilizer.

3. Results and discussion

In this preliminary test series, not including the reference samples, 15 samples with combinations of crosslinking temperatures of 160 °C, 180 °C and 200 °C, crosslinking degrees of 75 %, 80 %, 85 %, 90 % and 95 % and a fixed weight fraction of PRS of 20 wt% were tested for the size of the PRS and the glass transition temperature. The PRS were evaluated with regard to their size using SEM analysis. On average, these were 1.57 ± 0.23 µm in size. As no trends were discernible and the size values were very close to each other, it can be assumed that different crosslinking temperatures and degrees of crosslinking did not have a significant effect on the PRS size. The DSC results also showed no significant differences in relation to the glass transition temperatures of the PRS samples. Here too, the crosslinking temperature and degree of crosslinking do not appear to have affected the measurement. As the 180-80-20 sample reached a maximum value of 214.7 °C, this parameter combination should be decisive for the next series of tests. With this combination, PRS with an average diameter of 1.66 ± 0.49 µm were determined. All samples produced from then on should therefore have a crosslinking temperature of 180 °C and a degree of crosslinking of 80 %.

Fig. 4: SEM images of sample 200-80-20 at different magnifications.

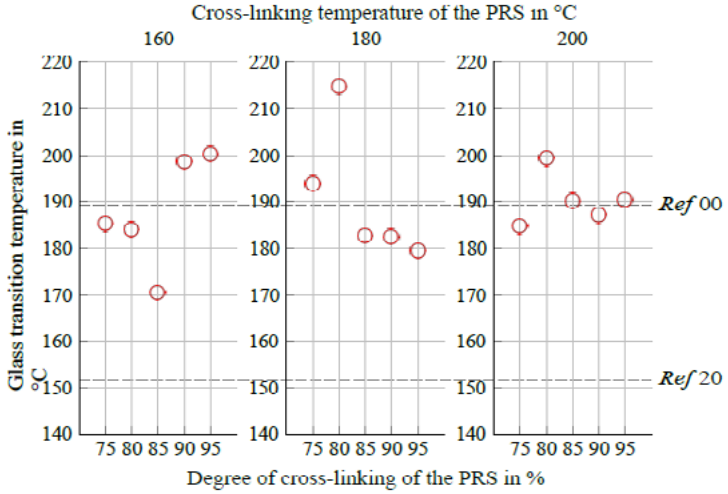

Fig. 5: Glass transition temperatures of the individual parameter combinations with a PRS weight fraction of 20 wt%.

In the second series of preliminary tests, the PRS sizes were influenced by the different weight proportions. Up to a weight fraction of 30 wt%, the size of the PRS increases from 0.91 ± 0.17 µm at 180-80-10 to a maximum value of 2.55 ± 0.72 µm. At 40 wt% the size decreases again, while in the 180-80-50 samples no more PRS can be determined. A significant trend can therefore be recognized, which leads to the largest PRS at 30 wt%. By forming the PRS, the glass transition temperature can be increased by around 20 °C to 30 °C compared to the corresponding reference. The flexibilizer units only

weaken the network locally and mean that the remaining polymer network can still exhibit high thermal resistance.

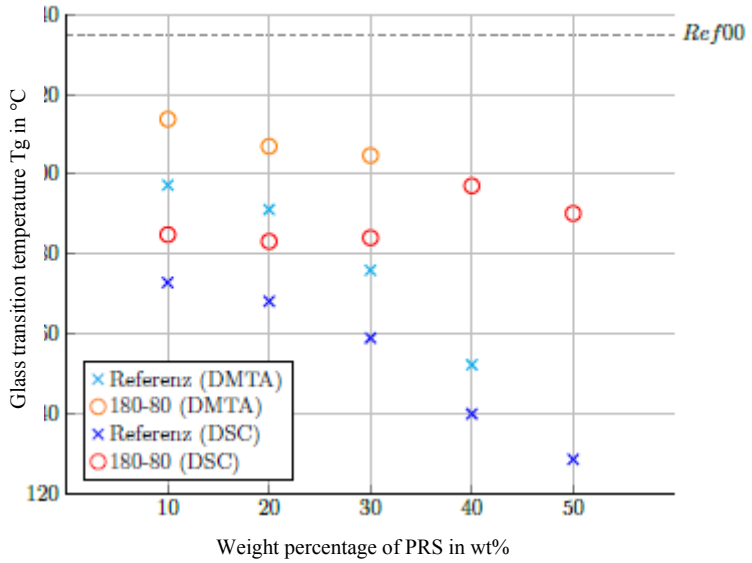

Fig. 6: Glass transition temperatures of DSC and DMTA in comparison.

In notched three-point bending test (SENB) light microscopic images of the fracture surfaces also confirm that the samples behave increasingly ductile with increasing flexibilizer content. While the K_{Ic} values show no significant change, G_{Ic} exhibit a clear increase with the amount of PRS. This is due to more energy absorbed during crack propagation and a more ductile behaviour.

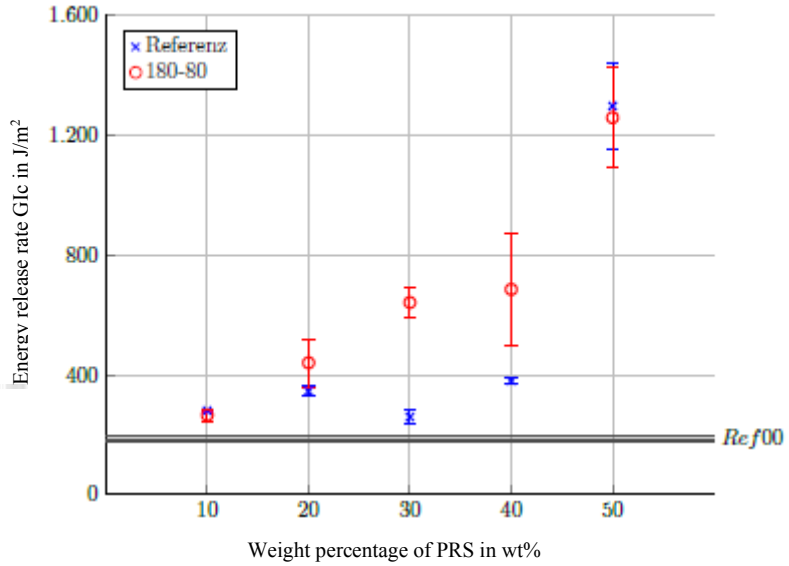

Fig. 7: Energy release rates of the samples from the second series of preliminary Tests measured by SENB.

In the main test series with the glass-fiber composite laminate, PRS were also detected in the samples of 180-80-10 and 180-80-30. No PRS could be detected in 180-80-50. Due to the dominance of the fibers in the SEM images, no meaningful size determination could be carried out, but their formation is nevertheless reflected in the results of the DCB and DMTA tests.

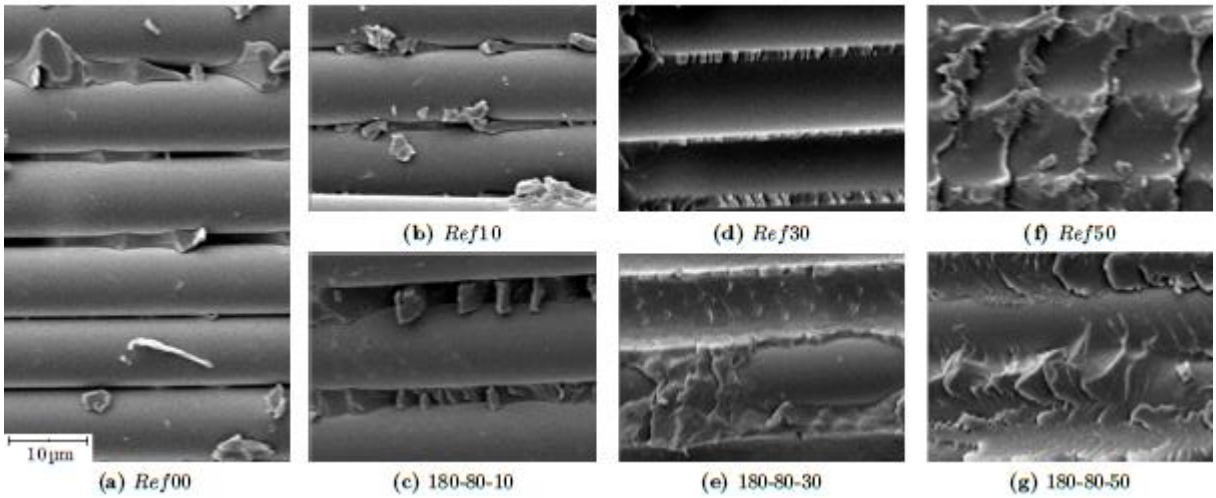

Fig. 8: SEM images of the delamination fracture surfaces of glass fiber composite samples.

180-80-30 also achieved the highest increases in the DCB results. While the samples with 10 wt%, both Ref 10 and 180-80-10, showed no significant increases compared to Ref 00, the samples with 50 wt% were able to achieve a significant increase compared to Ref 00, but not with each other. The 180-80-50 samples could not achieve an increase in interlaminar toughness compared to Ref 50, as no PRS could be detected in either the pure resin or the laminate.

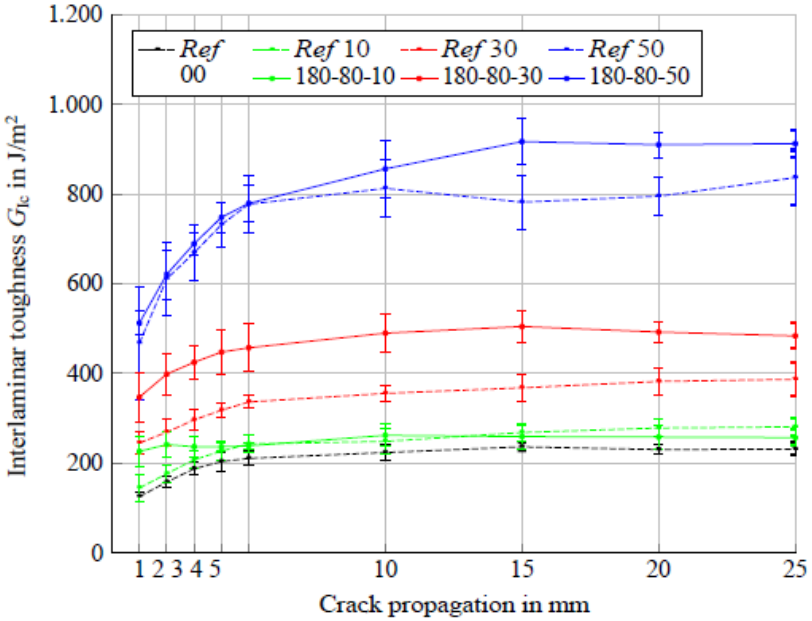

Fig. 9: Representation of G_{Ic} as a function of the crack propagation.

By introducing the unidirectionally oriented fibers, the stiffness at room temperature is increased compared to the pure resin samples. The glass transition temperatures are therefore also slightly higher. Figure 10 shows the glass transition temperatures of the samples measured with the DMTA. Due to the formation of PRS, an increased glass transition temperature can be measured in all three cases. An increase of 4 % is achieved with a weight proportion of 10 wt% and 7 % with 30 wt%. At 50 wt%, however, PRS does not form, so the increase of 5 % is not as high. The principle therefore only works up to a certain weight proportion.

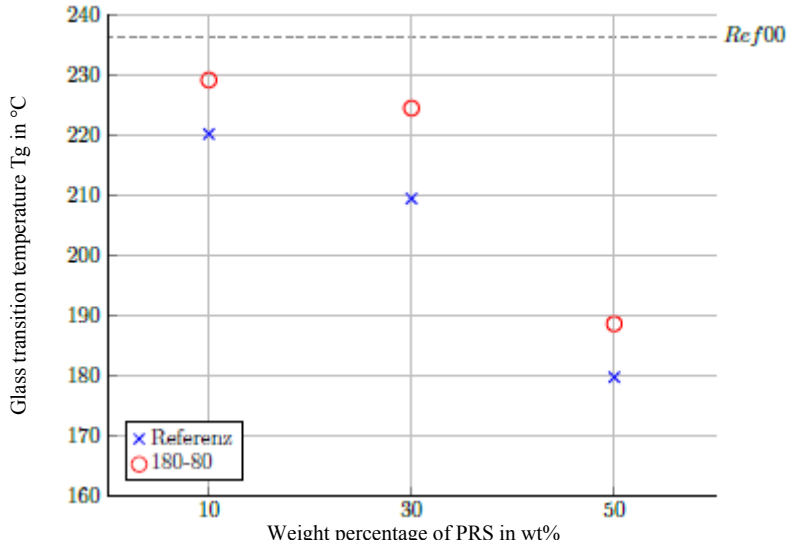

Fig. 10: Glass transition temperatures of the samples in the main test series determined with the DMTA.

4. Conclusions

The aim of this work was to transfer the principle of two-stage synthesis from the pure resin to the fiber composite in order to prevent a simultaneous reduction in the glass transition temperature while increasing the fracture toughness. The influencing factors for the formation of PRS were selected as 160 °C, 180 °C and 200 °C for the crosslinking temperature, 75 % to 95 % in 5 % steps for the degree of crosslinking and 10 wt% to 50 wt% in 10 wt% steps for the weight proportion of PRS in the composite. In two preliminary test series, these parameters were varied in pure resin tests in order to make the best possible selection for the main test series in the composite with glass fibers. The first series of preliminary tests resulted in PRS with an average size of 1.57 ± 0.23 µm at a fixed weight fraction of 20 wt%. No significant differences were found for the variation of crosslinking temperature and degree. The analysis using DSC also revealed no trends. Since sample 180 °C-80 %-20 wt% showed a maximum value, 180 °C and 80 % were used for further tests to vary the weight fraction. In the second series of preliminary tests, the PRS sizes were influenced by the different weight proportions. At 30 wt%, a maximum value of 2.55 ± 0.72 µm was achieved. No PRS could be detected for a weight proportion of 50 wt%. By forming the PRS, an increase in the glass transition temperature could be achieved for all parameter combinations compared to the respective reference. In the main test series, PRS were also detected in the fiber composite. Using DMTA, , the reference values decreased, while the values of the PRS samples were higher with increasing flexibilizer content. By forming PRS, 180 °C-80 %-30 wt% achieved the highest increase of 7 °C to 224.6 °C. Sample 180 °C-80 %-30 wt% also achieved the best results in the DCB test with regard to the percentage increase due to PRS formation. While at a weight fraction of 10 wt% the content was not high enough to achieve significant increases, 180 °C-80 %-30 wt% with a value of 490.05 ± 40.91 kJ/m^2, achieved an increase of 38% compared to the sample with 30 wt% uniformly distributed fexibilizer and 118% compared to the sample without any fexibilizer, confirming that the principle of two-step synthesis is applicable to the fiber composite.

Keywords: self-heating; IR thermography; composite material; thermodynamic model; fatigue degradation

Abstract
The infrared radiation (IR) thermography method has been applied to study the fatigue behavior of composite laminates by observing the temperature variation on the specimen surface during fatigue process, which is called self-heating phenomenon. Theories and models were proposed based on self-heating to evaluate the fatigue progress and predict the fatigue limit. In this work, a thermodynamic model was proposed to simulate the fatigue behavior and the self-heating temperature of composites, considering the effect of viscoelasticity. Two stiffness degradation laws determined by traditional fatigue tests and rapid fatigue tests based on thermography were implemented in the model, and the simulation results were compared with the experimental data. Results show that with the help of a rapid fatigue test based on thermography, a stiffness degradation law can be determined, and the process of building a thermodynamic fatigue model is greatly shortened.

1. Introduction

Carbon fiber reinforced polymer matrix composites (CFRPs) have been widely used in aerospace, automotive engineering and advanced sports equipment due to their high specific mechanical properties and their good corrosion resistance. Under complex serving conditions, composite structures can be subject to cyclic stresses, which can cause important and serious damages. Therefore, a comprehensive study of composite materials' fatigue behavior is necessary. However, the classic fatigue test to obtain fatigue limit and S-N curve is long and expensive, especially it takes months under low-stress levels.

During the last years, contributions have been made to find a rapid way to shorten the fatigue test process. The fatigue limit of material can be determined using advanced characterization technologies rather than practicing a traditional fatigue test. Among them, infrared radiation (IR) thermography is promising.

Indeed, during mechanical tests, a phenomenon called self-heating has been observed in homogenous metallic at first, then polymeric material and heterogeneous polymer CFRPs. So, the surface temperature rise of a sample can be recorded by an IR camera. Some research shows a connection between the self-heating temperature and fatigue limit [1]. Several thermography methods based on the self-heating principles have been developed to predict fatigue life such as Luong's method [2], Risitano's method [3] and Krapez's method [4]. Based on these works, recently, Huang [5] proposed a methodology based on IR thermography to determine the fatigue limit of CFRPs within a fairly short period. By applying a series of stair-like fatigue stress to a single specimen, a relationship between the stabilized self-heating temperature and the fatigue stress level can be found. Then the fatigue limit and the fatigue life in term of S-N curve [6] can be determined by a thermographic data treatment method. These methods provide a rapid and accurate prediction of the fatigue life.

Self-heating, a process characterized by energy dissipation, is influenced by many factors, such as the intrinsic properties of the material, the loading conditions, and the surrounding environment. Considering the nature of the material, for CFRPs, the viscoelastic and plastic behavior of polymer matrix can generate significant heat under cyclic loading. The damages such as the fiber breakage, delamination, matrix and matrix/fiber cracking can also produce heat with the fatigue process continuing. To describe this complex behavior, a fatigue model combined with a thermodynamic model has to be proposed. Shojaei et al. [7] considered fatigue, creep, and plasticity in a continuum damage mechanics model for polymers, and used thermodynamics principles to derive a constitutive relation between self-heating and dissipative energy, which predicts the temperature rise in polymers. Mirzaei et al. [8] investigated the self-heating phenomenon in laminated composites under fatigue loading and developed a generated-dissipated energy (GDE) model considering the viscoelastic behavior of polymer matrix to calculate the generated and dissipated energy.

These studies can help to build a model to describe the self-heating phenomenon in the fatigue process. However, still large amount of experimental works needs to be conducted to obtain the necessary parameters in the model, such as the material degradation laws during fatigue, the fatigue limits, etc. In this work, the rapid fatigue test based on thermography is applied to shorten this period of experiment. The purpose of this work is to explain this thermodynamic behavior in the first place, then develop a model to predict the fatigue process of CFRPs and the self-heating temperature, with the constrain of the need of as few experiments as possible for model parameters identification. By applying the rapid fatigue test based on thermography, the experimental time can be shortened to several hours and the fatigue model can be built and put to use within a short time. The comparison between the experimental data and simulation results of the self-heating temperature variation has been done to validate the methodology of modeling.

2. Thermography framework

To build the self-heating model, two aspects were considered: (i) the simulation of the fatigue process of CFRPs, including the material degradation and damage evolution, and (ii) the thermal behavior during the fatigue process. Considering the principle of the self-heating phenomenon in a material under cyclic loading, from the thermodynamic laws, the basic rules of self-heating modeling include heat generation and dissipation. To simplify the heat generation, the viscoelastic behavior of the polymer matrix is first considered for a unidirectional CFRP. For the heat dissipation, the conduction and convection were considered. The first law of thermodynamics defines an energy balance in a given system. Eq. 1 describes the energy balance in an arbitrary control volume:

$$\frac{dE}{dt} = \frac{dW}{dt} - \frac{dQ}{dt} \tag{1}$$

where E is the total internal energy, W represents the mechanical work due to the cyclic loadings, and Q is the thermal energy.

In recent studies [9,10], mechanical work W is considered as the energy generated by the viscoelastic behavior of polymer matrix, which is caused by the hysteresis between the cyclic load and the resulting displacement. To calculate the mechanical work, the hysteresis between the stress and resulting strain should be determined, as it is shown in Eq. 2.

$$\sigma = \sigma_0 \sin(\omega t) \rightarrow \varepsilon = \varepsilon_0 \sin(\omega t + \delta) \begin{cases} \delta = 0 & \text{for perfect elastic materials} \\ 0 < \delta < \dfrac{\pi}{2} & \text{for viscoelastic materials} \\ \delta = \dfrac{\pi}{2} & \text{for perfect viscous materials} \end{cases} \tag{2}$$

where σ is a fatigue stress in a sinus form, σ_0 is the amplitude of stress, while ε is a resulting strain with a lag phase δ, ε_0 is the amplitude of the strain.

For each loading cycle, the energy can be calculated and divided into two parts: elastic energy and generated energy (Eq.3). The elastic energy is stored inside the material and then totally released at the end of each cycle, while the generated energy due to viscoelastic behavior is transformed into heat. The heat generated by viscoelasticity behavior is not the only heat source during the fatigue test but the primary heat source throughout the whole fatigue cycle [11].

$$\begin{aligned} &\int_0^{\varepsilon_0} \sigma d\varepsilon = \int_0^{\pi/2\omega} \sigma \frac{d\varepsilon}{dt} = \omega \varepsilon_0 \sigma_0 \int_0^{\pi/2\omega} \left(\cos \omega t \sin \omega t \cos \delta + \sin^2 \omega t \sin \delta \right) dt \\ &= \underbrace{\varepsilon_0 \sigma_0 \frac{\cos \delta}{2}}_{\text{elastic energy}} + \underbrace{\varepsilon_0 \sigma_0 \frac{\pi \sin \delta}{4}}_{\text{generated energy}}. \end{aligned} \tag{3}$$

Generally, three heat dissipation behaviors are considered for the thermal energy Q: convection, conduction, and radiation [12]. Since the self-heating temperature of composite material under low frequency fatigue is relatively low, the heat dissipation through radiation can be ignored. To calculate the heat dissipation through convection for an elementary volume on the surface of the specimen, considering the shape of specimen used in the following experimental and simulation work, the heat transfer equation for a vertical plate is used, as shown in Eq. 4.

$$E_{\text{convection}} = ha\left(T_s - T_\infty\right) = \frac{Nu \cdot k_{\text{air}}}{l} a\left(T_s - T_\infty\right) \tag{4}$$

where the heat convection coefficient (h) between the composite laminate and air can be calculated by Nusselt number (Nu) and the heat conduction coefficient of the air (k_{air}), l is the length of elementary volume, a is the area of the elementary volume surface, T_s and T_∞ represent the surface temperature and environment temperature, respectively.

The Fourier law stated in Eq. 5 is employed to calculate the dissipated energy through heat conduction for an elementary volume:

$$E_{\text{conduction}} = 2k_{\text{ply}} a \left(\frac{\partial T}{\partial x} + \frac{\partial T}{\partial y} \right) \tag{5}$$

where k_{ply} represents the heat conduction coefficients of the composites, which differ according to the direction of the fiber. It can be calculated by Eq. 6:

$$k_{ply} = k_l \cos^2\theta + k_t \sin^2\theta \tag{6}$$

where θ represents the angle of the orientation of the fibers, k_l and k_t are the heat conduction coefficients in the longitudinal and transversal direction of the fibers, respectively, calculated by the following equation (7):

$$\begin{aligned} k_l &= k_m\left(1-V_f\right)+k_f V_f \\ k_t &= \frac{k_m + k_f - V_f\left(k_m - k_f\right)}{k_m + k_f + V_f\left(k_m - k_f\right)} \end{aligned} \tag{7}$$

where k_m and k_f are the heat conduction coefficients of matrix and fiber, V_f and V_m are the volume ratio of fiber and matrix, respectively [12].

3.Self-heating model

Based on the thermodynamic rules, the whole self-heating model can be considered as a combined model that can calculate step by step the fatigue process and the heat generation and dissipation condition, and finally the temperature variation, as shown in Figure 1. It consists two main parts: the first is for the fatigue damage process, within which the stress calculation, material degradation and failure criterion were considered; and the second is to calculate heat variation, then the self-heating temperature can be determined. This framework has been widely used in the internal energy variation of a structure under statical or dynamic mechanical tests [8]. It is a modular and flexible framework since the researchers can modify any of the thermodynamic principles according to their real conditions.

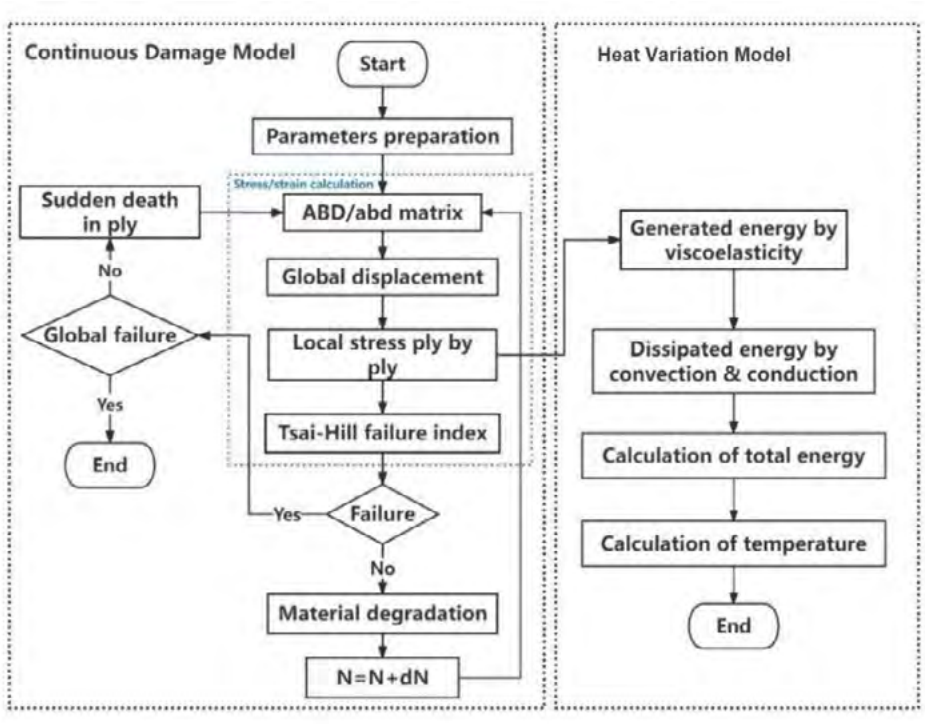

Figure 1. The calculation process of continuous fatigue damage and thermodynamic behavior.

In this model, the stress and strain calculation for each step during the fatigue process can be done by using the commercial software ABAQUS. In the first step, build an analysis model in ABAQUS based on the material properties, ply sequences and loading conditions in Huang's experimental work [13],

with specimen's dimension of 150 mm*25 mm*1.04 mm. A stair-like fatigue stress was applied to the model and during each iteration, the associated strain in each ply can be calculated using the ABD/abd matrix. Afterwards, with the information of stress and strain in each ply, the failure condition in each ply was checked. Then the material properties were upgraded based on the failure condition. If no failure happened, the material degradation rules were employed to do a deduction on the material properties due to the fatigue process, then the fatigue process continued in the next loop. Otherwise, the failure in the whole system should be checked to determine whether the fatigue process is stopped. To reduce the computational cost of the proposed coupled modeling approach, a cyclic jump approach is also incorporated and dN is set to 100. Then the whole process was repeated until the final failure of the entire composite structure. At the same time, in each step, the results of stresses and the strain calculation are transferred to the heat variation model to calculate the energy generated by viscoelasticity. Then considering the energy loss due to conduction and convection, the total energy variation was able to be calculated. Finally, the self-heating temperature can be determined.

The C3D8T element type was selected, which is an 8-node trilinear element coupled with temperature and displacement. A convergency test was done to well choose the element size to keep a balance between the simulation precision and computation time. A UMAT subroutine was designed to model the thermodynamic fatigue behavior of the composite samples for a 3D thermal-stress coupled analysis in ABAQUS software. Fatigue-induced stresses were replicated by applying the peak load onto the specimen. Benefiting from the inherent symmetry of the samples, only a quarter-section was used for computational modeling, ensuring efficiency.

During the fatigue modeling of CFRPs, it is crucial to understand how the material's properties evolve with the fatigue process. In this work, a continuous damage law based on traditional fatigue experiments has been applied firstly to describe the degradation in modulus of the material as a function of the number of fatigue cycles n, fatigue load σ and stress ratio κ, as it shown in Eq. 8.

$$E(n,\sigma,\kappa)=\left[1-\left(\frac{\log(n)-\log(0.25)}{\log\left(N_f\right)-\log(0.25)}\right)^{\lambda}\right]^{1/\gamma}\left(E_s-\frac{\sigma}{\varepsilon_f}\right)+\frac{\sigma}{\varepsilon_f} \tag{8}$$

where E_s represents the statical modulus and ε_f is the final displacement under the statical tensile test. λ and γ are parameters to be determined by experimental data fitting. The fitting method can be found in Shokrieh's work [14,15]. A normalized form of Eq. 8 which depends on the values of γ and λ is shown in Eq. 9. All different curves of degradation under different stress states collapse to a single curve.

$$k(n)=\frac{E(n)-\frac{\sigma}{\varepsilon_f}}{E_0-\frac{\sigma}{\varepsilon_f}}=\left[1-\left(\frac{\log(n)-\log(.25)}{\log\left(N_f\right)-\log(.25)}\right)^{\lambda}\right]^{\frac{1}{\gamma}} \tag{9}$$

Since the previous method to determine the degradation law demands the experimental data of classic fatigue tests, it still costs of large time. As mentioned before, Huang [13] roposed another law of modulus degradation which indicates the relationship between stiffness degradation and stable self-heating temperature, as shown in equation (10). Different levels of fatigue stress were applied to a single specimen and each stress level lasted for 10000 cycles to attend the stabilization of self-heating temperature, so the whole process took only hours, which greatly shortened the experimental process.

$$\frac{E(n)}{E_s}=k'(n)=1-p\Delta T_{stab}n^{1/q}\quad(q\geq 1) \tag{10}$$

where $k'(n)$ is the normalized stiffness at the n^{th} cycle, ΔT_{stab} is the stable temperature variation during the rapid fatigue test, p and q are material parameters to be determined by the fitting process.

4.Results and discussion

In the experimental works of Huang [13], classic fatigue tests were practiced. The necessary parameters are determined by applying a fitting method to the results of classic fatigue tests. The fatigue test data under the stress levels of 70% of the ultimate tensile strength (UTS) and 85%UTS were chosen to fit the law, as it shown in Figure 2, with λ=0.2006, γ=4.424 and the R-square of the fitting results is 0.947, which means a good fitting degree.

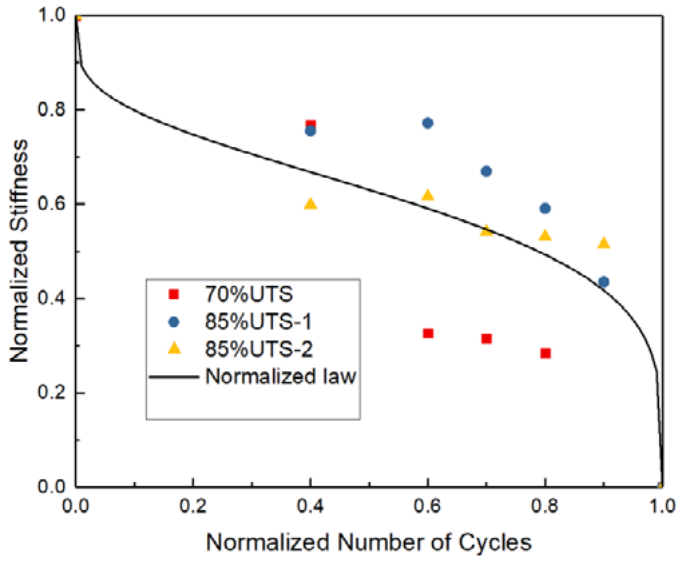

Figure 2. Fitting result with the normalized degradation law.

Applying the rapid fatigue test data in [5], as shown in Fig. 3 (a), a surface fitting process can be performed to obtain the model parameters, as shown in Fig. 3 (b), with p=1.87*10^{-2}(°C ×Cycle$^{1/q}$)$^{-1}$, and q=4.75.

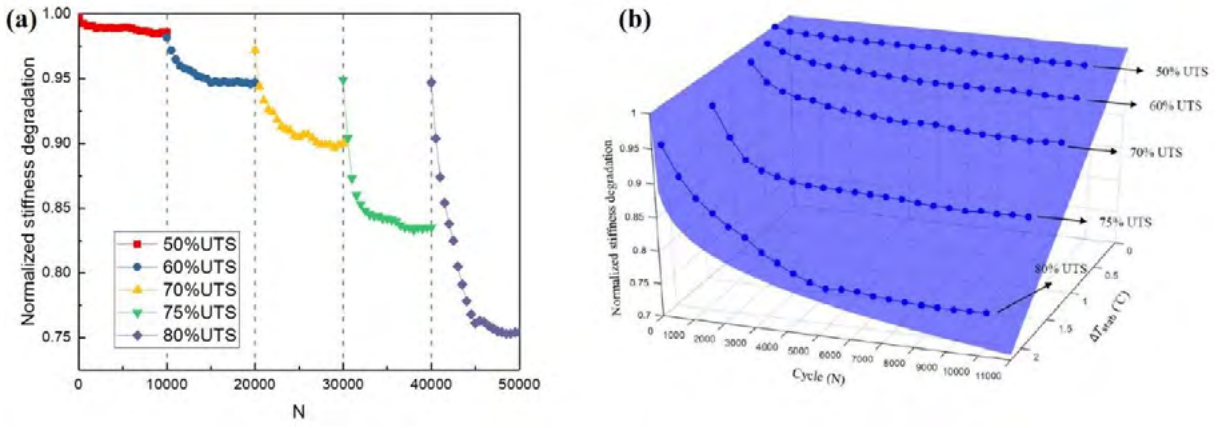

Figure 3. (a) Stiffness degradation determined by rapid fatigue test; (b) Fitting results of rapid fatigue tests.

The two stiffness degradation laws were then integrated into the self-heating model to simulate the temperature variation during the rapid fatigue test. The results are shown in Fig. 4, in which the dots represent the temperature variation captured by the IR camera, while the line and dotted line represent

the simulation results by using Shokrieh's model and Huang's model, respectively. The results show that the two simulation results have a good correlation at different stress levels, which means the model obtained by the rapid thermography method can well describe the stiffness degradation as the classic degradation model does. With the application of the stiffness degradation model based on the thermography method, only one group of fatigue experiment is needed and the experimental time can be reduced to hours to build a fatigue model. Meanwhile, by comparing the experimental data and simulation results, at a relatively low stress level, the results fit well, but with the stress level increased, the difference between them grew. This indicates that at low stress levels, viscoelasticity is the main reason for the self-heating phenomenon. But when the stress level increases, or the damage accumulates to a certain level, some other heat is generated due to the plasticity of matrix, fiber breakage, friction of the cracks and delamination, etc. These heat sources will be taken into consideration and added to the model in the following works.

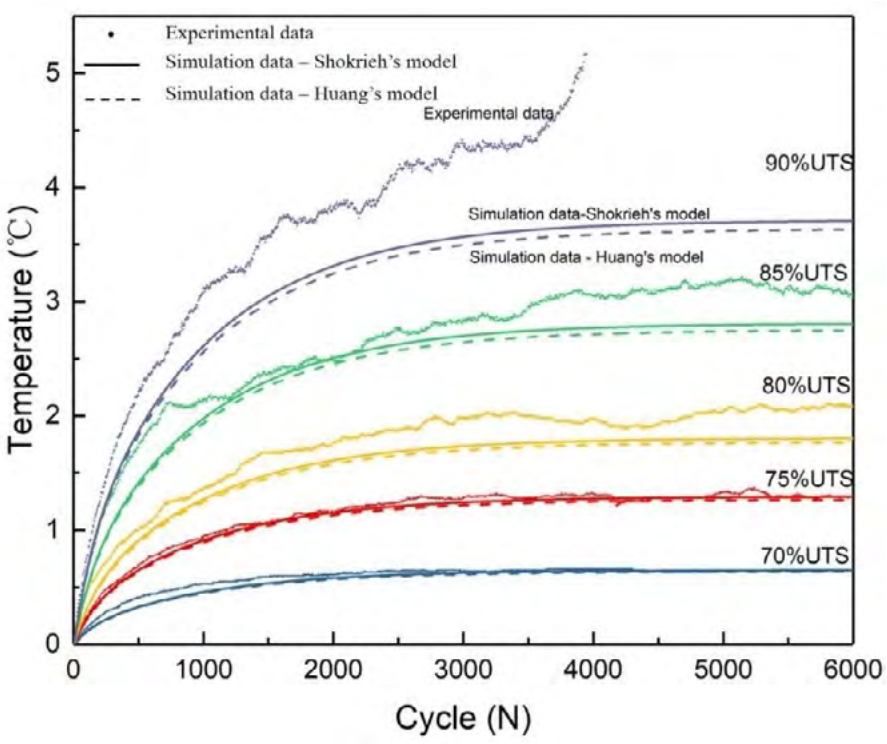

Figure 4. Comparison between the experimental and simulation data.

5. Conclusions

In this work, a self-heating model was built to simulate the fatigue behavior and the heat generation and dissipation during the fatigue process, as well as the self-heating temperature variation on the surface of the specimen. To simulate the fatigue process, two stiffness degradation laws based on the traditional fatigue test data and the rapid fatigue test data, respectively, were applied to the model. The viscoelasticity of the polymer matrix was considered as the main heat generation during the fatigue process, and there was also heat dissipation by conduction and convection. The comparison between the simulation results showed that the two degradation laws were equivalent for describing the evolution of material properties during the fatigue process. With the help of the thermography method in a rapid fatigue test, the determination of material degradation can be greatly shortened compared to the traditional fatigue test, only one group of rapid fatigue test based on thermography and the experimental time is greatly shortened to several hours, which will help build the fatigue model more efficient. Compared to the experimental data, the simulation results showed good fitness at the beginning while at high stress levels, the viscoelasticity was not the only heat generation source. Some other heat sources exist and have to be determined in the future work.

Abstract
This research examines the potential of glass fibre-reinforced polymers (GFRP) as bridge formwork in concrete bridge construction, with a particular focus on load-bearing capacity and modular design. It concludes with a preliminary exploration of GFRP-concrete hybrid structures. Previous work identified the potential of glass fibre-reinforced polymer as a formwork material for bridges through market research and technical exchange. The mechanical properties of standard GFRP profiles were determined in the interim through laboratory experiments, with the flexural modulus of GFRP ranging from 20 GPa to 45 GPa, depending on the fibre arrangement and reinforcement used. The experimental data was then combined with the boundary conditions of the bridge structure to create computational and finite element analysis models. Subsequently, a self-supporting, modular formwork system, comprising approximately 4-5 basic elements, was developed. The system is constructed from GFRP material and its feasibility was verified by constructing a bridge model.

1. Introduction

The repair and replacement of bridges is a crucial task in Germany's highly dense transport network. Extensive renovation work is necessary due to unforeseeable loads when the infrastructure was planned and built decades ago, such as increased traffic and the intensive use of road de-icing salt. For example, statistics indicate that there are approximately 120,000 bridges in Germany. Of these, 86% are concrete bridges. On a scale of 1.0 (Excellent condition) to 4.0 (Insufficient condition), more than 10% of the bridges on federal trunk roads and motorways no longer have a sufficiently safe load-carrying capacity and are in urgent need of repair and maintenance [1]. One potential solution is to use innovative materials and construction methods to build longer-life bridges more efficiently.

2. Current technology

The potential of fiber reinforced polymer (FRP) in construction has been extensively researched and developed in recent decades [2]. The high strength-to-weight ratio, high environmental stability and other properties of this material make it the most advantageous alternative to steel reinforcement in concrete structures [3] [4].The Acciona company manufactures beams, cables, bars or forged structures made of carbon fibre, glass fibre and polymers materials as a replacement for traditional steel and concrete materials in construction projects. In the 21st century, the potential of FRP materials in the field of traditional concrete construction, represented by bridges, has been further investigated [5] [6] [7]. In 2017, a road bridge with GFRP as the superstructure support was constructed in Poland. The bridge, with a load capacity of 40 t, is a 22.0 m long, 10.5 m wide, single-span, simply supported girder bridge. The bridge superstructure is composed of four GFRP composite beams and a 0.18-metre-thick concrete slab [8]. In 2020, construction company Kaj Bech built a pedestrian bridge made entirely of

GFRP in Sønder Felding, Denmark. The bridge is 5.5 m long and 2.5 m wide and has a total weight of just 625 kg, but it can carry up to 8 t [9]. This research presents the development of a self-supporting GFRP bridge formwork. The basic bridge formwork elements are standard profiles available on the market, and the modular design is the basic principle. The formwork will serve as the outer surface of the future concrete structure and will not be removed after the concrete has been poured and hardened. In addition to its protective function, the formwork will be equipped with sensors that will provide information about the condition of the bridge at any time.

3. Materials and methods

This research used standard GFRP profiles, comprising glass fibre and polyester resin, to investigate the mechanical properties of the materials and the standard profiles. Additionally, a preliminary research was conducted on the GFRP-concrete hybrid structure formed by fresh concrete poured onto the GFRP material.

3.1. GFRP and concrete

Compared to other fibre-reinforced plastics (FRP), GFRP can be used to produce large continuous profiles through automated pultrusion moulding processes. Their cross sections have relatively high design flexibility. This process enables continuous longitudinal arrangement of glass fibres along the profile, resulting in high strength and stiffness with a flexural elastic modulus ranging from 20 GPa to 45 GPa. This makes it an ideal choice for applications re-quiring high structural performance. Additionally, GFRP is highly resistant to corrosion and its polyester matrix provides exceptional UV resistance, making it an excellent option for protecting the exterior surfaces of bridges. Therefore, fiberglass plastic was chosen as the material for the bridge formwork. In this research were standard pultruded GFRP profile from Fiberline Building Profiles A/S, Denmark selected for the material tests.

The concrete of grade C35/45 produced by Dammer Betonwerk GmbH & Co. KG, Germany has been selected for use in conjunction with GFRP material and subjected to static loading experiments. The cement utilised in the concrete is of the CEM III/A 42.5 N variety. This cement is a blast furnace cement with an initial strength that is typical of the category and a high final strength. It is frequently used in the construction of buildings and civil engineering projects, as well as in road construction and the creation of carriageway surfaces. It demonstrates good resistance to frost and de-icing salts [10]. The concrete has a maximum particle diameter of 8 mm and a flow class of F3 for fresh concrete, as well as an exposure class of XC4, XD3, XF3 for the final hardened concrete. These exposure classes are suitable for resisting corrosion of the reinforcement due to carbonation, chloride corrosion of the reinforcement and frost attack in a humid and saline environment. [11] [12]

3.2. Methods

The cross-section of a GFRP double T profile with thicknesses of 6 mm is divided into five distinct areas, as shown in Figure 1.

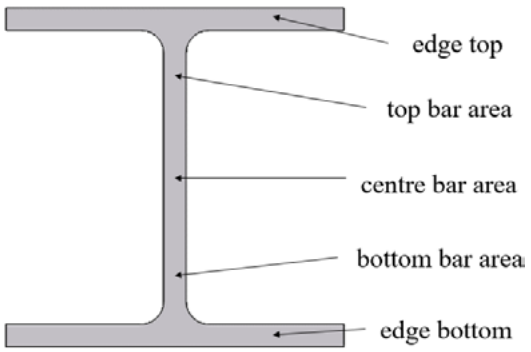

Figure 1. Five distinct areas in the cross-section of a GFRP double T profile: edge top, top bar area, centre bar area, bottom bar area, edge bottom

In order to analyse the reinforcement of the profiles, samples were selected from different areas and subjected to X-ray tests in the direction of the sample thickness. A four-point bending test was conducted on GFRP samples using a ZwickRoell LTM10 machine in order to determine their mechanical properties edge fibre elongation ε (1), bending stress σ_f (2) and flexural tensile modulus E_f (3) [13]. The experimentally determined material parameters are imported into the finite element method (FEM) simulation analysis model for the purpose of analysing and optimising the load capacity of individual formwork elements, the modularity of formwork and complete formwork systems.

$$\varepsilon = \frac{4.7sh}{L^2} \tag{1}$$

$$\sigma_f = \frac{FL}{bh^2} \tag{2}$$

$$E_f = \frac{0.21L^3}{bh^3}\left(\frac{\Delta F}{\Delta s}\right) \tag{3}$$

A preliminary investigation was conducted on the bond between concrete and GFRP using 3-point flexure tests [14] [15]. The formation of a GFRP-concrete hybrid structure begins with the combination of GFRP material and fresh concrete. This is followed by the hardening of the concrete on the GFRP material, which ultimately results in the formation of the hybrid structure. Two research directions have been identified with regard to the process of combining GFRP and fresh concrete. These are unbonded and bonded. In the unbonded method, the surface of the GFRP material is processed to form specific projections (T-slots). Fresh concrete is then poured directly onto the surface of the GFRP material, creating a mechanical interlock between the two components when the concrete hardens. Bonding is the process of applying an epoxy resin adhesive to the surface of the GFRP material, followed by the pouring of fresh concrete directly onto the wet epoxy resin adhesive [16]. In this research, an unbonded solution was selected. However, the GFRP material is a sheet with no T-slots, necessitating modifications to this solution, showed in Figure 2. Four distinct surface treatments were applied to the GFRP sheets. The first surface treatment is devoid of any alteration to the initial surface condition of the profile, which was manufactured by pultrusion. The second, third, and fourth methods used 2K epoxy resin adhesive to bond and cure alkali-resistant glass fibre wool, alkali-resistant short glass fibre bundles (13 mm long), and basalt grit (5–8 mm in diameter), respectively, to the surface of the GFRP sheets.

Figure 2. Four surface treatments (a), in the mould, fresh concrete is poured onto the surface treated GFRP sheet (b), GFRP-concrete hybrid structure formed after the concrete hardened in 28 days (c)

A GOM ARAMIS measuring system is used to determine the deformation of the entire surface of the concrete-GFRP composite struc-ture, the formation and development of cracks, and the relative displacement of the concrete and GFRP parts.

4. Experiments and results

The results section of the research primarily concerns X-ray inspection, the testing of the mechanical properties of the material, and the static load analysis of GFRP-concrete.

4.1. Reinforcement of the profiles

Four distinct types of fibre reinforcement for the GFRP-profiles in question have been identified through X-ray inspection, and are listed in Figure 3 using the symbols A, B, C and D, respectively.

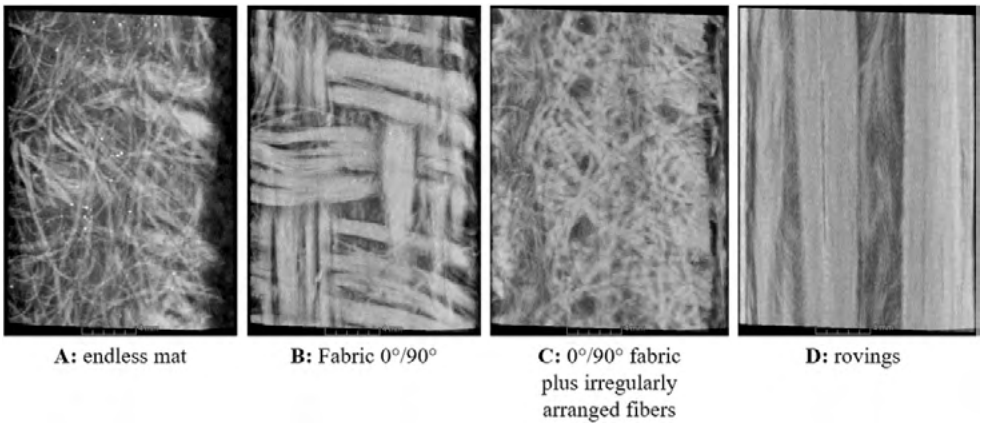

Figure 3. Four types of fibre reinforcement, endless mat (A), fabric 0°/90° (B), 0°/90° fabric plus irregularly arranged fibers (C), rovings (D)

Samples with a thickness of 6 mm were selected at the edge of the double-T profile and in the ribbed plate area. The arrangement and thickness of the different fibre reinforcements were recorded and measured.

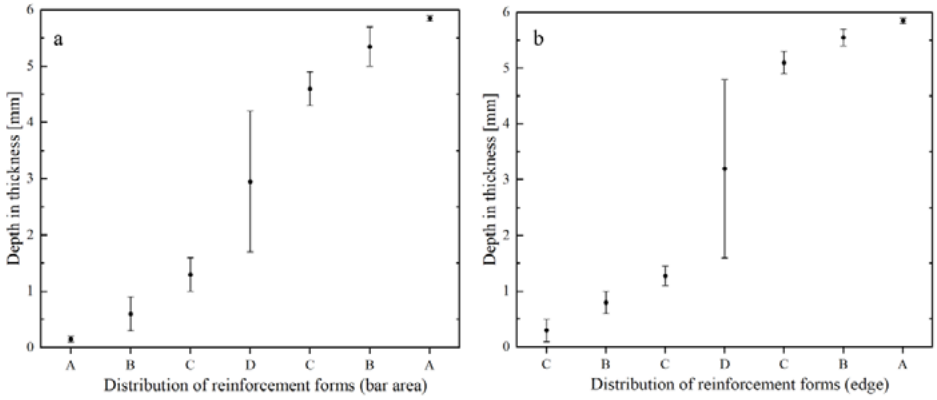

Figure 4. Method of reinforcement and thickness of fibres used in the bar area (a) and edge (b)

Figure 4 showed that the double-T profile exhibits a different fibre reinforcement distribution in the bar area and edge. The fibre reinforcement in the bar area is distributed in a symmetrical manner, with the central ply serving as the boundary. The predominant type of fibre reinforcement is rovings, accounting for approximately 43% of the total fibre reinforcement. At the edge, the fibre reinforcement exhibits a symmetrical distribution bounded by the central ply, although it differs slightly from the bar area. Firstly, the one side does not utilise endless mat. Secondly, the proportion of each fibre reinforcement is different, as the main fibre reinforcement is also rovings but accounts for 55% of the total fibre reinforcement. This is evidenced by the proportion of rovings being increased while the proportion of other fibre reinforcements is reduced.

4.2. Mechanical properties of GFRP

The material's flexural tensile modulus is determined through four-point bending experiments.

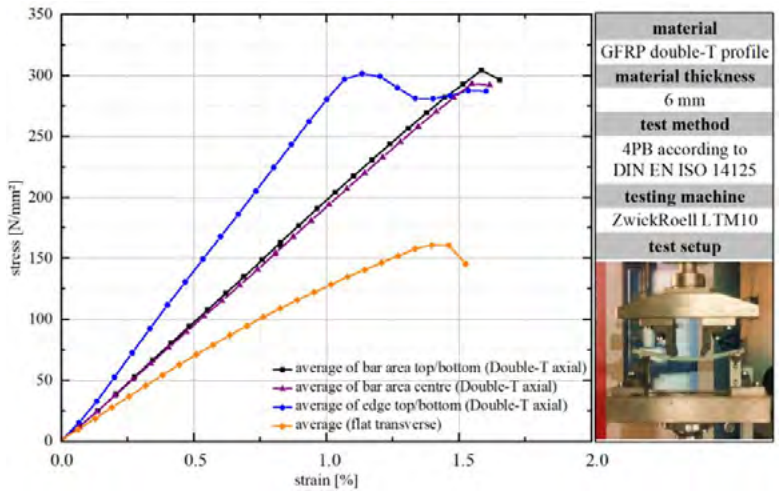

Figure 5. The axial stress and strain diagrams for the material in the bar and edge of the Double-T profile and transverse stress and strain diagram for the material of flat profile

The axial bending tensile modulus of the profile bar is experimentally measured to be around 19,000 MPa and the top and bottom edge positions can reach 28,000 MPa. In the transverse direction is lower and around 14,000 MPa. The axial direction represents the principal direction of fibre reinforcement of the profile, with the primary reinforcement material being rovings. Concurrently, the B, C and D fibre reinforcement methods are used for supplementary transverse reinforcement. Figure 6a presents the digital model of the modular formwork system established. A single module, as illustrated in Figure 6b, was selected for real load simulation in accordance with the dimensions of the laboratory prototype, combined with material experimental data. The results demonstrate that the GFRP formwork has an excellent load-carrying capacity, with a deflection of approximately 1 mm, which is less than the industry requirement of L / 300 (L: span). The results were validated by subjecting the prototype to load testing following the placement of concrete.

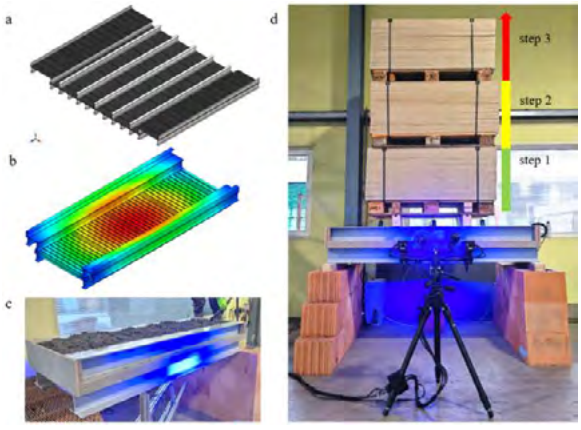

Figure 6. Digital model of the modular formwork system (a), realistic load simulation of a single module of the formwork with laboratory prototype dimensions (b), the assembly and concreting of prototypes of single modules (c), Prototype real load test (d)

4.3. GFRP-Concrete hybrid structure

The connection behaviour of GFRP-concrete hybrid structures was observed through the implementation of static loading experiments. The flexural tensile strength of concrete is approximately

6 N/mm², which is considerably less than the flexural tensile strength of GFRP material, which is 240 N/mm². The experiments were conducted using a load control mechanism, whereby the load was incrementally increased from zero at a rate of 1100 N per second until the experimental samples failed, i.e., the concrete fractured partially.

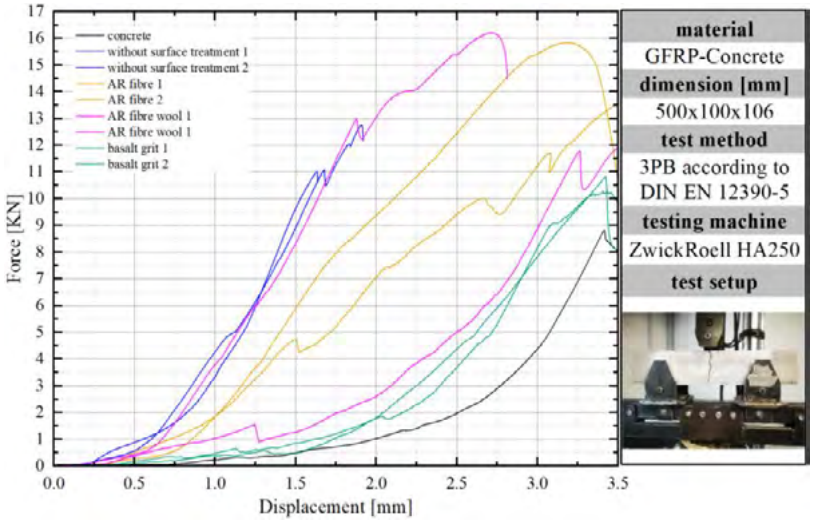

Figure 7. Force and displacement diagrams for GFRP and concrete hybrid structures

The force and displacement diagrams in Figure 7 demonstrate that the damage loads for the pure concrete specimens were below 9 kN, while the failure loads for the GFRP-concrete hybrids of the same dimensions were above 10 kN. GFRP-concrete hybrid mechanisms with alkali-resistant glass fibre wool and alkali-resistant short glass fibre bundles surface treatments can reach a failure load of 15 kN. The GFRP-concrete hybrids exhibited multiple load fluctuations before failure, but no cracks were observed. Photographs captured by the GOM ARAMIS measuring system illustrate the appearance and evolution of cracks in the GFRP-concrete hybrid structure subjected to static loading. The relative displacements of the GFRP and concrete areas were quantified at points L/4, L/2, and 3L/4 of the supported section of the GFRP-concrete hybrid structure, showed in Figure 8. A single crack was observed in all GFRP-concrete hybrid structures throughout the course of the experiment, with the initial appearance occurring at the contact surface of the hybrid structure in the middle of the structural support. This crack then progressed rapidly towards the point of application of the concrete side load within a short period of time. The GFRP material remained unscathed until the point of failure.

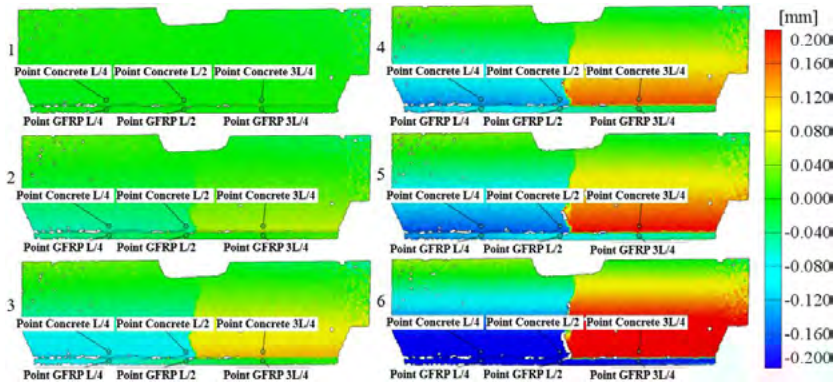

Figure 8. The surface displacement of a GFRP-concrete hybrid structure under static loading is analysed in stages, demonstrating the formation and development of cracks and the relative displacement between the two materials

The relative displacement between GFRP and concrete throughout the static loading experiment was quantified by recording the relative displacement between points, showed in Figure 9.

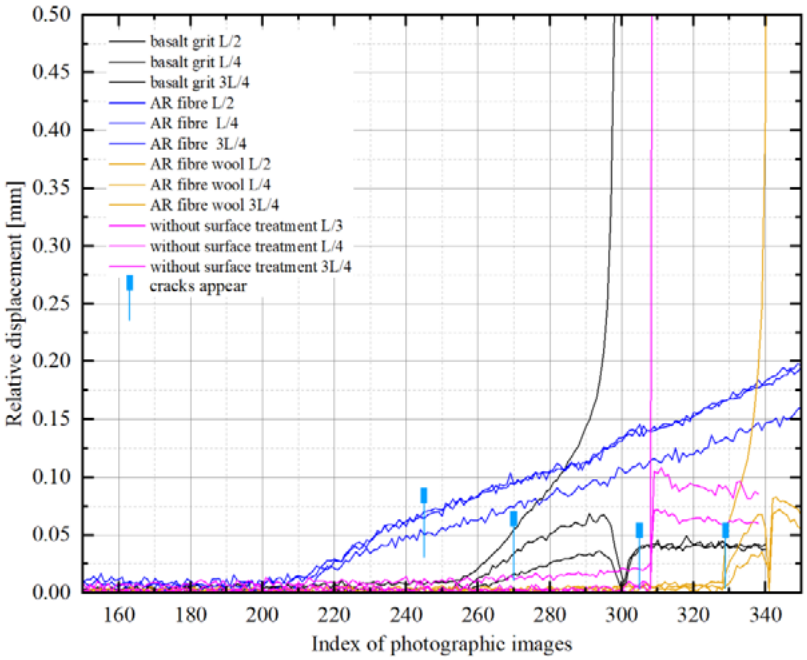

Figure 9. The relative displacements of the GFRP-concrete hybrid structure at L/4, L/2 and 3L/4 of its support section during the static loading experiments and the points of occurrence of cracks

The experimental results demonstrate that the GFRP-concrete hybrid structures exhibit relative displacements at the interface between the GFRP and concrete elements prior to the formation of cracks. The relative displacements at different measurement points of the same sample exhibit variability, yet the underlying trend remains consistent. Relative displacements and their trends are not uniform across samples that have undergone different surface treatments. The maximum relative displacements before the appearance of cracks were 0.069 mm for samples treated with AR fibre and 0.058 mm for samples treated with basalt grit, while the maximum relative displacements for the other two treatments were less than 0.050 mm. The state of a GFRP-concrete hybrid structure prior to the emergence of cracks under static loading can be described as an elastic composite exhibiting relative displacement. In this state, the two components are rigidly coupled in the vertical direction, while there are constrained relative displacements in the horizontal direction. [17]

5. Conclusions

This research demonstrates the feasibility of large continuous profiles produced by an automated pultrusion process as a bridge formwork. In addition to sufficient load-bearing capacity compared to traditional formwork, GFRP formwork can be used as permanent formwork to protect the concrete from environmental damage. A novel approach to the repair and reinforcement of concrete structures has emerged in recent years. This involves bonding GFRP or CFRP materials to the areas of the concrete elements that are subject to tensile stresses. The direct pouring of fresh concrete into the GFRP formwork in this research allows for intervention in the concrete building from the beginning of construction, thereby maximising the protection of the concrete and reducing the stress of subsequent repairs. Furthermore, the use of this material can result in a reduction in construction costs during the construction phase, due to its light weight and simple modular installation.

Subsequent research will investigate methods for establishing permanent and stable connections between concrete and GFRP profile surfaces. Ultimately, in future construction, the formwork system and cured concrete will share the load-bearing function of the bridge. This combination allows for

achieving the load-bearing capacity of conventional bridges, reducing the investment for concrete and reinforcement, and possibly dispensing with the use of reinforcement altogether.

Acknowledgments
This Project is supported by the Federal Ministry for Economic Affairs and Climate Action (BMWK) on the basis of a decision by the German Bundestag. The authors would like to acknowledge Central Innovation Programme for SMEs (ZIM), LohrElement GmbH, Autmaring Engineering GmbH and Dammer Betonwerk GmbH & Co.KG for their support of this research.

Keywords: Fibre-reinforced polymer (FRP), Hybrid FRP Sandwich Panels; Thermal Distribution Analysis; Environmental Thermal Loads; Numerical Modelling

Abstract
Fibre-reinforced polymers (FRP) show valuable features for civil engineering applications. However, the response of these structures to temperature fluctuations is often oversimplified. Structures experience daily, seasonal, and yearly variations in environmental temperature that can significantly impact their behaviour. This study investigates the thermal distribution across a hybrid FRP sandwich panel, comprising glass-FRP face sheets/webs and a polyurethane foam core, complemented by a top layer of steel fibre-reinforced self-compacting concrete, under controlled climatic conditions (constant and variable thermal loads). Through a combination of experimental analyses and numerical simulations, the research provides insights on the thermal distribution within this type of sandwich panel. Moreover, the investigation highlights the lack of established guidelines to predict temperatures in FRP composite materials, underscoring the importance of calibrated numerical models to accurately predict thermal distributions. This research contributes with valuable insights to enhance the understanding and prediction of thermal distributions in FRP composite structures, crucial for ensuring their structural integrity and performance under service environmental conditions.

1. Introduction

Fibre-reinforced polymer (FRP) composites, composed of fibres (providing strength and stiffness) and resin (ensuring fibre protection and binding) [1], have garnered growing attention in the construction sector, e.g. [2, 3]. This advanced material shows valuable features for structural applications, such as: (i) high overall durability [4], (ii) easy in-situ installation [4], (iii) high strength-to-weight ratio [1], (iv) corrosion resistance [5], and (v) excellent fatigue resistance [6]. Considering the numerous advantages offered by FRP materials, significant research efforts have been directed towards improving the understanding of their mechanical properties and structural behaviour [7, 8]. However, the response of these structures to environmental effects and temperature fluctuations is often oversimplified [8]. In fact, the behaviour and response of FRP structures under environmental thermal loads are still not fully investigated and understood [9].

Structures are subject to daily, seasonal, and annual environmental thermal conditions that influence their behaviour [10, 11]. The non-uniform temperature distribution resulting from temperature variations cause the structure to undergo thermal stresses [11]. In addition, in some cases temperature fluctuations can exert a more significant influence on the structural response than operational loads, becoming one of the main factors leading to deformations [10, 11]. This is particularly relevant considering how the mechanical properties of polymer composites are known to be strongly temperature-dependent; thus, minor temperature variations can lead to changes in their mechanical properties [12]. The significance of this issue has been identified by the CEN WG4.T2 project team, responsible for developing the CEN/TS 19101:2022 - Design of fibre-polymer composite structures [13], published in November 2022, as an urgent problem to be addressed.

The main objective of this work is to develop and refine numerical models of a specific FRP sandwich structure under controlled climatic conditions, allowing accurate prediction of thermal distribution in response to environmental thermal loads considering the effects of radiation, convection, and

conduction. The validation of these models involved a meticulous analyses of experimental results, focusing on the thermal analysis of a hybrid FRP sandwich panel, composed of a glass-FRP (GFRP) face sheets/webs and a polyurethane (PUR) foam core, complemented by a top layer of steel fibre reinforced self-compacting concrete (SFRSCC).

2. Experimental campaign

Two hybrid web-core FRP sandwich panels, with a cross section of 0.5 m width and 0.3 m height and a length of 1.5 m, were used. The panels were originally developed as part of the research project "Easyfloor-Development of Composite Sandwich Panels for Building Floor Rehabilitation" and consisted of a 6 mm thick GFRP face sheets/webs fabricated via the pultrusion method, a PUR closed-cell foam core and a 20 mm SFRSCC top layer (Figure 1). Further details about the sandwich panels, namely design, manufacturing, material characterization and structural and fire performance can be found in [14, 15]. Six Platinum 385 PT100 Resistance Temperature Detector (RTD) sensors, model NB-PTCO-002, were strategically installed inside the samples for monitoring the temperature evolution. These sensors were positioned along the vertical central axis of the cross section, as shown in Figure 1.

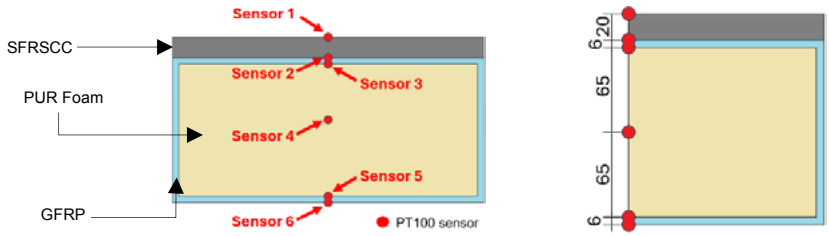

Figure 1. Experimental specimens: a) sensors numbering; b) sensors position (dimensions in mm).

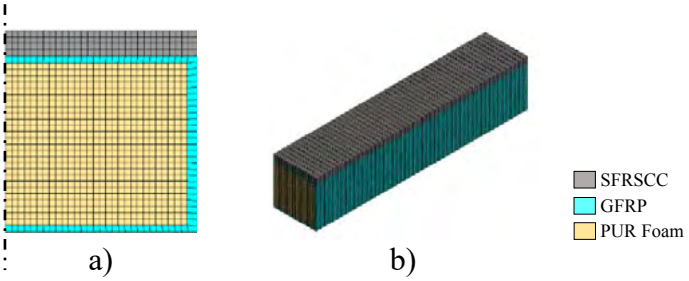
The experimental campaign was developed using a FITOCLIMA 6400EC25 climatic chamber, with dimensions of 2400 mm (length) × 1800 mm (width) × 2000 mm (height), range of temperature between -25±1 ºC and +80±1 º C and range of relative humidity between 30±2 % and 98±2 %. The temperature distribution within the specimens was monitored, under various conditions, which were carried out across a four-stage experimental campaign, as described in the following:

- **Stage I** consisted of reaching the equilibrium 20 °C and maintain it for 24 hours. Subsequently, the temperature was gradually increased at a rate of 0.33 °C per minute until it reached 40 °C. Likewise, the temperature of 40 °C was maintained for 24 hours. Afterwards, a controlled reduction in temperature began, at a rate of 0.33 °C per minute, returning to the initial temperature of 20 °C. The temperature was maintained again for a further 24 hours.
- **Stage II** included reestablishing equilibrium at 20 °C. Subsequently, the temperature was gradually reduced at a rate of 0.076 °C per minute until it reached -15 °C. Following this, the temperature underwent a controlled rise at a rate of 0.076 °C per minute, until it reached 40 °C. The heating process spanned over 12 hours, followed by a 12-hour cooling period. This 24-hour cycle was repeated 10 times. (For stages I and II, both specimens were placed inside the climatic chamber in a way to maximize the open space around the specimen's sides, as shown in Figure 2a).
- **Stage III** initiated from equilibrium at 20 °C, maintaining this temperature throughout the whole stage. The process involved subjecting the specimens to a 1000 W high-pressure sodium lamp (HPS) with a spectrum from UV to IR for 12 hours, followed by a 12-hour period without lamp exposure, completing a full 24-hour cycle. This pattern was repeated for 5 cycles. To optimize lamp exposure, only one specimen was kept inside the climatic chamber, centrally positioned, as shown in Figure 2b, with the lamp positioned 50 cm above the specimen.
- **Stage IV** is similar to Stage II. Additionally, the process included subjecting the specimen to the HPS lamp for 12 hours, followed by a further period of 12 hours without the lamp. This sequence completed a full 24-hour cycle. This cyclical exposure pattern was repeated for a total of 10 cycles. In particular, the activation of the lamp was synchronized with the increase in temperature, while the deactivation coincided with the decrease in temperature. The experimental setup was the same as in Stage III (Figure 2b).



a) b)

Figure 2. Setups for the experimental campaign: a) Stages I and II; b) Stages III and IV.

The data acquisition for this experimental campaign was conducted using a DataTaker DT85M device, recording data at a rate of 2 readings per minute. Additionally, two PT100 RTD Platinum 385 sensors were strategically positioned within the climatic chamber to improve temperature monitoring.

3. Numerical models

The DIANA finite element software [16] was used to develop numerical models to investigate the non-linear transient heat transfer phenomena for the specimens studied. The main objective of these models was to reproduce the observed experimental behaviours and subsequently validate their accuracy.
Given the non-uniform incidence of the lamp on the specimens, a 3D model was employed and meshed using twenty-node isoparametric hexahedron elements (CHX20H). Utilizing the central axis of symmetry, half of the cross-section and longitudinal length were modelled (Figure 3), employing element dimensions of 5 × 5 × 10 mm³ (width × height × length). The elements were optionally elongated to reduce the computational processing time.

a) b)

Figure 3. Developed numerical models – mesh adopted: a) front view; b) isometric view.

The properties of the materials used in these models are presented in Table 1. The GFRP properties were collected from the characterization made in [14, 15], while the properties for the other materials were estimated based on literature [9, 17, 18, 19]. The temperature data acquired within the climatic chamber was incorporated into the model as a convective boundary condition, applied uniformly throughout the model, excluding the axis of symmetry. The heat transfer coefficients for SFRSCC and GFRP were 30 W/m²°C and 40 W/m²°C, respectively, for simulations within the climate chamber as forced convection is involved. The lamp's irradiation pattern was simulated using a Gaussian curve and was introduced into the model as a heat flow boundary condition, exclusively affecting the top surface of the model. The lamp produced a heat flux of 595 W/m² at its central point, with this intensity dissipating in a range of 40 cm from the centre. Thus, the models comprehensively considered the interaction of thermal conduction, convection, and radiation phenomena.

Table 1. Thermal properties of the materials that constitute the panels.

Material	Density [kg/m³]	Specific Heat [J/kg°C]	Thermal Conductivity [W/m°C]
SFRSCC	2420	900	1.55
GFRP	1890	1053	0.2495
PUR Foam	60	1450	0.03

4. Results and discussion

Within this section, an in-depth analysis of the main findings derived from the results of the four phases of the experimental campaign, along with the numerical results, will be carried out. It will culminate in an evaluation of the thermal distribution within the specimens, with considerations made in light of current standards. Starting with the results obtained from the Stage I of the experimental campaign, Figure 4 highlights the results obtained for sensor 1 and sensor 6 (as indicated in Figure 1a) of both specimens (P1 and P2) for Stage I.

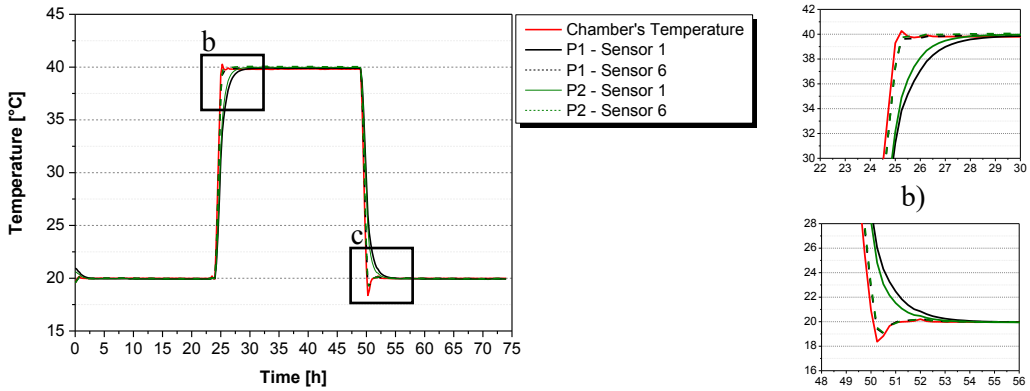


Figure 4. Stage I - Sensors 1 and 6: a) overview; b) detail b; c) detail c.

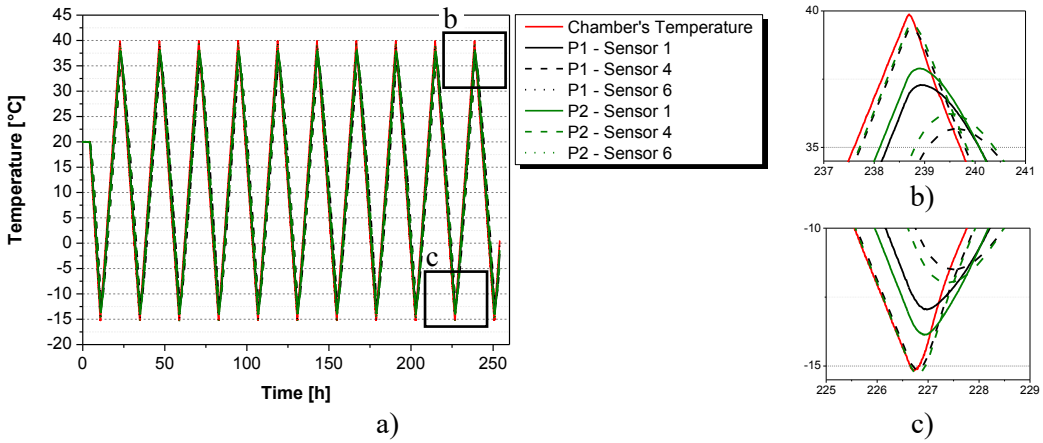
As evidenced by the Figure 4, the sensors positioned within the outermost layers indicate that the SFRSCC layer displayed a slower rate of heat exchange with its surroundings compared to the GFRP bottom face sheet. Specifically, sensor 1, located at the highest point of the SFRSCC layer, at the top of the specimen, took approximately 6 hours to achieve thermal equilibrium during heating, transitioning from 20 °C to 40 °C. Similarly, it required about 5 hours to reach equilibrium during cooling, from 40 °C to 20 °C. In contrast, sensor 6 at the outermost GFRP laminate (GFRP bottom face sheet) at the specimen base reached thermal equilibrium almost simultaneously with the climatic chamber in both heating and cooling phases, suggesting a higher convective heat transfer coefficient for GFRP compared to SFRSCC. Additionally, the entire specimen reached thermal equilibrium in approximately 7 hours during heating and 8 hours during cooling. Moreover, experimental data from panels P1 and P2 exhibited consistent results.

Furthermore, noteworthy is the observation that the highest and lowest temperature peaks depicted by the red line (representing internal temperature sensors) during heating and cooling processes, respectively, signify the climatic chamber's efforts to balance temperatures between those recorded by the sensors and the adjustments made to increase or decrease the temperature to the targeted one.

Advancing to Stage II, Figure 5 shows the data collected from sensors 1, 4, and 6, representing the outermost points at the top of the specimen in the SFRSCC layer, the innermost within the PUR foam, and the GFRP bottom face sheet at the panel, respectively.



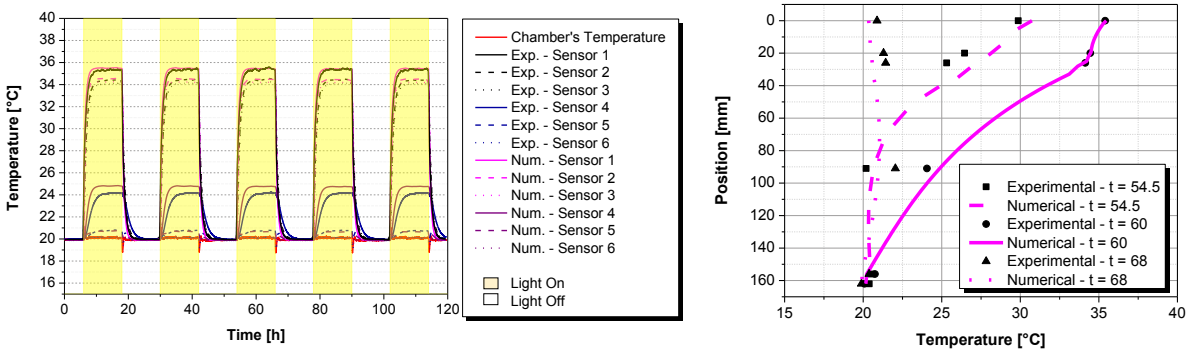


Figure 5. Stage II - Sensors 1,4 and 6: a) overview; b) detail b; c) detail c.

Stage II confirmed the findings from Stage I. The sensors positioned in the outermost layers clearly indicated that the SFRSCC layer exhibited a lower heat transfer rate with the surrounding environment compared to the GFRP. In contrast with the previous stage, constant temperature plateaus were not maintained during Stage II. Consequently, the maximum and minimum temperatures recorded by the various sensors differed.

Specifically, sensor 1 registered a maximum temperature of around 37.3 °C and a minimum temperature of approximately -12.5 °C throughout the process. Sensor 6 recorded a maximum temperature of approximately 39.4 °C and a minimum temperature of roughly -15 °C during the process. Sensor 4, located at the innermost part of the specimen, recorded a maximum temperature of about 35.6 °C and a minimum temperature of approximately -11.5 °C throughout this stage. This analysis provided valuable insights into the heat exchange occurring between the test specimens and their surroundings, as well as within the specimens themselves. Furthermore, it is noteworthy that the experimental data collected from test panels P1 and P2 exhibited consistent results, like the previous stage.

In the sequence of the experimental campaign, Figure 6a presents Stage III results for the 6 sensors, both experimental and numerical. In addition, Figure 6b presents the thermal profiles obtained for three specific points of interest: t = 54.5 hours, t = 60 hours, and t = 68 hours. These time instances correspond, respectively, to half an hour after the initiation of exposure to the lamp during the third cycle, six hours after the start of lamp exposure in the third cycle, and the midpoint between the interruption of lamp exposure in the third cycle and the moment when the specimen returns to thermal equilibrium at 20 °C.

a) b)

Figure 6. Stage III - Sensors 1 to 6: a) overview; b) thermal profiles.

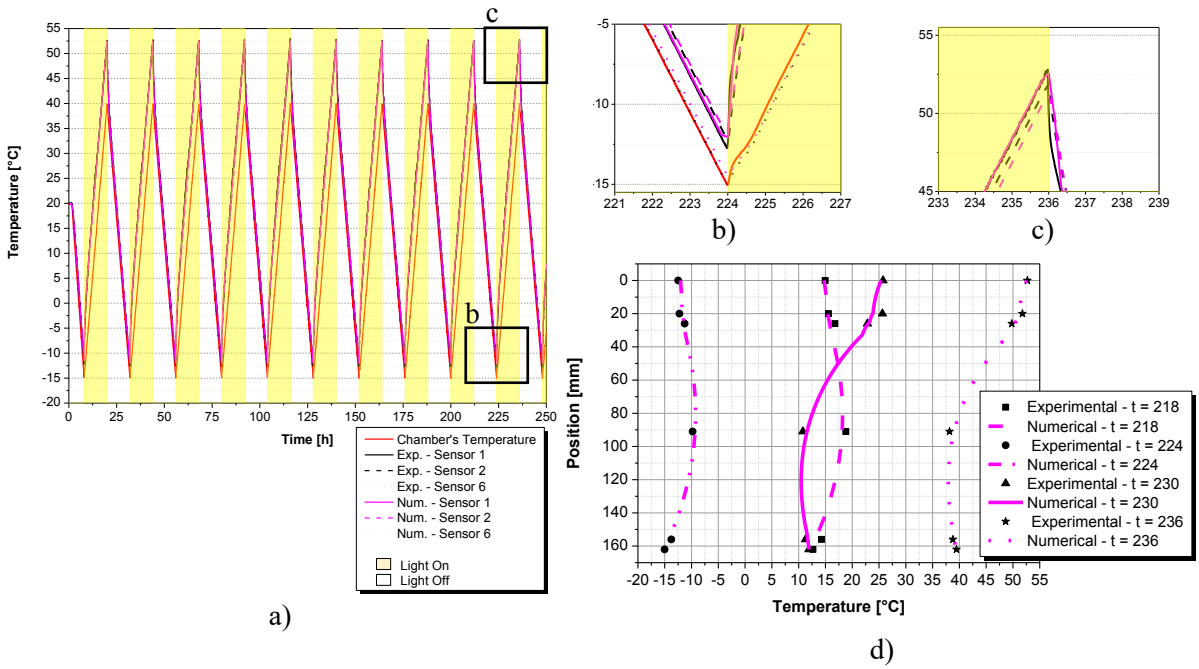
As depicted in the figure above, the proximity of the upper sensors to the lamp resulted in a more pronounced influence, as expected. This influence progressively diminished with the depth of the sensors within the specimen. Notably, sensor 6, situated farthest from the lamp, showed no noticeable impact, maintaining a temperature nearly identical to that of the climatic chamber. Sensor 1, for instance, required approximately 4 hours of lamp exposure to reach its maximum recorded temperature, reaching around 35.5 °C. In contrast, sensor 4, positioned more centrally within the specimen, needed roughly 6 hours of lamp exposure to reach its maximum recorded temperature, approximately 24.2 °C. Throughout the experiment, the specimen exhibited a temperature gradient of 15.5 °C across its cross-section.

Furthermore, upon deactivating the lamp, sensor 1 needed about 4.5 hours to return to thermal equilibrium with the climatic chamber. On a broader scale, the entire test specimen required approximately 7.5 hours to achieve a steady state after the lamp exposure ended.

Moreover, the numerical simulation demonstrated a considerable level of accuracy compared to the experimental results for most sensors. During this phase, sensor 4 emerged as the most critical point for the analysed time instants. However, the observed disparity did not exceed 4.9%, corresponding to an approximate temperature variation of 1.08 °C between the numerical and experimental data.

Concluding the experimental campaign, Figure 7 presents the experimental and numerical results acquired for sensors 1, 2, and 6, for Stage IV. These correspond to the outermost sensor located at the top of the specimen in the SFRSCC layer, the sensor positioned between the top layer and the laminate at the top face sheet of the GFRP component's panel, and the outermost sensor at the bottom face sheet of the specimen, respectively. Additionally, Figure 7d depicts the thermal profiles for four specific points of interest: t = 218 hours, t = 224 hours, t = 230 hours, and t = 236 hours. These time instants

correspond, respectively, to the midpoint between the 10th negative peak and the preceding positive peak, the 10th negative peak, the midpoint between the 10th negative peak and the 10th positive peak, and the 10th positive peak.



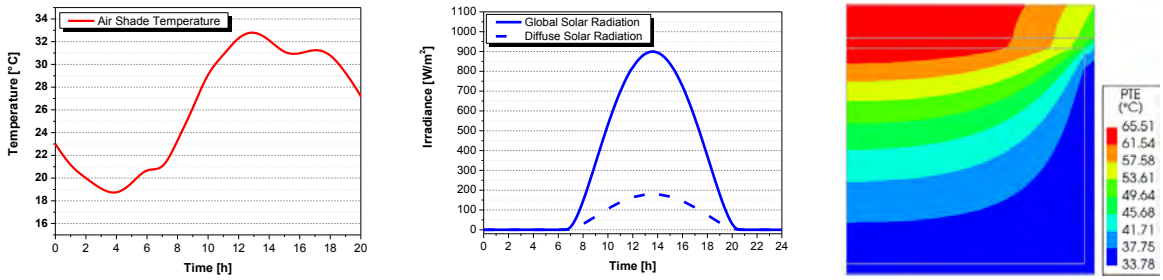


Figure 7. Stage IV - Sensors 1, 2 and 6: a) overview; b) detail b; c) detail c d) thermal profiles (all sensors).

The figures above depict temperature fluctuations within the specimen, influenced by cyclical thermal loads and exposure to the HPS lamp. At this Stage, sensor 1 reached a peak temperature of around 52.7 °C, surpassing the climate chamber's set temperature by 12.7 °C, with a minimum of approximately -12.6 °C. Sensor 6, however, recorded a maximum of about 39.5 °C and a minimum of -14.9 °C, closely mirroring the climate chamber's conditions. Positioned between the SFRSCC layer and the top GFRP face sheet, sensor 2 registered a maximum of approximately 52.2 °C and a minimum of about -12.2 °C. The maximum temperature gradient across the specimen's cross-section during this phase was approximately 14.5 °C. The numerical simulation closely matched experimental results; particularly highlighting sensor 2 as critical at t = 230 h (Figure 7d). The observed discrepancy did not exceed 6.8%, equivalent to a temperature variance of approximately 1.74 °C between numerical and experimental data. However, it's worth highlighting that during Stage IV, the applied temperature peaked at 40 °C, while the HPS lamp managed to emit a heat flow of 595 W/m² at its focal point, gradually dissipating over a 40 cm radius from the centre.

Finally, it is important to acknowledge the potential of the discussed numerical models, which have shown a high level of compatibility with the experimental data. They provide a promising way to explore the complexities of temperature distribution within the specimens. Once calibrated and validated, these models can be applied to practical scenarios, providing insights into how temperature gradients manifest in the specimens under real-world climatic conditions. Transitioning from the controlled environment of the climate chamber to simulations in the external environment, where the forced convection rate is expected to be lower, the following heat transfer coefficient values were used: 15 W/m²°C for SFRSCC and 25 W/m²°C for GFRP. All other parameters of the numerical model remain unchanged.

In Guimarães, Portugal, where the research centre (ISISE) conducting the test is situated, summer months witness solar radiation reaching up to 900 W/m² (which would have a near uniform incidence on the specimen, in contrast with the lamp). Furthermore, in 2023, the city experienced a maximum temperature of 33 °C. Figure 8c illustrates the thermal distribution of the test specimen under the most extreme conditions recorded in Guimarães in 2023, considering air temperature data from [20] (Figure 8a) and estimated solar radiation for a clear day in August/2023 at latitude 41.442, corresponding to Guimarães (Figure 8b).

a) b) c)

Figure 8. Guimarães worst-case scenario in 2023: a) solar radiation; b) air shade temperature; c) thermal distribution within the specimen.

Figure 8c indicates that under these extreme conditions, the specimen in Guimarães would reach a maximum temperature of 65.5 °C, while the GFRP structure would peak at 65.2 °C. Additionally, a thermal gradient exceeding 30 °C would be observed.

In Europe, the EN 1991-1-5 standard provides principles and guidelines for calculating thermal actions on buildings, bridges, and other structures, including their components. Although this standard does not address FRP composites, for comparative purposes, the most extreme scenario in terms of maximum temperature for a structure in Portugal would involve bridge decks, with the deck *type 1* (steel decks) being the most critical. The maximum temperature for such decks is calculated using the equation:

$$T_{e,max} = T_{max} + 16 \quad (1)$$

In this equation, $T_{e,max}$ represents the maximum temperature of an exposed surface, and T_{max} represents the maximum air shade temperature, determined by the Portuguese national annex for the specific zone. For Guimarães, this value is set at 40 °C.

According to EN 1991-1-5, the worst-case scenario would predict a maximum temperature of 56 °C for a structure in Guimarães, Portugal. However, the numerical analysis indicated that the specimen under study would reach 65.5 °C, surpassing the predicted worst case by 9.5 °C. It's crucial to emphasize that EN 1991-1-5 does not include provisions for FRP materials, thus its applicability to our case study is not fully covered. The *type 1* deck, exemplified in this context, regards to steel decks (steel box girder, steel truss or plate girder). As expected, the unique thermal properties of the hybrid panel's diverse components will yield a distinct thermal response.

5. Conclusions

This work provides insights into the thermal distribution over hybrid FRP sandwich structures subjected to different thermal loads. The experimental data obtained from both panels were consistent between themselves. Particularly noteworthy was the observation that the SFRSCC layer displayed a lower rate of heat transfer to the surrounding environment compared to the GFRP. Furthermore, the conducted numerical simulations demonstrated a very good agreement with experimental results, validating the developed models.

Numerical simulations demonstrated that under the most extreme conditions for Guimarães in 2023 (with an air shade temperature of 33 °C and maximum solar irradiation of 900 W/m²), a peak temperature of 65.5 °C would be reached at the upper surface of the specimen's cross-section. In contrast, with even higher air shade temperatures (40 °C), in accordance with the EN 1991–1–5, a bridge deck *type 1* (which regards to steel decks and represents the worst-case scenario for maximum temperature of a structure in Portugal) would reach a maximum temperature of 56 °C, indicating a shortfall of 9.5 °C.

It is essential to emphasise the lack of established guidelines for predicting temperatures in FRP composite materials. Moreover, this research demonstrates that even the most extreme scenarios in current standards for other materials may underestimate maximum temperatures if applied to FRP materials. Therefore, calibrated finite element-based numerical models serve as crucial tools for analysing thermal distribution in FRP composite structures. This significance is underscored considering that CEN/TS 19101:2022 provides a temperature conversion factor accounting for material property changes by temperatures diverging from 20 °C under service conditions. A discrepancy of more than 9 °C would be substantial in this context.

Keywords: composite patch, repair, cohesive model, toughness tests

Abstract
Classic repairs of corroded steel plates consist in cropping and renewing steel plates. Such repairs involve hot work which may not be compatible with Floating, Production, Storage and Offloading (FPSO) capacities content. It is necessary to carry out long operations of emptying, cleaning, and inerting in capacities surrounding the repair, implying long durations for which the production must be stopped. By using adhesively bonded repairs, described as cold work, tanks do not have to be emptied, and production can continue during repair.
In the Joint Industry Project (JIP) StrengthBond Offshore (SBO), a robust methodology for the design assessment of composite patch repairs on steel structure was developed. Typical stress approaches and energy approaches have first been tested using standard specimens for model calibration but the correlation with large scale samples (2 m) was not accurate enough. Thus, a new specimen called "equivalent interface", which includes several interfaces, was designed to be representative of the type of failure for this application, and used in toughness tests. Finally, a cohesive zone model was identified based on these toughness tests, in order to define a reliable failure criterion that can be used to design large composite repairs on steel structures with more confidence.

1. Introduction

Initiated in 2019, the JIP StrengthBond Offshore (SBO) developed a robust methodology for the strength assessment of composite patch repair bonded on corroded steel plates [1]. Several designs, with different geometries and manufacturing processes, were investigated with a large experimental and numerical campaign. Determination of failure of such composite/steel assembly is complex as it involves mixed material interfaces.

When designing bonded assemblies, simple approach involves stress analysis with analytical [2] or numerical models. Nonetheless, these approaches are limited when studying complex geometries and loadings, as is the case with large composite patch repairs. In our study, fracture mechanics approach in Finite Element (FE) and cohesive zone model were chosen to characterise the interfaces' behaviour involved in the patch repair resistance. Cohesive elements can predict both the delamination onset and crack propagation [3]. When modelling such elements, several methods exist to calibrate the parameters from behaviour laws, referred as cohesive laws. The inverse method, used in [4], where a high number of simulations is performed until fitting of both numerical and experimental results coincide, is the

method commonly used. Other calibration methods, as well complete methodology from characterisation to application on large scale steel-steel specimens are described in [5]. Experiments used to calibrate cohesive laws are typically toughness tests from standards ([6], [7], [8]). However, these tests require similar upper and lower adherents made of a single material and are thus non-suitable to model mixed material interface. A new specimen, named Equivalent Interface (EI), was designed during the JIP SBO to be used in toughness tests in order to characterise mixed-material interfaces as encountered in the composite patch repair. The objective of this specimen was also to limit the number of specimens needed for the characterisation campaign, by obtaining the critical energy release rate (ERR) of the weakest interface with a single specimen, rather than testing each interface. Cohesive laws calibrated with this new specimen are finally implemented in numerical models of large scale composite patch repair and compared to experimental results.

2. Method

2.1. Materials

The application described in this paper is on a composite patch repair on a steel substrate. Substrates were made of Strenx 1100 steel, with a minimum yield strength of 1100 MPa. The composite patch is composed of Carbon Fibre Reinforced Polymer (CFRP) with Unidirectional (UD) plies mainly, to restore the steel stiffness and some Glass Fibre Reinforced Polymer (GFRP) plies at the steel interface to prevent galvanic corrosion and to soften the interfacial stresses. UD carbon were oriented in the direction of the tensile loading. The composite patch was manufactured with infusion process using bi-component epoxy resin.

2.2. Equivalent Interface specimen

The objective of this specimen named equivalent interface (EI) specimens was to obtain the toughness of the weakest interface of the composite patch repair on steel plates. Thus, it had to be representative of where the failure would occur. The EI specimen included the several interfaces of the patch: steel/GFRP, GFRP/GFRP, GFRP/CFRP, CFRP/CFRP. Teflon inserts were placed at each interface. A large plate was manufactured by vacuum hand lay-up and cut into multiple EI specimens illustrated in Figure 1. The materials (resin, fibres) and the surface preparation, described in [5] were identical between EI and large composite patch specimens.

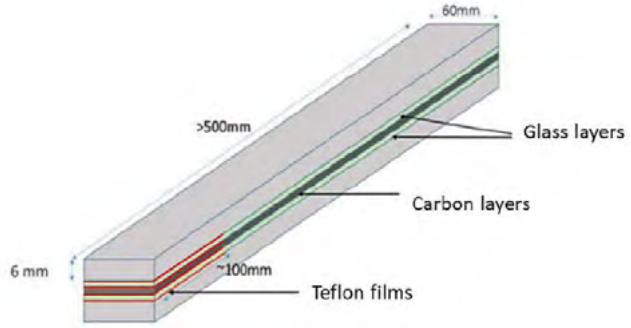

Figure 1. Equivalent interface specimen

2.3. Toughness tests

The EI specimens described earlier were used in toughness tests, namely Double Cantilever Beam (DCB) for mode I crack propagation, End Notch Flexure (ENF) for mode II and Mixed Mode Bending (MMB) for mixed mode I+II. From these tests, force-displacement curves, in pure mode I, pure mode II and mixed mode at ratio 50% and 75% mode II (ratio G_{II}/G_{tot}, ERR of mode II over total ERR) were obtained. Compliance Calibration Method was used to determine toughness values in pure mode I G_{Ic} and mode II G_{IIc} as described in [5]. Experimental set-ups of both DCB and ENF tests are shown in Figure 2.

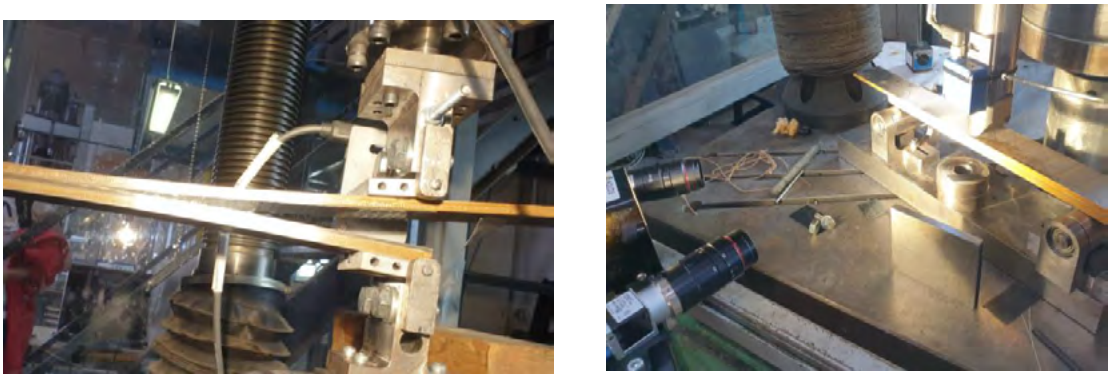

Figure 2. Experimental set-ups of DCB test (left) and ENF test (right) using EI specimens

2.4. Finite element models of EI specimens with cohesive elements

Finite models were performed in Siemens Simcenter Nastran with the SOL402 solver. Formulation of the cohesive elements is based on the continuum damage mechanics initially developed by the Ladevèze's team in Cachan [9]. Implementation in Nastran is further detailed in [3] with behaviour laws description.

The elements used in the model were solid volume elements. Isotropic properties were used for the steel substrates and 3D orthotropic properties used for the carbon and glass plies. In-plane properties were based on experimental tests while out-of-plane properties were calculated from BV rules NR546 [10]. Geometry and boundary conditions are shown in Figure 3. As Teflon was inserted at every interface except the CFRP/CFRP middle interface, contact was applied at each interface except this middle interface where nodes were merged. Contact surfaces were applied with default parameters from SOL402 solver and no friction was used. In the case of MMB setting, the beams of the test bench were modelled using rigid elements. A cohesive element layer was introduced at the interface between steel and the first ply of GFRP.

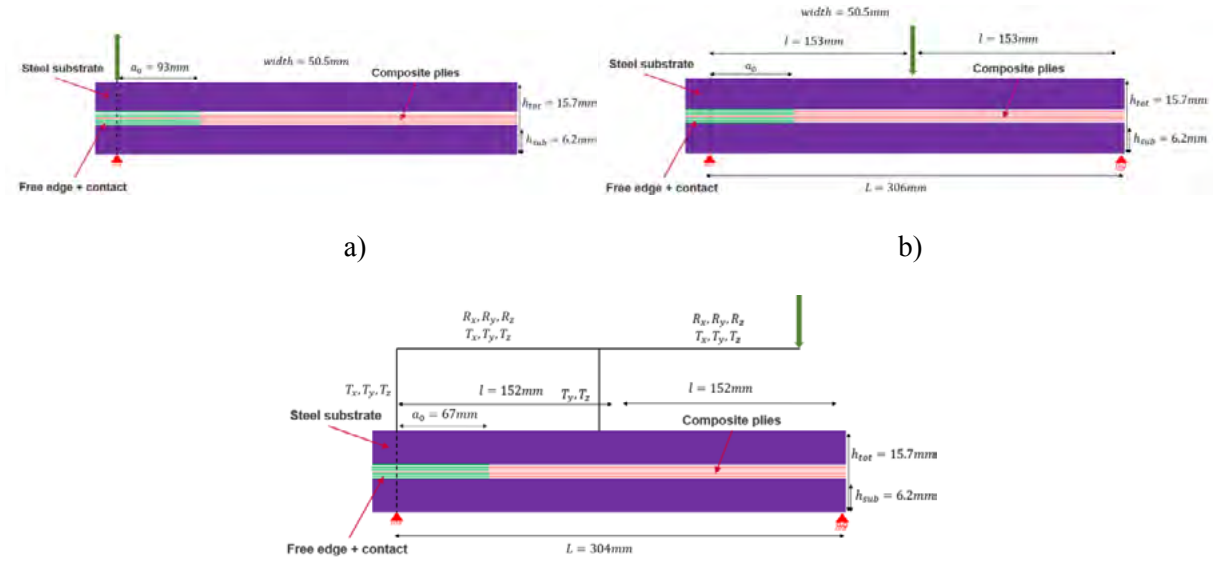

Figure 3. Geometry and boundary conditions of the used finite element model for: a) the DCB model, b) ENF model, c) MMB model

Figure 4 shows the mesh used for the ENF model (a similar mesh was used for the DCB and MMB models). Only one element in the thickness of each composite ply is considered. A mesh sensitivity study was carried out in the direction of crack propagation, resulting in a mesh size of 1 mm in this direction for each toughness test.

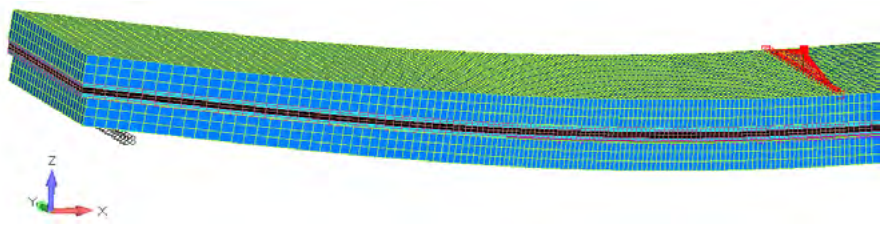

Figure 4. Illustration of ENF model mesh

2.5. Methodology for cohesive parameters calibration

A bilinear cohesive law shape was used for modelling the crack propagation for all modes. Thus, 3 different parameters had to be calibrated in pure mode I and II: the critical ERR G_c, the initial stiffness K and the critical stress before damaging σ_c. An example of mode I cohesive law is shown in Figure 5. Damage is referred as d.

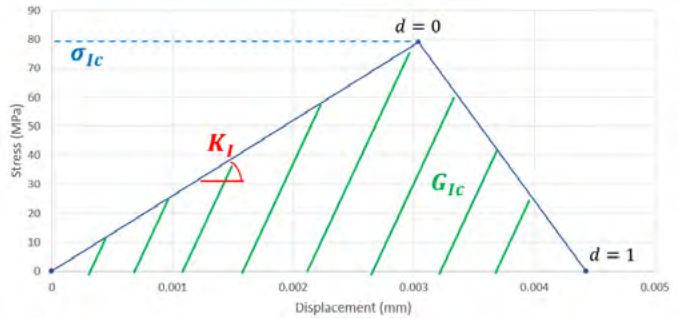

Figure 5: Example of bilinear cohesive law in mode I

The inverse method was used for the calibration of the cohesive law parameters. The toughness in pure mode I and II was determined thanks to the fracture mechanics tests, and the two other parameters from each mode were determined by fitting the numerical and experimental force-displacement curves. For MMB tests, the coupling between the modes is calibrated through a single parameter α determined by inverse method. The complete methodology is described below:

1. Measure the toughness experimentally from DCB, ENF, MMB using the EI specimen,
2. Assess the mesh sensitivity for all models,
3. Determine the cohesive law in mode II, with the only given value being G_{IIc},
   a. Evaluate the stiffness K_{II} sensitivity in ENF models,
   b. Evaluate the critical shear stress τ_c sensitivity in ENF models,
   c. Determine the cohesive law in mode II with optimal stiffness and critical shear stress,
4. Determine the cohesive law in mode I, with the only given value being G_{Ic},
   a. Evaluate the stiffness K_I sensitivity in DCB models,
   b. Evaluate the critical peel stress σ_c sensitivity in DCB models,
   c. Determine the cohesive law in mode I with optimal stiffness and critical peel stress,
5. Implement the resulting cohesive laws in mode I and II in MMB models and evaluate the sensibility of the coupling parameter,
6. Determine the optimal coupling parameter in MMB models for mixed mode.

2.6. Validation with large scale specimens

2.6.1. Specimen presentation

Large specimens were manufactured by infusion to validate the approach. Two different geometries were tested during the experimental campaign, corresponding to two different scarf angles (to minimise stress concentration at the edges), as illustrated in Figure 6, with the same thickness in the middle section of the composite patch. The length of the composite patch was 1.4 m, with a width of 50 mm for both geometries.

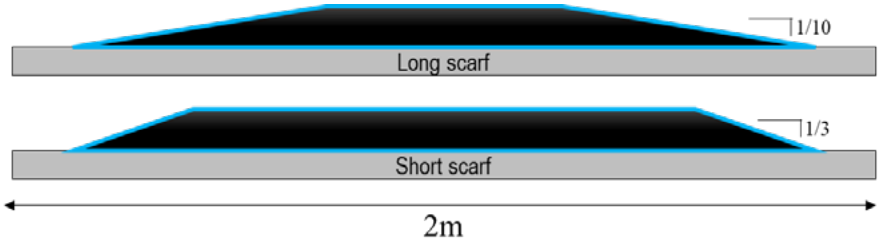

Figure 6. Illustration of long scarf and short scarf geometries

These specimens were tested both in tensile loading and bending loading, which provided four different configurations to compare numerical and experimental results.

2.6.2. Modelling of large scale specimens

The entire model was done with solid volume elements. The composite part of the specimen was modelled with 1 element per layer in the thickness and 3D orthotropic properties, similarly to the EI models. Two plies of GFRP were placed at the interface, as in EI specimens, and two other plies covering everything at the top for protection purposes. Two different positions were tested in two separate models for the cohesive element layer: at the steel/GFRP interface and the first two GFRP/GFRP plies, in separate models. A mesh sensitivity analysis was also performed. An illustration of the mesh is given in Figure 7, along with the 2 different cohesive element layer configurations. Boundary conditions and loadings are illustrated in Figure 8. The loading was applied as follows:

- Tensile: Clamp modelled by rigid element, with loading applied on it. All rotations and all displacements blocked on rigid element, except x-translation.
- Bending: Loading applied on rigid element at the mid-length. All rotations and all displacements blocked on rigid element, except z-translation.

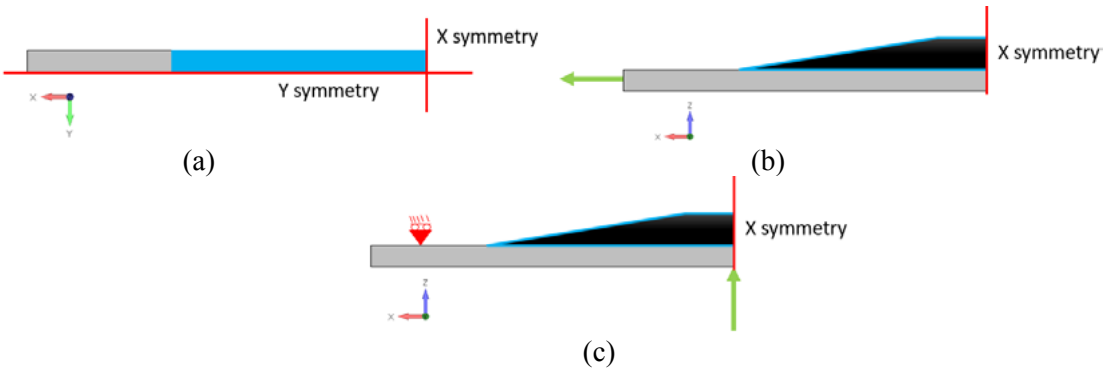

Figure 8: (a) symmetries used on both models; (b) loadings, boundary conditions on tensile model and (c) loadings, boundary conditions on bending model

3. Results

3.1. EI Model results and cohesive parameters

For DCB and ENF models where a stiffness sensitivity analysis was performed, it was found that the stiffness (values from 10^2 to 10^6 MPa/mm) had almost no influence on numerical force-displacement curves. The critical ERR has a lot of influence on the results but it was fixed from the experimental tests. Thus, the calibration of the cohesive parameters to fit to experimental results was done mostly by varying the critical stress before damaging, σ_c for DCB and τ_c for ENF.

Results for the DCB peel critical stress sensitivity is shown in Figure 9 where experimental and numerical force-displacements curves are plotted. All DCB specimens had the same initial crack size. For DCB models, it is clear that a small critical stress of 2 MPa represents well the experimental behaviour, with a progressive damaging that starts early in the tests. For ENF models, four configurations were used based on the standard, with four different initial crack sizes. Numerical results, with dots, represent well the behaviour of the tests. In the tests, there was a smaller slope at the starts from the testing set-up that induced some lateral offset but passed 0.5 mm displacement, the global stiffnesses of both numerical and experimental curves coincide. The calibration of the critical shear stress was done based on the failure load at one configuration and tested on the other three ones. It showed failure load difference between numerical and experimental below 5% for all configurations.

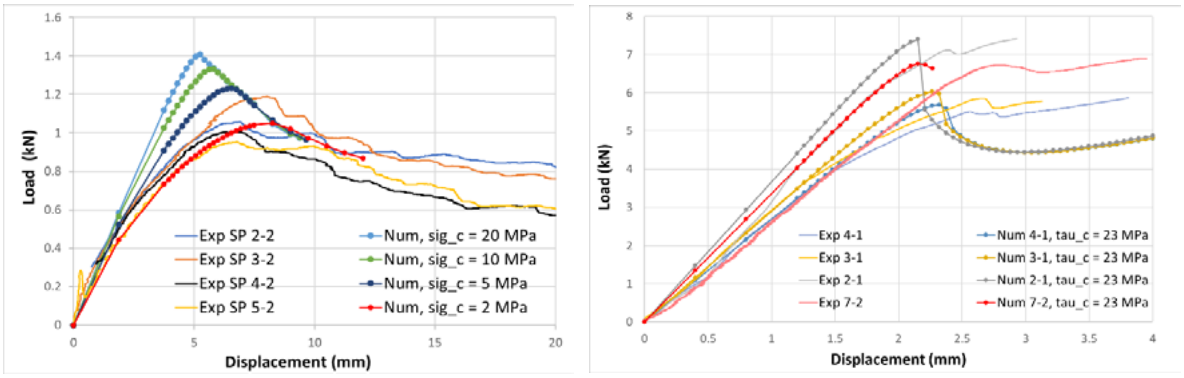

Figure 9. Comparison of numerical and experimental force-displacement curves for DCB (left) and ENF (right) at $\tau_c = 23$ MPa

The coupling parameter was also calibrated from MMB tests using inverse method and the final cohesive parameters are reported in Table 1.

Table 1. Resulting cohesive parameters from EI specimens

	Critical ERR (kJ/m^2)	*Critical stress* (MPa)	*Stiffness* (MPa/mm)	*Coupling parameter*
Mode I	1.74	2	1 000	0.6
Mode II	1.46	23	158 000	

3.2. Results on large scale specimens

For tensile and bending models, there was a competition between the two cohesive layer positions, as was observed during experiments where the failure occurred between the steel and first GFRP ply but also between the first two GFRP plies. The first cohesive elements to be damaged and reaching failure were those below the introduction of 0° UD CFRP plies in the patch.

Detailed results concerning the failure loads of the long scarf specimen in tensile loading are presented in Table 2. It can be seen that the failure loads for both cohesive layer position is quite close but failure would first occur at the interface between the first two GFRP plies for this configuration.

Table 2: Failure loads of tensile tests on long scarf specimens at both cohesive interfaces for different mesh sizes

Interface 1st GFRP ply/2nd GFRP ply			
Mesh size (mm)	*Failure load* (kN)	*Difference compared to finest mesh*	*Difference compared to experiments*
1	821	+0.3%	+4.2%
0.5	**818**		**+3.8%**

Interface steel/1st GFRP ply			
Mesh size (mm)	*Failure load* (kN)	*Difference compared to finest mesh*	*Difference compared to experiments*
2	857	+2.9%	+8.6%
1	828	+0.5%	+5.1%
0.5	832		+5.6%

Results of all configurations are summed up in the Table 3. They correspond to the lowest failure load of the 2 different cohesive element layer position. It can be seen that the difference with experimental results is below 25% in all cases. The behaviour in tensile loading, which is the main global loading on FPSO main deck, is also better represented in the models compared to bending loading.

Table 3. Comparison of numerical and experimental failure loads for all 4 configurations

Numerical and experimental failure loads comparison				
	Tensile loading		*Bending load*	
	Long scarf	*Short scarf*	*Long scarf*	*Short scarf*
Experimental (kN)	787	489	30	34
Numerical (kN)	818	406	37	27
Difference	+4%	-17%	+24%	-21%

4. Conclusions

The methodology presented in the paper with the newly designed equivalent interface specimens allowed to predict the failure loads of composite patch repair of corroded steel plates. The approach is based on fracture mechanics and the use of cohesive elements. The equivalent interface specimen is a non-standard symmetric specimen made of steel substrate and several composite plies, representative of the composite patch where failure occurred. This specimen was used in toughness tests to determine cohesive laws in mode I, mode II and in coupled mode I+II with an inverse method to fit numerical and experimental force-displacement curves. These laws were then input in the large specimens' model with composite patch on steel substrate. While methods using stress criteria or cohesive laws from standard specimens (steel/steel or GFRP/GFRP substrates) gave failure loads 50% above the experimental values, cohesive elements with equivalent interface laws resulted in smaller differences with experiments. For the tensile loading, the loading type most encountered for FPSO repair, the difference between numerical and experimental failure loads was below 20% for two different composite patch geometries.

The methodology to assess the strength of composite repair on steel structures was successfully applied for this design. To complete the design assessment methodology, durability of such repairs should be the subject of future work.

Abstract
Carbon fiber-reinforced epoxy composites are used in warm aero-engine parts to reduce weight and allow for more complex and efficient shapes. In these parts, the surrounding aero-thermal environment may promote high temperatures (over 100°C in an aircraft engine) leading to thermo-oxidation phrenomena. Thermo-oxidation may promote material properties change and embrittlement, leading to material degradation. Nevertheless, the laboratory aging studies have been carried out in oven only (in atmospheric condition or under oxygen pressure), but the parts in real conditions are exposed to temperature but also to air flow. The aim of this article is to understand the effect of the airflow and the influence of the aero-thermal boundary conditions on thermo-oxidative aging of the materials. As a first step, the polymer matrix was studied by comparing oven and wind tunnel aged samples. The wind tunnel aged sample showed faster degradation when aged in the wind tunnel which is mainly due to the temperature and pressure field in the flow.

1. Introduction

Composites, including carbon fiber-reinforced epoxy composites, have a multitude of applications in fields such as sports (sailing, automotive sports, and cycling) and transportation (cars, helicopters, and aircraft). These applications are often subjected to harsh conditions, necessitating the control of polymer aging. Humidity, ultraviolet radiation, and high temperatures can lead to thermo-oxidation, which can result in polymer matrix degradation. This study will investigate thermo-oxidation of epoxy polymer materials at high temperature.

Depending on the environment, samples can be exposed to different range of temperature. The degradation rate is proportional to the chemical kinetics which basicly follow an Arrhenius law with the temperature until the appartition of the first craks. The thermo-oxidation is faster close to the glassy transition temperature [1] [2] [3]. Temperature is also used as an acceleration factor to reduce the duration of test, nevertheless, at low or high temperature other phenomenom can occur such as physical aging, humidity aging (low temperature) or reticulation [4]. An other important parameter is the oxygen pressure. This parameter is widely used to accelerate the test as the oxidation rate is linked to the oxygen quantity available at the interface [3] [5] [6]. The chemical reactions are faster as more oxygen can react inside the polymer.

Thermo-oxidation results in a change in the chemical bonds (and thus chemical functional groups), which ultimately leads to yellowing in all polymers [7] [8]. The chemical changes also resulted in mechanical changes. The competition between chain scission and crosslinking outcomes in a modification of the glass transition temperature (and other phase transitions) [9] [10] [11]. Consequently, the polymer becomes harder and the modulus of elasticity increases [10] [2] [11]. The

polymer embrittlement alters the failure properties [12]. Furthermore, some decohesion between fibers and the polymer matrix can affect the failure properties even more.
Temperature and pressure are the most important factors to control the oxidation rate. In real conditions, specially in an aircraft, the composite parts are exposed to high temperature, variable pressure but also to an airflow. The effect of the airflow is still unknown whereas the boundary layer can increase the friction coefficient and mass transfer du to the velocity gradient near the wall. In order to understand the effect of airflow, this study will focus on the aging of the polymer matrix. The application to composites will be considered in a subsequent study. This work aims to give first answer on the effect of airflow on the thermo-oxidation of polymer.
Two set of samples will be examined. The first one will be aged in an oven under atmospheric condition and used as our reference. The second set will be aged inside a wind tunnel to reproduce the airflow aging condition.
To characterize the thermo-oxidation, mechanical property measurement will be done. The indentation technique has been demonstrated to be an effective method for characterizing thermo-oxidation processes, and linked to chemical modifications [13] [14] [15] [16].
The first part of the article will present the experiment and focus on the wind tunnel used to age the sample. Then, the indentation measurements on both samples aged in an oven and a wind tunnel will be shown. Finally, the effect of the temperature and the airflow on the aging will be discussed.

2. Experimental set-up and method

2.1. Materials and aging

In this study, an aromatic diamine epoxy resin was employed, exhibiting chemical similarities to both the DGEBF-CAF resin and the PR520 resin manufactured by Syensqo, which are commonly utilized in the aerospace industry [17] [18]. Samples, provided by SAFRAN Aircraft Engine company, were received in the form of 5mm thick rectangular blocks, with the exposed surface area measuring 8*8mm in a square configuration.
Reference samples were exposed to atmospheric air conditions at 150°C in an oven for durations ranging from 20h to 80h. The ventilation oven is set at a level where the oxygen is renewed and no flow is created around the sample.

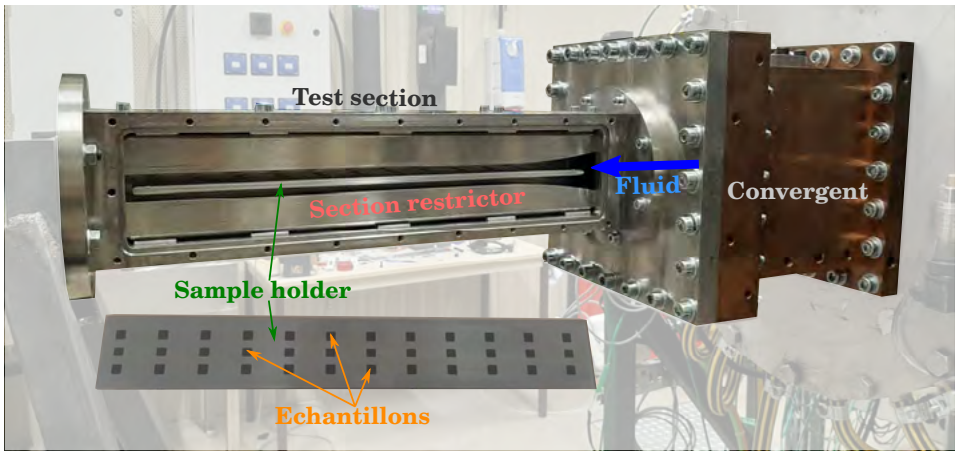

Figure 1. BATH wind tunnel geometry and samples positions.

The other set of samples have been aged in the BATH (Banc AéroTHermique) wind tunnel (for the detail of the bench, see [19]). A test section has been designed to put the sample inside the airflow (same aerothermal condition on each side) and avoid temperature gradient inside a sample. Fig.1 shows the geometry of the wind tunnel with the convergent shape until a constant reduced section to accelerate the flow until Mach 1. The samples are positioned inside the flow in a mount. This set-up avoid temperature gradient inside the sample. Both face of the samples are aged with the same airflow conditions.
Nevertheless, the samples undergoes different aerothermal conditions. The flow rate and the total temperature (flow temperature at static conditions) are the two regulated parameters inside the wind

tunnel: the pressure and temperature field is then a function of the flow and the geometry. It is not possible to adjust the temperature and pressure for each sample.
Fig.2(a) shows the temperature and Fig.2(b) the pressure and mach number for each samples estimated by numerical simulation (RANS simulation, StarCCM+). The increase of the Mach number in the constant test section is due to the thickening of the boundary layer conjugated with the decrease of the static pressure. The constant total pressure shows the lack of shock inside the canal where as the slighty decrease at the end is due to viscious friction.

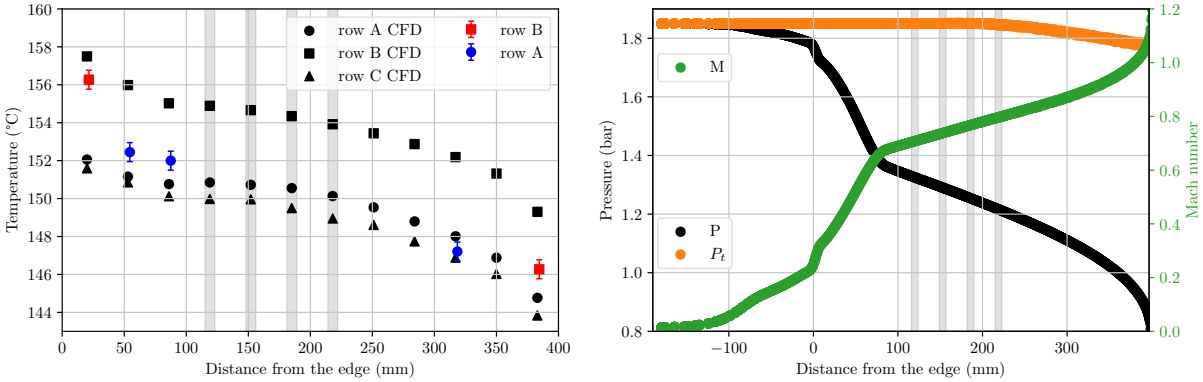

Figure 2. (a) Temperature insidethe samples in the wind tunnel. The black dots are from numerical simulation and colored dot from measurement which validate the simulation. (b) Mach number M, static pressure P and total pressure P_t profiles inside the wind tunnel. In both figures, the gray vertical lines shows the position of the samples.

The temperature inside the sample is not constant because the wind tunnel is inside a room at ambient temperature. The test section wall promotes thermal losses by convection with the environment and therefore conductive heat transfer inside the sample. The decrease of temperature between samples are due to the thickening of the boundary layer and therefore the reduction of the heat transfer coefficient coupled to the conductive losses. Nevertheless, only 2°C gap is noticed between studied samples. The simulation tends to overestimate the measurement between 1°C to 2°C. Small temperature (2°C to 5°C) deviation is noticed between oven and wind tunnel aging.

2.2. Indentation test

Nanoindentation analyses were conducted using the NanoTest Vantage instrument by MicroMaterials. Sample preparation involved halving the samples, put side by side them with an elastic band, and applying a coating (image of the sample Fig.3). This preparation strategy was employed to mitigate edge effects during indentation close to the interface, achieved by applying resin coating on the opposing side of the interface. The measurement surface underwent polishing to minimize roughness to levels below 10nm, thereby mitigating the influence of surface irregularities on nanoindentation measurements (refer to [20] [17]) for comprehensive details on sample preparation).

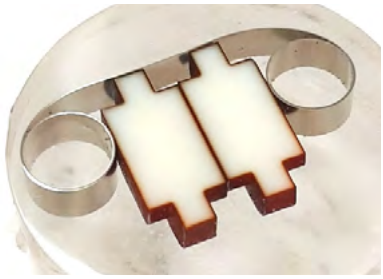

Figure 3 : Aged sample cut and coated.

Nanoindentation experiments utilized a spherical indenter with a radius of 5µm. The tests were conducted with force control, reaching a maximum force of 5mN over a 20s duration due to the

viscoelastic properties of the polymer. The velocity during both the loading and unloading phases was set at 0.5µm/s. Data collected during the unloading phase were employed to calculate the reduced elastic indentation modulus (E_{red}) using the method outlined by Oliver and Phar [21]:

$$E_{red} = \frac{\sqrt{\pi}\frac{dF}{dh}}{2\,\beta\sqrt{A_p}} \quad (1)$$

with $\frac{dF}{dh}$ the slope at the beginning of unload, A_p surface contact between the indenter and the sample and β, the indenter geometrical parameter ($\beta = 1$ for revolution indenter). Based on the properties of the indenter, the elastic indentation modulus *EIT* is estimated (Eq.2) :

$$\frac{1}{E_{red}} = \frac{1-\nu_{ind}^2}{E_{ind}} + \frac{1-\nu_{poly}^2}{EIT} \quad (2)$$

with $E_{ind} = 1141GPa$ and $\nu_{ind} = 0.07$ the elastic modulus and Poisson coefficient of the diamond indenter and $\nu_{poly} = 0.4$ the Poisson coefficient of the polymer (value from technical data).
The elastic indentation modulus profile of the oxidized layer was characterized at intervals of 5µm from the sample edge, with measurements taken every 15µm. This experimental profiling was repeated 10 times at intervals of 50µm. Each profile presented in this study represents the average of 10 profiles. Vertical error bars denote one standard deviation, with measurement uncertainty being at least 10 times lower than the variation observed between measurements.

3. Results

Samples aged 20h, 40h, 60h and 80h in oven and in BATH wind tunnel are compared to understand the effect of the airflow on thermo-oxidation aging. During the aging of thick samples, an oxidized layer appears because the chemical reaction are faster then oxygen diffusion, therefore, the oxygen affects the bulk more lately. Inside the oxidized layer, a mechanical property gradient can be measured. The indentation shows an increase in the elastic modulus due to the stiffening of the sample.

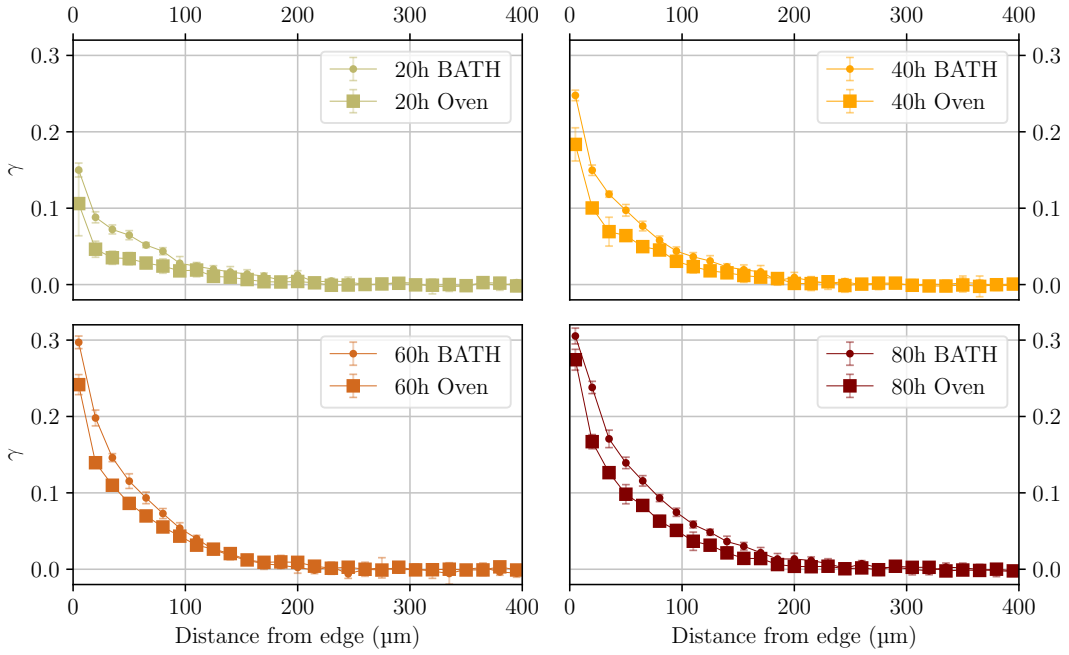

Figure 4. Adimensional indentation modulus profiles (γ, Eq.3) for samples aged during four times (20h, 40h, 60h, 80h) in the oven and in the wind tunnel (BATH).

Fig.4 shows the indentation modulus for samples aged the same duration in oven or in the wind tunnel. The parameter γ is plotted to avoid the dependency of the materials :

$$\gamma = \frac{EIT}{EIT_0} - 1 \quad (3)$$

with EIT_0 the indentation modulus of the virgin sample (it is estimated by averaging the 5 last measurements of the profiles).

For all exposure duration, the sample aged in the wind tunnel shows a higher value of indentation modulus which means a higher degradation and so a more oxidized layer. It can be interesting to extract a modulus increase factor Γ from each profile since each sample has been aged in a different position due to the experimental set-up. The modulus increase factor Γ is the ratio of the indentation modulus for the sample aged in the BATH wind tunel γ_{BATH} over the sample aged in the oven γ_{oven} : $\Gamma = \frac{\gamma_{BATH}}{\gamma_{oven}}$.

The modulus increase factor Γ is the average of each values computed from the experimental data shown in Fig.4 until a depth of 100µm.

Tab.1 summarises the modulus increase factor Γ and the aerothermal conditions enconters by the sample for four different aging times.

Exposure time (h)	Γ	T (°C)	P (bar)
20	1.78 ± 0.20	155,0	1,29
40	1.47 ± 0.13	154,3	1,25
60	1.32 ± 0.06	155,3	1,32
80	1.38 ± 0.11	154,7	1,21

Table 1. Experimental estimation of the modulus increase factor Γ from the samples aged in the wind tunnel and aerothermal aging conditions (temperature and pressure).

The effect of temperature, pressure and airflow will be discussed in the next section to explain this fater aging.

4. Discussion

The accelerated aging observed in this study may be attributed to the temperature, pressure, or airflow. Previous results (Fig.2(a)) have demonstrated slight differences in temperature-induced aging between oven and wind tunnel conditions. A time-temperature equivalence law will be employed to eliminate the influence of temperature on the results [22] [4]. For two aging temperatures T_A and T_B and aging durations t_{T_A} and t_{T_B}, the equivalence is given by Eq.4 :

$$\alpha_{\boldsymbol{T}}(T_A)t_{T_A} = \alpha_{\boldsymbol{T}}(T_B)t_{T_B} \quad (4)$$

with $\alpha_{\boldsymbol{T}}(T)$ the accelerating factor due to the temperature (Eq.5) :

$$\alpha_{\boldsymbol{T}}(T) = \exp\left(-\frac{E_a}{R}\left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right) \quad (5)$$

$E_a = 1.63\ 10^4 J\ mol^{-1}$ the activation energy, $R = 8.31 J\ mol^{-1}K^{-1}$ the universal gas constant, T and $T_{ref} = 126°C$ two temperatures.

It is then possible to calculate the time that should be considered to compensate the temperature difference between a sample aged in oven at 150°C and a sample in BATH wind tunnel. The temperature is not precisely known as explain with Fig.2(a). We considered the sample exposed at the higher at 155°C and at the lower at 152°C to take into count the uncertainy between reality and fluid simulation. By using Eq.4, it is possible to calculate the time that the sample should be exposed to compensate the temperature difference. Eq.5 is used to calculate the accelerating factor α_T value at the different temperatures. For example, the 40h aged sample at BATH should be compared to the sample aged between $\frac{\alpha_{\boldsymbol{T}}(152)}{\alpha_{\boldsymbol{T}}(150)} t_{152} = \mathrm{t}_{150} = 1.2 \times 40h = 48\mathrm{h}$ and $\frac{\alpha_{\boldsymbol{T}}(155)}{\alpha_{\boldsymbol{T}}(150)} t_{155} = \mathrm{t}_{150} = 1.5 \times 40h = 60\mathrm{h}$ in the oven at 150°C. In other words, the sample aged 48h at 150°C is equivalent to the sample aged 40h at 152°C.

The corresponding indentation modulus can be estimated by interpolating normalized indentation modulus γ over the time for each distance from the edge. Then, the equivalent indentation modulus is between $\gamma(t = 48h, x = 5\mu m) = 0.22$ and $\gamma(t = 60h, x = 5\mu m) = 0.26$ for the measurement at a

distance of 5 µm from the edge. For this example, the resulting modulus increase factor Γ_T, which traduce the variation of the indentation modulus whithout the temperature influence is between 0.96 and 1.13. This factor traduces if in addition of the temperature, there is still a faster oxidation. If the factor Γ_T is lower or equal to 1, the temperature is the only accelerating factor. If the factor is greater than 1, there is another cause of the acceleration.
This approach is employed for all the samples presented in Fig.4 to eliminate the influence of temperature. The calculated value of the modulus increase factor Γ_T (without temperature effect) is then used to assess whether there is a discernible difference in the rate of aging between the samples aged in the wind tunnel and those aged in the oven, once the temperature offset has been accounted for.
As illustrated in Tab.2, the modulus increase factor exceeds 1 in most of the case. It is also important to note that the temperature difference is not the only factor responsible for this acceleration.

Exposure time (h)	$\Gamma_{T=155°C}$	$\Gamma_{T=152°C}$	P (bar)
20	0.76	0.95	1,29
40	0.96	1.12	1,25
60	0.99	1.13	1,32
80	0.96	1.13	1,21

Table 2. Experimental estimation of the modulus increase factor Γ_T from the samples aged in the wind tunnel with corrected temperature offset and aerothermal aging conditions (pressure).

The pressure at the interface may also be a contributing factor in this aging acceleration. The more oxygen at the interface, the more oxygen is thus available for the chemical reaction and the easier it is for oxygen to go inside the sample by diffusion. The oxidized layer of the sample aged in the wind tunnel exhibits a greater modulus increase with more oxygen at the interface than the oxidized layer from sample aged in the oven.

The last parameter to be considered is the mass transfer due to the airflow. Due to the viscosity of the fluid, boundary layers are created close to the wall, exhibiting velocity, temperature, and mass gradients. The mass gradient induces a higher mass transfer exchange within the sample, analogous to heat transfer with the temperature gradient. The current study is unable to distinguish the effect of pressure from the boundary layer effect. However, further investigations are ongoing to identify the oxygen boundary condition and distinguish these two parameters.
Ultimately, the aging temperature difference between the oven and the wind tunnel represents a significant contributing factor to the acceleration of the aging process but it is not the only one. Additionally, the static pressure in BATH is higher than in the oven due to the link between airflow speed and static pressure, as well as the influence of convective mass transfer on accelerated aging. Further investigations are underway to ascertain the role of pressure and mass transfer at the interface. In real operating environments, such as turbine fan blades, local pressure and temperature may vary due to the slowing down of the flow and its subsequent understanding. This could explain the faster aging observed in laboratory tests than in real operating environments.

5. Conclusions

This article reports on a study of thermal oxidation aging in a realistic environment for an aircraft engine application. Both oven and wind tunnel aging tests were conducted. A test section was designed for wind tunnel aging with the objective of achieving the most controlled aerothermal conditions possible. These conditions were characterized in terms of temperature and pressure, as these two parameters exert the most influence on thermo-oxidative aging. The results demonstrated a faster rate of aging compared to the results obtained from oven tests.
To compare samples exposed in the oven and in the wind tunnel, indentation modulus measurements were made in the oxidized layer. The gradient of mechanical properties in the sample provides an indication of the degree of aging. The results demonstrated that the samples subjected to wind tunnel aging exhibited accelerated aging. This is primarily attributable to the slightly elevated temperature in

the wind tunnel relative to that in the oven. Furthermore, in the context of fluid flow, pressure and convective mass transfer have been identified as factors that accelerate the aging process.
Given the current understanding of the aging behavior of the polymer, it is crucial to ascertain whether the composite exhibits similar characteristics and to determine whether the carbon fibers influence oxidation. At present, tests on composite samples are being conducted.

Abstract
This paper investigates the in-plane shear behavior of flax fiber-reinforced polypropylene composites at a high temperature by linking numerical modeling tools with experimental results. For this purpose, the bias-extension experiment is performed on composite specimens at 160 °C. The study employs the Digital Image Correlation (DIC) technique to measure local deformations and strains on the specimen's surface during the test. Additionally, the Finite Element (FE) method is used to simulate the experiment. A hypo-elastic material model is implemented into the Finite Element model through a VUMAT subroutine to represent the material's in-plane shear behavior. The study compares the force-shear angle variations derived from the test and the numerical model.

1. Introduction

The mechanical behavior of fiber rainforced thermoplastic composites, particularly their response to in-plane shear deformation, is an important area of investigation for optimizing manufacturing processes like thermoforming. In-plane shear, characterized by the rotation of fibers within the composite structure, influences the material's overall performance [1]. One commonly employed method to study the in-plane shear behavior of composites is the bias-extension experiment [2]. This experiment involves subjecting composite samples to tensile loading, with the fibers being initially oriented at ±45 degrees with respect to the loading direction. Based on the Pin-Jointed Net (PJN) theory, a key requirement of this test is using an initial gauge length H that is at least two times larger than the specimen width W [2]. In addition, the PJN model assumes that fibers are inextensible and that there is no slip between them. These criteria ensure creating a pure shear region C (Figure 1) during the loading of the specimen. In such a condition, the existing four triangular regions B have half the shear value of region C. Lastly, two undeformed triangular regions A with zero shear values also exist, as shown in Figure 1.

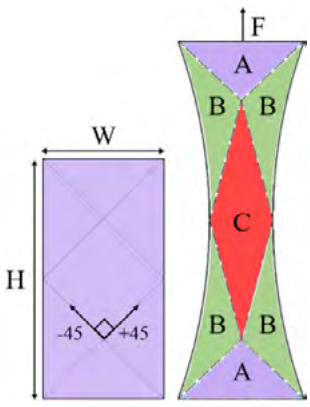

Figure 1. Pin-jointed net theory.

Thermoforming involves heating a thermoplastic composite sheet and shaping it into a mold to produce complex geometries. The material experiences various deformation modes during this process, with in-plane shear being the dominant one. Numerical simulations can be used to simulate and optimize the process parameters [3, 4]. Capturing the complex behavior of the composites during the thermoforming process is an essential step in simulating the process, which can be done by developing a constitutive model. By accurately characterizing the forming behavior of composite materials, manufacturers can tailor the thermoforming processes to optimize part quality, minimize defects, and enhance mechanical properties [5].

This paper investigates the in-plane shear behavior of flax fiber-reinforced polypropylene composites. For this purpose, first the bias-extension experiment was performed at 160 °C. The Digital Image Correlation (DIC) technique was continuously measuring the local deformations on the specimen's surface. This method provides full-field displacement and strain distributions on the specimen's surface as it deforms [6]. The Finite Element (FE) method was used in the next step to develop a numerical model of the bias extension experiment. This study examines the capability of a hypo-elastic shear model to represent the material behavior by developing a VUMAT subroutine. Based on the results, the suggested material model can be employed to simulate the samples' in-plane shear behavior during thermoforming.

2. Material and Methods

The tested samples were cut from a 4-ply spread tow woven composite laminate, made from polypropylene matrix and reinforced with flax fibers (40% fiber volume fraction), with an average thickness of 2.4 millimeters. The gauge section of the specimens was coated with two thin layers of white paint, followed by spraying a single layer of black paint to generate a speckle pattern for the DIC measurements. Additionally, four white points were marked on the specimen's surface (Figure 2 (left)) to measure the shear angle in zone C using the marker tracking method. An Instron universal testing machine with a TA Instruments climate chamber and a 10-kN load cell were used for the thermo-mechanical tests (Figure 2 (right)). During the experiments, the fibers were oriented at ±45 degrees with respect to the applied load, the climate chamber was set at 160 °C, and the displacement rate was 10 mm/min. The image acquisition frequency of the DIC measurements was 1 Hz. The experiment was repeated two times. In each test, a type-K thermocouple was connected to the sample to measure the temperature history. The measurements were logged using the 8000 Micro-Measurements data logger with a data sampling frequency of 1 Hz.

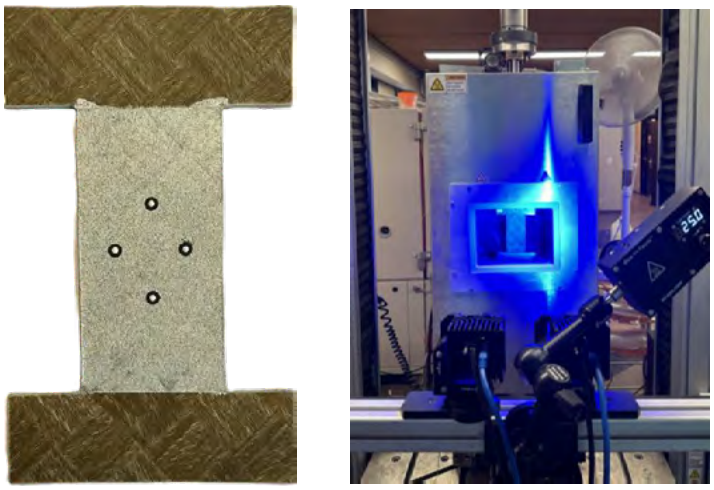

Figure 2. (left) Bias extension specimen, (right) clamped specimen inside the oven and DIC cameras.

3. Finite Element Model

A finite element model of the sample was developed in ABAQUS to investigate the in-plane shear behavior. A mesh sensitivity analysis was performed to ensure the solution is independent of the mesh size. Boundary conditions were defined so as to simulate the loading conditions at the top and the constraints at the bottom of the sample. A VUMAT subroutine has been introduced to the FE analysis to include a hypo-elastic material model into the composite's response [7]. The in-plane shear modulus constants, obtained from the force versus shear angle results, are incorporated in the VUMAT subroutine. The in-plane shear modulus in this simulation is given by (MPa):

$$G_{12}(\gamma) = 374.90\,\gamma^4 - 633.56\,\gamma^3 + 396.29\,\gamma^2 - 99.07\,\gamma + 9.96 \quad (1)$$

where γ represents the shear angle and defined as the angle between the two fiber directions during deformation. The model is compared with the experimental results by evaluating the obtained force-shear angle curves.

4. Results

An overview of the results obtained from both the experimental investigations and the finite element simulations is provided in this section. Figure 3 presents the average load-shear angle curve of the two specimens tested at 160 °C and at a 10 mm/min displacement rate. The results include the variation in the repeated tests using error bars. The initial load increase is due to the static friction between yarns and plies [8]. After that, the yarns are relatively free to rotate around their crossover points. Towards the end of the curve, at an approximate shear angle of 40° (identified as the locking angle), where the fibers come into contact and resist further deformation, a significant increase in the measured load is observed.

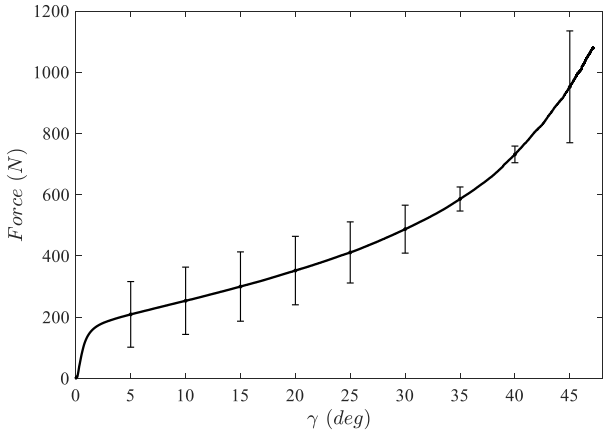

Figure 3. Average experimental force-shear angle curve with the corresponding variations.

Figure 4 shows the shear angle distribution obtained at 30 mm of displacement using the DIC method. As seen in this figure, the deformed shape matches well the predictions of the PJN theory. A pure shear zone is present at the center of the specimen. A gradient of deformation decreasing towards the four semi-shear triangular regions and two triangular regions that exhibit almost no shear are also evident.

Figure 5 illustrates a comparison between the load versus shear angle curves derived from the experimental data and the finite element simulation. The results indicate that the simulation underestimates the stiffness of the specimen, with the difference becoming more pronounced at higher shear angles. This difference reveals the need for further refinement of the finite element model to more accurately represent the in-plane shear mechanical behavior of the material at high temperatures.

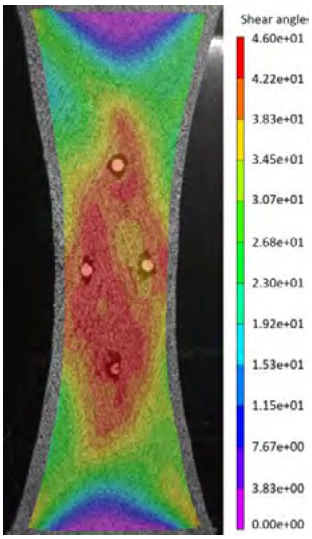

Figure 4. Shear angle distribution obtained by DIC at a displacement of 30 mm.

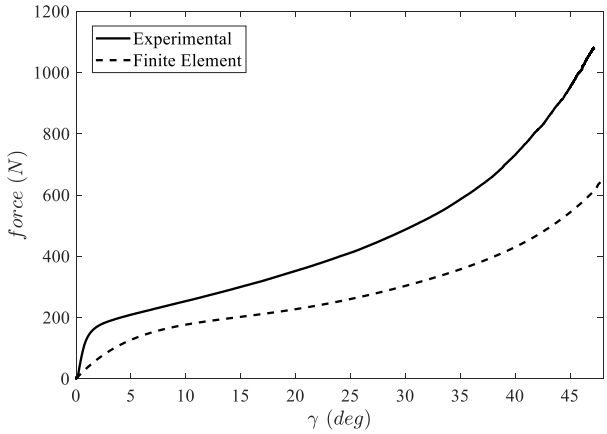

Figure 5. A comparison between the force-shear angle curves derived from the FE analysis and the experiments.

5. Conclusions

This paper investigates the in-plane shear behavior of flax fiber-reinforced polypropylene composites at high temperatures by linking numerical modeling tools with experimental results. The bias-extension experiment is used to investigate the behavior of a specimen at 160 °C and 10 mm/min displacement rate. The study applies the Digital Image Correlation (DIC) technique to observe local deformations and strains on the surface of the specimens. The FE method is used to simulate the tests, incorporating a hypo-elastic material model through a VUMAT user material subroutine. Based on the results, the comparison between the experimental and FE force-shear angle predictions shows that the finite element model underestimates the shear stress and predicts, hence, a lower shear stiffness. A possible reason for this miscalculation of the numerical model is that the reorientation of the fibers during the test is not taken into account [9]. Accordingly, the effect of the fiber reorientation will be examined in follow-up studies.

Keywords: 3D woven, Fatigue, Multi-axial, Traction/Torsion, Failure Envelop

Abstract

In this study, the failure analysis of 3D carbon fibre composite subjected to multiaxial traction/torsion (σ11/τ13) loadings is investigated. A rectangular specimen undergoes fatigue cyclic loading to understand how the material responds to such complex stress conditions. Various measurement techniques like stereo Digital Image Correlation (stereo-DIC), Acoustic Emission (AE), and in-situ microscopic observation track the material properties evolution after each cycle (N). Tests are conducted for different ratios of σ11/τ13. Furthermore, the damage mechanism, including its type and localization, is identified based on the material's meso-structure. The localization of damage in such specific areas of the specimen was attributed to both normal and shear stress distributions according to the numerical finite element model, rendering this observation more comprehensible.

1. Introduction

Over the past decade, three-dimensional (3D) composites have been gradually introduced into numerous applications, particularly in aeronautics. The incorporation of 3D weaving architectures into composite materials induces mechanical behavior and damage mechanisms that are entirely different from those of conventional unidirectional and bidirectional composites [1]. Thus, characterization methods, mechanical behavior, and damage mechanisms of two-dimensional composites cannot be directly extrapolated to 3D woven composites due to significant differences in their structure and behavior. Therefore, an effort is currently underway to understand the mechanical behavior of these materials. Most of these studies focus on quasi-static uniaxial loads, fatigue, and impacts, but very few have been conducted on multiaxial loading applied to 3D woven composites. Traditionally, material properties are determined using conventional uniaxial tests. However, these tests often inadequately represent the true material behavior, which is significantly influenced by the loading conditions experienced in real-world engineering applications. A more effective strategy for accurately characterizing mechanical behavior involves employing biaxial tests, which closely mimic the actual loading states encountered by composite structures. Among various biaxial testing methods, prominent ones include (i) proportional axial tensile and torsion tests conducted on tubular specimens [2], (ii) biaxial tensile tests utilizing cruciform specimens [3]. Despite the inherent complexities associated with specimen preparation and test setup, the application of these methods to composite materials has facilitated the determination of multi-axial combined in-plane tensile and in-plane shear stress failure envelopes.

In this study, the mechanical behavior of 3D woven composites subjected to tensile/torsional loading conditions is investigated. Initially, a description of the materials and equipment used is presented. Preliminary static tests are then discussed, establishing a damage threshold envelope. Based on this, fatigue tests are addressed, detailing the loading conditions and results obtained accompanied by analysis.

2. Material and equipment

The material under investigation consists of 3D woven intermediate modulus (IM) carbon fibers combined with epoxy resin. Rectangular specimens are cut from the thickness (plane 1,3) and equipped with aluminum grips (gage length of 220 mm, width of 38 mm, and thickness of 9 mm). Multi-axial tests, including monotonic and fatigue tests, are conducted using a hydraulic tension/torsion machine with a capacity of 100 kN in tension and 1000 Nm in torsion. The tests are followed by observations conducted using in-situ video microscopy, digital image correlation (DIC), and acoustic emission (AE). Figure 1 illustrates the material meso-structure and the equipment used for conducting the tests, providing a visual representation of the experimental setup employed in the study.

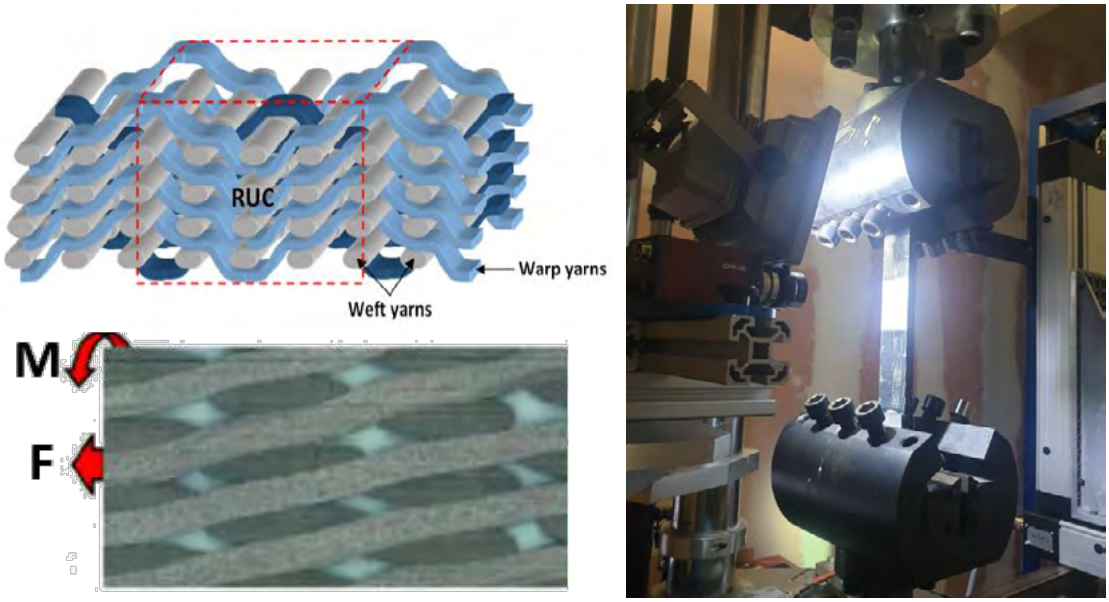

Figure 1. Material structure and used equipment

3. Experimental procedure and stress calculation

The first part of the study focused on determining the σ11-τ13 damage threshold envelope of the material. Static tension/torsion tests were conducted for various stress ratios σ11/τ13. A criterion based on the cumulative energy of the AE signals was utilized to determine this threshold, supplemented by microscopic observations to confirm damage initiation. This phase aimed to select stress levels to be applied during fatigue testing. The protocol followed during fatigue tests is illustrated in Figure 2 and consists of three parts: (i) scanning the specimen in its initial state using a video microscope, (ii) performing two static tests (pure tension and torsion) at stress levels below the damage threshold to measure the material's elastic moduli, deformations, and torsion angle in the usable region of the specimen, (iii) conducting a number N of sinusoidal fatigue cycles at a frequency of 2Hz and a load ratio R=0.05. Acoustic signals are recorded during the tests, along with the tensile and torsional stiffness derived from the angle measurement and displacement of the actuator. These three steps are repeated

until a significant decrease is observed in either of the two moduli E1 or G13 (approximately 20% of the initial value).

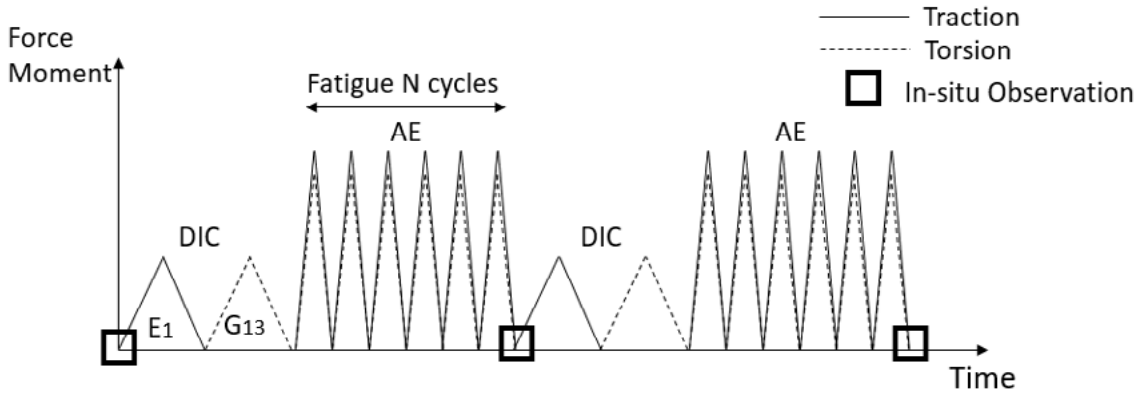

Figure 2. Fatigue test protocole

The load and moment to be applied to the specimen are determined based on Lekhnitskii's theory [4] and the works of Gong et al. [5]. A relationship between the maximum shear stress in the central zone of the specimen and the applied torque is established according to the following equations:

$$\tau_{13} = \frac{M_{eff}}{b\,h^2} k1 \tag{1}$$

$$M_a = M_{eff} + \frac{\frac{b\theta}{3L}\sqrt{1+\frac{1}{\varphi^2}}+\frac{1}{\varphi^2} ln\left(\varphi+\sqrt{1+\varphi^2}\right)}{\left(\frac{4}{E_{xx}hb^2}\right)} \tag{2}$$

Where Ma represents the applied moment, Meff is the effective moment inducing shear stresses, ϕ depends on the torsion angle of the bar (θ) and the length of the specimen (L) that has undergone twisting during torsion, b is the width of the sample, and Exx is the Young's modulus in the direction of the torsion axis. Considering the normal stresses, the relationship between the force to be applied and the average stress at the center of the specimen is given by the classical relation in equation 3. The results obtained from these analytical relationships linking torque and stress have been verified through finite element elastic calculations. A more detailed explanation of the calculation is presented in previous works [6].

$$\sigma = \frac{F}{S}\ ,\ S = bh \tag{3}$$

4. Results and discussion

4.1. Static tests

A previous study by the authors [6] identified four points on the material damage threshold envelope. Nine additional points were added in this study, including repeatability tests. Based on the obtained envelope, three distinct zones were defined for fatigue testing: (i) Zone A, which considers the variation of τ13 for pure torsion tests, (ii) Zone B, which refers to the effect of σ11 for high shear stresses, and (iii) Zone C, which refers to the effect of σ11 for mid-range shear stresses, as illustrated in Figure 3. The fatigue stress levels are chosen according to the stress levels at the damage initiation threshold.The choice of those 3 Zones allows for the study of the effect of shear stress τ13 during multiaxial testing. The elliptical shape of the failure envelope illustrates how the σ11/τ13 ratio would affect the material response.

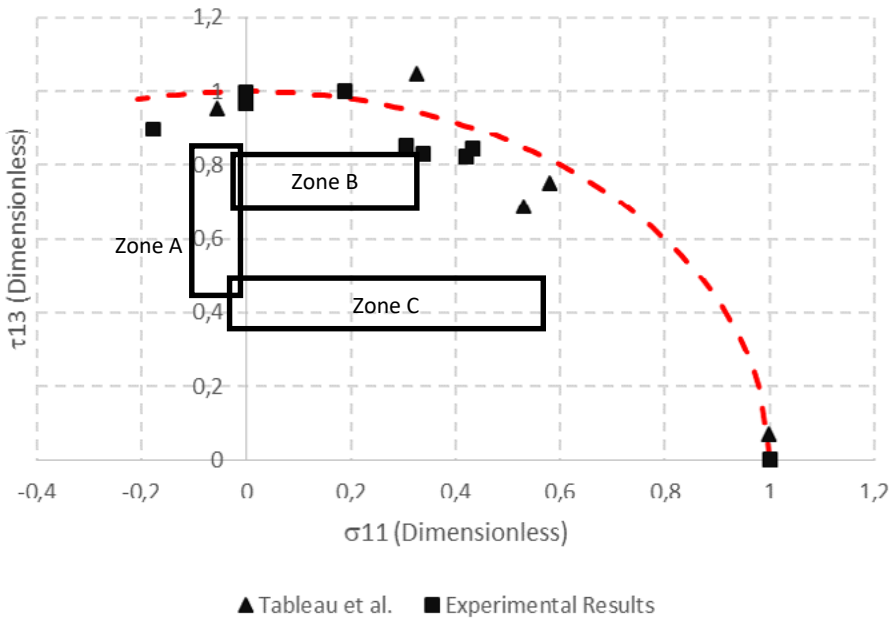

Figure 3. Damage threshold envelope of the 3D composite

4.2. Fatigue tests

The results obtained for the different zones indicate that the material damage is primarily influenced by the torsion of the specimen. Figure 4 illustrates the evolution of material stiffness (normalized) after each N fatigue cycle for the three different zones (two tests are considered per zone).

The trend curves reveal that in zone B (variation of σ11 for high τ13), the stiffness G13 decreases similarly, regardless of the σ11 value, suggesting that the test is primarily influenced by shear stress. In Zone C, where σ11 is varied and τ13 is fixed at a mid-range level, the effect of σ11 is noticeable at the beginning of the fatigue cycles, where a high applied normal stress leads to a lower shear modulus (as shown at 200,000 cycles). However, after a high number of fatigue cycles, the results show a similar shear modulus for both normal stress levels (700,000 cycles). In Zone A (pure torsion), the stiffness evolution depends on the level of applied τ13: a rapid loss is observed for high τ13, while the opposite is observed for low τ13. An example of the shear strain distribution for the specimen subjected to high τ13 shear stresses is illustrated in Figure 5. The figure depicts the localized concentration of shear strain along the warp direction resulting from the evolution of damage in the material after 190,000 cycles. This distribution is compared to the shear stresses at the beginning of the test for the same loading level. Considering the tensile behavior of the material, the evolution of Young's Modulus shows that the material retains its properties throughout the tests. A slight decrease is observed for specimens heavily damaged in shear.

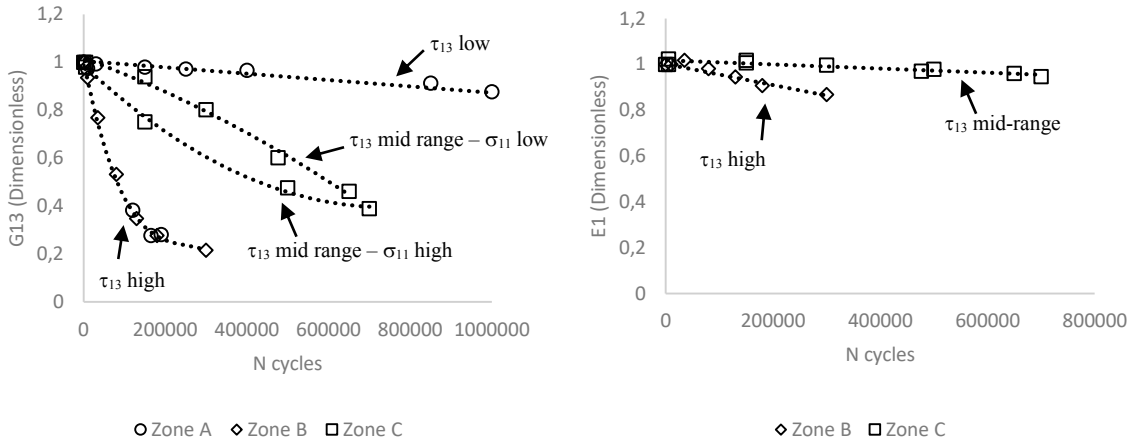

Figure 4. Damage threshold envelope of the 3D composite

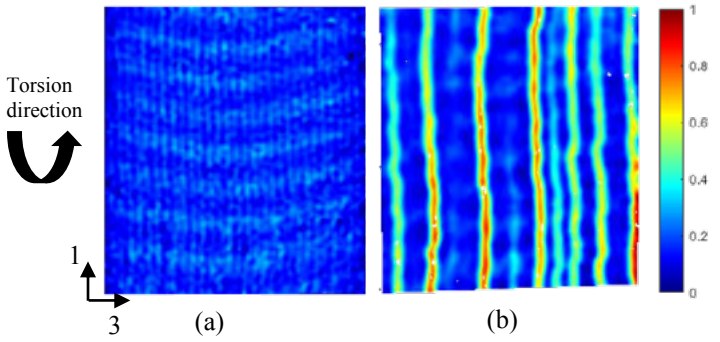

Figure 5. Shear strain distribution under torsion loading : (a) initial, (b) after fatigue

For the failure analysis, in-situ microscopic observations reveal that the cracks tends to initiate on the edge of the the weft fibers and propagates through the matrice to rejoin another crack. Macroscopically, the inspection shows a localized damage in the central zone and at two opposite diagonal sides of the specimen, while the rest show minimal damage. To better understand this localization, a numerical Finite Element model was developed using ABAQUS. The rectangular-shaped specimen is subjected to simultaneous traction/torsion loading applied on the aluminum tabs, with the composite modeled as a 3D orthotropic material.

The numerical results show a maximum homogeneous shear stress in the central zone, which explains the damage observed in that area. Additionally, the normal stress σ11 exhibits maximum values on both corners of the specimen. This localization of stress is attributed to the torsion effect of the bar. The normal stresses generated from the torsion of the bar combine with the stresses from traction to induce damage on two sides of the specimen, while others remain undamaged. A representation of both experimental damage and numerical stress distributions is illustrated in Figure 6.

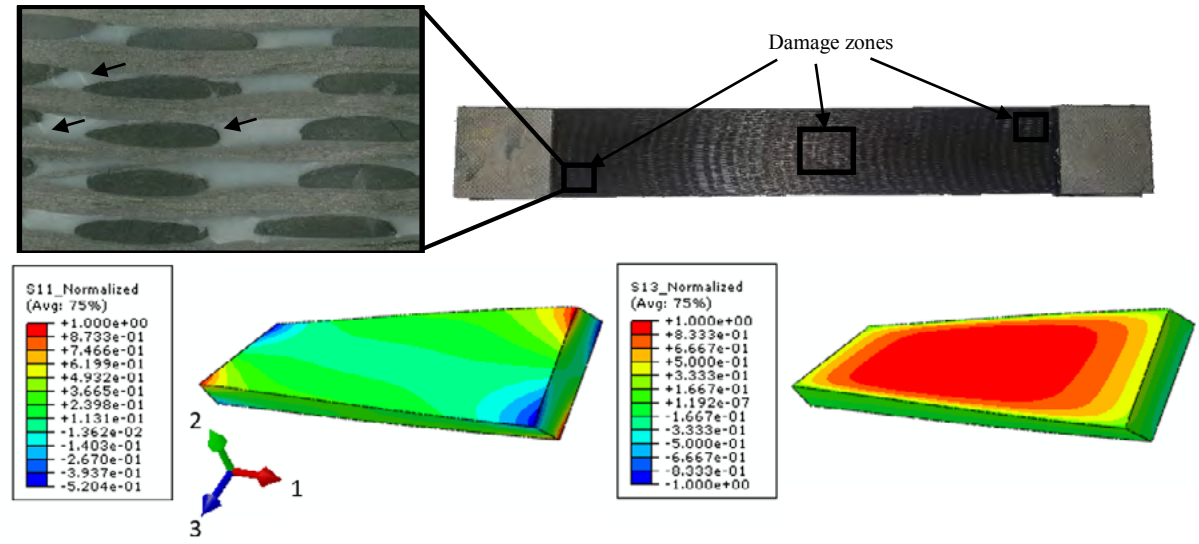

Figure 6. Damage localization and numerical stress distribution

3. Conclusions

The study focuses on investigating the damage of 3D woven composite materials. Static tension/torsion tests were conducted to determine the damage threshold envelope of the material. Based on this envelope, the effect of out-of-plane shear stress τ13 is analyzed in fatigue through different σ11/τ13 ratios. The evolution of the material's tensile and shear stiffness during fatigue testing highlights that the degradation of mechanical properties is primarily due to the effect of torsion. The in-situ investigation revealed the damage mechanism and localization, which aligns well with the stress distribution obtained in the numerical model.This study will contribute as a database for validation of phenomenological fatigue damage models.

Keywords: Temperature elevation, Dissipated energy, Strength degradation

Abstract

The observed temperature elevation during CFRP fatigue testing poses a significant challenge in accurately predicting fatigue. The temperature increase in laminates is attributed to the inelastic deformation of the resin. This inelastic deformation increases dissipated energy and subsequently leads to a rise in temperature. At lower frequencies of fatigue testing, a balance is achieved between heat release and dissipated energy generation, minimizing the temperature rise. However, at higher frequencies, the temperature of the laminate increases due to the heightened generation of dissipated energy. Therefore, it is crucial to consider this temperature rise when discussing CFRP fatigue. In this study, plastic deformation was introduced as a notable addition. Additionally, the code was modified to relate dissipated energy to temperature rise. In this modified code, as dissipated energy increases, the temperature also increases. In this study, we simulate cyclic loadings of epoxy resin at frequencies of 1 Hz, and 20 Hz. Since heat dissipation is considered, temperature elevation was different for each frequency.

1. Introduction

The number of cracks in fatigue tests of CFRP depends on its frequency[1, 2]. This is due to two reasons. The first is the inelastic deformation of the resin. When the frequency is low, the inelastic deformation of the resin increases. Since more inelastic deformation leads to more damage, the number of cracks is increased at lower frequencies. The second is temperature elevation. As the frequency increases, the temperature increases. As the temperature increases, the damage increases faster. At low frequency loads, the temperature does not rise due to high heat release. Therefore, the number of cracks increases due to inelastic deformation of the resin. At high frequency loads, the temperature elevation of the CFRP occurs because the heat generation is greater than the heat release. Therefore, cracks increase due to temperature elevation.

In the author's previous work[1, 2], a code was developed to predict the degradation of CFRP using Hashin's law. In this code, entropy based on dissipated energy causes strength degradation. In some

studies, entropy generation can be used as a failure criterion[3, 4, 5, 6, 7]. The code incorporated five Maxwell element models. However, in this paper, damage is only related to dissipated energy and omits consideration of temperature changes and permanent plastic deformation. In this study, plastic deformation was introduced as a notable addition. Additionally, the code was modified to relate dissipated energy to temperature rise. In this modified code, as dissipated energy increases, the temperature also increases. The temperature rise, according to the temperature-time conversion law, accelerates the movement of the dashpot, thereby amplifying dissipated energy. This implies that dissipated energy increases exponentially with rising temperature. This increase in entropy generation further accelerates the decrease in intensity. Furthermore, since heat dissipation is considered, frequency influences the number of fatigue failures. This study is unique in allowing for a comprehensive fatigue failure simulation that considers both temperature and frequency.

This study simulates the behavior of epoxy resin, commonly used in CFRP laminates. Dissipated energy is calculated by inelastic strain and stress, and it is used in calculating the heat generation. Surface heat transfer is considered on the model's surface. Using the model which considers heat release and heat generation, we simulate cyclic loadings at 1Hz and 20Hz. As a result, the loading at 20Hz has higher temperature than 1Hz. This suggests that fatigue failure with temperature elevation can be reproduced.

2. Numerical Method

2.1. Plastic deformation

Resin deformation can be divided into two types: elastic deformation and inelastic deformation. In previous study[8, 9], Maxwell elements are used for simulating the behavior of resin. However, in the previous study, the dissipated energy in the simulation depended solely on the stress level, thus it could not account for the influence of frequency. In this study, we use both maxwell elements and following plastic deformation equation.

$$\Delta\varepsilon_{\mathrm{p}} = \left(\alpha \times \varepsilon^{n} \exp\left(-\left(\frac{\varepsilon}{\varepsilon_0}\right)^{m}\right) + \beta\left(1 - \exp\left(-\left(\frac{\varepsilon}{\varepsilon_0}\right)^{m}\right)\right)\right) \times |\Delta\varepsilon|. \tag{1}$$

where $\Delta\varepsilon_{\mathrm{p}}$, ε and $\Delta\varepsilon$ represent the plastic strain increment, strain, strain increment and α, β, m, n, and ε_0 are fitting parameters. Positive and negative of the plastic strain increment are determined by stress. The validity of this equation will be discussed in a subsequent study, but for now, we will adopt it.

2.2. Time–temperature superposition principle

A polymeric material commonly follows the time–temperature superposition principle (TTSP)[10, 11]. Based on Arrhenius' equation, the following equation is used to simulate the resin behavior.

$$\log \alpha^{TR}(T) = \frac{\Delta H}{2.303R}\left(\frac{1}{T} - \frac{1}{T^{R}}\right). \tag{2}$$

where α^{TR}, ΔH, R, T and $T^{R}$are time factor, the activation energy, he gas constant 8.314 $\times 10^{-3}$ [kJ/(K mol)], test temperature, and reference temperature. In this study, the activation energy is 150kJ/mol, and the reference temperature is 333K.

2.3. The calculation flow of UMAT

Figure 1 shows the Viscoelastic/plastic model consisting of 15 Maxwell elements and a plastic element. Figure 2 shows the calculation flow of updating stress which is based on the model (Figure 1). In terms of the viscoelastic model part, the flow closely resembles that of the previous study[8, 9]. However, the

novel point of this flow is the calculation of plastic strain by using Eq. 1 which is independent for time increment.

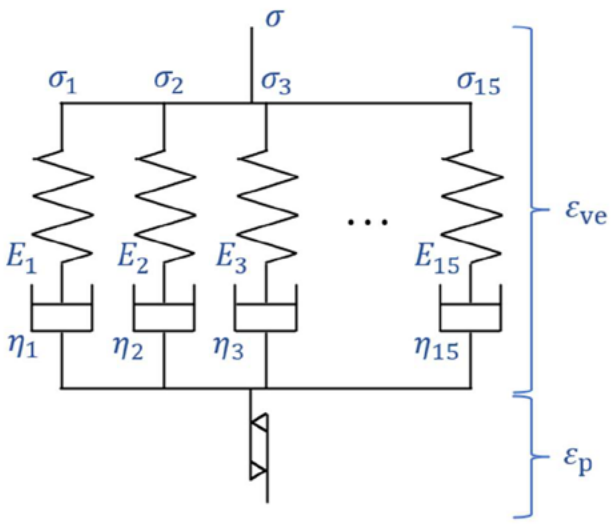

Figure 1. The Viscoelastic/plastic model.

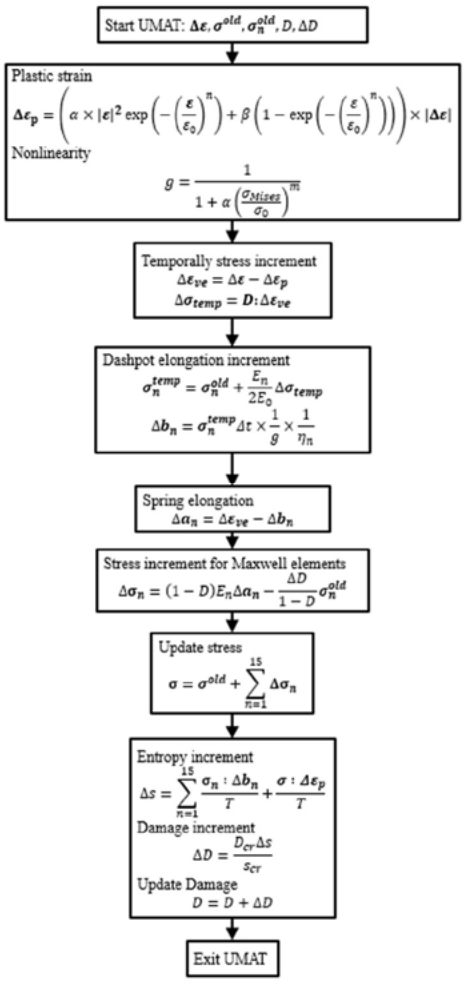

Figure 2. Calculation flow of updating stress.

3. Numerical Results and Discussions

As shown in Figure 3, dimensions of the resin in the simulation are 1 mm × 1 mm × 1 mm and boundary conditions are applied on surfaces ADHE, ABCD and DCGH. Heat transfer is given in the surfaces ABFE, BCGF, EFGH. The displacement boundary conditions is employed on surface EFGH at frequencies of 1 Hz and 20 Hz. The cyclic displacement is 0.01 mm for 30s. The cyclic loading behavior is simulated using Abaqus (2020, Dassault Système). The stress is calculated using a user-subroutine UMAT of Abaqus. UMAT is based on the calculation flow (shown in Figure 2.) and the material properties used in the calculation is shown in Table 1.

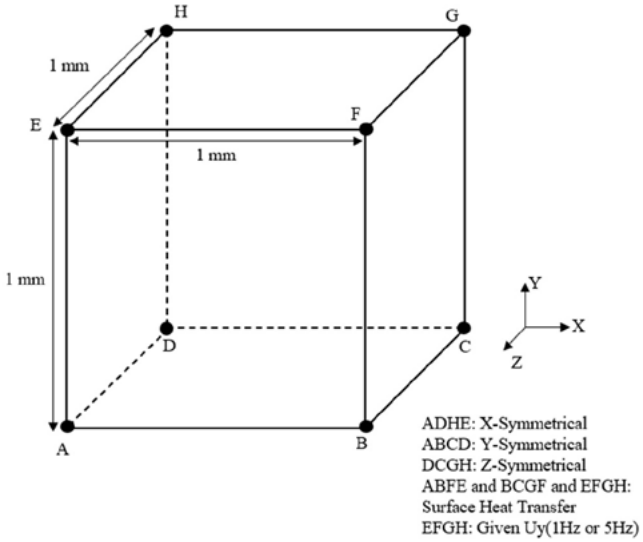

Figure 3. Boundary condition.

Table 1. Material properties of matrix resin.

n	E_n(MPa)	η_n(MPa·s)	Elasticity	
1	220	3.16E+01	E_n(MPa)	3300
2	220	1.26E+03	ν	0.3
3	220	3.16E+04	Nonlinearity	
4	220	2.51E+05	σ_0(MPa)	70
5	220	1.26E+06	α	2

13	220	2.51E+11	α_d	1000
14	220	3.16E+12		
15	220	7.94E+13		

Figure 4 shows the result of temperature elevations in cyclic loadings. The heat release and the heat generation are balanced at both 1 Hz and 20 Hz, but the temperature elevation at 20 Hz is higher than that of 1 Hz. Because the resin follows TTSP, the higher temperature, the movement of dashpot of the model (shown in Figure 1) is accelerated. Consequently, this leads to a higher dissipation of energy, resulting in a larger damage variable. The result suggests that the transverse cracking behavior of CFRP laminates under cyclic loading at different frequencies can be simulated by considering heat release and plastic deformation which are related to temperature elevation.

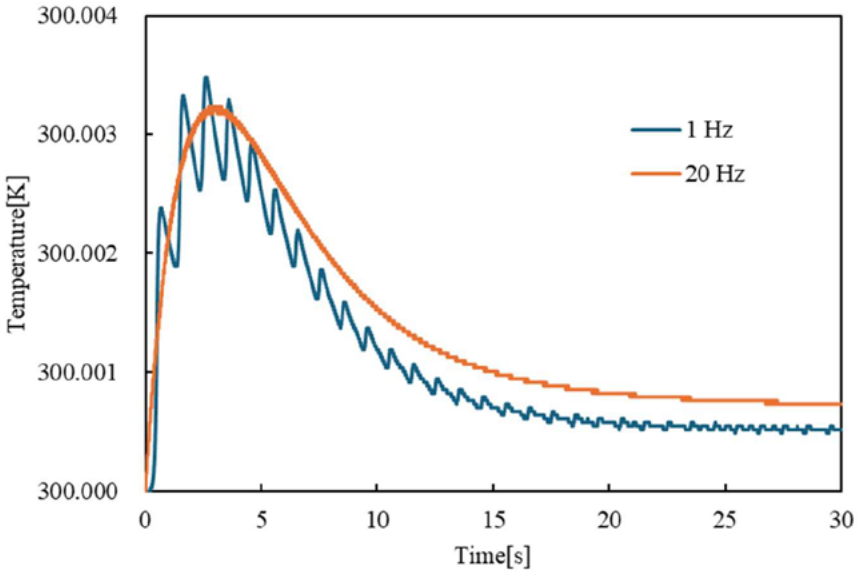

Figure 4. Result of cyclic loading simulation considering temperature elevation.

4. Conclusions

The plastic deformation is added to the previous study in order to consider the temperature elevation of epoxy resin under cyclic loading. It's because plastic deformation is independent of time increment, different temperature elevations occur depending on the frequencies of the cyclic loadings. Dissipated energy calculated in the suggested model increases exponentially with higher temperatures. the results suggest that this model can simulate the transverse cracking behaviors of CFRP laminates.

Keywords: GFRP, Web-to-Flange Junctions, fatigue, experiments

Abstract
The presented research aims to examine local fatigue failure modes of Glass Fiber-polymer Composite (a.k.a. GFRP), particularly how the bending of the Web-to-Flange Junctions (WFJ) and tensile loading of the material affects the composite's fatigue resistance. By conducting experimental analyses, the study investigates GFRP's efficacy both as a material and as a component element, drawing parallels with Eurocode standards for steel and concrete.
The coupon tests under static and fatigue loading conditions provided an empirical data on the Ultimate Limit State (ULS) and fatigue resistance of the GFRP composites, including a better understanding of the effects of variation in the facing's thicknesses in the web-core composite on the fatigue response. Subsequent three-point bending tests on the WFJ provided the insights into the strength of WFJ with the first indications on the governing failure mechanisms in the WFJ.

1. Introduction

For civil engineering applications, the renovation of existing bridges and the design of new structures demand innovative and sustainable materials. Glass Fiber-reinforced Polymer (GFRP) composites have emerged as a leading material in this transformation due to their durability, corrosion resistance, and lightweight properties, which are particularly advantageous for bridge construction [1]. GFRP composites represent a promising alternative to traditional materials like timber, steel, and concrete, which are susceptible to deterioration and corrosion over time [2]. The lighter weight of GFRP not only reduces installation costs but also minimizes the load on foundation structures. By replacing old bridges with GFRP structures, municipalities can achieve substantial improvements in durability and a reduction in maintenance costs [3].
Despite these benefits, the integration of GFRP into existing design frameworks like the Eurocode [4]for composite structures introduces complexities. The specificity required in the design guidelines can lead to increased construction costs and project delays. As noted by authors in [5], current design recommendations do not fully accommodate the unique properties of GFRP, necessitating additional research and modification of design codes to enhance their applicability to GFRP-based structures.
Focusing on the structural design innovations, this study examines the material and component properties of web-core panels in GFRP bridge decks. These panels employ unidirectional (UD) fabrics

on the facings to address bending and mitigate local buckling, while incorporating multidirectional laminates in the webs for effective shear transfer. For the continuous connections between the flanges and webs, components known as Web-to-Flange Junctions (WFJs) are constructed using 'wrap-layers', GFRP fabrics wrapped around foam blocks during production to form the outer layers of the webs and inner layers of the facings. To facilitate the design verification of WFJ components, more comprehensive information is required regarding their fatigue behavior. Currently, the existing design codes lack Stress-life (S-N) curves specifically tailored for WFJ components. Conducting fatigue tests on these components can provide the necessary data to establish an S-N curve, thereby aiding in the design process.

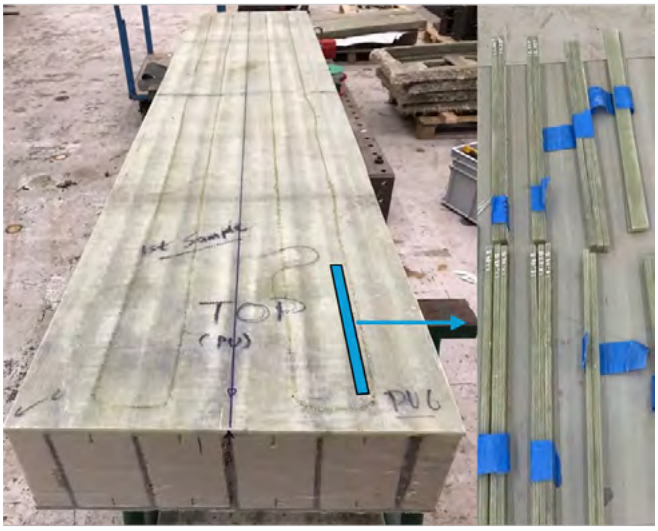

Figure 1. Coupons cut out from the sandwich panel.

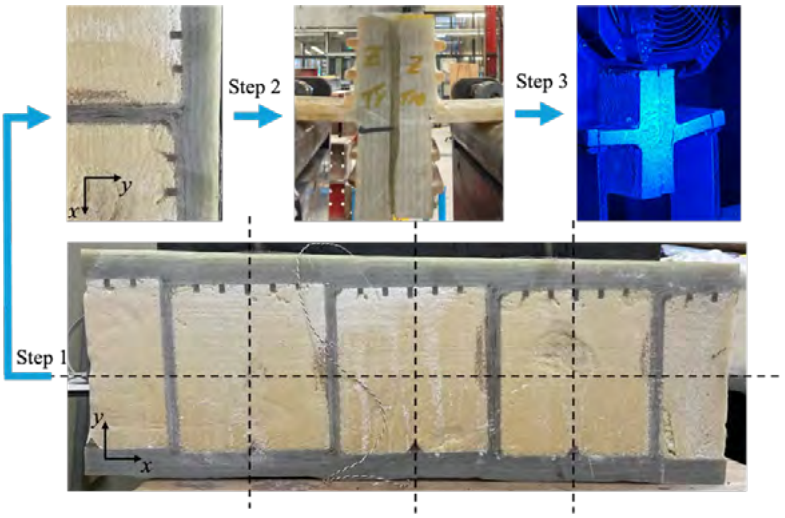

Figure 2. Extraction of web-facing junctions from the sandwich panel.

2. Materials and experimental methods

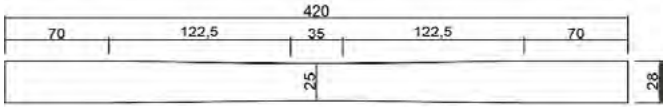
The coupons and the components (WFJs) are cut out of the GFRP bridge decks, as shown in Figure 1 and Figure 2. The bridge deck is manufactured with vacuum-infused GFRP panels and polyurethane resin that has a core of polyurethane (PU) foam. The deck laminate consists of a Z-shaped layering approach and integrates three types of fibre fabrics. Surrounding the foam blocks are layers of E-glass fabric angled at [+/-45 degrees]. Along the length, three layers of UD E-glass fabrics are laid, with overlaps of two blocks at the top and bottom. The Z-shaped configuration also includes two additional

layers of E-glass fabric oriented at [0/90 degrees] that overlap by 2.5 blocks. Facings have a higher volume fraction of the fibres compared to the webs, due to the production process. The top and the bottom facing of the deck have the lay-up of $[((0/90)_2/0_3)_4/0/90/\pm 45]$ and the web - $[\pm 45_2/(0/90)_2/\pm 45_2]$. The material properties of the composite plies can be found in [6].

2.1. Material tests on coupons

The coupons are cut out from the top and bottom facings of the sandwich panels of the deck as shown in Figure 1. The coupons are extracted from a scaled deck by a factor of 0.5 and the thickness of the coupon specimens is twice as low compared to the thickness of the tests on the WFJs.

The samples are precisely cut using a water jet technique with the dimensions of the coupon specimens to comply with ISO 527 – 4 standard [7] as shown in Figure 3. Owing to the Z-shape layup method used in the decks' production, specimen thicknesses ranged between 9 and 12 mm. The variance in coupon thickness introduces complications in the testing process, requiring the adjustments of modified testing techniques. These complications primarily occur in the gripping area of the testing apparatus, where the specimen's variable thickness causes uneven stress distribution due to a non-uniform clamping surface. Such stress concentrations can induce premature failure of the specimens at the clamping points, thereby complicating the assessment of material properties. Figure 4a highlights the thickness differences in the specimen cross-section A-A. To overcome the thickness transition issues, a mould is designed from timber, shown in Figure 4b. The specific purpose of this mould is to apply a two-component epoxy system [8] at the clamping points to have a flat surface to clamp the specimen in. This resin is fast curing and reaches its full strength in 3 days, after which it is strong enough to resist the high clamping force of the hydraulic wedge grips. Before the specimens are placed in the mould, surface preparation is performed on the regions near the clamps to prevent slipping between the resin and the specimens during testing.



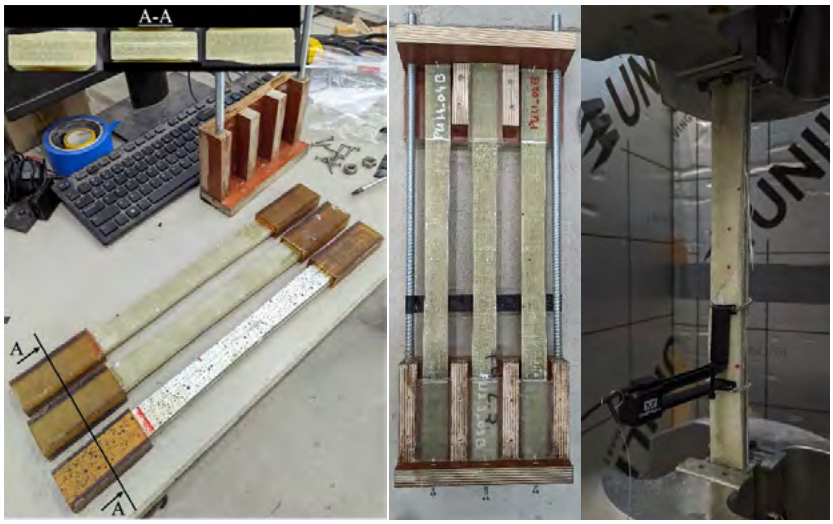


Figure 3. Coupon specimen dimensions.

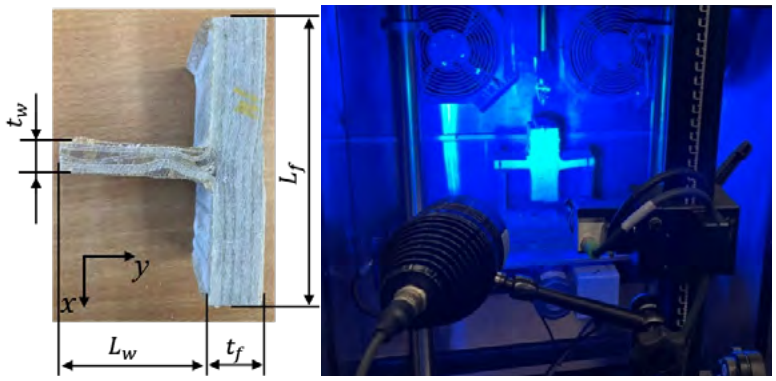
a) Specimen preparation b) Mould design c) Test set-up

Figure 4. Material coupon tests.

Static and fatigue tests are performed on a universal testing machine with a 100kN load cell. The test set-up is shown in Figure 4c. Each static test is subjected to a uniform loading rate of 1 mm/min until the point of failure. The tensile-tensile fatigue tests are performed under the loading ratio of 0.1



considering the three loads of 52%, 37% and 22% of the ultimate load capacity. For every load level a total of 3 successful tests are required, slipped specimens or specimens failing in the clamps are disregarded. The sinusoidal constant amplitude is utilized with frequencies of 2 to 6 Hz, depending on the load levels. During the fatigue tests, an extensometer is used with a gauge length of 50 mm, as shown in Figure 4c.

2.2. Component tests

The bridge deck's web-core sandwich panel contains WFJs, referred to as components, which are shown in Figure 2. The preparation process for these components involves several key steps: 1) Cutting the GFRP panels both in the XZ plane and through the thickness in the YZ plane, specifically between the web sections; 2) Removing the PU foam and using a structural adhesive quick set epoxy to bond the web-facing components together. Steel tabs 25x6x80 mm^3 are also glued in areas designated for load and supports; 3) Applying a thin layer of white, non-reflective paint on one side of the specimens, followed by a random black pattern using a spray gun. This is crucial for detecting crack initiation with the Digital Image Correlation (DIC) system.

Figure 5a shows the specimens' average dimensions, including a width of 50.02±0.53 mm, flange length and thickness ($L_f = 140 \pm 9.16$mm, $t_f = 26.22 \pm 2.25$mm), and web length and thickness ($L_w = 72.45 \pm 3.65$mm, $t_w = 12.86 \pm 2.16$mm).

For testing, a universal testing machine equipped with a 15kN load cell and a total span of 175 mm is used (see Figure 5b). A DIC system featuring a 50.6 MPa camera and polarized blue LED lights captures full-field displacements on the specimens' side surfaces during tests, synchronizing photos with load and displacement data.

Figure 5. Component tests.

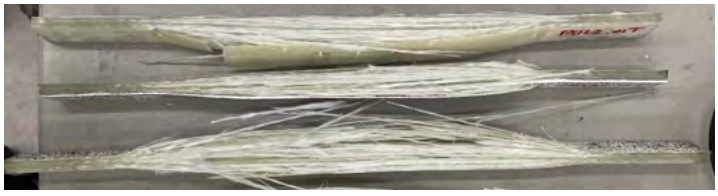

Figure 6. Delamination and fibre failure. Static material tests.

3. Results and discussion

3.1. Material coupon tests

Prior to fatigue tests, static tests are conducted on a set of three specimens to determine the failure loads and stresses. The failure modes are visually inspected, which included delamination and fibre breakage, and consistent across all tests and are shown in Figure 6. The analysis of the specimens is detailed in Figure 7, where the average failure load, displacement and stress are F_{max}=137.68kN, $w_{max} = 11.89$mm and $\sigma_{max} = 577.75$MPa, respectively. The tensile stress is calculated by dividing the applied

load by the initial cross-sectional area at the failure region of the specimen. All three tests show a linear relationship between the applied load and displacement.
Figure 8 illustrates the fatigue response of the tested coupons. Each load level is evaluated with three specimens, resulting in a total of nine tests. The analysis of the material's fatigue performance is carried out in accordance with ASTM E739-10 [9] standards, which involves establishing the S-N relationship through linear regression. The S-N relationship is presented in the following format:

$$\log N = A + B(\log \sigma) \quad (1)$$

where σ is the maximum cyclic stress; N is the number of cycles to failure; A and B are the fitting parameters.
The plot in Figure 8 includes data points, a solid black line representing the logarithmic fit to the data, and dashed black lines are representing the 95% confidence bands for the fit. The fit equation is indicated in Figure 8.

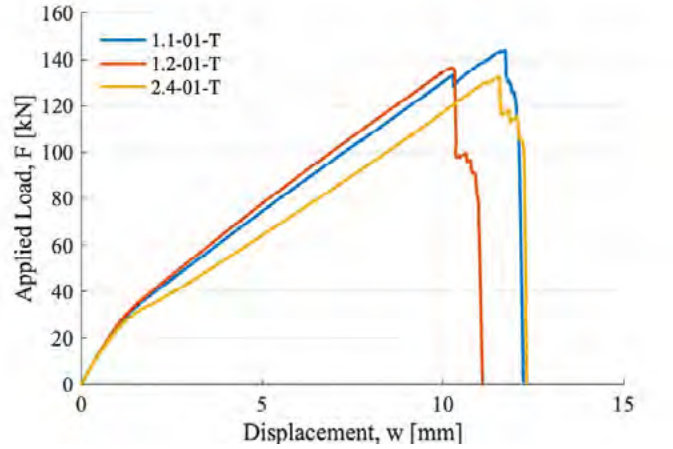

Figure 7. Load-Displacement curves. Static material tests.

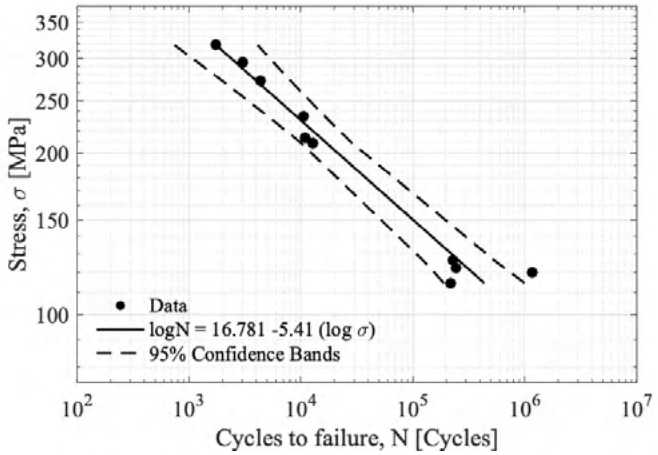

Figure 8. S-N curves of the material tests.

The fatigue tests are force controlled and are set to 30 kN, 50 kN and 70 kN. A higher force resulted in immediate failure of the ±45° plies at the outer surface. Due to large thickness differences in the specimens the forces are converted to stresses where the areas are evaluated at the location of failure, shown in Figure 9. Almost all locations of failure are concentrated in the middle region of the coupon with the narrowed cross-section according to ISO 527 – 4 to trigger the failure in this region. Due to some margins in the cutting process not all specimens had the smallest cross-section precisely in the middle, this explains why the failures don't occur precisely in the middle.

The governing failure modes occurring during the fatigue tests are delamination and/or fibre breakage respectively. This can also be seen in Figure 9. In some cases the fibre breakage progressed through the specimen in longitudinal direction towards the clamped region, while in most cases the specimen broke in the middle straight away. This progress of fibre breakage and delamination towards the clamps is better visible on the side view which is shown in Figure 9d.

Figure 10. Failure initiation and delamination. Static component tests.

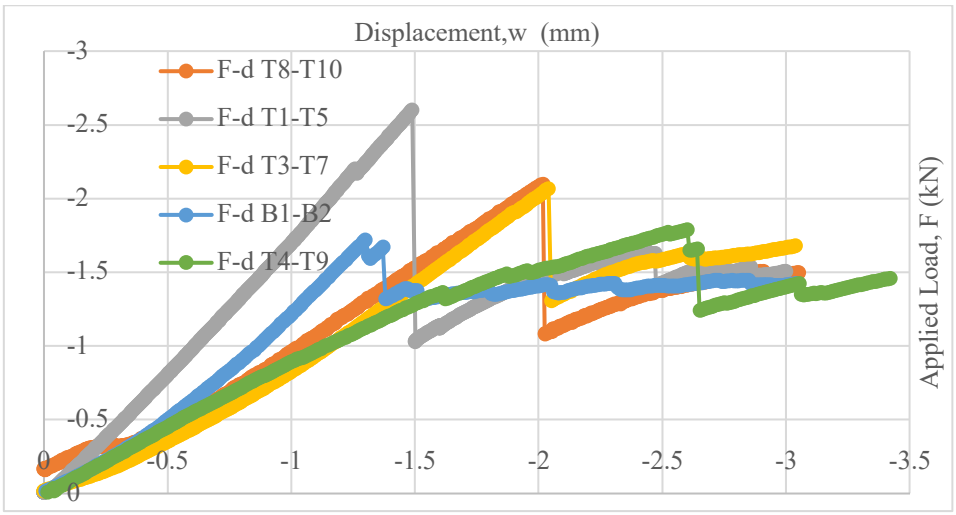

Figure 11. Load-Displacement curves. Static component tests.

3.2. Component tests

Static tests are conducted on 5 pairs of WFJ, in which one out of two connected together WFJ failed during each test. The failure modes are visually inspected, shown in Figure 10, which are similar across all the tests with the delamination between the 'Wrap' and 'UD'-layer of the WFJ. The Force-Displacement plots of the specimens are shown in Figure 11 indicating an average failure load, displacement and nominal bending stress are F_{max}=2.04kN, w_{max} = 1.90mm and σ_{max} = 50.90MPa, respectively. The nominal bending stress is determined by multiplying the reaction force from the support by the distance from the support to the beginning of the radius to obtain the bending moment. This is then divided by the elastic section modulus of the web just before the junction. All five tests show a linear relationship between the applied load and displacement.

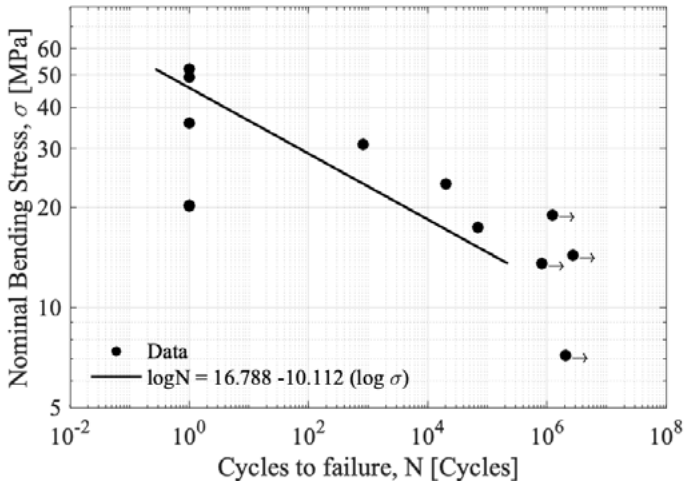

Figure 12. S-N curves of the component tests.

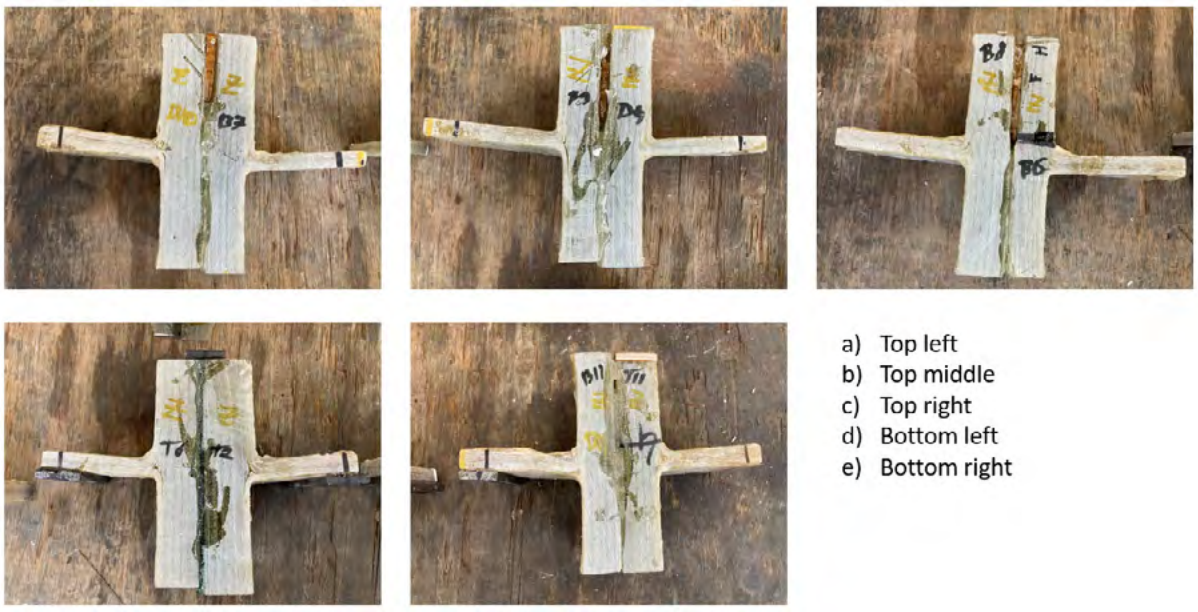

Figure 13. WFJ Component damage, fatigue tests.

The analysis of the WFJ component fatigue tests is presented in Figure 12. The tests are force-controlled with an R = 0.1. The plot includes data points along with a solid black line that represents the logarithmic

fit to the data. All the data points, except for one ($\sigma_{nom} = 7.16$MPa) are included in the fit. The equation for the fit is also shown in Figure 12.
Multiple WJF have failed at the first cycle with the applied load of 50% to 70% of ULS. Those specimens had a resin reach region in the corners of WJF, as shown in Figure 12a) and b). The specimens indicated with the arrow are stopped at around 10^6 cycles and are indicated as outruns. Similar to the static tests, the fatigue tests revealed the same failure mode: delamination between the 'wrap' and 'UD' layers, see Figure 13. The criteria for failure in the fatigue tests is determined to be crack initiation between these layers, specifically when the tangential strain in the crack direction (measured using a virtual extensometer with a 10 mm gauge length on DIC data via GOM correlate software) exceeded 0.1215% strain from the static tests. The stress correlated with the number of cycles until failure represents the nominal bending stress at the initial load cycle. Compared to the static tests, crack initiation often occurred in both junctions during the fatigue tests. This is likely due to the lower occurring stresses and longer testing times, allowing for stress redistribution and crack initiation in both junctions. However, despite quick crack initiation at low stress levels, crack growth was retarded, and no complete failure of the junction occurred in any fatigue tests.

4. Conclusions

The experimental analysis of GFRP material and WFJ components in web-core composite bridge deck panels reveals consistent failure modes across all specimens, characterized by delamination and fiber breakage during material fatigue tests, and delamination between the 'wrap' and 'UD' layers in component fatigue tests. WFJ components typically initiated fatigue under low bending stresses yet did not experience the abrupt failures with the retardation of crack propagation in between the UD layers. Although the coupon fatigue tests indicated a steep fatigue slope of 5.41, it's important to note that the material coupons tested were half the thickness of the actual deck laminate, which may influence the results' applicability to real-world scenarios.

Acknowledgments

The authors would like to express their gratitude to Rijkswaterstaat, the Directorate-General of the Ministry of Infrastructure and Water Management of the Netherlands for the financial support, and FibreCore Europe for the production of the panels.

Keywords: Nonlinear dynamic, ceramic matrix composite, constitutive mode

Abstract

During the service life of high-performance engines, essential components in the high-temperature parts undergo simultaneous exposure to high temperatures and aerodynamic vibrations. Elevated vibrations in high-temperature conditions not only influence engine performance, but also expedite structural fatigue, resulting in premature failure. Selected SiC/SiC composite materials, renowned for their superior high-temperature performance, present considerable advantages and application potential. However, under such multi-field coupling hush service conditions, ceramic matrix composites (CMCs) demonstrate complex dynamic nonlinear and hysteresis behavior, which limits the ability to predict material failure. Thus, establishing a dynamic failure model and efficient computational methods for high-temperature CMCs are crucial. These advancements will accelerate structural material design and validation, enabling real-time monitoring and prediction of failure behavior in high-temperature composites, with significant engineering application potential.

To address the aforementioned challenges, this study developed mechanical loading and vibration experiment systems to obtain constitutive and dynamic data, respectively, at 1100℃. Tension and loading-unloading mechanical tests were conducted to obtain the tensile curves and skeleton curves for 2.5D CMCs at 1100℃. These data were used to establish arbitrary cyclic tensile and compressive constitutive model. A numerical model was stablished to simulate the stress-strain curves. This model integrated matrix cracking, interface friction and fiber fracture, and is applicable to 3D stress states. The calibrated parameter values in the constitutive model were applied to calculate the response of CMCs to dynamic loading at 1100℃. Combining the constitutive model and an explicit dynamic numerical method, a nonlinear dynamic simulation model was established for CMCs structures, to predict the first-order natural frequency and amplitude of 2.5D CMCs at 1100℃. This work contributes a better understanding of the CMCs' behavior under high-temperature dynamic loads.

1. Introduction

Ceramic-matrix composites (CMCs) have become indispensable in replacing high-temperature alloys in aero-engines due to their high strength, temperature resistance, excellent toughness, crack resistance,

and low density. Exposed to prolonged high temperatures and vibrations, aero-engines exhibit significant behavioral changes, necessitating a nonlinear dynamic calculation methodology to accurately assess CMCs' responses in such environments.

The theoretical framework for analyzing composite materials has evolved considerably. Love [1] introduced the classical laminate-plate theory, simplifying calculations significantly. This theory was further developed by Mindlin [2] and Naghdi [3], who included considerations for transverse shear and extrusion, thus enhancing dynamic response accuracy. Advances by Nagesh and Hanagud [4] using finite element methods revealed natural frequency reductions due to delamination. Librescu and Nosier [5] further refined dynamic equations with transverse shear deformation and higher-order effects, surpassing classical theory accuracy.

Recent studies have further examined the vibrational behaviors of composites under varied conditions. Lee et al. [6] analyzed carbon-fiber epoxy composite plates in supersonic airflow at different temperatures, while Xia et al. [7] developed models for wall plate vibrations under constant temperatures, linking decreased vibration frequency to thermal stresses. Fu et al. [8] created a dynamic model for composite beams across different temperatures.

Experimental validations by Spivey et al. [9] on aircraft structures under thermal loads confirmed the effectiveness of finite element methods, clarifying modal characteristics in high-temperature environments. Jeyaraj et al. [10] observed natural frequency variations in composite plates across temperatures. Birman et al. [11] studied the impact of matrix cracking on woven CMCs, finding minimal effects on stiffness and natural frequency. Gao et al. [12] introduced a three-dimensional shear lag model to analyze the vibration response of unidirectional CMCs, integrating multiscale simulation with finite-element methods.

While much research has focused on laminate-plate composites, the dynamic responses of CMCs with complex woven structures in high-temperature environments have received less attention.

This study conducts tensile, loading and unloading, and vibration tests on 2.5D woven SiC/SiC composites under high-temperature conditions to establish a macroscopic intrinsic model, assess high temperature's impact on natural frequency, and predict the first-order natural frequency and amplitude.

2. Methods Experiment

2.1. Specimen and Material

The material investigated in this study comprised a 2.5D woven shallow-bend SiC/SiC ceramic matrix composite (CMCs). In order to enhance the material's mass density, we utilized Chemical Vapor Infiltration (CVI). Through multiple cycles of vapor deposition applied to the preform surface using CVI, the preform was filled with SiC matrix, effectively compacting the CMCs. Consequently, CMCs composite plates were produced, boasting a density of approximately 1.8 g/cm³ as determined by displacement method.

The 2.5D woven SiC/SiC composites were prepared with a thickness of 3 mm, and for processing the CMCs test pieces, waterjet cutting [13], selected for its superior processing efficiency and cutting precision, was employed.

The specimens obtained through water cutting were utilized for mechanical property tests, and their dimensions and physical conFigureurations are depicted in Figure 1. The overall length of the specimen measured 200 mm, with a clamping end length of 25 mm, width of 12 mm, test section length of 100 mm, and width of 6 mm.

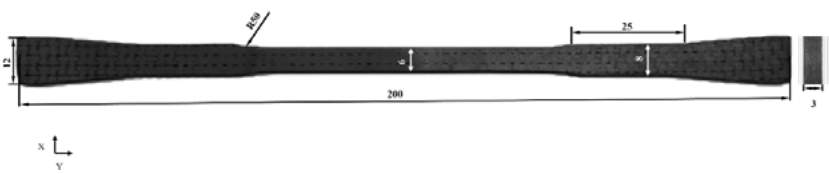

Figure 1. Dimensional drawing and picture of the dog bone specimen of 2.5D woven CMCs(mm)

Additionally, water jet cutting was utilized to procure rectangular specimens for dynamic response testing. These specimens measured 143 mm in length, 10 mm in width, and 3 mm in thickness. The clamping end was positioned on one side of the rectangle, featuring a clamping length of 20 mm, as depicted in Figure 2.

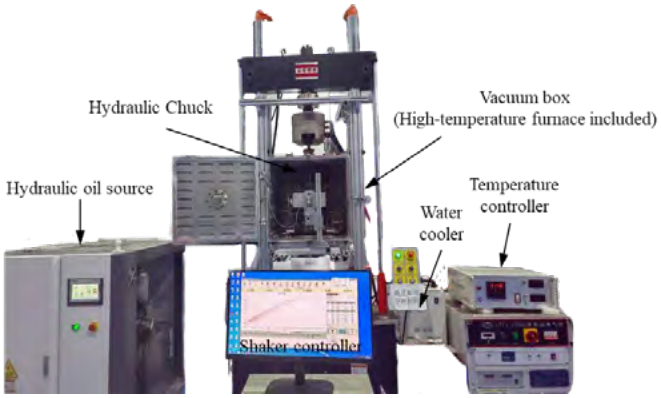
Figure 2. Dimensional drawing and picture of the rectangular specimen of 2.5D woven CMCs (mm)

2.2. Experimental Method

2.2.1. Intrinsic structure response test

Tension and loading-unloading mechanical tests were performed to obtain the tensile curves and skeleton curves for 2.5D CMCs at 1100℃. These data were utilized to establish an arbitrary cyclic tensile and compressive constitutive model.

To conduct static tensile, loading, and unloading tests on 2.5D woven SiC/SiC composites at 1100℃, a test system illustrated in Figure 3 was devised in this study. The test system primarily comprised a fatigue testing machine, high-temperature furnace and temperature control device, vacuum apparatus, water circulation cooling system, and strain measurement device.



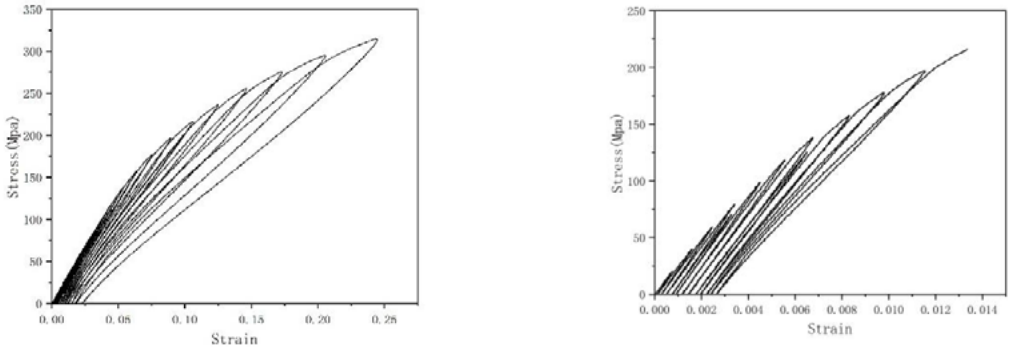


Figure 3. High temperature tensile, loading and unloading test system

The tensile test was executed under force loading at a loading rate of 0.05 kN/s until fracture occurred in the test specimen. For loading-unloading tests, force-controlled loading was employed at a loading rate of 0.05 kN/s, and loading paths were governed by a programmed sequence. Initially, tensile loads were applied until reaching the specified load, followed by unloading and reloading according to the program's parameters. Multiple loading-unloading cycles with decreasing maximum loads were included to validate the arbitrary nature of loading-unloading and the randomness of vibrational loads, thereby mitigating potential anomalies, as depicted in Figure 4.

(a) 25℃ (b) 1100℃

Figure. 4 Loading and unloading curves and skeleton curves of SiC/SiC composite.

The skeleton curves depicting cyclic loading and unloading stress–strain behaviors of the 2.5D woven CMCs at various temperatures closely mirrored the overall shape and trend observed in the monotonic tensile curve. These curves exhibited three distinct segments: initial linear, nonlinear, and secondary linear sections. The specimens' strength under cyclic loading and unloading conditions notably lagged behind that of monotonic tensile test specimens. This disparity stemmed from frictional forces between internal fibers, the matrix, and the interfacial layer, encompassing warp and weft yarns along with different transverse and longitudinal layers. Such frictional forces dissipated energy, consequently diminishing material strength [14-16].

At room temperature, the stress–strain curves of the 2.5D woven CMCs in the low-load range of the skeleton curves displayed almost linear profiles with minimal hysteresis, suggesting negligible frictional damage and energy dissipation. Conversely, in the high-load range, hysteresis loops formed in the cyclic loading and unloading stress–strain curves, with the loop area expanding alongside increasing loads. This occurrence arose from heightened interfacial frictional damage as load intensified, leading to gradual reduction in interfacial shear stress and increased interfacial debonding length. Consequently, residual strain and energy dissipation during loading and unloading augmented, contributing to a decline in material elastic modulus. Notably, the history of maximum load influenced the hysteresis loop's configuration [17].

In scenarios where tensile stress persisted at the maximum load point of the hysteresis loop, the stress–strain curve followed a monotonic tensile trajectory. This was attributed to the Ceramic-matrix's low fracture toughness, rendering it resistant to damage under cyclic loading, thereby exhibiting a "memory effect" within the hysteresis loop [18].

Comparatively, the high-temperature cyclic loading and unloading stress–strain curve largely retained its characteristics observed at room temperature. However, it no longer precisely mirrored the hysteresis loop of room-temperature loading and unloading, particularly in traversing through the historical maximum load point. This deviation became more pronounced with escalating temperatures. The weakening of initial interfacial bonding, expansion of interfacial slip zones, and exacerbation of interfacial wear at higher temperatures led to additional material damage during unloading and reloading processes. This observation underscores that elevated temperatures exacerbate material degradation [19].

2.2.2. Dynamic tests

Experimental setups suitable for high-temperature vibration tests were developed for 2.5D woven SiC/SiC composite flat-plate structures at 1100℃, as shown in Figure 5. This apparatus, designed to facilitate vibration performance testing, incorporated a vibrator, a high-temperature furnace, and precision measurement equipment, among other components. The system enabled vibration tests and dynamic response analyses under elevated temperatures.

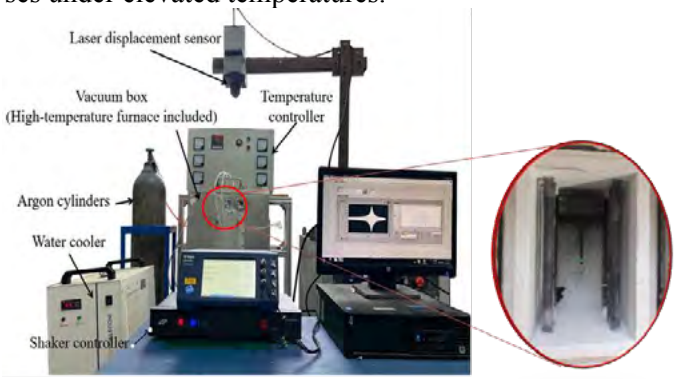

Figure. 5. High-temperature vibration experiment system

The high-temperature furnace, equipped with water cooling and gas filling functionalities, maintained a controlled environment. It featured quartz glass windows and a high-temperature resistant glass cover plate to minimize heat loss while ensuring a sealed environment. The vibration table, connected to the furnace through a vacuum-sealed interface, supported fixtures made of 310S stainless steel.

During the experiments, the vibrator's sampling frequency was set to 8192 Hz with an accuracy of 0.1μm. Initial tests involved a rapid sinusoidal sweep across a broad frequency range to estimate the first-order resonance frequencies of the undamaged CMCs. Subsequent tests increased the vibration load to

examine the material's nonlinear stress-strain characteristics. The acceleration excitation of the vibration table was set to 5 m/s², scanning frequencies near the first-order resonance frequency at a rate of 0.5 Hz/s. This method successfully captured the first-order natural frequency of the material at 1100℃. Fourier transform analysis converted time-domain data to frequency-domain signals for precise vibration analysis.

Figure 6 illustrates the vibration sweep tests on the 2.5D woven CMCs plates, demonstrating how frequency sweeping through the first natural frequency induced resonance and a significant displacement increase at 25 ℃ and 1100 ℃. This result confirmed the test data's integrity and showed a gradual increase in the first-order natural frequency with rising temperature, which, however, decreased at 1100 ℃. This behavior reflects changes in material stiffness due to temperature variations, influencing the natural frequency. Below 1100 ℃, as temperature increases, the difference in thermal expansion coefficients between the fibers and matrix decreases, enhancing material stiffness and increasing natural frequency. Above 1100 ℃, however, high temperatures cause SiC matrix degradation, fiber damage, and matrix cracks, reducing the composite's structural stiffness and lowering its natural frequency.

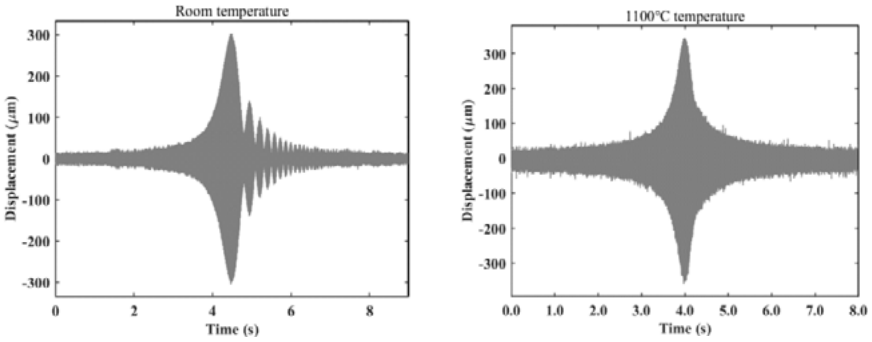

Figure. 6 Vibration time domain plot

2.3. Numerical modeling

The vibrations of CMCs beams involve individual units undergoing arbitrary cyclic tensile and compressive loads. Accurate simulation of these vibrations necessitates an intrinsic model that captures the repetitive stress behaviors under vibrational conditions. Establishing this model requires high-temperature tensile tests on 2.5D woven CMCs.

We utilized the cyclic loading and unloading stress-strain curves from these tests to model the behavior of 2.5D woven CMCs at high temperatures. This model, derived from the skeleton curves' trends, establishes a relationship between the historical maximum strain and the stress-strain response during each cycle.In the low-load range, linear fitting addressed the loading and unloading behaviors, where the modulus decreased in line with the skeleton curve. At high loads, direct fitting of the hysteresis loop was impractical due to the lack of a memory effect and material damage from high temperatures. However, the sub-loop displayed nearly linear behavior with minimal hysteresis, suggesting that friction damage had largely stabilized after the initial cycle. This finding highlighted the role of historical maximum stress in assessing material damage.

In conclusion, the completion of fitting arbitrary cyclic tensile and compressive stress–strain curves for 2.5D woven CMCs in 1100℃ environments provides a comprehensive understanding. Based on this macroscopic intrinsic model, stress at a given time can be calculated when the stress and strain at that time, the strain at a previous time, and the historical maximum stress and its corresponding strain are known., as shown in Eqs. 1:

$$^{t+\Delta t}\sigma = f(^{t}\sigma, ^{t}\varepsilon, ^{t+\Delta t}\varepsilon, \varepsilon_{\max}, \sigma_{\max}) \tag{1}$$

A finite-element model of the CMCs beam, matching the dimensions of the test specimens, was developed to simulate the effects of sinusoidal gravity fields at varying frequencies. This model helps to mimic the conditions of vibration tests effectively.

The structure of the cantilever beam is simple, and during its bending vibration, normal stress acts along the axial direction. Thus, each small element on the beam can be considered to undergo arbitrary tensile

and compressive behavior. Therefore, it is reasonable to use a CMCs arbitrary loading and unloading constitutive model considering temperature effects for dynamic response calculations, which can reduce computational complexity.
The vibration of the fixture base has been reflected in the equation through the global inertial load , and the displacement of the vibrator is very small and can be ignored in the simulation. Hence, this boundary condition is set:

$$u(x = 0) = v(x = 0) = w(x = 0) = 0 \tag{2}$$

$$\boldsymbol{f} = (0, 0, f)^T = (0, 0, \bar{f} \sin \omega t)^T \tag{3}$$

Based on the principle of virtual displacement, the dynamic control equation for CMCs is established as follows:

$$\int_\Omega \sigma_{ij} \delta \varepsilon_{ij} dV - \int_\Omega \rho \ddot{u}_i \delta u_i dV - \int_\Omega c \dot{u}_i \delta u_i dV - \int_{\Gamma 2} q_i \delta u_i ds - \int_\Omega \rho \bar{f} \sin(\omega t) \delta u_i dV = 0 (i, j = 1, 2, 3) \tag{4}$$

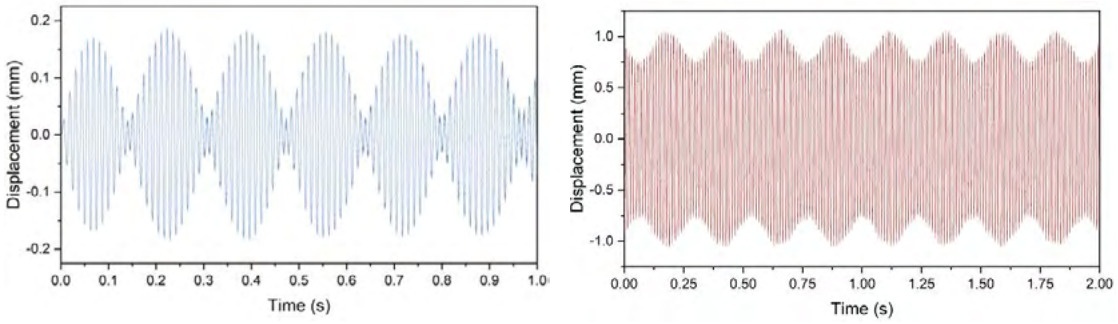
Where u, v, and w represent displacements in the x, y, and z directions, respectively.

By balancing (stress) differential equations and geometric differential equations, the control equation is simplified to:

$$\boldsymbol{K}^T \delta \boldsymbol{a} - \ddot{a}^T \boldsymbol{M}^T \boldsymbol{a} - \dot{\boldsymbol{a}}^T \boldsymbol{C}^T \delta \boldsymbol{a} = \boldsymbol{Q}^T \delta \boldsymbol{a} \tag{5}$$

Where:

$$\begin{cases} \boldsymbol{M} = \sum_e \int_{\Omega^e} \rho \boldsymbol{G}^{eT} \boldsymbol{N}^{eT} \boldsymbol{N}^e \boldsymbol{G}^e \mathrm{d}V \\ \boldsymbol{C} = \sum_e \int_{\Omega^e} c \boldsymbol{G}^{eT} \boldsymbol{N}^{eT} \boldsymbol{N}^e \boldsymbol{G}^e \mathrm{d}V \\ \boldsymbol{K} = \sum_e \int_{\Omega^e} \boldsymbol{G}^{eT} \boldsymbol{B}^{eT} \boldsymbol{\sigma}^e \mathrm{d}V \\ \boldsymbol{Q} = \sum_e \int_{\Gamma^e} \boldsymbol{G}^{eT} \boldsymbol{N}^{eT} \boldsymbol{q} \mathrm{d}S \end{cases} \tag{6}$$



It should be noted that K here is not the stiffness matrix, but a vector with the same dimensions as the degrees of freedom of the structure. Writing the dynamic equation in this form facilitates the subsequent solution of the dynamic equation. Although not a stiffness matrix, it effectively reflects the stiffness of CMCs, and material nonlinearity is manifested in K.
This study employs the center difference method to solve the dynamic equations. This method is based on the finite difference method rather than the derivative of displacement with respect to time. The velocity and acceleration are obtained using the first-order and second-order derivatives of displacement, respectively. Utilizing the center difference method not only avoids matrix inversion but also accelerates the calculation speed and does not produce mathematical discontinuity points in the calculation process of the intrinsic model, effectively avoiding iterative operations and saving space in the calculation. This method is very suitable for calculating the nonlinear vibration response of CMCs.
Based on the established macroscopic arbitrary tensile and compressive intrinsic model of 2.5D woven CMCs in different temperature environments, a self-developed solver was programmed to import the material properties. Subsequently, leveraging the theory of the central difference method, self-developed solver was developed to calculate the vibration response.

3. Conclusions

The nonlinear constitutive behavior of CMCs is calculated using the shear-lag model, and the parameters involved in the calculation are shown in Table 1.

Table 1. Parameters of constitutive model.

Item	Value	Item	Value
E_m / GPa	369.75	τ_i /MPa	50
E_f / GPa	223.80	r_f / μm	6
α_m /$\times 10^{-6}$ / ℃	4.53	L_{sat} / mm	0.54

Abstract

Rapid Gas Decompression (RGD) is a concern when using polymeric material in gas transport pipelines. To better understand the mechanism of RGD, this study investigates high-density polyethylene (HDPE) liners used in pressurized CO_2 pipelines for carbon capture and sequestration (CCS). We propose a coupled deformation-diffusion model tailored for polymeric materials under pressurized gas conditions. An extensive parametric study was performed using the model to assess cavity growth in relation to variations in maximum pressures and depressurization rates. The results were consistent with the experimental observations, emphasizing the potential of such numerical model in estimating RGD damage and maintaining the integrity of polymeric materials in gaseous environments.

1. Introduction

The energy industry is particularly interested in pressurized CO_2 pipelines for carbon capture and sequestration (CCS). These pipelines play a pivotal role in various CCS applications, with two prominent ones being sustainable hydrogen production (SHP) and enhanced oil recovery (EOR)[1]. Carbon steel is widely used in many oil and gas operations due to its low cost and strong performance, which is complemented by extensive familiarity with its operational and maintenance procedures. However, the presence of water and impurities in captured CO_2 can drastically increase the corrosion rate of steel pipelines. This corrosion not only compromises the integrity of the pipelines but also poses environmental and safety risks[2]. Composite pipelines, on the other hand, exhibit superior performance compared to steel in numerous aspects, including weight, spoolability, ease of installation, reduced greenhouse gas emissions during production, longevity, and maintenance expenses. High-Density Polyethylene (HDPE) is the main liner material used in these pipes. HDPE is widely used in industrial pipelines due to its mechanical properties, barrier properties, chemical resistance, and low cost [3], [4].

Nonetheless, challenges arise in terms of chemical compatibility, permeability, low-temperature performance, and resistance to rapid gas decompression (RGD) when using polymeric materials in gas transportation [5], [6]. The permeation of gases through polymer materials, particularly under high temperatures and pressures, is an important consideration for system integrity [7]. HDPE is utilized in environments where it is exposed to corrosive fluids at high pressures and temperatures up to 300 bar and 85°C and. Rapid Gas Decompression (RGD) refers to the phenomenon in which pressurized gases absorbed into a polymer material are suddenly released due to a rapid decrease in external pressure. This phenomenon can result in structural damage or failure [8], [9].

The goal of this study is to investigate the viability of HDPE liners for CO_2 composite pipelines, driven by the pressing need to address critical challenges in carbon capture and sequestration (CCS) during the ongoing energy transition. In this work, we propose a coupled deformation-diffusion model tailored for polymeric materials under pressurized gas conditions. Our proposed model offers insights into the effects of rapid gas decompression (RGD) on HDPE liner materials. Through a comprehensive parametric study, we investigate how environmental factors such as maximum pressure and depressurization rate affect the integrity of HDPE liners in a harsh CO_2 environment.

2. Methodology

In this section, we present the different components of the coupled model and its numerical implementation.

2.1. Problem description

Here, we propose a coupled diffusion-deformation model to assess the growth of a pre-existing cavity within the polymer. This cavity may arise from manufacturing defects or nucleate due to prior rapid gas decompression (RGD) events. We proceed with the assumption of a perfectly spherical cavity, and that the surrounding area of the cavity is initially free of residual stresses. To mimic a pipe liner (Figure 1), we adopt a rectangular HDPE coupon, with one dimension smaller than the other two representing the thickness.

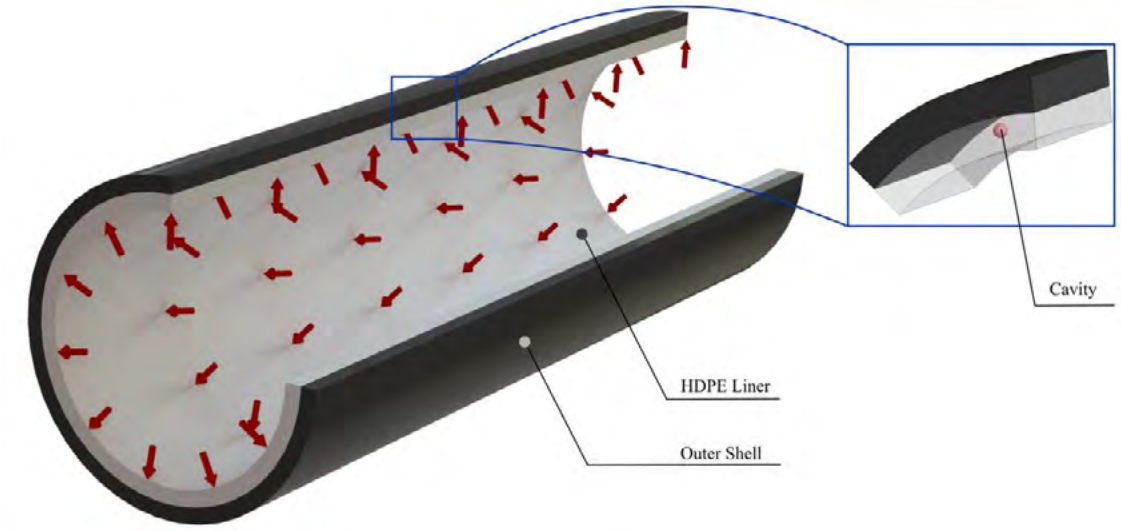

Figure 1. Schematic of a Pipe with HDPE liner under CO_2 pressure. The detail shows a coupon with a spherical cavity

For numerical simulations, we consider a 2D square Representative Volume Element (RVE) containing a single cavity. The RVE is subjected to CO_2 pressure from both faces along the thickness while being periodic along the other faces. (See Figure 2).

The substantial difference in scale between liner thickness (on the order of millimeters) and cavity size (on the order of micrometers) complicates the implementation of the entire structure, resulting in numerical problems. Consequently, we adopted a global-local approach (see Figure 3), where we first obtain the solution for the larger scale without the cavity, and then use it to solve for the smaller scale problem. The global solution is transfered to the local problem as boundary conditions. This method not only overcomes numerical challenges but also significantly reduces computation time, as we can derive an analytical solution for the large scale problem.

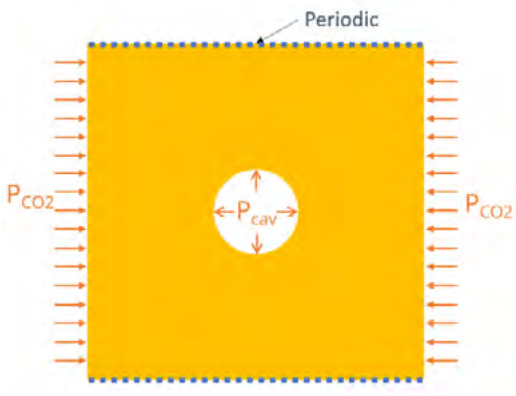

Figure 2. Boundary conditions of the RVE

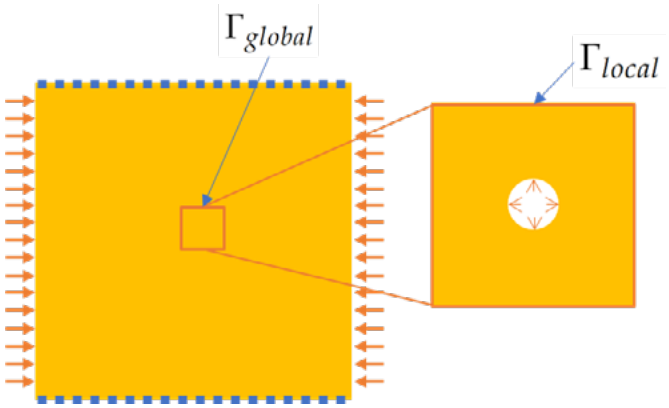

Figure 3. Schematic representation of the Global-Local modeling approach

2.2. Governing equations

In this section, we describe the governing equation for the coupled multiphysics model, which incorporates deformations and CO_2 gas transport in the HDPE. From a mechanical standpoint, the RVE is subjected to pressure boundary conditions on the inner and outer surfaces, and on the cavity boundary, where the gas accumulates. Further, periodicity is imposed on the other surfaces. The boundary value problem for deformation is governed by the following equations.

$$\begin{aligned} &\underline{div}\,\underline{\underline{\sigma}} = \underline{0} && \forall \underline{x} \in \Omega \\ &\underline{\underline{\sigma}}.\underline{n} = -p\underline{n} && \forall \underline{x} \in \partial\Omega_T \end{aligned} \tag{1}$$

Where $\underline{\underline{\sigma}}$ is the stress tensor, $\underline{n}$ is the outward normal at point of the boundary, and p is the prescribed pressure at the pressurized boundaries $\partial\Omega_T$.

For the constitutive law, we assume an elastoplastic material with nearly perfect plasticity. The yield stress σ^y of HDPE at a temperature T was obtained using the law given by [10] expressed as

$$\sigma^y(T) = 112.85 - 0.305T \tag{2}$$

In terms of gas transport, we assume that CO_2 transport in HDPE under the given conditions is governed by Fickian diffusion. We prescribe the Dirichlet BC on the pressurized surfaces, including the cavity boundary. For periodicity, we assume continuity of concentration and a zero gap for normal flux. The following equations give the boundary value problem for diffusion.

$$\begin{aligned} &\frac{\partial c}{\partial t} + div\underline{J} = 0 && \forall (\underline{x},t) \in \Omega \times [0,T] \\ &\underline{J} = -D\underline{\nabla c} && \forall (\underline{x},t) \in \Omega \times [0,T] \\ &c(\underline{x},0) = 0 && \forall \underline{x} \in \Omega \\ &c(\underline{x},t) = c_d && \forall (\underline{x},t) \in \partial\Omega \times [0,T] \end{aligned} \tag{3}$$

Where c is the gas concentration, $\underline{J}$ is the diffusive flux, D is the diffusion coefficient, and c_d is the prescribed concentration at the boundary.

The cavity is modeled as a closed sink where gas accumulates, resulting in pressure buildup. Assuming the gas behaves ideally, the ideal gas law, $PV = nRT$, can be used to calculate the pressure at the cavity's surface. The total number of moles inside the cavity is obtained by mas conservation law which states that: the evolution of the mass inside the cavity is equal to the total flux crossing the boundary. Thus, the number of of moles is obtained by solving

$$\frac{d\,n_{cav}}{dt} = \int_{\partial\Omega_{cav}} \underline{J}.\underline{\nu}\, dS \tag{4}$$

Where $\underline{\nu}$ is the outward normal at the cavity boundary.

The gas pressure and the gas concentration at the pressurized boundaries are coupled via Henry's law

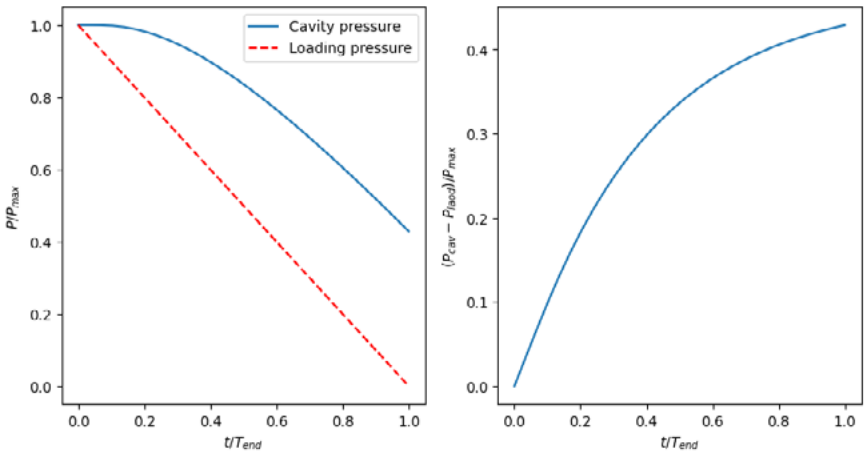
$$\begin{aligned} c_g &= P_g\ S \\ c_{cav} &= P_{cav} S \end{aligned} \tag{5}$$

Where S is Henry's Solubility.

2.3. Numerical Implementation

The model was implemented in COMSOL Multiphysics software due to its simplicity in solving coupled physics. For the cavity growth assessment, we focus only on the depressurization period where the cavity will be expanding due to the difference between the loading pressure and cavity pressure. Furthermore, due to the simplicity of the global problem we get an analytical solution for the stress and for the concentration. Thus, we only have to simulate the local part. For the deformation part, the stress is uniform and it's given as

$$\underline{\underline{\sigma}} = -p\,\underline{e_x} \otimes \underline{e_x} \tag{6}$$



And for diffusion, the concentration of CO_2 is given at any time during the depressurization $0 \le t \le T_{dp}$ and at any position x along the thickness by the following expression

$$\frac{c(x,t)}{c_{\max}} = 1 - r\,t + \sum_{k=1}^{\infty} \frac{4r}{(2k+1)^3 \pi^3} \mathrm{Sin}\left((2k+1)\pi x\right)\left(1 - e^{-(2k+1)^2 \pi^2 t}\right) \tag{7}$$

The depressurization was assumed to be of the form $P_g = P_{\max}(1 - r\,t)$, where $P_{\max}$ is the saturation pressure and r is the depressurization rate.

3. Results

In this section, we present the results obtained from various parametric studies conducted using the model described earlier to evaluate cavity growth in HDPE liners. For each simulation, we calculate the final cavity volume after complete depressurization. Additionally, we focus our study on a single point that is located at the mid-thickness, as it represents the position experiencing the most severe pressure accumulation. For all the reported results, the temperature was kept constatnt at $T = 85°C$ and the coupon thickness was set to 1 mm.

(a) (b)

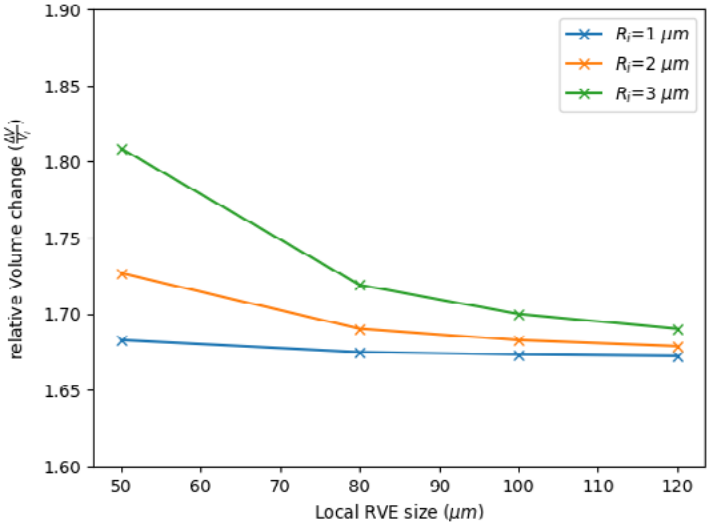
Figure 4. (a) Normalized Cavity pressure and loading pressure versus normalized time. (b) difference between cavity and load normalized pressures versus time

3.1. Maximum Pressure difference

The analytical solution for diffusion provided in the previous section provides quick insight into the pressure profile at the cavity during depressurization. Figure 4 exhibits the cavity and load pressure profiles (4a), as well as their differences across the depressurization time (4b). We see that difference is maximum at the end of depressurization (Figure 4b). As a result, we anticipate that the cavity will expand the most when the loading pressure hits zero. Afterwards, the gas will continue to evacuate slowly and the cavity will relax.

3.2. Results objectivity

To ensure the objectivity of our results, we must verify that the local RVE size (referred to as the scale size) does not impact the results. Therefore, we perform a sensitivity analysis to assess the effect of the scale size. We conduct simulations with various initial cavity sizes and scale sizes. Employing an almost instantaneous depressurization rate, which is anticipated to induce the most significant change in cavity volume. Figure 5 illustrates the relative change in volume as a function of the scale size for different levels of initial cavity sizes. We observe that the results saturates for higher scale size. For the following simulations, we fix the scale size to 100um.



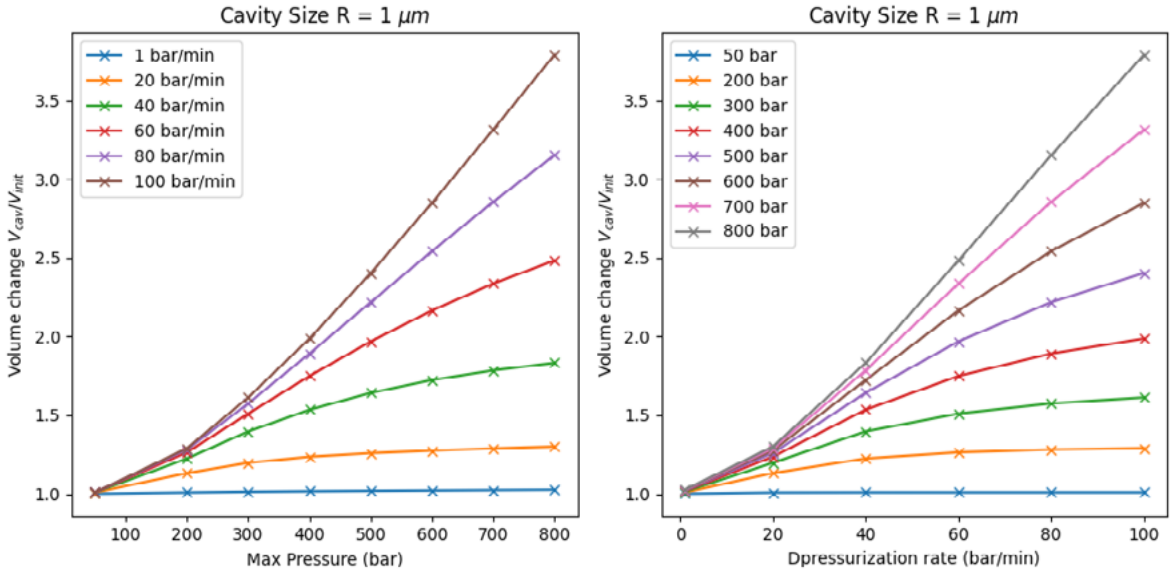


Figure 5. The relative change in the cavity volume for various local RVE size.

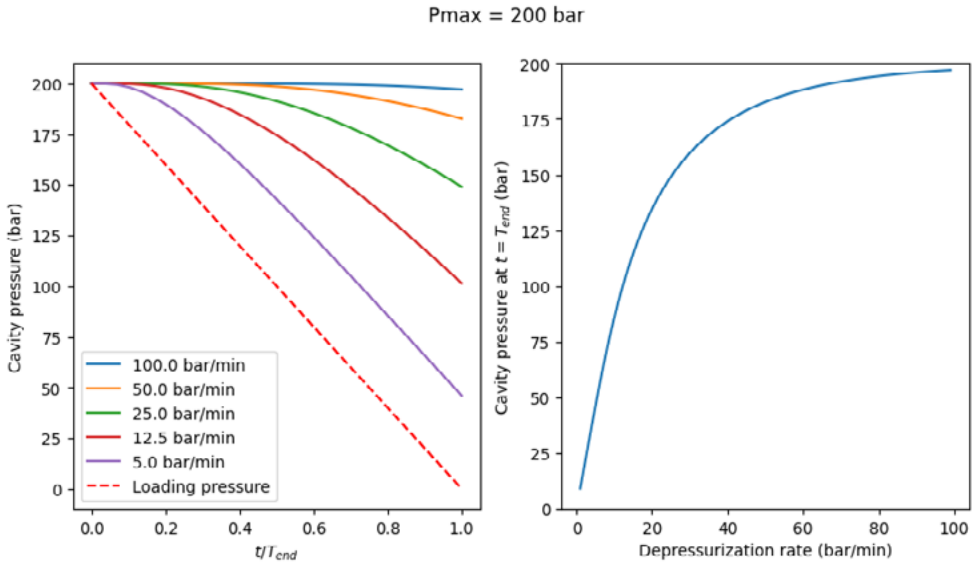
3.3. Parametric study



In this section, we conduct multiple simulations with varying depressurization rates and maximum pressures, while keeping the initial cavity size fixed at 1 µm. The results are presented in Figure 6. Our findings indicate the absence of cavity growth for low maximum pressures (<100 bar) and slower depressurization rates (<1 bar/min). Above these thresholds, the model starts to predict volume change in the cavity. The damage becomes more severe when going to high pressures and high rates. Additionally, the figure reveals a saturation feature, particularly evident for medium pressures and rates. This suggests that damage is limited for a fixed parameter (maximum pressure or depressurization rate). In other words, for a set rate (resp. maximum pressure), the cavity growth is limited to a certain value, even for higher pressures (resp depressurization rates).

(a) (b)

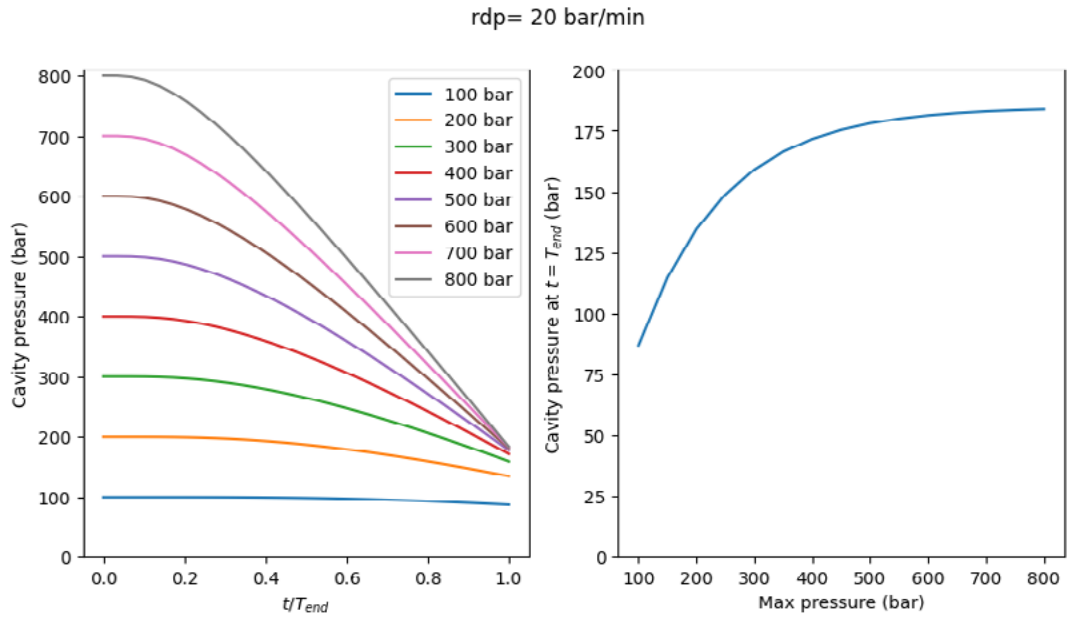


Figure 6. Parametric study results for Maximum pressure and the depressurization rate. (a) we plot the cavity growth vs the maximum pressure for different levels of depressurization rate. (b) we plot the cavity growth vs the depressurization rate for different levels of maximum pressure.

To explain the saturation features, we plot the cavity pressure at the end of depressurization against various depressurization rates (Figure 7) and maximum pressures (Figure 8). Figure 7 shows that the change in final cavity pressure is significant at low rates before saturating to the maximum loading pressure. This revealed that before reaching a critical depressurization rate (depending on the maximum pressure), we detect a change in cavity expansion as the rate increases. Following that, the cavity growth becomes less sensitive to the depressurization rate. A similar observation is made with the variation of the maximum pressure (Figure 8), where we can plainly see that the final cavity pressures concentrate to a particular level when the rate is fixed and the maximum pressure is varied.

(a) (b)

Figure 7. (a) Plot of the cavity pressure evolution with different depressurization rates. (b) Plot of the cavity pressure at the end of depressurization versus the depressurization rates

(a) (b)

Figure 8. (a) Plot of the cavity pressure evolution with different maximum pressures. (b) Plot of the cavity pressure at the end of depressurization versus the maximum pressure

Conclusions

In this study, we present a coupled multiphysical model that assesses the growth of a pre-existing defect in polymeric materials under rapid gas decompression. Our model effectively illustrates the impact of both the depressurization rate and the maximum pressure on cavity growth. Notably, it accurately captures the phenomenon where slow decompression limits the defect growth. Similar behavior is observed concerning the loading pressures. Furthermore, our model predicts saturation behavior for medium depressurization rate and load pressure. These parametric study results are in accordance with the phenomena observations. Therefore, it demonstrates the model's utility in predicting rapid gas decompression damage, and offering quantification of the cavity growth. Notably, our model's applicability extends to various polymeric materials in gas environments, provided no chemical reactions occur. Overall, our findings suggest promising potential for using this model to anticipate and manage rapid gas decompression-induced damage in practical applications.

MECHANICAL CHARACTERIZATION AND MODELING OF FIBER REINFORCED POLYAMIDES IN CONTACT WITH COOLANT

Gilles ROBERT[1], Florent ALEXIS[1]

[1]Application Center, DOMO Chemicals, avenue Ramboz, Saint Fons, France
Email: gilles.robert@domo.org, Web Page: https://www.domochemicals.com/en

Keywords: Polyamide 6.6, coolant, ethylene glycol, short fibers, meta-models

Abstract
Mechanical and viscoelastic behavior of fiber reinforced polyamide 6.6 has been characterized before and after hydrolytic ageing. The level of properties achieved has been shown to depend only on the average molecular weight, and not the couple time/temperature used for ageing. Results have then been inserted into a meta modeling approach based on a generalized time temperature superposition method that was proven effective for several water, ethylene glycol and coolant concentrations, and easily adaptable to aged materials.

1. Introduction

Many short fibers reinforced polyamide 6.6 parts under the hood are in contact with coolant. It is true for internal combustion engines, or batteries electric and hybrid vehicles, not to mention fuel cells. The interactions between polyamide and coolant main components, water and ethylene glycol include plasticization, which decreases strongly the compound's glass transition temperature and hence mechanical properties in standard operating conditions. They also include chemical degradation, through hydrolysis of the polyamide chains[1]. Simulation of parts in contact with coolant is key to optimize their design. To perform it accurately, all the relevant parameters must be taken into account, and a specific simulation chain must be developed.

To face this challenge, a collaborative project has been built. Project team includes OEMs, Renault and TOYOTA, the tier one supplier SOGEFI Filtration, two French academic labs, CEMEF and LEM3, ADI a toolmaker, NOVITOM, specialized in analytical techniques involving synchrotron X-rays beams, AROBAS technologies, Hexagon Manufacturing Intelligence, editor of the Software Digimat™ and DOMO chemicals as material supplier and project coordinator. Project was funded by Banque Publique d'Investissement, and local communities Grand Lyon and Auvergne Rhône Alpes.

One of the main challenges before these new simulations become a reality is the reinforced materials characterization and modeling. In parts, local water or ethylene concentrations, temperatures and average molecular weight are highly variable. The influence of all these parameters must be characterized, and a way to manage them in simulations must be found. This is the target of this study.

2. Materials and methods

The materials under investigation are commercial compounds of polyamide 6.6 reinforced with glass fibers, TECHNYL A218 V30 34NG. They are used to mold plaques with the following geometry: length 360mm, width 100mm, thickness 3mm. The gating system ensures that fiber orientation is homogenous over the volume. The fiber orientation is measured using high resolution CT-scans performed in ESRF and post processed to extract fiber orientation tensors in the thickness of the plaques. Figure 1 illustrates the orientation across the specimens for two different specimens locations and demonstrates orientation homogeneity across the plaque. All the specimens machined have been cut along the symmetry axis of the plaque, between the two points where fiber orientation have been characterized. Three different orientations have been machined: 0°, 45° and 90°. Unfilled specimens made with the same formulation as the reinforced compounds, without glass fibers, have also been molded.

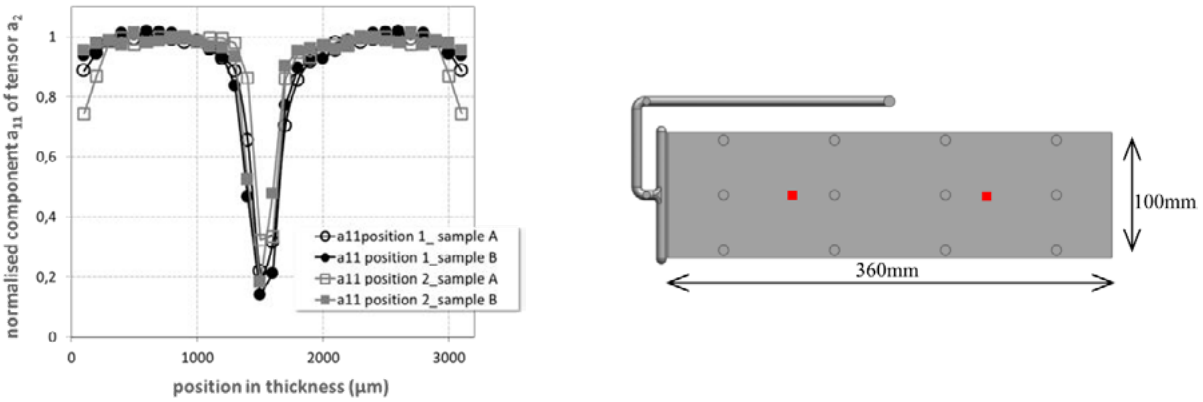

Figure 1. orientation tensors in two different locations of a plate illustrated above for a short fiber reinforced polyamide 6.6 reinforced with 30% of glass fibers

Aging of materials have been performed in autoclaves, at temperatures ranging from 110°C to 125°C, in contact with a mixture of ethylene glycol and water. Volume ratio used is 50% of each liquid. The ethylene glycol used is a commercial product, CCI L255N. Times used at each temperature have been adjusted to reach after treatment 68%, 56%, 44% and 32% of the initial average molecular weight in number. At a temperature of 120°C, the different times used are 408h, 624h, 948h and 1800h. For three of the molecular weight targeted, several couples time-temperature have been obtained.
Specimens molded and machined have been characterized using tensile tests for reinforced compounds and DMTA for unfilled specimens. Tensile tests have been realized using a specific experimental setup. Longitudinal and transverse strain have been measured using a first camera. A second camera is used to measure the strain in the thickness thanks to a PROVISYS video extensometer. This leads to true strain – true stress tensile curves. The longitudinal strain rate is also kept constant during the whole tensile test. DMTA tests are frequency scans between 0,01Hz and 20Hz, led at several constant temperatures between -100°C and 210°C. After tests, a time-temperature superposition procedure is applied in order to create a mastercurve, following a method classical in polymer science [2].

3. Consequences of hydrolysis on viscoelastic properties

Viscoelastic properties have been characterized at different levels of hydrolysis and compared with the properties of a material saturated with coolant, but without any significant loss of its average molecular weight M_n.

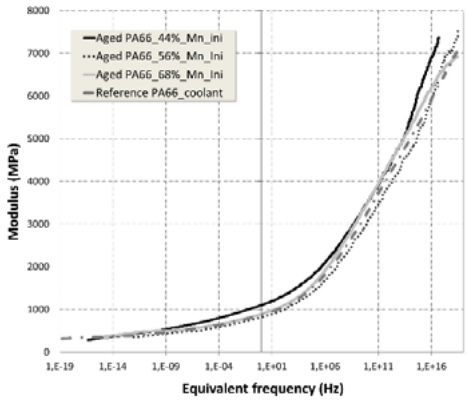

Fig. 2a: mastercurves obtained on PA66 saturated with coolant at different levels of average molecular weights after ageing

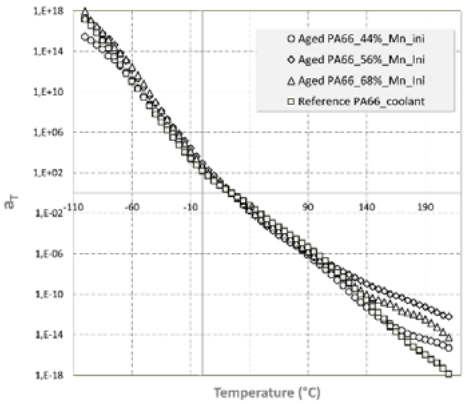

Fig. 2b: shift factors computed during the building of mastercurves on PA66 saturated with coolant after ageing

Results are illustrated on figure 2 for both the mastercurve and the shift factors associated. The mastercurves and shift factors are extremely similar to each other. Hydrolysis effects on viscoelastic properties are weak or even negligible. The only temperature range where curves can be differentiated is above 140°C, which is (a) the maximum usage temperature of reinforced PA6.6 in contact with coolant ; (b) a temperature where coolant desorption in the material is fast and makes the DMTA results questionable anyway. In conclusion, it is safe to say that viscoelastic processes are not strongly affected by hydrolysis in the average molecular weight domain explored and useful temperature range.

4. Consequences of hydrolysis on tensile properties

The first key result obtained comes from the comparison of materials aged in different conditions: 110°C/1392h, 115°C/936h, 120°C/624h, 125°C/432h. The final average molecular weight in number M_n of all these materials is 56%±1% of their initial average molecular weight. Results are pictured below on figure 3a and 3b. The main conclusion is that the mechanical behavior depends only on the average molecular weight, and not on the aging temperature or aging time. On figure 3a, the tensile curves obtained with the different aging conditions can't be differentiated. On figure 3b, failure strains for a 45° orientation are given for various temperatures and compared with the reference without hydrolysis. It can be checked on the figure that there is no noteworthy influence of aging conditions on failure strain, as long as the same average molecular weight is achieved.

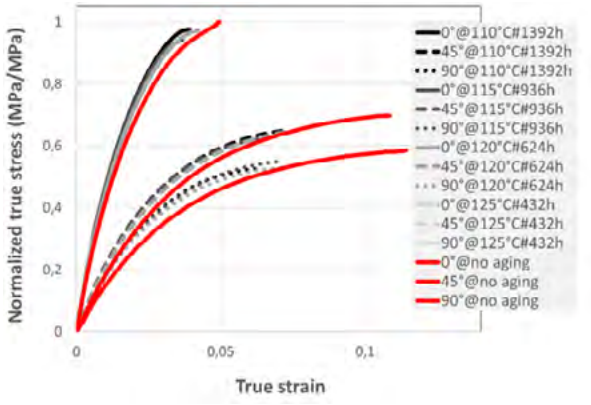

Fig. 3a: Tensile curves measured at 23°C and $10^{-3}s^{-1}$ for three different orientations on a 30% fibers reinforced PA6.6. Red curves: material saturated with coolant without hydrolysis. Grey curves: hydrolysed materials saturated with coolant

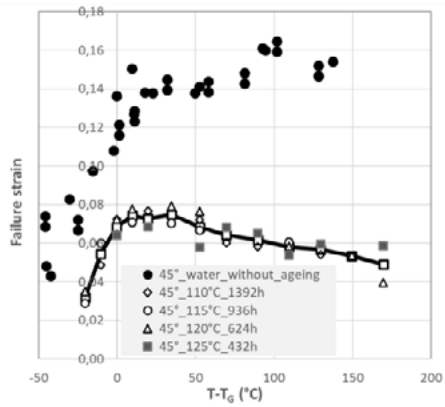

Fig. 3b: failure strain after aging in coolant for 30% glass fibres reinforced PA6.6. Comparison of several couples temperature/time leading to the same average molecular weight. Results are given for a fibre orientation of 45°.

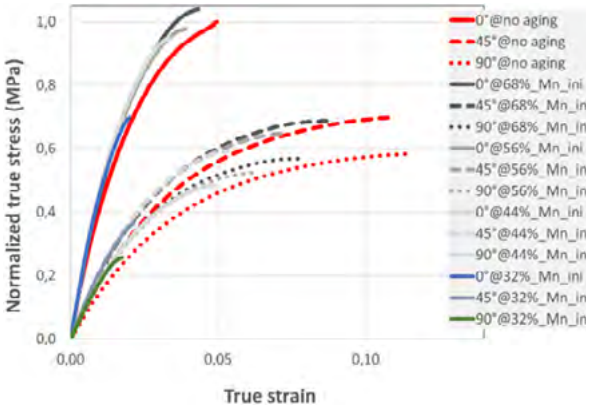

Fig. 4a: Tensile curves measured at 23°C and 10-3s-1 for three different orientations on a 30% fibers reinforced PA6.6 at different levels of hydrolytic ageing

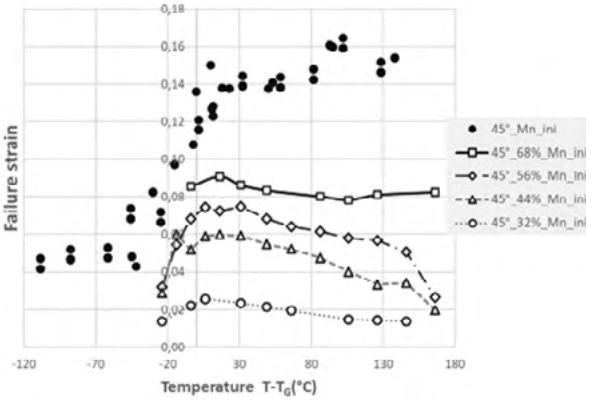

Fig. 4b: progressive embrittlement after aging in coolant for 30% glass fibers reinforced PA6.6 with a fiber orientation of . 45°

The main consequence of hydrolytic aging is a progressive embrittlement of the material. The tensile curves shape is not modified significantly by aging. Oppositely, failure strain decreases strongly. It becomes very low for the minimum value of average molecular weight studied, as shown by figure 4.
An interesting effect is the difference of performance evolution after ageing for different fibers orientations. This effect is stronger at high temperature and is illustrated on figure 5 for a tensile test temperature of 120°C. In initial conditions failure strain at 45° and 90° are bigger than for longitudinal orientation. Aging leads to a decrease in failure strain that reaches 80% of the initial value for longitudinal orientations, and 96% for transverse orientations. It leads to lower failure strain at high temperature for orientations of 45° or 90° compared to longitudinal orientations. This means that in these conditions the loss of matrix ductility is partially compensated by fibers, that hinder crack propagation[3].

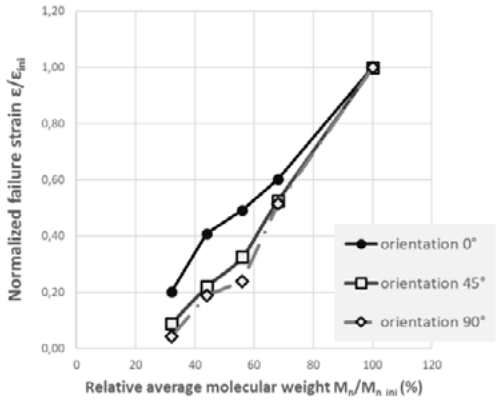

Fig. 5: relative loss of failure strain for different glass fibers orientations after hydrolytic ageing

5. Framework for material modeling and meta-modeling

Materials of this study have been characterized in order to obtain data for integrative finite elements simulation, using Digimat™ Software. Integrative simulation takes into account the forming process to predict the final mechanical performance of a part. To do so, Digimat uses the information generated during process simulation about fiber orientation to compute on every integration point of the finite elements mesh the behavior of the anisotropic composite material[4]. It uses Mori-Tanaka model to compute composite properties from fibers orientation, aspect ratio and mechanical properties on one hand, and matrix constitutive model on the other hand. Information about fiber properties are extracted from CT-scans and fiber length measurements. Tensile data on reinforced materials are used to reverse engineer matrix constitutive model. Digimat allows to use the model defined in equations (1) and (2) where E is matrix modulus in given conditions of temperature and strain rate, R_E is the elastic limit, R_∞ is the hardening modulus, m the hardening exponent, and p the plastic strain.

$$\sigma = E.\varepsilon \text{ if } \sigma \leq R_E \tag{1}$$

$$\sigma = R_E + R_\infty[1 - e^{-m.p}] \text{ if } \sigma \geq R_E \tag{2}$$

Having the possibility to express all these parameters as a function of temperature, strain rate and plasticization is important for industrial applications, especially in the context of parts in contact with coolant, where temperature, water and ethylene glycol concentrations are highly variable. A meta-modeling approach has been developed using a generalized time-temperature superposition method initially proposed by Billon and coworkers[5,6] and adapted to the present case. The different parameters can be plotted as a function of $\dot{\varepsilon}.a_T/a_{T_G}$ a generalized strain rate, where $\dot{\varepsilon}$ is the strain rate, a_T and a_{T_G} are the shift factors corresponding to the horizontal frequency shift applied between the temperature T or glass transition temperature T_G and the reference temperature used to build the storage modulus

mastercurve. The glass transition temperature definition used here is the temperature where the tan δ peak reaches a maximum for a frequency of 1Hz.

It appears that all the parameters of the elastoplastic models can be adjusted accurately when a generalized time-temperature superposition method is used. In this paper, a focus will be done on the yield R_E, but all the other parameters follow the same trends. A first key result is that in the case of water, materials containing various levels of water concentration follow the same mastercurve as illustrated by figure 6a. This result is valid for a wide range of aliphatic and semi-aromatic polyamides, and for mixtures such as PA6/PA6.6 or PA6.10/PA6.6. Figure 6.b shows another key result: the meta-modeling approach can be considered as valid even when applied to ethylene glycol or a mixture of water and ethylene glycol.

Data coming from reverse engineering can be adjusted using a purely phenomenological equation given in (3), with five adjustable parameters R_{E_0}, ΔR_E, β, λ and μ.

All the different parameters evolution with the generalized strain rate $\dot{\varepsilon}.a_T/a_{T_G}$ are available on both virgin materials and aged materials after hydrolysis. An interesting point is that the different parameters stabilize very quickly for limited agings, while failure behavior goes on evolving.

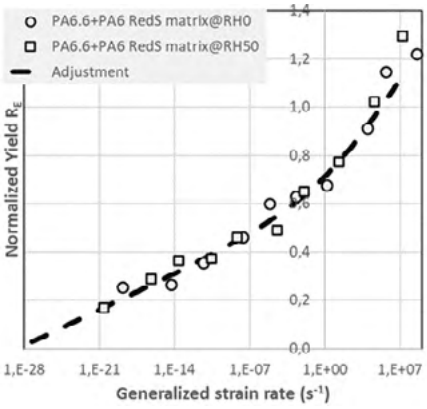

Fig. 6a: evolution of the yield R_E as a function of generalized strain rate for a blend of PA6 and PA66 and two different water concentrations (0,3% and 3% in the polymer)

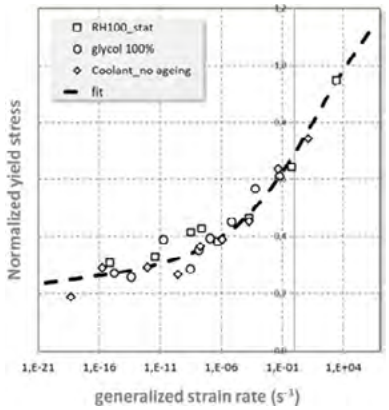

Fig. 6b: evolution of the yield R_E as a function of generalized strain rate for PA66 plasticized with different substances

$$R_E = R_{E_0}.\left(1+\beta.\ln\left(\frac{\dot{\varepsilon}.a_T}{a_{T_G}}\right)\right) + 0{,}5.\Delta R_E.\left(1+\tanh\left(\lambda/2.\left(\ln\left(\frac{\dot{\varepsilon}.a_T}{a_{T_G}}\right)-\mu\right)\right)\right) \quad (3)$$

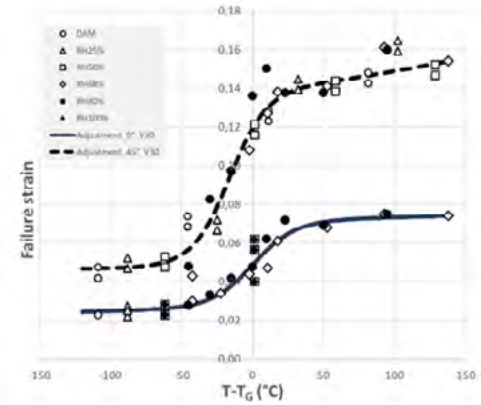

Figure 7: evolution of failure strain as a function of T-T_G for two different glass fibers orientations

Failure behavior can also be modeled in a simple way, at least if only moderate strain rates, lower than $10^{-2}s^{-1}$, are considered. Several levels of water concentration in the matrix have been tested on PA6.6 reinforced with various fibers concentrations and orientations. The figure 7 illustrates the results obtained for a 30% GF material with fibers oriented at 0° or 45°, for water concentrations in the matrix ranging from 0,3% to 8,4% and strain rates ranging from $10^{-4}s^{-1}$ to $10^{-2}s^{-1}$. As can be observed, failure behavior of all specimens follow the same global mastercurve, and failure depends on T-T_G.

6. Extension to general mixtures of polyamide 6.6/water/ethylene glycol and related assumptions

In an industrial part, local concentrations of water or ethylene glycol are far from constant. Solutions have to be found to parameterize matrix local constitutive models. Some assumptions have been made from the available results to generalize them.

(a) the results obtained for variable water concentrations, polyamide 6.6 saturated with ethylene glycol and coolant can be extrapolated to any water or ethylene concentration. If $a_T(T)$ and a_{T_G} are known, determining the parameters of an elastoplastic model is possible.
(b) The shift factors $a_T(T)$ do not depend on aging. Those determined without significant hydrolysis can be used for any average molecular weight.
(c) Failure behavior depends on T-T_G for any molecular weight and can be predicted if T_G is known.

From these assumptions, all that is needed to complete the available results is a mapping of viscoelastic properties at various water and ethylene glycol concentrations, and for any average molecular weight. This mapping is now available, and the material models are ready to be tested in full scale finite elements simulations.

7. Conclusion

A meta-modeling strategy has been developed in order to model the behavior of generic mixtures of polyamide 6.6, water and ethylene glycol with or without hydrolysis. It is based on a generalized time temperature superposition method which has been proven effective for several polyamide matrixes and several water concentrations already. The effect of hydrolysis on the properties is now also taken into account. It is too soon to know which level of accuracy these material models will allow on finite elements simulations, but the first case studies are running, and a final evaluation of the full simulation workflow is under way.

Abstract

The dynamic mechanical properties of fiber reinforced composites could depend on several factors including geometrical parameters, fiber volume fraction, orientation and other aspects. This paper focuses on determining the impact of volumetric fraction of fibers on the dynamic mechanical properties of composites. The study involves analyzing the dynamic properties of composites reinforced with unidirectional fibers using a multiscale numerical model. Additionally, the results are compared with experimental approaches to assess and validate the accuracy of the model.

1. Introduction

Composite materials are increasingly crucial in various sectors as the demand for materials with enhanced properties growths. Recent improvements have focused on enhancing properties such as high damping capacity, flexural modulus, specific strength, and corrosion resistance to compete with some conventional materials [1]. These enhancements are influenced by several factors, including the fabrication method, fiber length, fiber weight ratio, fiber orientation, fiber and matrix nature, and the interfacial interaction between the fiber and matrix [2].

With a growing need for materials sourced from renewable origins, bio-based composites are becoming increasingly popular. Plant fibers, serving as an alternative to widely used glass fibers and even in certain conditions carbon fibers, are gaining attention due to their sustainability, renewability, environmental friendliness, lightweight nature, and cost-effectiveness [3]. The distinctive focus lies on the unique properties of these plant fibers, highlighting their contribution to the overall composite's profile. Additionally, bio-based composites exhibit superior damping properties compared to conventional alternatives [4]. Despite these promising advantages, there remains a gap in our comprehensive understanding about the origin of the damping in plant fiber composites.

In addressing this gap, a multi-scale finite element method is proposed in this study to assess the damping behavior of composite materials. This approach operates on two distinct scales: micro-level and macro-level. The micromechanical approach examines the overall composite behavior by analyzing the properties of its constituents (fiber and matrix) within a representative volume element (RVE). Conversely, the macromechanical approach simplifies the composite's heterogeneous structure by substituting it with a homogeneous medium possessing anisotropic properties [5]. Homogenization plays

a pivotal role in multiscale modeling, enabling the derivation of properties for a homogeneous model at a specific scale from a heterogeneous model constructed at a lower scale [6].

This proposed modeling methodology serves as a complementary approach to experimental techniques for assessing composite damping behavior. Commonly used techniques in the experimental approach include dynamic mechanical analysis (DMA) and modal analysis [7]. DMA, conducted within a lower frequency range, focuses on controlled volume fractions of fibers in both synthetic and bio-based composites, aiming to measure their viscoelastic properties. Meanwhile, modal analysis, performed under free-free boundary conditions and covering a broad frequency spectrum, is employed to identify the dynamic properties of the composites at the macroscale.

2. Finite element model

Understanding and modeling natural fiber reinforced composites has become a significant challenge in bio-based materials research. Both bio-based and synthetic composites possess complex properties, making it difficult to accurately evaluate their overall characteristics using traditional methods designed for metals [8]. Consequently, more efficient techniques are needed to characterize composite materials due to their intricate microstructure. Among the methods proposed multi-scale modeling is employed to analyze the constituent materials (fibers and matrices) and predict their characteristic behavior.

2.1. Multi-scale modeling

Analyzing the dynamic behavior of a complex structure can pose challenges, especially when dealing with numerous small components or when assembly properties are unknown. In such cases, the concept of homogenization becomes crucial [9]. Homogenization techniques offer a solution by simplifying the complex structure into a single material with macroscopic properties that reflect its overall behavior. This simplification proves especially useful within composite laminas, where the distribution of fibers across the cross-section tends to be random. To simplify analysis, many micromechanical models presume a periodic layout of fibers, enabling isolation of a RVE or unit cell. This RVE shares identical elastic constants and fiber volume fraction with the composite.

In order to analyze an RVE, careful consideration of the applied boundary conditions is essential. Additionally, selecting the appropriate RVE that matches the assumed fiber distribution is critical for obtaining reliable results [10]. Commonly employed periodic fiber arrangements include the square array and the hexagonal array. As shown in Figure 1, we have chosen to investigate a unidirectional fiber inside a square array of quadrilateral elements, which correspond to the fiber volume fraction of interest.

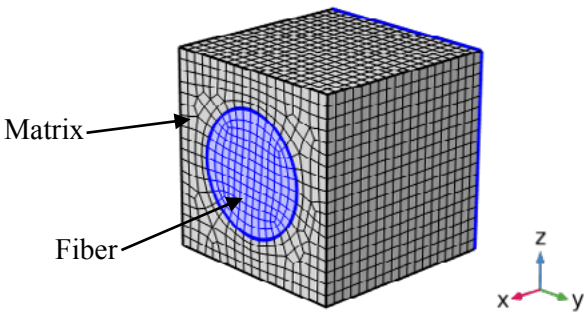

Figure 1. RVE meshed with COMSOL

One way to think of composite materials is as a periodic array of RVEs. Therefore, applying periodic boundary conditions (PBC) to the RVE models becomes imperative. These boundary conditions require the imposition of continuity criteria at the RVE boundaries connected to neighboring RVEs, ensuring

the integration of all individual RVEs into a structural continuum body [11]. The periodic boundary conditions are expressed as:

$$u_{dst} - u_{src} = \bar{\varepsilon}\,(X_{dst} - X_{src}). \quad (1)$$

where $\bar{\varepsilon}$ is the average strain, u_{dst} and u_{src} are the displacement components at the destination and source faces of the RVE respectively, and X is the postion. To fulfill this requirement, we utilized the cell periodicity feature in COMSOL®, with steps provided in Figure 2. At the microscale, homogenized properties are computed through a complex stationary analysis, neglecting the dynamics effects occuring at the scale of the cell.

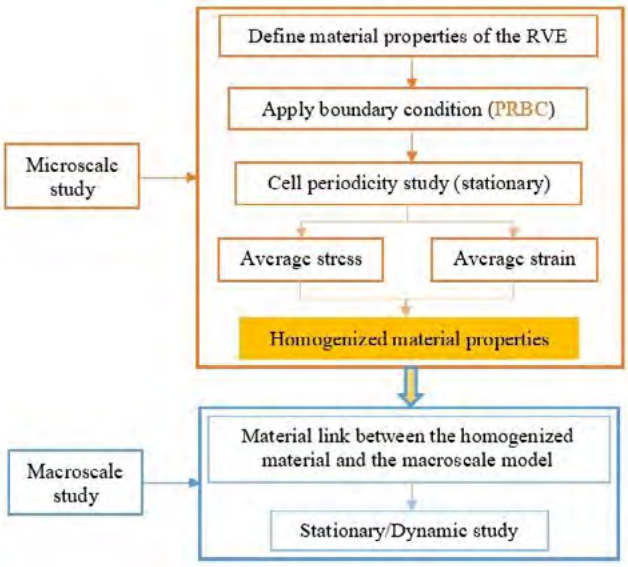

Figure 2. Steps performed on COMSOL

In the study of the micromechanics of fiber-reinforced materials, it is convenient to use an orthogonal coordinate system that has one axis aligned with the fiber direction. In this setup, the x-axis coincides with the fiber direction, while the y and z axes lie within the plane of the RVE and are perpendicular to the fibers, as illustrated in Figure 1. For our analysis, we consider dimensions of l = 10 µm for a square RVE, with fiber radii corresponding to volume fractions ranging from 30 to 70%. The simulations have been performed on a glass fiber reinforced epoxy with the elastic stiffness and damping properties represented in table 1 [12].

Table 1. Basic properties of glass fibre-reinforced epoxy

Properties	Glass fiber	Epoxy
$\boldsymbol{E}$ $\boldsymbol{(GPa)}$	72.4	2.76
$\boldsymbol{G}$ $\boldsymbol{(GPa)}$	30.2	1.02
$\boldsymbol{\nu}$	0.2	0.35
$\boldsymbol{\eta}$	0.0018	0.015

3. Results

In Figure 3, as expected, we observe that as the volume fraction of fiber varies between 30% to 70%, the stiffness of the composite increases by 58% in the longitudinal direction and by 70% in the transverse direction. In terms of shear modulus, there is a 68% increase in the fiber direction and a 62% increase in the transverse direction. To confirm our findings, we compare them with those from Devireddy, S. B. R., & Biswas, S. [13], showing a strong agreement between the two sets of results.

Once we obtain the complex modulus from the elasticity matrix, we proceed to calculate the loss factor by taking the ratio between the imaginary and real parts of the modulus. As shown in figure 4, it is

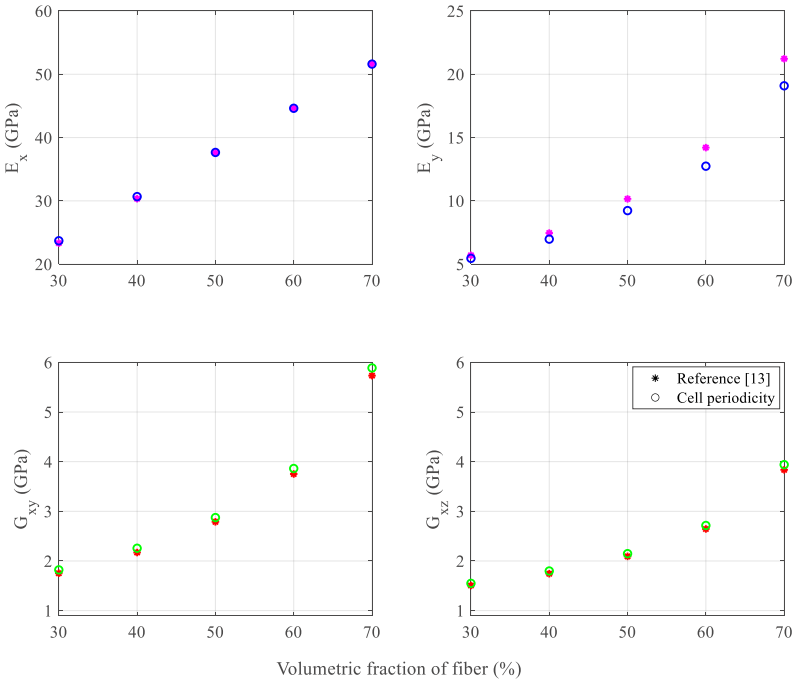

Figure 3. Evolution of Young's modulus and shear modulus with increasing volume fraction

evident that the damping of the composite decreases by 39% for 0° orientation of the fiber as the volume fraction of the fiber increases from 30% to 70%, with a similar decrease of 24% observed in the transverse direction of the fiber. Similarly, examining the shear modulus reveals a decrease of 17% in the longitudinal direction and 6.9% in the transverse direction of the fiber. These results are then compared with the findings presented by Rezaei A. et al. [14].

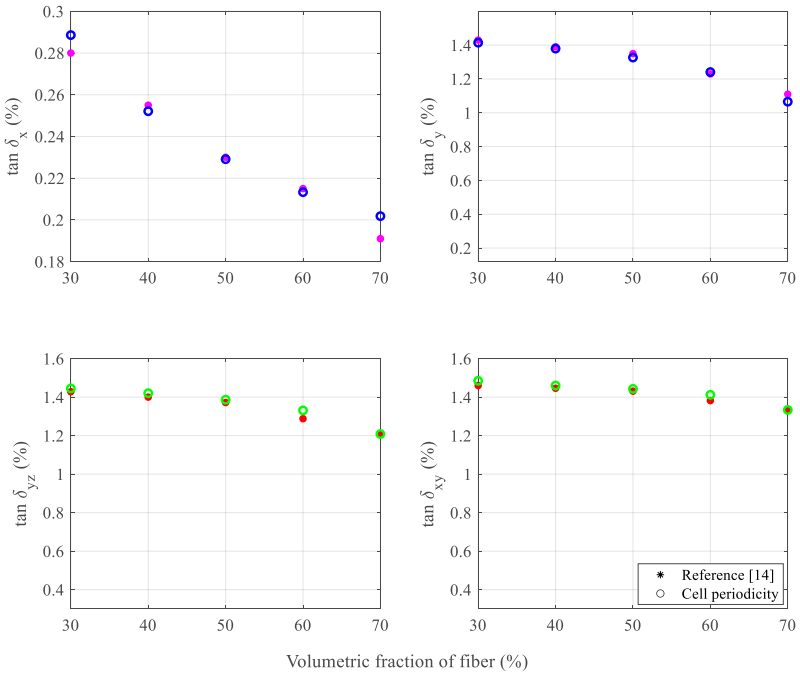

Figure 4. Evolution of damping with increasing volume fraction

Now that we have obtained the effective properties of the composite material from our micro-scale study, we can construct a macro-scale model where the composite consists of homogeneous effective properties determined from the homogenization study. We considered the same glass-epoxy composite, modeled as a solid plate measuring 300 mm * 200 mm * 1.5 mm, and subjected to fixed-free boundary conditions. Here, we conducted a complex eigenfrequency analysis to determine the composite's overall damping property.

We conduct a similar study for the flax fiber reinforced epoxy composite. Although information on the damping properties of flax fibers is limited, some literatures suggest that the damping value ranges from 0.9% to 11% [15,16]. For our simulations, we selected a value of 0.9%. Figure 5 illustrates a comparison between the damping values of glass fiber reinforced epoxy composites and those of flax fiber reinforced epoxy composites. Eigenfrequency study indicates that at each frequency, the loss factor for the flax-epoxy composite exceeds that of the glass-epoxy composite.

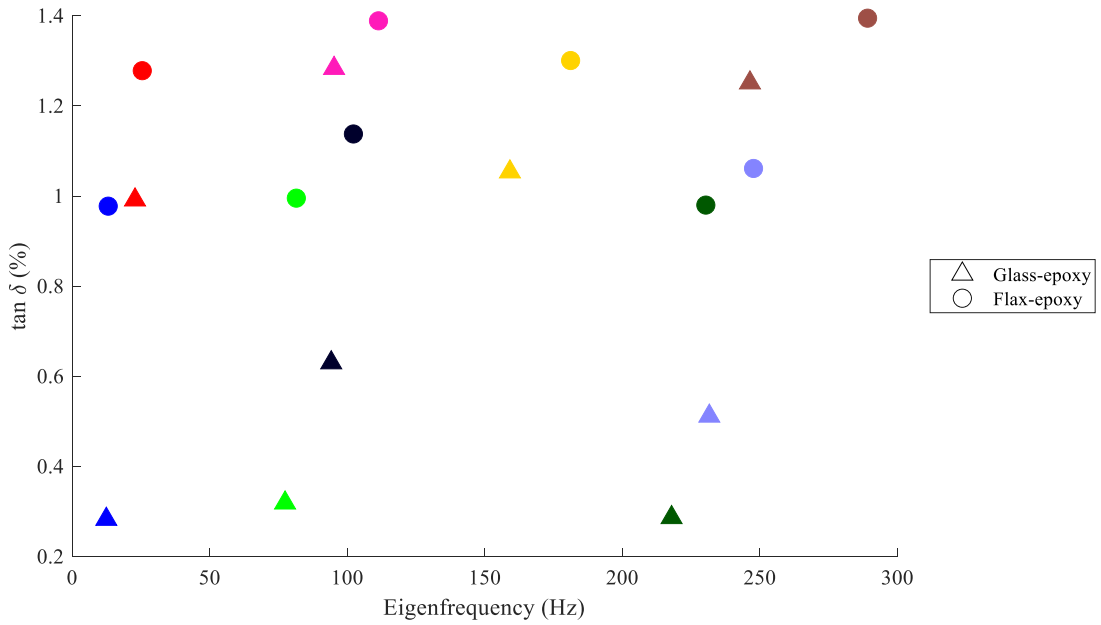

Figure 5. Damping properties of unidirectional fiber reinforced epoxy composites

These findings are consistent with the experimental research conducted by Duc F. et al [4], where they perfomed DMA tests at 1 Hz and ambient temperature. The incorporation of flax fibers into epoxy leads to a notable increase of 52% in the composite's damping values compared to those achieved with glass fibers. This highlights the enhanced damping characteristics offered by flax fiber reinforcement, affirming its potential for improving composite materials' performance in various applications.

4. Conclusions

In this paper, we propose a multi-scale model to simulate the damping behavior of fiber reinforced composite materials. At the micro-scale, the constituents of a composite are simulated as isotropic materials to obtain homogenized elastic properties. These properties are then utilized in a macro-scale study to determine the overall damping of the composites.

Using the proposed method, we investigated the impact of fiber volume fraction on the behavior of a unidirectional fiber reinforced composite. Our findings highlight the significant role of fiber volume

fraction, showing that higher fiber fractions result in increased stiffness and decreased damping, considering that the damping values of the matrix is dominant over the damping of the fiber.

Our analysis suggests that with accurate information, the multi-scale approach can serve as an effective tool for predicting the dynamic mechanical properties of composites. This numerical method can also incorporate an interface between the fiber and the matrix, aiming for an optimal balance between rigidity and damping in the composite.

Abstract

Due to high complexity, expensive filament-wound CFRP products such as Composite-Overwrapped Pressure Vessels (COPVs) Spacecraft Structures require appropriate witnessing coupons, such that in case of deviating manufacturing processes the part can be released for use by verifying the structural behaviour of the witnessing coupon via destructive testing.

A tubular coupon with a ±45 degree cross-ply layup with an inner diameter of 50 mm was designed based on the standardized coupon for in-plane shear testing as per ASTM D3518 [1]. To avoid stress concentrations and guarantee homogeneous shear loading in the gage section, the layup of the clamping section was reinforced with staggered hoop layers.

In a preliminary test campaign several coupons were manufactured and submitted to tests. This campaign confirmed the coupon design not only to be suitable for witnessing and controlling serial production but also to result in similar structural properties as evaluated on comparable flat coupons.

1 Introduction

Since components such as Composite-Overwrapped Pressure Vessels (COPVs) or large tubular composite structures used for aerospace applications, as shown in Figure 1, have either undergone costly preceding processes or are simply expensive due to their size and the associated material costs, appropriate process control is essential.

To avoid scrapping such high-priced components, e.g., most commonly due to deviations of the autoclave cure cycle, a witnessing coupon was developed. Its aim is to verify both the quality of the filament winding- and the subsequent autoclave curing process.

The component, for which the witnessing coupon was designed, is filament-wound with a Toray T800SC-Epoxy tow preg. However, the test method presented in this article can also be applied to other materials.

b: Space Structure

Figure 1. High-Priced Filament-Wound Space Components

2 Methodology

2.1 Prerequisites

The requirements considered in the design of the witnessing coupon are:

- to allow a similar manufacturing process by filament winding and autoclave curing,
- to allow simple structural testing of both fiber- and resin-dominated properties, and
- to allow simple and quick processing with low material consumption, resulting in low cost.

These are answered by a coupon combining the testing of both fiber- and resin-dominated properties: The fiber-dominated properties are required to verify the use of an acceptable raw material- and filament winding quality, while the resin-dominated properties verify the acceptance of the curing process. These material properties are inherited by the in-plane shear behaviour of the composite, as standardized, e.g., according to ASTM D3518 [1] by tensile testing of flat plates with a layup of ± 45 degree. The principle of this test method is the baseline for the design of the witnessing coupon.

2.2 Coupon Design

Based on experience, the manufacture of flat coupons by filament winding using tow preg is leading to several unwanted effects, which are not present in rotationally symmetric parts:

- The tow preg tends to be necking when wound over a flat mandrel. This is leading to gaps of adjacent tows, see Figure 2.

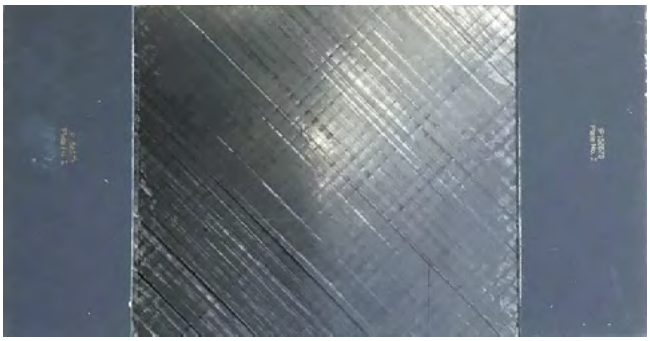

Figure 2. Gaps between adjacent Tows on Flat ASTM D3518 In-Plane Shear Coupon Plate

- Due to setting effects the remaining pretension applied to the tows at the winding process is dissimilar for subsequent layers, potentially leading to process-induced deformations of the manufactured coupon plates.

- Even though considered as negligible for this test method [1], edge effects are present on flat coupons, including the necessity to cut the fibers to get individual coupons out of the test plate such as shown in Figure 2.
- In addition to these effects, flat coupons require additional process steps such as tab-bonding, including surface preparation, and cutting of individual coupons is needed prior to testing of the coupons, increasing manufacturing complexity and cost.

To overcome all these issues a tubular coupon geometry as shown in Figure 3 was established.

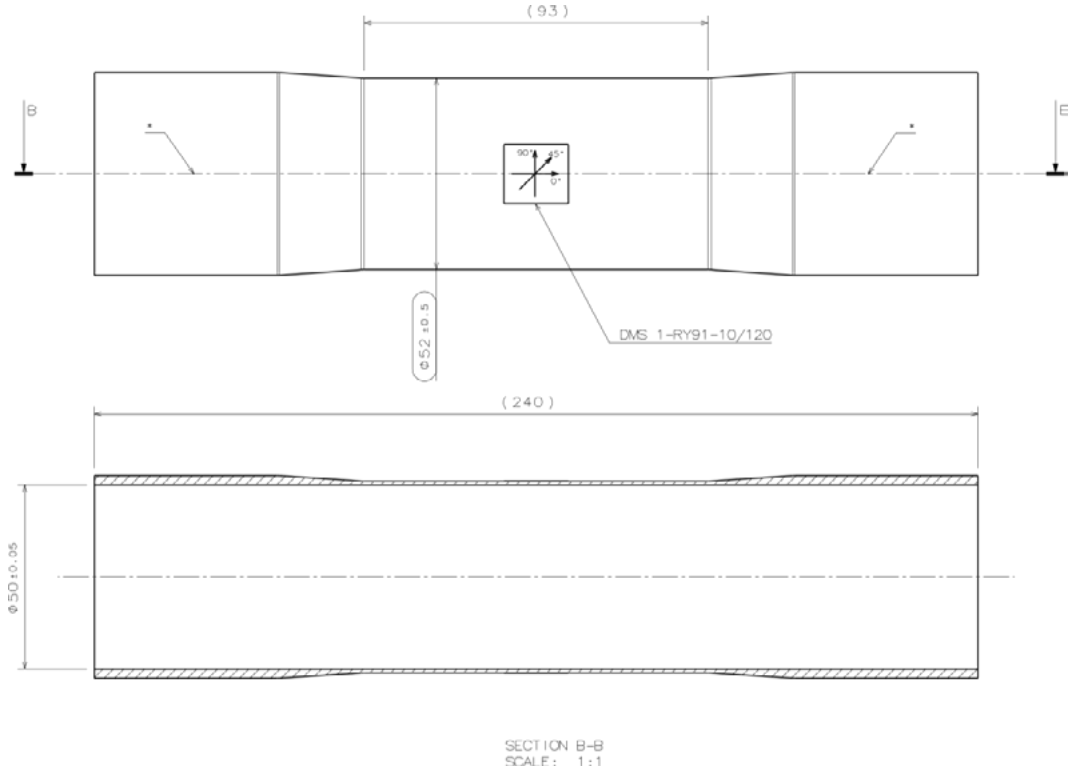

Figure 3. In-Plane Shear Witnessing Coupon

The coupon is entirely rotationally symmetric with an inner diameter of 50 mm and a layup of $(\pm 45 \text{ degree})_2$ in the gage section. The ends of the tube are reinforced locally with staggered hoop layers, which are evenly distributed in the ±45 degree layers outside of the gage section, allowing homogeneous load introduction to the gage section similar as tabs for flat coupons. If wound on a sufficiently long mandrel, several coupons could be manufactured at a time in near-net shape, including the local reinforcements with the above-mentioned hoop layers. After curing, only a cutting operation is required to trim the coupons to final length.

Two mechanical locking assemblies clamp the tube from the inside during tensile testing and allow load transmission through friction. Therefore, the coupons do not require any machining operation prior to test.

2.3 Test Method

The test method for determination of in-plane shear properties by tensile testing of ±45 degree laminates as defined in ASTM D3518 [1] is considered as baseline for test execution and evaluation.

For strain measurement, each tube is instrumented with a 3-grid strain gauge rosette *HBK 1-RY91-10/120* with a gauge length of 10 mm and a resistance of 120 Ω, applied in axial direction in the middle of the gage section, see Figure 3. The displacement rate during tensile testing is defined as

2 mm/min. Since it is assumed that a fiber scissoring effect occurs on the ±45 degree layup, no ultimate failure of the coupon is expected. Therefore, the test is aborted at 5 mm crosshead displacement of the universal testing machine, ending up in an Engineering Shear Strain of approximately 1 % and 2 %.

The following parameters are evaluated, see Figure 4:

- Principal Strains and Maximum Shear Strain
  Based on the strain signals of the strain gauge rosette, the Principal Strains ϵ_1 and ϵ_2 are derived as defined in [2]. The Engineering Shear Strain γ_{12} is calculated as defined in [1].
- Shear Modulus G_{12}^{s}
  The Shear Modulus is evaluated in an Engineering Shear Strain range between $0.002 < \gamma_{12} < 0.006$.
- Offset Shear Strength $F_{12}^{s,0.2\%}$
  The Offset Shear Strength is evaluated at 0.2 % plastic shear deformation as defined in [1].

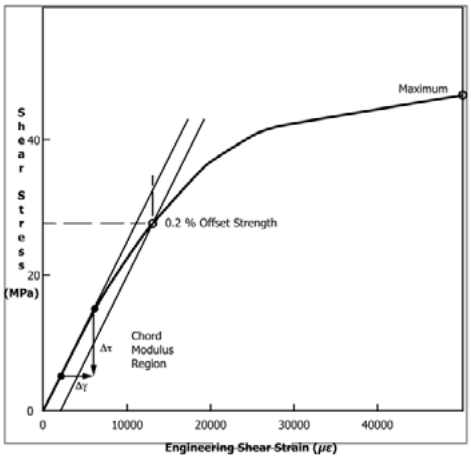

Figure 4. Illustration of Shear Modulus- and Offset Shear Strength Evaluation [1]

The following effects expectedly could be identified with the presented witnessing coupon test, when compared to the structural response of a set of reference coupons:

- Winding angle (fiber-dominated)
  If process- or winding machine errors lead to a change in the planned ±45 degree layup angle on the witnessing coupon, the evaluated Shear Stiffness of the coupon would change.
- Temperature and consolidation during cure cycle (resin-dominated)
  An improper cure, e.g., due to loss of vacuum or insufficient cure time, is expectedly resulting in a softening of the coupon. This would be manifested in both a reduced Offset Shear Strength and Shear Stiffness.
- Resin batch quality (resin-dominated)
  Significant changes of the resin quality would expectedly end up in both a reduced Offset Shear Strength and Shear Stiffness.

The fiber batch quality itself cannot be tested with the presented method. However, this is not required, as a Certificate of Conformity (including material test reports for the neat fiber) is required for every batch of raw material supplied for aerospace applications.

2.4 Implementation into Manufacturing Process

Two witnessing coupons are manufactured before and/or after the space component. The filament winding of both the space component and its witnessing coupons is conducted on a numerically controlled winding robot with a customized filament winding head, that lays four tows at a time. Curing is conducted in an autoclave oven for 135°C / 3 h, with a preliminary dwell at 90°C, where the witnessing coupons and the component get cured in the same vacuum bag. After application of strain

gauges one coupon is submitted to a destructive test to verify the in-family behaviour against already tested coupons, whereas the second coupon is delivered together with the component to the customer. It could be tested upon request, e.g., in case of deviating transportation- or storage conditions of the space component.

2.5 Verification Tests

Prior to initiating the manufacture of the space components, a test campaign was carried out. Aim of this verification tests were:

- in addition to the virtual testing to validate the function of the coupon geometry in practice,
- to capture the structural response (Shear Stress vs. Shear Strain curves) of at least ten (10) coupons, being the baseline for comparison of the witnessing coupons in terms of in-family behaviour, and
- to derive robust acceptance limits with statistical validity.

Therefore, 15 coupons were manufactured and submitted to tests. 3x2 coupons of which were manufactured together with prototype space components, the remaining coupons were manufactured in individual manufacturing batches.

The tests were conducted with a universal testing machine *Hegewald & Peschke Inspekt 200*, being equipped with a 100 kN load cell, see Figure 5. Data acquisition of the strain gauge rosette was performed with a *HBK Quantum X MX1615B* amplifier. Strain control via the strain gauges was not feasible in the test configuration. Hence, the test was conducted up to a pre-defined crosshead displacement. To avoid parasitic bending moments the locking assemblies were fixed to the universal testing machine with each one uniball clevis.

Figure 5. Tubular In-Plane Shear Witnessing Coupon

3 Results

3.1 Test Results and Discussion

The Shear Stress vs. Principal- and Engineering Shear Strain curves of the tested coupons are displayed in Figure 6, while the test results are summarized in Table 1. Coupon 10 could not be evaluated due to a strain gauge failure and is therefore not considered.

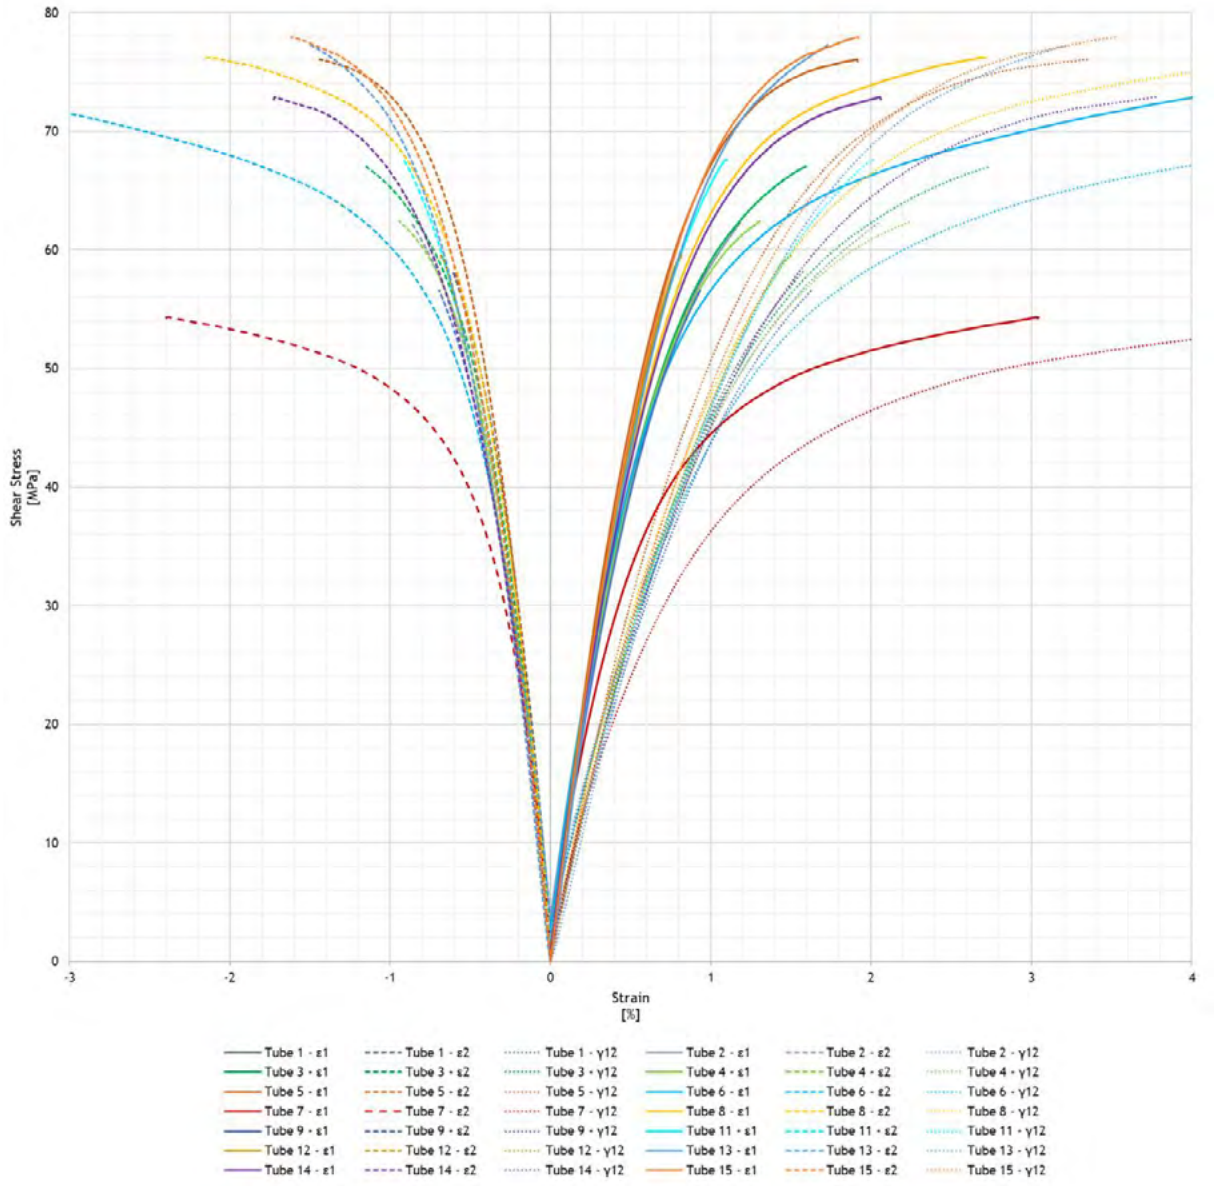

Figure 6. Shear Stress vs. Principal- ($\boldsymbol{\epsilon_1}$, $\boldsymbol{\epsilon_2}$) and Engineering Shear Strain ($\boldsymbol{\gamma_{12}}$) of Witnessing Coupon in Universal Testing Machine

The following observations are derived:

- Except of Coupon 7 the structural response of all coupons is similar.
- As mentioned in Section 2.3 the tests are terminated at a crosshead displacement of 5 mm. However, e.g., Coupon 6 and Coupon 8 are straining significantly more than others. On Coupon 6 the issue is originating from the strain gauge. The scatter on the other coupons is expected to originate in slipping and / or setting effects of the clamping.

- Coupon 7 shows an out-of-family behaviour of the Shear Stress vs. Principal Strain response. Also, the Offset Shear Strength and the Shear Modulus are significantly lower than for all other coupons. The root-cause was found in the autoclave cure being terminated four (4) consecutive times, always caused by a loss of vacuum.
  Coupon 9 was cured together with Coupon 7. In the first curing attempt the vacuum bags of both coupons were experiencing a leak right after the end of the 90°C dwell. On all further attempts Coupon 7's leaking vacuum bag was causing the termination of the cure cycle.
  The out-of-family behaviour of Coupon 7 is concluded to originate from the four consecutive cure cycles with improper consolidation due to loss of vacuum. Since the vacuum pressure on Coupon 9 remained OK and the termination of the first cure cycle happened at an early stage of the cure before passing the resin's gel point, it behaved in-family.
  This observation confirms that the in-plane shear witnessing coupon is capable to reveal improper curing of the composite, in this case an improper consolidation due to a loss of vacuum.
- The 13 valid test results were used to define acceptance criteria for the witnessing test, which are based on the average Shear Modulus and the A-Basis of the Offset Shear Strength of the verification test campaign.

A-Basis (1)	46.0	3.66	

3.2 Potential for Material Characterization

To assess the potential of the presented test method for material characterization, the discussed results were compared against the flat-plate results tested according to ASTM D3518 and used for sizing of the space components, see Table 2. The comparison shows that the flat coupons as shown in Figure 2 result in a lower standard deviation but also in a reduced performance in their structural response. Both tendencies were expected, since the tubular coupons were manufactured with a different raw material batch and in different filament winding/curing lots. This explains an increased standard deviation compared to the flat coupons, which are manufactured from one flat plate made of the same material

and as part of the same process. Parasitic side effects, as present in the flat plate testing and described in Section 2.2, are non-existent in the tubular coupons, which explains the better average structural properties.

Table 2. Comparison of In-Plane Shear Test on Flat vs. Tubular Coupon
Note 1: A-Basis evaluated based on [3], Chapter 8, considering a Gaussian Distribution

Shape	Flat Coupon	Tubular Coupon	Flat Coupon	Tubular Coupon
Structural Property	Offset Shear Strength $F_{12}^{s,0.2\%}$ [MPa]		Shear Modulus G_{12}^{s} [GPa]	
Average	49.9	54.9	4.41	4.83
Std Deviation	0.81	2.45	0.09	0.32
No Coupons	10	13	10	13
A-Basis (1)	46.7	46.0	3.97	3.66

Based on these observations, the coupon design was already applied successfully to derive the in-plane shear characteristics of a novel raw material, comprising of an Ultra-High Modulus (UHM) Carbon Fiber, which was used for the manufacture of the space structure shown in Figure 1.a.

4 Conclusions

A witnessing coupon in tubular shape was designed based on the standardized coupon for in-plane shear testing as per ASTM D3518. The tube design is of low complexity, allows near-net shape manufacture and low additional manufacturing efforts prior to testing. The interface towards the universal testing machine functions based on locking assemblies, which allow load introduction to the coupon by friction.

Since in-plane shear properties are both dependent on fiber- and resin quality, the presented coupon allows the verification of:

- Winding angle (fiber-dominated)
- Temperature and consolidation during cure cycle (resin-dominated)
- Resin batch quality (resin-dominated)

An incident during the cure of one test coupon confirms the ability of the presented test method to detect faulty consolidation quality.

The tubular design is not subjected to unwanted side effects such as tow gapping and edge effects as present on comparable flat coupons. This was confirmed by comparing the test results of the tubular coupons against those of flat coupons manufactured from the same tow preg. Expectedly, the strength and stiffness of the tubular coupons show a higher standard deviation, since they are manufactured individually and of different raw material batches. As the tubular coupon better reflects the production of filament-wound components, the test method could be used not only for process control but also for characterizing new types of materials.

Keywords: Interlaminar stresses, Energy release rate, Semi-elliptical crack, Free edge effect, Finite Fracture Mechanics

Abstract
The interlaminar stresses at the dissimilar interface near the free edges of the composite laminates are weakly singular due to the material mismatch. These stresses can induce delamination between the dissimilar plies. The free edge delamination is investigated in the present study in the framework of Finite Fracture Mechanics. Dimensional analysis is performed to evaluate the two quantities (interlaminar stresses and incremental energy release rate) required for the FFM criterion for any arbitrary load and ply thickness. The non-dimensional functions of these quantities are determined semi-analytically by utilising the expressions derived from dimensional analysis and Finite Element models. The energy release rate is calculated by considering a semi-elliptically shaped crack emanating from the dissimilar interface at the free edge. Since the crack has two dimensions the FFM system of equations leads to infinitely many solutions. Therefore, a hypothesis is made to introduce an additional inequality that the crack extension occurs homothetically, i.e., the crack retains its aspect ratio while extension. The unknown variables (failure load and crack nucleated dimensions) are determined by solving an optimisation problem to find the minimum load corresponding to a specific crack and satisfying both the stress and energy criterion. The prediction of a failure of laminate exhibiting free edge effects using introduced 3D FFM criterion is compared against experimental results from literature and good agreement is attained.

1. Introduction

The traditional Composite Plate Laminate Theory (CPLT) is not suitable for the evaluation of the free edge stresses due to its two-dimensional nature. Also, the exact solution of these stresses does not exist. Therefore, different closed-form analysis [1] and numerical approaches [2] have been developed to compute interlaminar stresses. The prediction of delamination due to singular nature of interlaminar stresses is not feasible using either traditional strength-of-materials or fracture mechanics-based criterion. Therefore, there exist non-local strength-of-materials [3,4] and fracture mechanics-based [5,6] criterion to predict the free edge delamination induced by free edge stresses. However, all of them depend on having the pre-requisite information about the characteristic length to function. To avoid this issue, Leguillon [7] proposed a new coupled criterion within the framework of Finite Fracture Mechanics (FFM), which supports the idea that both stress and energy criteria are necessary and together they form a sufficient one. FFM yields both failure load and its corresponding unknown finite crack size. Therefore, avoiding the prior requirement of an unknown length parameter.
The present paper introduces a 3D FFM criterion for the free edge delamination for symmetric angle-ply laminates. A semi-elliptically shaped crack is assumed to emanate from the free edge and the energy release rate (ERR) is calculated using Virtual Crack Closure Technique (VCCT) through a three-dimensional numerical model built in Abaqus. This type of crack provides flexibility to calculate mixed-mode energy release rates. The interlaminar stresses are computed, from the integration points within a

thin resin-rich layer introduced at the interface, using a second finite element model. Using the equations from dimensional analysis, an average quadratic stress and mixed-mode energy criteria are established. The non-dimensionalised functions from the dimensional analysis let's to work and solve the system of equations semi-analytically. Finally, the results obtained by FFM are compared to experimental results found in literature to validate the criterion using different laminate configurations. This approach can accurately predict free edge delamination onset provided the interlaminar strengths and the interfacial fracture toughness are available

2. Theory

2.1. Semi-analytical framework

Consider a symmetric angle-ply laminate with length L, width $2W$, and h as ply thickness. The symmetry only holds through the thickness. This reduces the required FEM modelling to half ($0 < z < 2h$) and the resulting two-layer laminate with appropriate boundary conditions is illustrated in Fig. 1 for interlaminar stress calculations and in Fig. 2 for ERR calculations. A thin resin-rich layer is introduced at the $(+\theta/-\theta)$ interface for computation of interlaminar stresses. A parametric study of the thickness of the resin-rich layer revealed that the thickness of resin-rich layer of 2% of parent ply thickness is enough to calculate interlaminar stresses precisely. The interlaminar stresses are calculated within this layer at the integration points by using commercial Finite Element Analysis (FEA) software Abaqus. The 3D model in Abaqus uses 8-node linear brick, reduced integration, C3DR8 element.

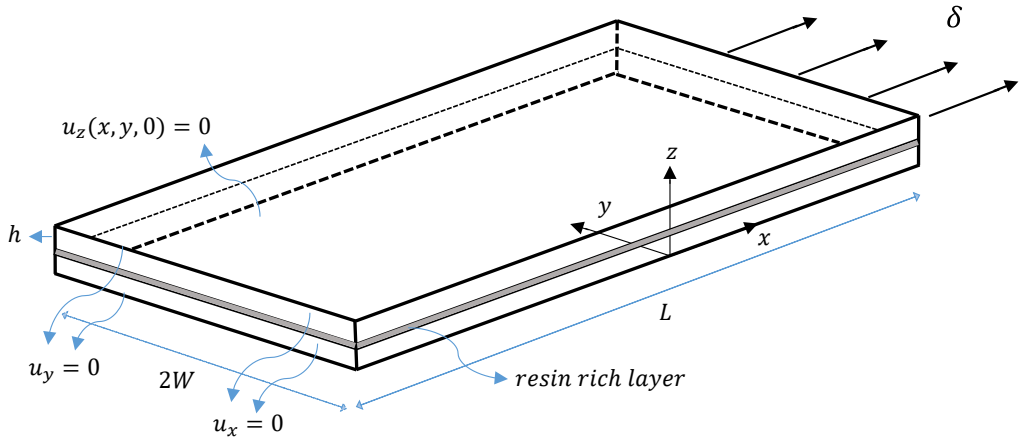

Fig. 1: The boundary conditions used for the half-uncracked model with a transitioned resin rich layer at the $(+\theta/-\theta)$ interface.

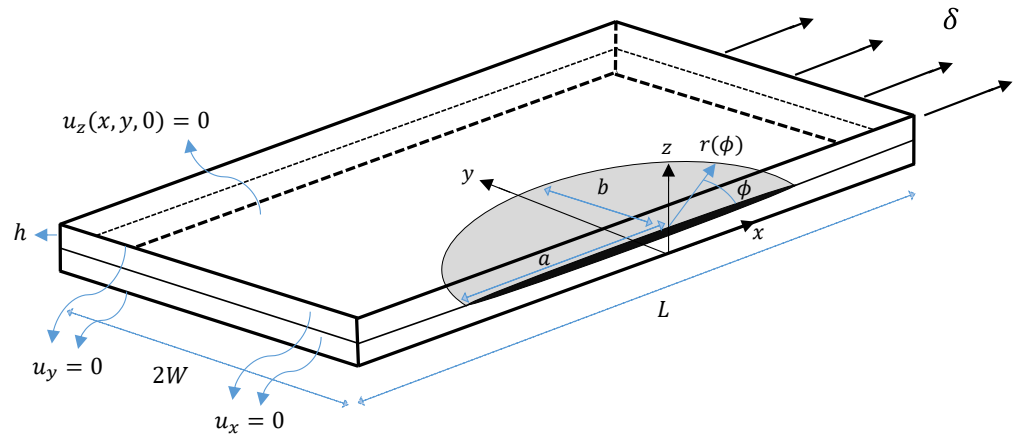

Fig. 2: The boundary conditions for a half-cracked model considering only one semi-elliptical crack at the $(+\theta/-\theta)$ interface.

The ERR for mode I, II and III along the semi-elliptical crack front are calculated using Abaqus in-built Virtual Crack Closure Technique (VCCT) for a given remote load. Due to symmetry only through the

thickness, the top half of the laminate ($0 < z < 2h$) is modelled. The adjacent cracks in the top half of the laminate are assumed to be far from each other without influencing the stress distributions of each other. Therefore, only one crack is considered for the fracture mechanics analysis. This is illustrated in the Fig. 2 along with the appropriate boundary conditions used. The 3D model for the ERR computation incorporates 8-node linear brick, reduced integration, C3DR8 elements.
For the general representation of unknown interlaminar stresses, dimensional analysis is performed. For a material $(E_1, E_2, G_{12}, \upsilon_{12}, \upsilon_{23})$, ply thickness h, ply orientation θ, and remote load σ_∞, interlaminar stress component is written as:

$$\sigma_{ij} = \sigma_{ij}\begin{pmatrix}\sigma_\infty, y, h, \theta, \\ E_1, E_2, G_{12}, \upsilon_{12}, \upsilon_{23}\end{pmatrix}, \tag{1}$$

where y is a distance from the free edge. The material invariant 3D trace $\Im$ [8] is used instead of elastic properties for carbon fibre reinforced polymer (CFRP) composites. The CLPT is employed to generate the trace-normalized 3D stiffness components for various CFRP composite materials, and the **Master ply** is defined based on the average values of these components. The incorporation of the trace enables the calculation of individual elastic constants for any CFRP using their individual traces and the **Master ply**. Following the sequential elimination, Eq.(1) in terms of non-dimensionalised groups for a given material and ply orientation can be written as:

$$\pi_\sigma = \pi_\sigma\left(\frac{\sigma_{iz}}{\sigma_\infty}, \frac{y}{h}\right) \quad i \in \{x, y, z\}, \tag{2}$$

The interlaminar stress components for a symmetric laminate at $(+\theta/-\theta)$ interface is written as:

$$\sigma_{iz} = \sigma_\infty\, \chi_{iz}\left(\frac{y}{h}\right), \tag{3}$$

where χ_{iz} is a non-dimensional stress function component.
To derive a general expression for ERR for a symmetric angle-ply laminate at $(+\theta/-\theta)$ interface, the procedure is analogous to interlaminar stresses. The ERR (G) is a function of the following input parameters:

$$G = G\begin{pmatrix}\sigma_\infty, a, b, \phi, \theta, h, W, L, \\ E_1, E_2, G_{12}, \upsilon_{12}, \upsilon_{23}\end{pmatrix}, \tag{4}$$

where ϕ is a polar angle along crack front (see Fig. 2) and a, b are the semi-axes of a semi-elliptical crack. For a long laminate $(L \gg a, h)$, $(W \geq 3b)$ with given material and ply orientation, Eq.(4) is expressed in the following dimensionless form:

$$\pi_G = \pi_G\left(\frac{G\Im}{{\sigma_\infty}^2 h}, \alpha, \beta, \phi\right). \tag{5}$$

Finally, the ERR of a semi-elliptical crack front at the $(+\theta/-\theta)$ interface of a symmetrical angle-ply laminate is written as:

$$G_i = \frac{{\sigma_\infty}^2 h}{\Im}\psi_i^2(\alpha, \beta, \phi), \qquad i \in \{I, II, III\}, \tag{6}$$

where ψ_i is a non-dimensional correction factor and subscripts (I, II, III) refer to different modes of fracture.
The stress functions χ_{iz} and correction factors ψ_i need to be calculated only once using Eq.(3) and (6), respectively, after the interlaminar stresses and ERR are computed numerically (using Abaqus) for a given material system and ply orientation. These non-dimensional functions can then be used to compute the interlaminar stresses and ERR for any arbitrary load and ply thickness without re-solving the underlying boundary value problem. Therefore, the current framework reduces the numerical effort significantly.

2.2. Finite Fracture Mechanics

Finite Fracture Mechanics (FFM) is a coupled stress and energy criterion proposed by Legullion [7], that predicts the spontaneous nucleation of a finite crack at initiation. FFM yields both, the prediction of the unknown finite crack size and corresponding failure load if two necessary stress and energy

conditions are fulfilled simultaneously. As a result, it only requires intrinsic material properties such as fracture toughness and strength.

The average stress criterion based on single interlaminar stress component for the free edge delamination is written as [3]:

$$\frac{1}{y_0}\int_0^{y_0} \sigma_{iz}\, dy = \overline{\sigma}_{iz} \geq S_i, \tag{7}$$

where y_0 is a critical distance and S_i the corresponding strength. Based on Eq.(7), the average stress criterion for the nucleation of a finite semi-elliptically shaped crack is written as:

$$\frac{1}{A}\int_{-a}^{a}\int_0^{b/a\sqrt{a^2-x^2}} \sigma_{iz}\, dy\, dx \geq S_i, \tag{8}$$

where $A = \pi ab/2$ is the finite area of a semi-elliptical crack. Eq.(8) can be written explicitly for remote stress σ_∞ using Eq.(3) and the stress criterion is written as:

$$\sigma_\infty \geq \frac{A\, S_i}{\int_{-a}^{a}\int_0^{b/a\sqrt{a^2-x^2}} \chi_{iz}\, dy\, dx}. \tag{9}$$

The energy condition for a structure with no inherent flaw such as laminate exhibiting free edge effects is written as:

$$\overline{G} = \overline{G}_I + \overline{G}_{II} + \overline{G}_{III} \geq G_c, \tag{10}$$

where G_c is mixed-mode interface fracture toughness and $\overline{G}$ is the total incremental ERR (IERR) relating the total change in energy $\Delta\Pi$ to the finite size ΔA of an emerging crack and is written as:

$$\overline{G}_i = -\frac{\Delta\Pi_i}{\Delta A}, \quad i \in \{I, II, III\}. \tag{11}$$

For the limiting value $\Delta A \to 0$, IERR $\overline{G}$ becomes Griffith's ERR G and vice-versa. Therefore, IERR can be interpreted as the integral average of G:

$$\overline{G}_i = \frac{1}{\Delta A}\int_0^{\Delta A} G_i\, dA. \tag{12}$$

Combining equations (6), (10), and (12):

$$\overline{G} = \frac{2{\sigma_\infty}^2 h}{\pi ab\Im}\int_{-a}^{a}\int_0^{b/a\sqrt{a^2-x^2}} \left({\psi_I}^2 + {\psi_{II}}^2 + {\psi_{III}}^2\right) dy\, dx \geq G_c. \tag{13}$$

Also, the normalised IERR, denoted by Λ, from Equation (13) can be written as:

$$\Lambda = \frac{\overline{G}\Im}{{\sigma_\infty}^2 h} = \frac{1}{A}\int_{-a}^{a}\int_0^{b/a\sqrt{a^2-x^2}} \left({\psi_I}^2 + {\psi_{II}}^2 + {\psi_{III}}^2\right) dy\, dx. \tag{14}$$

Equation (13) is the mixed-mode energy condition for nucleation of semi-elliptically shaped crack at a given interface in laminates exhibiting free edge effects. For angle-ply laminates only interlaminar shear stress σ_{xz} is predominant and stress condition (9) should be written for the corresponding interlaminar shear strength S_x. Consequently, these laminates have insignificant contribution to ERR in mode I along semi-elliptical crack front. Therefore, by means of both stress and energy subcriteria, the FFM criterion for angle-ply laminate reduces to:

$$\begin{cases} \dfrac{2\sigma_\infty}{\pi ab}\displaystyle\int_{-a}^{a}\int_0^{b/a\sqrt{a^2-x^2}} \chi_{xz}\, dy\, dx \geq S_x \\ \dfrac{2{\sigma_\infty}^2 h}{\pi ab\Im}\displaystyle\int_{-a}^{a}\int_0^{b/a\sqrt{a^2-x^2}} \left({\psi_{II}}^2 + {\psi_{III}}^2\right) dy\, dx \geq G_c \end{cases}. \tag{15}$$

By assuming linear behaviour between individual modes of fracture toughness, the interfacial fracture toughness G_c, considering negligible mode I contribution in angle-ply laminates, is written as [9]:

$$G_c = \left(G_{IIc} + (G_{IIIc} - G_{Ic}) \frac{\overline{G}_{III}}{\overline{G}} \right), \tag{16}$$

For the AS1/3501-6 laminate, according to [9], the mode III fracture toughness is approximately equal to 1.5 times mode II fracture toughness ($G_{IIIc} \sim 1.5 G_{IIc}$), and thus Eq.(16) can be written in terms of G_{IIIc}.

The system of equations (15) represents the 3D FFM criterion that can be used to predict the critical remote stress load σ_∞^c and its corresponding area of finite crack A^c (expressed in the form of a^c and b^c). For a given interface properties (S_x, G_{IIIc}), two equations in (15) has three unknown variables (σ_∞^c, a^c, b^c), that corresponds to the critical state and hence infinite many solutions exist. Furthermore, as semi-elliptical crack is assumed to nucleate, Eq.(15) poses a challenge in determining the dimensions and shape of the crack during extension. Therefore, the unique solution of (15) is determined by solving a standard non-linear optimisation problem that satisfies both stress and energy conditions for a minimum remote stress. Also, the issue with crack front shape is resolved by assuming the homothetic crack extension, i.e., semi-elliptical crack extends in a self-similar manner by keeping the aspect ratio constant.

3. Results

The interlaminar stresses and ERR are determined using semi-analytical framework, as discussed in Section 2.1. The material system considered is AS1/3501-6 with $[\pm \mathbf{15_n}]_\mathbf{s}$ layup. The elastic constants for AS1/3501-6, listed in Table 1, are adopted from a closely related material system (AS4/3501-6), that exhibit similar properties [10] and are taken from [11].

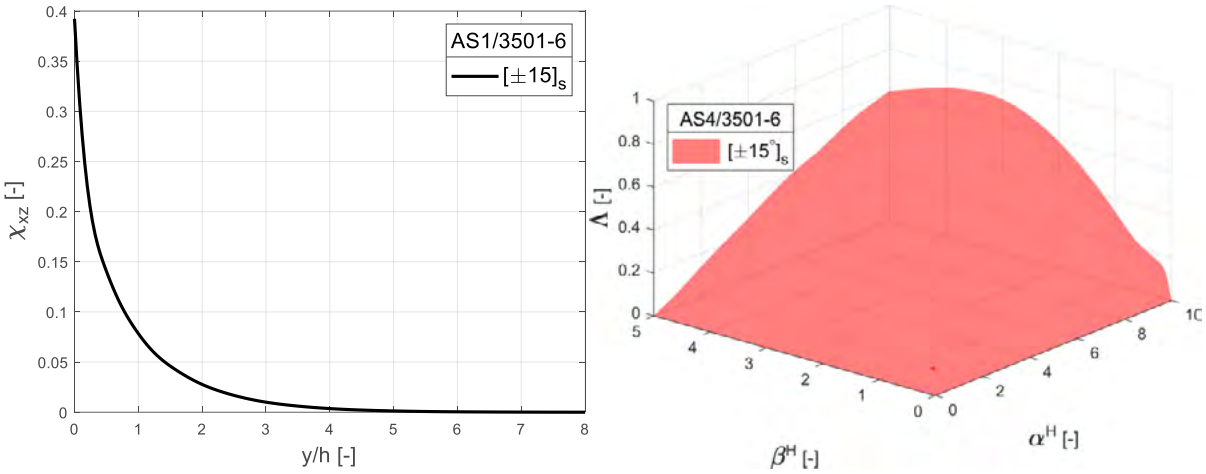

Table 1: Elastic properties of AS4/3501-6 graphite/epoxy composite system.

Laminate	E_1 (GPa)	E_2=E_3 (GPa)	υ_{12}=υ_{23}	G_{12}=G_{23} (GPa)	υ_{23}	S_x (GPa)	G_{IIIc} (N/mm)
AS4/3501-6	144	9.65	0.31	5.24	0.52	110	0.37

The normalised interlaminar shear stress distribution as a function of normalised distance from free edge for the selected laminate configuration is illustrated in Fig. 3 (a). The interlaminar shear stress is only concerned due to its prominent significance in angle-ply laminates. It is evident that there exists a stress singularity at the free edge that decreases rapidly as towards inside of the laminate. The normalised IERR corresponding to total mode (I, II, III) is presented in Fig. 3 (b) as a function of homothetic crack parameters, denoted by α^H and β^H. The homothetic coordinate system represents here that each point within the domain is a potential crack initiation configuration which must have extended through propagation of semi-similar semi-elliptical cracks, i.e., aspect ratio remained constant. The normalised IERR increases with α^{H} and decreases slightly at higher values of β^{H}.

Following the implementation of standard non-linear optimisation to 3D FFM equations (15), the system yields the failure stresses along with finite crack size. The intrinsic properties (S_x, G_{IIIc}) are generally unknown and therefore are evaluated by a reverse fit for a given different ply thicknesses considered. A unique couple (S_x, G_{IIIc}) can be found by minimising the deviation between experimental results and predictions for both failure stresses and crack initiation length. The identified couple are listed in Table 1.

For the selected laminate, the failure stress prediction as a function of normalised ply thickness n is shown in Fig. *4* and is compared against the experimental results taken from literature [12]. The current prediction of 3D FFM is also compared with the predictions of quadratic stress criterion from [12]. The current fracture predictions are in good agreement with the experiments in the sense that size effects are well reproduced. The corresponding finite delamination size is plotted also in the same figure. The absolute values of which increase with increasing normalised ply thickness n, while normalised values decrease.

(a) (b)

Fig. 3: Normalised (a) interlaminar shear stress distribution as a function of normalised distance from free edge and (b) IERR as a function of normalised homothetic crack parameters α^H and β^H, for the selected laminate.

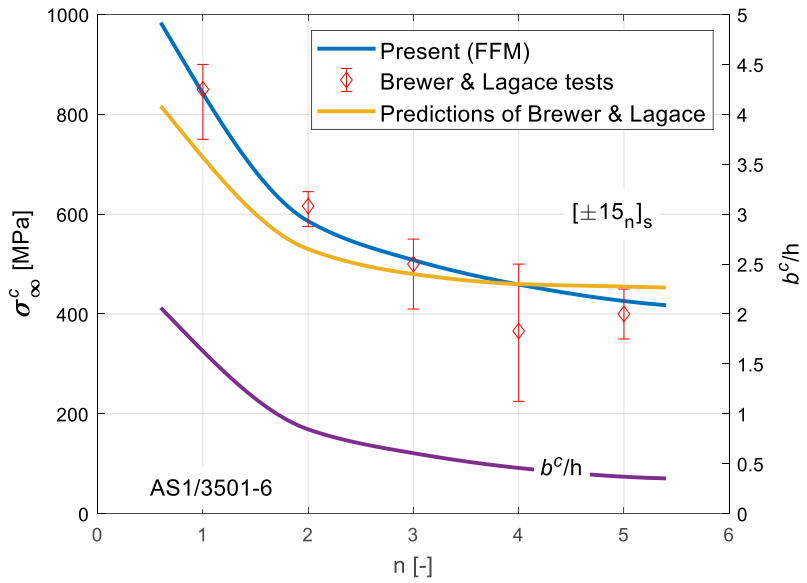

Fig. 4: Predicted failure stresses (blue line) in comparison to experimental tests (error bars) and corresponding normalised crack width onset (right y-axis) with respect to normalized ply thickness n for as1/3501-6 laminate with $[\pm 15_n]_s$ layup.

4. Conclusions

The present paper predicts the free edge delamination of symmetric angle-ply laminates by introducing a 3D FFM fracture criterion. Semi-elliptical crack is considered to emanate from free edge and the issue of crack front extension is solved by hypothesising homothetic crack extension, i.e., aspect ratio remains constant while propagation. Since the crack has two lengths that leads FFM to have an infinite many solutions, the system of equations of the criterion is solved using a standard optimisation technique. The intrinsic interfacial material properties (interlaminar strength and toughness) are identified by minimising the deviation between the proposed FFM criterion and experimental test results. The predicted results are compared against experiments available in literature and good agreement is obtained.

Keywords: generic laminates, transverse cracks, delaminations, variational analysis, effective properties.

Abstract
An approximate stress field in laminates with parallel intralaminar cracks and local delamination is derived using the principle of minimum complementary energy. Simple matrix expressions are obtained that define the effective compliance matrix, thermal expansions and curvatures, and specific heat of a cracked laminate. The method allows to analyze laminates with various stacking sequences and cracking patterns at negligible computational costs. Results for the stress distribution are presented for symmetric and non-symmetric crack, as well as the corresponding energy release rate associated with interlaminar crack propagation.

1. Introduction

Delamination cracks in fiber reinforced composite laminates can form at various stages of the laminate service and often present the main reason for final failure. Whether the delamination cracks are formed due to monotonous, cyclic or thermal loadings, it is desirable to know their effect on the mechanical properties of the cracked laminate and the stress distribution perturbation due to the cracks.

The variational approach adopted in this paper was originated by Hashin [1] for a symmetric cross-ply $[0_n/90_m]_S$ is one of the most accurate methods to analyze the stress fields in a cracked laminate. The main idea of the approach consists of developing a stress state that satisfies all equilibrium, boundary and traction continuity conditions, and minimizes the complimentary energy of the laminate in attempt to have the best approximation for the stresses. It has been widely used and extended to different cases. One can refer to work by Nairn, who has extensively used the variational analysis, extended it to thermal loading, and used it with an energy based fracture criterion to describe crack accumulation in cross-ply laminates (see, e.g. [2] and references therein). Li and Hafeez [3] looked at a general symmetric cross-ply with symmetric periodic arrangement of transverse cracks. Vinogradov and Hashin [4] looked at an angle-ply laminate with cracks in the middle ply. Recently, the method has gained more attention, e.g. [5,6]. Vinogradov [7] expanded the approach to estimate the effective thermoelastic properties of generic laminates with parallel but not necessarily coplanar matrix cracks. Fikry et. al. [8] developed a variational analysis to explain an experimentally observed crack pattern in unidirectional laminate with a resin pocket.

The variational analysis has also been applied to study effects of delamination cracks [9,10] on the effective properties of cross-ply laminates and associated energy release rate. The present work extends the approach to generic laminates and arbitrary transverse and delamination crack pattern and in-plane loadings.

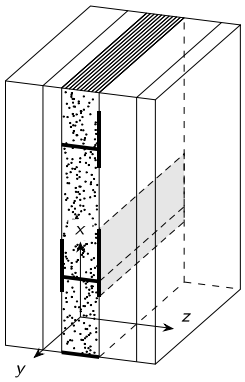

Figure 1. Schematic presentation of a cracked laminate with transverse and delamination cracks.

2. Problem formulation

2.1. Admissible stress field and energy functional

Consider an n-ply laminate sample in the xy plane under a uniform in-plane membrane forces N_{xx}, N_{yy}, N_{xy} and moments M_{xx}, M_{yy}, M_{xy}. We next impose an arbitrary state of damage in a family of plies defined by a certain fiber orientation θ, when the intralaminar cracks are parallel to the fiber direction, but not necessarily coplanar. One can then rotate the coordinate system such that the crack surfaces are normal to the x-axis and the cracked plies become 90° plies (see Figure 1). The front of interlaminar cracks is assumed to be parallel to axis y.

For an arbitrary orientation of plies in the laminate, when there are no cracks, the in-plane stresses $\sigma_{xx}^{0(m)}$, $\sigma_{yy}^{0(m)}$ and $\sigma_{xy}^{0(m)}$ in any ply (m) are linear function of the transverse coordinate z, which can be obtained from a simple analysis using the classical laminate theory, and the rest of the stress tensor components σ_{yz}^{0}, σ_{xz}^{0} and σ_{zz}^{0} are equal to zero. The cracks introduce stress perturbations, which are denoted $\sigma_{ij}^{(m)}$, and the total in-plane stresses in the cracked material become

$$\sigma_{ij}^{C(m)}(x,z) = \sigma_{ij}^{0(m)}(z) + \sigma_{ij}^{(m)}(x,z), \quad \text{for} \quad i,j = x,y \tag{1}$$

It is assumed that the in-plane perturbation stresses $\sigma_{xx}^{(m)}$, $\sigma_{yy}^{(m)}$ and $\sigma_{xy}^{(m)}$ in ply m are linear functions of z everywhere in the cracked laminate, i.e. for any x. According to this assumption the in-plane perturbation stresses can be expressed in terms of yet unknown functions $\phi_i^{(m)}(x)$ and $\psi_i^{(m)}(x)$:

$$\sigma_{ij}^{(m)}(x,z) = \phi_{ij}^{(m)}(x) + \psi_{ij}^{(m)}(x)z, \quad \text{for} \quad i,j = x,y \tag{2}$$

The out-of-plane stresses σ_{xz}, σ_{yz} and σ_{zz} are derived from (2) using differential equilibrium equations

$$\sigma_{ij,j}^{(m)} = 0, \quad \text{for} \quad i,j = x,y,z \tag{3}$$

which are integrated considering traction continuity at the ply interfaces. The result is expressed in a matrix form:

$$\sigma^{(m)} = A_0^{(m)}(z)\phi(x) + A_1^{(m)}(z)\phi'(x) + A_2^{(m)}(z)\phi''(x), \tag{4}$$

where $\sigma^{(m)}(x,z) = \left[\sigma_{xx}, \sigma_{yy}, \sigma_{zz}, \sigma_{yz}, \sigma_{xz}, \sigma_{zz}\right]^T$ is a (6×1) vector of the stress components in ply m, $\phi(x)$ is a $(6N \times 1)$ vector of all the unknown functions:

$$\phi^T(x) = \left[\phi_1^{(1)}, \psi_1^{(1)}, \phi_2^{(1)}, \psi_2^{(1)}, \phi_6^{(1)}, \psi_6^{(1)}, \ldots\right]^T, \tag{5}$$

and A_0, A_1 and A_2 are $(6 \times 6n)$ z-dependant matrices, whose elements are explicitly given in [7].

The complementary energy of a cracked laminate is now expressed in terms of the perturbation stresses:

$$\boldsymbol{U_C = U_C^0 + \frac{1}{2}\int_V \sigma^T S \sigma dV = U_C^0 + \frac{1}{2}\int_L \sum_{p,q=0,1,2} \phi^{pT} M_{pq} \phi^q dx}, \tag{6}$$

where U_C^0 is the complementary energy of the uncracked laminate, $S(x,z)$ is the local compliance matrix, ϕ^p denotes the p-th derivative of $\boldsymbol{\phi(x)}$, and

$$\boldsymbol{M_{pq} = \sum_{m=1}^{n} \int_{z_m}^{z_{m+1}} A_p^{(m)^T}(z)\, S^{(m)}\, A_q^{(m)}(z) dz}. \tag{7}$$

Here $\boldsymbol{z_m}$ and $\boldsymbol{z_{m+1}}$ are $\boldsymbol{z}$-coordinates of the top and bottom interfaces of ply $\boldsymbol{m}$. The elements of matrices $\boldsymbol{A}$ and $\boldsymbol{M}$ have simple analytical expressions and can be found in [7]. For monoclinic and higher ply material symmetries the matrices $\boldsymbol{M_{01}}$, $\boldsymbol{M_{10}}$, $\boldsymbol{M_{21}}$ and $\boldsymbol{M_{12}}$ vanish, leading to the following expression for the complementary energy:

$$\boldsymbol{U_C = U_C^0 + \frac{1}{2}\int_L F(x) dx}, \tag{8}$$

where

$$\boldsymbol{F(x) = \phi^T M_{00} \phi + \phi^T M_{02} \phi'' + \phi''^T M_{20} \phi + \phi'^T M_{11} \phi' + \phi''^T M_{22} \phi''}. \tag{9}$$

The problem is to determine unknown functions $\boldsymbol{\phi(x)}$ that minimize the energy functional (8).

2.2. Constraints

The perturbation stresses must satisfy global equilibrium constraints as well as zero traction on the delamination surfaces. The overall membrane perturbation forces N_{xx} and N_{xy} and moments M_{xx} and M_{xy} must vanish independently of crack geometry and must remain zero for any x due to the plate equilibrium constraints:

$$\frac{\partial N_{xx}}{\partial x} = \frac{\partial N_{xy}}{\partial x} = \frac{\partial M_{xx}}{\partial x} = \frac{\partial M_{xy}}{\partial x} = 0,$$

that hold due to independence of the stress field of y. Therefore, taking the corresponding rows of (2) and integrating them over the laminate thickness, we obtain

$$\begin{bmatrix} N_i \\ M_i \end{bmatrix} = \sum_{m=1}^{n} \int_{z_m}^{z_{m+1}} \sigma_i^{(m)} \begin{bmatrix} 1 \\ z \end{bmatrix} dz = B_0^T\, \phi(x) = 0\,, \quad \text{for } i = xx, xy \tag{10}$$

forming four linear constraints for the unknown functions $\phi(x)$.

Force N_{yy} and moment M_{yy} are treated differently, since they are not subjected to any differential constraints. According to Saint-Venant's principle, away from the y-edge of the laminate plate, where the forces are applied, a different but statically equivalent distribution is formed. If the edge effects and y-dependence of the stress field close to the force application are ignored, only the total force and moment should vanish:

$$\int_L N_{yy} dx = \int_L \int_{-\frac{h}{2}}^{\frac{h}{2}} \sigma_{yy}\, dz\, dx = 0, \quad \text{and} \quad \int_L M_{yy} dx = \int_L \int_{-\frac{h}{2}}^{\frac{h}{2}} \sigma_{yy}\, z\, dz\, dx = 0, \tag{11}$$

which after substitution of the corresponding stress in (2) and explicit integration over the laminate thickness can be written in the matrix form:

$$B_y^T \int_L \phi(x) dx = 0, \tag{12}$$

where B_y is a constant matrix. In case of a periodic crack geometry, the above integral should be evaluated over the length of the periodic cell.

In the regions with delamination cracks, zero traction conditions are also required. For each delamination crack at interface z_d with the normal in the z-direction, one has:

$$\sigma_{xz}(x, z_d) = \sigma_{yz}(x, z_d) = 0, \tag{13}$$

which, given the shear stresses are proportional to the first derivative of $\phi(x)$, is written in the matrix form as

$$B_1^T \phi'(x) = 0. \tag{14}$$

Additionally, we require

$$\sigma_{zz}(x, z_d) = 0, \tag{15}$$

which also should hold for each delamination crack and is combined to a system of second order differential constraints

$$B_2^T \phi''(x) = 0. \tag{16}$$

Linear equations (10), differential equations (14) and (16) and integral relations (12) form a set of constraints that the admissible stress field must satisfy.

3. Energy minimization

Consider now a fragment of a laminate between two (adjacent) transverse cracks that can serve as a periodic cell or representative volume element, such that the cracked laminate can be reconstructed by either translation of the fragment or reflection about its end planes. The fragment is then divided into several intervals having different delamination geometries; the interval boundaries can be defined by the tips of the delamination cracks. In each interval different delamination arrays impose different constraints on the stress field, hence different solutions for $\phi(x)$.

Let us write the energy functional as a sum of energies of the intervals

$$U_C = U_C^0 + \sum_{k=1}^{n_{int}} \int_{L_k} \frac{1}{2} F^{(k)}(x) dx, \tag{17}$$

where the Lagrangian $F^{(k)}(x)$ for interval k is defined by (9) expressed in terms of functions $\phi^{(k)}(x)$, n_{int} is the number of intervals with different delaminated interfaces in the periodic cell. The constraints are also written for different intervals:

$$\begin{aligned} B_0^T \phi^{(k)}(x) &= 0, \\ {B_1^{(k)}}^T \phi'^{(k)}(x) &= 0, \\ {B_2^{(k)}}^T \phi''^{(k)}(x) &= 0. \end{aligned} \tag{18}$$

Matrix B_0 is the same for all intervals, however matrices $B_1^{(k)}$ and $B_2^{(k)}$ are written with superscript (k) to emphasize that they depend on the locations of the delamination cracks. The integral constraints defined in (12) obtain the form

$$B_y^T \sum_{k}^{n_{int}} \int_{L_k} \phi^k(x) dx = 0. \tag{19}$$

Finally, the problem is formulated as following: determine vector functions $\phi^{(k)}$ that minimize the perturbation part in (17) subject to constraints (18) and (19):

$$\min_{\phi^{(k)}} \sum_{k=1}^{n_{int}} \int_{L_k} \frac{1}{2} F^{(k)}(x) dx, \quad \text{s.t.} \quad (18) \text{ and } (19). \tag{20}$$

The constrains are now added to the perturbation energy with Lagrange multipliers to form the extended Lagrangian:

$$U_C' = \sum_{k=1}^{n_{int}} \int_{L_k} \left[\frac{1}{2} F^{(k)}(x) + \omega_0^{(k)^T} B_0^T \phi^{(k)} + \omega_1^{(k)^T} B_1^{(k)^T} \phi'^{(k)} + \omega_2^{(k)^T} B_2^{(k)^T} \phi''^{(k)} \right]$$
$$+ \omega_y^T B_y^T \sum_{k}^{n_{int}} \int_{L_k} \phi^{(k)}(x) dx \,. \tag{21}$$

Here ω_0, ω_1 and ω_2 are Lagrange multipliers for constraints (18) that must hold at every point x along the fragment, hence they are functions of x. Constraints (19), however, are integral constraints and the corresponding Lagrange multipliers ω_y are constant.

Perturbing the unknown functions and requiring that the corresponding perturbation of the Lagrangian in (21) vanishes when the unknown functions are the minimizers, we arrive at the following Euler-Lagrange equations

$$M_{00}\phi + (M_{02} + M_{20} - M_{11})\phi'' + M_{22}\phi'''' + B_0\omega_0 - B_1\omega_1' + B_2\omega_2'' + B_y\omega_y = 0 \tag{22}$$

where the superscript (k) is omitted for simplicity. Together with constraints (18) they form a system of ordinary differential equations with constant coefficients for $\phi(x)$, $\omega_0(x)$, $\omega_1(x)$ and $\omega_2(x)$. The constant Lagrange multipliers ω_y will be treated as known and determined later using (19).

The differential constraints in (18) can be integrated:

$$\begin{bmatrix} B_0^T \\ B_1^T \\ B_2^T \end{bmatrix} \phi = \begin{bmatrix} 0 \\ c_1 \\ c_{20} + c_{21}x \end{bmatrix} = \begin{bmatrix} 0 \\ c_1 \\ c_{20} \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ c_{21} \end{bmatrix} x \tag{23}$$

where c_1, c_{20} and c_{21} are some constants. The above can be written as

$$B^T\phi = p(x) \tag{24}$$

which defines matrix B and vector $p(x)$. One can also introduce vector

$$\omega = \begin{bmatrix} \omega_2 \\ -\omega_2 \\ \omega_2 \end{bmatrix} \tag{25}$$

With help of those definitions the system of equations can be written in the following convenient form:

$$\begin{aligned} M_{00}\phi + B\omega &= -(M_{02} + M_{20} - M_{11})\phi'' - M_{22}\phi'''' - B_y\omega_y \\ B^T\phi &= p \end{aligned} \tag{26}$$

The vector multipliers $\omega(x)$ can be excluded from the first system of equations yielding the resultant equations

$$M_{00}\phi + P(M_{02} + M_{20} - M_{11})\phi'' + PM_{22}\phi'''' = B(B^T M_{00}^{-1} B)^{-1} p - PB_y\omega_y \tag{27}$$

where $P = I - B(B^T M_{00}^{-1} B)^{-1} B^T M_{00}^{-1}$ is the orthogonal projection matrix. The solution of the above system of differential equations is a combination of a homogeneous and particular solutions

$$\phi = \phi_h + \phi_p \tag{28}$$

Here ϕ_h is the solution of the homogeneous equation obtained by setting the right-hand-side of (27) to zero

$$\phi_h = \sum_i c_{h,i}\, v_i \exp(r_i\, x) \tag{29}$$

with v_i being the i-th eigenvector, r_i – corresponding eigenvalue, $c_{h,i}$ – an arbitrary scalar constant. The particular solution for the current ODE and linear in x right-hand-side of (27) has the form

$$\phi_p = M_{00}^{-1}\left[B(B^T M_{00}^{-1} B)^{-1} p(x) - PB_y\omega_y\right] \tag{30}$$

Finally, the yet unknown constants c_h, c_1, c_{20}, c_{21} and ω_y are determined from boundary conditions at the end planes of the fragment, comprising zero (total) traction conditions on transverse crack surfaces and periodic or symtery boundary conditions, continuity of traction at the interfaces between intervals of different delamination geometries and the integral constraint (19). Typically, these physical boundary conditions do not suffice to determine the constants and should be supplemented by natural boundary conditions, obtained as part of perturbed functional (21). Alternatively, the complementary energy can be expressed as a quadratic form in the vector of all the unknown constants c, and minimized over c, while subject to the above set of physical boundary conditions which are linear in c, using again the method of Lagrange multipliers. Details of the procedure can be found in [7].

Once the unknown constants are obtained, functions $\phi(x)$ and the stress tensor components can be calculated, as well as the minimum value of the energy functional. The minimum value of the complementary energy defines the lower bound for the effective ABD* compliance matrix and elastic properties of the cracked laminate.

4. Numerical examples

The derived solution for the stress distribution and effective properties of a laminate is concise and requires negligible computational efforts. At the same time, the method is very robust and applicable to a variety of crack geometries and laminate systems. It has also been shown [7] that the results for effective thermomechanical properties of laminates with transverse cracks (no delamination cracks) agree very well with experimental data.

Figures 2-4 show the results of axial stress σ_{xx} in $[\pm 45/90_2]_S$ GFRP laminate due to axial tensile loading in three different developed delamination crack geometries: symmetric, antisymmetric (T-type) and periodic Z-type delamination. The thick black solid line indicates the locations of cracks. In these examples, the plies are subdivided, and more nonlinear stress distribution in the thickness direction is revealed, with clear stress concentrations (singularities) at the tips of the delamination cracks and significantly higher stress concentrations at the tips of transverse cracks arrested at ply interfaces without initiating delaminations (Figure 3).

The energy release rate associated with interlaminar crack propagation is obtained by differentiating the complementary energy respect to the crack length. The results for the three cracking patterns are shown in Figure 5. While the energy release rate at delamination initiation is approximately the same for the three cases, they demonstrate quite different behavior at the advanced stages of crack propagation.

5. Conclusion

An analytical solution based on the principle of minimum complementary energy is proposed for an approximate stress field, effective elastic properties and energy release rate of an arbitrary laminate with transverse cracks and delaminations. Using Lagrange multipliers, linear, first and second order differential and integral techniques are imposed on the admissible stress field to satisfy equilibrium and conditions and traction free crack surface conditions. The computational costs required to solve the problem are negligible in comparison to the Finite Element method due to the fact that the solution is analytical in each ply. At the same time the method allows application of so called “ply refinement technique” for more accurate stress distributions, which reveal different stress intensities around the transverse and delamination crack tips, and different crack patterns in general, as well as a strong dependence of the associated energy release rate on the formed crack geometry.

Abstract

Natural fiber-reinforced composite materials present several advantages, such as low density and environmental friendliness. In particular, sandwich composite materials based natural fibers have gained significant traction in various industries due to their good characteristics, offering an exceptionally high stiffness-to-weight ratio and energy absorption capabilities. Their lightweight nature and high strength-to-weight ratios make them ideal candidates for various applications, including aerospace, automotive, and medical industries. For this purpose, four core geometries of sandwich composites composed with flax fiber reinforced PLA were considered: sinusoidal (SN), triangular (TR), double triangular (DT), and trapezoidal (TP). This study used the FDM technique to manufacture the sandwich structures and to assess and compare their properties with mechanical testing. The experimental results show that the trapezoid structure exhibited the best maximum load and load-displacement fitted stiffness among all the structures considered.

1. Introduction

Synthetic fibers reinforced petrochemical polymer matrices pose a threat to the environment when they reach the end of their useful life. Environmental concerns and the issues of pollution are driving the development of sustainable materials suitable for emerging applications. There is a growing emphasis each year on the adoption of biodegradable or eco-friendly products sourced from renewable materials. Recent years have

witnessed a surge in the utilization of environmentally responsible polymers and composites within industrial sectors. This shift is not only motivated by the ecological harm caused by plastics but also by the risk of depleting oil reserves and the unchecked proliferation of landfills. With the increasing frequency of environmental disasters and the looming specter of global warming, governments are increasingly compelled to champion the use of biodegradable and eco-friendly materials in industrial contexts[1][2].

Natural fiber-reinforced polymer composites are considered promising alternatives to petroleum-based synthetic fiber-reinforced composite materials. The former exhibits satisfactory mechanical, thermal, and acoustic properties, and thus, they have been used as structural materials in constructions, furniture, automobiles and aircraft, etc[3][4]. Commonly used natural fibers are sourced from materials such as wood, flax, jute, sisal, abaca, and cotton. These natural fibers are characterized by their environmental friendliness, widespread availability, renewability, cost-effectiveness, and lightweight properties[5] [6] [7] .

PLA (Polylactic acid) is a biodegradable, thermoplastic polymer that is commonly used in Fused Deposition Modeling (FDM) 3D printing method[8].The origins of PLA lie in replenishable sources such as tapioca roots, corn starch, or sugarcane, facilitating production in diverse hues and qualities. In contrast to alternative 3D printing substances, PLA boasts several merits, including its minimal toxicity, commendable mechanical attributes, and facile processing[9]. Exhibiting a remarkable strength-to-weight ratio, PLA combines strength and rigidity with lightweight properties. Moreover, it demonstrates impressive resistance to impacts and fatigue, rendering it capable of enduring repeated stress without succumbing to breakage. These characteristics render PLA highly suitable for applications where robustness and rigidity hold significance, such as in structural components or operational prototypes.

Nowadays, polymer materials like PLA find increasing utility, particularly in crafting minor structural elements susceptible to modest loads. In this study, the cores and panels of sandwich structures were concurrently fabricated using a 3D printer employing FDM, utilizing flax-reinforced PLA material. Based on four different core models, sandwich structure samples[10] were manufactured from iso-mass configurations and then compressive tests were carried out. The aim was to compare the performance and characteristics of these different natural-fiber-reinforced composite sandwich structures.

2. Sample preparation and testing method

2.1 Material properties

The tested materials are flax fiber reinforced polymer composites based on short fibers of flax and polylactic acid (PLA)

The PLA/flax fiber filament was purchased from the Nanovia company in France. Each roll weighs approximately 500g, with a filament diameter of 1.75mm ± 0.05mm.

According to the technical specifications, tensile coupons were tested for flax fiber reinforced materials, and the mean value of the results is depicted in Table 1, where fy, y, fu, u, and E refer to the yield strength, yield strain, tensile strength, ultimate strain, and elastic modulus, respectively.

Table 1: Tensile properties of PLA flax reinforced composite

Material	Thickness(mm)	Width(mm)	f_y(MPa)	ϵ_y(%)	f_u(MPa)	ϵ_u(%)	E(GPa)
PLA/flax	4.00	10.00	13.76	0.46	41.31	2.46	3.11

2.2 Design and optimization of sandwich structure geometries

Four different core patterns of sandwich composites composed with flax fiber reinforced PLA were considered: sinusoidal (SN), triangular (TR), double triangular (DT), and trapezoidal (TP), as shown in Figure.1. The masses of these geometries were controlled to be consistent to better compare the effects of different patterns on the mechanical properties of the samples. So a python model has been developed to define samples with different sandwich core geometries of the same length, width and height with the same guaranteed mass. In order to reach iso-mass configurations (with a tolerance below 3%), it was necessary to define the following parameters to describe each structure: the length L, the width b, the thickness of core structure e_c, and the thickness of skin structure e_s.

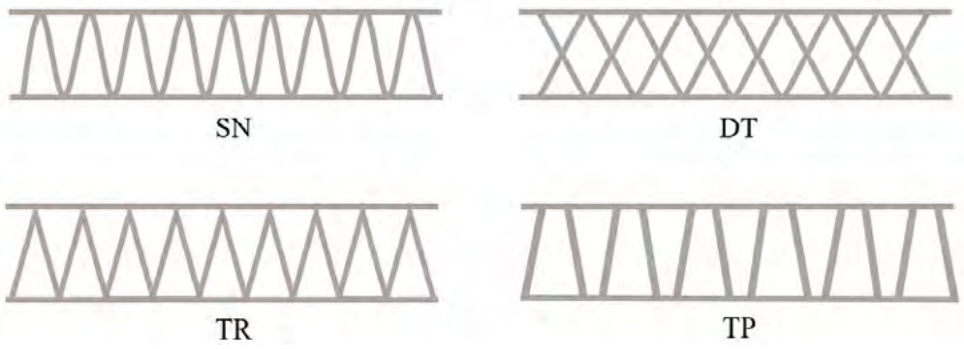

Fig. 1. 4 different core geometries of sandwich structures

2.3 Manufacturing process

The experimental study is made on FDM printed part. 3D printing is mostly used by importing CAD files into slice software such as ideamaker or curamaker, slice and use the resulting gcode file for printing. In this paper, MATLAB programming is used to draw the print path to generate the gcode file instructions directly. This way of printing can avoid line crossing during the printing process. The printing material is a 1.75 mm ABS filament from 3D Printing machine. The printer is a semi-professional RAISE2 from RAISE3D. Printing parameters are as follows, nozzle diameter is 0.8 mm, printing head

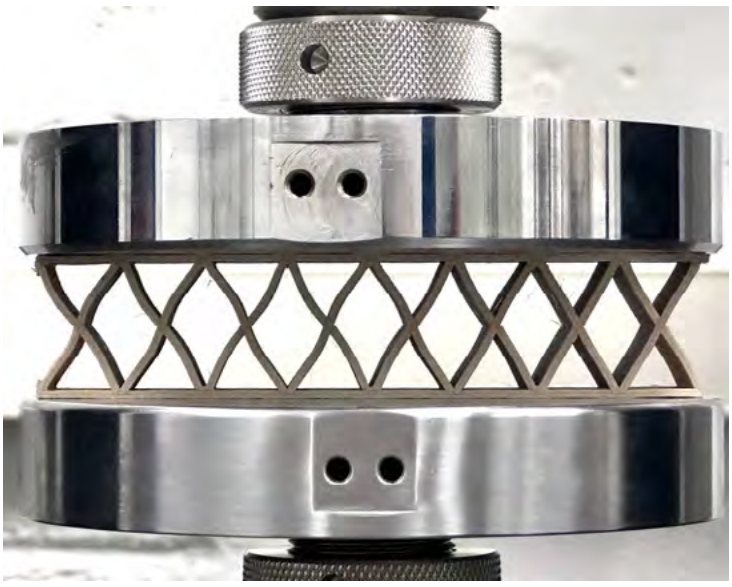
temperature is 215°C, bed temperature is 65°C, printing speed is 40 mm/s except for the first layer that is printed at 15 mm/s. For each geometry, 5 separate samples have been printed for conducting the experiments in the later section. Table 2 shows the real parameters measured for these samples fabricated.

Table 2: Parameters of different geometries

	L(mm)	b(mm)	h(mm)	e_c(mm)	e_s(mm)	m(g)
SN	139.27±0.05	29.89±0.01	31.00±0.04	1.66±0.01	1.66±0.01	45.97±0.14
TR	139.28±0.03	29.91±0.03	31.06±0.04	1.69±0.02	1.64±0.02	46.38±0.21
DT	139.29±0.06	29.90±0.02	31.13±0.02	1.75±0.02	1.63±0.01	46.33±0.27
TP	139.21±0.07	29.92±0.03	31.03±0.01	2.51±0.02	1.70±0.02	45.74±0.25

2.4 Compressive tests

A universal mechanical testing machine Instron 3300 has been used to realized the compressive tests. The compressive load is applied gradually and uniformly to the specimen at a constant rate, with a cross-head speed of 2mm/min. For each core geometries path, five specimens were tested for each set of samples according to ASTM D695 standard. Load application continues until the specimen undergoes significant deformation or failure. Figure shows the experimental machine assembly used, and the DT sandwich structure undergoing compressive tests.



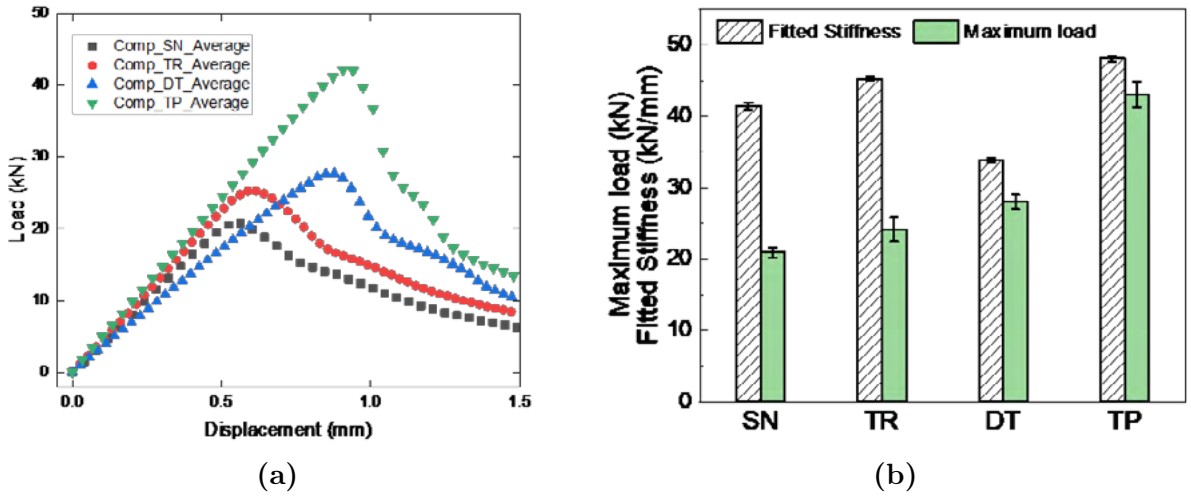


Fig. 2. DT sandwich structure undergoing compressive tests

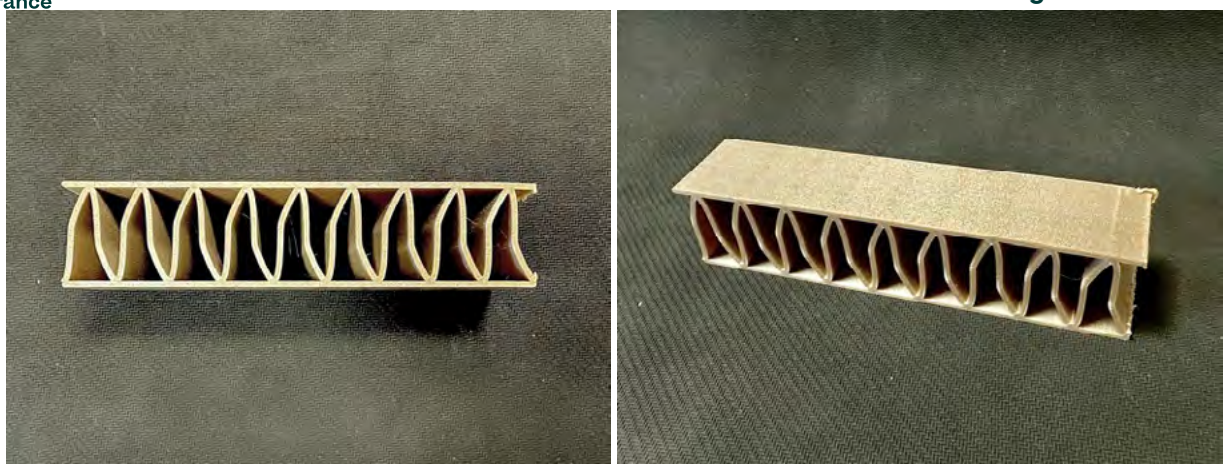
3. Results and discussions

The Figure 3 illustrates the load-displacement curves obtained from compressive tests conducted on the four investigated core patterns. As depicted in Figure 3a, the axial



load-displacement curves of the sandwich structures exhibit a linear segment during the initial loading phase. Subsequently, as the load increases, localized buckling occurs in both the skin and core, resulting in a reduction in the slope of the curves. With further continued loading, the local buckling of the specimen became more serious, and the load-displacement curves decreased slowly. The experimental findings indicate that among all the structures examined, the trapezoid structure demonstrated the highest maximum load and stiffness that best fit the load-displacement relationship, with the best compressive mechanical performance. One possible explanation for this observation could be attributed to the greater number of contacts between the skin and core of the compressive side of the trapezoid pattern, totaling 12, as opposed to the remaining three patterns which each have 9 contacts. Furthermore, it's worth mentioning that certain structures seem to have minimal influence on the fitted stiffness, similar to the apparent akin Young's modulus. The load-displacement curves of SN and TR geometries are close to each other, probably because their geometries are also very similar. The core thickness of TP is 1/3 higher than the other three, but the fit stiffness does not increase significantly, so the relevance of the core thickness parameter needs to be further investigated and discussed.

(a) (b)

Fig. 3. (a) Averaged load(kN)-displacement (mm) curves with four different patterns (b) Fitted stiffness (kN/mm) and maximum load (kN) of four different patterns with error bar

At the beginning of the experiment, the sample is uniformly pressurized from above, and as the force increases, the displacement of the sample in the y-axis direction correspondingly increases. After that, the sandwich structure starts to bend internally, and eventually the force reaches its highest point and starts to drop slowly. The color change of the bent part of the sandwich structure can be clearly observed according to the Figure 4, which describe the damage of this part. To delve deeper into the microscopic alterations occurring during this process, future investigations can employ a broader array of analytical techniques. This may encompass leveraging advanced microscopy methodologies to meticulously scrutinize distinct stages of damage progression.

(a) (b)

Fig. 4. A sample of PLA/Flax with sinus structure after compressive tests

4. Conclusion

In summary, we explored various core geometries of biobased sandwich structures using PLA/Flax fiber. We designed and optimized samples of the same length, width and height with different sandwich core geometries: sinus, triangular, double triangular, trapezoid, for the same total mass. Utilizing continuous extrusion printing optimized by MATLAB, the gcode has been regenerated automatically and these samples have been manufactured sequentially. Through experimentation, we investigated the compressive mechanical properties of samples with different core patterns, aiming to compare the performance and characteristics of natural fiber-reinforced composite sandwich structures under different core patterns. Among these patterns, the trapezoid pattern exhibited superior performance relatively, this may be related to the number of contact points between sandwich core and skin. Based on experimental observations, this study provides insights for further analysis and research into the failure mechanisms of such materials in the future.

Keywords: Interface, Microscale modelling, Carbon fibre, Epoxy, Cohesive zone modelling

Abstract
While a strong fibre-matrix interface yields a composite with high strength and stiffness, it often leads to brittle failure and limited energy absorption. By deliberately weakening the interface, one can enhance toughness by creating longer debond lengths and subsequent pull-out mechanisms. However, this strategy comes with the drawback of reducing both strength and stiffness, necessitating a careful balance between these competing factors in composite design. Drawing inspiration from nature's mechanisms to enhance toughness, the overarching objective of this study is to thoroughly comprehend and leverage the potential of intermittent interfaces to engineer fibre-reinforced composites with an outstanding combination of mechanical properties. The proposed microscale numerical model proves invaluable in enhancing the efficacy of subsequent experimental pursuits in manufacturing intermittently-treated fibre-reinforced composites. This finite element model addresses the research question of identifying the mechanisms behind intermittent interfaces with a synergistic blend of high strength, stiffness, and toughness. It also investigates how design parameters, such as the length and interval length of intermittent areas and their locations relative to the fibre break plane, influence the mechanical behaviour of these composites. The model predictions reveal that the proposed intermittent approach results in larger debond lengths and, consequently, higher energy dissipation values.

1. Introduction

One of the most ambitious goals in structural materials is to achieve exceptional mechanical properties with an ideal combination of low density, high strength, and high toughness. The strength and toughness of different materials, including fibre-reinforced composites, are usually intertwined. The amount of stress that a material can support without cracking and then fracturing increases when the strength of the material is high; however, toughness increases only when the energy required to cause a crack to grow to fracture also increases and is coupled to more deformation of the material. This intricate relationship implies that enhancing one attribute inevitably comes at the expense of the other. However, natural materials, such as bone, have exceptional properties that can combine both high strength and high toughness by an ingenious structural design [1]. For biomaterials, strategies to achieve unification between structure and mechanical properties have been through millions of years of evolution. Nacre is a good example of a material that combines strength, stiffness, and toughness. When this material is subjected to stress and a crack is produced, it follows a complex path to grow in a very complex pattern [2]. The tortuous crack paths and pull-out of the mineral platelets provide a major contribution to toughening. The result is a material with a toughness of at least an order of magnitude higher than either of its constituents [3].

High toughness holds particular significance in applications which suffer impact or for components where fracture could have catastrophic consequences. Composite materials emerge as a compelling

alternative to traditional counterparts, offering superior strength-to-density ratios that translate to reduced fuel consumption, especially in the aviation and automotive sectors. Carbon and glass fibre-reinforced composites, in particular, are light, stiff and strong. However, their brittleness remains a limitation.

The pioneering work of Atkins (1975) [1] described theoretically the failure mechanism of composites reinforced with long fibres with alternate sections of high and low adhesion, showing its capability for improving composite toughness without a reduction of stiffness and strength. Although he was only able to produce irregular intermittent areas of lengths around 19 to 51 mm on thick boron fibres (diameter 140 µm) and on monofilament tapes (not individual fibres), the translaminar fracture toughness of boron/epoxy unidirectional composites increased from 50 kJ/m² to 150 kJ/m² while retaining rule-of-mixtures tensile strength, demonstrating the validity of the approach.

The intricate nature of crafting alternative sections brought this field to a standstill for years. Only in 2017 did Grappe et al. [2] propose a new attempt to obtain intermittent sizing on CF yarns for composite applications. The approach consisted of an intermittent spray sizing of CF bundles (80k individual filaments) and was developed specifically for sheet moulding with the aim of improving diffusion of resins on the alternate sections without sizing. Although the aim of this research was to improve composite processability only, an increment of 100% and 60% for the tensile strength and tensile modulus, respectively, was reported when compared with untreated samples. No description of the mechanisms that allowed the significant improvement in the mechanical performance was given. More recently, in 2018, Greenfeld et al. [2] proposed an intermittent approach on single fibres for the first time, by creating beads of cured epoxy evenly distributed on a single glass fibre [26]. Pull-out and fragmentation tests showed an improvement in toughness while keeping tensile strength. However, this approach is based on mechanical interlocking created by the beads during failure, producing energy dissipation due to the deformation of the matrix during pull-out of the fibres and not to the development of a tortuous crack path for energy dissipation (“brick and mortar” concept).

Inspired by nature’s strategies to increase toughness, this study proposes a novel numerical approach for the development of tough CF composites, creating micro mechanisms for energy dissipation at the interface of individual fibres while maintaining good load transfer. This can be achieved by creating areas of high and low shear strength in an orderly position on brittle fibres, controlling the local damage process to promote crack propagation (low shear stress areas), as well as inhibiting crack propagation and sustaining the filament strength (high shear stress areas). Our approach consists of defining the best compromise between strong and weak fibre/matrix interfaces distributed alternatingly along single fibres to improve the toughness of composites. While an interface with high shear strength produces composites with high strength and stiffness, brittle failure and low energy absorption, an interface with low shear strength produces large delamination and high energy absorption (given an optimum length) but reduces the strength of the composite. If we are keen to tailor the interface and balance these two areas of high and low shear strength, then an advancing crack tip will be blunted by fibre debonding in the weak interface regions, whereas the strong part of the interface can prevent the debond length from becoming too large.

An intermittent interface influences the longitudinal crack growth (mode II) produced by shear debonding, generating a tortuous path which increases the surface area that must be created during fracture until the crack reaches the strong areas. In this way, the strong regions ensure that the filament strength is taken, while the weak areas weaken the running crack, creating a complex pattern for crack evolution. Then, strong interfacial areas can maximise the use of fibre strength, while the weak interface can increase energy absorption.

2. Numerical model

A modelling approach (as exemplified in [3,4] for a continuous interface) is imperative to comprehensively understand how intermittent surfaces impact the adhesion between carbon fibres and

polymer matrices so that the experimental methods, such as plasma activation and deposition processes, are guided and optimised.

A single-fibre model is generated to establish and validate the methodology. Considering a cylindrical coordinate system, r and θ are the radial and angular coordinates, respectively, and z-axis is the axial (fibre) direction of the composite (see Fig. 1a). The length and the radius of the model were set to 6 *mm* and 0.5 *mm*, respectively. These large dimensions help to diminish the apparent stiffness loss of the simulated specimen due to a fibre break and debonding. The nodes on the $\theta = 0°$ and 30° planes are constrained in the direction. At the plane, a z-symmetry boundary condition is applied, excluding the broken fibre surface (traction-free). The outer cylindrical surface ($r = 0.5$ *mm*) is traction-free, enabling Poisson contraction. The plastic response of the epoxy matrix is modelled using the Abaqus plasticity model. The engineering constants for the transversely isotropic CF, macroscale epoxy properties and their thermal expansion coefficients are given in [4].

The fibre-matrix interface of the broken fibre is modelled by adopting a surface-based cohesive contact with a bilinear traction-separation law. The mixed-mode debond initiation is based on the quadratic traction criterion. An energy-based damage evolution with a linear softening law is considered for debond propagation. The contact definition in our proposed model couples the cohesive zone model with the Coulomb friction model as of the initial step (thermal cooldown of −100 °C), leading to a continuous transition from debond initiation to its completion and then frictional sliding. Fig. 1a-b illustrates the conceptual foundation of this numerical investigation, depicting the assigned interfacial properties for both weak and strong interfaces using cohesive surface pairs. A high initial penalty stiffness is assigned to eliminate interpenetration of the crack faces. The simulations are performed in Abaqus/Standard 2023, using quadratic, reduced integration hexahedral elements (C3D20R). Fig. 2 shows the mesh quality with a highly dense mesh assigned to the broken fibre and the matrix in the vicinity of the interface, which is gradually coarsened out radially away from the interface using a logarithmic bias.

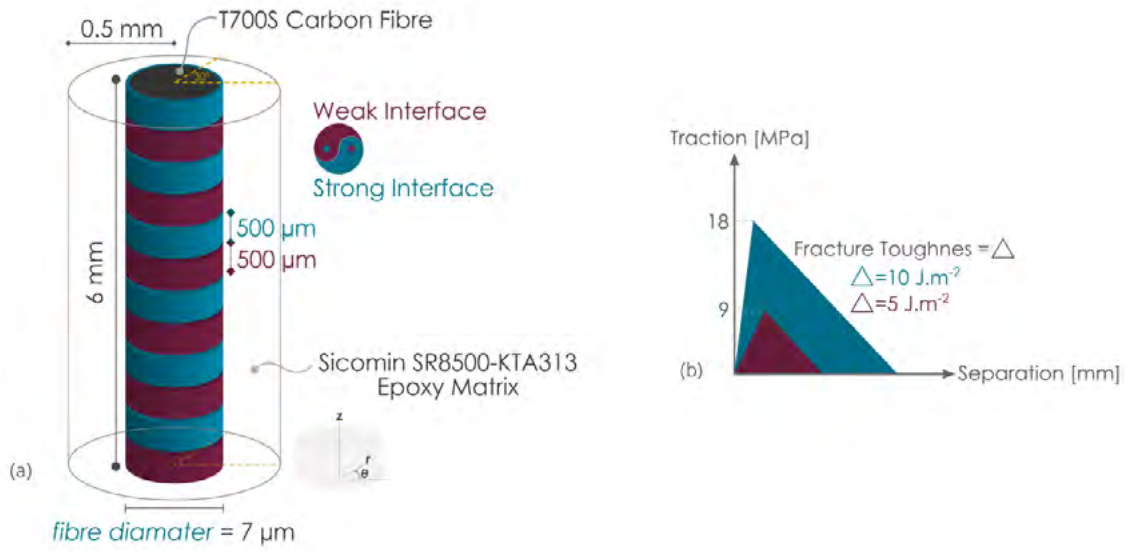

Figure 1. (a) Schematics (at adjusted scale for enhanced clarity) of the microscale model for intermittent fibre-matrix interfaces, and (b) assigned bilinear cohesive zone models for the weak and strong interfaces.

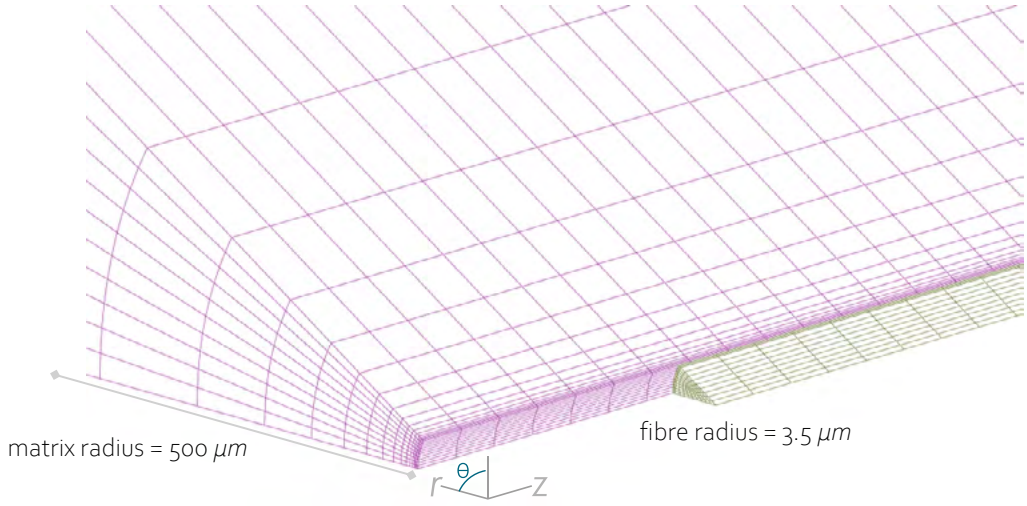

Figure 2. The FE model and mesh quality visualisation of a 30°-wedge single fibre-epoxy model for intermittent interfaces with the frictionally-slided debonded broken fibre at the end of a simulation ($\varepsilon = 2\%$).

Six models have been developed for the initial analysis. Among these, two focus on *continuous* (or *uniform*) interfaces, distinguished by their interfacial properties—one characterised by high interfacial properties (*strong*) and the other by low interfacial properties (*weak*) as shown in Fig. 1b. The remaining four models adopt an intermittent approach, featuring intermittent lengths of either 100 or 1000 μm. These intermittent models are further differentiated based on whether the weak or strong interface is adjacent to the fibre break plane.

Fig. 3 illustrates the interface status of the "100-μm intermittent model" as strain levels increase, notably featuring a weak interface positioned adjacent to the fibre break plane. In this depiction, an interface damage parameter of 1 signifies complete debonding of the interface. Observably, interfacial debonding initiates from the side adjacent to the fibre break plane, particularly from a weak interface. Subsequently, the adjacent weak interface, separated by a strong interface, undergoes debonding as strain increases, albeit without achieving full debonding initially. At higher strain levels, the central strong interface initiates debonding, merging with the debonding of the first weak interface, ultimately connecting these two weak interfaces and resulting in fully debonded regions. For fibre axial stress, all Gaussian points' stress is averaged within each layer of the cross-section. As seen from the longitudinal stress recovery profile of the broken fibre (Fig. 4), the proposed intermittent approach will result in a larger debond length (~4-4.7 *mm* compared to 1.1 *mm*) and, consequently, higher energy dissipation values.

Moreover, it is imperative to investigate the significance of the quality of the first neighbouring interface adjacent to the fibre break plane and its correlation with the interfacial debond length. As seen in Fig. 4, when the initial interface is weak, the increase in debonding length is only marginally larger compared to a strong initial interface, particularly with a small intermittent size (e.g., in 100-μm model). However, this discrepancy amplifies notably with larger intermittent sizes, such as in 1000-μm model.

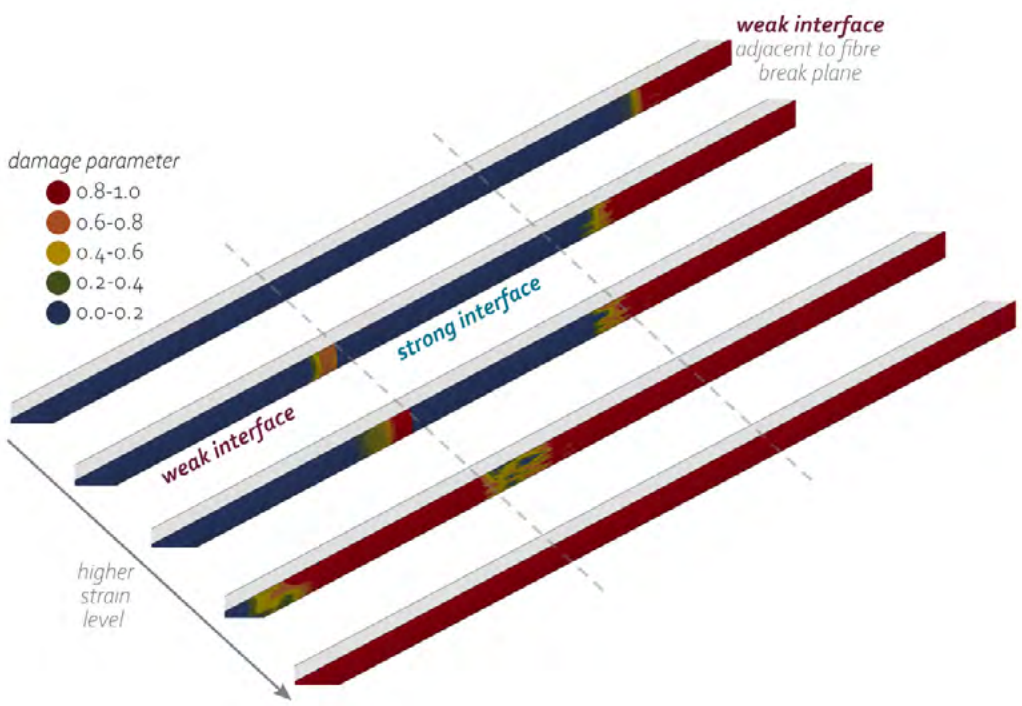

Figure 3. The progressive debonding of weak interfaces, subsequent to the debonding of the intermediate strong interface, leading to their eventual merging within the "100-μm intermittent" model, delineated against strain progression.

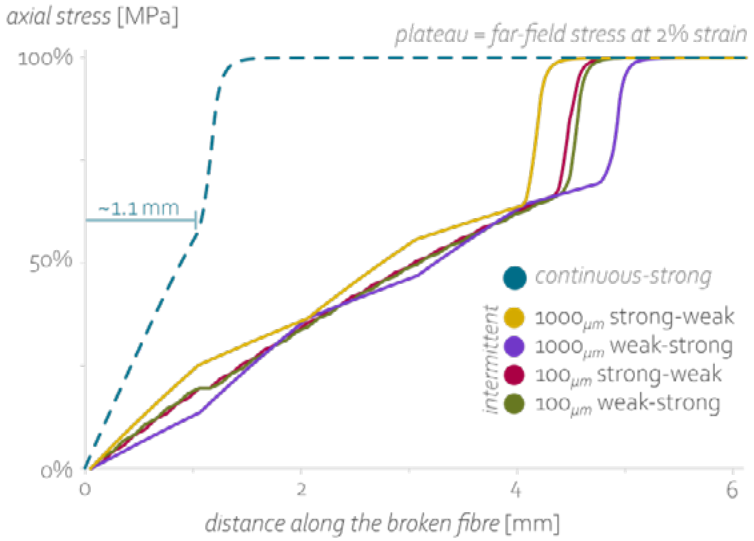

Figure 4. The load-displacement response across varying lengths (100 μm and 1 mm) of intermittent interfaces and the interface quality adjacent to the fibre break plane. Note that the debond length corresponds to the slipping extent of the *contact status output*, aligning with the linear segment of the stress recovery profiles.

3. Conclusions

As a general approach, it is possible to weaken the interface, but this is accompanied by a significant reduction in strength and stiffness; therefore, intermittent modulation of fibre-matrix interfaces provides an interesting compromise, as a propagating crack tip can be blunted by fibre debonding in the weak

interface regions, while the strong area of the interface can limit the extent of the debond length and preserve the overall strength and stiffness. In a nutshell, the strong interface can maximise the use of the fibres, while the weak interface can improve energy absorption. This study underscores the potential of intermittent interfaces in advancing the performance of composites, offering a pathway towards achieving a harmonious blend of stiffness, strength, and toughness.

Through stress recovery profiles, it became evident that the proposed intermittent approach facilitates larger debond lengths and, subsequently, higher energy dissipation values, offering potential enhancements in composite performance. Additionally, the investigation emphasised the critical role of the quality of the initial neighbouring interface adjacent to the fibre break plane, showcasing its correlation with debond length. These findings underscore the significance of tailored interface design strategies in optimising composite properties and advancing materials engineering. Moreover, this numerical model plays an essential role as the guideline for experimental methods in creating regular and precise intermittent areas (with controlled height at the nano/micro scale) on an individual fibre using a combination of techniques such as micro-plasma and the formation of a precursor micro/nano layer during the spreading of a molten thermoplastic. Moreover, the stress recovery library, within the feasible range of interfacial properties, as reported in [5], can be utilised in the KU Leuven strength model to predict the optimal longitudinal tensile strength.

Abstract
A study was conducted on the electrical behavior of carbon fiber composite for anti-icing applications in structures like wind turbine blades and aircraft wings. Both experimental and numerical methods were used to analyze how different layer orientations ($[0_2]_T$, $[90_2]_T$, $[0/90]_T$, $[\pm45]_T$, $[0/45/-45/90]_T$) and plate dimensions affect the electrical resistance and heat generation of the carbon fiber composite. To simulate this behavior a numerical model using the finite element method (FEM) with Thermal-Electric element (Coupled-Field Solid) was used. The capacity of the carbon fiber composite laminate to generate heat under electrical load was predicted. A good agreement between experimental results and numerical simulations was obtained. This study found that the 0° layer had the lowest electrical resistance and highest heat generation capacity compared to other layups with the circuit configuration studied. The 90° layer demonstrated very high electrical resistance due to inter-fiber dominated behavior. The conclusion based only on the performance to generate heat under electrical load is that unidirectional lamina with 0° fiber orientation is best suited for this task. However, complete design should consider various mechanical and thermal loads. The results provide valuable insights into the performance of carbon fiber composite for de-icing applications in various structures.

1. Introduction

The remarkable mechanical and electrical properties of carbon fibers promote use of carbon fiber-reinforced plastics (CFRPs) in various applications where multi-functionality is required. These materials are utilized in various ways, such as de-icing aircraft components, preventing icing on wind turbine blades, design of heated CFRP molds. Additionally, the advancement of specialized non-destructive testing techniques, like electrical measurements, has allowed for the detection and assessment of damages in CFRPs [1]. The heating systems play a crucial role in maintaining the operational efficiency and safety of both wind turbines and aircraft, especially in cold climates. In these applications, the growth of ice on critical surfaces can compromise performance, increase energy consumption, and pose significant safety risks. In wind turbine applications, icing on the blades can disrupt airflow, decrease aerodynamic efficiency, and lead to structural concerns. Similarly, for aircraft, ice formation on wings, engines, and other surfaces can decline lift, increase drag, and impact control, posing serious risks during flight. Consequently, it is very important to focus on how to improve the performance of these heating systems. More specifically, for CFRP based on continuous fibers discrete conductive pathways (fibers) are distributed within an insulating matrix, providing the entire CFRP with local conductive or insulating properties [2,3]. Moreover, it has been observed that CFRP has a much higher electrical conductivity along the direction of the fibers, while the conductivity is significantly lower perpendicular to the fiber orientation [4]. It is commonly assumed in the field of CFRP that, in ideal conditions and without considering capacitive or inductive couplings between fibers, electrical current flows primarily through individual carbon fibers due to the insulating properties of the surrounding polymer material. Theoretically, in a scenario where carbon fibers were perfectly straight

and did not come into contact with adjacent fibers, CFRP would exhibit extremely high insulating characteristics in a direction perpendicular to the fibers. Nevertheless, it is important to note that the assumption of perfectly unidirectionally aligned fibers in an CFRPs is in practice never completely fulfilled. In reality, individual carbon fibers do not completely follow the same alignment and they can also have a tendency to exhibit waviness along fiber direction. As a result of this characteristic, there are occasions where adjacent fibers come into contact with each other, allowing for the flow of electric current between them [5].

Unidirectional carbon fiber-reinforced plies are expected to conduct electricity similarly in transverse and out-of-plane directions (as both are perpendicular to the fiber orientation). However, the potential presence of resin in between layers, e.g. in multi-directional composites or in textile based composites, acts as an insulator and hinders flow of current in an out-of-plane direction, resulting in even lower conductance than in the transverse direction [6]. Since the conductance in both directions is affected by the contact between fibers, the overall electrical impedance of a CFRP sample depends on the electric resistance of all fibers present [7].

There are a number of studies [8–11] that are dealing with the prediction of heat generation by CFRP subjected to the electrical load. A numerical model is presented in [8] to calculate temperature distribution during induction heating with a circular coil. The study shows the significance of including temperature-dependent thermal properties in the numerical model, while the addition of temperature-dependent electrical conductivity may not be important given its negligible influence on the calculated heat generation and temperature. The feasibility of simulating temperature distribution in the induction heating of carbon fiber-reinforced polymer woven fabric using a finite element model with a simplified unidirectional layer representation is demonstrated in [9]. The simulation shows good agreement in predicting peak temperature, with around a 10% difference in comparison with the experimental results. Another numerical model is presented in [10] to calculate temperature and heating power distribution in cross-ply CFRP plates during induction heating. Different fibre volume fractions and layer thicknesses were used in experiments which were validated by the numerical model. The model in [11] represents CFRP as a network of discrete resistors, with local currents determined by Kirchhoff's circuit laws and temperature distribution calculated using the finite difference method. The current and temperature distribution in CFRP during induction heating were simulated. This model complements traditional finite element simulations, providing an understanding of current paths and heating patterns on a tow size level. Experimental thermographic recordings during induction heating experiments support the validity of the model.

The above studies render a lot of useful results for particular cases, however, the influence of fiber orientations on the electrical conductivity of CFRP composites, especially in scenarios where fibers are not perfectly aligned, has not been carried out. The coupling capacitance between fibers in CFRP composites and its effect on electrical current flow has not been properly studied either. The current work tries to address some of these issues to generate more knowledge for future studies related to the conductivity of composite laminates with defects as well as recommendations for efficient repairs of composites to maintain the same performance.

2. Experimental work

The fast-curing carbon fiber prepreg (T700S/ #2300) was used to manufacture composite laminates. The sandwich panels made of glass fiber composites and foam core (supplied by PODCOMP, in Piteå) were used as a support material for the carbon fiber layers (to simulate the structure of the turbine blade). To ensure good connection between the carbon fibers and the stainless-steel electrodes, the metal stripes were embedded between the carbon layers. The distance between the metal stripes defines the effective width of the plate. The whole assembly (carbon fiber layer, glass fiber panel, and stainless-steel electrodes) were placed in a hot press (Phi Pasadena Hydraulics, inc) at 130°C, 3 bar for 30 minutes.

Two different distances between the metal stripes (16 cm and 28 cm) were employed to see if it has any effect on heat generation. Five different fiber lay-ups ($[0_2]_T$, $[90_2]_T$, $[0/90]_T$, $[\pm45]_T$, $[0/45/-45/90]_T$) were

used to study how fiber orientation and lay-up affects electrical performance and consequently temperature generation.

To initiate the experiment to measure electrical conductivity and temperature generation, the electrodes (stainless-steel stripes) are connected to a power supply (metal bolts were used to ensure a stable connection between the wires and the electrodes). To prevent the heat reflection into the thermal camera from the surfaces around the sample, a protective shield was used (box made out of glass fiber sandwich panels), as shown in Fig.1. 2 voltage was applied on all the plates in order to accurately comparison for the results. A thermal camera (FLIR series-A6000) and ResearchIR software were used to monitor the temperature generation and distribution within the plate.

To determine the resistance of the plate, various voltage values were systematically applied to the plate while measuring the corresponding currents. By plotting the relationship between electrical voltage and current, it is possible to determine the slope of the curve which represents the resistance. The resistance value for each tested plate is adjusted to exclude additional wire resistance from measurements (by subtracting the wire resistance from measured values).

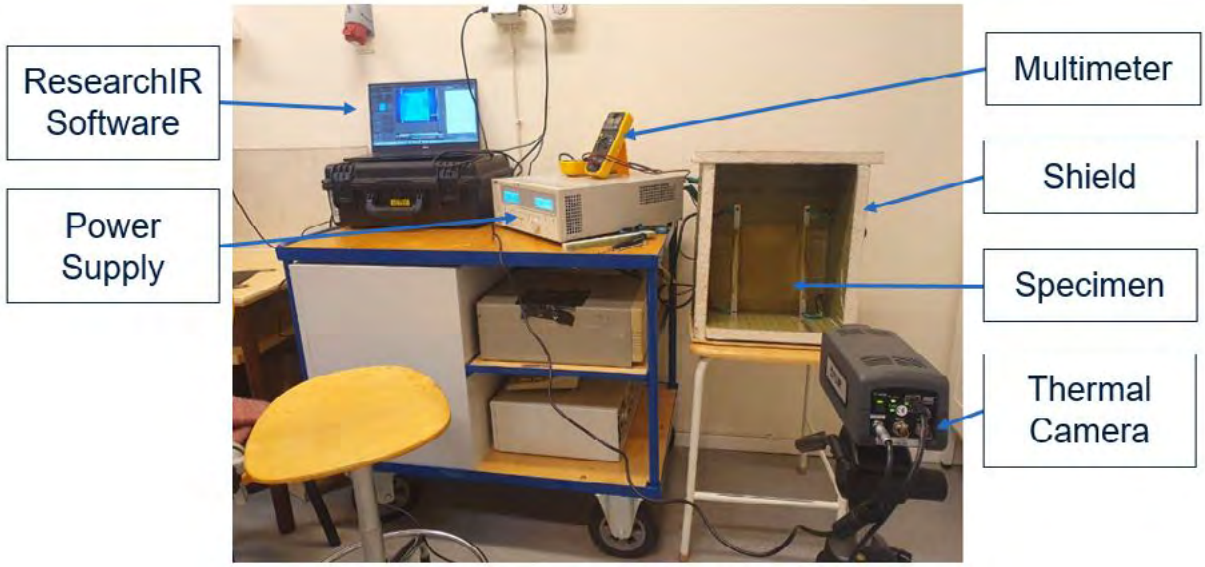

Figure 1. Experimental set-up for the test.

3. Finite element model

In this study, the numerical analysis of thermal and electrical performance for a rectangular carbon fiber composite plate with different fiber orientations in layers and various plate dimensions subjected to an electrical field (by applying voltage) was carried out. The simulations were done by using a commercial FEM package ANSYS 2023 R1 (utilizing APDL codes). A 3D coupled-field solid element (SOLID226) [12] with twenty nodes were used to create the uniform mesh for the whole plate with the same element size. The convergence of the results was obtained by monitoring the influence of the mesh size on the thermal value. In this simulation, two different materials are used through the thickness of the plate in order to simulate the real scenario of the turbine blades which consists of glass and carbon fiber layers. The same geometry and dimensions of the experimental specimens are used with the following boundary conditions applied: the electrical load is applied on both ends of the plate (at the same location as the electrode in the experimental setup in the locations X=-L/2 and X=L/2). The surface loads are applied on the outer areas of the plate which has convection with the surrounding air. The mechanical, thermal, and electrical properties are supplied to the program for the standard linear orthotropic material model implemented in ANSYS in order to be used for simulations.

4. Results and discussion

As was mentioned earlier the aim of the study is to gain a better understanding of how different layer orientations and sample dimensions (plate sizes) affect the electrical resistance of the composite and the amount of heat it produces. Thus, the analysis is focused on the comparison of the experimental results of the electrical resistance, temperature generation and distributed within the carbon layer of the flat plate. The comparison between experimental and numerical results is presented for these parameters.

4.1 The effect of fiber orientation

The comparison between different carbon layer orientations is discussed in this section. The results of the experiment are presented in Table 1. It was found that the plate with a $[0_2]_T$ layup exhibited the lowest electrical resistance compared to other configurations. Accordingly, the $[0_2]_T$ plate showed the highest heat generation capacity compared to other layups with the circuit configuration studied as shown in Fig. 2. The electrical resistance of the cross-ply laminates, $[\pm45]_T$ and $[0/90]_T$, were higher than the resistance of unidirectional $[0_2]_T$ lamina by 80% and 97% respectively. While, the quasi-isotropic laminate $[0/45/-45/90]_T$ showed only a 2% difference in resistance when measured in absolute values, but it is important to consider the effect of any changes in the cross-sectional area of the plate. Thus to exclude the effect of change in the cross-section area of the plate the value should be normalized with respect to thickness. Once this normalization is applied, the difference in resistance is actually increased to 102%. Notably, the $[90_2]_T$ layer alone demonstrated a very high electrical resistance, approximately 2000 times higher than that of the $[0_2]_T$ laminate. This is expected, since ideally, no electrical current should pass through the $[90_2]_T$ layer (fibers are insulated by matrix). However, due to inevitable small misalignments, waviness of carbon fibers resulting in inter-fiber contact points along the length of continuous fibers, current may flow from one fiber to another even in 90° layer. This inter-fiber behavior also results in the electric conductance of the out-of-plane direction being very similar to that of the transverse direction.

Table 1. Electrical resistance for different laminates

Stacking sequence	Thickness (mm)	Width (mm)	Distance between the electrodes (mm)	Resistance (ohm)
$[0_2]_T$	0.5	200	160	0.0647
$[0/90]_T$	0.5	200	160	0.1275
$[45/-45]_T$	0.5	200	160	0.1185
$[90_2]_T$	0.5	200	160	134.37
$[0/45/-45/90]_T$	1	200	160	0.0653

Furthermore, it was observed from Fig. 2 that the temperature increase for the $[0_2]_T$ plate was approximately twice as high as that for the $[0/90]_T$ plate under the same applied electrical voltage. While it is approximately 40% and 4.5 times higher than the $[45/-45]_T$ and $[90_2]_T$ plates respectively. However, the $[0_2]_T$ showed only a 25% higher than for the quasi-isotropic laminate $[0/45/-45/90]_T$ which is related to an increase in the contact points between the fibers, but at the same time, more layers are needed to reach the same temperature as for $[0_2]_T$. Consequently, in general, a lower electrical current (approximately around 25% of the value compared to laminates with different layups) needed to be applied to the $[0_2]_T$ plate to achieve the same temperature increment as for the other laminates.

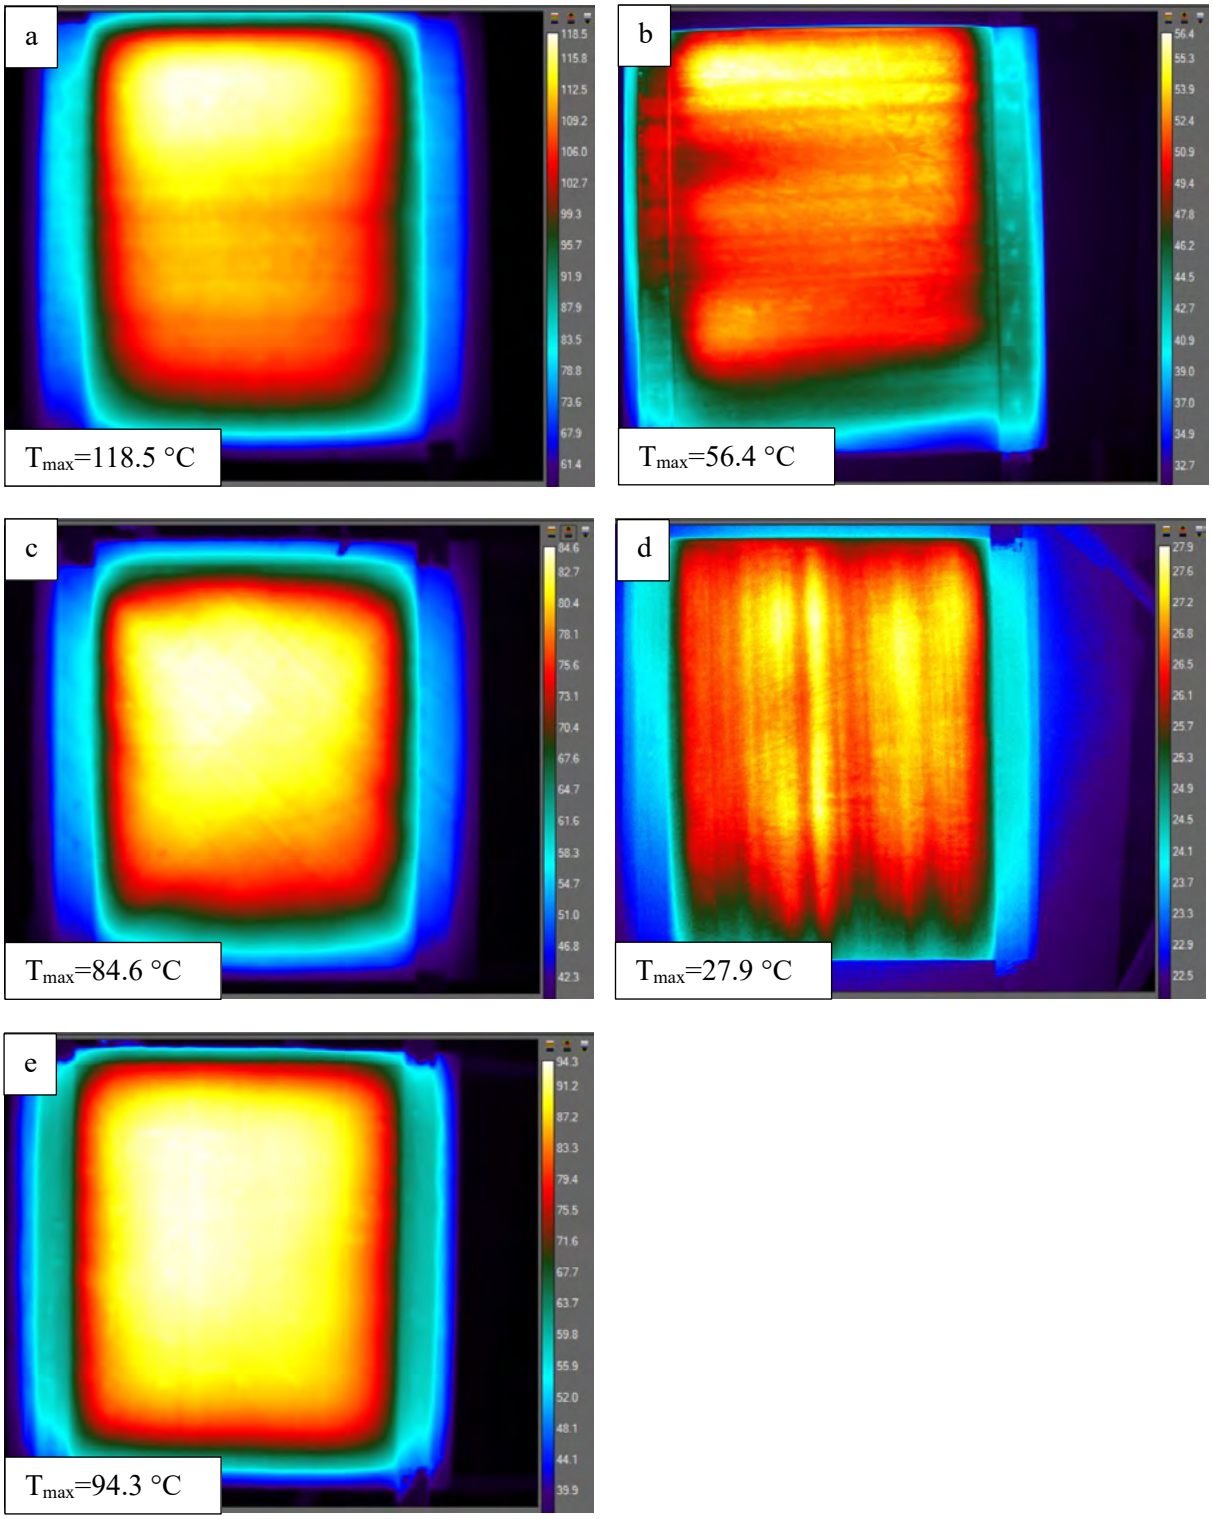

Figure 2. The experimental results of thermal distribution and the maximum temperature under the same applied electrical voltage (2 V) for different carbon layer orientations: a) $[0_2]_T$, b) $[0/90]_T$, c) $[\pm45]_T$, d) $[90_2]_T$, e) $[0/45/-45/90]_T$.

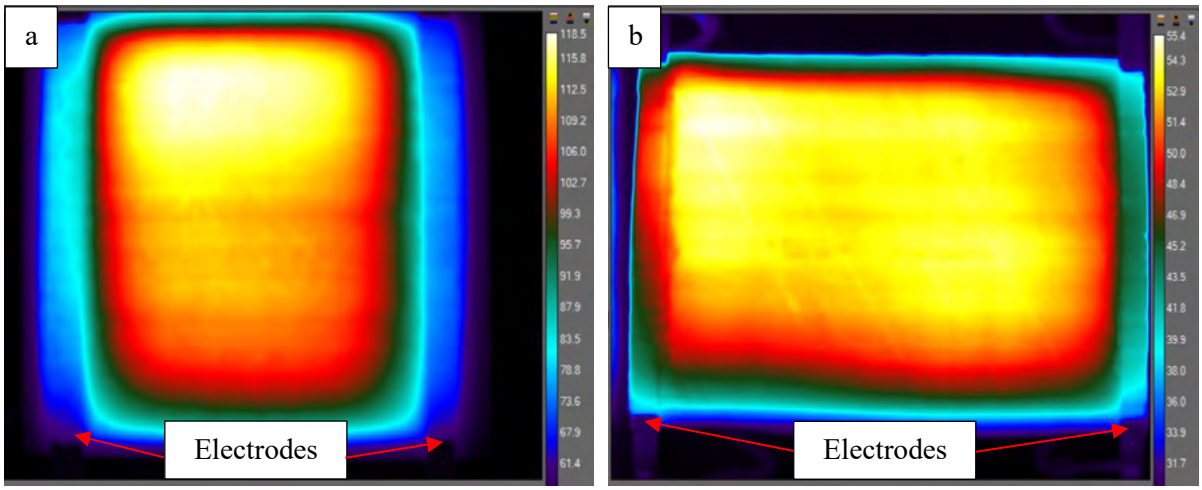
4.2 The effect of plate size

In this section, the comparison between two carbon fiber composite plates with different widths is discussed. The results of the experiment are presented in Fig. 3. The results show that increasing the length of the plate by 80% leads to an increase of the plate resistance by 65%. It results in a reduction in temperature by 53% compared with the original size of the plate (160mm). This is somewhat expected since the cross-section area for the current flow is unchanged and the resistance is increasing due to the longer fiber.



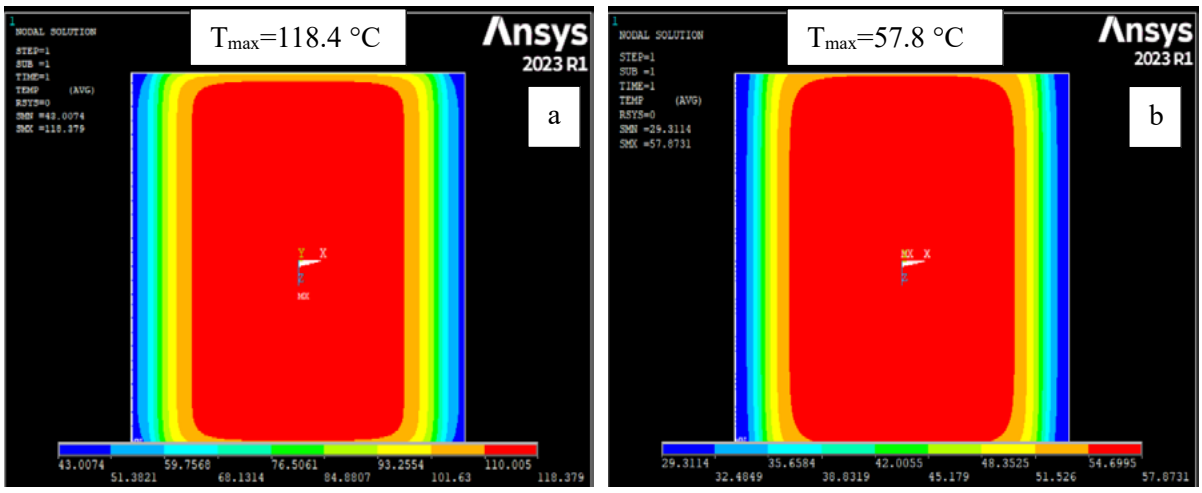


Figure 3. The experimental results of thermal distribution and the maximum temperature under the same applied electrical voltage (2 V) for different distances between the electrodes: a) 160 mm, b) 285 mm.

4.3 Comparison between the experiment and numerical simulations

The numerical simulation results for the laminates with the same stacking sequence as used in experiments are presented in this section, see Fig. 4. The results showed a very good agreement with the experimental results (Fig. 2). The maximum difference between experiment and simulation is around 3.5% which is acceptable accuracy. Thus, the developed model can be considered as validated and it can be used for further calculation for laminates with defects as well as repaired plates (this work is planned as a future study).

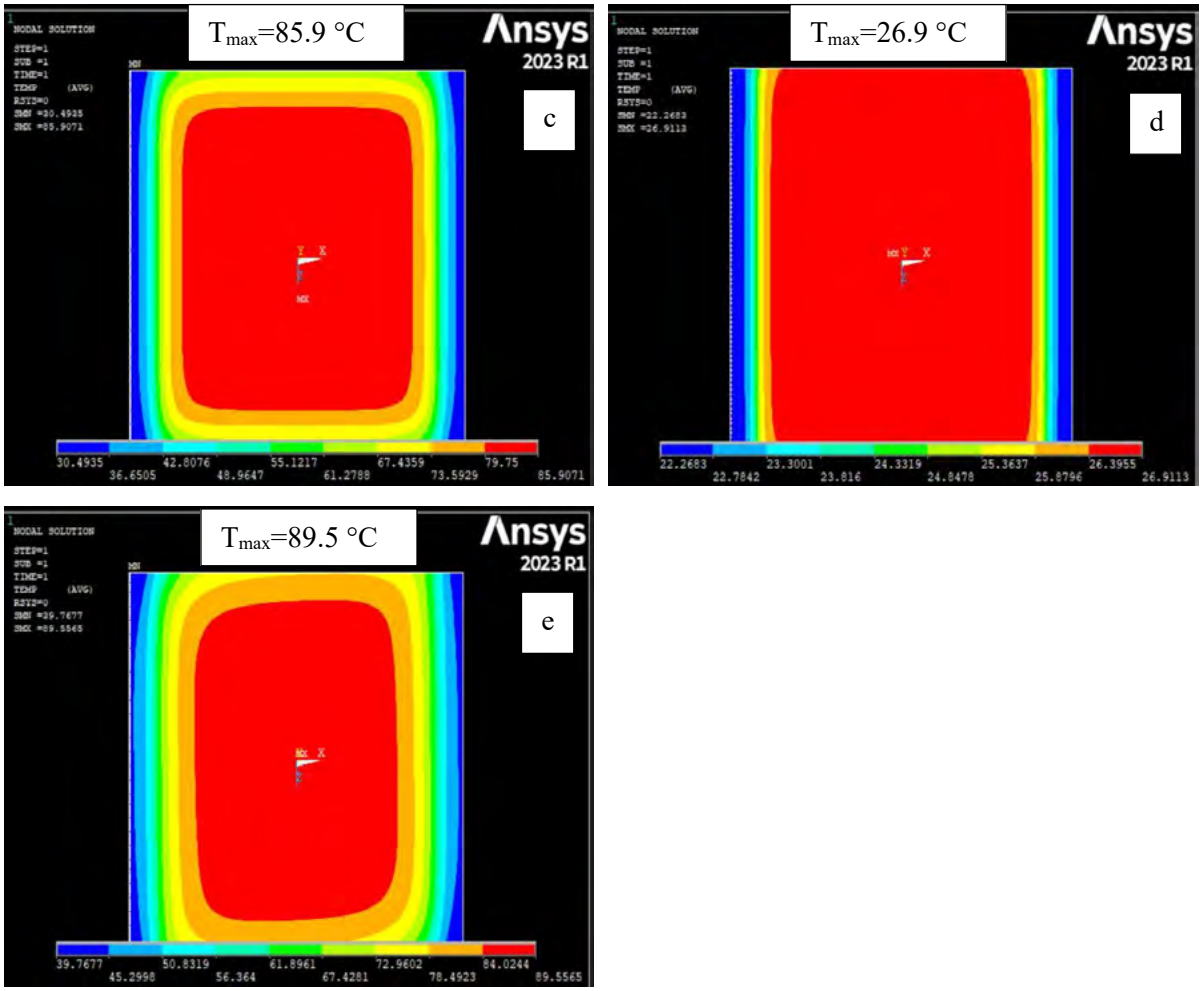

Figure 4. The numerical results of thermal distribution and the maximum temperature under the same applied electrical voltage (2 V) for different carbon layer orientations: a) $[0_2]_T$, b) $[0/90]_T$, c) $[\pm45]_T$, d) $[90_2]_T$, e) $[0/45/-45/90]_T$.

5. Conclusions

This study has shown that the highest surface temperatures, yielding in suitable composites for electrical and thermal applications, is the prepreg-based unidirectional lamina with fiber aligned at 0°. However, when designing laminates for particular application (e.g. multi-axial mechanical loads) it is crucial to take into account various factors such as mechanical and thermal loads, expected location, direction, and the potential risk of damage. Additionally, the design of the plate should aim to cover the necessary area using the shortest possible fiber length to improve heat generation. This investigation offers useful observations regarding the electrical performance of carbon fiber composites which can be used to define recommendations for design of composites with multi-functional properties for application in different structures.

Acknowledgement

The authors would like to acknowledge Nour Labidi, a Master's student for help with experiments. The authors also express gratitude to Birgitha Nyström from PODCOMP for providing the glass fiber sandwich panels. Additionally, thanks are due to Greger Nilsson from Blade Solutions company for his valuable guidance as an advisor and insightful discussions on the results.

Keywords: High-pressure hydrogen tank, Fatigue damage, Stiffness degradation, Residual strength after fatigue

Abstract

Type IV tanks, composed of a plastic liner and CFRP, are expected to greatly enhance hydrogen storage capacity. However, CFRP high-pressure tanks have shown damage like matrix cracking and delamination under typical operating pressures, escalating with repeated loading. Cracks and delamination within the tank can diminish structural rigidity, potentially reducing strength compared to the original state, even if total tank failure is prevented. To tackle this, the development of numerical analysis techniques considering fatigue-induced residual strength is vital, not only to adjust the design safety factor for failure strength but also to meet the growing demand for further lightweight solutions. This study endeavored to forecast the internal damage progression due to internal pressure fatigue and the residual burst pressure following fatigue in composite tanks. By employing static damage analysis using the fatigue damage distribution derived from fatigue analysis as initial values, residual strength predictions were conducted. Consequently, it was demonstrated that the residual burst pressure post-fatigue decreased due to heightened tank susceptibility to deformation from fatigue damage.

1. Introduction

CFRP (Carbon Fiber Reinforced Plastic) is expected to be used in the structural components of high-pressure hydrogen tanks due to its high specific strength and specific stiffness. Type IV tanks, consisting of a plastic liner and CFRP, are anticipated to significantly improve hydrogen storage capacity. However, in the CFRP high-pressure tanks, damage such as matrix cracking and delamination has been observed under normal operating pressures, with further progression under repeated loading. Cracks and delamination occurring within the tank can reduce structural stiffness, leading to a potential decrease in strength compared to the initial state, even if complete tank failure is averted. To address this, the development of numerical analysis techniques considering fatigue-induced residual strength is crucial,

not only to accommodate potential relaxation in the design safety factor for failure strength but also to meet the growing demand for further lightweight.

In this study, we defined an intralaminar damage model based on continuum damage mechanics to analyze the damage evolution in composite laminates under fatigue loading. We employed a methodology that combines these damage models with finite element analysis [1]. Additionally, we created a finite element analysis model simulating a tank structure manufactured through filament winding. Applying fatigue analysis to the 2D tank model, we evaluated the stiffness values for each fatigue cycle and attempted to predict the residual strength after fatigue. For residual strength prediction, we performed fatigue analysis up to a predetermined target fatigue cycle, used the evaluated damage variables as initial values for strength prediction, and assessed the internal pressure until the tank burst.

2. Numerical simulation method

2.1. Continuum damge mechanics and static damage model

In continuum damage mechanics, the deterioration behavior of materials due to damage occurring within the material is described by a parameter called the damage variable, which is used to formulate the residual stiffness. The damage variable represents the extent of damage, with 0 indicating an undamaged state and 1 indicating a state where the load transfer capability is completely lost due to full damage. In this study, to describe the intralaminar damage occurring within composite materials, three components of in-plane damage variables, d_{ij} (ij = 11: fiber direction, ij = 22: transverse direction, ij = 12: shear direction) are utilized.

The model for damage progression under static loading is presented in Eqs. (1) to (3) [1,2]. Taking into account the brittle fracture in the fiber direction, the damage variable $d11$ abruptly increases from 0 to 1 when fiber failure occurs. The thermodynamic force at d_{11}=1 is determined from the fiber direction strength obtained from tensile testing of 0° unidirectional specimens (see Table I). Damage evolution laws for the transverse and shear directions are formulated as second-order functions of the square root of the equivalent thermodynamic force Y_{12}+b_2Y_{22}. The parameters of the model are determined through best fitting to experimental results. The experimental data used consisted of stress-strain curves obtained from tensile loading-unloading tests conducted on various types of laminates.

$$d_{11} = \begin{cases} 0 & \text{if } Y_{11} < Y_{11}^{s} \\ 1 & \text{if } Y_{11} \geq Y_{11}^{s} \end{cases} \tag{1}$$

$$d_{12} = f_1\left(\sqrt{Y_{12} + b_2 Y_{22}}\right)^2 + f_2\sqrt{Y_{12} + b_2 Y_{22}} + f_3 \tag{2}$$

$$d_{22} = b_3 d_{12} \tag{3}$$

2.2. Fatigue dmage model and simulation method for prediction of residual strength

In this study, a fatigue simulation based on continuum damage mechanics was applied [3]. Intralaminar damage, predominantly characterized by resin cracking, was considered dominant, with the influence of fiber direction properties deemed insignificant. Thus, fatigue damage calculations were conducted for in-plane shear d_{12}, and transverse direction d_{22}. Fatigue simulation was performed using the fatigue damage models proposed by Ref. [3]:

$$\frac{d(d_{12})}{dN} = c_{1,12}\tilde{Y}\exp\left(-c_{2,12}\frac{d_{12}}{\sqrt{\tilde{Y}}}\right) + c_{3,12}d_{12}\tilde{Y}^2 \tag{4}$$

$$\frac{d(d_{22})}{dN} = b_3 \frac{d(d_{12})}{dN} \tag{5}$$

For the determination of parameters ($c_{1,12}$, $c_{2,12}$, $c_{3,12}$) of the fatigue model, data of normalized stiffness from three-point bending fatigue tests conducted on laminates with two different curvatures were utilized.

In this fatigue analysis, it was assumed that fatigue damage progresses at the point where maximum load is applied during fatigue loading, and a method of repeating the analysis at the maximum load was adopted. The flow of this analysis begins with performing finite element analysis with the maximum load starting from cycle number $N = 1$. Subsequently, the damage variables d_{ij} are computed for every ΔN cycles. At cycle number N^k where the analysis is conducted, a stiffness matrix utilizing the damage variables d_{ij} is created, finite element analysis is performed, and the displacement field is converged. Upon convergence, the damage after ΔN^k cycles is updated using the following equation.

$$d_{ij}^{k+1} = d_{ij}^{k} + \left.\frac{d(d_{ij}^{k})}{dN}\right|_{N^k} \times \Delta N^k \tag{6}$$

The updated damage variables d^{k+1} are used as inputs to proceed with the calculation steps for the next N^{k+1} cycles. This procedure is repeated until the desired number of cycles is reached.

This study presents an overview of the proposed residual strength calculation method. To predict the residual strength, damage occurring in CFRP is represented using damage variables d_{ij} based on continuum damage mechanics. In the proposed residual strength calculation, fatigue analysis based on continuum damage mechanics is applied as a method to predict fatigue damage. Initially, fatigue damage analysis is conducted up to a specific number of cycles, and the post-fatigue damage variables for each element of the FEM model are outputted. Subsequently, this data is provided as the initial damage state for each element of the FEM model, and residual strength is predicted by conducting static damage analysis using the static model.

3. Static burst simulation

3.1. FEM model and simulation condition

Figure 1 illustrates the FEM model of the composite tank utilized in this study. The laminate configuration of the tank model is summarized in Table 1. A 2D mesh is converted into a 3D model with thickness in the θ direction in cylindrical coordinates, with each layer having a thickness of 1°. Analysis was conducted with boundary conditions to achieve axisymmetric analysis for this FEM model. Additional boundary conditions include imposing symmetry conditions assuming symmetry along the longitudinal direction and restraining the radial displacement to 0 at the tip of the dome section. In the static analysis, the internal pressure was gradually increased from 0 MPa across the entire inner surface to simulate a burst test. The analysis was continued until the tank deformed significantly or the calculation no longer converged.

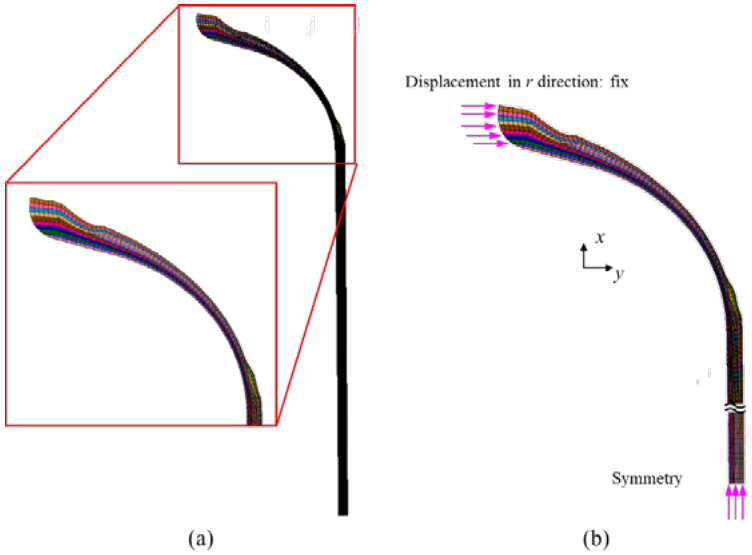

Figure 1. (a) FEM model of composite tank and (b) boundary conditions.

Table 1. Stacking sequence of composite tank.

	Numberof ply	Angle [deg.]
Helical	2	21.0
Hoop	3	88.9
Helical	4	17.0
Hoop	2	88.9
Helical	2	30.0
Helical	2	15.1
Hoop	2	89.0
Helical	2	73.0
Helical	2	15.1
Hoop	2	89.0

3.2. Results

Figure 2 and Figure 3 depict the damage distributions at failure obtained from the static damage analysis. When the internal pressure was increased from 0 MPa to 70.2 MPa, Figures 2 and 3 represent contour plots of the damage variables d_{11} (fiber direction damage) and d_{22} (transverse direction damage), respectively. Regarding the fiber direction damage, it can be observed that as the internal pressure is increased to a certain extent, fiber rupture occurs in the hoop layer at the center of the cylinder section, leading to significant deformation of the cylinder section and subsequent propagation of fiber rupture throughout the cylinder section. On the other hand, for the transverse direction damage d_{22}, although there are localized areas of failure at some parts of the tip, damage and failure predominantly occur in the helical layer of the cylinder section prior to fiber rupture. Eventually, it was confirmed that failure occurred throughout the entire cylinder section up to 70.2 MPa. In this analysis, the pressure of 70.2 MPa, at which significant deformation occurred, was predicted as the burst pressure of the tank in numerical analysis.

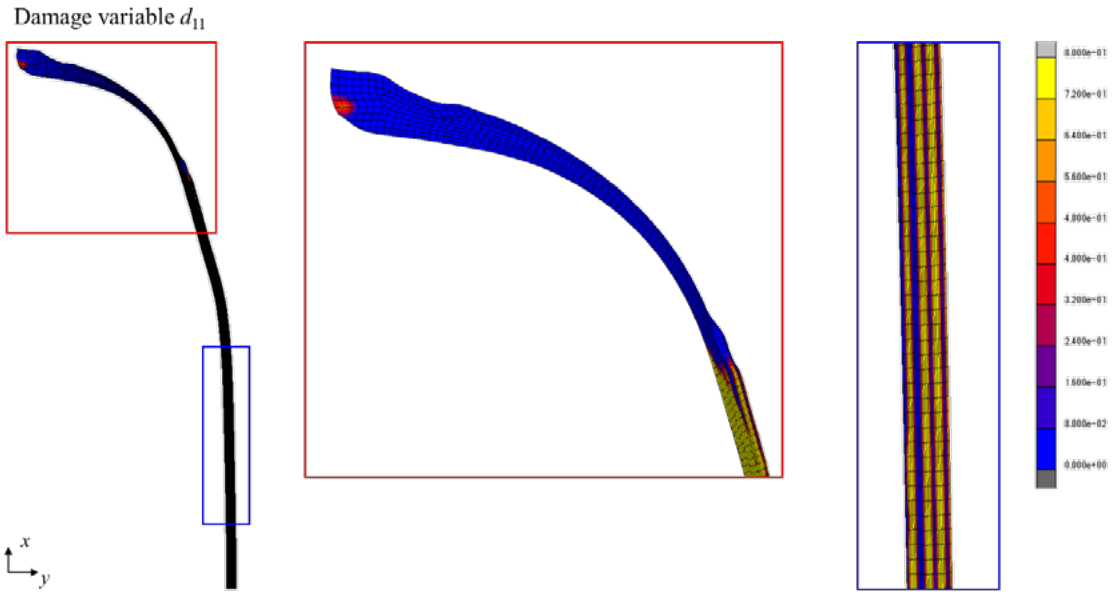

Figure 2. Damage distribution d_{11} at tank burst.

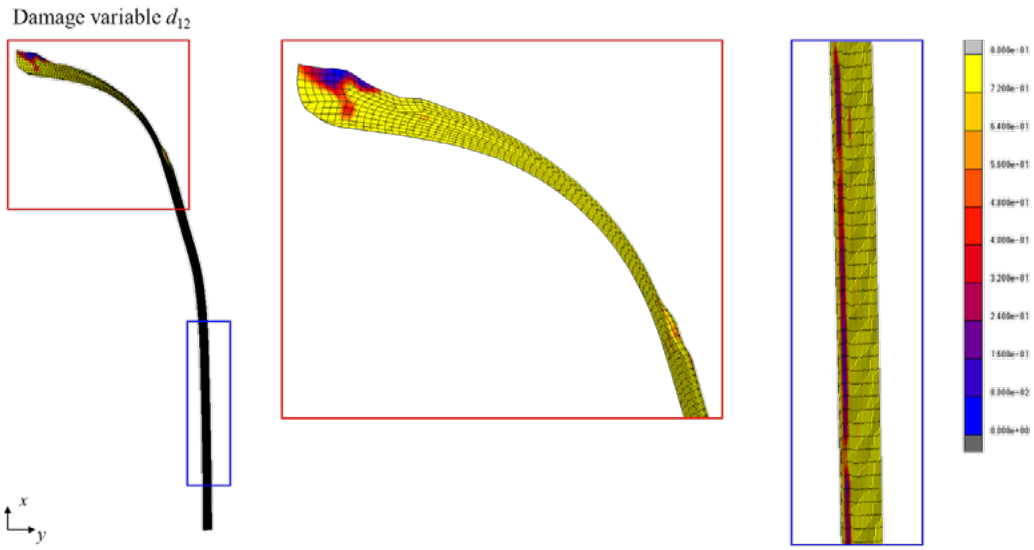

Figure 3. Damage distribution d22 at tank burst

4. Fatigue simulation

4.1. Simulation condition

Regarding the conditions for fatigue analysis, the same boundary conditions as those for static damage analysis were applied. Symmetry conditions were imposed assuming symmetry along the longitudinal direction, and constraints were applied to fix the radial displacement to 0 at the tip of the dome section. For the internal pressure, it was gradually increased from 0 MPa across the entire inner surface until reaching the target pressure. In fatigue analysis, the analysis was continued until the tank deformed significantly and the calculation no longer converged or until the target number of cycles was reached. For the fatigue conditions, internal pressure levels of 30%, 50%, and 70% were considered, with corresponding maximum internal pressures of 21, 35, and 49 MPa, respectively, for each fatigue cycle. The target number of cycles was set to 10,000 cycles for all internal pressure levels, and fatigue analysis was conducted accordingly.

4.2. Results

Figure 4 and Figure 5 show damage distributions of resin in the dome and cylinder parts, respectively, obtained from fatigue analysis. They present contour plots of the damage variable d_{22} at cycle numbers of 1 cycle and 10,000 cycles. When considering the 50% internal pressure level, at 1 cycle, except for the region where the dome tip is fixed, damage occurs predominantly in the outermost layer of the bent portion, resulting in resin cracking. As the fatigue cycles increase, it can be observed that the region of failure in the bending portion of the dome expands longitudinally. At the 30% internal pressure level, almost no resin damage occurs even at 10,000 cycles, whereas at the 70% level, matrix failure is widespread.

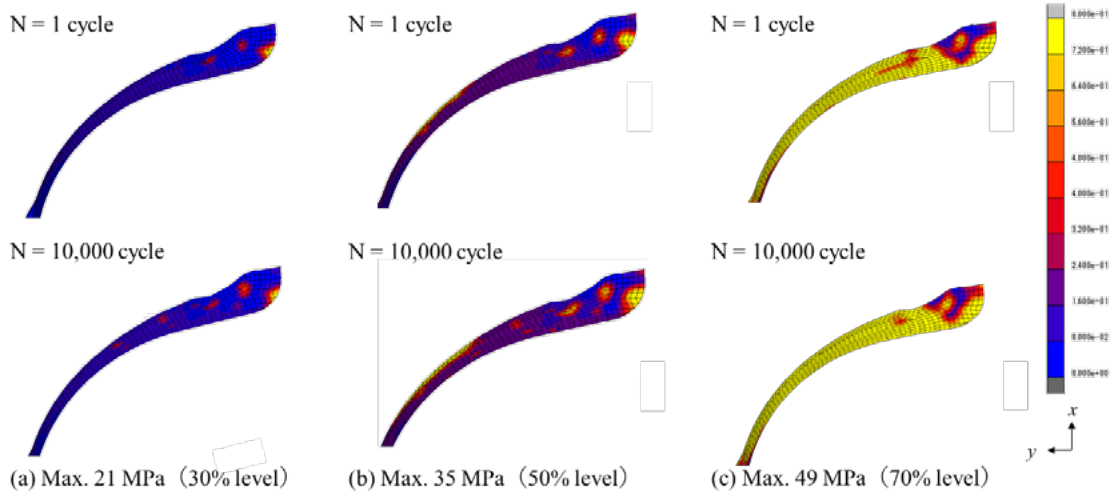

Figure 4. Fatigue damage distribution d_{22} in dome section of composite tanks.

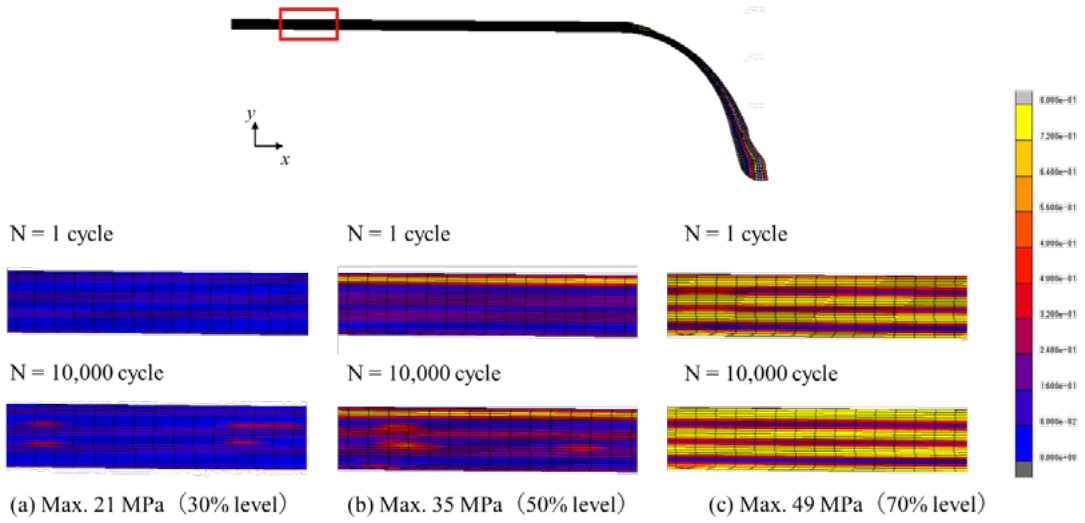

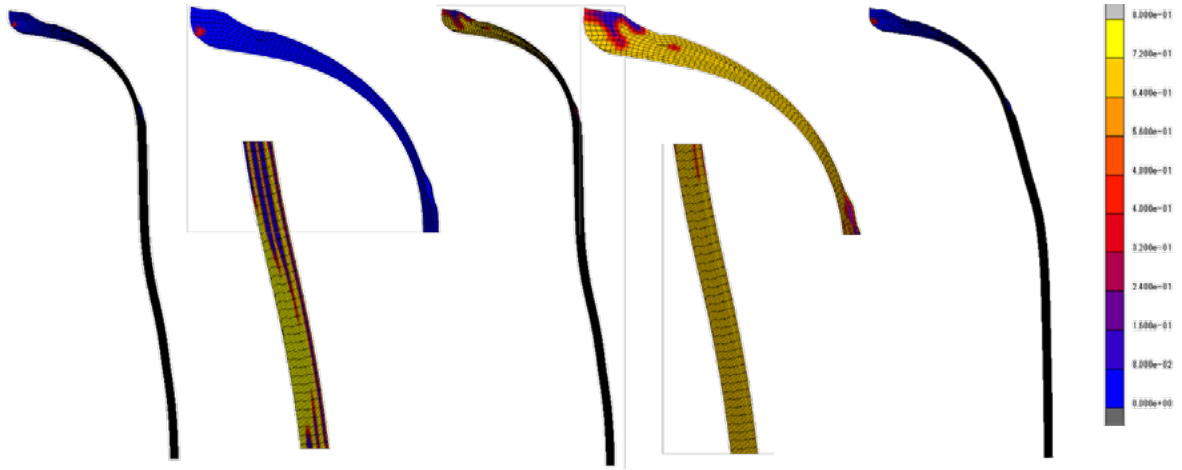

Figure 5. Fatigue damage distribution d_{22} in cylinder section of composite tank.

5. Prediction residual burst pressure after fatigue

We conducted a prediction of residual strength under the fatigue analysis conditions presented in the previous section, specifically focusing on the 50% internal pressure level condition. Following fatigue analysis of 10,000 cycles at the 50% internal pressure level, we performed static damage analysis using

the resulting damage distribution as the initial state.

The results of residual strength prediction at the 50% internal pressure level are shown in Figure 6. In burst failure after fatigue at the 50% internal pressure level, similar to the case without fatigue, fiber failure occurred in the hoop layer at the center of the cylinder, leading to final rupture. After fiber fracture in the cylinder section, significant deformation of the cylinder section occurred, and the propagation of fiber fracture within the cylinder section was observed. The burst pressure after fatigue at the 50% internal pressure level was 61.2 MPa, approximately 13% lower compared to the case without fatigue. Deformation is prone to occur due to resin damage caused by fatigue, resulting in an increase in stress along the fiber direction, which likely led to earlier rupture compared to the fatigue-free case.

(a) Case: 50% level
Damage variable d_{11}

(b) Case: 50% level
Damage variable d_{22}

(c) Case: No fatigue

Figure 6. Damage distribution at tank burst in residual strength prediction.

6. Conclusions

This study attempted to predict the internal damage progression due to internal pressure fatigue and the residual burst pressure after fatigue in composite material tanks. The internal damage of composite material tanks was represented using damage variables based on continuum damage mechanics. We applied damage progression models under static loading and fatigue loading based on continuum damage mechanics. A two-dimensional finite element model of the composite material tank was created, and static damage analysis was first conducted to predict the burst pressure. Subsequently, fatigue analysis under three internal pressure conditions was performed to predict the fatigue damage progression inside the tank. Finally, an attempt was made to predict the residual burst pressure after fatigue. By conducting static damage analysis using the fatigue damage distribution obtained from fatigue analysis as initial values, predictions of residual strength were made. As a result, it was demonstrated that the residual burst pressure after fatigue decreased due to the increased susceptibility of the tank to deformation caused by fatigue damage.

Keywords: 3D printing, continuous fibre-reinforced polymers, variable-stiffness, vibration, natural frequency

Abstract
In the present study, variable-stiffness 3D printed continuous carbon fibre-reinforced thermoplastic laminates were designed, manufactured, and tested, to improve the dynamic behaviour of plates. The fibre trajectory of the variable-stiffness laminates was described by a curvilinear function; this way, the design-oriented model could be parametrized based on the finite element method. Fibre orientation angles were considered as design variables. A genetic optimisation algorithm was used to obtain the laminate configuration for different optimisation cases over the first two natural frequencies for a plate with one embedded edge and three free edges. Finally, the most promising laminates were printed and tested. The non-conventional 3D printed laminates showed an improvement of the individual natural frequencies of more than 25%, a combined increase of the first two natural frequencies of more than 10%, and a spacing of the first two natural frequencies of up to 45% compared to the quasi-isotropic reference laminate. This study is a contribution to the design and manufacture of 3D printed continuous fibre composites, and an additional step towards producing high-performance functional components for actual applications using 3D printing.

1. Introduction

The 3D printing technology of fused filament fabrication of continuous fibre-reinforced thermoplastics shows great potential for the production of the next generation of lightweight structural parts [1]. One of the most promising possibilities offered by this technology is its ability to steer fibres through curved tracks making it suitable for manufacturing variable-stiffness (VS) laminates [2]. These laminates can be used to customise the behaviour of panels, such as the vibration behaviour [3]. The effectiveness of these laminates in improving vibration performance has already been studied in recent years for traditional composites [4,5]. However, the applicability of 3D printing technology to manufacture non-conventional laminates for vibration attenuation has not been explored to date.

The aim of the present study, therefore, is to evaluate the capacity of continuous fibre 3D printing to manufacture variable-stiffness laminates that enhance the dynamic response of structural components. To this end, we designed, manufactured, and tested variable-stiffness plates with optimised vibration behaviour (natural frequencies). The performance of these non-conventional laminates was compared to that of a reference constant-stiffness quasi-isotropic laminate.

2. Problem statement and methodology

In this study, rectangular plates with a length L of 180 mm and a width W of 90 mm were analysed, resulting in a L/W ratio of 2. The boundary conditions were one embedded edge and three free edges, as shown in Figure 1.

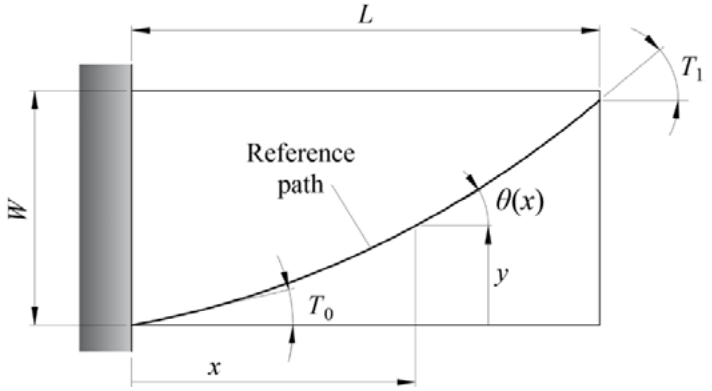

Figure 1. Embedded plate configuration and $\langle T_0|T_1\rangle$ reference fibre path.

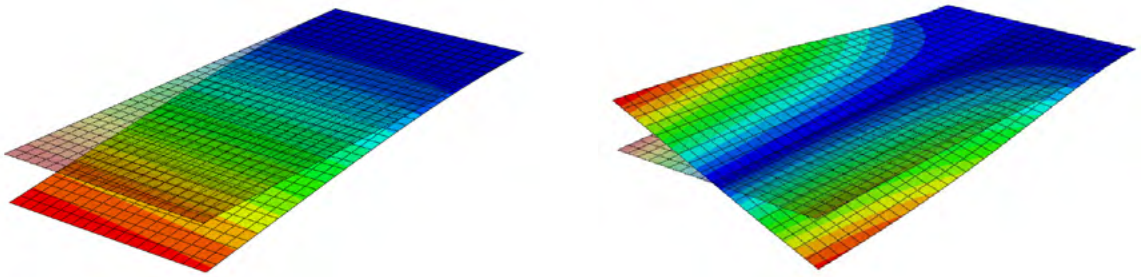
To manufacture the laminates, we used the fused filament fabrication (FFF) 3D printing technology of preimpregnated filament from Markforged®. Among the materials available for this technology, continuous carbon fibre reinforced polyamide (cCF/PA) was chosen because of its higher stiffness. Previous studies [1,6] analysed and reported on the microstructure, content, and mechanical behaviour of cCF/PA. This technology includes bottom and top layers of Onyx™, a polyamide 6 reinforced with carbon micro-fibres. In this study, only a top and bottom layer of Onyx were included. Curvature radii of up to 1 mm can be created with this technology; however, radii smaller than 15 mm should not be used to avoid twisting and fibre breakage [7]. The 380 µm diameter filament is flattened during the process to a thickness of 125 µm (the printed layer's thickness) and a bead width of about 0.9 mm.

The widely used definition of fibre orientation proposed by Gürdal and Olmedo [8] was applied in the steered-fibre layers. The orientation angle $\theta(x)$ of the reference fibre path varies linearly with respect to the x-position, from T_0 at the embedded edge to T_1 at the opposite free edge (Figure 1 and Eq. 1). By shifting the reference path in the direction of the y-axis, the entire steered-fibre layer is produced. As a result, each layer's orientation is specified by just two parameters (T_0 and T_1), which are referred to as $\langle T_0|T_1\rangle$. Layers having equal but opposing orientations, $\pm\langle T_0|T_1\rangle$, are typically combined by employing this solution.



$$\theta(x) = \frac{(T_1 - T_0)}{L}x + T_0 \tag{1}$$

The designed laminates are symmetrical and balanced with 18-ply (16 cCF/PA and two outer Onyx), resulting in a nominal sample thickness of 2.25 mm. A quasi-isotropic (QI) laminate of $[0/45/90/\text{-}45]_{2s}$ stacking sequence was assumed as the reference laminate. The designed VS laminate consists of 2 pairs of steered-fibre layers on each face and eight inner layers of straight-fibres, in a $[\pm\langle T_{10}|T_{11}\rangle/\pm\langle T_{20}|T_{21}\rangle/0/45/90/\text{-}45]_s$ stacking sequence. Straight-fibre layers were included to minimise the effect of manufacturing constraints in the steered-fibre layers and to stiffen the weaker directions.

With this approach, the design variables of the VS laminate were reduced to four, the orientation of the outer steered-fibre layers: $\pm\langle T_{10}|T_{11}\rangle/\pm\langle T_{20}|T_{21}\rangle$. These orientations were determined by optimisation studies in the 0°–90° range of $\langle T_0|T_1\rangle$ potential angles using the commercial finite element method (FEM) package Abaqus and the genetic algorithm (GA) optimization method implemented in Matlab programming platform. The parametric FEM model configuration was implemented in a user-developed

Python script for Abaqus. Reduced integration quadrilateral shell elements (S4R) were used in the model, with a general edge length of 5 mm. Each element of the FEM model was associated with a specific lay-up based on the centroid position of each element. Optimisation of the fibre orientation was carried out using the GA method implemented in Matlab. For each individual of a generation, the Python script was adapted and its behaviour (natural frequencies) was determined. The GA Matlab code was configured with a number of generations of 20 and a population size of 100.

Figure 2 shows the first two vibration modes of the QI laminate determined by FEM. The first is the fundamental bending mode with a natural frequency f_1 of 50.7 Hz. The second is the fundamental torsional mode, with a natura frequency f_2 of 175.4 Hz. Four cases were studied for the design of the laminate using the FEM-GA optimisation method, depending on the objective: (1) f_1 maximisation, (2) f_2 maximisation, (3) $f_2 - f_1$ maximisation (i.e. maximise the separation between the two natural frequencies), and (4) equally weighted maximisation of f_1 and f_2.

(a) (b)

Figure 2. First two modes of the QI laminate determined by FEM: (a) first fundamental bending mode at 50.7 Hz, and (b) second mode, torsional, at 175.4 Hz.

Finally, the most promising laminates were manufactured and tested. The plates were made 30 mm longer so that they could be clamped between two steel profiles bolted to a test platform (Figure 3). The natural frequencies were obtained from the characteristic frequency response functions (FRF). A medium-sized impact hammer (B&K 8206-003 REF) was used to excite the plate and the response was measured with a light triaxial accelerometer (B&K 4525 B REF). To minimise the influence of the accelerometer mass, it was placed close to the mounting, at 30 mm from the embedment in the x-axis and 20 mm from the free side in the y-axis (Figure 3). Excitation was performed with an impact hammer at a point symmetrical to the accelerometer position. The signals were recorded and processed in the PULSE Labshop spectrum analyser. A time period of 4 s was measured for a frequency resolution of 0.25 Hz and a frequency range of 1600 Hz was obtained with a sampling frequency of 4096 Hz.

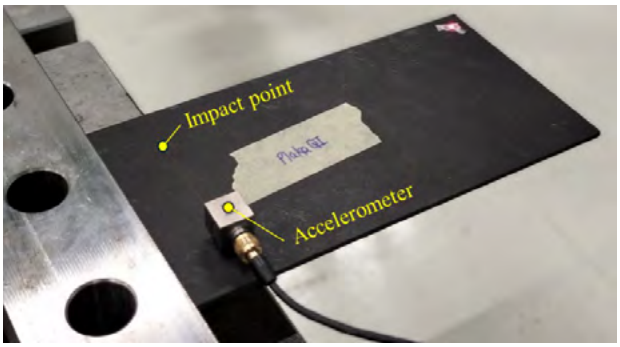


Figure 3. Experimental set-up of the measurements of the dynamic behaviour of the plates.

3. Results and discussion

The optimal fibre orientations and natural frequencies obtained with the FEM-GA method are shown in Table 1 for the four cases considered, as well as the results for the reference QI laminate.

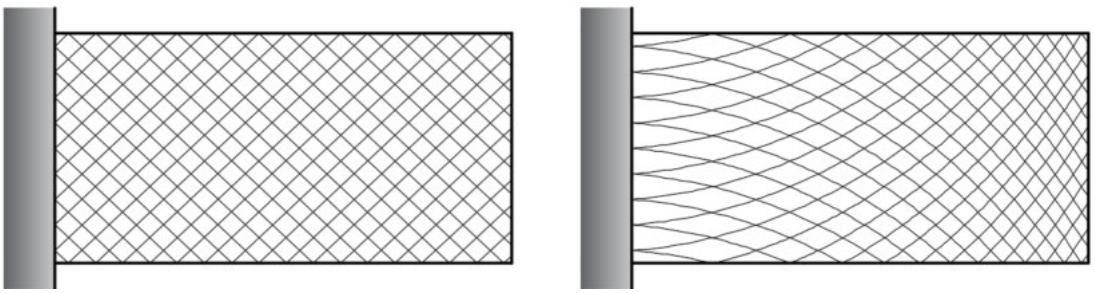

Table 1. Results obtained with the FEM-GA method: optimal fibre orientations and the corresponding first two natural frequencies.

Case	Objective	$\pm\langle T_{10}\|T_{11}\rangle$ / $\pm\langle T_{20}\|T_{21}\rangle$ (º)	f_1 (Hz)	f_2 (Hz)
Ref.	QI reference	-	50.7	175.4
1	f_1 maximisation	$\pm\langle 0.3\|0.3\rangle$ / $\pm\langle 0.1\|0.4\rangle$	69.0	126.5
2	f_2 maximisation	$\pm\langle 32.8\|54.8\rangle$ / $\pm\langle 32.6\|56.6\rangle$	42.7	226.3
3	Δf maximisation	$\pm\langle 45.6\|39.1\rangle$ / $\pm\langle 42.9\|46.8\rangle$	37.3	223.6
4	f_1 & f_2 maximisation	$\pm\langle 4.8\|50.5\rangle$ / $\pm\langle 2.7\|73.0\rangle$	60.9	201.1

The first case, which seeks to maximise the first natural frequency f_1, gives a result that tends towards a constant-stiffness (CS) laminate with fibres oriented in the longitudinal direction (0°). This is consistent because it is a bending mode. With this configuration, the first natural frequency increases by 36%, while the second natural frequency decreases by 28% compared to the QI laminate. For the maximisation of the second natural frequency f_2 of the torsional mode (Case 2), the optimal result is a VS laminate with fibres oriented from approximately 33° at the embedded edge to 55° at the outer free edge (Table 1). In this case, the second natural frequency increases by 29% versus QI, while f_1 decreases by 16%.

To maximise the separation between the first two natural frequencies (Case 3), the model proposes a solution that tends towards a CS laminate with straight-fibres with an orientation close to 45° (Table 1). With this configuration, the natural frequencies separation is increased by 49% compared to the QI laminate. Finally, in Case 4, where weighted maximisation of the first two natural frequencies is sought, the FEM-GA method results in a VS laminate with steered-fibre having a longitudinal orientation at the embedded edge and an oblique orientation at the free edge. With this configuration, the natural frequencies are increased by up to 20% compared to the QI laminate.

The two most interesting configurations (Cases 3 and 4) and the QI reference laminate were manufactured and tested. The configuration of these laminates is shown in Table 2 and Figure 4. For Case 3, which seeks to maximise the separation between natural frequencies, a CS laminate was manufactured with the outer layers at ±43 (Figure 4a), the optimal orientation determined with the FEM-GA method. For Case 4, where weighted maximisation of the first two natural frequencies is sought, a VS laminate with steered-fibre outer layers was manufactured at $\pm\langle 4.2|57.2\rangle$ (Figure 4b). Unlike the initial optimisation where the laminate contained two pairs of different steered-fibre layers, in this case we opted for two pairs of the same type of steered-fibre layer, as the results are similar but the fabrication is simpler. The manufacturing by 3D printing of the steered-fibre layer is shown in Figure 5.

(a) (b)

Figure 4. Configuration of the manufactured laminates: (a) ±43 fibre orientation for the CS laminate, (b) $\pm\langle 4.2|57.2\rangle$ steered-fibre layers configuration for the VS laminate.

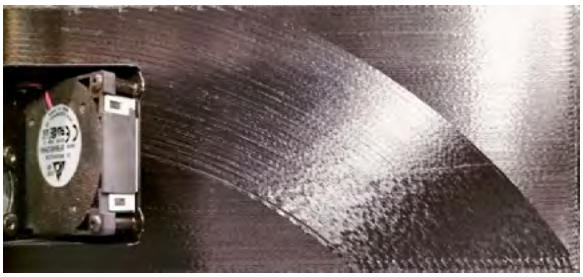

Figure 5. Manufacturing by 3D printing of the steered-fibre -⟨4.2|57.2⟩ layer.

The results of both the FEM model and the tests for the three laminates are given in Table 2, and the measured experimental FRFs are shown in Figure 6. The natural frequencies determined with the model are slightly higher than those measured in the test (below 10%). This may be due to factors such as the difficulty of reproducing an ideal embedding in tests, the low interlaminar properties of the printed material or the influence of defects produced in 3D printing. The difference is smaller for the torsional mode (mode 2), less than 4%. This may be because this mode is less sensitive to the way the plate is embedded.

Table 2. Characteristics and results of the three laminates manufactured and tested.

Laminate type	Objective	Stacking sequence	f_1 (Hz)		f_2 (Hz)	
			Test	Model	Test	Model
QI	Reference	$[0/45/90/-45]_{2s}$	47.5	50.7	172.5	175.4
CS	Δf max.	$[\pm 43_2/0/45/90/-45]_s$	35.0	38.2	216.0	224.3
VS	f_1 & f_2 max.	$[\pm\langle 4.2\|57.2\rangle_2/0/45/90/-45]_s$	54.5	59.7	192.0	198.6

Experimental results confirm the behaviour predicted by the FEM model (Table 2 and Figure 6). The CS laminate extends the frequency range between the first two modes by 45% compared to the QI laminate. It is also observed in the FRF of the CS laminate that the third mode is close to the second mode (Figure 6). This is because this laminate configuration causes the third mode, corresponding to a bending mode, to experience a decrease in its natural frequency, approaching the torsional mode.

In the VS laminate, the experimental results also evidence an increase in the natural frequencies of the first two modes, as shown in Table 2 and Figure 6. The first natural frequency increases by 15% and the second by 11%. The reason for this improvement is a favourable stiffness distribution that favours both bending and torsional modes. This requires an orientation of the fibres from an oblique orientation at the free edge to a longitudinal orientation at the embedded edge.

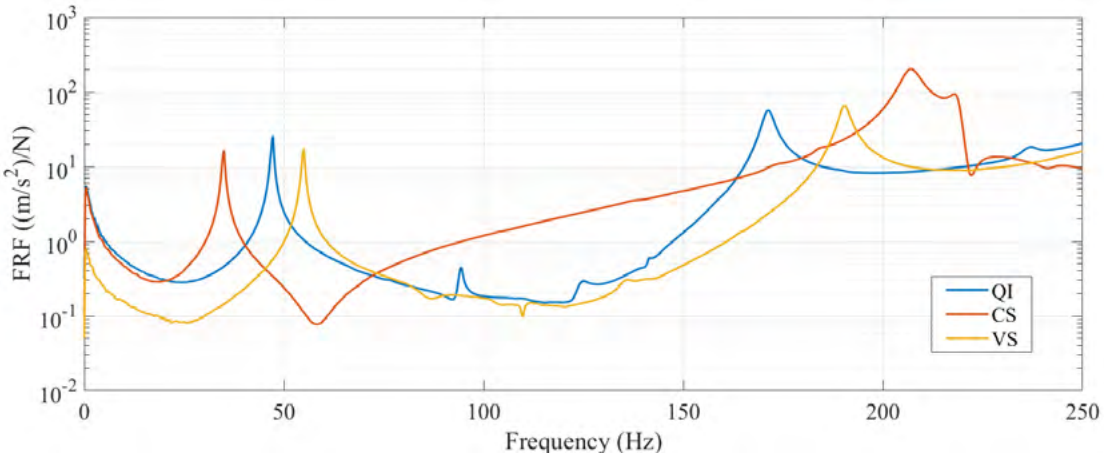

Figure 6. Experimental FRFs of the three types of laminates for a range between 0 and 250 Hz. The displacement of the modes can be observed relative to the QI laminate.

4. Concluding remarks

This study has demonstrated that continuous fibre 3D printing technology is valid to manufacture non-conventional laminates that improve the dynamic response of structural components. Compared to a constant stiffness QI laminate, the first two natural frequencies can be increased by more than 10% or spaced by up to 45%.

These results encourage further progress in the use of 3D printing to manufacture high-performance functional components in real applications, with emphasis on capabilities of this technology such as: high steering capacity of the fibre path, higher damping properties of thermoplastic matrices compared to thermosets, and the potential to print multi-material and functionally graded structures.

Keywords: Mode II, Fatigue, Composite Material

Abstract
Understanding the behavior of composite laminates against fatigue crack initiation and growth is essential to accurately predict component life and establish safe maintenance periods.

In this paper we present and validate an extrapolation procedure to characterize the mode II fatigue behavior based on the $\boldsymbol{J}_{0i}$ **-**$\boldsymbol{C}_{0i}$ and $\boldsymbol{\Delta}_{0i}$ **-**$\boldsymbol{C}_{0i}$ master curves.

The extrapolation procedure, based on compliance variation, assumes that all effects associated with damage are included in the equivalent crack length. In this method, new factored expressions of compliance ($\boldsymbol{C}_{0i}$), *J*-Integral ($\boldsymbol{J}_{0i}$) and crack tip displacement ($\boldsymbol{\Delta}_{0i}$) are defined. According to their polynomial expressions with respect to the equivalent crack length, invariant relationships between $\boldsymbol{J}_{0i}$ **-**$\boldsymbol{C}_{0i}$ and $\boldsymbol{\Delta}_{0i}$ **-**$\boldsymbol{C}_{0i}$ are obtained for a given material system and test configuration.

Once the master curves have been calibrated, the extrapolation procedure enables the characterization of a material system's fatigue behavior by determining the Paris law during the fatigue test. This is done by monitoring only the test compliance and the maximum load concerning the number of cycles.

1. Introduction

The use of composite materials in structural components within the automotive and aeronautical industries has been increasing due to their numerous advantages, such as high stiffness, superior fatigue resistance, and significant potential for weight reduction. However, composite materials are prone to delamination damage because of their low interlaminar strength in the thickness direction, which can occur during both manufacturing and service. Additionally, delamination damage can propagate during use due to fatigue loading, which can impact the service life of the component. Therefore, it is

crucial to understand the initiation and growth behavior of delamination damage to accurately predict component life and establish safe maintenance intervals. [1].

In composite laminates, crack growth is assessed through fatigue tests using the energy release rate G as the loading parameter to obtain the experimental fatigue crack propagation curve da/dN versus G. While there is no standardized method to characterize the fatigue behavior of composite laminates under Mode II loading, the End-Notched Flexure (ENF) test setup is the most widely used for Mode II fatigue-induced delamination studies. [2,3].

Measuring crack growth under cyclic loading in Mode II is challenging because the crack propagates without a clear opening, making visual inspection difficult. To address this, numerous researchers have proposed various compliance-based strategies to monitor crack length during fatigue testing. [4,5]. These methodologies eliminate the need for visual inspection, enabling uninterrupted testing and providing real-time experimental data..

Renart et al. [4] proposed a procedure to determine the crack length of a specimen by continuously monitoring its compliance. They defined a dynamic compliance to avoid the effects of initial nonlinearities that can occur during experimental tests, as the ratio between displacement and load amplitudes.

On the other hand, de Moura et al [5] proposed and validated a data reduction procedure based on the equivalent crack concept, taking into account the effect of the fracture process zone (FPZ).

The aim of this work is to validate the extrapolation procedure based on the master curves recently presented [6], to characterize the fatigue behavior in mode II.

2. Metodology

Recently, a compliance-based data reduction method has been proposed to determine the energy release rate J and the relative crack tip displacement Δ in both Mode I and Mode II as a function of the equivalent crack advance[7,8]. This method, based on beam theory, assumes that all effects associated with damage development are included in the equivalent crack length obtained from the compliance variation. Analytical expressions have been derived for the compliance C, the relative displacement at the crack tip Δ, and the J-Integral, all as functions of the elastic properties of the adherends, the test configuration, the cross-sectional dimensions of the specimens, the applied load, and the equivalent crack length (a_e).

By rewriting the expressions of C, the Δ and the J-Integral in the form of a multiplication of separate functions, new factored expressions are defined with respect to the applied load and the adhesive and adherend thicknesses, of the compliance ($\boldsymbol{C}_{0i}$), the J-Integral ($\boldsymbol{J}_{0i}$) and the crack tip displacement $\boldsymbol{\Delta}_{0i}$.

Assuming that all effects associated with damage are included in the equivalent crack length, and according to the polynomial expressions of $\boldsymbol{J}_{0i}$, $\boldsymbol{C}_{0i}$ and $\boldsymbol{\Delta}_{0i}$ with respect to it, invariant relationships between $\boldsymbol{J}_{0i}$ -$\boldsymbol{C}_{0i}$ and $\boldsymbol{\Delta}_{0i}$ -$\boldsymbol{C}_{0i}$ are obtained for a given material system and test configuration.

Assuming the invariant character of the curves $\boldsymbol{J_{0i}}$ **-**$\boldsymbol{C_{0i}}$ and $\boldsymbol{\Delta_{0i}}$ **-**$\boldsymbol{C_{0i}}$, the *Master Curves* for mode II are extracted from the data of a single specimen following the flow chart shown in Fig. 1.

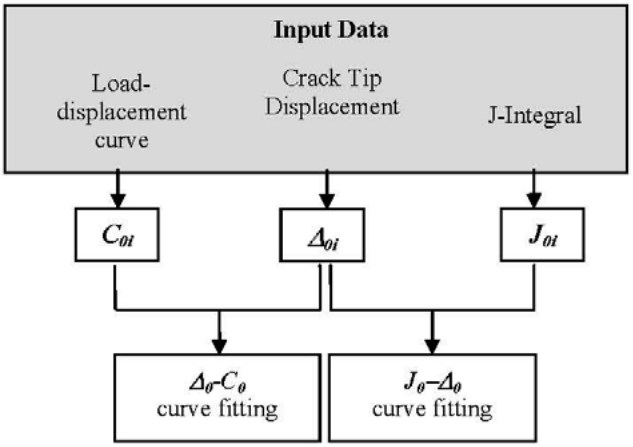

Figure 1. Flowchart to obtain the Master Curves

Once the *Master Curves* have been obtained, following the extrapolation procedure shown in Fig. 2, the results can be extrapolated to different specimen configurations by processing only the test compliance and the maximum load with respect to the number of cycles.

In this case, by applying the extrapolation procedure, both the *J*-integral as a function of the number of cycles and the crack growth rate are obtained.

$$J = \frac{3{P_{max}}^2}{w^2(2h)^3}\ \boldsymbol{J}_0(a_e) \tag{1}$$

$$\frac{da}{dN} = \frac{1}{2J_0}\frac{dC_0}{dN} \tag{1}$$

It is also feasible to experimentally analyze the fatigue-induced degradation of the Cohesive Zone, assessing the impact of severity on the variation of cohesive laws and the evolution of cohesive stress over the number of cycles.

$$\tau_{max} = \frac{6P_{max}}{w(2h)}\ \frac{\boldsymbol{J}_0(a_e)}{\Delta_0(a_e)} \tag{2}$$

$$\Delta_{t\,max} = \frac{P_{max}}{w(2h)^2}\ \Delta_0(a_e) \tag{2}$$

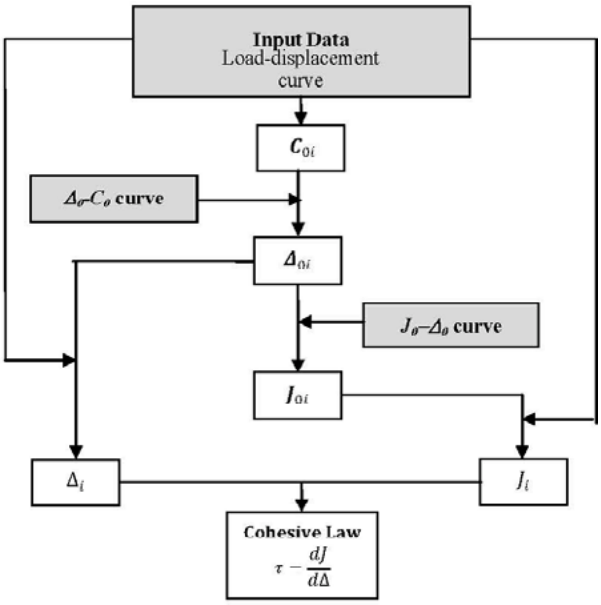

Figure 2. Flowchart for extrapolating the cohesive law

3. Verification of the proposed method and results

In the ENF mode II fracture test, the range of the crack growth rate curve obtained in a single test under constant cyclic displacement is very narrow; therefore, Carreras et al [1] proposed a methodology to measure, in a single test, a region of the crack growth rate curve more extensive than that achieved in a constant cyclic displacement test. The procedure consists of varying the applied displacement, δ_{min} and δ_{max}, keeping constant the displacement ratio, $R= \delta_{min}/\delta_{max}$.

The validity of the extrapolation method for characterizing mode II delamination growth is evaluated by comparing the crack growth rate curves obtained by the extrapolation procedure with those obtained by [1] for variable cyclic displacement tests.

The unidirectional carbon fiber/epoxy specimens tested were 25 mm wide, 3 mm thick and 200 mm long, with an initial crack of 35 mm.

In the ENF test, **Fig.** 3, the support span was 2L = 120 mm and the support rollers had a radius of 5 mm.

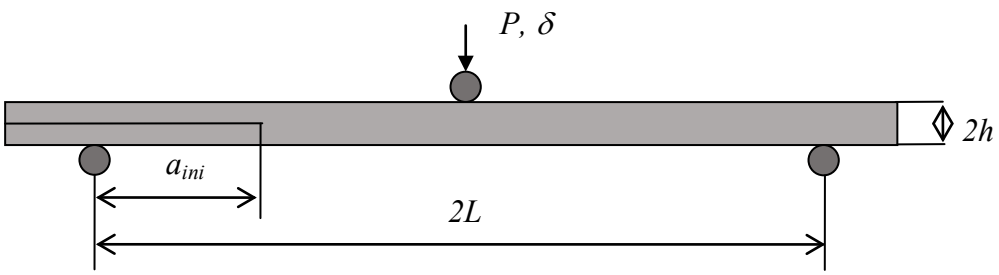

Figure 3. ENF test configuration.

Fig.4 shows the J_{0i} -C_{0i} and Δ_{0i}-C_{0i} curves for different mode II fatigue tests with variable cycling displacement, where the properties of the adherend and the initial crack are maintained.

According to **Fig. 4**, it is found that the curves J_{0I}-C_{0I} and Δ_{0I}-C_{0I} are invariant for a given material system and test configuration also in fatigue.

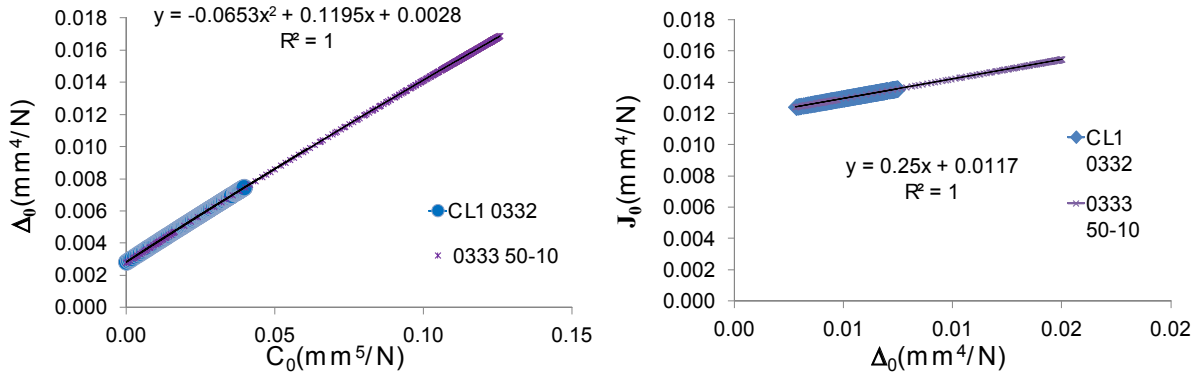

Figure 4. Master Curves J_{0I} -C_{0I} and Δ_{0I} -C_{0I} in mode II.

Applying the extrapolation procedure described above, **Fig. 5** shows the results obtained for the test where the severity varies from %50 to %10.
As observed, the results align with those obtained in [1], indicating that the extrapolation method yields suitable results in fatigue as well.

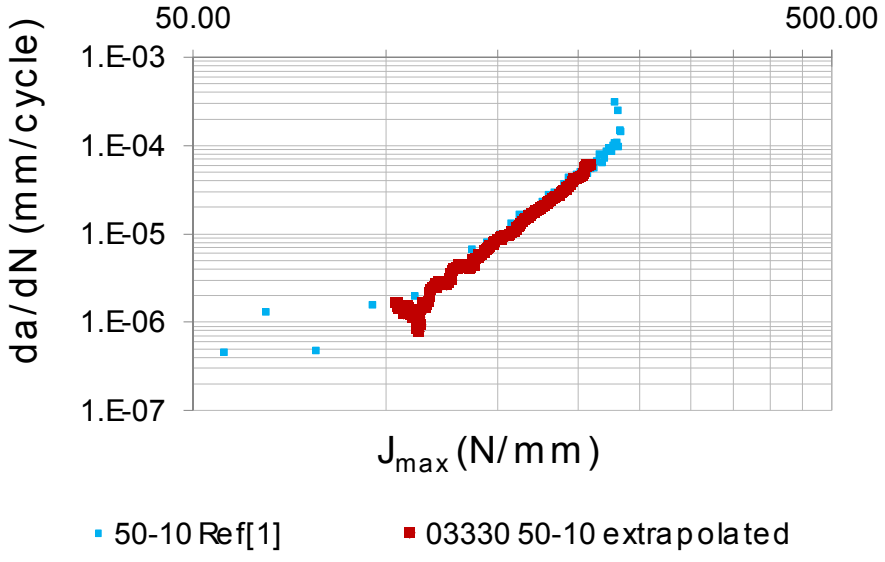

Figure 5. Experimental fatigue crack propagation curve.

Finally, in **Fig. 6a**, the Fatigue-Induced Degradation of the Cohesive Zone is depicted for tests conducted under constant cyclic displacement for varying severities. In **Fig. 6b** the variation of cohesive stress as a function of the number of cycles and severity is illustrated.

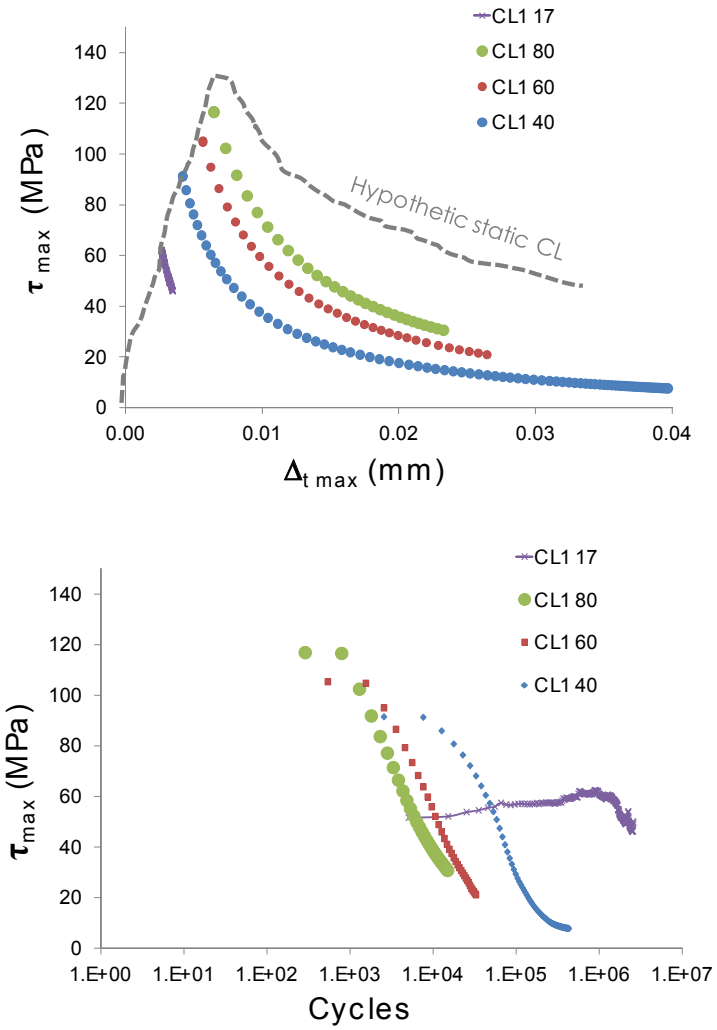

Figure 6. Experimental Fatigue-Induced Degradation of the Cohesive Zone

3. Conclusions

The extrapolation method has been validated to predict the fatigue behavior of composite laminates by determining the experimental fatigue crack propagation curve da/dN versus J, monitoring only the compliance and the maximum load per cycle. The degradation of the Cohesive Zone by Fatigue has also been experimentally determined, analyzing the effect of severity both on the variation of the cohesive laws and on the evolution of the cohesive stress as a function of the number of cycles.

Keywords: Multiscale modelling, Second-order homogenisation, Woven composites, Shell elements

Abstract
Composite materials are extensively used in aerospace, automotive, and construction for their higher strength-to-weight ratio, corrosion resistance, and good fatigue properties. However, their limitations in load-bearing applications, such as poor impact performance and delamination resistance is due to a lack of through-thickness reinforcement in the laminated pre-preg material format. 3D woven composites by contrast, offering through-thickness reinforcement via binder yarns, enhance inter-laminar toughness, impact, and energy absorption, making them ideal for impact-critical structures. Despite these advantages, accurately modelling these composites is challenging due to their complex internal structure and multi-scale nature. Traditional first-order homogenisation is limited by its assumptions on scale separation and representative volume element size, particularly when structural scales are similar to substructural scales. To overcome these issues, advanced second-order homogenisation techniques have been developed, integrating strain gradients and higher-order deformation modes to improve accuracy in bending-dominated scenarios. The current study implements a thick-shell based second-order framework for modeling 2D and 3D woven composites, evaluating their mechanical performance through ASTM standardized tests and comparative studies. It highlights the limitations of conventional shell elements in capturing through-thickness stress variations, suggesting the need for a solid-element based, second-order homogenisation framework for thick structures, indicating future research directions.

1. Introduction

3D-woven composites are becoming prominent in multiple industrial applications, including aerospace, due to their enhanced mechanical properties. As summarised by Tong et al. [1], this includes higher delamination toughness, and better impact damage resistance and post-impact mechanical properties due to the presence of through-thickness reinforcements. As a result, these materials have been used in high loading and impact-prone aerospace structures, such as wing panel joints, landing gear braces, and turbofan engine blades. Manufacturing of woven composites is also cost efficient, since components with complex geometries can be woven to near-net shape, thus providing design flexibility. These advantages also come with challenges, especially when it comes to mathematical modelling, due to their complex internal architecture, and multi-scale behaviour.

Meso-scale deformations have significant effect on global performance, and therefore these deformations need to be modelled accurately in a multi-scale manner. Even though the complex internal architecture can be accurately predicted through experiments and simulation, this information is not enough to predict the final structural behaviour. In conventional solid mechanics problems, scale separation between material properties and global structure is possible using an equivalent constitutive model. This kind of separation is not possible in 3D woven composites since the material behaviour is dependent of manufacturing process and final structural geometry, and therefore the properties can not be calculated at a scale larger than that of the constituents. On the other hand, building detailed models for the full scale structure including all the complex internal architecture is not computationally feasible.

Hence, there is a need for multiscale modelling methods which can link the constituents across the multiple length scales [2].

2. Computational Homogenisation

Homogenisation based approaches are a good choice for problems where scale separation hypothesis is valid. Among the different homogenisation methods presented in literature, computational homogenisation is one of the most accurate schemes to upscale the non-linear behaviour of a well-defined microstructure. It involves solving a set of nested boundary value problems, where both the fine and coarse scale models are solved concurrently. This allows for the evaluation of effective properties from a digital definition of microstructure, without explicit description of all heterogeneities at structural level. This approach is also known as the FE^2 method, as proposed by Smit et al. [3] and Feyel et al. [4].

The first-order (1OH) framework is well-established and has been developed over time for large deformations and with nonlinear behaviour at the fine scale (Fig. 1). However, the assumptions on which the framework is built upon presents certain limitations [5]:

- Separation of scales principle assumption remains valid only in cases where macro-gradients are small and material failure does not occur. So, even if there are higher-order deformation modes like bending at the macroscale, the assumption leads to constant macroscopic deformation gradients (tension, compression and shear) over the RVE length scale.
- Dimensions of the RVE have no effect on the averaging procedure, i.e. if we increase the scale of the microstructure, it will give us the same results. For example, even though 1OH can distinguish between an RVE with a large void and a small void, it can't predict the effects of position of the void. Hence, microstructural and geometrical size effects cannot be accounted for.
- 1OH is not applicable in cases where the substructural length scale becomes comparable with length scale associated with macroscopic spatial variability in the loading, due to the highly localized deformation.

2.1. Second-Order Homogenisation

The second-order homogenisation (2OH) framework was developed to address the limitations mentioned in the previous section. The 2OH framework takes into account the strain gradient, which is the gradient of the macroscopic deformation gradient tensor, thus partly alleviating the assumption of separation of scales (Fig. 1) [6].

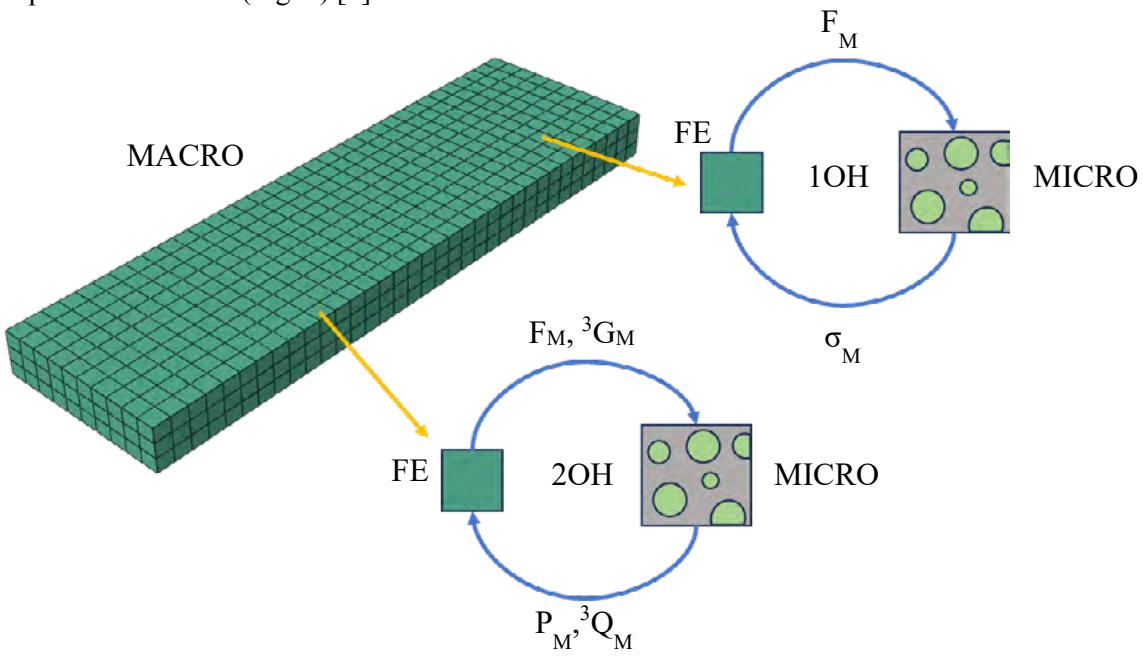

Figure 1. First (1OH) and second (2OH)-order computation homogenisation of continua

Here, the deformation at the mesoscale can be written as:

$$\Delta\vec{x} = F_M \cdot \Delta\vec{X} + {}^1/_2\,\Delta\vec{X} \cdot {}^3G_M \cdot \Delta\vec{X} + \vec{w} \tag{1}$$

Using this Taylor series expansion, the macro-scale kinematics are determined through the deformation gradient tensor F_M and its Lagrangian gradient ${}^3G_M = \vec{\nabla}_{0M}F_M$. (3) is applied to a representative part of the microstructure, such that a classical boundary value problem is obtained at the micro-scale. The macroscopic kinematics are transferred to the RVE through a set of boundary conditions, i.e

$$\vec{u}^* = \vec{f}(\vec{X}, F_M, {}^3G_M) \tag{2}$$

The second-order framework employs higher-order continuum models like strain gradient continuums or shell models at the macroscale, while maintaining first-order for the small-scale boundary value problem. This framework uses an averaging of the Representative Volume Element (RVE) stress field to generate macroscopic and higher-order stress tensors. Unlike the first-order approach, 2OH incorporates a specific length scale defined by the RVE size, which is bounded by macroscopic strain variations and statistical representativeness. This method enhances the assessment of second-order constitutive relations, accommodates micro-length scales, and addresses issues like material gradient sensitivity and macroscopic problem ill-posedness due to localisation and mesh dependency.

2.1. Second-Order Homogenisation using Shell Elements

Shell models, a subset of strain gradient continuum models, are particularly effective in macroscale applications in industry due to their ability to incorporate bending deformations and non-zero strain gradients in a computationally efficient manner. These models are utilised in second-order homogenisation to capture non-linear fine-scale behaviors through numerical averaging, which is crucial for addressing heterogeneities in the through-thickness direction [7] . The homogenisation process within shell models involves discretising the global structure using shell elements, each linked to an underlying solid RVE that resolves full shell thickness. This integration process includes projecting shell basis modes onto the RVE using specific boundary conditions that align with macroscopic gradient averages. Upscaling then involves deriving equivalent shell stresses and constitutive properties from the fine-scale model, which is based on the modified Hill-Mandel condition that ensures consistent strain energy variation across scales [8].

The nonlinear shell homogenisation method developed by Hii and El Said [7] integrates accurate constitutive relations for transverse shear, membrane, and bending components using orthogonality conditions by Luscher et al. [9] This method introduces a novel volumetric constraint that enhances the projection of transverse shear strains to the fine scale, ensuring traction-free conditions on shell surfaces and eliminating spurious modes in RVE transverse shear responses, regardless of its size. Additionally, the framework is adaptable to include material and geometric nonlinearities across various scales, making it suitable for both thick and thin shells. The present study implements this framework to woven composites and the observations are explained in the next section.

3. Observations and Results

Weave models used in the study are built in SimTex (Simulation of Textile Composites), a software suite developed within Bristol Composites Institute. SimTex uses the multi-filament (MF) method to model the inter- and intra- yarn interactions occurring in textile composite fabrics and preforms during the weaving process, to obtain a realistic description of the fabric's internal architecture. SimTex can be used to model the internal architecture of 2D and 3D fabrics. The final simulated fabric geometry is extracted from MF model and is meshed using voxels, where the voxels are assigned yarn or matrix properties depending on the location of its centroid. The voxels must be small enough to represent the yarn cross-sectional geometries and prevent overlapping of element surfaces and stress discontinuities at the yarn-matrix boundaries.

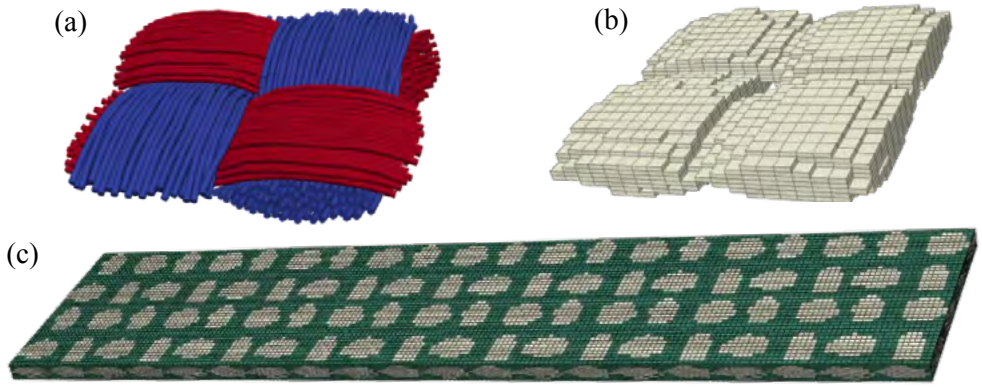

Figure 2. (a) Plain weave simulation and compaction, (b) Voxelised yarn elements, (c) Tessellated high-fidelity macroscale model

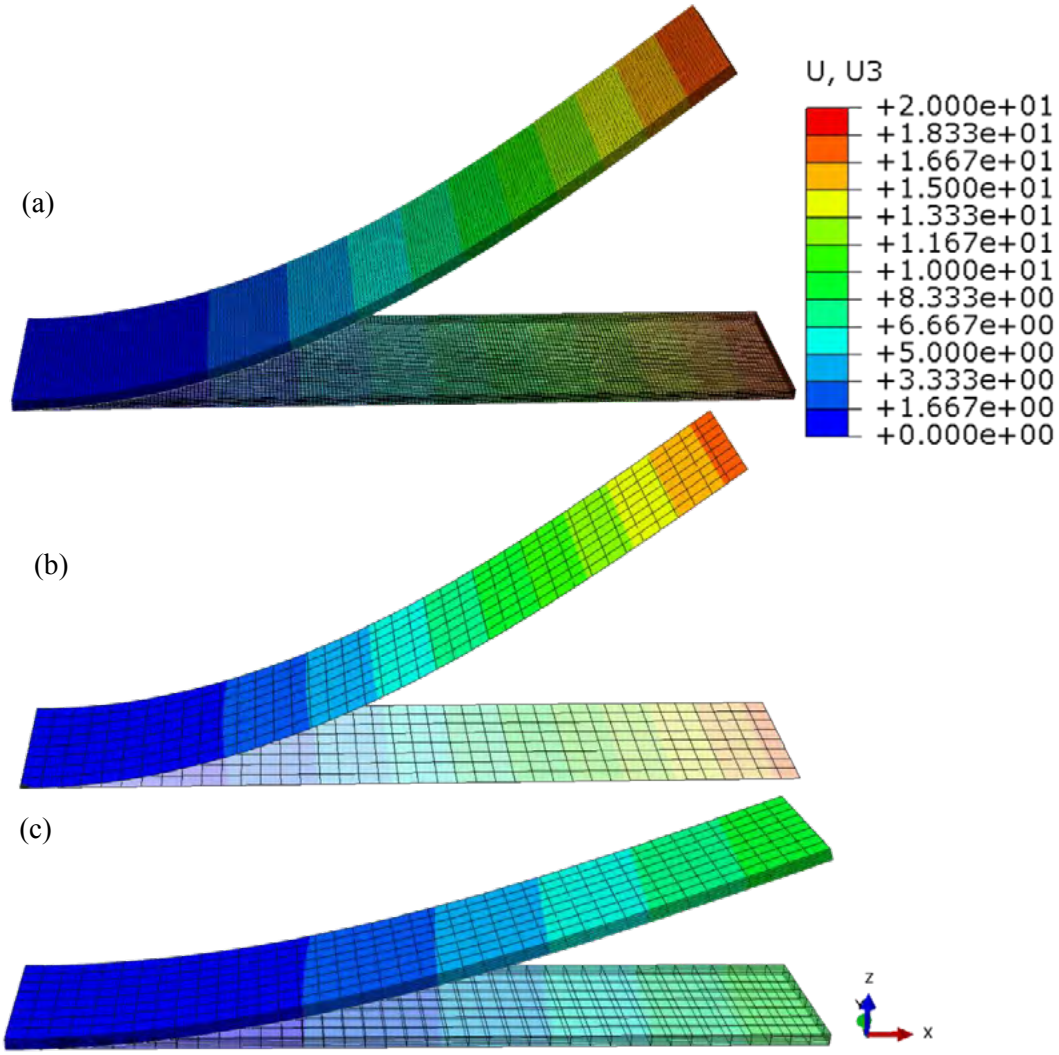

Figure 3. Macroscale models undergoing bending (a) high-fidelity plain weave model, (b) shell model based on 2OH of mesoscale plain weave RVE, (c) solid model based on 1OH of mesoscale plain weave RVE.

Prior to conducting the ASTM standard tests, a preliminary cantilever test was executed for a single-layer plain weave model. The comparative analysis revealed a strong correlation between the second-order response and the high-fidelity model, where the latter was constructed by tessellating the RVE in the in-plane direction. This test primarily aimed to assess the compatibility of the 2OH framework with woven composites, as evidenced by the U_3 responses depicted in Fig.3.

Four-point bending test of a single layer plain weave model showed promising results, where the 2OH response has a good agreement with the high-fidelity response, while the first-order response deviates significantly (Fig.4 (a)). This validates the proficiency of the 2OH framework in precisely replicating bending responses. On the other hand, a short beam shear test, which induces significant shear stress between the loading rollers, showed deviated responses for both 1OH and 2OH framework with respect to high-fidelity response (Fig. 4(b)). This test highlights the material's shear response due to its distinct through- thickness stress distribution, and shows the limitation of 2OH shell framework, since it can not capture this variability of stress. Similar responses were observed for multi-layer 2D and 3D woven cases.

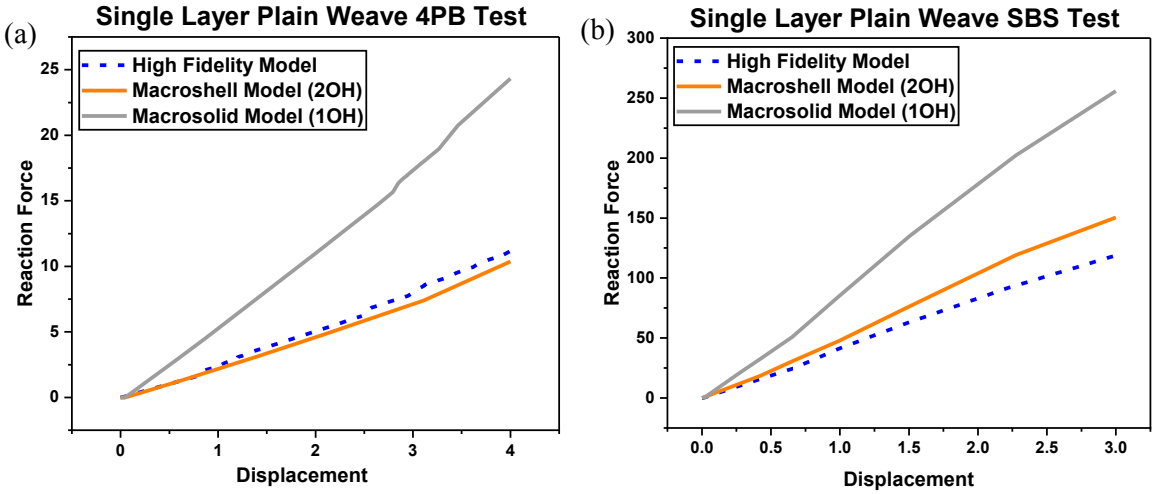

Figure 4. (a) 4 Point Bending and (b) Short Beam Shear responses of high fidelity, 2OH-based macroshell and 1OH-based macrosolid, single layer plain weave models

3. Conclusions

The present study implements a shell element-based second-order homogenisation framework to woven composites, and showcases its ability to capture complex responses like bending, which is not possible with the classical first-order framework. However, the use of shell elements at the macroscale makes it difficult to capture through-thickness variability of stresses, which is highlighted through the simulation of a short beam shear test, thus laying the groundwork for a multi-scale homogenisation framework using solid elements at the macroscale.

Keywords: Non-destructive Testing (NDT), Carbon fibre reinforced polymers (CFRPs), eddy currents, penetration depth, stacking sequence, ply orientation, structural performance.

Abstract

Performing non-destructive testing (NDT) on carbon fibre reinforced polymers (CFRPs) is challenging. Eddy current testing (ECT) offers a promising approach for inspecting CFRPs. However, due to their low and anisotropic conductivity, a complete understanding of how eddy currents flow in these materials is missing, preventing accurate inversion and characterization of parts. This study explores, how the magnetic field is attenuated through CFRPs as a function of stacking sequence. A through transmission ECT measurement was employed involving different orientations of ply layers. Starting with two uni-directional plies, we progressively altered the layers arrangement, studying the impact of relative orientation of plies on eddy current behaviour. The experimental results reveal that CFRP samples with (0/90) ply orientation exhibits a higher degree of magnetic field shielding compared to those with (0/0) ply orientation, indicating that stacking sequence and symmetry between the layers significantly influence the penetration depth of magnetic fields. This knowledge is crucial for improving ECT simulation models, sensor designs and improving quality control of CFRP composites, enhancing their structural performance in diverse engineering applications.

1. Introduction

A major concern for composite manufacturers is how to enhance the structural performance of CFRP composites, which are now widely used in the aerospace and automotive industries [1]. NDT of the CFRP components is required to ensure that those manufactured of CFRP material are fit for purpose. However, the lack of NDT techniques for the characterization of CFRP composites is a significant challenge for many real-world uses of the material, particularly in the aerospace sector.

Numerous NDT techniques have been developed to non-destructively characterise CFRP structures, including ultrasonics, scanning acoustic microscopy, embedded optical fibre, microwave technology scanning to optimise CFRP manufacturing [2]. Because eddy current testing (ECT) is quick, easy, portable, and non-contacting, it has become popular for in-service inspection and quick quality control in the manufacturing of CFRPs [2,3]. ECT offers advantages in cost, development time, and efficiency compared to other more developed and extensively used non-destructive testing methods.

ECT relies on electromagnetic principles and can only be used with electrically conductive materials. CFRPs present a challenge for ECT because their low electrical conductivity. Although carbon fibres themselves are electrically conductive, the resin matrix in these composites is electrically insulating, resulting in a low overall electrical conductivity [4]. This disparity in electrical conductivity is also

influenced by the orientation of the fibres; typically, the electrical conductivity of CFRPs is several orders of magnitude higher along the fibre direction compared to perpendicular to it [4]. This makes it difficult to interpret the results from ECT. Furthermore, the physical structure and inherent anisotropy of CFRPs raise questions about how eddy currents actually flow within these materials, leaving the precise mechanism of eddy currents in CFRPs somewhat unclear. Some researchers have reported in finite element modelling (FEM), that orthogonal unidirectional ply layers exhibit stronger eddy current responses compared to other stacking sequences [5]. To evaluate whether this simulated effect is true and to better understand how eddy currents interact within CFRP, a through transmission ECT measurement is used to measure magnetic flux that passes through 2-ply structures. This knowledge is important for developing faster simulation models and optimizing sensor designs. This development can then be used to inspect CFRPs in a much more systematic way which can ultimately enhance the structural performance of CFRPs in a wide range of engineering applications.

This paper is organised as follows: Section 2 describes the theory behind this experimental study. Section 3 provides details of the through transmission ECT experimental system and the specifications of the CFRP samples. Section 4 shows the results of the experimental study. The conclusions are drawn in Section 5.

2. Theory

2.1 Eddy current testing (ECT)

In ECT, an alternating current is passed through the probe (transmitter coil). Due to faradays law of electromagnetic induction an alternating magnetic field is produced around the transmitter coil. When the coil is moved close to another electrical conductor, the alternating magnetic field around it permeates the material and, according to Lenz's Law, causes an eddy current to flow in the conductor. This eddy current, in turn, generates its own magnetic field. This ‘secondary' magnetic field opposes the 'primary' magnetic field, influencing the current and voltage flowing through the coils. Finally, electromagnetic induction in a receiver coil, or a set of coils, detects both the primary and secondary magnetic fields. Eddy currents exhibit a skin effect. That is, current density is maximum at the material surface and decreases exponentially with depth and it depends on frequency, conductivity, and permeability of the material [6]. In our work we used two sperate coils, the transmitter coil (T_x) for generating eddy currents in the material and the receiver coil (R_x) for detecting magnetic field leaking through the other side of the material. This type of system is commonly known as through-transmission system where one coil is used to excite the eddy currents and the other is used to sense changes in the test material. Figure 1 shows an eddy current system with transmitter and receiver coil in proximity to an electrically conductive sample.

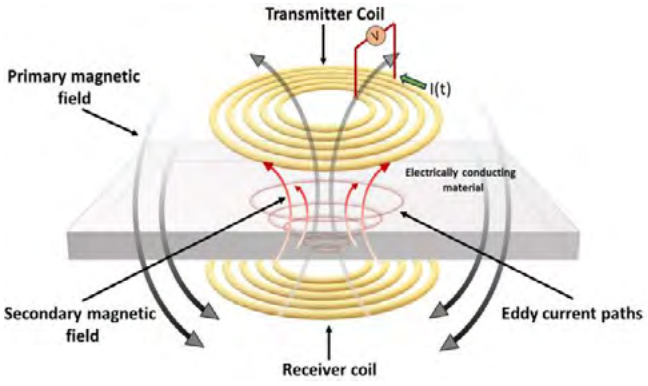

Figure 1 : Schematic of through transmission ECT

2.2 Transformer Model

When an inductor is brought into the proximity of another inductor, they both will electromagnetically couple with each other and there will be a certain amount of mutual inductance (M) between them. When an electrically conducting sample is bought between the two inductors it changes the coupling coefficient (k) between the two inductors which is an important parameter for our experimental study. The coupling interaction can be modelled as a transformer circuit shown in figure 2. The mutual inductance, M, between the circuits is defined as

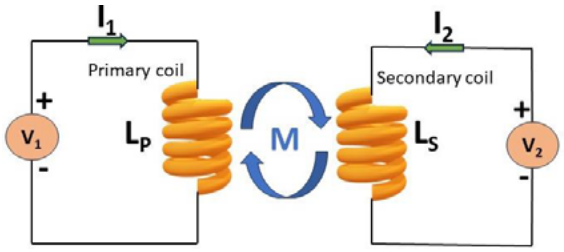

Figure 2: Simple transformer circuit model

$$M = k\sqrt{L_p L_s} \tag{1}$$

where k is the coefficient of coupling between the two inductors.

Kirchhoff's laws are used to find out the relationship between k and other parameters.

$$V_1 = i\omega L_p I_1 + i\omega M I_2 \tag{2}$$

$$V_2 = i\omega M I_1 + i\omega L_s I_2 \tag{3}$$

Using (1) (2) and (3) and $I_2 = 0$ as there is no current in the secondary coil, we get,

$$k = \frac{V_2}{V_1}\sqrt{\frac{L_p}{L_s}} \tag{4}$$

The values of V_1 and V_2 are voltages in the primary and secondary coil.

3. Experimental method and Sample preparation

3.1 Through-transmission measurement

A through transmission ECT measurement was developed consisting of two PCB coil (T_x and R_x) and a 3D printed rig which holds the two coils. PCB coils are used due to their efficient manufacturability and precise alignment capabilities. It also consists of a Zurich Instruments HFLI2 lock-in Amplifier which houses an integrated excitation function generator and measurement scope, which monitors the complex voltage across both Tx and Rx coils via the Howland current source (SonEMAT Ltd, Coventry, UK), which, for a constant output excitation waveform, is proportional to the electrical impedance of the coils testing CFRP sample at different frequencies.

The input voltage (1V) excited by the amplifier is converted to the sensor coil's equivalent frequency current excitation (30 mA). The current source is mounted directly above the Tx coil to eliminate the detrimental high-frequency shunt effects generated by the connecting cables. A frequency sweep was performed using LABONE software of the lock-in amplifier and the voltages on the T_x and R_x coil were measured. The collected data is saved in MATLAB for post-processing.

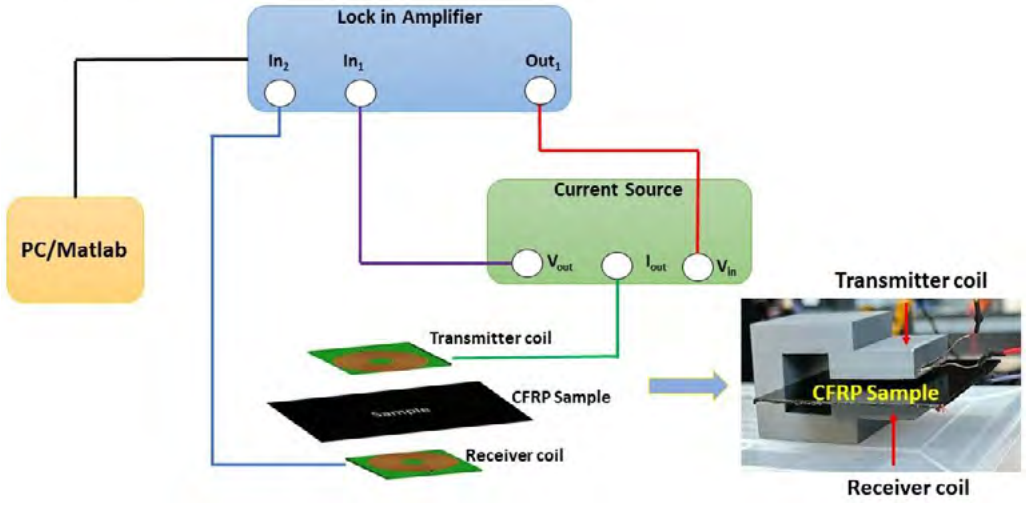

Figure 3 : Schematic diagram of the experimental setup showing through transmission ECT measurement with 3D printed rig

3.2 CFRP Samples

Seven CFRP samples are used in this study. These samples are all defect-free, 2-layered with the first layer being 0 degree and second layer changing from 0 to 90 with an increment of 15 degrees. This will give 7, 2-layerd samples with different orientation. The samples are IM7/8552 prepreg manufactured in-house with specific ply structures (0/0, 0/15, 0/30, 0/45, 0/60, 0/75, 0/90) as shown in table 1.

Table 1: Specification of two-layer, defect-free samples

Sample	No. of Layers	First Layer (degrees)	Second Layer (degrees)	Material
0/0	2	0	0	IM7 8552 Prepreg
0/15	2	0	15	IM7 8552 Prepreg
0/30	2	0	30	IM7 8552 Prepreg
0/45	2	0	45	IM7 8552 Prepreg
0/60	2	0	60	IM7 8552 Prepreg
0/75	2	0	75	IM7 8552 Prepreg
0/90	2	0	90	IM7 8552 Prepreg

4. Results and Analysis

One of the critical properties for this experimental study is the coupling coefficient (k) between the 2 coils (Tx and Rx) as described in section 2.2.

Figure 4 shows the coupling coefficient (k) against the relative angle of the samples at three randomly selected frequencies (0.9 MHz, 1 MHz, 1.8 MHz), with both coils having N=30 turns and resonance frequency of 12.4 MHz. The data reveals that, at each frequency, the 0/90 sample has the lowest coupling coefficient. Since the coupling coefficient is related to magnetic flux through Faraday's Law of Electromagnetic Induction which states that voltage induced in the coil is proportional to the rate of

change of magnetic flux through the coil [6]. This suggests that inserting a 0/90 sample between the coils disrupts the coupling more than a 0/0 sample, which has a higher coupling coefficient at these frequencies. The most likely reason for this is that in a 0/90 orientation, there are more contact points among the fibres as shown in Figure 5. This led to stronger eddy currents circulating in closed loops as shown in figure 5, thereby creating stronger opposing magnetic field, reducing the primary magnetic field from the transmitter coils, thereby diminishing the magnetic flux that penetrates to the other side of the sample. In contrast, the (0/0) ply orientation samples screen the magnetic flux to a lesser extent because their orientation allows for fewer circular eddy currents. This observation suggests that the (0/90) ply orientation yields higher current densities, a finding consistent with the finite element method (FEM) study conducted by Qiuji et al. [4].

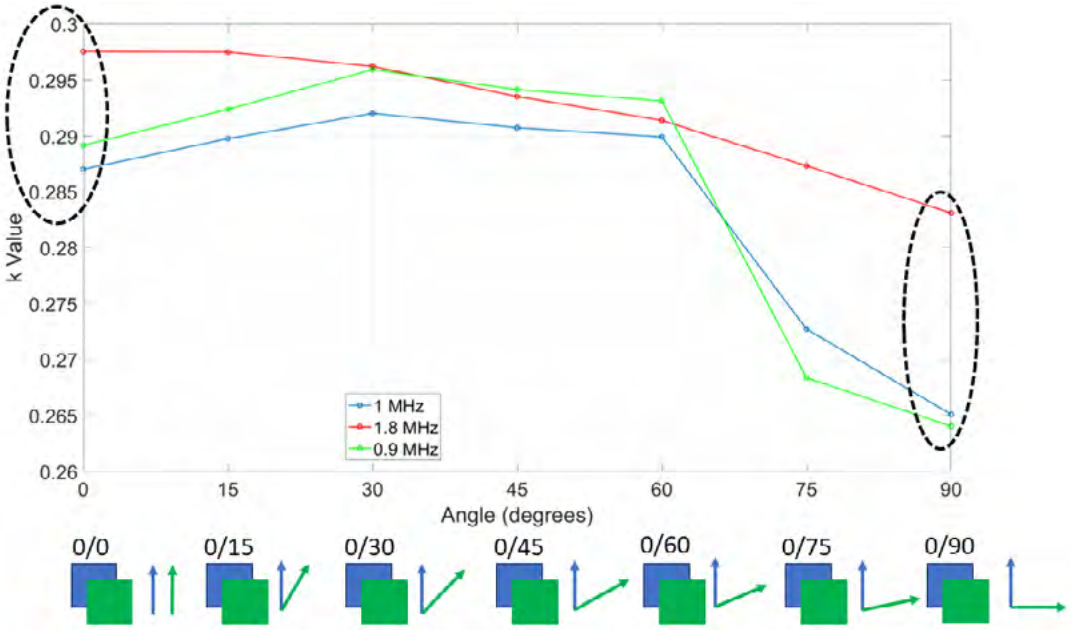

Figure 4 : Coupling coff (K). vs Ply orientation for N=30

It is also observed that there are different values of coupling coefficient (k) for different orientations of samples which signifies that stacking sequence plays an important role in shielding the magnetic field reaching the other side which ultimately affects the depth of penetration in CFRPs.

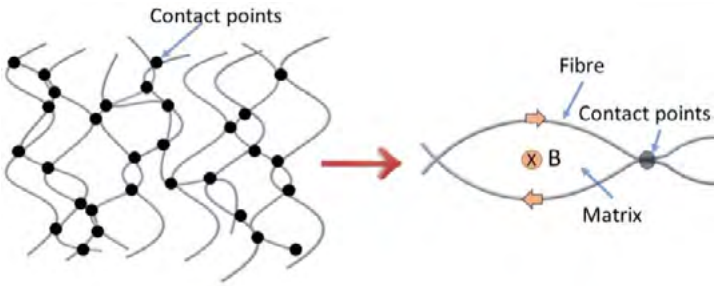

Figure 5 : Contact points and possible eddy current paths in CFRP layers

5. Conclusion and Future works

This work has developed a through-transmission ECT methodology to evaluate the electromagnetic interactions within CFRPs and how the stacking sequence in CFRPs affect the ECT response.

The proposed methodology shows that (0/90) ply orientation shields more magnetic field as compared to their (0/0) ply orientation. This also suggests that in (0/90) ply orientation there are higher current densities between the interfaces. It means that stacking sequence/symmetry plays a significant role in shielding the magnetic field reaching the other side which ultimately affects the depth of penetration in CFRPs. It is clear that frequency also plays a significant role in the penetration depth in these materials in a way that is not yet fully understood.

Future works will include finite element method FEM models to validate the experimental findings and a systematic study will be conducted to enhance existing FEM models, optimize sensor configurations, and eventually improving the structural performance of CFRP composites in diverse engineering applications.

Keywords: Delamination, Element test specimen, Cyclic loading, Fatigue crack growth, Wind turbine rotor blade

Abstract
A novel element test specimen, considered to be representative of a thick composite laminate in a wind turbine rotor blade, is investigated in cyclic loading for fatigue delaminations. The element test specimen has an embedded artificial defect to mimic the delaminations in the spar cap of a 31 m wind turbine rotor blade. The aim was to measure the growth rate of delamination cracks and the temperature rise during the cracks propagation. It was noticed that four delamination cracks initiated and propagated, out of which two cracks were along the embedded defect interface planes and the other two originated from the crack-tips of a transvers tunneling crack in the resin pocket. The initial difference in the crack lengths of the four cracks translated throughout the cyclic loading. Initiation and propagation of multiple delamination cracks documented by the optical images were well correlated by the temperature distribution recorded from the thermal images.

1. Introduction

Fatigue failure in large composite structures like wind turbine rotor blades, typically made from fibre reinforced polymers, is one of the major design concerns. With the current trend in increasing sizes of the rotor blades, a full-scale blade test becomes quite challenging as it demands many resources, high costs, and a great deal of time. The conventional method for designing against fatigue failure involves several tests performed at various length scales and is referred to as the building block approach [1] or the testing pyramid approach [2]. At the pinnacle of the testing pyramid, very few full-scale blade tests are performed as in comparison with the base of the pyramid where numerous coupon tests are performed. The intermediate level involves testing of smaller blade sections like critical substructures, subcomponents that are connected by adhesive bondlines to evaluate their structural integrity [3].

On the similar lines of substructure tests, element tests aim to understand the evolution of multiple damage mechanisms and their interaction. An element test specimen can be designed for specific damage types to understand and document the details of the interaction between the damages. It is worth mentioning that the damage evolution in these element tests should be predicted using material laws such as cohesive laws, crack growth laws etc. measured from the material characterization tests at the bottom of the test pyramid.

Delamination is one of the common damage types seen in composite structures [4]. The damage is progressive in nature and leads to unfavorable conditions such as loss of stiffness, cause vibrations, can even promote buckling and may eventually lead to final collapse of the rotor blade [5, 6, 7]. Jensen et

al. [8] investigated a 34 m full-scale blade under flap-wise loading and observed that post outer skin debonding delamination buckling led to the final failure of the blade. Haselbach et al. [9] uncovered that near surface delamination of about 30% of spar cap width led to crack growth at normal operating conditions. Lee and Park [10] tested a 48.3 m blade in static loading after cyclic testing and attributed delamination as the root cause for the blade collapse.

Samareh-Mousavi et al. [11] tested a 31 m wind turbine rotor blade with an artificial defect embedded in the spar cap under cyclic flap-wise bending. Noticing multiple delaminations that grew from the artificial defect, an element test specimen was manufactured based on the design analysis by Erives et al. [12]. This study is an experimental investigation to understand the evolution of multiple delaminations and their interaction by isolating the complexities like curvatures, ply drops etc. those are pertinent to a full structure.

The current paper is organized as follows; an introduction along with a brief motivation behind the study is presented in section 1 followed by the material system and experimental setup in section 2. Results of delaminations crack growth and thermography are discussed in section 3. Lastly, conclusions are summarized in section 4.

2. Materials and testing

2.1. Material system

The material investigated was a glass fibre/epoxy composite made up of E-glass fabric, E-1182 Saertex, and Hexion RIMR 035c epoxy. For the layup, a total of 16 UD layers were used. The central 8 UD layers were cut at half-length and then wrapped by a 35±15 µm thin Teflon slip foil (which acts as a defect) on one side of the cut fabrics as shown in Figure 1. A plate with dimensions of approximately 600 mm x 600 mm was manufactured by vacuum assisted resin transfer molding process. The plate was cured for 19 hrs. at 40°C followed by a post-cure for 10 hrs. at 80°C. Tabs covering a length of 70 mm each on both sides of the plate were glued onto the plate and thereafter, test specimens of dimensions 500 mm × 50 mm were cut from the plate. Figure 1 shows the geometry of the element specimen.

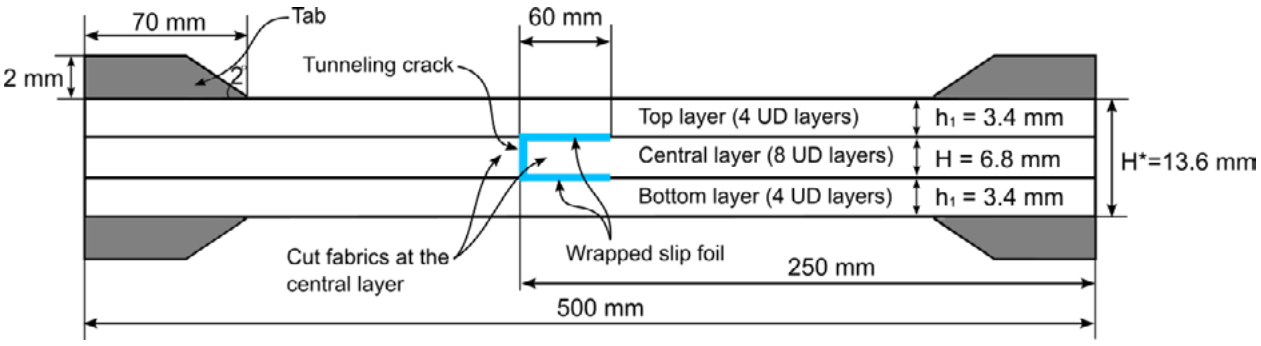

Figure 1. A schematic illustration of the geometry of the element test specimen. The artificial defect is a tunneling crack and two delaminations made by a slip foil, shown in thick light blue colored lines.

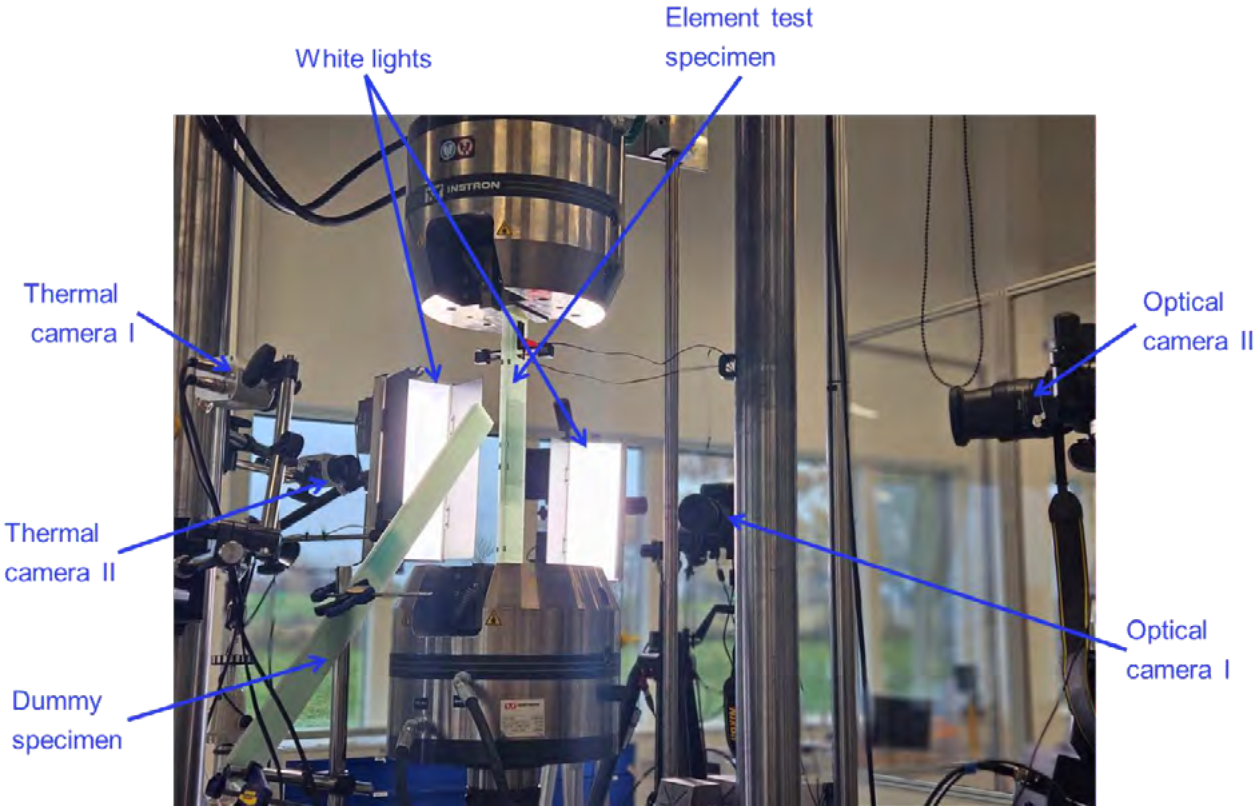
2.2. Test setup

An experimental campaign was carried out on a universal servo-hydraulic Instron 250 kN test machine equipped with a 100 kN load cell. Cyclic tension-tension loading test was performed on the element test specimen with a load ratio, $R = F_{max}/F_{min} = 0.1$ (F being the applied force), and at a frequency of 2 Hz. A strain level of 0.3% was applied for the first load cycle and the test ran up to 10,000 cycles. Digital image correlation, white light and infrared imaging were used as instrumentation. As shown in Figure 2, one optical camera (Nikon D7200 with 4000×6000-pixel resolution) and one thermal camera (Optris PI 640i equipped with a 640×480-pixel resolution and 40mK thermal sensitivity uncooled detector) were

placed in a way to observe cracks propagation from the sideways i.e., thickness view of the specimen, while the second optical and thermal cameras look at the front and back surfaces of the test specimen.



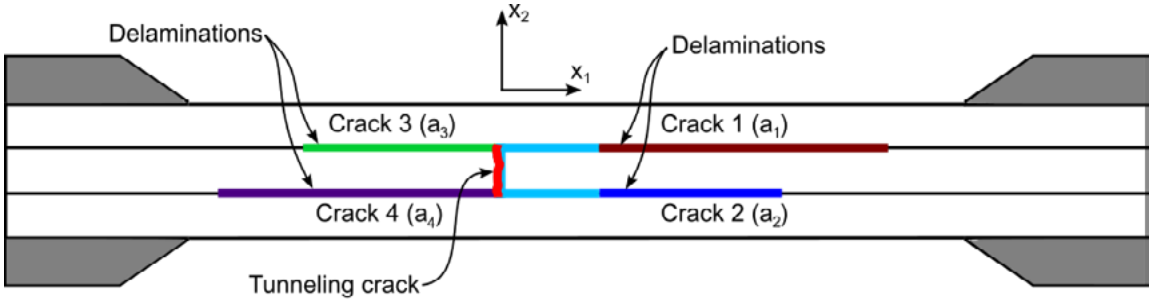


Figure 2. Test setup used for monitoring fatigue delaminations in the element test specimen.

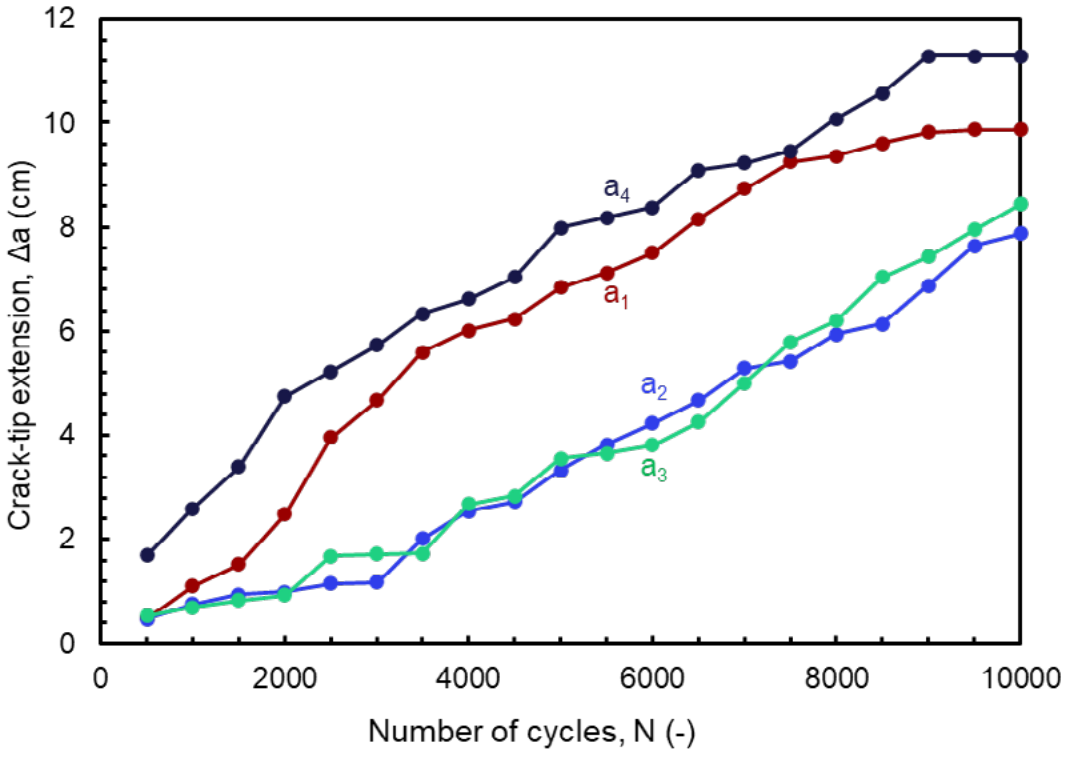

3. Results and discussion

3.1. Crack growth

A total of four delamination cracks initiated and propagated in the element test specimen as shown in Figure 3(a). Two cracks (a_1 and a_2) along the slip foil planes and the other two (a_3 and a_4) originating from the crack-tips of a tunneling crack in the resin pocket that is located in between the cut central layers. The crack-tip extension recorded for each delamination crack against the number of load cycles, viewed from the thickness side is plotted in Figure 3(b). The cracks a_1 and a_4, propagated approximately at the same rate and were longer than, a_2 and a_3, which were also found to grow in tandem. The difference between the crack growth rates of a_1, a_4 and a_2, a_3 is attributed to the initial cracking length differences observed during the early load cycles.

(a)

(b)

Figure 3. a) Schematics of the multiple delamination cracks observed in the element test specimen and b) measured crack-tip extension of each delamination plotted as a function of number of load cycles.

3.2. Infrared thermography

Figures 4 and 5 show the fatigue crack propagation from the initial pre-cracks in comparison with the corresponding thermal images at the same cycles from the front and side faces, respectively. Since the thermal and optical cameras were pointed to the opposite faces, the thermal images were mirrored vertically to facilitate comparison. The temperature range of the color bar is considered constant to have consistent and comparable thermal images over time, that covers temperature variation from the beginning to the end of the test. In Figure 4, the temperature contours on the front face show highest temperatures around the initial pre-crack fronts and tunneling crack at the early cycles. As cracks propagate, the distances between four crack fronts increases and as a result, large area of the specimen warms up. In addition, several hot spots evolve which distance from each other by cycles and their positions correlate with the crack fronts during the test. Several mechanisms could be involved in heat generation and temperature evolution such as viscoelastic hysteresis dissipation, friction between the crack faces and crack growth energy release. With increasing crack lengths, stress free region in the middle layer enlarges in the x_2-direction (Poisson's effect) and its load is transferred to the upper and lower layers which means higher cyclic stress range and more hysteresis dissipation. The higher hysteresis dissipation and larger rubbing faces can explain an overall warmer region in the middle of the specimen. At the very tip of the crack fronts, stress is singular which dissipates high amount of hysteresis energy and crack growth related energy release in a small volume. The trace of higher heat dissipation near crack fronts was observed with a delay in the thermal images due to low thermal conductivity of the glass fiber composites.

The surface temperature field is influenced by material thermal conductivity, depth of crack from surface and the rate of heat dissipation. Moreover, the area near to tunneling crack is consistently hot from the

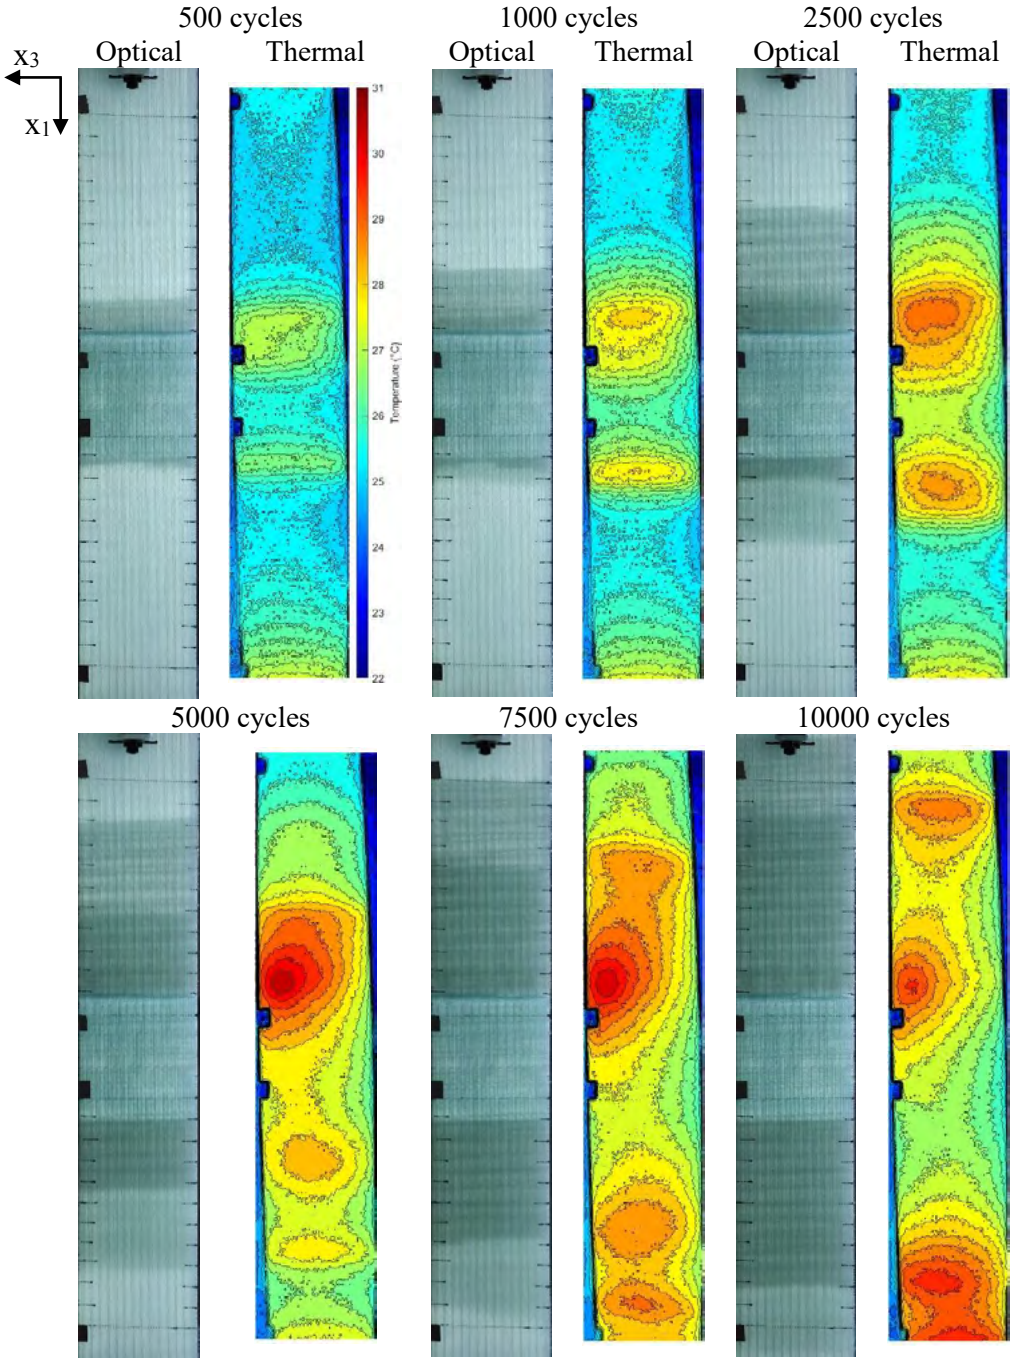

Figure 4. Comparison of multiple delamination cracks from the optical images (taken from front face) with their corresponding thermal images (taken from back face) at different load cycles.

beginning to the end that significantly affects temperature field. More investigation and post-mortem analysis is essential to uncover the dominant heat source near to the tunneling crack.

Figure 5 shows the optical photos taken from the right side and thermal images from the opposite side. The positions of four crack fronts are shown with arrows in the optical photos. The crack growth can be tracked from thermal images, however hot spots do not precisely follow the crack fronts' positions, due to variation of the crack front position along the specimen's width (in x_3-direction). Like the front face, the tunneling crack is observed as the hottest point on side face thermal images and its reason is unclear

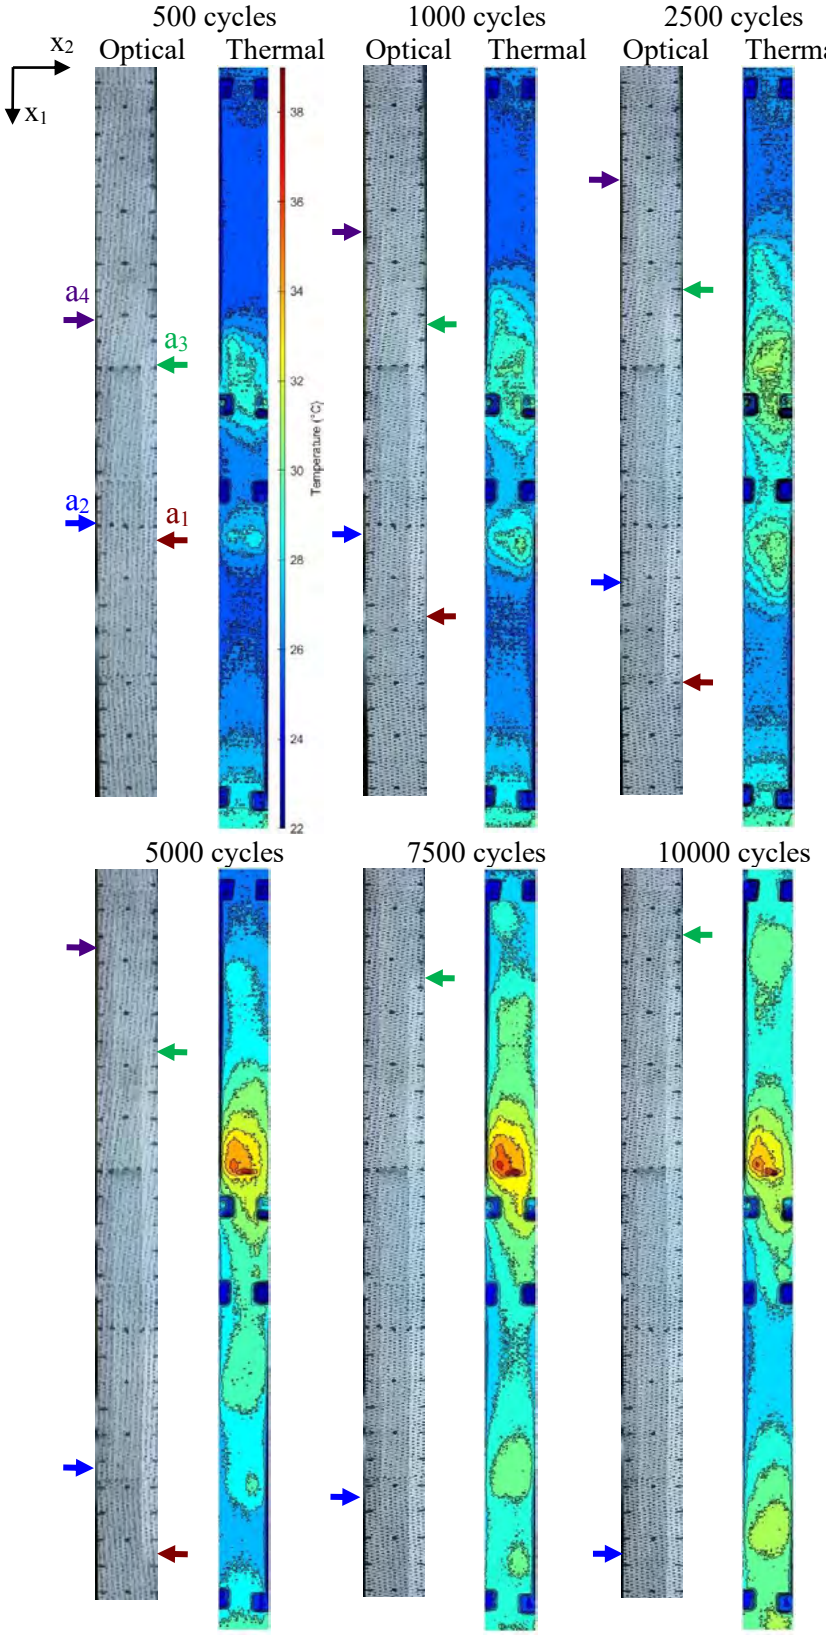

Figure 5. Comparison of multiple delamination cracks from the optical images with their corresponding thermal images viewed from the sideways. The arrows indicate each delamination crack-tip position.

for the authors. Due to significantly higher temperature near to the tunneling crack, it is difficult to distinguish temperature contours around the crack fronts at the early cycles. However, hot spots related

to crack fronts are observed by increasing the distance of crack fronts from the initial pre-cracks and the tunneling crack positions. Moreover, it is observed in the side face thermal images that the temperature is higher very close to the crack tips and decreases towards specimen's front and back faces that explain the difference of maximum temperature in the front and side faces.

4. Concluding remarks

Fatigue delaminations were investigated under cyclic loading on an element test specimen with an intentionally embedded defect (in the form of a slip foil) that is intended to imitate a thick laminate in main spar of the wind turbine rotor blade.Two cracks were found to initiate and propagate from the tips of the slip foil, and further, two more cracks initiated and propagated from the tips of the tunneling crack in the resin pocket. Out of the four cracks, set of two cracks each recorded approximately same crack-tip growth when plotted as a function of number of load cycles. The difference between the crack lengths observed is attributed to the initial cracking difference occurred from the early load cycles. The hot regions detected on the thermal images were well correlated by the position of crack-tips seen in the optical images, however, further investigation is needed to know the source of increasing heat dissipation near the tunneling crack.

Acknowledgments

This work is carried as a part of the research supported by the AINDT project (Artificial Intelligence-based Non-Destructive Techniques for reduced service costs for wind turbine blades) through the Innovation Fund Denmark (0224-0011A). The author would like to acknowledge the assistance provided by Christian H. Madsen, for manufacturing of the element test specimens, and Steffen Rasmussen, and Nicolai Frost-Jensen Johansen for the experimental test setup. Further, the author would also like to thank the associate professor Xiao Chen for the scientific discussions throughout the work.

Keywords: In-situ impregnation, Transverse fabric compressibility, Test fluid influence

Abstract
In this study, the influence of different fluids on the transverse compressibility behaviour of technical reinforcing fabrics was investigated. Specifically, a glass fibre woven and a non-crimp fabric with comparable fibre areal weight, were studied in a novel test-rig with in-situ impregnation of the samples under transverse load. Four test fluids with varying viscosity and polarity, respectively, were chosen to analyse the influence of fluid viscosity and polarity on the relaxation behaviour. In addition, silicone oil with four different levels of viscosity across three orders of magnitude was used to isolate the influence of fluid viscosity, as no significant difference in polarity was observed.
A qualitative analysis showed that the fabrics reacted significantly different to the impregnation, as with lower flexibility and increasing viscosity, hydrostatic effects in the compressed area counteracted a lubricating effect. However, only in the fabric with lower fibre bundle flexibility a slight to significant relative pressure relaxation was measured only as a result of fluid polarity.
In addition, the viscosity of the fluid had no significant effect on the relative relaxation at the same polarity, but with increasing viscosity the time to reach pressure equilibrium increased significantly.

1. Introduction

Process optimization of composites manufacturing requires fundamental understanding of the most relevant phenomenological mechanisms. This involves reliable data on material behaviour and a good understanding of the process. To determine this data under process-like conditions, a novel in-situ test method was proposed [1]. The present work uses this test method and a broad selection of fluids to analyse the influence of fluid viscosity and polarity on transverse fabric compressibility.

2. Materials and methods

Two glass fibre textiles were selected in order to simplify the transfer of this research into industrial applications and to take account of the more than 90% mass share of glass fibres in the global composites market [2]. The materials are characterised by a comparable fibre areal weight (FAW) of around 300 g/m² and at the same time represent the most frequently used textile reinforcement structures, i.e. woven (WF) and non-crimp fabrics (NCF), for structural and mechanically stressed components. In addition, the selected WF corresponds to the textile used in the latest international benchmark exercise (IBE) [3] and therefore allows for comparability of the results. The following table provides an overview of important textile parameters of the two materials.

Table 1. Overview of the analysed textile reinforcements with their respective FAW according to the technical data sheet labelled (*), as well as their measured average FAW and coefficient of variation (CV) labelled (**).

Manufacturer	Textile name	Fibre material	Textile structure	FAW (*) [g/m²]	FAW (**) [g/m²]	CV (**) [%]	Data sheet
Hexcel Corporation	01202	GF	Twill 2/2 (WF)	290	291.36	0.56	[4]
Saertex GmbH	X-E-302	GF	Bi-axial (NCF)	302	305.14	0.23	[5]

Both materials are slightly heavier than the specification, but the deviation is very small at approximately 0.5% (Hexcel) and 1.0% (Saertex) and the variability is very low for both materials. This aspect is very important for the significance of the measurements, as the expected influence of fluid polarity on the compaction behaviour is likely to be very small.
Table 2 lists the fluids used for the in-situ impregnation tests, their average dynamic viscosity and the CV from 10 consecutive measurements. The viscosity measurements were carried out at 20 °C in a shear rate range of 1-500 1/s in 15 logarithmically distributed steps.

Table 2. Overview of test fluids with their average dynamic viscosity.

Manufacturer	Fluid name	Material	Dynamic viscosity [mPa·s]	CV [%]	Data sheets
Carl Roth GmbH + Co. KG	n-Decane	n-Decane	0.94	1.34	[6]
-	Tap water	H_20	1.03	0.97	-
DOW Europe GmbH	Si-oil 10	Silicone oil 10 m·Pas	10.29	0.36	[7]
DOW Europe GmbH (mixture)	Si-oil 71	Silicone oil 71 m·Pas	69.06	0.19	-
DOW Europe GmbH	Si-oil 100	Silicone oil 100 m·Pas	105.88	0.04	[8]
Sigma-Aldrich	PEG 400	Polyethylene glycol	117.87	0.02	[9]
DOW Europe GmbH	Si-oil 1000	Silicone oil 1000 m·Pas	1071.60	0.27	[10]

In order to achieve a better understanding of the comparisons made in the following, the viscosity curves of the test fluids are illustrated in Figure 1. Particular attention is drawn to the fluid groupings i) tap water & n-Decane at 1 mPa·s, as well as ii) PEG 400 & Si-oil 100 at around 100 mPa·s. Due to the almost identical to closely related viscosity within their respective grouping, differences in the compaction behaviour cannot be attributed to this parameter and could therefore indicate another influencing factor, such as polarity.

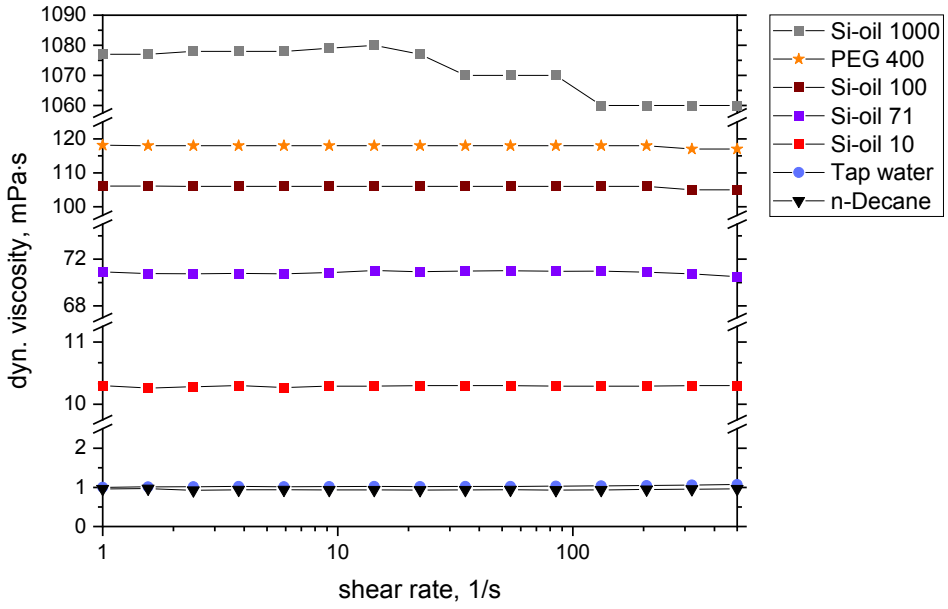

Figure 1. Dynamic viscosity of the test fluids in a shear rate range relevant for the applied in-situ impregnation method.

Figure 1 also shows that all fluids exhibit an almost constant dynamic viscosity within the measuring range, with the sole exception of Si-oil 1000, which shows a small drop at higher shear rates. This however can be attributed to the test method, in which a modular compact rheometer from Anton Paar, type MCR 501, was used in combination with a double-slit measuring system, specifically DG26.7/T200/AL, in accordance with DIN 54453 [11] and ISO/WD 3219-2 [12]. The use of this double-slit measuring system enables the measurement of dynamic shear viscosity in a wide range, especially for fluids with very low viscosity values, e.g. water and n-Decane. However, the measurement data sheet for DG26.7/T200/AL [13] states, that this method is only applicable for fluids with a viscosity of less than 200 mPa·s, which may explain a change in the result for increasing shear rates.

Both textiles were tested with all liquids using the in-situ impregnation method [1], as detailed in Figure 2. This method allows to test the effects of fluids of different viscosity and polarity on textile structures with different fibre bundle fixation to gain a deeper understanding of the underlying mechanisms.

In order to ensure comparability with each other and with the results of the IBE, the dry and the wet stress relaxation phase were set at 1800 s [3]. Furthermore, the impregnation phase was selected so that complete impregnation at 2 bar injection pressure was achieved under the plunger, which was indicated for all fluids after 900 s at the latest by a fluid outflow over the entire circumference of the plunger. For the Si-oil 1000 the impregnation phase had to be extended to 1800 s due to the high viscosity and thus slow impregnation of the test specimen. Due to limited fluid quantities, especially of n-Decane and Si-oil 10, it was not possible to use the longer impregnation phase for all fluids.

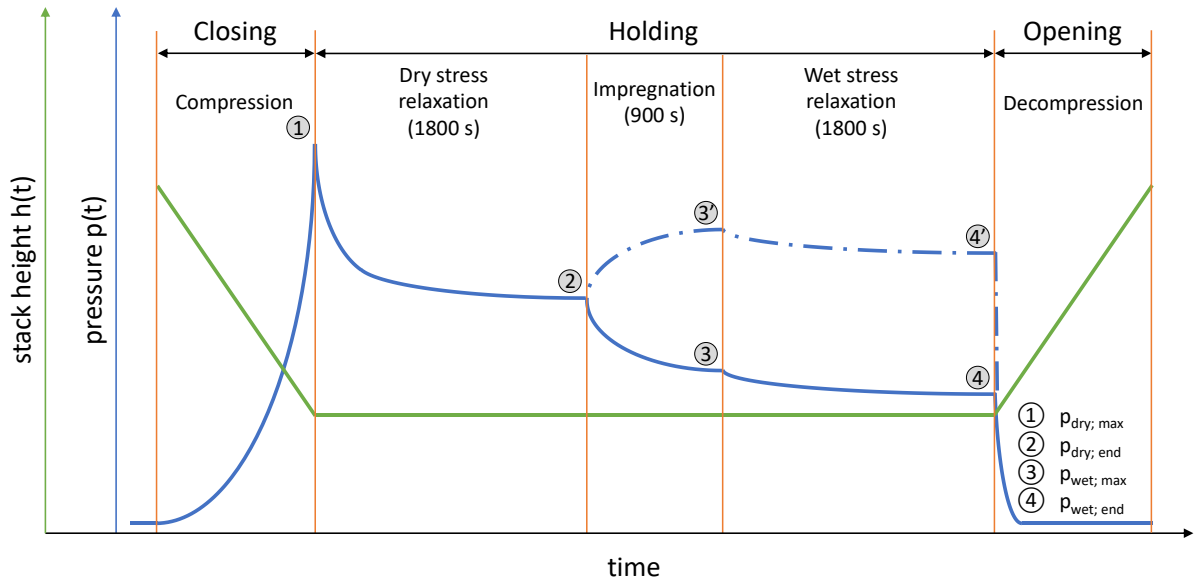

Figure 2. Schematic in-situ impregnation method and characteristic points during the test as detailed in [1]. Paths 3 and 3' show two possible pressure responses to the impregnation of a specimen with a test fluid. The exact characteristic of the measured behaviour depends on the respective fixation of the fibre bundles (textile structure) as well as the viscosity and polarity of the test fluid.

The test specification regarding the specimen were adopted from the IBE for both fabrics, test specimen of 14 layers each with 120 mm x 120 mm were prepared, which enables direct comparability within the measurement series and with the IBE [3].
In order to reduce the negative influence of manual movement during the stacking process and thus reduce the scattering of the tests, 7 layers of textiles were simultaneously cat by a CNC-based cutting system (Zünd Systemtechnik AG, type G3) and stacked uniformly in a 7+7 configuration.
All test fluids were degassed at 0.05 bar pressure for one hour, to avoid any effect of air bubbles during the impregnation stage. Furthermore, the injection set-up was completely disassembled and thoroughly cleaned, and all fluid lines were replaced while changing test fluids, to avoid any cross-contamination.
Before each test every specimen was weighed and its FAW was calculated. The average results are listed in Table 1. The specimen was then transferred to the thoroughly cleaned test area and the testing procedure was started. After each test the saturated weight of every specimen was also noted, as any significant change would indicate a measurement error such as dry spots or fibre wash-out.
For each fluid and textile combination, a set of ten successful in-situ impregnation tests were conducted. Obvious measurement errors such as a premature start of impregnation due to a leaking magnetic valve or insufficient fluid quantity in the pressure pot were declared as incorrect and not evaluated.

3. Results

It is known that the relationship between the fibre volume fraction (FVF) and the compression pressure follows a power law equation [14]. For this reason, even small fluctuations in the dry weight and thus the FVF at a certain gap height, especially at high FVF, lead to large variations in the compaction pressure. As an example,
Figure 3 displays all individual test data of the relaxation behaviour of both textiles with tap water and n-Decane as test fluids. One way to reduce the effects of these fluctuations and improve the conclusion drawn is to normalize the pressure data by the maximum compacting pressure $p_{dry;\,max}$, or point ① as shown in Figure 2. This does not change the qualitative character of the statement, but increases the distinctness of small effects by suppressing a significantly larger basic variation.

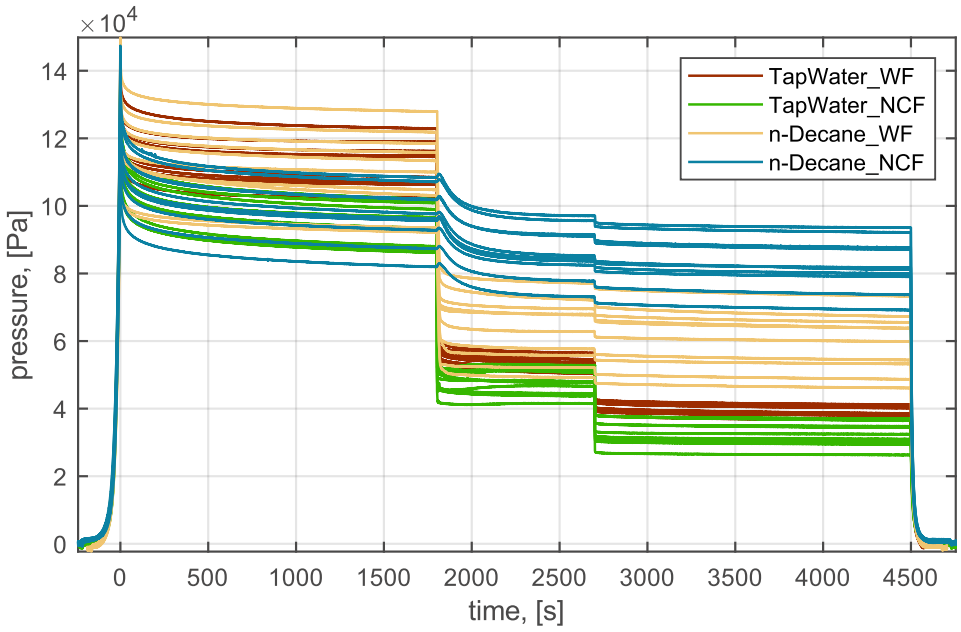

Figure 3. Individual relaxation characteristics of both textiles with tap water and n-Decane as test fluids.

It becomes clear, that due to the considerable scatter of $p_{dry;\,max}$ not all four characteristics can be distinguished. However, if all relaxation measurements are normalised to their respective $p_{dry;\,max}$, as shown in Figure 4, subtle details can be recognized. For this reason, only the normalised pressure characteristics are shown in the following.

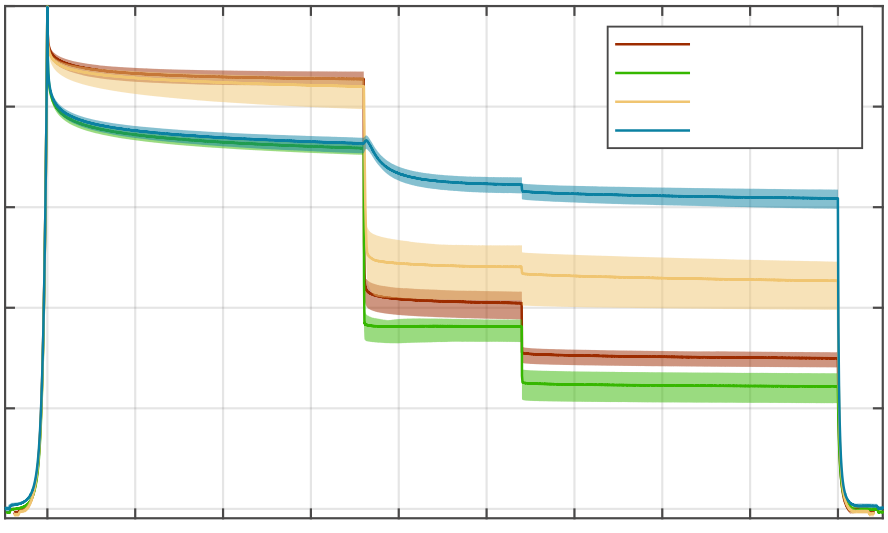

Figure 4. Min-max-envelopes of the relaxation characteristics of both textiles with tap water and n-Decane.

©2024 | <Sans lien d'intersection>

As expected, the dry compressibility behaviour is identical for both textiles, with only very small min-max deviations from the arithmetic mean, which are characterised by the coating and the relative dry relaxation, which is about twice as high for the NCF. This changes drastically with the start of impregnation. For the WF, there is an immediate drop in pressure for both fluids with a fluid viscosity at around 1 mPa·s, with tap water showing a slightly higher relaxation. However, this does not apply to the NCF. The combination NCF and tap water shows a relative relaxation comparable to that of the WF with tap water. Opposite to this the combination NCF and n-Decane shows a relative relaxation which is significantly lower, compared to the combination WF and n-Decane, and even shows a slight pressure increase at the start of impregnation phase. It also takes considerably longer to reach pressure equilibrium during the impregnation phase. In addition, the pressure drop at the end of the impregnation phase is significantly lower with n-Decane than with tap water. Overall, tap water leads to lower $p_{wet;\,end}$ values than n-Decane with approximately the same remaining pressure level of around 25-30% for both textile structures. In comparison, impregnation with n-Decane leads to drastically different results for different textile structures, not only in the relaxation behaviour during impregnation, but also in the remaining pressure level of about 45% for NCF and 60% for the WF.

Increasing the fluid viscosity from 10 mPa·s to approximately 100 mPa·s changes the results significantly, as can be seen in Figure 5.

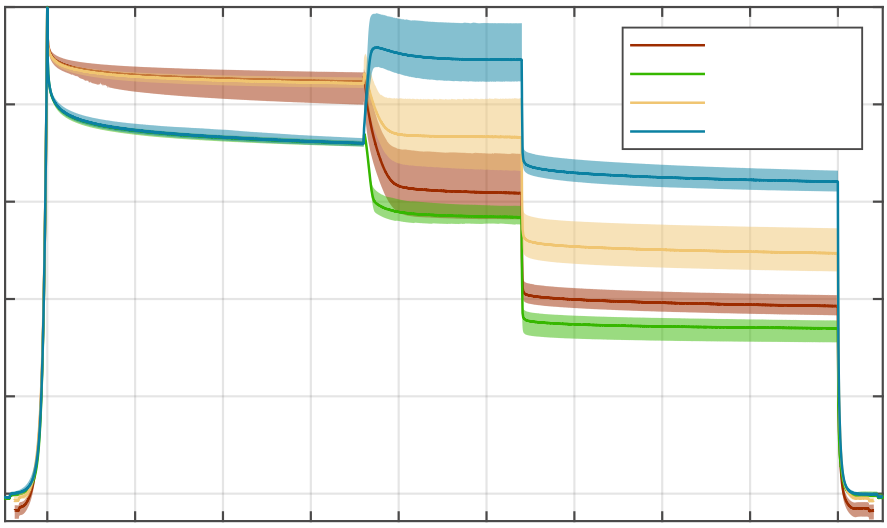

Figure 5. Min-max-envelopes of the relaxation characteristics of both textiles with PEG 400 and Si-oil 100.

It becomes clear, that only the combination of the non-polar silicone oil with NCF leads to an increase in relative pressure during the impregnation phase. This increase for NCF and Si-oil 100 is most likely due to opposing effects of textile relaxation due to nesting and fibre reorientation and the build-up of a pressure field in the impregnated areas. The other three combinations again show a drop in relative pressure after the start of impregnation, as the pressure release due to a lubrication effect is significantly greater than a pressure increase due to the build-up of a pressure field in the compressed area. The total pressure release of the combination of Si-oil 100 and NCF could most likely also be achieved dry relaxation over the whole test time, while a significant lubrication effect can be recognised in all other combinations.

This leads to an interesting result, because although NCF showed the highest relative relaxation during the initial dry relaxation phase, the significantly different behaviour during the impregnation phase leads to NCF showing the highest and also the lowest relaxation characteristics of the four combinations, only depending on the test fluid.
In addition, a further effect can be observed due to the increased fluid viscosity, as this is equivalent to a slower flow front propagation. Due to the generally lower permeability of the WF compared to the NCF, it takes longer to reach pressure equilibrium, which was less pronounced at lower viscosity, but is now clearly visible.

In addition to comparative measurements of two fabrics in combination with four fluids, the relaxation characteristics of the WF with four silicone oils with viscosity of 10 .. 1000 mPa·s were compared. As the high viscosity of Si-oil 1000 meant that complete impregnation was not fully achieved during the impregnation phase under the stamp, it was extended to 1800 s. Figure 6 shows the results of these tests.

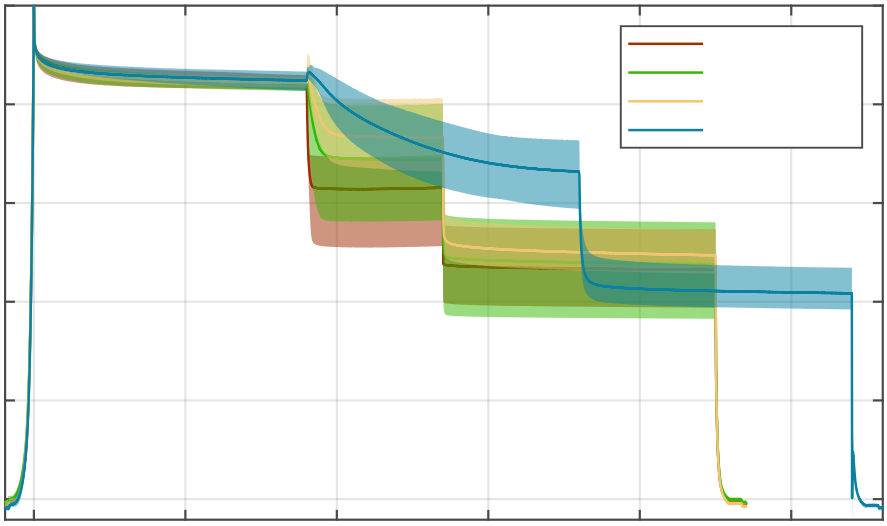

Figure 6. Min-max-envelopes of the relaxation characteristics of the WF with all four silicone oils, Si-oil 10, Si-oil 71, Si-oil 100, Si-oil 1000, spanning two decades of fluid viscosity, without significant differences is fluid polarity.

There is no significant difference in $p_{wet;\,end}$ for all four fluids, although their respective viscosity differs significantly. However, as the viscosity of the fluid increases, the time until pressure equilibrium is reached increases. Furthermore, it can be seen that there is no significant difference in the remaining pressure level at the end of the test, even though the test time for one fluid was increased by 20%. It can be deduced that there is no residual nesting potential after the introduction of the silicone oil, which acts as a lubricant, as soon as pressure equilibrium is reached in the impregnation phase.

4. Conclusion

A qualitative analysis of the in-situ relaxation characteristics of two textile structures with eight different test fluids was conducted. The relaxation characteristics during the different stages of the in-situ impregnation method were compared in each case of two fluids with comparable viscosity, but significantly different polarity. It became clear that even though the fluid viscosity within the

groupings were very close, significantly different relaxation behaviours could be observed, which must be caused by another fluid property, most likely polarity. This is especially pronounced for NCF, as very little up to a high relative pressure relaxation can be observed, which is not the case for the WF, as differences in fluid polarity result in only minor relaxation differences.
Also, the impregnation characteristics of four silicone oils with comparable polarity, but viscosity spanning two decades were analysed. In this case three aspects became obvious. First of all, the relative relaxation during the impregnation phase decreased with increasing fluid viscosity, while overall relative relaxation at the end of the wet holding phase was almost identical. Second, the time necessary to reach a pressure equilibrium during the impregnation stage increases with higher viscosity. Third, the remaining relative pressure level seems to be independent on the fluid viscosity and previous relaxation characteristics.
As the qualitative analysis has shown interesting, novel aspects of the influence of fluid properties on transverse fabric compressibility during in-situ impregnation, a quantitative study with the aim to develop a theoretical model to predict textile behaviour should be conducted.

Abstract

Polymer composite material properties such as strength and stiffness can be degraded over time due to moisture absorption. While macroscale mechanical tests exist to measure the change in bulk properties due to moisture, the microscale effects of moisture diffusion have not been well characterised. This insight would allow better modelling of degradation. To characterise this on a micromechanical level, unidirectional carbon fibre epoxy composites were immersed in water at elevated temperatures to simulate accelerated ageing, and a method has been developed using nanoindentation to measure changes in hardness, modulus, and viscoelastic behaviour at various depths through the material's thickness. These micromechanical results were correlated with macroscale mechanical tests (four-point bend flexure) and optical microscopy to assess microstructural changes over time. The findings highlight the micromechanical response of carbon fibre epoxy composites to water uptake, providing deeper insights into degradation mechanisms. This knowledge is essential for developing predictive models and optimising the design of composite structures for improved durability in various environments.

1. Introduction

Carbon and glass fibre epoxy composites are commonly used in structures that require a resistance to environmental degradation, such as in marine, offshore, construction or aerospace applications, where their performance can degrade due to moisture absorption [1], [2], [3]. Understanding these degradation mechanisms in different environments is crucial for durability assessment and good predictive modelling of lifetime. Traditional accelerated ageing tests for polymers evaluate the rate of diffusion through the material [1], [4], [5], [6], [7], but do not fully explain how moisture uptake degrades these materials.

The absorption of water in polymer and polymer composite materials has been found to reduce the strength and the glass transition temperature (T_g) [8], [9], [10], due to a decrease in molecular friction, increased mobility of the polymer chains, and therefore plasticisation of the polymer matrix. This plasticisation is often reversible, and the properties are recovered once moisture is removed. Epoxy polymers are hydrophilic due to the presence of polar groups on the polymer chain available for hydrogen bonding [11], but more permanent chemical degradation is possible due to hydrolysis. In polymer composite materials, carbon fibres are typically considered to be inert to chemical degradation, whereas E - glass fibres have been shown to be susceptible to degradation due to moisture exposure where there is leaching of alkali oxides from the fibre surface [8].

Previous research on a carbon fibre epoxy composite material suggests moisture absorption causes significant degradation at the fibre-matrix interface, reducing the bulk flexural strength and modulus [12]. This has been evidenced by scanning electron microscopy analysis of the fracture surfaces after failure in mechanical testing, where fibre – matrix adhesion is disrupted after prolonged exposure. However, this is only a qualitative measure, therefore micromechanical testing is required to determine a more quantitative measure of degradation around the interface, and through the thickness of a material.

Nanoindentation has been shown to be an effective tool for assessing the viscoelastic and mechanical properties of materials and has shown use for assessing the composite interface and interphase regions [13]. One recent study uses this technique to investigate the through thickness micromechanical property characterisation to assess the manufacture of CF/PEKK composites under either automated tape placement or compression moulding [14]. The method enables indents in an array at various locations through a composite cross section to evaluate the differences in hardness and elastic modulus in the bulk resin and close to the fibre surfaces, in this interphase region.

In this research, specimens of a unidirectional carbon fibre epoxy composite pultrusion were subjected to an accelerated ageing regime, using immersion in water at elevated temperature. Testing through the thickness was then conducted using nanoindentation on different locations through the cross section of the composite material. The nanoindentation results are complemented by macroscale mechanical testing (four-point bend flexure) and optical microscopy to correlate changes in mechanical properties with variations at the microstructural level, through the thickness of the material, as well as compared between materials exposed for increased exposure times. Measurement of the micromechanical response of carbon fibre epoxy composites to water uptake offers a more nuanced understanding of the underlying degradation mechanisms. This improved understanding is required for the development of predictive models for the mechanical performance of these materials due to exposure to moisture, aiding in the design and optimisation of composite structures for enhanced durability.

2. Materials and Methods

2.1. Materials

For this work, an Easycomposites unidirectional (UD) pultruded carbon fibre epoxy resin strip with dimensions 2 mm thickness, 12 mm width and 2 m long has been used. This material was purchased from the manufacturer's agent.

All test specimens were cut to size from these strips prior to exposure using a CompCut diamond saw. The material was tested as received as well as the conditioned state following accelerated ageing procedures. For the Easycomposites material the specimens only had two cut surfaces at the end of the strips, transverse to the length, due to the pultrusion width being suitable for testing.

2.2 Accelerated ageing

Composite specimens were immersed in a water bath in distilled water at 60°C in a Grant GD120 bath. Specimens were immersed for pre-determined time intervals of 28 and 84 days, with the moisture content determined by gravimetric measurements. This procedure was based on guidance for water absorption in plastics from ISO 62 [15]. Specimens were removed from the water bath, surface water dried off, and each weighed prior to either returning to the water bath immediately or storing in deionised water at room temperature prior to testing within 72 hours. The moisture content of the specimens was calculated as a weight percentage of the material (Equation 1):

$$Moisture\ content(\%) = \frac{m_w - m_d}{m_d} \times 100\% \quad (1)$$

Where m_w is the mass of the aged specimens, and m_d is the mass of the unaged specimens prior to any testing. It has been assumed that there is no mass change due to leaching from the specimens.

2.3 Macroscale mechanical testing

Four-point bend flexure tests were conducted following BS EN ISO 14125 [16]. Tests were carried out on an Instron 4507/5570R machine with a 20kN load cell. The test speed was at 2 mm/min, and the test spans were 81 mm and 27 mm. The specimens were placed on the four-point bend fixture with a linear variable displacement transducer (LVDT) mounted underneath the central span to measure the deflection due to flexure in the centre of the bending beam. This enabled determination of both the flexural strength and flexural modulus of the unaged and aged composite specimens. Specimens for this test were cut to dimensions 2mm × 12 mm × 100 mm as per the standard recommendations using a CompCut diamond saw.

2.4 Micromechanical testing: Nanoindentation

Samples measuring approximately 10 mm in length (12 mm width and 2 mm thick) were cut from the pre-immersed CF epoxy strips with a hand saw and were mounted in epoxy resin, exposing the cross-section of the laminate. These were polished with silicon carbide discs, followed by diamond suspension polishing down to 1 µm particle size. The nanoindentation tests were performed using a UNHT CSM Nanoindenter, with a diamond Berkovich-type indenter tip.

Load – unload indentation cycles were performed at a frequency of 10 Hz, load rate of 4 mN/min, to 400 nm depth, and a dwell period of 30 s, in order to produce indents of a 2 – 3 µm diameter size; this was to ensure indents smaller than the comparable 10 µm fibre diameter. This was influenced by the nanoindentation method used by Perez et al. [14]. The elastic modulus and hardness values were then determined using the load – displacement curves, from the method defined by Oliver and Pharr [17].

All samples were indented as marked in Figure 1. Each sample was indented at four locations, from the top edge of the cross section, approximately 50 µm from the edge, through to approximately 350 µm, 650 µm, and finally to the centre at 950 µm into the cross section. At each location, a series of indentations were performed: two individual indents on resin rich areas to measure the bulk matrix hardness and elastic modulus, two individual indents on the fibres to measure the same for the fibres, and finally a 5 x 5 array of indentations to obtain hardness and elastic modulus values of the composite material. A micrograph using an optical microscope was taken of each location.

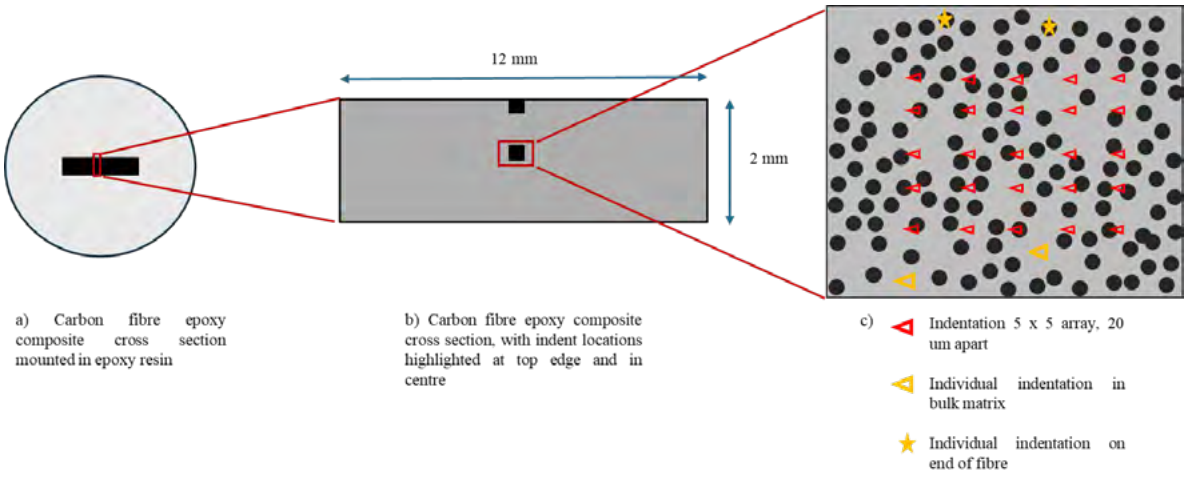

Figure 1 *Schematic example of the indentations performed on the carbon fibre epoxy composite cross section, showing the individual bulk matrix and fibre indents, the 25 indents in an array, and the location of these indents at both the top edge and the centre of the cross section*

3. Results and discussion

3.1 Accelerated ageing

The results of the accelerated ageing tests, as further discussed by this author in a previous paper [12] and reproduced in Figure 2, show how as moisture content increases, the flexural strength and flexural modulus of the carbon fibre epoxy composite material were reduced, as was the glass transition temperature (T_g). Microscopy suggested that interfacial degradation due to moisture absorption was the likely cause of this, therefore nanoindentation could provide further insight into this degradation.

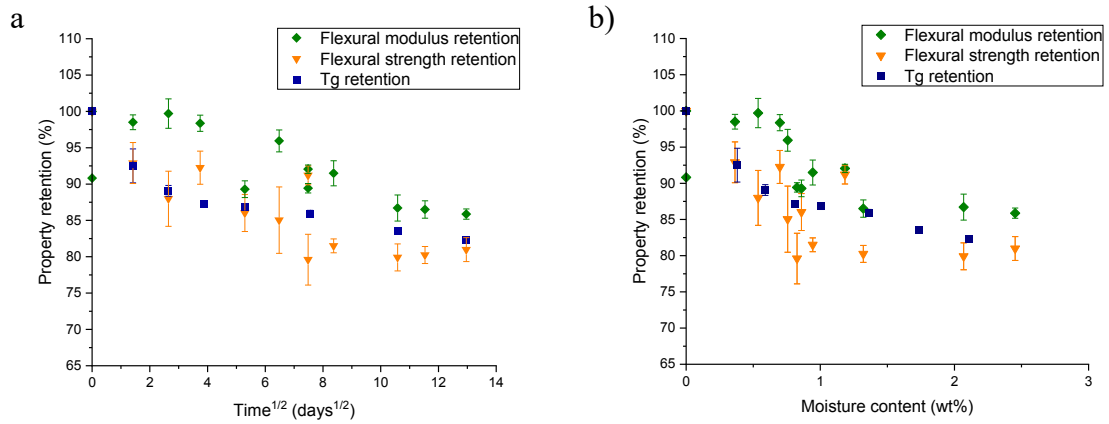

Figure 2 *Changes in material properties of the carbon fibre epoxy composite with increase exposure time, and increase in moisture content* [12]

3.2 Nanoindentation: load – displacement curves

The load – displacement curves from the nanoindentation tests are shown in Figure 3. These show three distinct regions for the responses of either “matrix”, “interphase”, or “fibre”, as measured by the initial individual indentations at specific matrix and fibre locations to establish these bounds of the measurements. Indentations from the 5 × 5 array may be assigned any of the three measurement responses, depending on if the indentation is made in a bulk matrix area, on a fibre, or in a matrix region but close in proximity to a fibre surface.

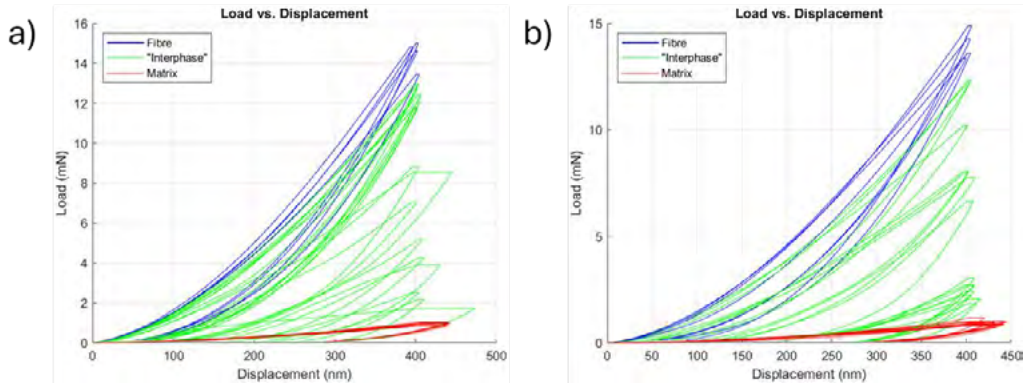

Figure 3 *Load – displacement from indents in the unaged carbon fibre epoxy composite, a) at the top edge and b) in the centre of the cross section.*

The fibres show a stiffer response and have the largest elastic recovery, as was found by Perez et al [14]. Additionally, the fibres showed a higher load response of 13 – 15 mN. Due to this elastic response, no indentations were left permanently in the fibres, which is why no indents are visible in the fibres on the micrographs of the indentation arrays. In contrast, the indents in the matrix regions are clearly observed in the images in Figure 4.

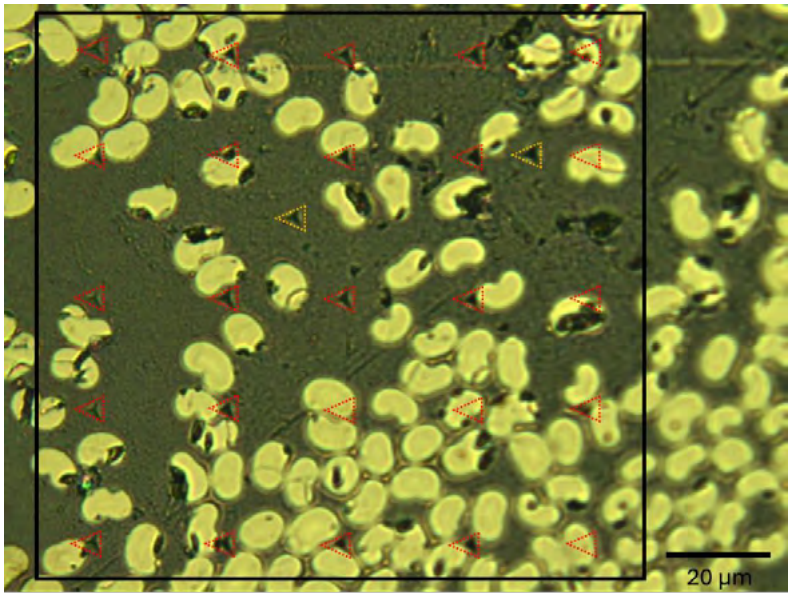

Figure 4 Micrograph of unaged carbon fibre epoxy composite cross section, with the 5 x 5 indentation array highlighted in red, and the matrix indents highlighted in orange.

Unlike the fibres, for the matrix behaviour, which is the bulk matrix response where indents resulted in similar load – displacement curves, there is a clear hysteresis loop which is due to the viscoelasticity in the polymer. This can be seen in Figure 3, where the load – displacement plot shows that the indent depth is retained at 280 - 320 nm, after the indenter tip has been withdrawn. In contrast to the fibres, the load response for the bulk matrix was much lower, at 0.8 – 1.2 mN.

The regions labelled as “interphase”, are those where the response is clearly neither bulk matrix or fibre but within a range of mechanical results, with hardness values between 0.3 and 5.5 GPa, and a load response over a range over 1.2 mN and less than 13 mN, due to close proximity to a fibre surface. While still indenting into a resin matrix area, these indents show a stiffer response than the bulk matrix due to this fibre proximity. Comparable results have been found for polymer composite materials in the

literature, where the distinction between matrix, interphase and fibre responses is clear [14], [18]. In this work, for all indentation locations in the sample, and across the variously aged samples, this response of fibre, bulk matrix, and interphase was observed in the load - displacement curves.

3.3 Nanoindentation: mechanical property results

When comparing the measured hardness and modulus values for indents on each sample at different locations, the results are mixed. The average hardness and modulus values for the bulk matrix are shown in Table 1. Firstly, for the unaged specimen, the values measured at the top edge were 0.24 GPa hardness and 4.50 GPa elastic modulus. At the centre of the specimen, the values were 0.22 GPa hardness and 5.44 GPa modulus. It may have been expected that the properties through the specimen would be of equal value, however the measured discrepancy shows the microscale differences in material properties, which could be attributed to variations in polymer crystallinity due to the manufacture process. However, the measurements of bulk matrix hardness and modulus were averaged only over a small number of indentations, and the modulus values show a larger error.

Table 1. Hardness and elastic modulus results from nanoindentation tests on CFRP samples

Specimen	Hardness (GPa)	Modulus (GPa)
Unaged top	0.24 (± 0.013)	4.50 (± 0.22)
Unaged middle	0.22 (± 0.017)	5.44 (± 1.46)
28-day aged top	0.22 (± 0.011)	4.83 (± 0.72)
28-day aged middle	0.23 (± 0.010)	4.90 (± 0.75)
84-day aged top	0.21 (± 0.006)	4.85 (± 0.81)
84-day aged middle	0.20 (± 0.042)	4.47 (± 0.83)

For specimens that had been immersed in water for 28 days, the bulk matrix hardness at the top edge of the specimen was 0.22 GPa, and modulus 4.83 GPa, whereas in the centre of the specimen was 0.23 GPa and 4.90 GPa for the hardness and modulus respectively. After a total of 84 days of exposure in water, the indentation results were 0.22 GPa hardness and 4.85 GPa elastic modulus at the top edge of the specimen, and 0.20 GPa hardness and 4.47 GPa modulus. The slight changes in values of the specimens exposed for 28 days show lower hardness and modulus at the tope edge compared to the middle, suggesting the water diffusion front was at a higher concentration at the surface and so reduced the mechanical properties compared to the centre. After 84 days immersion, the mechanical properties were reduced compared to 28 days, suggesting greater degradation due to moisture ingress, however it cannot be concluded that the indents show the reduction in mechanical properties through the thickness from the edge to the centre of the specimen.

The bulk mechanical properties after immersion in water for 28 days, when tested in flexure showed a reduction of 12% in strength, and 9% modulus with a 1wt% increase in moisture content [12]. After 84 days immersion, and a 1.5wt% increase in moisture, the properties reduced by 20% strength and 12% modulus. In previous work, when dried out to remove the water, flexural tests were repeated to ascertain the recoverability of these mechanical properties, or if moisture diffusion had caused a permanent degradation and therefore reduction in properties [19]. The results showed a permanent degradation in strength and modulus of 5% after 28 days immersion in water, and microscopy of the fracture surfaces indicated some interfacial degradation even after 7 days immersion in water. This supports the hypothesis from the nanoindentation results – where specimens are dry – that there is not only a permanent reduction in mechanical properties compared to unaged specimens but suggests a more nuanced understanding through the thickness of the material. However, due to small number of indents this is not particularly a statistically significant comparison, therefore further testing is planned for a larger array on indents, in addition to further analysis of the “interphase” indents in relation to their distance from the fibres and resulting hardness and modulus.

4. Conclusions

Nanoindentation is a useful tool for the micromechanical characterisation of through thickness properties in a polymer composite material. In this work, the nanoindentation tests supported bulk scale flexural tests results from previous work [12], where the moisture diffusion in a carbon fibre epoxy UD material caused a permanent reduction in strength and modulus. The nanoindentation tests indicated a reduction in bulk matrix properties from the top edge of the specimen cross sections to the centre due to moisture absorption, but it is not yet clear if this is indeed an effect of water uptake and the diffusion front, or if it is merely variations in the material crystallinity.

Therefore, further work is planned to relate the measured hardness and stiffness data to the distance of the indents from the fibre surface. This will better assess the "interphase" region and highlight the degradation in this region, as suggested by bulk testing and microscopy of fracture surfaces. This also requires improved image analysis. Additionally, further work has begun to increase the statistical relevance of the measured through thickness changes in hardness and modulus by using a NanoTest to conduct 20 x 20 indent arrays through the samples.

Keywords: Digital Image Analysis, Reverse Engineering, Natural Fibres, Failure Modes.

Abstract: The characterization of natural fibers, particularly in understanding their morphological features, and their influence in their mechanical behavior, faces several challenges. On the morphology perspective factors as aspect ratio, geometrical transitions of the organic geometry, presence of defects play a role in the material response. Moreover, the degree of crystallinity, molecular alignment, presence of amorphous regions and elementary fiber arrangement, too. Conventional methods for measuring natural fiber geometry, e.g. micro tomography, can be time-consuming, labor-intensive, and costly, involving complex sample preparation and data analysis procedures. These limitations become more pronounced when physics-informed models require extensive sources of smoothed geometrical data to accurately predict the behavior of natural fibers. An exploratory study was conducted in this work to study samples of bamboo fibers *Guadua Angustifolia* via fracture patterns 3D reconstruction, to provide insights into stress occurrence, fracture mode, crack propagation. This study employs a reverse engineering method, incorporating digital image analysis for measuring the fibers 3D geometry. A monitoring system was developed to reconstruct the fiber's fracture areas which were contrasted with the stress-strain functions and resilience. These findings indicate that the proposed approach can identify failure modes, opening avenues for advanced studies in fracture mechanics of natural fibers.

1. Introduction

The precise understanding of natural fiber's mechanical behavior is challenging given the intricate connection between the mechanical properties and geometry. Firstly, factors such as the variability in the cross section, defects induced from the fiber's extraction process may act as a source uncertainty in the mechanical characterization. Secondly, testing conditions such as gauge and span length can influence the probability that the fiber fracture at different points resulting in a challenge for studying mechanical stress evolution and fracture. Therefore, it is crucial to address with precision the nature of the variability in mechanical properties, whereas notably existing literature emphasizes significant

differences in the tensile strength of natural fibers of the same species and bunch, such as bamboo ranging from 391 to 700 MPa [1, 2]. This fact highlights the necessity of accurately creating 3D reconstructions of the fiber, particularly in the regions where fractures occur. These detailed analyses are made possible by the micro-scale robotized monitoring equipment developed for this research. Gaining a precise understanding of the variability in the mechanical properties of natural fibers is essential for identifying the true origins of failure. This knowledge is crucial for developing composite materials that incorporate natural fibers.

In estimating the mechanical properties of complex natural fibers, digital image correlation (DIC) analysis demonstrates potential for analyzing intricate behavior at the microscale, specifically in the context of elastic local behavior. However, DIC encounters challenges when estimating fracture metrics, as the misalignment that occurs during sample damage in tensile testing complicates the identification of patterns in the final failure mode [3, 4, 5]. These issues underscore the necessity of proposing methods that further complement the DIC technique in studying the fracture geometry of tested fibers. For instance, in the case of hemp fibers, strain maps obtained through the DIC technique indicate that fractures can occur at the interface, but the specific fracture areas could not be evaluated. Therefore, alternative approaches are needed to conduct tests that effectively monitor the damage shape, as fractures can occur at various points and no clear strategy currently exists for identifying damage patterns [5]. The Digital Image Correlation (DIC) technique, while widely used for strain measurement, faces certain limitations when it comes to analyzing fracture events. At the point of fracture, the rapid release of energy can pose challenges for the DIC system. To accurately capture the dynamics of fracture, the recording system requires a higher sampling rate, which can be achieved by using high-speed cameras. However, the use of high-speed cameras often necessitates additional hardware for data acquisition, increasing the complexity and cost of the setup.

While DIC has limitations in capturing the rapid dynamics of fracture, analyzing the fracture surfaces offers an alternative approach to understanding fracture modes without requiring high-speed cameras. Complementary to the DIC technique, the proposed methodology presents an opportunity to develop reverse engineering protocols assisted by image processing techniques. This study aims to correlate the fracture geometry with the fiber toughness.

2. Materials and Methods

2.1. Geometrical characterization of the samples

Bamboo technical fibers *Guadua Angustifolia* were selected bamboo for being studied by a robotized micro-scale geometrical characterization device was developed for the mechanical analysis of natural fibers in the frame of this project. Using this technology, a 3D reconstruction protocol was implemented for estimating volume shape applying a reverse engineering approach to generate a digital mesh of the fibre subsequently converted into a CAD model. The protocol was calibrated contrasting the measurements of one technical fibre of 580 μm average major diameter with a high-resolution tomography (voxel size:700 nm) equipment with 3% of relative error. For the calculation the cross section was measured and compared at 8 points of the length of the sample (See **Figure 1**).

The implemented 3D reconstruction method was applied to calculate an easier to handle geometry compared to micro-cT in terms of computational cost. A typical scan plus reconstruction of a 3D fibre using tomography specialized equipment should take 1.5 hours. Our scanning process using the developed technology reduces this time to (10-15 minutes). For the case of tomography, the resulting DICOM files conversion for obtaining a STL file geometry, mesh errors, overhangs and thin walls can put challenges in the verification and repair for getting the geometry. We point out that our purpose we are oriented to study the external volume and surface of the fibre. In that sense a protocol was implemented to defeature unnecessary details in the studied samples to increase the computational efficiency in the study of the geometry. Due to confidential reasons the process to obtain the mesh is not disclosed in the present manuscript. We point out that for this study the geometry of interest is the shape

external surface of the technical fibers without taking into consideration the middle lamella, elementary fibers, and lumens.

Once the fibre is scanned with our device scanning with triangle geometrical elements, a mesh regularization process is applied to smooth the geometrical transitions of the geometry. The generated mesh was assessed and regularized using Meshmixer software and repaired using Spaceclaim from Ansys 2024 r1 to provide a more homogeneous size of elements. This process was done fixing remaining crossed facets of the mesh and then applying automated skin surface generation. Then, the geometry is converted into a CAD model covered in the surface by the generated skin patches. The reduce the computational cost of the fibre model.

From the tensile tests that will be exposed in the section 2.2, samples of bamboo fibers 5, 9 and 15 were selected for stress-elongation analysis after exploratory experiment. A 2.0 mm extra length from each of the fibers was separated and 3D scanned for having the reference pristine cross-section measurement for each fiber. From the scanned length three cross sectional areas are measured at three different measuring planes over the skinned surfaces, with average diameters ($d1$=226 μm, $d2$= 119.45 μm) micrometers (See scanned samples and shapes in **Figure 2**). Considering the typical irregular cross-sectional shape of the fibers we point out the importance of properly recognize two diameters.

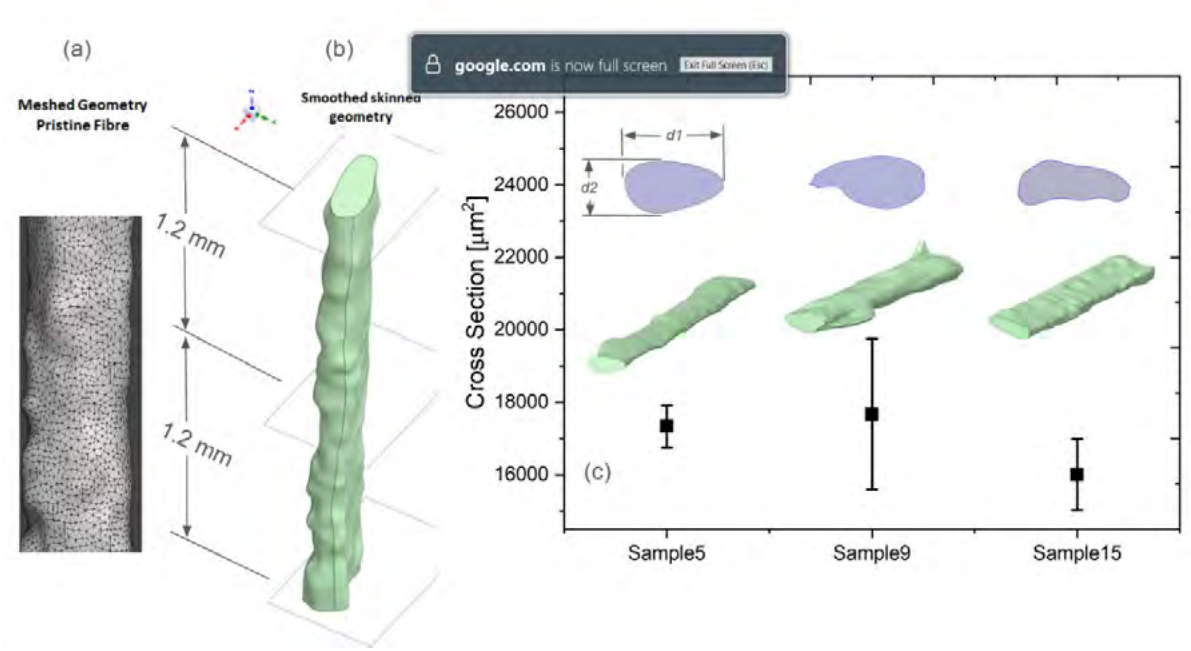

Figure 2. Cross sectional measurements applied in samples for stress-elongation analysis of section 2.2. a) Mesh obtained after measuring with the device). b) Reconstructed fiber skinned geometry c) Cross sectional area and cross sectional shapes for samples 5, 9 and 15.

2.2. Tensile tests and fracture digital reconstruction

A population of 20 bamboo technical fibers randomly selected were experimented in single fibres tensile testing ($d1$=226 μm, $d2$= 119.45 μm). From this population ten fibers were tested with a gauge length of 15 mm and other ten fibers with 20 mm. Following the initial analysis, nine technical bamboo fibers that presented similar trends in their force-displacement behavior were chosen among these for the calculations. We highlight that these samples did not present damage in the gripping zones and not slippage was evidenced in the tests.

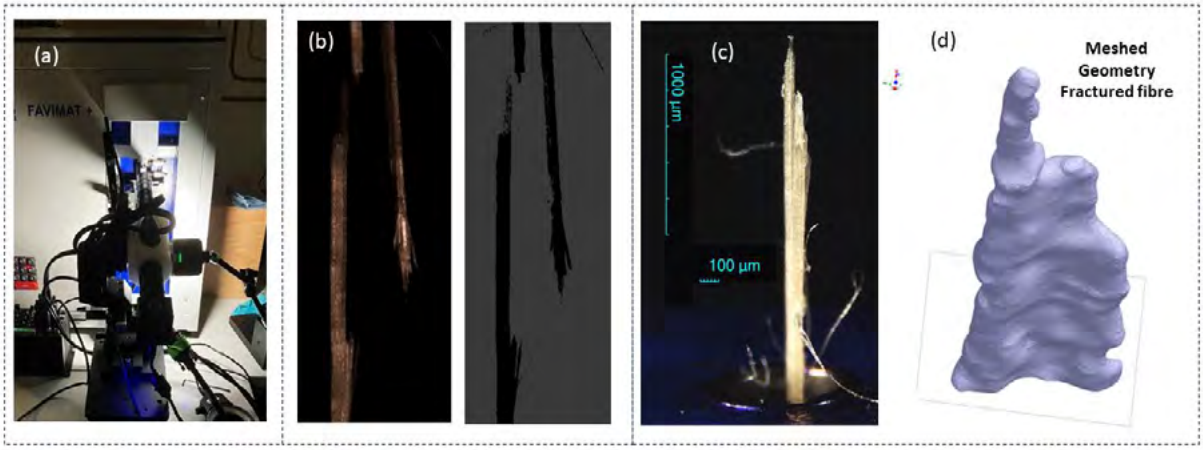

Figure 3. a) Tensile test and recording of the sample failure with the device. b) Image segmentation of the damage mode. c) Image of the fracture 2.4 um/ pixel d) Meshed geometry calculated with the implemented reverse engineering protocol.

The nine selected samples were categorized in tree groups as follows; Group 1 fibers were tested with a 15 mm gauge length and 23 mm span length, while Groups 2 and 3 fibers were tested with a 20 mm gauge length and 28 mm span length. All single-fiber tests were conducted using a TEXTECHNO FAVIMAT tensile testing machine equipped with a 3200 cN capacity load cell, a 0.2 mm/min load rate,

and Plexi polymer 4 mm gripping clamps. From each defined group one representative sample was selected for scanning the damage shape of the resulting damage mode for the 3D reconstruction of the damaged region were the fracture propagated. This selection enabled the categorization of fibers into three groups for 3D reconstruction of the damaged regions. Video recordings of the tests were taken to capture the resulting fractures, with the goal of determining the 3D reconstruction of the fiber at the tip after testing. An explanation of the process is depicted in **Figure 3**.

According to the sample shape, the fracture paths are determined in the CAD model obtained from the mesh. The generated skin divided into surfaces are used to cover the model. To represent the fracture paths and evaluate the area of influence.

3. Results and discussion

After executing the single fiber tests, the force-displacement functions up to the fracture force were obtained and gathered in three groups, as depicted in **Figure 4a**, **b** and **c**. The working hypothesis for the proposed methodology is that samples with similar cross sections and same testing conditions should exhibit a similar characteristic fracture pattern. The resulting testing conditions were established after testing 20 bamboo fibers chosen. The fibers passed the loop test applied to verify that each one did not have preexistent breaks as applied in the methodology for quality assessment of bamboo technical fibers used in epoxy composites samples for flexural characterization [3]. As can be seen in **Figures 4a group 1**, **4b** group 2 and **4c** group3 samples that presented similar force-displacement measurement concerning slopes were conveniently grouped. The sample that exhibited a clear fracture was chosen to be measured and as a representative sample from each group. For the case of the group 1 sample 5, in the group 2 sample 9 and from the group 3 sample 15, as shown in **Figure 4a**, **b** and **c**, respectively. One part of the divided fiber after the damage was chosen for the observation to see in detail the shape in microscope and having initial insights concerning the path in which the crack passes. In the case of samples 5 and 9 the ends these fibers seem to become more sharp suggesting that these shapes have defibrillation appearance with pulled out elementary fibers (see ref [3] description of elementary fibers). Distinctly, Sample 15 is showed to have asymmetric dome appearance at the tip suggesting that probably this fiber of damage was partially presenting defibrillation for the lateral right side see **Figure 4c**.

For each group, one sample was chosen in the group for a microscopic image-measurement with a resolution of 3.45 μm/pixel, to visualize the fracture shape. The morphology of bamboo fractures has been evidenced by SEM measurements as investigated by [3]**.** However, for the reverse engineering of the fracture and modeling purposes it is required to develop cost and time-effective geometry informed models to construct enough databases with smoother and easier to manage geometrical approximations.

Stress-strain function up to the failure was calculated for the selected fibers (samples 5, 9 and 15) and are represented in **Figure 5a** and using calculated cross section in the section in **Figure 2b**. for each sample. The tensile strength of these fibers resulted in mean value of 585.08 ± 50.69 MPa with elongations to failure 1.67 ± 0.17 % elongation. Likewise, the mean of the young modulus among these was obtained to be 35.15 ± 3.83 GPa.

For the scanned fractured fibers and damages, the peak force is represented with respect to the strain value for samples 5, 9 and 15. Sample 15 exhibited the lowest peaks of force, followed by sample 9 and sample 15 (see **Figure 5b**). Fracture of sample 5 seems to be a semi clean shape with almost symmetric appearance, sample 9 appears to be with some symmetric trend with Y shape and sample 5 seems to be asymmetric. In this case it can be inferred that sample 15 can be more influenced by normal stress and more stress transfer capacity in longitudinal direction. Meanwhile samples 9 and 5 seem to be influenced by a combination of shear and normal stress.

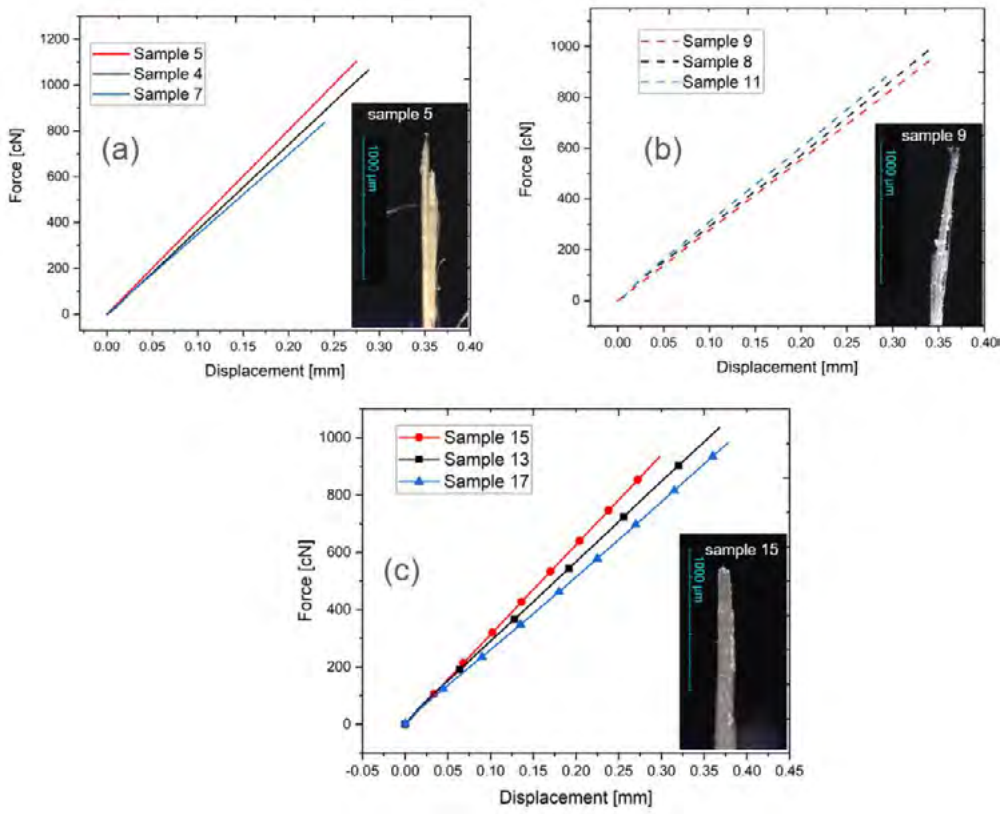

Figure 4. Force displacement functions for the single fiber tensile testing experiments a) Samples of the group 1. b) Samples of the group 2. c) Samples of the group 3

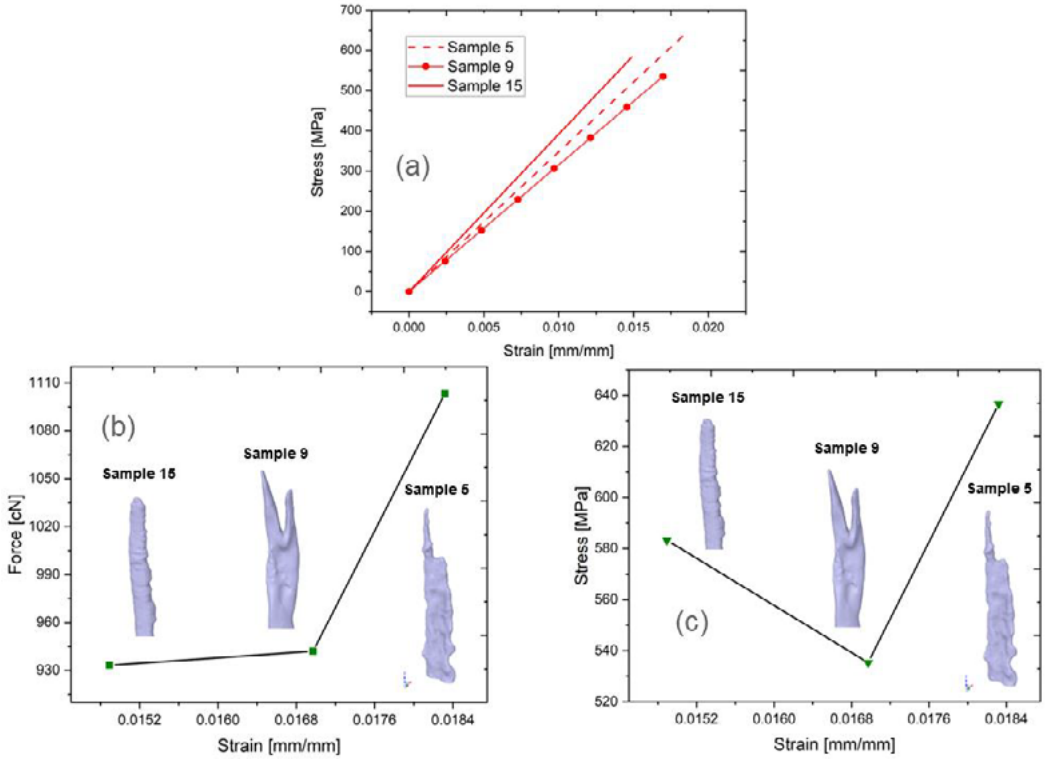

Figure 5. Samples 5, 9 and 15 a) Stress-strain function. b) Force vs strain to failure. c) Stress vs strain to failure

A defibrillation failure results in a larger elongation which is logical since the shear articulate bigger displacements and more force is required to conduct the failure. Moreover, the force-elongation ratio was calculated in the group of samples to monitor the damage. According to the findings, fibers that fail via defibrillation have bigger ratio which can be an indicator of stiffness. Considering the analysis the area in the zone of damage can be linked to the force to determine an approximation of the stress in the surface area.

In what concerns to toughness the area under the curve of the stress-strain was used to determine the Toughness of each sample which from bigger to smaller resulted to be 5.83 J/m^3 (**Sample 5**), 4.54 J/m^3 (**Sample 9**) and 4.34 J/m^3 (**Sample 15**), as depicted in **Figure 6a, b** and **c**.

4. Conclusions

This investigation presents a novel methodology for the geometrical and micromechanical characterization of bamboo fibers (*Guadua angustifolia*) using fracture geometrical measurements. The primary aim of this methodology is to expedite material studies and gain deeper insights into failure mechanics. The geometry of bamboo fibers was determined using a calculated mesh generated from advanced digital image processing techniques. During single fiber tensile testing, samples exhibited failures that directly correlated with the resilience of the material and the specific fracture areas. Notably, sample 9 and sample 15 showed 22.11% and 25.51% less toughness, respectively, compared to sample 5.

Damage modes such as defibrillation and semi-clean failure were categorized and quantified in the geometrical representation at the tip of the fracture damage. These damage morphologies align with the failure modes reported in the literature, where semi-clean failure and defibrillation have been studied using SEM microscopy. The expertise gained from this investigation suggests the establishment of new standards for experimenting with bamboo natural fibres and analysing data sets of geometries to create predictive models. Moreover, topological information patterns are being measured with the device for the implementation of machine learning models for composite modelling applications. Also, future works will be undertaken to complement the methodology with Digital Image Correlation technique. The contribution of this work is oriented to the development physics-informed models.

Keywords: Pultruded composite, Hygrothermal effect, Mechanical testing

Abstract: Nowadays, mobility is experiencing numerous transformations driven by the need to reduce carbon footprint. The INFRAlight project aims to develop an environmentally friendly composite railway infrastructure to reduce the carbon footprint in economic development. Rails are subjected to severe natural and mechanical weather conditions such as temperature variations, relative humidity, UV radiation. Therefore, the study of durability under severe service conditions is essential to the industrial exploitation of these materials. One of the materials considered for this application is a pultruded fibre-reinforced plastic (FRP) made of polyamide 6 (PA6) and glass fibres (GF). Literature shows that the durability of pultruded composite materials is still an understudied topic. However, several studies have shown that PA6 polymers are sensitive to moisture, leading to changes in their physicochemical properties and a decrease in their mechanical properties. In this study, accelerated hygrothermal ageing at 70 °C and 80 %RH was applied to the PA6/GF pultruded composites. The results show a decrease in mechanical properties during water absorption, followed by a recovery upon drying, highlighting the reversibility of the ageing process.Viscoelastic characterisation from vibration analysis complement these results to understand the effect of moisture on the material.

1 Introduction

Polyamide 6 (PA6) reinforced with glass fibres (GF) is widely used in many industrial sectors due to its mechanical performance and chemical properties. Pultrusion is a continuous process for producing composite profiles with uniform cross-sectional areas.. However, several studies have shown that PA6 intensively absorbs water due to the presence of amide groups (-HN) in the amorphous part of the polymer. Initially,water occupy the available space (free volume) and then form hydrogen bonds.As more molecules accumulate,the polymer's chain mobility is activated, reducing the attraction between molecules and increasing flexibility.This phenomenon explains the plasticization of PA6 after the absorption of water.This sensitivity to hygrothermal conditions has a significant impact on its mechanical and physicochemical properties. This effect has been extensively studied in the literature [1,2]. For example Taktak et al. [4] observed a loss of approximately 60% in tensile strength and 74% in Young's modulus for PA6 specimens subjected to hydrothermal ageing at temperatures between 70°C and 90°C, while Pivdiablyk et al. [3] showed a decrease of the shear modulus, shear stress at yield and shield stress at rupture for woven PA6/GF composites after hygrothermal ageing (-40°C<T<80°C)and (0<RH<85%).

This paper aims to study the effect of water absorption at 70°C and 80% RH on the mechanical and physicochemical properties of a PA6/GF pultruded composites to assess the suitability of such materials for outdoor use on rails. To evaluate this effect, mechanical tests, vibration analysis and dynamic mechanical analysis were performed before, during and after ageing.

2 Materials and methods

The material used in this study is a pultruded PA6/GF composite 100% UD. This pultruded material is made up of two types of rovings the first is a 2400 tex roving with 17 µm filaments and the second is a 4800 tex roving with 24 µm filaments.On the outer layers are found the 2400 roving and in the core the 4800 roving.This led to a fibre volume fraction of 68 %. The pultruded profiles were cut, using water jet cutting, into specimens of different sizes in three orientations 0°, 45° and 90° relative to the fibre orientation. All cut specimens were then conditioned in a regulated room at 22 °C and 50 %RH to ensure that the specimens were in the same initial state. Table 1 shows the dimensions of the different samples.

Samples	Length (mm)/length between stubs (mm)	Width(mm)	Thickness(mm)
Fibre orientation 0°	250/150	25	2
Fibre orientation 45°	100/50	20	2
Fibre orientation 90°	90/50	20	2

Table 1: Dimensions of samples in the different orientations

2.1 Sorption

Moisture absorption tests were conducted by placing the specimens in climatic chambers at 70 °C and 80 %RH. The percentage of water absorbed was periodically measured by weighting the specimen with a scale of 0.1 mg accuracy (Sartorius Secura225D-1S) according to ASTM D5229/D 5229M-92 standard specifications [5]. The absorption curves were then obtained by the gravimetric method by averaging the percentage of water absorbed on five samples. The moisture content of a sample at a given duration, M_t was determined as follows:

$$M_t(\%) = \left(\frac{W_t - W_0}{W_0}\right) \times 100 \quad (1)$$

Where W_t and W_o are the weights of the sample at a given time and before ageing, respectively.

After reaching the saturation point, quasi-static mechanical tests were conducted on half of the specimens and the rest were placed for 50 days in a desiccator which in turn was placed in an oven for drying at 70 °C and 0 %RH. Desorption was monitored through gravimetric analysis until an equilibrium state was reached. The mechanical properties were also examined to evaluate the reversibility of the ageing process.

2.2 Quasi-static mechanical analysis

All tensile tests were conducted according to ISO 527-4 on an MTS Criterion C45.105 tensile machine equipped with a 100 kN load cell at a speed of 3 mm/min for specimens with a 0° fibre orientation, and 1 mm/min for specimens with a 45° or 90° fibre orientation. This difference in the loading speed aims to match the same strain rate for all the tested samples (0.0003 s^{-1}). These different tests were instrumented by a digital image correlation (DIC) technique to evaluate the in-plane strain tensor. Young's modulus was calculated using linear regression between 0.05 % and 0.25 % strain on five samples in each case and the shear modulus G_{LT} was calculated from tensile test results for each sample as follows:

$$\frac{1}{G_{LT}} = \frac{4}{E_{45}} - \frac{1}{E_L} - \frac{1}{E_T} + 2\frac{\nu_{LT}}{E_L} \quad (2)$$

Where E_L, and E_T are Young's moduli measured from tensile tests in the longitudinal and transverse directions, E_{45} is the apparent modulus measured from the off-axis test, and ν_{LT} is the Poisson's ratio measured from tensile tests in the transverse direction.

2.3 Vibration analysis

The viscoelastic parameters (elastic modulus and damping factor) of the composite specimens were determined using impulse modal analysis. The principle of this non-destructive method is to study the dynamic behaviour of a coupon through its natural vibration modes. In practice, the samples were suspended with elastic bands to simulate free-free boundary conditions. The samples were subjected to

a longitudinal or transverse mechanical impulse using an impact hammer. An accelerometer positioned on the sample captured its transient vibratory response(in traction/compression and flexion). Through signal acquisition and Fast Fourier Transform (FFT) analysis, the frequency response function can be determined. Considering sample dimensions, the dynamic elastic modulus is calculated from beam theory as follows:

$$E_t = 4 \times \rho \times L^2 \times f_t^2 \quad (3)$$

$$E_f = 0.946 \times \rho \times \frac{L^4}{e^2} \times f_f^2 \quad (4)$$

Where E_t and E_f are the dynamic elastic modulus in traction/compression and flexion, respectively, ρ is the material density, L the sample length, e the sample thickness and f_t, f_f the resonance frequencies of the first tensile and first flexural vibration modes, respectively.

2.4 Dynamic mechanical analysis

This technique allows for the characterisation of the viscoelastic parameters of the material. The viscoelastic behaviour is evaluated through forced dynamic tension-compression testing as a function of temperature. After verifying the linear domain range, a displacement amplitude of 1 µm was imposed at a frequency of 10 Hz to the PA6/GF composites with fibre orientations of 90°. A heating rate of 2 °C/min was applied to identify the evolution of the glass transition temperature T_g. The dimensions of the specimens used for this test were 60 × 10 × 2 mm. The complex dynamic elastic modulus E^* and loss factor $\tan(\delta)$ can be written as:

$$E^* = E' + iE'' \quad (5)$$

$$\tan(\delta) = \frac{E''}{E'} \quad (6)$$

Where E' is the storage modulus (real part) related to the material elastic behaviour, and E'' is the loss modulus (imaginary part) related to the material viscous behaviour. The loss factor $\tan(\delta)$ represents the ratio of the viscous to elastic effects.

3 Results and discussion

3.1 Water sorption

Around 30 specimens were aged in a climate chamber at 70 °C and 80 %RH. The absorption curves of PA6/GF in different orientations are shown in Figure 1. It's apparent that the water uptake of PA6/GF follows a two-stage process: an initial stage leading to maximum moisture absorption where the absorption phase appears to be linear with the square root of time. However, in the second stage, the diffusion behaviour shows a decreasing trend after reaching maximum moisture absorption. A similar behaviour was already observed by Lin Sang [6] where the moisture diffusion was investigated for woven carbon fabric reinforced PA6 after hydrothermal ageing. This loss was attributed by the authors to the cleavage reactions of macromolecular chains during ageing, known as leaching. Both phenomena start at the same time when the composite to hygrothermal ageing. The phenomenon of sorption is predominant at short times and becomes less and less important (Fickian behaviour),while leaching is initially very slight and then becomes more pronounced and predominant.

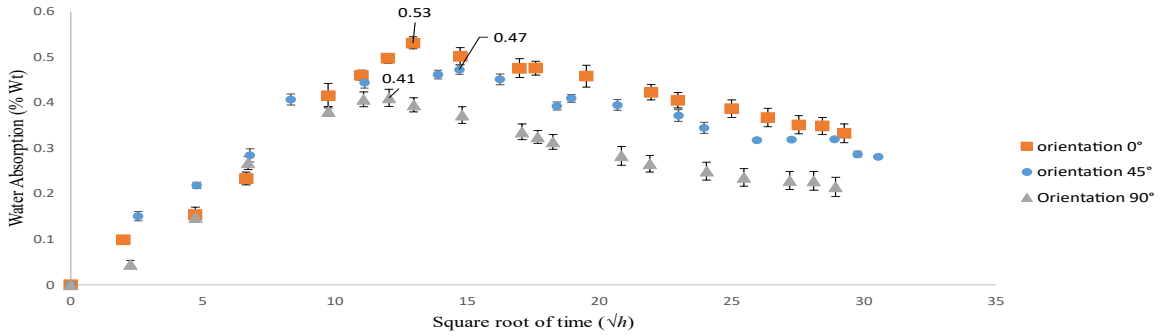

Figure 1 : Moisture uptake curves of PA6/GF specimens in three orientations 0°, 45°, 90°.

3.2 Water desorption

To examine the reversibility of ageing mechanisms, the PA6/GF specimens were dried at 70 °C and 0 % RH. The desorption curves show that the amount desorbed at equilibrium is 0.81 % for the specimens with a 0° fibre orientation, 0.92 % with a 45° fibre orientation, and 0.86 % with a 90° fibre orientation, different from the saturation values reached during the absorption phase. This saturation is confirmed by the vibrational analysis data that shows that dynamic moduli in bending and tension reach constant values at these points.

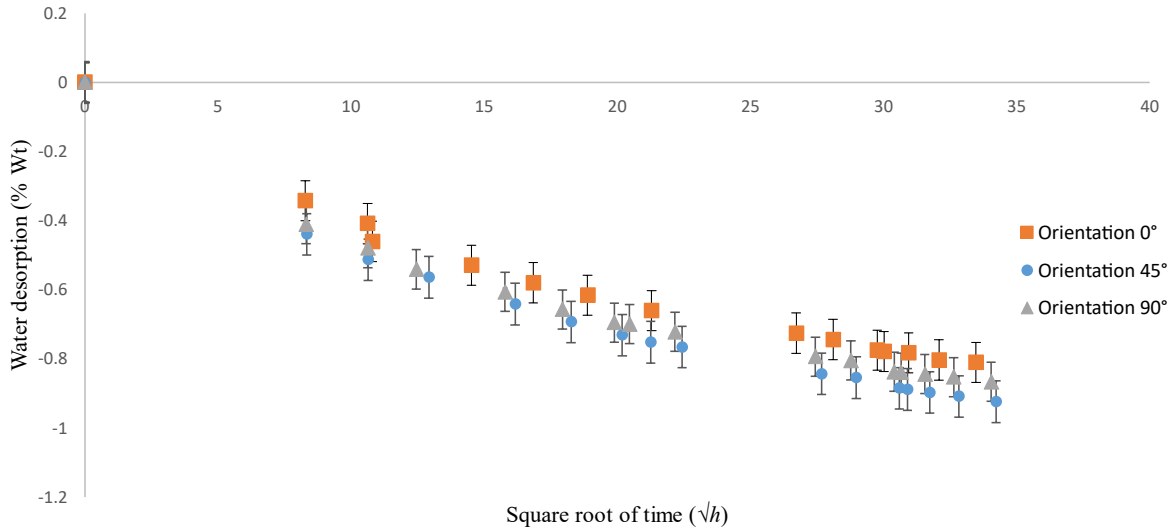

Figure 2. Desorption curves of PA6/GF after drying.

3.3 Quasi-static mechanical properties

Uniaxial tensile tests were conducted on unaged (reference condition), aged and dried states. Figures 3 and 4 summarise the mean values and standard deviation of the quasi-static mechanical properties.

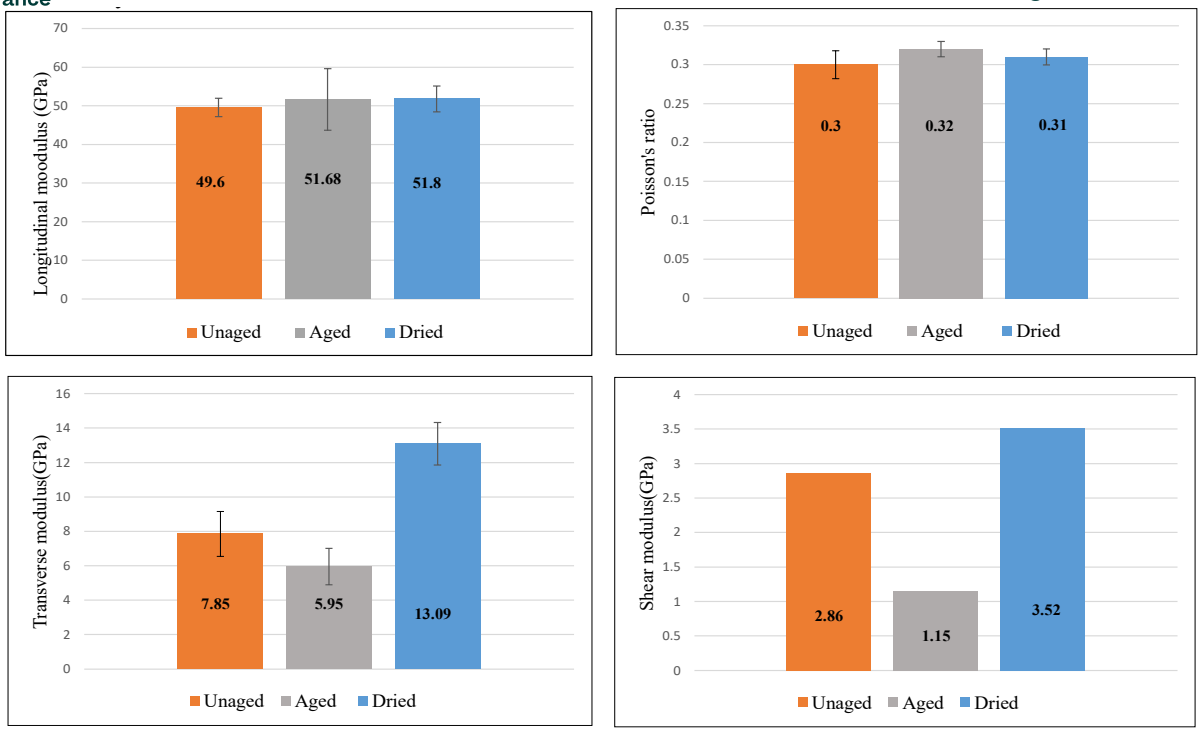

Figure 3: Comparison of elastic properties between unaged, aged, and dried samples.

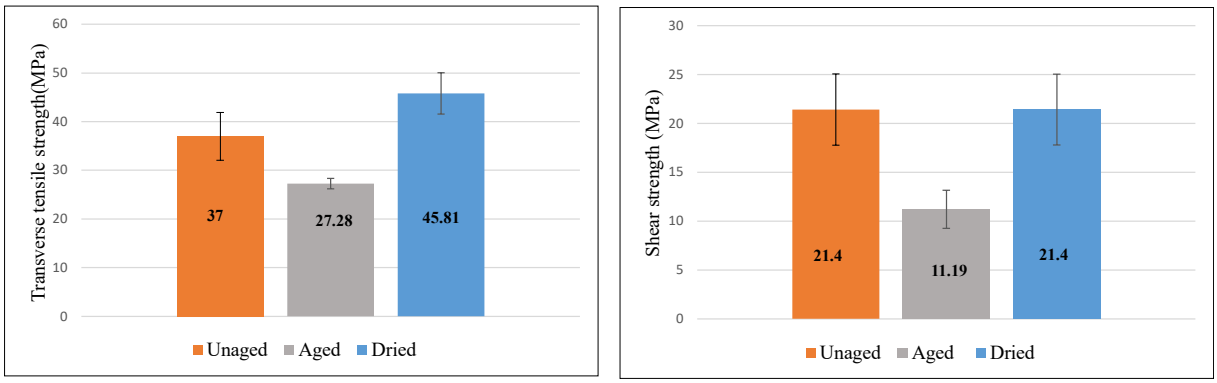

Figure 4: Comparison of ultimate properties between unaged, aged, and dried samples.

First, tests carried out on the materials along fibre directions allow to obtain the longitudinal modulus and the Poisson's ratio. No difference is observed for these parameters between the unaged, aged, and dried state. This result confirms that the mechanical performance PA6/GF along the fibre direction is dominated by the glass fibre which is unaffected by the absorption of water.
The second test is the transverse tensile test. A decrease in transverse modulus from 7.85 GPa to 5.95 GPa (24.2% loss) is observed as well as a decrease of transverse tensile strength from 37 MPa to 27.28 MPa (27% loss). Then this value increases respectively to 13.09 GPa and 45.81 MPa after drying.
The third test shows the same trend where the shear modulus decreased from 2.86 GPa to 1.15 GPa (60% loss) and the shear strength from 21.4 MPa to 11.19 MPa (48% loss). After drying, these values increase respectively to 3.52 GPa and 21.4 MPa.
During ageing, water diffuses into the composite mainly through the resin, even though diffusion may also occur at the resin/fibre interfaces. Water absorption in the resin leads to a decrease in its inherent rigidity due to plasticization (increased mobility of macromolecular chains). After drying PA6 polymer gains a certain rigidity leading to an increase in the mechanical properties of the PA6/glass fibre in the directions 90° dominated by the matrix behaviour. This gain of properties after drying is due to an additional water loss related to the difference between storage conditions (22°C,50% RH) and drying conditions.

3.4 Vibration analysis

To gain a deeper understanding of how hygrothermal ageing impacts the mechanical properties of PA6/GF, non-destructive testing by impulse modal analysis was conducted. Figures 4 and 5 display the evolution of the dynamic elastic modulus during ageing and drying, respectively in tensile and flexural mode. Each point reflects the average of five measurements. For specimens with fibre orientations at 0°, it can be observed that the longitudinal modulus did not vary during ageing and drying, confirming that glass fibres, which are not affected by water absorption dominate the mechanical properties in this orientation. But for the other orientations, Young's modulus decreases with ageing, due to a plasticisation of the matrix. Once saturation is reached and samples dried, an increase in this modulus is observed, confirming the gain of rigidity of the material as observed with the quasi-static tests.

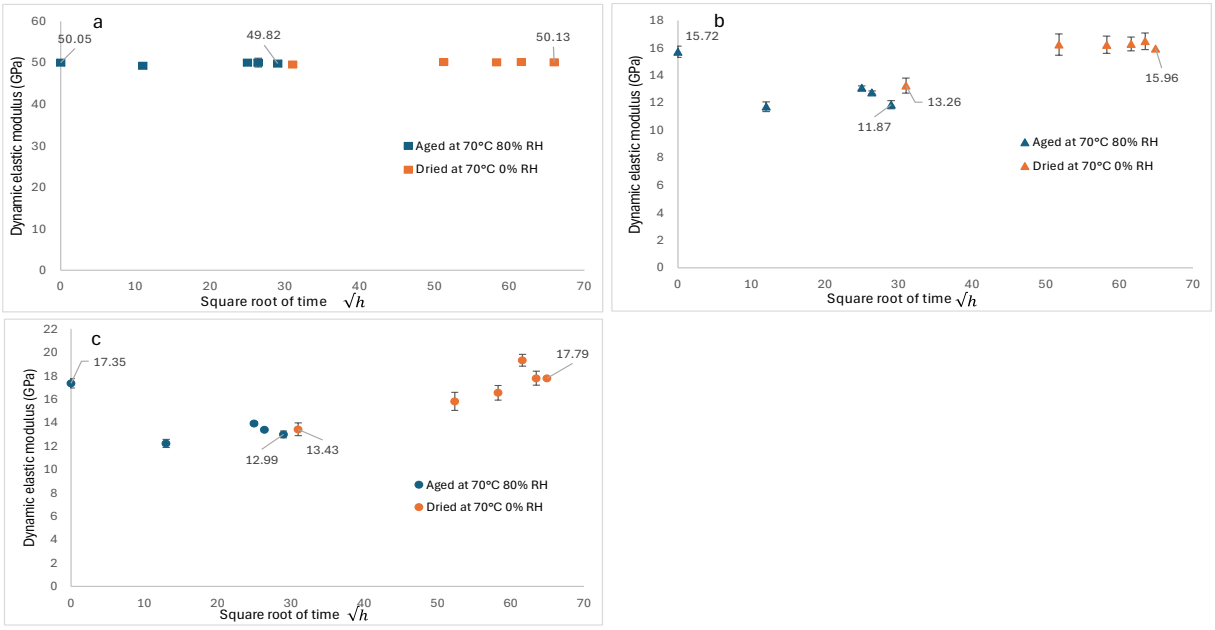

Figure 5:Evolution of dynamic elastic modulus in traction mode during ageing and drying for samples with a) 0° fibre orientations b) 90° fibre orientations c) 45° fibre orientations.

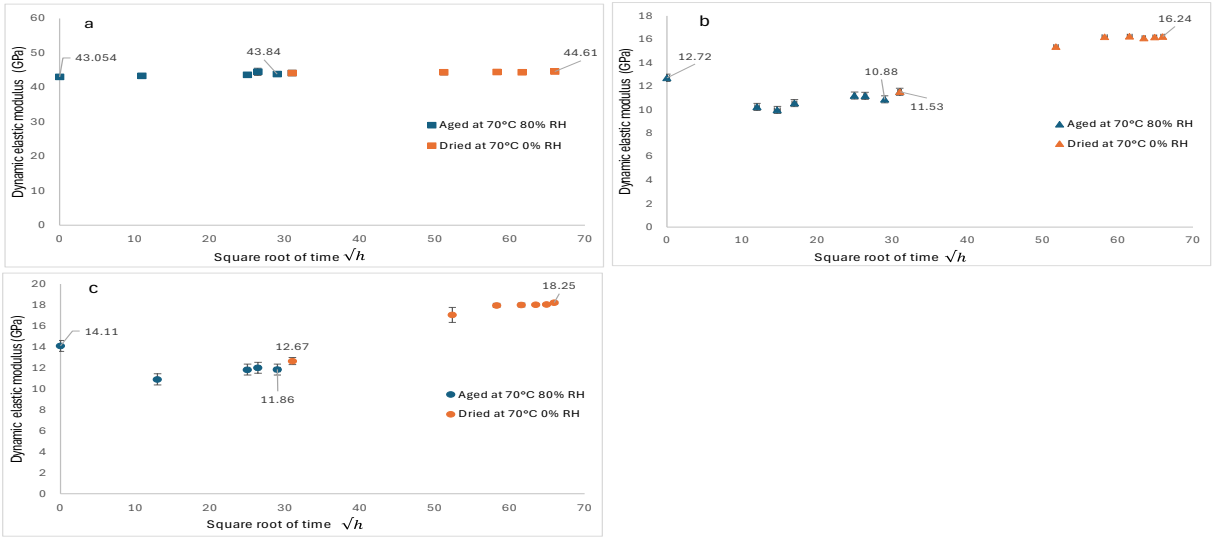

Figure 6: Evolution of dynamic elastic modulus in flexion mode during ageing and drying for samples with a) 0° fibre orientations b) 90° fibre orientations c) 45° fibre orientations.

3.5 Dynamic mechanical properties

Many studies confirm that hygrothermal ageing induces physical and chemical degradation which can affect the mechanical response of the composite material. A DMA test was conducted to identify changes of storage modulus (E') and loss factor tan(δ) between the unaged and the aged states.

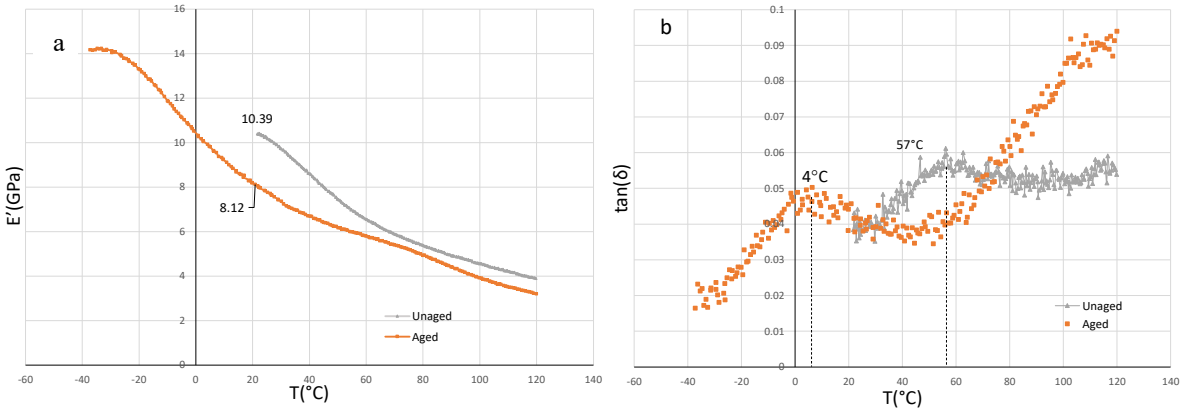

Figure 7:DMA (a) storage modulus and (b) loss factor results of unaged and aged PA6/GF fibres.

Figure 7 shows a 22 % decrease in the storage modulus at 20 °C from 10.4 GPa to 8.1 GPa due to ageing. The results indicate a pattern like that observed in quasi-static experiments and vibrational analysis, with a 24.2% (Figure 3) and a 25.5% (Figure 5) decrease respectively in the quasi-static and dynamic transverse modulus. This decline is attributed to the influence of water, caused by the plasticizing impact of molecules within the polyamide [7]. Besides, there is a significant decrease in T_g (i.e. the temperature corresponding to the peak of the loss factor) from 57°C to 4°C after ageing. The decrease of T_g can be related to the increase in the mobility of the PA6 polymer chains due to the formation of hydrogen bonds between the amide groups and water [8][9].

The results obtained from this article show that the absorption curve of PA6/GF at 70°C and RH=80% shows two stages: the first is a rapid water uptake and the second is a mass loss due to polymer degradation. This water uptake leads to a decrease in mechanical properties especially for samples with fibre orientations of 90° and 45°due to a plasticization effect. Then DMA test shows a decrease in the Tg,this effect is widely shown in the literature where the water absorbed breaks the secondary bond between the polar groups leading to a decrease in the Tg.

4 Conclusion

In this study, hygrothermal ageing of pultruded PA6/GF in the different orientations at 70°C and 80% RH were investigated. The absorption curves exhibit two distinct phases: an initial stage in which water absorption rises until it reaches a peak, followed by a subsequent phase characterized by a steady decline in mass relative to the square root of time.

To study the effect of water molecules on the mechanical properties of pultruded PA6/GF, tensile tests, and vibrational analysis were evaluated. A decrease in the mechanical properties for the specimens with 90° and 45° of fibre orientations is observed, while these properties are not affected for the specimens with 0° of fibre orientations. DMA analysis shows a significant decrease in the T_g due to an increase in the mobility of PA6 chains. This study will be complemented by a numerical model to predict the response of the material after other hygrothermal conditions.

Abstract
Bimaterial interface cracks in composite materials can either continue propagating along the interface or deviate their path, an event known as crack kinking, which can heavily impact structural integrity. To understand the crack kinking phenomenon, in literature is proposed a linear mathematical model based on six coefficients, which depend only on the kink angle and material properties. While earlier studies offer limited data on these coefficients for specific bimaterials, our work presents a verified semi-analytical approach that served as the foundation for the newly developed Matlab app introduced to compute coefficients for a wider range of bimaterial combinations.

1. Introduction

Composite materials have a big importance in various industries due to their exceptional combination of high stiffness and low weight. However, their widespread application is often hindered by susceptibility to damage, including debonding and cracking. These issues are critical and challenging to detect, potentially compromising structural integrity significantly. This vulnerability to damage, which arises from factors such as manufacturing processes, fatigue cycles, and impacts, highlights the importance of understanding and mitigating these risks. An intriguing phenomenon in this regard is crack kinking, where cracks deviate into adjacent layers at specific angles. Therefore, the understanding of the behavior and propagation path of the kink crack can be helpful to mitigate the damage in bimaterial layers.

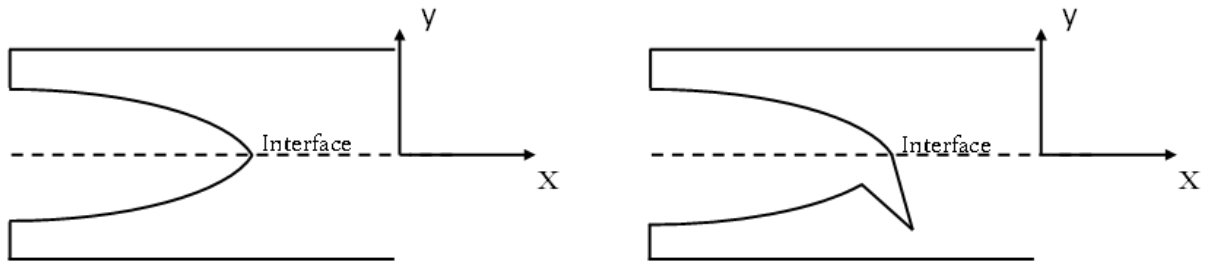
The mathematical model for addressing kinking in isotropic bimaterial solids was formulated by Hutchinson and He [1] and extended further by He et al. [2], who, under linear elastic fracture mechanics (LEFM) assumptions, connected linearly the complex stress intensity factor (SIF) of the interface, the complex SIF of the kink crack and in-plane stress at the crack. The relationship is based on three complex coefficients which depend on the kink angle Ω and the Dundurs' parameters α and β. The values of several coefficients were tabulated for limited combinations of α and β by Hutchinson and He in [3], while other values were provided in a plot by He et al. [2] for many values of α and $\beta = 0$.

Subsequently, Wang [4] and Wang et al. [5] further expanded the kinking model to include interface cracks occurring between two dissimilar anisotropic elastic solids. In addition to the Dundurs'

parameters and kink angle, the coefficients now also rely on dimensionless parameters λ and ρ defined in [6], which give information on the anisotropy level.
However, despite these advancements, a straightforward method for determining coefficients for the kinking model for generic bimaterial layers remained non-existent. Yet, more recently Jakobsen et al. [7] proposed and verified a semi-analytical alternative strategy based on finite element (FE) analyses and algebraic manipulation to find the coefficients in isotropic elastic bimaterials. The approach was adopted also by Noijen et al. [8] who built a Response Surface Model (RSM) [9], thanks to which it is possible to obtain immediately the solution of the coefficients for any isotropic bimaterials as a function of α, β and Ω.
In this work, the same semi-analytical approach is adopted, and its functionality is verified for anisotropic materials. Based on the obtained results, a newly developed Matlab app is introduced to compute the coefficients of the kinking model straightforwardly for various bimaterial combinations.

2. Mathematical model of a crack kinking out of an interface

The Dundurs' parameter α and β, the oscillatory index ϵ, the dimensionless anisotropic parameters λ and ρ for anisotropic bimaterial solids are defined in [6].



The mixed-mode angle ψ measures the type of loading acting at the crack tip. For the interface crack in a bimaterial it is defined as follows:

$$\tan(\psi) = \frac{\mathrm{Im}\left(Kl^{i\epsilon}\right)}{\mathrm{Re}\left(Kl^{i\epsilon}\right)} \tag{1}$$

where K is the complex SIF of the interface crack, with $K = K_1 + iK_2$; l is a characteristic length for the problem of the interface crack. If $\psi = 90°$, the loading condition is a pure mode-II, while if $\psi = 0°$ it is pure mode-I. The characteristic length must be chosen accurately because it can shift the value of ψ.
The event of a crack kinking out from an interface is illustrated in Figure 1. Phenomenon of a crack kinking out from an interface.The complete 2D model formulated by Hutchinson and He [1], and extended further by He et al. [2], describes the phenomenon and defines the kink crack complex SIF as a linear combination of the interface complex SIF and the crack tip in-plane stress through the complex coefficients c , d and b. It is the following:

$$K^{kink} = cKa^{i\epsilon} + \overline{dK}a^{i\epsilon} + b\sigma_0\sqrt{a} \tag{2}$$

where a represents the length of the kink crack; σ_0 is the in-plane stress generated by either residual stresses or external loads; the overline represents the complex conjugate; K^{kink} is the complex SIF at the kink crack, with $K^{kink} = K_I + iK_{II}$.

a) Interface crack b) Crack kinking from an interface

Figure 1. Phenomenon of a crack kinking out from an interface.

The coefficients c, d and b used in Eq. (2) are complex and defined as follows:

$$\begin{aligned} b &= b_1(\alpha,\beta,\lambda_j,\rho_j,\Omega) + ib_2(\alpha,\beta,\lambda_j,\rho_j,\Omega) \\ c &= c_1(\alpha,\beta,\lambda_j,\rho_j,\Omega) + ic_2(\alpha,\beta,\lambda_j,\rho_j,\Omega) \\ d &= d_1(\alpha,\beta,\lambda_j,\rho_j,\Omega) + id_2(\alpha,\beta,\lambda_j,\rho_j,\Omega) \end{aligned} \tag{3}$$

where the subscript j = 1, 2 refers to material above and below the interface, and Ω is the kink angle.

If Eq. (2) is expanded, it becomes:

$$\begin{aligned} K_I^{kink} &= c_{11}\mathrm{Re}\left(Ka^{i\epsilon}\right) + c_{12}\mathrm{Im}\left(Ka^{i\epsilon}\right) + b_1\sigma_0\sqrt{a} \\ K_{II}^{kink} &= c_{21}\mathrm{Re}\left(Ka^{i\epsilon}\right) + c_{22}\mathrm{Im}\left(Ka^{i\epsilon}\right) + b_2\sigma_0\sqrt{a} \end{aligned} \tag{4}$$

where Re and Im denote, respectively, the real and imaginary parts of the complex terms. The new coefficients correspond to:

$$\begin{aligned} c_{11} &= \mathrm{Re}(c+d) = c_1 + d_1 \\ c_{12} &= -\mathrm{Im}(c+d) = -c_2 - d_2 \\ c_{21} &= \mathrm{Im}(c-d) = c_2 - d_2 \\ c_{22} &= \mathrm{Re}(c-d) = c_1 - d_1. \end{aligned} \tag{5}$$

3. Methodology

3.1. Analytical approach

The method proposed by Jakobsen et al. [7] and adopted also by Noijen et al. [8] consists in solving a 6x6 linear system to find the coefficients $b_1, b_2, c_{11}, c_{12}, c_{21}, c_{22}$. These coefficients are determined by constructing six equations based on Eq. (2) or Eq. (4), each corresponding to three loading conditions with different ψ values, ensuring that the determinant of the system matrix is non-zero.

Jakobsen et al. [7] solved the system in two steps by decoupling the problem. The first step consisted in deriving the coefficients c_1, c_2, d_1 and d_2 by solving a 4x4 linear system obtained setting the value of $\sigma_0 = 0$. The second step is built upon the solutions of the first one and is a 2x2 linear system to find coefficients b_1 and b_2.

However, Noijen et al. [8] directly solved the 6x6 system in one step, employing a strategy that eliminates the need to search for loading conditions with a null in-plane stress σ_0.

The 6x6 linear system is the following:

$$\underbrace{\begin{bmatrix} c_{11} \\ c_{12} \\ c_{21} \\ c_{22} \\ b_1 \\ b_2 \end{bmatrix}}_{\boldsymbol{c}} = \underbrace{\begin{bmatrix} f_1^{\psi_1} & f_2^{\psi_1} & 0 & 0 & f_3^{\psi_1} & 0 \\ 0 & 0 & f_1^{\psi_1} & f_2^{\psi_1} & 0 & f_3^{\psi_1} \\ f_1^{\psi_2} & f_2^{\psi_2} & 0 & 0 & f_3^{\psi_2} & 0 \\ 0 & 0 & f_1^{\psi_2} & f_2^{\psi_2} & 0 & f_3^{\psi_2} \\ f_1^{\psi_3} & f_2^{\psi_3} & 0 & 0 & f_3^{\psi_3} & 0 \\ 0 & 0 & f_1^{\psi_3} & f_2^{\psi_3} & 0 & f_3^{\psi_3} \end{bmatrix}^{-1}}_{\boldsymbol{F}} \underbrace{\begin{bmatrix} K_I^{kink,\psi_1} \\ K_{II}^{kink,\psi_1} \\ K_I^{kink,\psi_2} \\ K_{II}^{kink,\psi_2} \\ K_I^{kink,\psi_3} \\ K_{II}^{kink,\psi_3} \end{bmatrix}}_{\boldsymbol{K^{kink}}} \tag{6}$$

with the components of the matrix $\boldsymbol{F}$ to be:

$$\begin{aligned} f_1 &= [K_1\cos(\epsilon\log(a)) - K_2\sin(\epsilon\log(a))] \\ f_2 &= [K_2\cos(\epsilon\log(a)) + K_1\sin(\epsilon\log(a))] \\ f_3 &= \sigma_0\sqrt{a}\,. \end{aligned} \tag{7}$$

The superscript ψ_j with $j = 1,2,3$, refers to the three needed loading conditions.

3.2. Numerical procedure

The components of matrix $\boldsymbol{F}$ and vector $\boldsymbol{K^{kink}}$ are found by solving three different FE models: the *interface crack* model, *interface stress* model and the *kink crack* model.
The *interface crack* model represents the crack at the interface of a bimaterial structure. It is used to obtain the relative displacement δ_x and δ_y of the crack flanks. These values are post-processed with the crack surface displacement extrapolation (CSDE) method [10] to calculate the energy release rate (G_{i_j}) and the phase angle (ψ_j) of the interface crack for the given loading condition. These values are needed to compute the SIFs of the interface crack.
The *kink crack* model represents the crack kinking from the interface into one of the layers. It is used to compute the SIFs at the tip of the kink crack at various kink angles.
The *interface stress* model is similar to the interface crack model but without a crack. It is used to obtain σ_0, which represents the stress in the direction of the interface (σ_{xx}). This value is obtained at the node of the material where the crack is assumed to kink and at the same location as the interface crack tip.

3.3. Iterative process and curve fitting

The analytical and the numerical procedures were performed in an iterative loop for many bimaterial combinations, and the coefficients obtained were stored in a large set of data. Then, these values were used to create 8D fitting polynomials able to find straightforwardly the value of the six coefficients without going through the classic procedure. During the iterative process, while α and β were left varying through their entire range, to limit the computational time, it was only possible to cover a limited domain for λ_j and ρ_j of the materials of the two layers. The domains are described below:

$$\begin{gathered}\lambda_1 \in [0.05, 1] \\ \lambda_2 \in [0.05, 1.5] \\ \rho_1 \in [1, 2.75] \\ \rho_2 \in [0.25, 3]\,.\end{gathered} \tag{8}$$

4. Developed tool

The developed tool is a simple Matlab app which contains a tabbed panel where the plot of the desired coefficients is shown. The required inputs include α, β, $\lambda_1, \lambda_2, \rho_1, \rho_2$ and the desired kink angles Ω, which can be specified with maximum and minimum values and a step size for the range between them. Additionally, the outputs include the values of the coefficients at the specified parameters and the coefficient of determination (R^2), which measures the accuracy of the regression model.
The app performs polynomial curve fitting on sub-domains created from values in Eq. (8) to enhance the accuracy. Subsequently, the input values are substituted into the polynomial equation to determine the coefficients.
In Figure 2 a screenshot of the Graphic User Interface (GUI) of the Matlab app is presented.

5. Conclusions

The reliability of the semi-analytical method proposed in [7] to determine the coefficients of the kinking model was verified for anisotropic bimaterial layers. A Matlab app was developed to find the coefficients for a much wider range of anisotropic and Dundurs' parameters, respectively λ_j, ρ_j and α, β, in order to make the model applicable for broader and realistic material configurations.

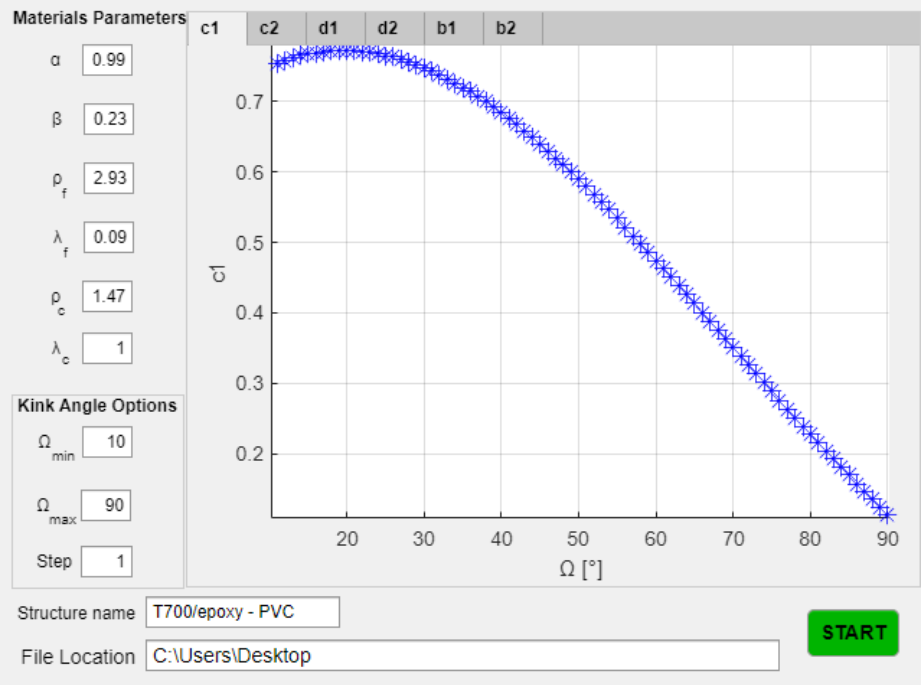


Figure 2. Screenshot of the GUI of the developed Matlab app to compute the coefficients.

Keywords: ultra-thin plies, cross-ply laminates, microscopical inspection, longitudinal debonds

Abstract
Ultrathin layers (UTP) are present in a relevant number of studies, from quasi-static to cyclic loading. Important through-the-thickness stresses may especially appear in the 90º ply block of a cross-ply laminate when there is a relevant restraint between the 0º and 90º ply block thicknesses. This leads to a biaxial stress state even only due to the residual thermal stresses due to the curing process.
In this study, the biaxial stress state that occurs in an ultra-thin 90º ply block of a cross-ply laminate was completely defined after its thermal and mechanical edge-effect analysis. Once the laminates were cured, the samples were carefully inspected by optical microscopy, showing longitudinal fibre/matrix debonds in the ultra-thin 90º ply block (parallel and aligned to the fibre direction of the 0º ply block). These non-conventional damages that appeared were registered, and the specimens were also mechanically loaded. In a second stage T-T cyclic testing was performed and the total extension of the debonds was monitored up to a permanent growth stage. These experimental results were compared with numerical analyses of the Energy Release Rate (G) using a BEM model to predict the fibre/matrix interface crack growth under the biaxial stress state. The results showed that there is an excellent agreement when the biaxial stress state (caused by the edge effect phenomenon) is considered in the numerical model.

1. Introduction

During the performance of micromechanical studies on the appearance of fatigue damage in cross-ply laminates containing ultra-thin plies (Sánchez-Carmona et al. [1]), 'non-conventional damages' were detected in the 90° ply-block of the tested laminates. These damages were longitudinal fibre-matrix interface debonds, i.e. debonds parallel to the 0° layers of the laminate.

In Sánchez-Carmona et al. [2] an explanation was given for the appearance of these debonds based on the stress state caused in the 90º ply-block by the so-called edge effect, Mittelstedt et al. [3]. Specifically, the presence of this effect produces, among others, the appearance of an out-of-plane transverse tension component in the 90º layer, which is found to be greater as the thickness of the 90º layer increases. These stresses derived from the edge effect are generated both by residual thermal curing stresses and by mechanical loads. As a consequence, the 90º ply block is subjected to a state of transverse biaxial stresses capable of causing longitudinal debonds.

This fact was the starting point for the present work. A detailed microscopic observation of the 90º ply block of cross-ply laminate specimens was carried out in order to find fibre-matrix debonds in quasi-isolated fibres in the post-curing situation. Later, these specimens were subjected to T-T cyclic loads and the growth of the previously detected debonds was monitored, Section 2. In addition, a BEM model was developed, based on previous works by the authors, see for instance Sandino et a [4], in order to find an explanation for their extension, Section 3.

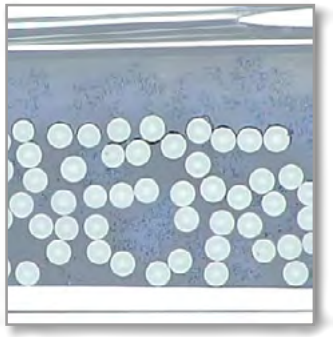

Figure 1. Longitudinal debonds observed in a UTP 90º ply block of a cross-ply laminate.

2. Experimental study

The study carried out focuses, in a first stage, on the observation of longitudinal debonds in cross-ply laminate specimens, just after the material has been cured. The cross-ply laminate selected was $[0_4/90/0_4]$, manufactured with T700S/TP402 carbon/epoxy prepreg unidirectional tape supplied by North Thin Ply Technology. 150 g/m^2 pre-preg was used for the 0° layers and 30 g/m^2 for the 90° layers, Figure 2. The manufacturing was carried out by manual stacking and the laminate was cured in an autoclave following the recommendations provided by the supplier.

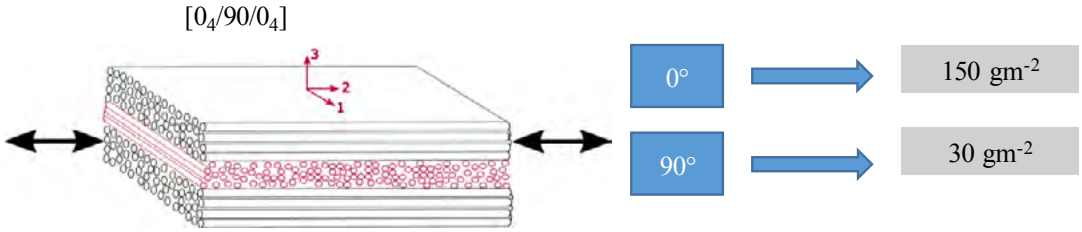

Figure 2. Scheme of the cross-ply laminate stacking sequence used for the experimental study.

After manufacturing, the specimens were sanded, polished and microscopically inspected. Longitudinal debonds were observed, as expected given the configuration of the laminate and the ultra-thin 90º ply used. The proximity of neighbouring fibres to those housing longitudinal debonds was analyzed and a selection was made of the debonds that may be considered as quasi-isolated. Specifically, 22 debonds were chosen. The extension of these debonds was measured. An example of a debond detected during this stage is presented in Figure 3. The results of the experimental measurements carried out show an average debond extension θ_t=189.1º (CV=11.9%).

Figure 3. Experimental measurement of a quasi-isolated debond detected after curing.

In a second stage, the specimens were subjected to 100 T-T loading cycles (σ_m=36.9 MPa, R=0.1). The tests were carried out with intermediate stops at N=5, 10 and 50, measuring the growth of the selected debonds after each step and of course at the end of the test. As remarkable results, it should be mentioned that the debonds grew only during the first cycles. Specifically, an important part of the debonds just grew during the first 5 loading cycles and the rest reached their final length in the second step, not growing after 10 cycles. Secondly, it was found that the average extension of the set of debonds in this cyclic loading stage was θ_t=239.5º (CV=6.2%).

From the comparison of the average values between the post-curing stage and the cyclic loading stage it is immediately evident that the scatter is considerably reduced from the first stage to the second. There are a few connected elements that explain this fact. First of all, it must be taken into account that the debonds found in the post-curing stage were not perfectly symmetrical; this lack of symmetry depends on the local configuration and distance of the neighboring fibres since the debonds are not completely isolated. Secondly, it is very interesting to observe that as the number of cycles increases, the debonds become more symmetrical, therefore reaching a more homogeneous group of debonds, which explains the reduction in the scatter of the results.

3. Numerical study

The objective of the numerical study was to be able to create a model that could reproduce the growth and extension of the longitudinal debonds. To this end, a single fibre BEM model was chosen. This model considers the presence of a fibre-matrix interface crack that grows under a biaxial stress state both in Modes I and II, Sandino el al [4].

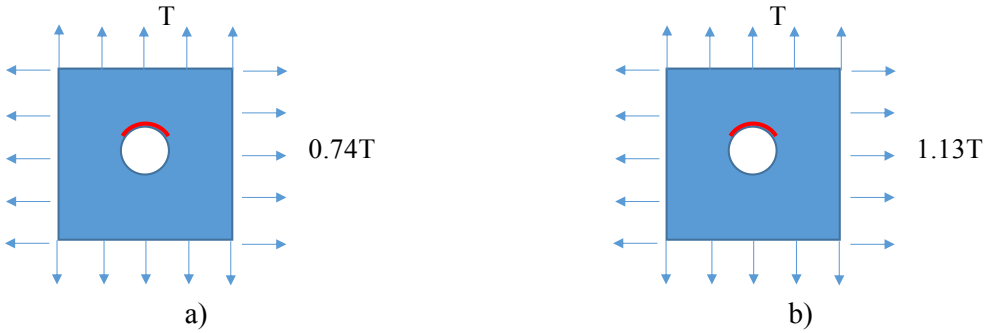

Figure 4. Biaxial stress states: a) Case 1, b) Case 2.

The key point in the model definition was the estimation of the external loads to which it should be subjected. The stress situation of the post-curing case (case 1) and the stress situation during the loading cycles (case 2) were analyzed. Specifically:
Case 1: Residual thermal stresses provoked by the cooling thermal decrement (both at mesomechanical and micromechanical level) and thermal edge effect stresses. The resulting biaxial stress state is a T-nT type, Figure 4a, with a biaxiality ratio n=0.74. This stress state justifies the preferential appearance of a longitudinal debond once the corresponding critical values at the interface are overcome.
Case 2: Partially relaxed residual thermal stresses provoked by the cooling thermal decrement (both mesomechanical and micromechanical), the mechanical load and the edge effect stresses (both thermal and mechanical). The resulting biaxial stress state is a T-1.13T type, Figure 4b.

Using Irwin's approach [5] for calculating the Energy Release Rate, G, of the fibre-matrix interface crack, and the proposal of Hutchinson and Suo [6] for estimating its critical value, G_c, it was possible to make a prediction of the debonds growth. Specifically, Figure 5 presents the results (G versus $\theta_d = \theta_t/2$), of the model associated with Case 1 verifying that, for values of the parameter λ in the expected range for the expected bi-material system [4], it is expected that the final extension of the debonds after curing should be within $195° \leq \theta t \leq 215º$, showing an excellent fit with the experimental observations under the hypotheses assumed.

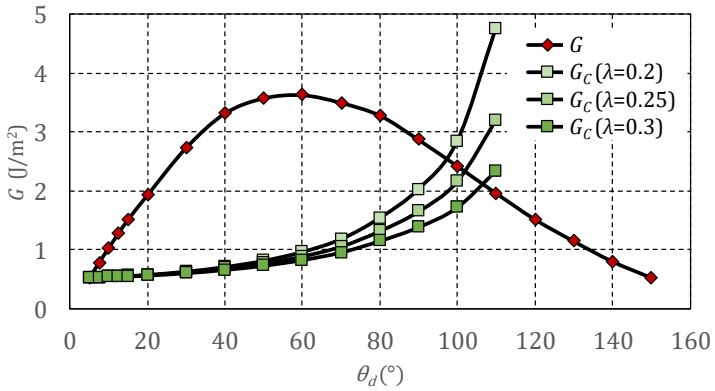

Figure 5. Energy Release Rate distribution versus semi-debond extension in the post-curing situation.

4. Conclusions

The appearance and growth of non-conventional (longitudinal) debonds in a cross-ply laminate with an UTP 90º layer was studied. An experimental campaign, microscopically detecting the longitudinal debonds nucleated during the cooling down stage after the curing process, and monitoring their growth under T-T cyclic loads, was performed. A numerical BEM model was carried out predicting the extension of the observed debonds. The key point for the agreement between the experimental and the numerical results was the consideration of the complex biaxial stress state locally acting in the surroundings of the 90º ply block fibres highly conditioned by the edge effect phenomenon.

Abstract *: Mechanical testing of materials implies the measurement of the displacement field resulting from the application of a force or a displacement at sample boundaries. Different techniques can be used to access the displacement field, but all rely on hypotheses on the field for lack of a complete full field measurement. This study considers the usage of computed tomography (CT) to access macroscopic displacement field through the Digital Volume Correlation (DVC) method. The material considered is a laminate oxide/oxide ceramic matrix composite for which accessing the 3D displacement field during a mechanical test as well as damage (cracks) which are known to develop to accompodate the strain is particularly relevant. The in-situ testing equipment and the CT sequipment used are described, as well as the method used to measure the displacement fields. Although measurements parameters and analysis protocol are still under optimization, a first result of the displacement field is presented.Although this result is in line with expectations, further progress is expected. Influence of the 3D image constrast and noise on the displacement field precision is discussed.*

1. Introduction

Ceramic Matrix Composites (CMCs) are lightweight materials with excellent mechanical properties at elevated temperature, making them promising candidates for various advanced applications. Oxyde/Oxyde (Ox/Ox) laminates are particularly relevant for moderate thermo-mechanical loadings due to their favourable balance of mechanical properties and cost. However, these materials experience damage even at low load levels, resulting in an highly non-linear behaviour. The determination of a constitutive law requires a precise understanding of their mechanical behaviour, including at the ply level, as well as rigorous observation and measurement of their damage mechanisms.

X-Ray Computed Tomography (CT) is a widely recognized imaging method allowing access to a material structure in 3D provided local absorption coefficients provide enough contrast in the resulting 3D image. In the same way that the observation of a surface speckle pattern can be used to compute a displacement field during a mechanical test [1], the material structure may provide a natural pattern that can be used to compute a 3D displacement field through Digital Volume Correlation (DVC), [2]. In addition to the 3D determination of the displacement field, the advantage of CT is that temperature has no effect whatsoever on X-Ray absorption and material contrast. Thus temperature measurements are no different than room temperature measurements if the X-Ray absorption of the furnace windows is put aside. This allows to overcome experimental issues related to measuring strain fields at elevated temperatures (strain gauges, high-temperature speckles for 2D Digital Image Correaltion (DIC)...) and

it is one of his most important adavantage oindustrial this application. However, in situ mechanical testing requires a specific device which will be discussed further on.

The material considered is this study is a quasi-isotropic 2D woven Ox/Ox laminate. Our primary objective is to identify a constitutive law (eg ONERA Damage Model (ODM) [3]) through mechanical tests and measurements carried using CT in situ testing to access 3D displacement fields.. The goal of this study is first and foremost to optimize CT parameters and DVC analysis and then conduct a series of various tests such as tension, flexion, torsion, etc.

First, the computed tomography setup (*section 2.1*) is presented. This specific device can reach a resolution of 15-30 µm on macroscopic samples (dimension 50 mm). The CMC ox/ox material and the sample geometry considered for the tensile tests are then presented (*section 2.2*) to conducted tensil test. The DVC method is briefly discussed, key aspects like regularisation being of primary importance (*section 2.3*). As the mechanical test has to be paused during CT scans, a protocol had to be defined in order to limit the influence that the CT scans may have on the stress/strain behaviour characterisation (*section 3.1*). Finally, a DVC analysis of a tensile test on [-45°,45°] layup CMC ox/ox sample is then shown and discussed (*section 3.2 and 3.3*).

2. Experiemental setup and methodology

2.1 Experimental Setup

The tomography device considered in this study is a Nikon C3 equipped with two X-Ray tubes : a 450 kV microfocus (max resolution 60 µm) with rotating anode and a 225 kV microfocus (max resolution 5 µm). This device is much larger in dimensions compared to standard laboratory µCT scanners (Figure 1). Featuring a cone-beam geometry, it is equipped with a Varex 1611 detector (4k pixels, 41cm x 41cm) placed on a 4 positions translation which allows to image a width of 1600 cm. In this study, only single detector position scans are considered in order to minimize scan durations and complexity. This equipment is primarily designed to study the interior of industrial parts and assemblies such as hydrogen tanks. With the addition of a Deben 25 kN open frame rig, it can perform standard as well as complex in-situ mechanical tests (tension, torsion, tension/torsion, pure bending) on samples similar if not identical to those tested in stand alone mechanical testing machines.. Top and bottom jaws are mounted on rotation stages which allow a full 360° rotation to perform the CT scan as well as apply torsion up to 100 N.m. It is also equipped with an air-cooled furnace allowing in-situ tests up to 1200°C. Two windows limit the amount of matter that the X-Rays have to go through and thus the additional absorption brought by the furnace.

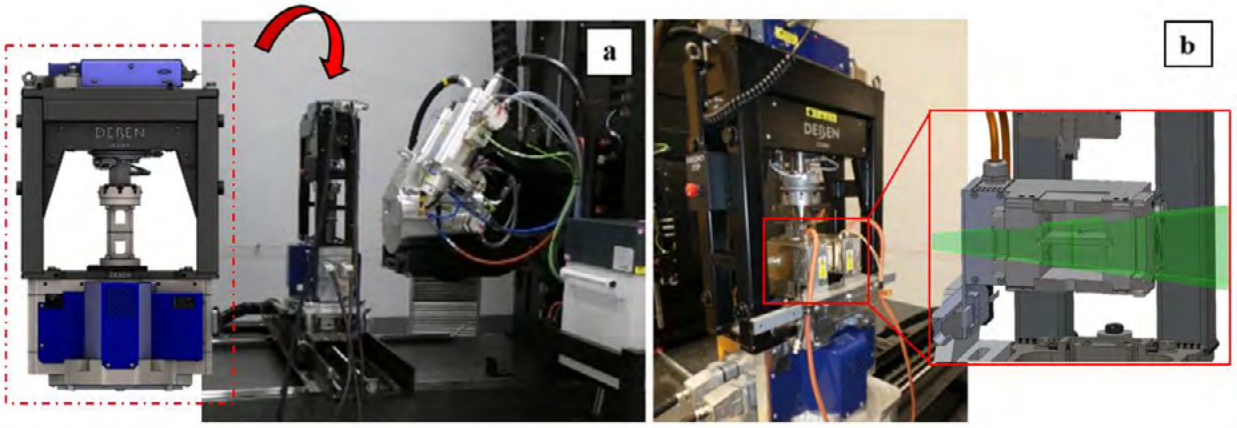

Figure 1. CT-Scan with in-situ mechanical testing machine inside (a) and his air cooled furnance (b)

Several parameters have to be taken into account when considering CT scans. The first one is the total amount of time it takes it perform the whole test. Each point on the force/displacement curve is measurement from a single scan. Considering that the whole curve should be sampled by about ten

points and that an experiment should not exceed one day, this leads to a typical CT scan duration of about 1/2 hr. A small voxel size (high resolution) ensures a better constrast in between pores and material and also discontinuities in fiber density in the threads. However, high resolution and high contrast is maximum at low energy and power which, when considering a fixed scan time, lead to more noise when compared to higher energies (X-Ray yield increase with energy) and power. Moreover, a low X-Ray intensity leads to an increase in the detector gain in order to be able to measure a projection and thus increase the detector reading noise. Scan parameters considered in this paper are not yet fully optimized and we expect to obtain better results in the future. Nevertheless, these results illustrate very well the analysis conducted. The overall scan time was 35 minutes, tube voltage was set to 210 kV, power was set to 30 W and geometric resolution to 12.7 µm. At this power, the focus size is expected to be wider than the geometric resolution, but as the resolution loss is not straightforward to estimate it was decided to use a small geometric resolution even if the real resolution is greater. The number of projections used to reconstruct the 3D volume by backprojection is 2,100.

2.2 Sample

Rectangular shape specimens without fillets are used in this study and present the following dimensions: l x w x h with l = 160 mm length, w = 20 mm width, and h = 3.30 mm thickness. This thickness corresponds to a 2D woven laminate made of 16 plies oriented at $[(+45°/-45°)_4]_s$. These specimens have the advantage of failing in the Region Of Interest (ROI) (110 mm of total length) without the need for fillet machining, unlike their counterparts at $[0/90]_s$, and they present a slightly higher theorical strain at faillure in tension ($5.0x10^{-3}$ compared to $3.5x10^{-3}$ for $[0/90]_s$). This is an interesting testing case (but more complex to conduct than a classical cross-ply tensile test with a simili quasi linear behaviour) because it allows for a larger deformation range and a high non linear part before failure [4], allowing to study the different damage occurring in the material.

To avoid some sliding during the tensile test, copper interleafs of 0.1 mm thickness have been glued between grips and sample. To address issues arising from too small sample sizes, as highlighted by [5], the samples used in this study will present a minimum size larger than 1.5 times the Representative Elementary Volume of the ply (REV) (Figure 2). Considering a $[\pm 45°]_s$ laminate, this imposes to consider a larger specimen because the REV expressed in the specimen axis is larger (7.5 mm x $\sqrt{2}$) than that associated to a cross-ply laminate.

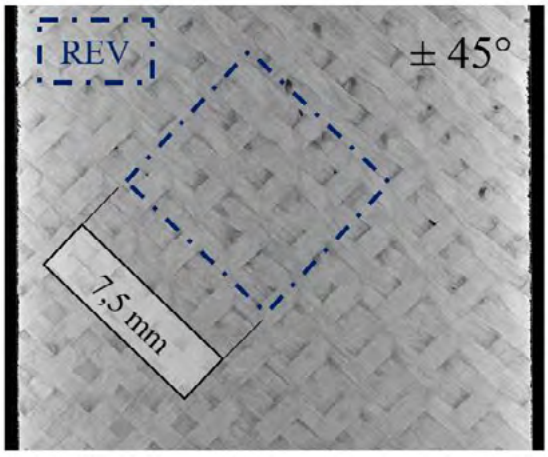

Figure 2. REV of 2D Ox/Ox CMC on ± 45° oriented ply draw to illustrated sample type use in this study, (8 hrs scan)

The maximum volume obtained by backprojection of is 4000x4000x4000 pixels, which, at a resolution of 12.7µm/voxel, allows us to study approximately a 50x50x50 mm area at the center of the sample (Figure 3).The edges of the observed zone at the top and bottom (rotated here by 90° in the illustration)

exhibit artifacts due to the conical shape of the X-ray beam. The anlysed ROI is thus reduced to 200x1500x3500 pixels to avoid these artifacts, as well as the periphery of the sample which is affected by beam hardening. The volume obtained after crop is still large (2Go for each volume, 16 bytes integer format).

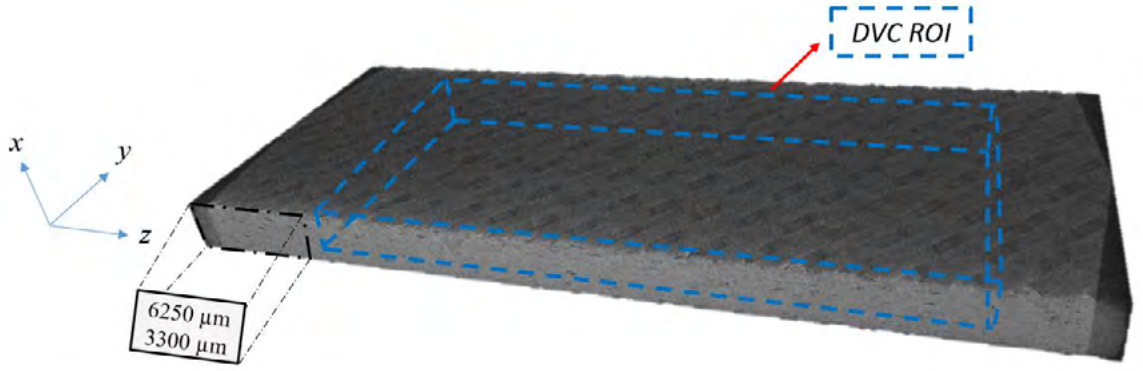

Figure 3. 3D volume of the total ROI. A 3D Gaussian convolution of isotropic width of 2 voxels has been applied so as to improve the 3D visual of the scan.

2.3 Global DVC principle

There are two possible approaches: global or local, which mainly differ in how the displacement field is computed. In the local approach, the studied zone **Ω** is subdivided into small zones of interest Ω_i. For each of these small zones, the average mechanical transformation is estimated between the reference state and the deformed state. This approach has the advantage of being easier to implement and can be easily parallelized, and this is the reason why it is currently the most used correlation method, particularly in commercial software. However, although the results can be interpolated over the entire reference zone **Ω**, the continuity of the displacement field between sub-volumes is not. In contrast to local methods, global methods rely on defining a continuous kinematic field *u(x)* over the entire region of interest examined.The formalism of this method is thoroughly described in [6]. The main advantage of this approach lies in ensuring the continuity and regularity of *u(x)* on **Ω**, thanks to local support from finite elements. This aspect is moreover interesting in the determination of constitutive equations, because the same finite elements framework can be used for DVC and numerical computations. In this study, we will consider a global DVC method using and a tetrahedral mesh created with the software “GMSH”, which will serve as local support for finite elements. The global DVC software used is "Kintsugi" [7], which is mechanically regularized [8]. In u nutshell, a rigid registration of rigid body movements is performed beforehand to estimate rigid translations and compute an initial solution for the DVC algorithm. The DVC is then conducted in a pyramidal manner to help the system to gradually converge from the largest to the smallest regularization length, starting from binned volumes to full volume.

3. Results and discuss

3.1 Tensile test

In this paper, results obtained on an in-situ tensile test are presented. The aim of this test, as explained in the introduction, is to validate the DVC displacement field analysis before conducting extensive campaigns on more complex tests (torsion, pure bending, etc.) and at higher temperatures (until 1000°C). The test curve for the ±45° specimen is reported in Figure 4, plotting the tensile force as a function of the applied displacement of the test machine crosshead. It should be noted that two discharges were made during the two nights that interrupted this three-day test, which enabled 22 scans of 35 minutes each to be performed (originally planned for 10 scans and 1 day). These scans are numbered S01, S02.... and are represented by dotted lines. In order to summarise the information presented, only the DVC

displacement fields of the scan indictaed with a black dotted line are discussed in the rest of this study. Scan denoted "S22" represents the post-mortem scan.

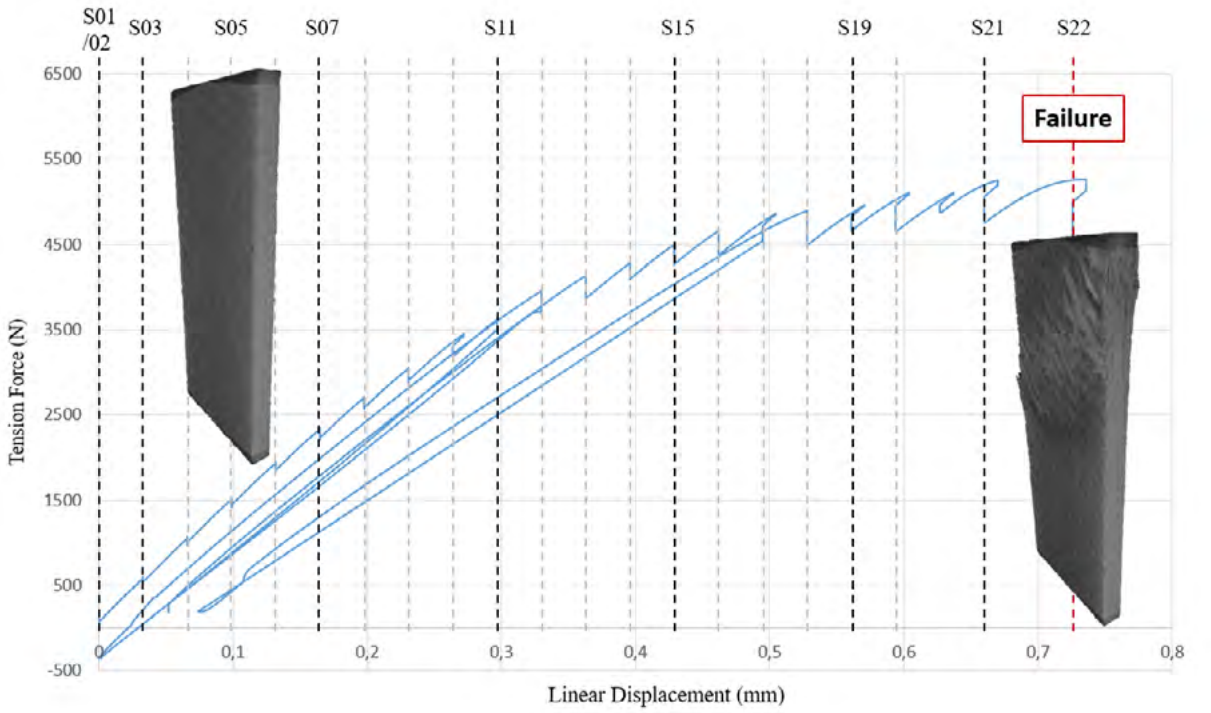

Figure 4. Experimental curve with each scan conduct during the tensile test (scans S01 to S22)

This test have been conducted at 0.1 mm/min linear tension rate and with a 33µm step between each scan. Only scans S21 and S22 were carried out with a step of 66µm so as to achieve failure faster. It is important to point out, at this stage, that force variations of the order of $\Delta F = 150$ N (*i.e.* ± 75 N) are observed during each scan when the sample is rotated 360° and the CT scan is performed. As lateral misalignment of top and bottom would only mainly result in lateral force, this variation is attributed to an overall distance variation between top and bottom during the full turn. It is however estimated from the stiffness of the material at less than 5 µm and is acceptable. An increasing relaxation during the test is also noticeable during the pauses before the scans and adds to the phenomenon of force variation observed. This could be due to over-critical cracking of the material during these tension maintenance phases. As for the discharges carried out during the night breaks, they make it possible to appreciate the loss of linearity of the behaviour, which is due to the decrease of the apparent modulus by the damage that has occurred within the material. They also highlight a fairly significant residual displacement.

3.2 Uncertainties on measurements and noise

Two scans S01 and S02 have been conducted at the initial state (0mm of linear displacement) to estimate the displacement uncertainty. This study is performed on a small crop in center of the ROI (200x400x400 voxels) and it is shown on Figure 5. DVC have been carried out with a mesh size of 16 pixels and 128 pixels of regularisation length. The DVC displays high extremum values at the edges and on the surface of the crop, as well as a spread which originates from the noise which is quite noticeable on the tomograms. The standard deviation of the displacement along the tension direction Z is -0.15 voxels, the mean displacement value being -0.55 voxels. These values are calculated with an offset of 10 pixels towards the inside of the ROI so as to avoid the artifacts observed at the free edges/surfaces. The standard deviation measured is consistent with what is expected and is a satisfactory value, even if the regularization length has to be kept quite large due to the noise on the 3D images.

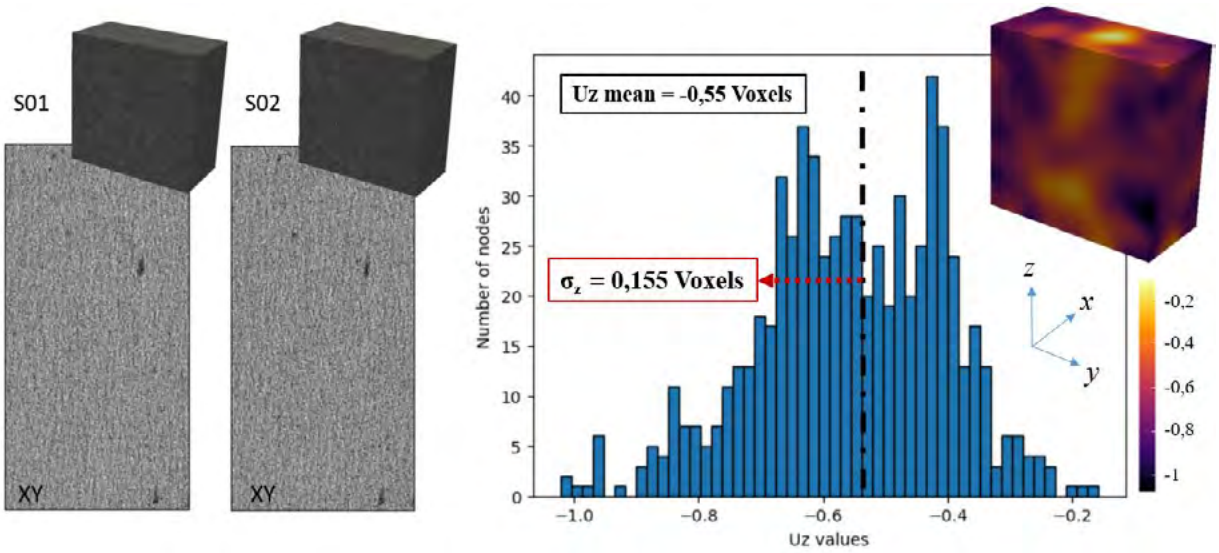

Figure 5. Small crop taken in the middle of the ROI (left) and histogram of Uz values with his mean and his standard deviation (right).

The theoretically zero deviation from the average can be explained by a dilatation of the X-ray tube target, which may result in a shift of focus of a few µm. This can happen during the first few hours of emission (in our case, 1 hour of conditioning was carried out before the S01 scan, which precedes the S02 scan).

3.3 DVC Results on displacement field and strain measurement

The displacement fields in the tensile test direction (noted U_z and expressed in voxels), determined with DVC comparing each scan with the reference scan, are presented on Figure 6. Theses displacement fields have been determined considering a mesh size of 16 pixels and 128 pixels of regularisation length (which corresponds nearly to the width of one fiber bundle of the laminate fabric). The poor quality of image contrast inside a fiber bundle and the noise impede to conduct DVC on smaller regularisation length. This is not an issue for this first test, because a tensile test just requires to evaluate the relevance of the global, smooth, displacement field measured by DVC. In order to optimise computation time, 3D volumes have been binned, which is equivalent to conduct DVC on 8 pixels mesh size and 64 pixels of regularisation length.

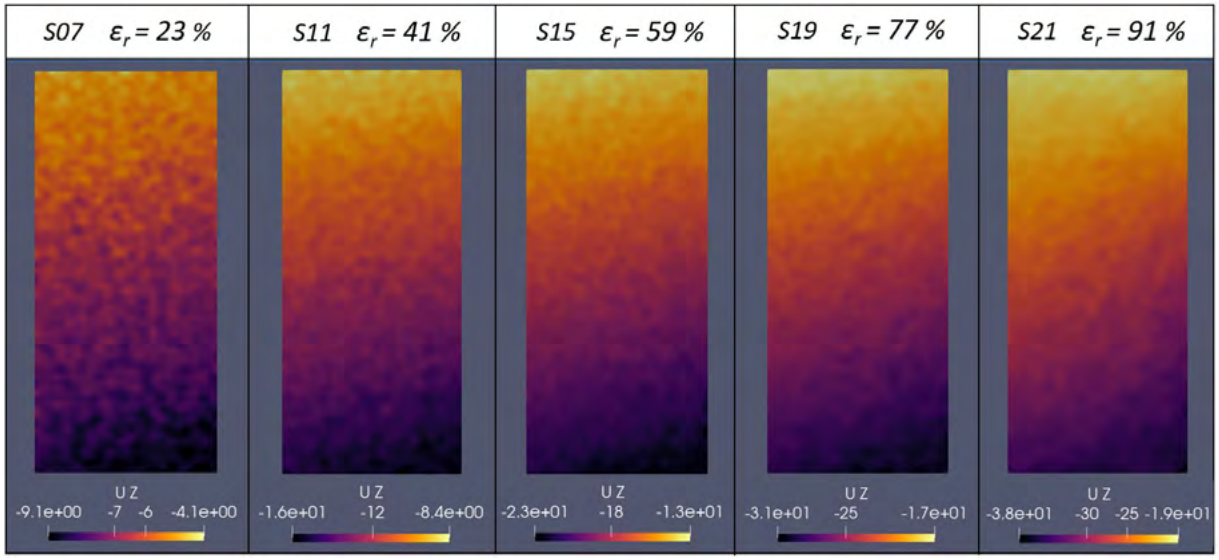

Figure 6. U_z displacement field in DVC ROI at different percents of strain at failure ε_r

In order to assess the relevance of the displacement field measurements, a 200x400x400 voxels ROI is considered to compute an averaged displacement value at the centre of the specimen. Assuming that the CT-Scan is halfway up the specimen and that there is no rigid body movement (*e.g.* slippage), this should be equal to half the machine top jaw displacement value. The tensile force curve is then plotted against the linear machine displacement value and that obtained with the DVC, as reported in Figure 7.

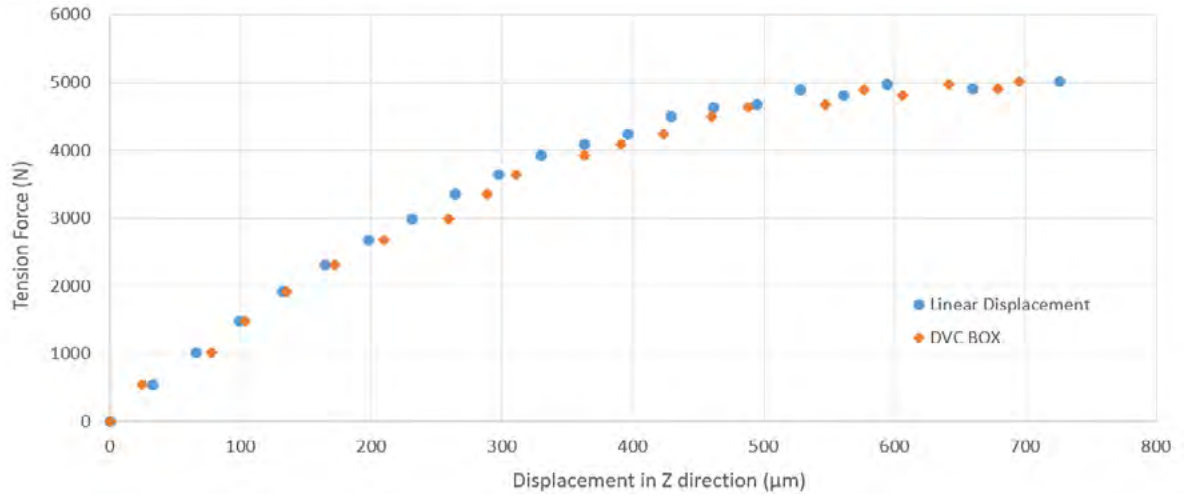

Figure 7. Tension force ploted against linear (U_z) displacement measured by testing machine curse (linear displacement) and DVC (DVC BOX)

The displacement curve measured with the DVC is in very good agreement with the linear displacement imposed by the testing machine. The small discrepancies observed can be explained by the force variations occurring during CT scans. If slippage had occurred, there would have been a clear offset between these two curves. In our case, therefore, it can be concluded that slippage is either almost non-existent or perfectly symmetrical between the two jaws during loading (which is very unlikely).

In order to minimize the effect of the spread of the displacement values on strain, the mean tensile strain value ε_{zz} is estimated from the displacement field *Uz* over the height of the scanned ROI. This value is computed considering the difference between the top and the bottom mean *Uz* values of the DVC ROI (i.e. 3500 voxels in Z direction). The different values obtained are plotted for each scan from S01 to S21 on Figure 8.

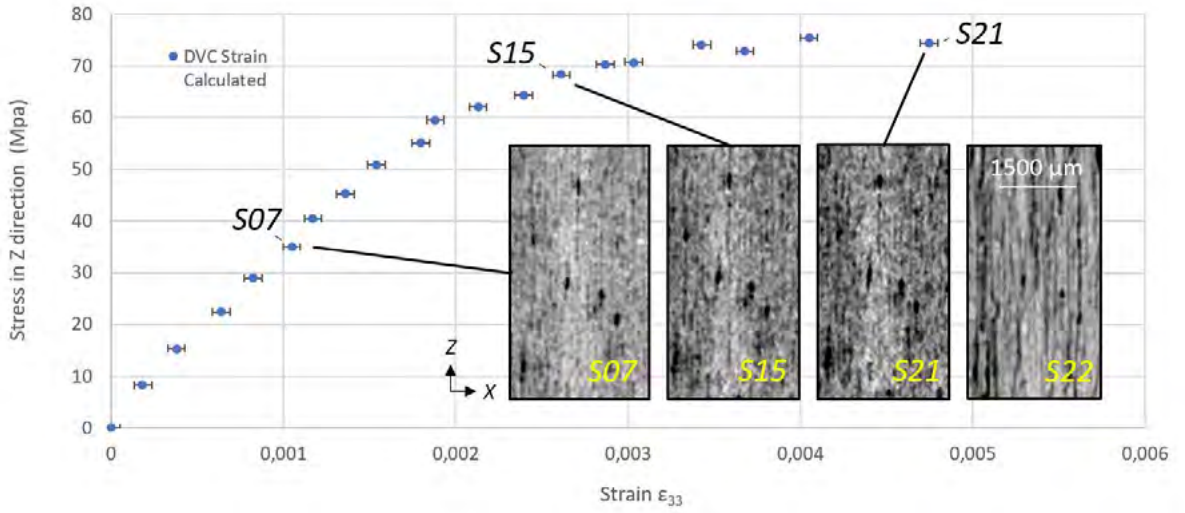

Figure 8. Stress/Strain curve in tensile direction (Z) with strain calculated by DVC in the total length of the "DVC ROI"(3500 voxels) and local damage evolution along the tensile test (viewed with 3D gaussian convolution of 2 pixels to reduce noise).

The non-linear behaviour in tension after the damage threshold (≈ $1.5x10^{-3}$) is in good agreement with classical mechanical tests performed previously in the laboratory. The damage seems to correspond to the global (45° oriented) and local fracture facies, with the development of increasing delamination cracks from the initial voids as described by [2]. Delamination seem to originate from, or at least is predominant, pores in between plies as can seen on Figure 8, although this phenomenon does not seem to be systematic.

4. Conclusion and perspective

This first result show that a full DVC analysis carried out on CT scans on a sample undergoing a mechanical test make it possible to obtain a full 3D displacement field on a macroscopic region while retaining an alsmost microscopic resolution. While the result presented here show a noise level that prevents from allowing the displacement field to vary locally, parameters have since been optimized and we expect that the final regularization length to consider (128 pixels reported here) can be decreased. A full signal/noise ratio analysis is being performed with formulae suggest by [9]. When the optimal parameters are determined, it will be also possible to analyse local damage more accurately (measurement of delamination, crack orientation and growth, etc…). Whereas a time/signal quality compromise will probably still limit the analysis, measurements of 3D displacement fields using in situ CT scans will give valuable insights on more complex tests like tension-traction combined tests, pure beding, etc. It is even more true when considering temperature experiments up to 1000°C.

Keywords: Luffa fibres, porous structure, sound absorption, surface roughness

Abstract
This study investigates the effect of integrating cellulose nanocrystals on the sound absorption properties of luffa, a natural porous material. Employing locally deposited cellulose nanocrystals (CNCs), we developed a hierarchical natural fibre composite and evaluated the effects of CNC loadings (1 and 3 wt.%) on acoustic performance using the impedance tube method. The impact of panel density and thickness on sound absorption has also been evaluated. Modification of luffa with 3 wt.% CNC led to a 13% increase in the average sound absorption coefficient compared to the unmodified luffa, across the frequency range of 300 Hz to 2000 Hz. In particular, the addition of 1 wt.% CNC has significantly enhanced the sound absorption coefficient, reaching 0.8 at 1550 Hz. The study demonstrates the capabilities of integrating bio-based nano-reinforcements such as CNC in natural materials for tailored acoustic properties, offering a promising approach to developing eco-friendly acoustic materials with enhanced performance.

1. Introduction

The use of modern materials that provide improved sound absorption has become necessary due to the significant health risks associated with noise pollution [1]. One typical method of noise reduction is the use of porous materials, such as polyurethane foams , which have the unique property of converting sound waves into heat [2, 3].

More recently, the selection of acoustic materials is undergoing a significant change towards bio-based alternatives, mostly due to the negative environmental and health effects linked to synthetic options like polyurethane (PU) foam. The porous and hierarchical structures of many natural materials made them an interesting option for sound absorption, while the sound absorption coefficient of panels produced from natural fibre such as coir and tea leaf has been examined [4, 5].

However, limited research can be found on the acoustic properties of luffa fibre and composite materials [5, 6], although their highly porous structures could be highly efficient in such applications. In addition, to the best of our knowledge, no research has been conducted on the use of nanofillers to tailor the interface and tune the sound absorption properties of luffa panels, nor has the significance of employing green nanofillers such as cellulose nanocrystals (CNCs) been emphasised.

Due to their large surface area [7, 8], CNCs are also expected to adhere to the cellular walls of the luffa structure. This adherence can potentially increase the density and hierarchy of the luffa's internal network. The nanomodifications to the micro-architecture are expected to affect the sound wave interference and absorption in the material, thus leading to a change in the total sound absorption coefficient.

In this work, hierarchical natural fibre composites based on luffa and CNCs were fabricated and characterised. Different CNC loadings (1 and 3 wt.%) have been deposited onto the luffa structure, with

various panel thicknesses ranging from 6 to 12 mm manufactured. The acoustic properties have been characterised using an impedance tube method, with an systematic analysis conducted to evaluate the impact of various CNC loadings on the acoustic efficiency.

2. Materials and methods

2.1. Unmodified Luffa and CNCs Modified Luffa

The luffa sponge, derived from the matured fruit of the luffa plant, was used as the primary material. Commercially sourced dry luffa sponges used in this work have an average length of 10 cm and a diameter of 6 cm. For CNCs modification, 1 wt.% and 3 wt.% cellulose nano crystals (CNCs) solutions in water were prepared. Luffa sponges were soaked in the solutions for one hour, then left at room temperature for one day, followed by drying in an oven at 80°C for 24 hours to ensure complete drying.

2.2. Preparation of samples for sound absorption test

Cylindrical luffa sponges were halved longitudinally, and the residual seeds were extracted. The desirable thickness was achieved by layering different amounts of sponges in compression moulding, with spacers to achieve final sample thicknesses ranging from 6 mm to 12 mm. The luffa layers were compression moulded into flat sheets using a Dr. Collin P300E press (Germany) at 120°C and 30 bar pressure for a duration of 20 minutes. For testing purposes, the sheets were subsequently prepared into 100 mm-diameter discs.

3. Characterization

3.1. Bulk density

The density of various thickness samples was calculated by dividing the mass of the disc (g) by its volume (cm^3). The average density values were taken from three samples.

3.2. Scanning Electron Microscopy

The morphology of the unmodified and CNC-luffa surfaces was examined using a Scanning Electron Microscope (SEM) (FEI Inspect-F, Netherlands) to examine the impact of CNCs coating on the surface and the structure of luffa samples.

3.3. Sound absorption measurements

Sound absorption tests were conducted using the one-microphone impedance tube method, in accordance with ASTM C384 [9] (Figure 1). The standing wave apparatus was made of polycarbonate tube (wall thickness of 3 mm) with an inner diameter of 9.4 cm and length of 100 cm. A circular 10 cm diameter luffa sample was inserted inside the tube and sealed with an 8mm thick polycarbonate backing plate from the outside. A loudspeaker on the other side of the tube to produce the sinus sound using a function generator (RS PRO GFG-8216A). The oscilloscope (RS PRO RSDS 1052 DL + 50MHz) was used to measure and record the maximum (V_{max}) and minimum (V_{min}) amplitudes in volts as the microphone moved along the tube. The sound absorption coefficient (SAC) was calculated using SWR(x) as the standing wave ratio at position x and α_n as the SAC (equation 1 and 2).

$$SWR(x) = V_{max}(x)/V_{min}(x) \quad (1)$$

$$\alpha_n = 1 - ((SWR - 1)/(SWR + 1))^2 \quad (2)$$

The SAC (α_n) was measured at frequencies between 300 and 2000 Hz, while the noise reduction coefficient (NRC) was calculated for the complete range.

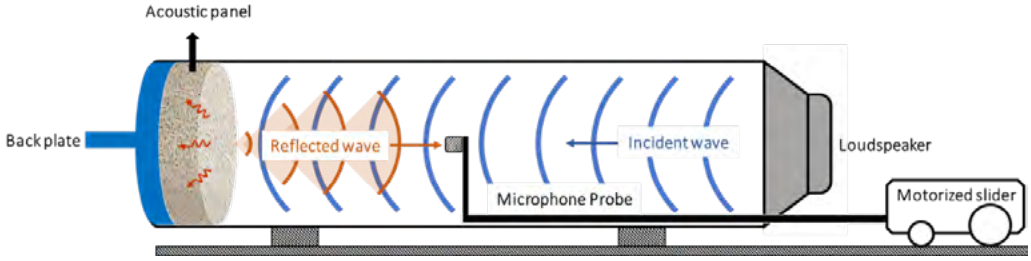

Figure 1. Schematic diagram of the instrumentation for the impedance tube method used in measuring sound absorption coefficients.

4. Results and Discussion

4.1. Morphologies and structures of neat and modified luffa

Figure 2 shows the surface of the luffa fibre, with an uneven and a porous structure observed. With the CNC deposited onto the luffa surface, a fine and relatively uniform coating can be found from the SEM images, with an increased surface roughness. The dimensions of certain cavities in luffa structures have been reduced slightly, while evidence of CNC exposed at cavities was also noticed.

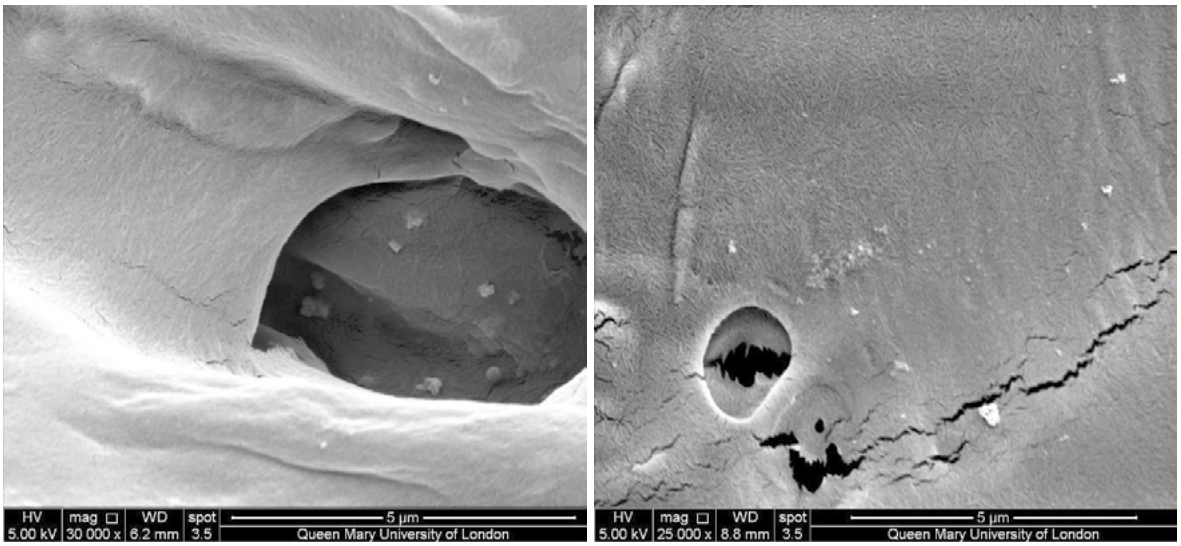

Figure 2. SEM images of neat luffa (left) and 1 wt.% CNC coated luffa (right).

4.2. Sound absorption properties

The neat luffa samples without any modifications, exhibited a noise reduction coefficient (NRC) of 0.46 in Figure 3, although a relatively large variation can be found due to the porous and varied structures between samples. When introducing CNC at concentrations of 1 and 3 wt.% to the luffa samples, a slightly improved NRC was obtained, with values slightly above 0.5 for both cases, in the frequency range of 300 to 2000 Hz.

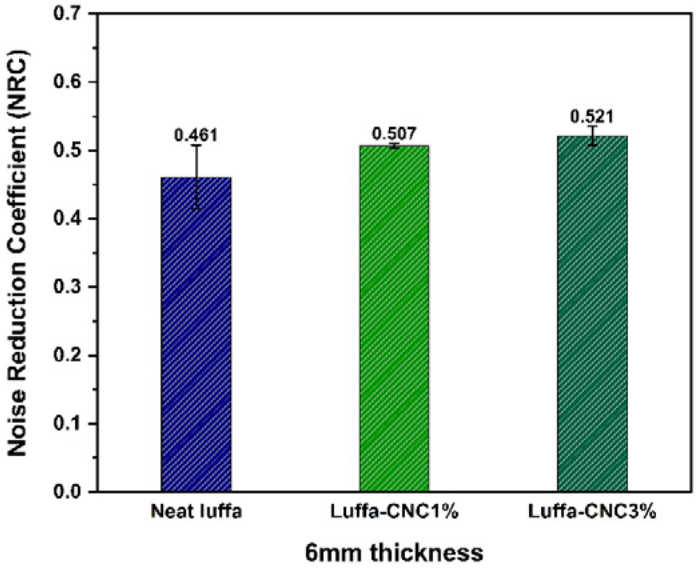

Figure 3. Noise Reduction Coefficient (NRC) comparison among unmodified luffa and CNC-enhanced luffa composites.

The effect of CNC on luffa structures has been examined with a series of panel thicknesses. In Figure 4, it can be seen that the addition of 1 wt.% CNC clearly enhanced the sound absorption values across all thicknesses. As acoustic waves enter these fibrous materials, the airflow inside the pores causes the cellular walls to vibrate and experience friction. This interaction results in the generation of a high resistance, converting sound energy into heat energy, thus increasing the reduction of sound vibrations [10]. The introduction of CNC is expected to enhance the sound energy dissipating process, hence increase the sound absorption properties. In addition, the modified surface feature of CNC is also expected to affect the reflection patterns of sound waves hence the dampening of the structure. It is worth noting that the SAC value was approaching to 0.8 at the frequency 1550 Hz, highlighting the potential of developed hierarchical natural fibre composites in acoustic applications.

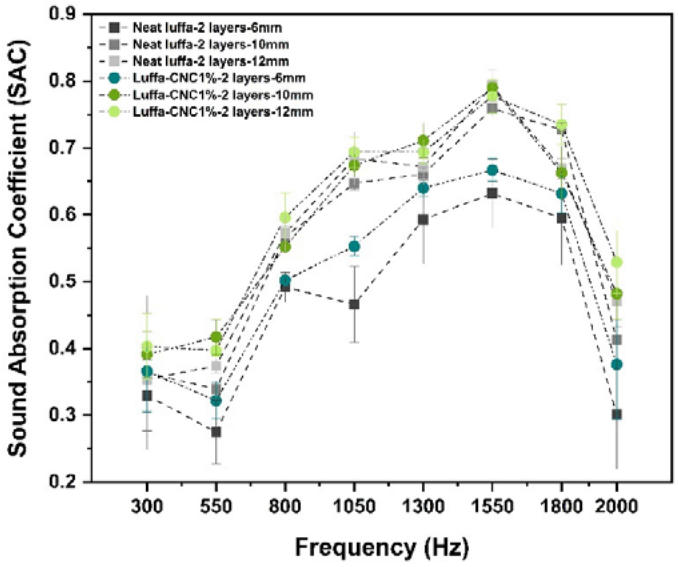

Figure 4. Effect of CNCs modification on the sound absorption coefficient of the luffa panels over various panel thicknesses.

Table 1 summarises the calculated density, porosity, and NRC of the fabricated panel. It is commonly observed that a greater sample thickness is often associated with a higher sound absorption coefficient. The improvement with increased thickness is believed due to the increased porosity in luffa's structure, as seen by the porosity values. However, with the introduction of 1 wt.% CNC, an increased NRC can be found for the panels with same thickness due to enhanced sound energy dissipation, despite the slightly reduced porosity.

Table 1. Panels characteristics and NRC values of neat and CNCs-modified luffa panels.

Sample Name	Thickness (mm)	Calculated density (g/cm³)	Porosity (ε)	NRC (300 Hz - 2000 Hz)
Neat luffa	6	0.239 (±0.0193)	0.730	0.46 (±0.047)
	8	0.218 (±0.0527)	0.753	0.55 (±0.009)
	10	0.150 (±0.0151)	0.830	0.56 (±0.017)
	12	0.165 (±0.0053)	0.813	0.57 (±0.023)
Luffa-CNC1%	6	0.279 (±0.0219)	0.686	0.51 (±0.003)
	8	0.251 (±0.0074)	0.718	0.58 (±0.011)
	10	0.201 (±0.0135)	0.774	0.59 (±0.012)
	12	0.193 (±0.0114)	0.784	0.60 (±0.012)

5. Conclusions

This study demonstrated the capability of luffa sponge as a highly efficient porous material for sound absorption applications, especially when modified with cellulose nanocrystals (CNC). The addition of 1 and 3 wt.% CNC resulted in enhancements in sound absorption coefficients, particularly in the frequency range of 1050-1550 Hz, with the NRC value of 0.52 achieved.

INFLUENCE OF LARGE-SCALE FIBRE BRIDGING IN THE CRACK GROWTH RATE OF MIXED-MODE DELAMINATION OF A UNIDIRECTIONAL GLASS-EPOXY COMPOSITE

Keywords: Composite fatigue, Crack Growth Rate, Fibre bridging

Abstract
In the present research the influence of large-scale fibre bridging on the crack growth rate in mixed-mode delamination of unidirectional glass-epoxy composites was investigated. The study employed double cantilever beam specimens subjected to cyclic even and un-even bending moments, i.e., steady-state specimens. In the study, the bridging ligaments at fracture process zone (developed after several cycles) were cutoff and the tests are then subject to the same previous load. This led to an accelerated crack growth rate. Varying the length of the bridging zone (while keeping everything else, e.g., load, the same) has a strong effect on the crack growth rate.

1. Introduction

There is a large interest in understanding the propagation of delamination in composite materials under cyclic loading. For instance, in wind turbine rotor blades, delamination of the main spar-cap is of great concern, especially considering the continuous trend of upscaling to very large blades, exceeding 100m in length.

Predicting the crack growth rate (CGR) of a delamination crack is a difficult task given the large uncertainty of the external loading, e.g., variable amplitude loading history, as well as the uncertainty on the material response to loading, i.e. the CGR. Currently, most predictive models of composite delamination are based on the Paris-Erdogan relationship [1] [2] [3] [4] [5]. However, implicit in this relationship is the assumption of small-scale fracture (i.e., the assumption that the size of the fracture process zone (FPZ) is negligible in comparison with all other geometric dimensions). This is, however, not valid for delamination cracks with a large-scale fracture process zone, which is observed in most fibre reinforced polymer (FRP) composites due to fibre bridging.

Although fibre bridging is a toughening mechanism with positive effects on the material's resistance to fracture, the effect of fibre bridging on cyclic crack growth is not sufficiently well understood, and there are no design criteria that accounts for large scale fibre bridging. This means that fibre bridging as a toughening mechanism is largely, if not completely, under-exploited. Promising ideas for developing materials with passive crack arrest and crack stability [1] [6] among other can be derived from an understanding of fibre bridging.

Fibre bridging can affect the crack propagation in two stages, during the formation of a large-scale fracture process zone and during propagation of the fully developed FPZ, where the CGR is near-constant. In the later, fibre bridging enhances crack resistance by shielding the crack-tip from the remote load [7]. In the former, the formation of a large-scale fracture process zone dissipates energy due to the presence of different damage mechanisms, e.g., fibre full out. When a delamination crack is initiated, a crack front is formed. Then, the FPZ is only composed by the crack front and is thus negligible in size. However, with increasing number of load cycles the crack-tip advances leaving bridging ligaments in its wake. The zone from the microscopic crack-tip (in the fracture plane) until the last active (loaded)

bridging ligament becomes the new large-scale FPZ. Ligaments are created until a certain crack separation is reached and the ligaments are overloaded and break. At this stage, the FPZ is fully developed, and the small-scale fracture assumption is no longer valid, so the entire fracture process zone needs to be modelled. From this point, the FPZ will translate in a self-similar fashion in steady-state specimens, at the same, near-constant CGR as the crack-tip. Note that for non-steady-state specimens, the bridging length will not be constant [8]. In a crack propagation curve, the previously described process would resemble that of the schematic shown in Figure 1.

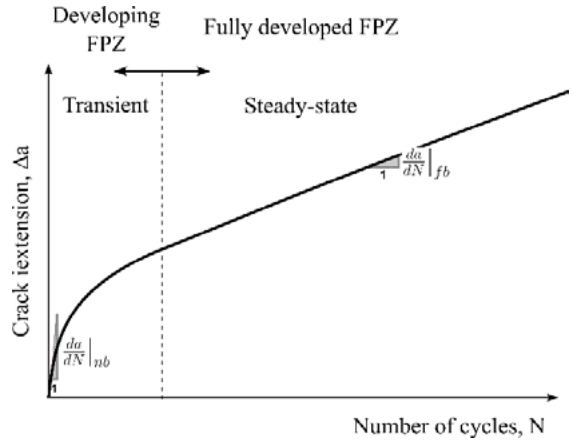

Figure 1. Schematic of the crack length of FRP composites undergoing delamination with fibre bridging

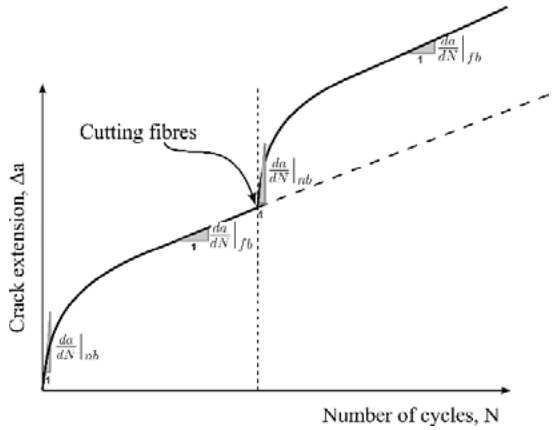

Figure 2. Visual illustration of proposed hypothesis

The scenario described above has been documented for glass-fibre composites where testing was conducted on double cantilever beams (DCB) specimen loaded by un-even bending moments (DCB-UBM), which is a steady-state specimen [9]. There are however, only few experimental studies on cyclic crack growth in composites under large-scale bridging [10] [11].

In the present work, we have conducted series of cyclic DCB experiments with un-even bending moments (DCB-UBM) to investigate the effect of fibre bridging on the crack growth rate of a delamination crack at different mixed-mode values. In particular, we have modified the length of the bridging zone by cutting off fibre ligaments, and studied how this affected the crack growth rate.

2. Problem statement

The hypothesis to be tested can be summarised as follows:

The development of the fracture process zone (from a “sharp” crack tip to large-scale fracture process zone) under cyclic loading leads to the shielding of the crack-tip, and thus slows the initial crack growth rate $da/dN|_{nb}$(where the subscript nb stands for “no-bridging”) until the fracture process zone (FPZ) is fully developed. Once the FPZ is fully developed it retains its characteristic length (length of the fully developed fracture process zone) and starts translating. The crack-growth rate takes a constant value $da/dN|_{fd}$ (where fd stands for “fully developed”) provided the cyclic loading remains constant. This is schematically illustrated in Figure 2.

In the present work we have tested the hypothesis using the following procedure; First, a DCB is subject to a cyclic loading with a fixed ratio of maximum and minimum values of the applied load (in the form of bending moments) until it develops its FPZ. Second, the test is stopped, and the length of the bridging zone is reduced by cutting the bridged ligaments (details of this procedure are given in the methods section). Third, the specimen is loaded again under the same applied cyclic loading as previously until its FPZ is fully developed, which is when da/dN becomes constant again. This sequence is conducted once for the nominal mode I, and twice for the mixed-mode.

3. Methods

3.1. Materials

DCB specimens were manufactured using a unidirectional (UD) glass fabric (E-1182 Saertex) embedded in Epoxy Hexion. The curing process involved 12 hours at 40°C followed by 10 hours at 80°C. The laminate was constructed with 20 layers, incorporating a 20 mm long Teflon insert of 15µm thickness in the middle plane to serve as the crack initiator. All laminates utilized strands of glass fibres, oriented perpendicular to the UD direction, as backing, all of which were positioned facing downwards at every laminae. The nominal dimensions of the specimens were a length (L) of 500 mm, a width (W) of 30 mm, and a thickness corresponding to 20 layers (~17 mm) [12].

3.2. Experimental setup and instrumentation

The DCB specimens were fixed at the uncracked end and subjected to uneven bending moments at the cracked end to induce mixed-mode conditions, in accordance to the test configuration described in [9]. A schematic of the test configuration is shown in Figure 2. The cyclic loading is imposed using a hydraulic cylinder which pulls on a wire that is attached to the lever arms (fixed in length). The loading ratio was set at R=0.1, a commonly used value in the literature for comparative analysis, with a cyclic loading frequency of 2 Hz to minimize frequency effects. A lower frequency also helped to minimize dynamic conditions arising from the inertia of the lever arms.

Stand-off distance	≈ 200 mm
Patterning technique	Ink-pad speckle

Table 2: List of DIC-parameters

DIC software	GOM Correlate 2019 [13]
Subset size	~50 pixels
Subset interpolation	Bicubic
Extensometer size	10x100 mm
Displacement noise floor	~1-6 µm

*Pictures were taken at the maximum and minimum amplitude every cycle for cycles 1-100, then every 10 cycles for cycles 100-1000, then every 100 cycles for cycles 1000-10,000, then every 1000 for cycles 10000-100000, and every 10,000 afterwards.

The test setup was instrumented with a machine vision camera (EVO8050) aimed at the crack. All specimens were marked with an ink speckle pattern pad from iMetrum [14] on the visible side of the DCB where images were captured at maximum and minimum amplitude following a logarithmic cycle increment*. The images were analysed using GOM Correlate Pro 2019 [13] software for a 2D digital

image correlation (DIC) analysis to obtain displacement fields of the visible surface of the DCB. The optical experimental setup and the parameters used for the DIC measurement of the opening displacement are detailed in Table 1 and Table 2.

Some of the specimens where also instrumented with acoustic emission (AE) sensors (two daisy-chained 1283 USB AE nodes from MISTRAS group physical acoustics each with R15-alpha sensors). The sensors were located 10 mm, and 110 mm ahead of the crack initiator. The AE win set-up file for the tests specified a detection threshold of 45 dB and a hit data set including rise time, counts, MARSE energy, duration, amplitude, and average carrier frequency.

3.3. Automatic crack tip location measurements based on DIC

With a full-field displacement measurement of a the measured DCB surface, a "continuous virtual extensometer" can be used to post process the opening displacements. The virtual extensometer was created using two parallel curves aligned with the crack plane. In an unloaded state the initial distance between the parallel lines is Δ_0. As soon as the DCB is loaded, the separation between the parallel lines i.e., $\Delta u_i = u_i^+(x_1) - u_i^-(x_1)$ will take on values larger than zero in the locations where a crack has formed. The largest positive location in the x_1 direction along the crack plane where $\Delta u_i > 0$ can thus be considered as the current position of the crack-tip. In practice, a small threshold value (as small as possible, but larger than the measurement noise floor) must be used to identify such a transition given the displacement noise from DIC measurements. We used a value of ~2 times the displacement noise floor, which is between 1-6 μm depending on the image quality of at a given test set-up and current cycle. Effects such as light variation, and machine vibration can lead to lower image quality, and therefore higher displacement noise floor. A schematic of the procedure is shown in Figure 3.

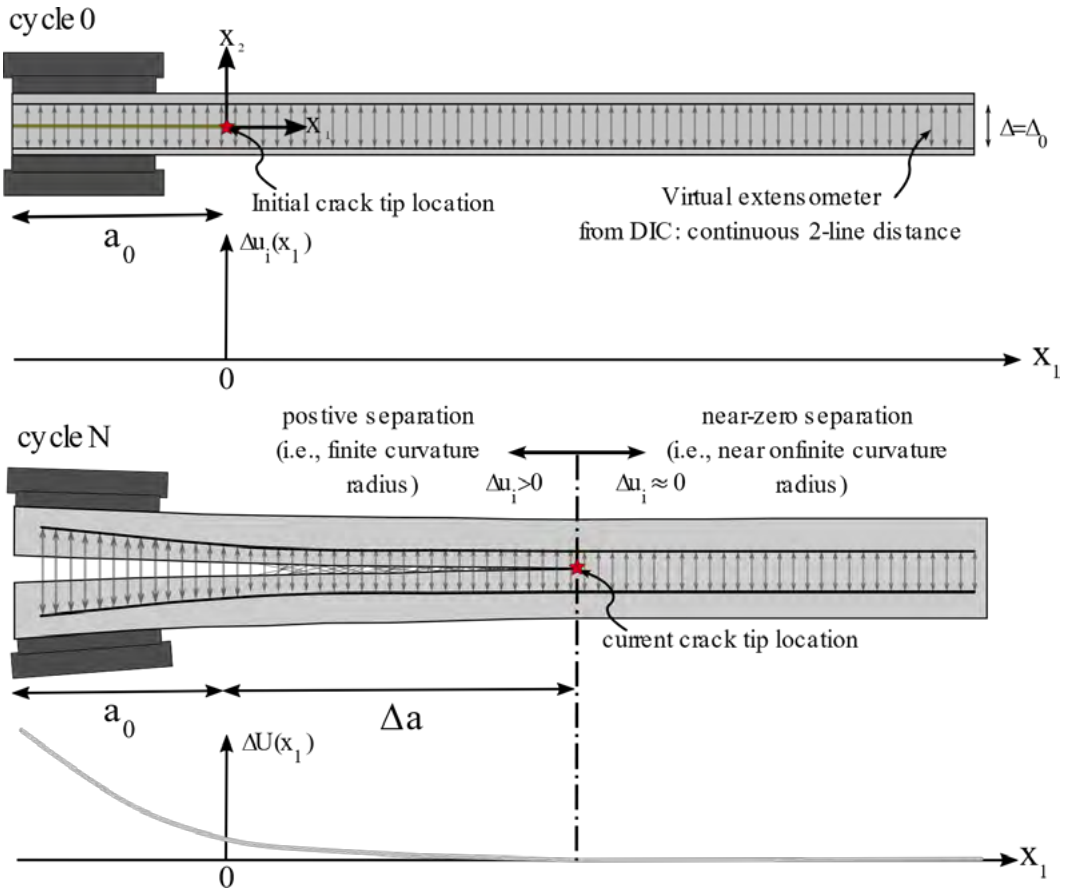

Figure 4. Schematic of the determination of the crack-tip location as a function of the cycle count

3.4. Cutting fibre bridging to restore FPZ

To cut the bridged ligaments of the test specimens after their initial block of cyclic loading the following procedure was implemented. After stopping and unloading the specimen, the test setup is change towards nominal mode I. Prior to loading the specimen (in nominal mode I) a clamp was placed at the current crack-tip ($x_1 = \Delta a$) location so that the crack tip is prevented from experience any opening. The specimen is then loaded so that the ligaments are visible, which are then cut-off using a thin razor blade (blade thickness of 10 μm, which is thinner than the original slip foil acting as the crack starter).

3.5. Data analysis

The nominal mode mixity of the specimens was calculated using an analytical solution for orthotropic DCB-UBM specimen [15] as:

$$\psi(\lambda, M_1/M_2) = tan^{-1}\left\{\lambda^{-1/4}\frac{\sqrt{3}}{2}\frac{1+M_1/M_2}{1-M_1/M_2}\right\}, \quad \text{for } |M_1| < M_2, \tag{1}$$

where M_1 and M_2 are the applied moments, and λ is an elastic non-dimensional parameter $\lambda = E_{11}/E_{22}$.

The maximum and minimum values of the fracture resistance (J_{max}, and J_{min} respectively) were calculated from an analytic solution of the J-integral for a DCB-UBM specimen [16].

$$J = \frac{21(M_1^2 + M_2^2) - 6M_1M_2}{4B^2H^3E_1'}, \quad \text{for } |M_1| < M_2, \tag{2}$$

where B is the width of the specimen, $2H$ is the height of the specimen, and E_1' is the young's modulus under plain strain.

4. Results and discussion

The crack growth as a function of the number of cycles is shown in Figure 3 for the specimen loaded under nominal mode I, and in Figure 4 for the one loaded with a mixed mode. The data corresponding to the crack growth is shown in blue curves. The different shades of blue indicate different blocks, where the dark blue corresponding to the first cyclic block, and the lighter curves correspond to sub-sequent blocks. The end of each block, which is when the ligaments are cut-off, is marked with a vertical dashed line. Note that the process of stopping and cutting off the developed fibre ligaments is carried once for the specimen under nominal mode I, and twice for the specimen under mixed mode. In Figure 3 the cumulative energy obtained from the AE sensors is superpose to the crack growth rate and shown with red curves. The same convention of colour shades is followed.

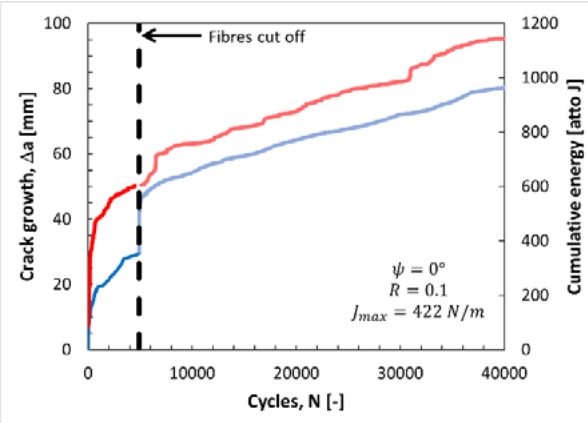

Figure 5. The crack growth as a function of the number of cycles of the nominal mode I ($\psi = 0°$) test specimen shown in shades of blue, where the darker blue represents the first block, and the light blue the subsequent block. The red curve represents the cumulative energy from the AE sensors.

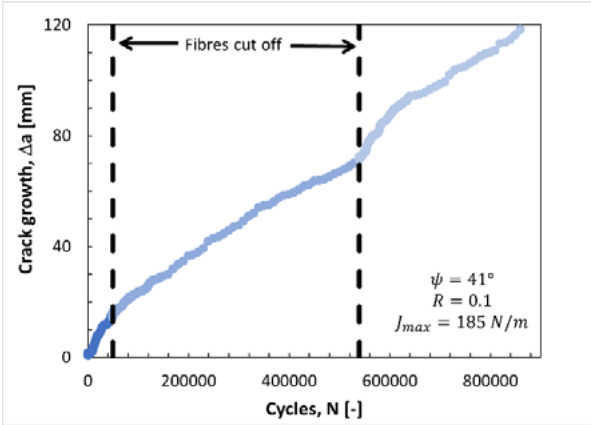

Figure 6. The crack growth as a function of the number of cycles of the mixed mode ($\psi = 41°$) test specimen shown in shades of blue, where the darker blue represents the first block, and the lighter blue the subsequent blocks.

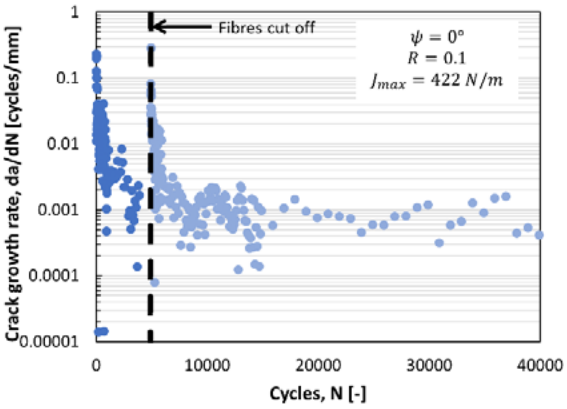

Figure 7. Crack growth rate as a function of the number of cycles of the nominal mode I ($\psi = 0°$) test specimen shown in dark blue markers for the first block and light blue for the subsequent block.

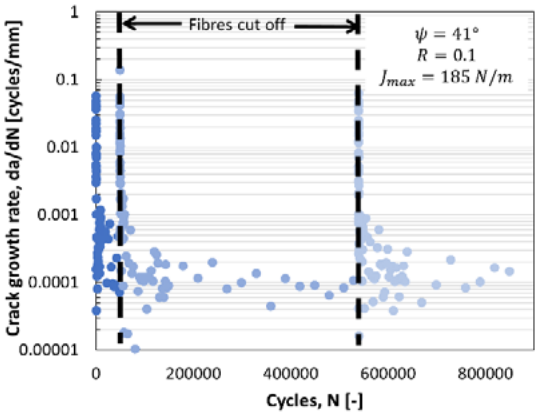

Figure 8. Crack growth rate as a function of the number of cycles of the mixed mode ($\psi = 41°$) test specimen shown in dark blue markers for the first block and lighter blue markers for the subsequent blocks.

In Figure 5 and Figure 6 the crack growth rate as a function of the number of cycles is shown for the specimen under nominal mode I, and mixed mode respectively. The same plotting convention as in the previously shown figures is used.

The CGR of the initially unbridged crack is in the order of 0.1 mm/cycle (or higher), while the CGR of the fully developed bridged crack is 0.0001-0.001 mm/cycle, i.e., a growth rate of ~100 times that of the unbridged crack.

The effect of cutting off the fibres is very clear, specially from the crack growth rate data. It is worth noting that such the effect of cutting off the fibres is not always easy to identify directly from the crack growth data. Take the first time the fibres were cut off in the mixed-mode specimen, with the current x and y scales in the figure its effect on Δa are not easy to appreciate (Figure 5). However, the higher CGR after cutting off fibres is evident, see Figure 8. It is worth noting that, a similar behaviour i.e., rapid increase after fibres are cut-off, can be seen in the cumulative energy obtained from the acoustic

emission signals. Although we have chosen to present the cumulative energy only (Figure 4), the same pattern was found in all the recorded AE signals i.e., duration, amplitude, amplitude frequency, hit count, and rise.

5. Conclusions

Experimental evidence of the effect of large-scale fibre bridging in the crack growth rate of a delamination crack in a UD composite has been presented. It can be concluded that the crack growth rate of a delamination crack with large-scale fibre bridging depends strongly on the size of the FPZ.

Keywords: Graphene protective coating, radiative flux, CFRP

Abstract
The demand for lightweight multifunctional materials is increasing in the automotive and aerospace industries. Protective coatings are required for polymer-based composite materials, especially in the case of high-temperature applications. Carbon fibre reinforced Plastic (CFRP) exhibits poor performance when exposed to high temperatures, mainly due to the decomposition of the organic matrix, resulting in a deterioration of the material's mechanical performance. In this work, graphene nanoplatelet (GNP)/Epoxy nanolayered films are employed as barrier coatings from radiative thermal fluxes (TBCs) to mitigate the thermal degradation in CFRP. The performance of the composite to high-power radiative heat flux has been investigated by laser spot heating tests and the post-heat mechanical response has been assessed through flexural elastic modulus and post-heat interlaminar shear strength (ILSS). The performance has been assessed for two levels of protection, considering #1 to #2 GNP layers. When exposed to heat fluxes, a significant reduction of the maximum temperatures on the heated surface and the damaged area is observed in the protected samples compared to the unprotected CFRP. This effect improves with the increasing level of protection. Mechanical tests on burned samples at 100 kW/m^2 showed a significant increase of the post-heat flexural elastic modulus and post-heat ILSS in the case of #1 GNP-layer protection of +260% and +90% respectively compared to the unprotected sample, which further improves with increasing thickness of the protective layer.

1. Introduction

Carbon fibre-reinforced plastic (CFRP) finds applications in various sectors thanks to its high specific strength and stiffness, good fatigue, and chemical resistance. However, their applications are still limited by the poor thermomechanical behaviour of the polymer matrix, characterised by very low thermal conductivity and low thermal stability. Composite components placed in proximity to a heat radiative flux can deteriorate and experience failure [1], [2]. To preserve the mechanical performance of CFRP composites from exposure to high temperatures thermal barrier coatings (TBCs) may be applied on the surface of the laminates. This system provides additional thermal conductivity and gas/liquid barrier, without impacting the structural properties of the material. TBCs mitigate the thermal degradation in composites protected, showing a steep thermal gradient through their thickness [3]. Anisotropic thermal conductivity and barrier to vapour and gases are required for managing the conductive heat exchange, blocking the oxygen and pyrolysis products' and reflecting the incoming radiative heat flux. Coatings with brick-and-mortar architecture are suitable for this application thanks to intrinsic properties that such

kind of architecture may exhibit [4], [5]. But even if the thermal barrier properties of such thin films have been published [6], [7], no works have been devoted to evaluating the effect of the application of such coating as protective layers of CFRP composites. To guarantee a safe application of CFRP in different sectors, it is necessary to investigate the mechanical and thermal properties as well as the degradation mechanism of the material in case of heat-induced damage. One-sided thermal loads, such as hot engine gases and electronic components overheating, cause a temperature gradient through the material. When striking the material on the front side, the absorbed thermal radiation is conducted to the back side. Consequently, thermal, chemical, and physical decomposition processes occur and the damaged material loses its mechanical performance [8]. Up to now, investigations on the thermal degradation of CFRP with and without coating are mostly conducted in the context of fire scenarios. However, other heat sources responsible for thermal degradation can affect the service life of a composite. Indeed, the thermal degradation processes and damage progress depend on the heat flux and can affect the mechanical properties differently. A laser heating test is a reasonable-cost method to investigate the thermal degradation of CFRP with and without protection and allows for modulating the desired heat flux.
In this work, graphene nanoplatelet (GNP)/epoxy nanolayered films are evaluated as barrier coatings to radiative thermal fluxes (TBCs) to mitigate the thermal degradation of Carbon fibre reinforced Plastic (CFRP). The GNP protective film was bonded on the surface of the CFRP laminate with a compression moulding process using a platen press and cured for 1 hour at 120°C with a pressure of 3 bar. Samples protected with #1 GNP layer (60 μm thickness) and #2 GNP layers (120 μm thickness) have been fabricated and tested. The performance of CFRP composite to high-power radiative heat flux has been investigated by laser spot heating tests of a duration of 15 min and magnitudes ranging from 25 to 150 kW/m^2 and the post-heat mechanical response has been assessed through flexural elastic modulus and post-heat interlaminar shear strength (ILSS).

2. Materials and methods

Carbon fibre pre-pregs are supplied by Technologycom S.r.l. They consist of high-strength carbon fabrics twill 2/2 of 600 g/m^2, impregnated with a standard epoxy resin.
GNP/Epoxy films consist of flexible and conductive free-standing sheets with an average thickness of 62 ± 7 μm and a nominal nanoplatelet/epoxy resin content ratio of 70/30 wt/wt. The films are produced by a top-down fabrication process based on a spray deposition process of a dilute solution of GNP/Epoxy/Acetone followed by a calendering process. The complete procedure is illustrated in [9].
Composite laminate panels with different levels of protection (#0,#1 and #2 GNP/Epoxy layers) are fabricated by a compression moulding process using a platen press and cured for 1 hour at 120°C with a pressure of 3 bar. In the case of coated samples, the films are easily integrated into the panel, by overlaying them on the pre-preg surface. The adhesion is guaranteed without the addition of any binder. According to the test, 8 plies (C8) and 24 plies (C24) are used to fabricate balanced laminates, obtaining samples with different thicknesses as reported in Table 1.
Specimens of dimensions 50 x 50 mm^2 were tested for 15 minutes changing the heat flux in the range of 25-150 kW/m^2 (i.e. by changing the laser power percentage). The irradiated area was set at 28% of the total area, by considering the laser spot of 30 mm diameter. In Table 1 the test conditions are summarised. During the heating tests, an IR camera (FLIR A655SC), was adopted to monitor the temperature on the specimen surface exposed to the laser radiation. On the surface opposite to the irradiated one, two K-type thermocouples (TESTO, 0602 064, -50 to +400 °C, accuracy class 2) were adopted to monitor the temperatures in real-time. They were placed at the centre of the irradiated area (10 mm from the centre) and bonded with epoxy adhesive.
Residual mechanical properties were performed on C8 samples tested at 100 kW/m^2 and were evaluated with dynamic mechanical analysis using TA Instrument DMA-Q800 equipped with a dual cantilever clamp. Rectangular specimens of 35 x 15 mm^2 were cut from the central area of the burned coupons. Tests were conducted with an initial amplitude of 20 μm, at room temperature. Data were elaborated according to the ASTM D790 standard for the flexural behaviour of composites [10].
The ILSS of C24 composites tested at 100 kW/m^2 was determined using the short-beam shear (SBS) test method following the ASTM D2344 standard. The interlaminar shear is generated indirectly through

the three-point bending of specimens in the SBS method. The tested specimens were compliant with the dimensions of 36 × 12 × h mm^3 where h was the actual thickness of the specimens.
The ILSS (MPa) values were calculated by Equation (1):

$$\mathrm{ILSS} = \frac{3P_{max}}{4bh} \tag{1}$$

where P_{max} (N) is the maximum load, b (mm) is the sample width, and h (mm) is the actual thickness of specimens.

Table 1. List of tested samples and performed test (*T*=Laser heating test, *ILSS*=Interlaminar shear test, *E'*=Elastic behaviour from DMA test)

Sample code	N° layers	N° plies	Thickness [mm]	Power density [kW/m^2]				
				25	50	75	100	150
G0-C8	#0	8	1.70±0.22	*T*	*T*	*T*	*T, ILSS, E'*	*T*
G1-C8	#1	8	1.75±0.13	*T*	*T*	*T*	*T, ILSS, E'*	*T*
G2-C8	#2	8	1.82±0.18	*T*	*T*	*T*	*T, ILSS, E'*	*T*
G0-C24	#0	24	6.31±0.35	*T*	*T*	*T*	*T, ILSS, E'*	*T*
G1-C24	#1	24	7.13±0.51	*T*	*T*	*T*	*T, ILSS, E'*	*T*
G2-C24	#2	24	4.39±0.12	*T*	*T*	*T*	*T, ILSS, E'*	*T*

3. Results

Samples with #0, and #1 GNP/Epoxy layers were tested at different laser power densities, while sample #2 GNP/Epoxy was only at 100 kW/m^2. The maximum temperatures recorded on the face exposed to the radiative source have been acquired and reported in Table 2.
Protection with the #1 GNP layer guarantees a significant reduction in the maximum temperature with respect to the value reached by the unprotected sample for all power densities. In the case of an incident power of 150 kW/m^2, a high temperature was measured due to the occurrence of swelling of the protection with a sudden release of pyrolysis products that produced an immediate flame on the surface of the sample.

Table 2. Maximum temperatures recorded on the face exposed to the heat flux for samples C8

	#0	#1		#2	
Laser power [kW/m^2]	$T_{max,\#0}$ [°C]	$T_{max,\#1}$ [°C]	$\Delta T/T_{\#0}$ [-]	$T_{max,\#2}$ [°C]	$\Delta T/T_{\#0}$ [-]
25	360.6	255.1	-29%	-	-
50	501.8	410.5	-18%	-	-
75	571.2	493.0	-14%	-	-
100	659.5	593.9	-10%	526.1	-20%
150	897.8	1366.0	52%	-	-

By increasing the thickness of the protection (#2 layers), a further reduction (-20%) of the maximum temperature was found at 100 kW/m^2. The highest the thickness of the protection, the lowest the maximum temperature reached on both sides of the samples. The time-temperature history during the test performed at 100 kW/m^2 on both the uncoated CFRP (#1-C8) and 2-layer coated CFRP (#2-C8) samples is reported in Figure 1a-b. Temperatures are acquired by an IR camera within the circle of radius 20 mm centred in the laser beam spot. In both cases and for all the distances, *R*, from the centre of the laser beam, the temperatures rapidly increase up to a plateau, indicating that the thermal equilibrium is achieved and remains almost constant up to laser irradiation off. After the heating phase, the temperature rapidly drops to the ambient one. The maximum temperatures, measured at the laser beam centre, are considerably different, reaching the value of 675°C for the unprotected specimen and ≃500°C for the specimen protected with #2 graphene layers. In addition, the initial heating rate reduces by 60% from 10°C/s to 25°C/s, when the coating is applied, indicating that the graphene layer significantly delays the heating time. On the surface opposite to the heating source, recorded temperatures follow the same dynamic maintaining a noticeable difference in the maximum temperatures reached during the test of about 120°C. Also, a significant reduction in the heating rate (40%) is observed in the case of the coated sample.

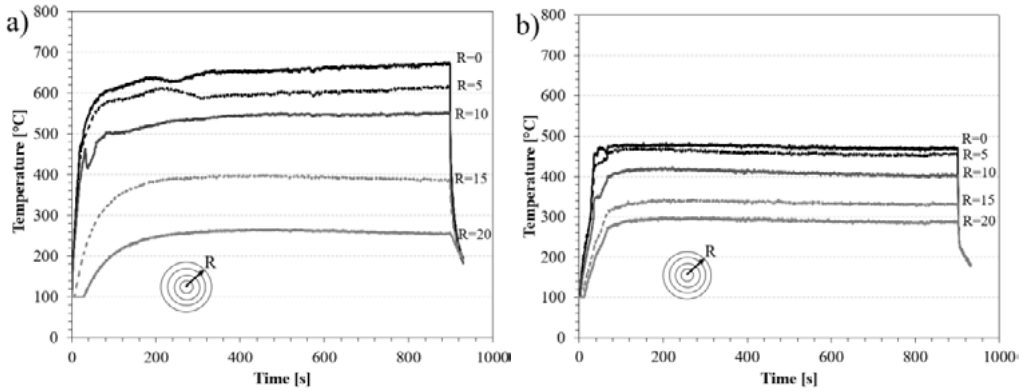

Figure 1. Evolution of temperature with time of the upper face at different distances R from the centre of the laser beam for (a) #0-C8 and (b) #2-C8

The spatial distribution of temperatures after 13 minutes of both uncoated and coated samples is reported in Figure 2. The shape of the curve significantly modifies from the uncoated to the coated sample. As stated before, the peak temperature is achieved for all cases under the laser beam and reduces at an increasing distance from the centre. By increasing the coating thickness, the curve flattens, and the maximum temperature approaches the average value. The ratio between the average and maximum temperatures are 0.65, 0.70, and 0.75 for #0-C8, #1-C8 and #2-C8 respectively.

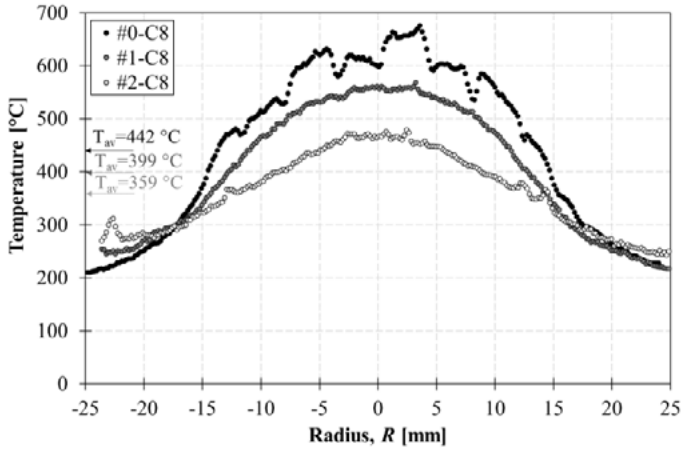

Figure 2. Spatial temperature distribution after 13 min of #0-C8, #1-C8 and #2-C8 samples.

The typical damage progression visually detected on both sides of the specimen as a function of the protection level is shown in Figure 3. Due to the different optical properties of the resin and burned carbon textile, it is possible to evaluate and compare the level of damage of the tested samples. The damaged area is clearly visible and identifiable from an optical analysis of the sample on both the upper and lower surfaces of the uncoated sample. In the case of coated samples, the presence of the GNPs-rich layer makes the evaluation of upper surface damage status not straightforward. However, they do not experience severe damage on the lower surface. In the case of #1-C8, the lower face only turns brown (Figure 3b), while in the case of #2-C8, no visible damages are observed (Figure 3c).

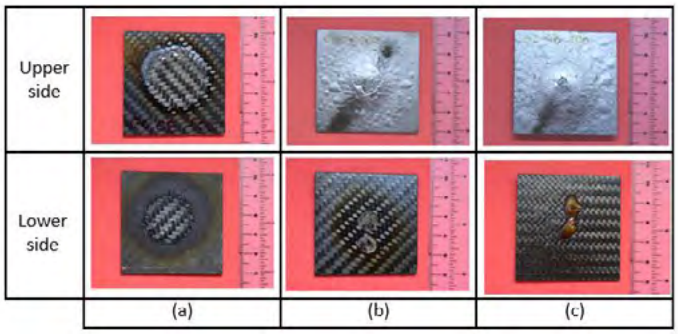

Figure 3. Optical damage of tested samples (a) #0-C8; (b) #1-C8; (c) #2-C8

Figure 4a shows the ILSS values for C24 samples tested at 100 kW/m^2. Samples coated with GNP layers showed higher values of ILSS compared to the unprotected CFRP. In the case of the #2-C24 sample, the ILSS increases by 71% compared to the unprotected CFRP, while in the case of the#1-C24 by 48%. In addition, it is found that the ILSS is 43% and 50% of the pristine value (53 MPa) for #1-C24 and #2-C24 respectively.

An inspection of the cross-section of C24 samples tested at 100 kW/m^2, further highlighted the effect of protection of the GNP layers. A sensible reduction of the damaged area can be detected with increasing thickness of the coating: the laser imprint is visible in the unprotected sample and tends to vanish for #1-C24 and #2-C24 samples.

Similarly, the beneficial effect of GNP layer protection on the elastic properties was found and reported in Figure 4b. Indeed, the residual elastic modulus of samples tested at 100 kW/m^2 is reduced by 88% compared to the reference unexposed CFRP (20 GPa), as shown in Figure 4. The effect of protection is clear in the case of #1-C8 and #2-C8, where the residual elastic modulus is 45% and 50% of the pristine value respectively. In the latter case, the elastic modulus is 4 times higher than the unprotected sample [11].

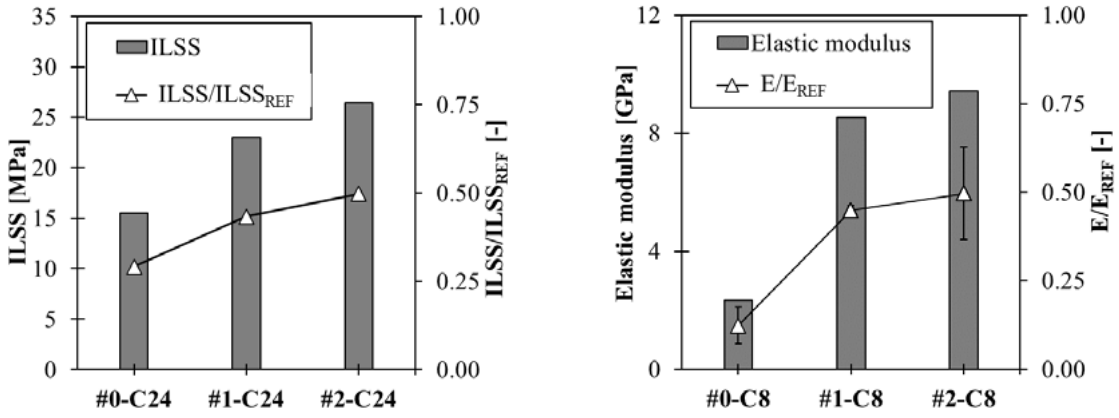

Figure 4. ILSS of C24 samples (a) and residual elastic modulus of C8 samples (b)

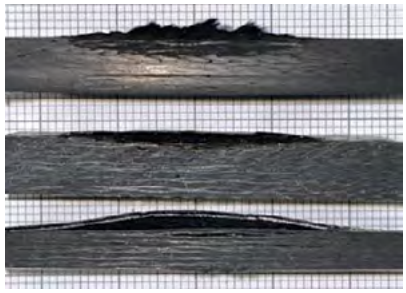

Figure 5. Cross section of #0-C24 (a) #1-C24 (b), #2-C24 (c) samples

4. Discussion

Experimental results show a sensible reduction of the maximum temperatures on both the upper and lower surfaces and an improvement of the mechanical properties of the protected samples, compared to the unprotected laminate.

The heat dissipation mechanism in the graphene-coated sample is based on different mechanisms.

(i). Unlike uncoated CFRP, in graphene-coated samples, the temperature field is uniform since the thermal energy spreads on the entire surface of the specimen thanks to the anisotropic thermal conductivity of graphene coating [12]. The effect of heat spreading increases with the increasing thickness of the coating and efficiently contributes to preventing major damage to the composite by removing the temperature peaks.

(ii). In addition, radiative heat transfer mechanisms should be considered. When panels are thermally loaded from one side, the incident radiation is reflected, emitted, or absorbed by the surface. Given the lower emissivity coefficient of graphene coating compared to the CFRP, the energy absorbed by the coated sample is much lower. Graphene layers efficiently reflect electromagnetic waves thanks to the laminated nanostructure made of GNPs well-aligned in the planar direction [13]. Consequently, they act as shielding against thermal radiation not only reducing the absorbed energy but also reducing the peak temperatures, preventing severe damage and preserving the structural properties.

5. Conclusions

In the present work, the ability of GNP coating to protect CFRP panels from high-power radiative fluxes was investigated. A testing procedure based on laser irradiation has been adopted for the verification of the performances of uncoated and coated CFRPs.

The experimental analysis showed that thanks to the high degree of orientation of highly conductive GNPs within the coating, the maximum temperature, and the temperature gradient onto the exposed heat flux surface are mitigated by spreading the thermal energy over the sample volume. The high anisotropy between the in-plane and cross-plane thermal conductivity of the graphene layer makes the heat diffusion capacity the main protection mechanism significantly reducing the thermal degradation of the material. Non-destructive analysis revealed that the presence of the coating on the surface subjected to laser irradiations preserves the sample from through-thickness damages at an energy level of 100 kW/m^2.

Finally, the graphene-based coating preserves the mechanical performance of CFRP when it is exposed to high heat fluxes. Specimens extracted from the damaged samples showed a residual mechanical performance four times higher than the CFRP without protection, with a residual mechanical performance of up to 50% of the pristine value.

Graphene coatings act as TBCs slowing down the degradation rate of components caused by heat flux and decreasing the surface temperature of the protected material. The coatings improve the operating temperature range, performance, and efficiency of CFRP laminates.

Abstract
Eco-efficient electrical low speed flight concepts like City-Airbus NextGen need ultra lightweight load adapted designs combined with a high robustness. SoA monolithic fiber reinforced or sandwich design do not provide sufficient robustness. This research focus on the investigation of a disruptive skin architecture combining robust membrane materials with a hierarchical reinforcement. 5 different membrane material classes covering a wide range of relevant properties (stiffness, elongation at break, energy absorption, area weight) were processed and tested. Numerical simulation based design investigations show that the hierarchical reinforced membrane materials concept provide a much higher robustness (e.g. for an Endumax membrane concept up to 3*) with equal weight compared to SoA building methods. In conclusion, the study presents a promising approach to the synergy of material design, processing, and simulation for an eco-efficient flight concept. The detailed exploration of material properties and their integration into innovative wing structures positions this research as a significant contribution to the field of composite materials and aeronautical engineering.

1. Introduction

With the trend to eco-efficient travel and also new technologies available the idea of urban air mobility is becoming more tangible than ever. Nevertheless those low-velocity public aircrafts require different construction concepts than those used in commercial aviation to date. As often in research there is the idea to borrow from nature and e.g. employ bionic wings similar to the wings of a dragonfly (see Figure 1, left). The idea hereby would be to transfer the composition of a hierarchic gride-like reinforcement structure combined with a flexible but also tough membrane to wings for the new aircraft type. Though similar approaches have been used for e.g. sails with reinforcement of carbon fibre rods or fibres and a flexible membrane, a bionic approach has never been used in commercial aviation.

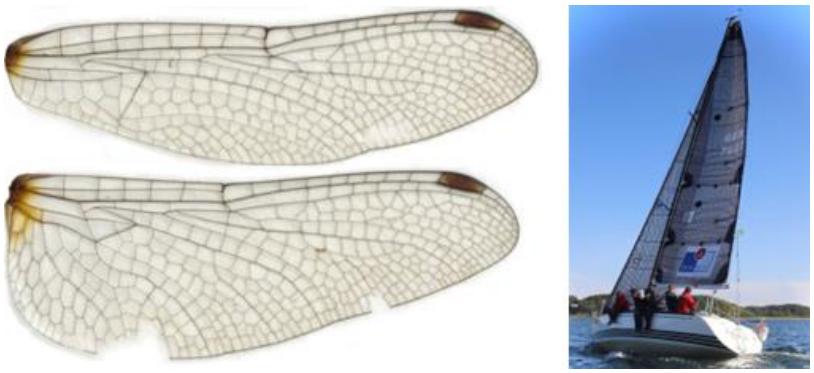

Figure 1. Dragonfly wings (left) [1], carbon fibre reinforced sails (right) [2]

The resulting findings serve as an initial assessment of such a covering material with the aim of achieving a technology readiness level of TRL 2-3 and address the technological trend of "unmanned flight" as well as the trend towards increasing the eco-efficiency of flight.

2. State of the art

State of the art lightweight building concepts consist either of monolithic fiber reinforced skin materials with stringer reinforcement or of sandwich structures. These minimize skin ripple under the acting flight and air loads and therefore keep drag as low as possible during cruise flight. Furthermore, this design takes into account the robustness requirements with regard to impact events in the context of high speeds. If you adopt the designs according to the lower acting loads to save weight, this leads to thinner skins and hence to lower robustness. Thus slow-flying sports aircraft in ultralight construction with significantly lower air loads and also wing span already take already different approach and use membranes to cover a supporting structure. For the urban aircrafts addressed in the publicly funded project *Robust Skin*, an unreinforced covering solution was yet not an option. Instead the goal was a simulation-supported development of material and process solution for damage-tolerant hybrid materials consisting of a highly flexible fibre-reinforced soft component (e.g. fibre reinforced elastomeric materials - FRE) and a load-bearing rod structure (e.g. C-fibres with duromeric matrix). Though some approaches of combining robustness with flexibility (e.g. carbon fibres in flexible epoxy matrices) have already been made in literature [3-5] non of them yet targeted a hierarchical bionic approach for an aircraft wing.

3. Materials, processing and investigation methodologies

3.1 Materials

To determine suitable ultra-light yet robust membrane materials also considering ecological aspects, multiple material classes were investigated of which 4 shall be further described. An overview to the examined material compositions is given in the following:

A. Carbon reinforced EPDM: *Rubber with unidirectional carbon fiber reinforcement, resulting in a combination of robustness and stiffness.*

For the EPDM trial series a EPDM film AA9KFZ from KRAIBURG Holding SE & Co. KG with a thickness of 0.35 mm, a density of 1 g/cm³ and a modulus of (30 – 40 MPa) has been used. Amongst others three different reinforcing fibre materials have been combined with the EPDM:

- Hexcel coorporation CFRP prepreg (HexPly® M21)
- A non impregnated spread tow from ZOLTEK Corp. (Zoltek PX35) with a width of 40 mm
- 3K-Rovings from Teijin Limited (Tenax HTA 40 / 3k / 200 tex)

B. Endumax: *A fabric composed of stretched ultra-high-molecular-weight polyethylene (UHMW-PE) fibers, which has a very high weight-specific tensile strength and robustness.*

The second approach was done with a UHMW-PE fabric from Teijin Limited with a width of 133 mm and a thickness of 100 µm which were consolidated together with LDPE-foils provided by Teijin with a thickness of 8 µm. The LDPE-foils act as a binder during the consolidation process to reach the desired final thicknesses. Additionally Flexon as an UHMW-PE fabric with additional erosion and UV-protection already in use in sails industry was investigated.

C. Twaron: *An elastomer-embedded aramid fabric with high intrinsic robustness*

As the third approach an aramid fabric was considered, since these have very good impact properties (e.g. use in ballistic applications). The used fabric from Teijin Limited (Twaron T750, 3360 dtex - Type 1000) has a areal wight of 460 gsm and a thickness of 0.65 mm. The aramid fibres in this fabric have a rubber coating.

D. NorthThinPly (NTPT): *An ultra-thin ply epoxy CFRP enabling ultra-lightweight membranes*
NTPT offers high-performance composite materials for sailing and other applications. The in delivery state uncured prepregs comprise of UD-carbon fibres and an epoxy-based matrix system

E. Reference-Sandwich:
In order to be able to compare the membrane materials with regards to an extremely light (755 gsm) fibre composite sandwich, a reference sandwich was manufactured using thin-layer CFRP (45 gsm) with a tough cryomatrix and a light Nomex honeycomb. The target design of membrane plus stiffeners in the background should achieve this weight as a reference value, but exhibit improved damage tolerance under impact.

3.2 Processing

A. EPDM
The elastic EPDM needed to be reinforced with fibres to improve its mechanical properties. Consolidation was done by a static press process. The process parameters that have been found to lead to the best results are given in **Table 1**.

Table 1. Process parameter used in the static press process

Specimen Type	*Temperature* (°C)	*Pressure* (bar)	*Time* (min)	Use of additional vacuum
EPDM + HexPly®	180	7	120	No additional vacuum
EPDM + Zoltek PX35	140	15	30	Additional vacuum
EPDM + Tenax 3K	140	15	30	Additional vacuum

The schematic structure of the EPDM reinforced with HexPly® is shown in Figure 2. The prepregs are placed on both the top and bottom side to avoid warping of the samples.

Figure 2. Structure of EPDM + HexPly®

B. Endumax
The UHMW-PE was consolidated in a static press process using the parameters specified by the vendor (T = 130 °C, p = 10 bar and t = 120 min). Due to the resistance to bird strike in the subsequent application, two LDPE-foils were placed over each of the individual fabric layers. The centre layer again consists of two films (see also Figure 3).

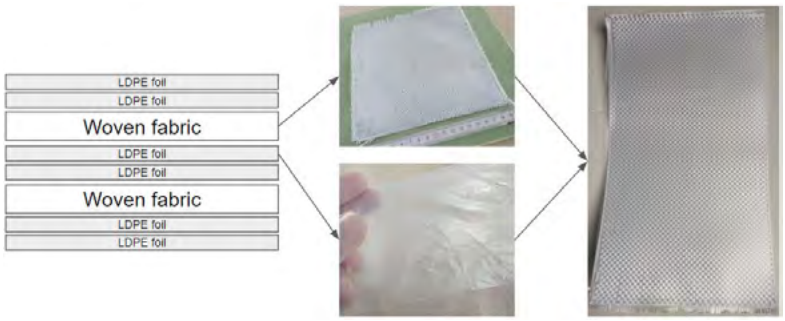

Figure 3. Schematic illustration of the composition of the samples made of Endumax UHMW-PE

C. Twaron

Due to the already high areal weight a single layer was used and the material was tested as delivered without any processing needs.

D. NorthThinPly

The prepregs have been processes in a static press process with parameters provided by NTPT. Two different layer compositions have been produced:

- NTP1: QI-layup with 8-layers (each 40 gsm) resulting in a total areal weight of 320 gsm
- NTP2: 0°/90° layup with 4-layers (each 20 gsm) resulting in a total areal weight of 80 gsm

3.3 Microscopic examinations

Digital microscopy images of the fibre-reinforced EPDM from Kraiburg were taken. The analyses were carried out on a Keyence 3 digital microscope VHX-7000. The advantage over optical microscopy is the sample preparation, as no embedding resin is required. The samples were cut to size using special fibre scissors and then fixed to the sample plate. In addition to being analysed using a digital microscope, selected samples were examined using a Zeiss EVO MA15 scanning electron microscope (SEM).

3.4 Set-up for static tensile tests and impact testing under pre-loading conditions

For a first material screening tensile tests according to ASTM D3039 are done. Therefore the specimens are tensioned until failure at constant displacement of 2 mm/min. According to the general design concept, first a pretension of 100 N is applied on the test coupon after which a physical extensometer is attached to the test coupon for an exact strain measurement.
The concept to consider the pretension load of the investigated membrane materials is also considered for the impact testing. Therefore an impact device was designed enabling impact testing on thin membranes that are bi-axially stressed before and during impact. The achieved continous impact area is 100 * 100 mm. Four load cells are installed on the clamping interfaces to measure the preload of the membrane. Here 2 manual applied pre-load settings are tested: 1 kN/1 kN and 1 kN/2 kN. Furthermore the load cells measure the force time signal during the impact with 4.8 kHz. In order to limit the strain/stress concentrations near the clamping area's due to bi-axial loading, a cruciform coupon shape is required as shown in **Figure 4** (right). The impactor radius is 15.75 mm having a weight of 1.917 kg. The lowest possible impact energy is 2 J.

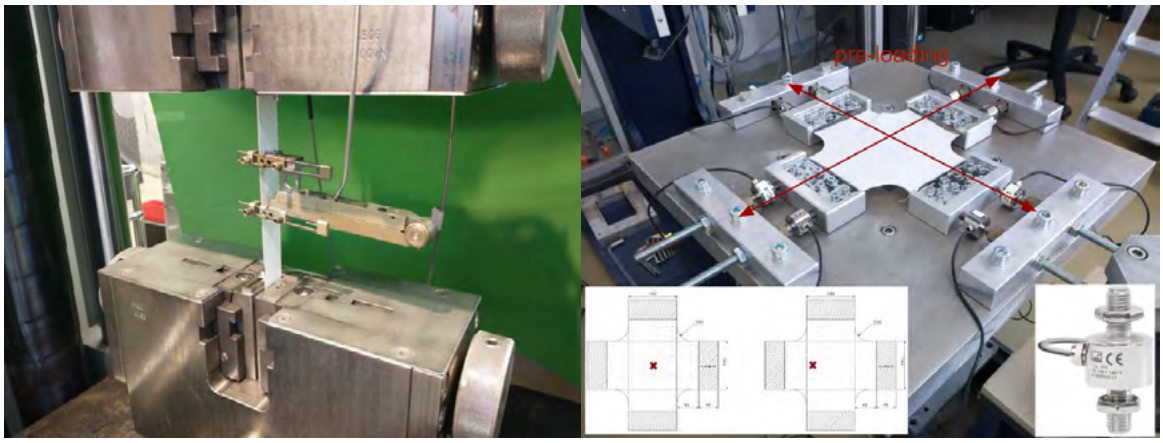

Figure 4. Static (left picture) and non-standard dynamic impact test device (right picture)

4. Results and discussion

4.1 Analytical investigations of processed materials

Digital microscope images of EPDM with the both non pre-impregnated 3K rovings and Zoltek PX35 were done in order to investigate the fibre-matrix adhesion. Unfortunately a bad adhesion (black cavities) between the Zoltek spread tow and the EPDM was detected in Figure 5 (right). For the 3K rovings especially at 140 °C and additional vacuum a good wetting of the outer fibres of the roving could be detected (left), though black areas are also detectable within the roving. Yet further SEM investigations show for the 3K rovings a poor wetting of the fibres within the rovings, resulting in unsufficient load transfer. Although progress had already been made in the impregnation process during the project, it was not possible to produce sufficiently good samples. Therefore, these were not subjected to mechanical testing. However, further optimisation could still lead to progress here.

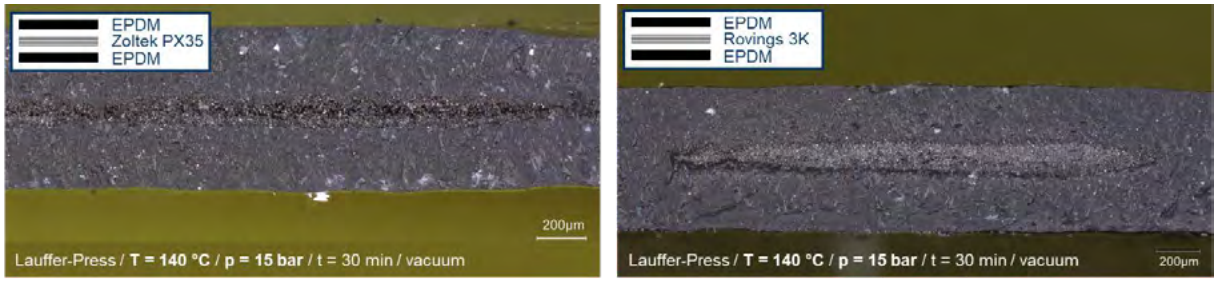

Figure 5. Digital microscopy images of the EPDM reinforced with the both non-pre-impregnated Zoltek PX35 spread tow (left) and 3K rovings (right)

4.2 Static tensile tests

Figure 6 shows the result summary for static tensile tests for the selected membrane materials. The materials Endumax and Twaron offer a very good compromise between strength, rigidity and elongation at break. EPDM/HexPly® material configurations show during the tests (in fiber direction and transversal) a high scattering and by far not the expected high elongation in transverse tension. In conjunction with the in Figure 5 shown process results and the low elongation at break this material class was not pursued further for the subsequent robustness and aging tests.

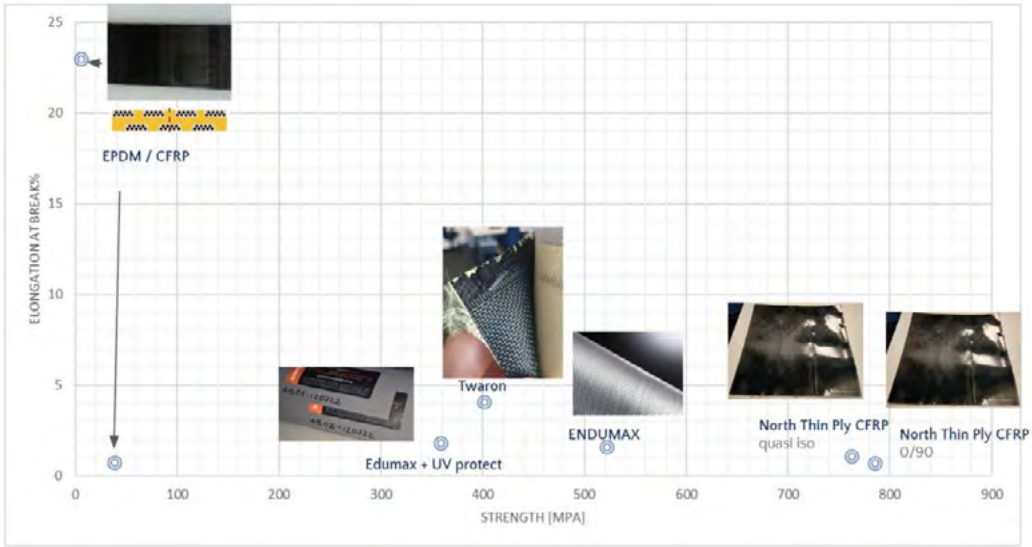

Figure 6. Results of static tensile testing

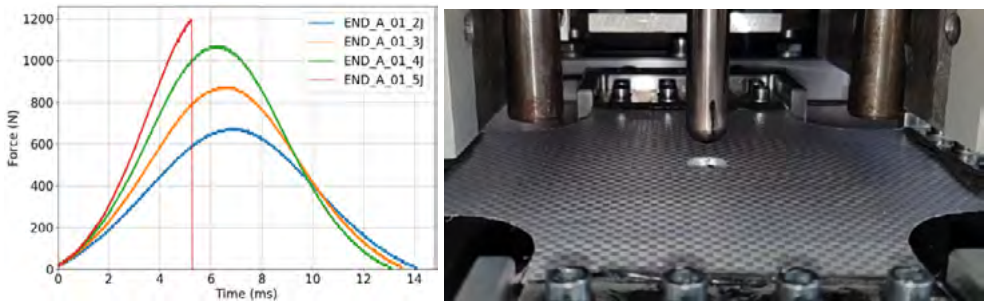
4.3 Validation of low velocity impact without and with grid reinforcement

Figure 7 shows for the example of ENDUMAX on the left hand side the force time signal of one load cell for different impact energies. The impact load is increased on the coupon in 1 J steps until the coupon is penetrated as shown on the right side. The very local penetration leads to a sudden drop of the force signal down to 0 N as no interaction between impactor and coupon exists anymore.



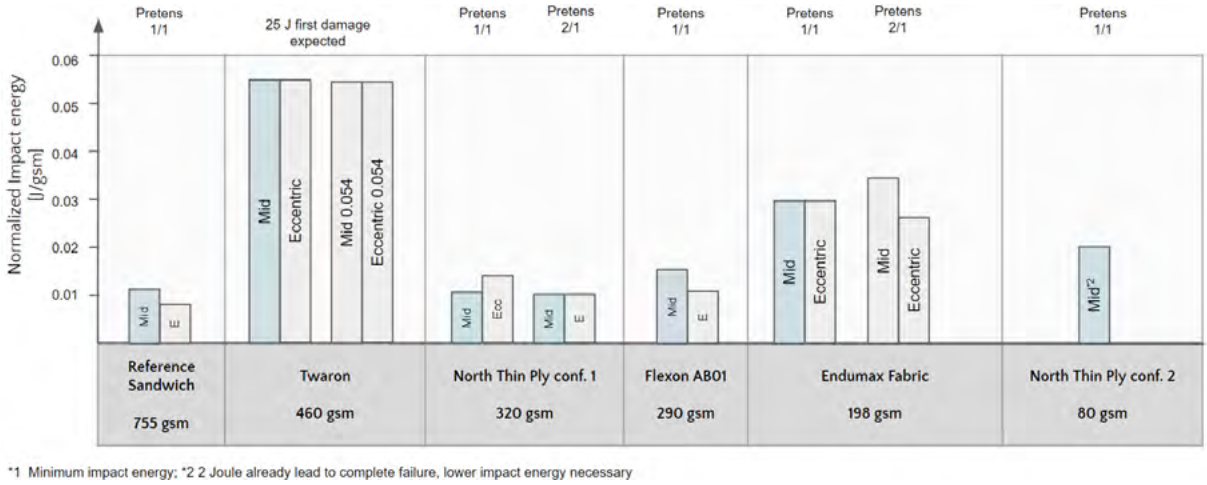


Figure 7. Force signal of load cells (left), penetrated ENDUMAX fabric [5 J impact] (right)

For a better robustness comparability of the tested membrane materials the respective energies leading to penetration are summarized in Figure 8 in a normalized way considering their areal weight. An ultra lightweight sandwich reference architecture (see also 3.1 Materials) was also tested in this campaign showing a very low impact resistance. Twaron, which could not even be penetrated in the test device up to 20 J impact energy, has the best normalized impact behavior of all materials. The Endumax material also performs very well. For both the choosen pre-tension (1 kN / 1 kN & 2 kN / 1 kN) as well the position (mid & 30 mm eccentric) of the impact have only a marginal influence on the overall results.

*1 Minimum impact energy; *2 2 Joule already lead to complete failure, lower impact energy necessary

Figure 8. Summary of impact tests on membrane materials – normalized impact energy [J/gsm]

To prove the influence of reinforcements on the impact performance, Endumax and NTPT1 coupons were equipped with rectangular struts (4 & 10 mm edge length, 3 different positions) which are bonded on the backside of the membrane. As expected the direct impact on the grid structure increases the impact energy leading to penetration for both materials. Tests with distance (15 mm & 50 mm) of the impact position to the grid element showed very similar penetration energies.

4.4 Numerical simulation

Various numerical simulations on different levels supported the experimental investigations to cover the mechanical requirements regarding stiffness and damage tolerance. The design approach of a thin membrane covering a reinforcing grid structure required the consideration of both a global stiffness requirement and a local stiffness requirement to ensure a low skin waviness for the aerodynamic surface.

Therefore, complete homogenization ("smeared modelling") of all components of the “Robust Skin” was not a sufficient solution, as this would not be usable for the optimization or local adaptation of the reinforcement structure, taking into account the aerodynamic requirements. The discrete reinforcements (grid structures) were modelled as computationally efficient beam elements for the stiffness investigations. Shell elements were used to model the thin membranes. The two components were perfectly connected using tie interactions. This approach ensured low computational costs for studying many parameters and later transferring the approach to larger models. Using the described approach, different regular grid patterns were evaluated for their stiffness in a periodic unit cell model. An uniform pressure distribution was chosen to represent flight loads to evaluate skin waviness and global stiffness. Parallel to that, the impact tests and further coupon tests were simulated to calibrate energy-based continuum damage models for the membrane materials. Finally, the modelling approaches were transferred to a larger scale represented by a wing box section. This was simplified as a connection of two panels in the form of the “Robust Skin” material solution with I-beams as spars. The unit cell simulations showed that a multi-hierarchical reinforcement grid is the preferred solution for a weight-efficient fulfillment of the waviness requirement as the allowable maximum size of a non-reinforced skin field is comparably small to the overall dimensions. Despite a non-regular, fully load path-optimized structure with a large number of hierarchies would be able to reach higher lightweight design potential, the solution was restricted for the demonstrator to a regular iso-grid with two hierarchies due to manufacturing reasons. The resulting unit cell of the demonstrator grid consists of an Endumax membrane and CFRP hollow profiles with quadratic cross-sections shown in the Figure 9 (left).
A full panel of multiple cells was modelled on the wing box level to predict the impact behavior for boundary conditions that are closer to the real application than the impact investigations on coupon level. The wing box was loaded by uniform pressure at the top and bottom to introduce pre-tension similar to flight conditions. After application of the surface pressure, the structure was impacted with the same geometry and kinetic energy as in the coupon tests.

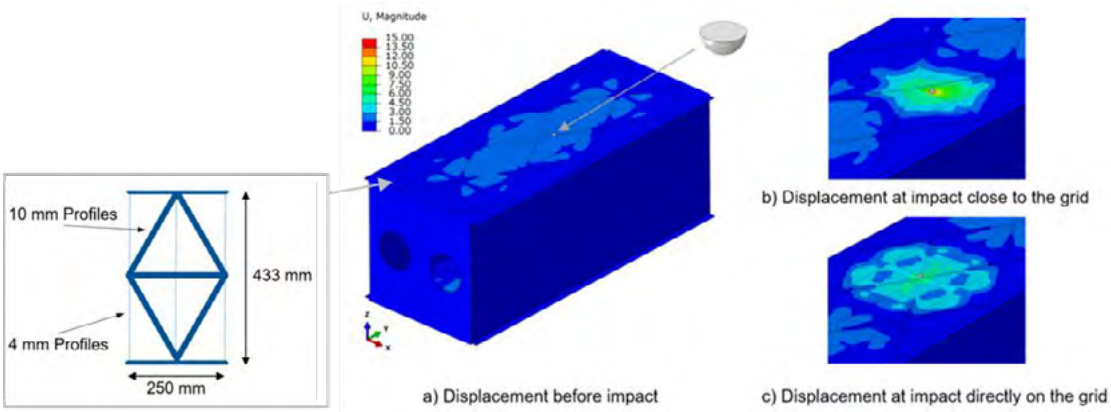

Figure 9. Resulting unit cell of the grid (left); displacement in mm before and after impact (right)

Figure 9 (right) shows the displacement due to the surface pressure before impact and the resulting impact for a kinetic energy of 8 J at two different impact locations. In both cases, there was no element that was fully damaged. While one element of the membrane reached 30% of the allowable damage for the impact close to the grid, the damage initiation criterion (maximum stress) was not even reached for the impact directly on the grid. These findings show that the results from the coupon impact tests should be transferable to the actual application of the “Robust Skin” while being more conservative.

5. Summary and outlook

Based on a numerical design, an demonstrator was built showing a possible architecture for ultra lightweight Robust Skins. In detail an Endumax membrane was hierarchically reinforced with 4 mm and 10 mm quadratic CFRP rods which are connected with 3D printed PA11 node-elements and bonded using a paste adhesive (**Figure 10**).

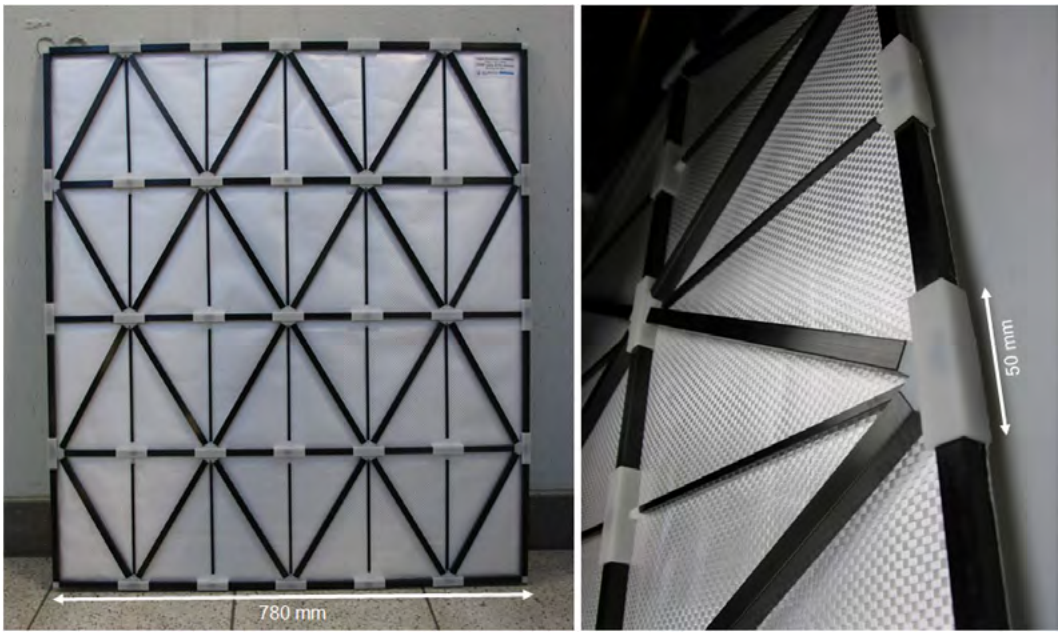

Figure 10. Demonstrator showing the global architectural concepts (left) und detail thereof (right)

A numerical sized reference use case of a wing box cover comparing SoA materials & architectures with Robust Skin concepts, show that the Robust Skin architecture can be realized weight neutral combined with a much higher robustness. To validate the approach, a detailed sizing and design loop within a program developing low speed vehicles need to be done considering all relevant aspects like e.g. load introductions. Furthermore aspects with regards to aging, lightning strike protection as well as paint application need to be investigated. In conclusion, the study presents a promising approach to the synergy of material design, processing, and simulation for an eco-efficient flight concept. The detailed exploration of material properties and their integration into innovative wing structures positions this research as a significant contribution to the field of composite materials and aeronautical engineering.

Acknowledgments
We would like to extend our sincere gratitude to BFS – Bayerische Forschungsstiftung for their support and funding of the project Robust Skin. Their commitment in advancing ultra lightweight and robust skin materials for low speed air vehicles has been instrumental in bringing this initiative into fruition. We also express our appreciation to all stakeholders and participants who contributed their time, expertise and resource to the success of this project. Together we made significant strides showing the potential of disruptive lightweight and robust skin architectures.

Keywords: Fatigue, Composites, TDCB, Self-healing, Adhesive

Abstract
The failure of thick adhesive joints within wind turbine rotor blades (WTRBs) is often observed, and their performance could be improved by developing self-healing adhesives that heal small cracks before failure. Self-healing epoxy adhesives that were developed from earlier experiments, containing poly(ε-caprolactone) (PCL) microparticles and fumed silica are used here to fabricate Tapered Double Cantilever Beam (TDCB) specimens to investigate their fracture and fatigue performance. The fracture toughness showed ca. 60 % recovery with good healing repeatability through three healing phases. The fatigue crack growth (FCG) curves of virgin and healing phases exhibited similar slopes and the healing efficiency is thus the comparison of the stress intensity factor difference (ΔK) at the same crack growth rate, hence 58 %.

1. INTRODUCTION

The rated power of a wind turbine is determined by the length of wind turbine rotor blades (WTRBs). The urge for energy production led to a continuous increase of the blades' length over the last few decades with contemporary WTRBs reaching or exceeding 100 m [1]. WTRBs consist of composite shells and webs and large quantities of structural adhesives (hundreds of kg) are required to fabricate adhesive joints connecting them together [2]. The adhesive layer thickness can be up to 30 mm depending on the size and the position within the WTRBs [3].

Epoxy structural adhesives with low shrinkage rates are widely used for WTRB manufacturing. Although commercial state-of-the-art adhesives with high fracture toughness have been developed [4], failure of thick adhesive joints was still observed from post-mortem examinations and full-blade experiments [5], [6], mainly induced by voids and the complex stress state within the adhesive layers. Depending on the size and shape of voids, they may form crack initiation sites and influence the crack propagation path [7]. Developing new formulation adhesives with self-healing capabilities in addition to the usual processing and service requirements, as well as moderate cost, is one possible strategy to delay fracture by healing the crack and therefore improve the thick adhesive joint performance.

The new formulation adhesives should meet the requirements throughout the manufacturing process and the use phase, including low curing temperature, sufficient rheological yield stress, good adhesion, adequate tensile properties, good fracture and fatigue resistance. The adequate rheological properties are essential for the manufacturing process. One critical fabrication step is the mix of structural adhesives with an adhesive batch blender and dispensing adhesives through tubes on the composite shell and web surfaces, which have variable shapes. Therefore, the flow of adhesives on the vertical surface has to be prevented until the next step, during which the separated parts are assembled together. This is achieved by adding fillers into the adhesives to form a 3D filler network. Nanofillers with high surface-to-volume

ratios are optimal as only a small amount of nanofiller is sufficient to achieve the desired properties. Fumed silica with a relatively low cost is one promising candidate for the development of a new adhesive formulation [8].

Self-healing epoxies have been intensively studied, and one method is to add thermoplastic into epoxy blends, where the thermoplastic serves as the healing agent, flowing upon moderate heating to fill cracks. Cohades et al. [9] investigated epoxy/thermoplastic blends with low-melting temperature thermoplastic, PCL, which was introduced into epoxy through melting at a high temperature (120 °C). The morphology of the blend was determined by the PCL concentration. Good mechanical properties and high healing efficiency were achieved with a complex morphology, i.e. bi-continuous phases composed of PCL-rich matrix and cross-linked epoxy-rich spheres. This method is suitable for structures with long design lifetime, since it can heal cracks several times. However, due to the size of WTRBs, the curing temperatures of the adhesives need to be low to minimize energy demand. As a result, the phase separation approach is not applicable in this case, and a filler replacement method is proposed. Cryo-milled PCL microparticles are added into the adhesive to replace some of the fumed silica with dual purposes: acting as fillers to achieve sufficient yield stress by synergizing with fumed silica, and acting as the healing agents. The healing principle is the differential expansive bleeding phenomenon [10]. The expansion of the PCL liquid phase at high temperatures is greater than the epoxy phase due to the liquid transition and the higher expansivity. Therefore, the PCL phase could flow into the crack region and heal the crack after cooling. A formulation was developed that fulfills the requirements for application, mechanical and adhesive properties, as compared to a benchmark commercial epoxy.

The fracture and fatigue behavior of thick adhesive joints is critical for WTRBs, since their design lifetime is 20-30 years. Therefore, the fracture and fatigue behavior of self-healing adhesives needs to be investigated before their application to joints. TDCB is a commonly used configuration for self-healing investigations under both quasi-static and fatigue loadings. However, the TDCB fatigue investigations are mainly focused on the epoxy system with external healing agents contained in microcapsules, hollow fibers, and networks [11]–[13]. The fatigue investigations on repeatable epoxy/thermoplastic blends using TDCB specimens are rare.

This research thus investigates the fracture and fatigue behavior of self-healing adhesives developed for WTRBs with TDCB specimens to study their healing efficiency under quasi-static and displacement control fatigue loading.

2. MATERIALS AND METHODS

The baseline epoxy (BL) was provided by Sika Technology AG (mixing ratio 100:36.7 by weight). CAB-O-SIL® M-5 fumed Silica was purchased from Thermo Scientific. CAPA® 6500 PCL pellets were provided by Nordmann Switzerland AG, which were cryo-milled by Axalta Polymer Powders Switzerland Sàrl. The microparticles smaller than 150 μm were collected and used as the fillers.

The optimized adhesive determined by earlier investigations contains 20 wt% PCL microparticles, 4 wt% fumed silica, 55.6 wt% BL resin, and 20.4 wt% BL hardener. High temperature benefits the dispersion of fumed silica, while the PCL microparticles need to be processed at low temperatures (room temperature, RT). Consequently, the adhesive was processed in 4 steps: First, the BL resin and half amount of the fumed silica were mixed together with a mechanical stirrer at an elevated temperature (60 °C). An IKA T-25 Ultra-Turrax® disperser (at 24000 rpm, 20 mins) and Branson Digital Sonifier® SFX 550 (ultrasonic homogenizer) were used in sequence to disperse the fumed silica and break the agglomerate of fumed silica. The ultrasonic homogenizer was operated at 30% power and the pulsed mode with 15 s on and 60 s off. The total accumulated pulsed time was 10 mins. Second, the PCL microparticles were added to the fumed silica and BL resin mixture at RT. Only a mechanical stirrer with a cooling water bath was used and the speed was controlled (< 600 rpm) with several pauses to avoid heat accumulation. The total mixing time was 15 mins. Third, the other half amount the fumed silica was mixed with the BL hardener, using a mechanical stirrer and the same ultrasonic homogenizer in the first step with the same operation parameters. The last step is to mix the two components with a

vacuum mixer. The container was also surrounded with a cooling water bath and the new adhesives were mixed at 150 rpm for 10 mins. The mixture was then transferred to a silicon mold. TDCB specimen was cured at RT for 48 h and post-cured at 70 °C for 4 h. After demolding, the pre-crack (5 mm) was cut with a 0.16 mm thick jewelry saw. The detailed TDCB dimensions are shown in Figure 1 [14].

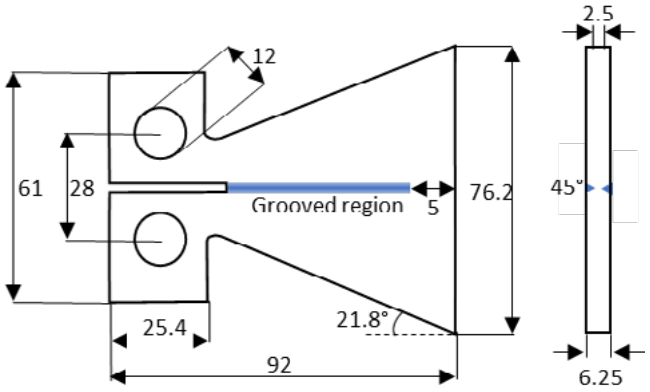

Figure 1: TDCB specimen sketch with dimensions (unit:mm) [14].

The fracture toughness recovery was first investigated through TDCB tests under quasi-static loading. The experiments were conducted with a universal testing machine (Walter + Bai AG, Switzerland, 125 kN capacity) and a 1 kN load cell (± 1 % accuracy). The load cell speed is 0.24 mm/min. After this, the specimen was dismounted and then it was clamped and put into an oven to heal at elevated temperature (120 °C for 1 hour), finally the specimen was cooled down to room temperature inside the oven. The specimens were fractured under the same conditions as the virgin specimens. Three specimens were studied and for each specimen, the healing process was repeated three times.

Table 1. Summary of TDCB fatigue test methodology and outcomes.

Specimen	Virgin	Healing phase 1	Healing phase 2	Healing phase 3
Static loading Speed	0.24 mm/min	0.24 mm/min	0.24 mm/min	0.24 mm/min
Max static loading force	120 N	80 N	80 N	80 N
R_d	0.5	0.5	0.5	0.5
Frequency	5 Hz	5 Hz	5 Hz	5 Hz
Total number of cycles	$3.62*10^5$	$3.80*10^5$	$8.30*10^4$	$5.80*10^4$
Max displacement	1.060 mm	0.714 mm	0.948 mm	0.780 mm
Final crack length	44 mm	42 mm	44 mm	42 mm
ΔK at the final cycle	0.43 MPa√m	0.27 MPa√m	0.33 MPa√m	0.28 MPa√m
Pairs' law equation with fitting parameters	$\frac{da}{dN} = 10^{-2.41}\Delta K^{6.77}$	Including 3 phase data: $\frac{da}{dN} = 10^{-0.84}\Delta K^{6.55}$		

The fatigue experiments were conducted with an MTS Landmark servo-hydraulic testing machine. The load cell was calibrated to 5 kN load capacity. The frequency was 5 Hz and the sample was loaded under displacement control at a constant amplitude with $R_d = \frac{D_{max}}{D_{min}} = 0.5$, where D_{max} and D_{min} are the max and min displacement. The virgin specimen was loaded to 120 N at 0.24 mm/min and the displacement between 20 and 120 N was considered as the $D_{max,virgin}$. When the crack length is larger than 50% of the total length, there is an increasing deviation of the stress intensity factor values compared with the calculated values [14]. Therefore, the fatigue experiment of the virgin specimen was stopped when the crack propagated approximately 15 mm (near the middle of the specimen). The healing process was the same with the quasi-static tests. To achieve a similar crack growth rate for the healed specimen compared to the virgin specimen, the healed specimen was loaded to 80 N and the displacement between 20 and 80 N was set as the $D_{max,healed}$. The crack length was measured with Image J with the help of a stamped ruler on the specimen surface. The healing specimen fatigue experiments were stopped when the crack

was approaching the final crack front of the one in the virgin specimen fatigue experiment. The healing process was also repeated three times, and the experiments conducted after each healing process are named as healing phase 1, 2 and 3 respectively. The summary of the test methodology is presented in Table 1.

The crack growth rates were calculated based on ASTM E647-23a [15]. The initial and final points of crack growth rate were calculated by the secant method, while the remaining points were calculated by the incremental polynomial method with 3, 5, and 7 consecutive crack length data points depending on the data availability. For example, the second point is calculated with 3 successive points. Due to the shape of the TDCB specimens, the stress intensity factor (K) is only related to the load (P) (equation 1). Here, $\alpha = 11.2 \cdot 10^{-3}\ \mathrm{m}^{-3/2}$. ΔK is then calculated based on the max and min load in one cycle (equation 2) and equation 3 shows the Paris' law, which presents the relation between crack growth rate ($\frac{da}{dN}$) and ΔK. C and m are Paris' law parameters.

$$K = \alpha \cdot P \tag{1}$$

$$\Delta K = \alpha \cdot (P_{MAX} - P_{MIN}) \tag{2}$$

$$\frac{da}{dN} = C\Delta K^m \tag{3}$$

3. RESULTS AND DISCUSSION

The virgin and three healing phase loading curves of one sample under quasi-static loading are plotted in Figure 2. The virgin fracture toughness was calculated using equation 1 with the virgin peak load. The average fracture toughness is 1.96 ± 0.13 MPa√m, which is adequate for real applications. The three healing phase curves shown in Figure 2 are consistent with each other, representing no degradation and good healing repeatability. The healing efficiency is calculated based on the fracture toughness (K_{Ic}) recovery as outlined in equation 4. The average healing efficiencies of the three phases are 62 ± 5 %, 61 ± 8 %, 61 ± 6 % separately. The high healing efficiency demonstrates the potential of prolonging the service life of thick adhesive joints. Therefore, the fatigue behavior was investigated to evaluate the recovery of fatigue properties.

$$\eta_{static} = \frac{K_{Ic,healed}}{K_{Ic,virgin}} = \frac{P_{c,healed}}{P_{c,virgin}} \tag{4}$$

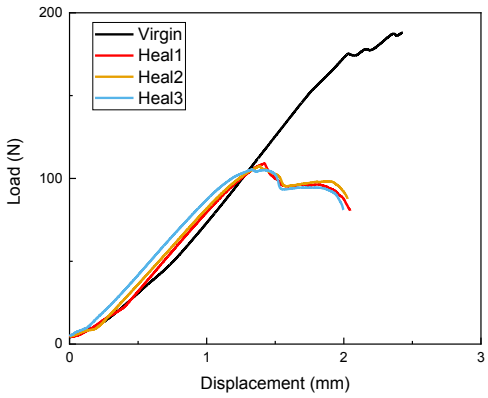

Figure 2: The virgin and three healing phase loading curves of one self-healing TDCB specimen.

A picture captured at the last cycle of the virgin phase is shown in Figure 3. The upper fixture remains stationary, while the lower fixture undergoes the predefined sinusoidal cyclic displacement with constant amplitude. The force is transferred with the load pins. The crack propagates within the grooved plane. The determination of the crack front relies on the contrast in color, i.e. the white and gray regions, as observed in the red rectangle. The crack length is the distance between the loading axis and the crack front, and the final crack front is near the middle of the specimens.

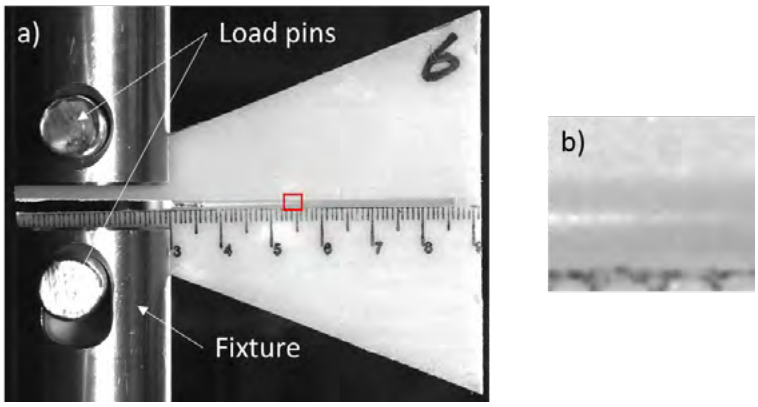

Figure 3: a) A typical picture captured at the last cycle during the virgin specimen fatigue experiments, and b) the picture enlargement within the red rectangle.

The evolution of the crack length of the virgin and three healing phases is thus presented in Figure 4. The corresponding maximum load values are also depicted in Figure 4. The crack length (closed symbols) steadily increases with a progressively decreasing crack propagation rate for both virgin and healed specimen results. The corresponding maximum cyclic force (open symbols) decreases with a progressively decreasing rate. After each healing process, the crack is healed and the crack propagation restarts from the pre-crack, as observed in Figure 4. The healing phase 1 shows lower crack propagation rates compared with phase 2 and 3. This may be attributed to the undesired specimen bending during the second healing process.

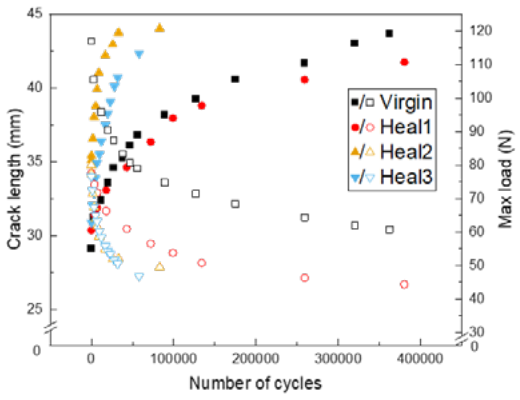

Figure 4: Crack length and the max load evolution with number of cycles for virgin and three healing phases. Solid points are the crack length and the hollow points are the corresponding max load in the corresponding cycle.

Figure 5 presents the FCG curves of the virgin and three healing phases. The typical FCG curves can be separated into three regions, i.e. subcritical, linear, and unstable phases. The data shown here mainly falls into the linear region. All the FCG curves exhibit comparable ranges of crack propagation rates, but all three healing phase curves are positioned to the left of the virgin curve. The healed FCG curves

are plotted using data acquired by restarting the crack propagation from the pre-crack and allowing the crack to propagate within the previously healed region. The healed FCG curves exhibit higher crack growth rates than the virgin curve at the same ΔK, indicating partial recovery of the fatigue properties after healing. The specimen would eventually break after a certain number of cycle loading at a specific ΔK, without the healing intervention. However, by applying the aforementioned healing process, the crack could be healed and restart from the initial point. Although the healed crack would propagate faster within the healed region, the overall fatigue lifetime could be extended with multiple healing processes.

Since the fatigue experiment of the virgin specimen was terminated when the FCG only reached the intermediate crack propagation rate (> 10^{-5} mm/cycle), the FCG curve at lower ΔK cannot be plotted. Therefore, the overlap of virgin and healing FCG curves only occurs within the range of 0.4 MPa√m < ΔK < 0.6 MPa√m. More investigations are necessary to start the virgin fatigue experiments at lower ΔK to complete the full curves.

The first healing phase FCG curve shows similar trends with the virgin one, The bending of the specimen during the second healing process only results in a shift of the second and third FCG curves to a higher ΔK range with higher crack growth rates. The slope of the curves and the healing efficiency (the relative position compared to the virgin curve) are similar for all three phases. Consequently, all the data were considered when calculating the Paris' law parameters.

The data points that may represent the transition between the three regions are not included for the Paris' law fitting, as they exhibit very high or low crack growth rates. The fitting equations are presented in Table 1. The slopes (m value) of the two fitting curves are similar to each other. Therefore, the healing efficiency can be calculated by comparing the ΔK at the same crack growth rate using equation 5. The fatigue healing efficiency (η) is thus 58 %, which is consistent with the healing efficiency obtained from quasi-static experiments.

$$\eta_{fatigue} = \frac{\Delta K_{healed}}{\Delta K_{virgin}} = \frac{\sqrt[m]{\frac{da}{dN} \cdot \frac{1}{C_{healed}}}}{\sqrt[m]{\frac{da}{dN} \cdot \frac{1}{C_{virgin}}}} = \sqrt[m]{\frac{C_{virgin}}{C_{healed}}} \tag{5}$$

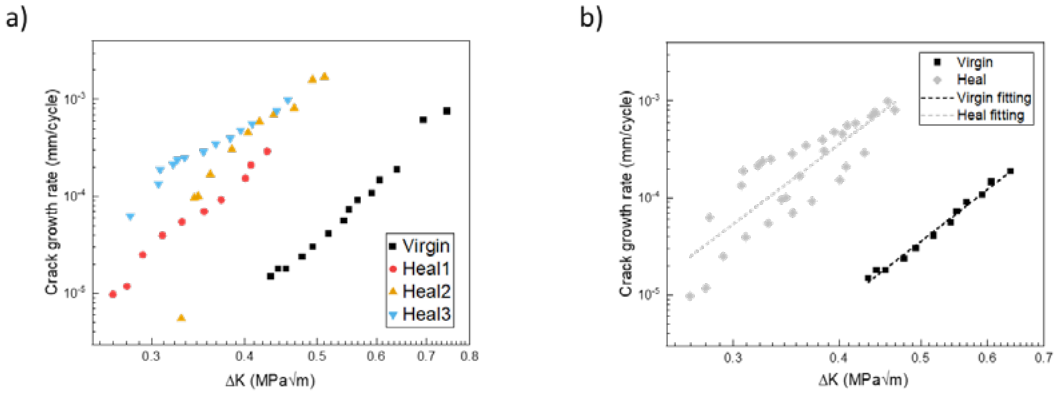

Figure 5: a) Crack growth rate vs. ΔK of virgin and three healing phases b) the comparison of the Paris' law fitting curves and experimental data points.

4. CONCLUSIONS

The self-healing adhesive TDCB experiments were conducted under quasi-static and constant amplitude loading conditions. High fracture toughness recovery (ca. 60%) with good healing repeatability was obtained from quasi-static experiments. Consequently, the fatigue property recovery was further investigated by comparing the relative position of FCG curves. The specimen bending problem that occurred in the second healing process may be the reason for the higher propagation rates in the second and third healing phase fatigue experiments. However, the bending had limited influence on the FCG curves. All the FCG curves of the three healing phases exhibit similar slopes, as reflected in the similar slope values (parameter m) of the Paris' law fitting equations. Therefore, the fatigue healing efficiency was calculated by comparing the ΔK values at the same crack growth rate, resulting in a value of 58 %, which is consistent with the quasi-static investigations. Further experiments with double cantilever beam specimens are required to understand the fatigue behavior of thick adhesive joints fabricated with self-healing adhesives. The healing repeatability and bending influence will also be studied with several TDCB specimens through multiple healing processes under fatigue loading.

Keywords: Adhesively bonded joints, Epoxy adhesive, Durability, Moisture diffusion, Interphase.

Abstract
The use of adhesively bonded composite reinforcements is increasing in various industries for which they encounter diverse environmental conditions throughout their operational lifespan. Moisture absorption stands as a common aging factor leading to the deterioration and weakening of mechanical properties in these materials. Moreover, there is limited knowledge regarding the durability of bonded joints in wet environments. Consequently, moisture diffusion continues to hinder their widespread application across multiple fields. This study will focus on studying the durability of bulk adhesives and adhesively bonded joints under various wet conditions: exposure to 98% relative humidity, immersion in artificial sea water as well as in demineralized water.

In this study, water diffusion was first examined in bulk adhesives, and subsequently in two bonded assemblies having different adhesive thicknesses. Gravimetric measurements were carried out to obtain the corresponding diffusion coefficients. The experimental results revealed Fickian behavior for the studied epoxy bulk adhesives, while a non-Fickian diffusion was obtained for the studied methacrylate adhesive. Regarding the bonded assemblies, those with a 1 mm adhesive thickness exhibit faster diffusion compared to those with a 3 mm adhesive thickness.

1. Introduction

Adhesively bonded joints are increasingly being used in several fields such as aerospace, transport and marine sectors. Their widespread use in many civil engineering applications is due to several advantages. Indeed, compared to the traditional joining techniques (like fastening and riveting) they provide lightweight structural assemblies and allow dissimilar materials joining with no damage during manufacturing process. Moreover, they also permit to obtain more uniform stress distributions along the bonded zone.

Bonded assemblies are exposed to several environmental conditions such as high humidity levels specially in marine environment. Thereby, they should be designed to withstand such environmental conditions. Hence, predicting the long-term behavior of adhesively bonded joints in different environmental conditions is of crucial interest.
Water sorption by polymers is considered as one of the major setbacks in adhesive's application under humid conditions. Water and humid air are known to cause a reduction in strength, durability and service

life of adhesives joints [1]. Moisture degradation of adhesives can result in a decrease in their mechanical properties and can cause both reversible effects, such as plasticization and swelling, as well as irreversible ones, like hydrolysis and oxidation. The detrimental effects are more significant in adhesive joints since degradation of the interface between adhesive and adherend could initiate an interfacial failure. Some authors in the literature found that water penetration is faster in bonded joints than in bulk adhesives [2,3]. This phenomenon was attributed to the presence of interphase and/or interface between adherends and adhesive within the bonded assembly. Furthermore, it was found that in thinner joints, where the ratio of the interphase's thickness to adhesive's thickness is larger than that for thicker joints, there is a greater uptake of water.

Although it has been reported in the literature that water diffusion is often governed by Fick's laws, several authors have demonstrated deviations from Fickian diffusion. Other models have been developed for these cases, such as the Langmuir model [4], the dual Fickian diffusion [5] and the delayed dual Fickian [6].

This paper initially outlines the experimental investigation of water sorption behavior for three structural bulk adhesives using a high-precision balance. Then, the same procedure is also carried out for bonded assemblies with steel substrates and epoxy adhesive, where a comparison of the water sorption profiles for different bonded joint thicknesses is conducted. Additionally, another comparison is made between different humid environments.

2. Experimental methods

2.1. Materials and sample preparation

In this study, three commercial adhesives were used: two epoxy-based adhesives labeled as E1 and E2, and a methacrylate adhesive marked as M. The selection of these materials was driven by their industrial interest and also by their frequent applications in marine environment, which represents the case and condition of this research.

Bulk adhesive discs have been manufactured by pouring the adhesives into circular molds. To facilitate the demolding process, the used molds were made from non-adherent materials: Teflon molds for the M and E1 adhesives and modified polyethylene molds for the E2 adhesive. The discs made for both adhesives E2 and M have the same diameter d of 80 mm and the same thickness e of 1 mm ($\pm$ 0.05 mm). For the adhesive E1, the discs have a diameter of 70 mm and a thickness of 2 mm ($\pm$ 0.09 mm). The dimensions were selected with an aim to consider a 1D surface diffusion i.e., along the thickness direction ($d>>>e$), this allows to simplify the studied diffusion phenomena (figure 1).

The E2 discs were cured at 80°C for 3 hours, the E1 discs were cured at 80°C for 16 hours and the methacrylate adhesive was cured at 25°C for 24 hours according to their technical data sheets. According to [7], taking a slightly higher curing time than that suggested in technical data sheet is much more preferable.

Figure 1. 1D water diffusion through the thickness e of bulk adhesive discs .

Regarding the bonded assemblies, E1 was used as an adhesive, with stainless steel plates serving as adherends. Stainless steel was specifically chosen to prevent corrosion, which could complicate the studied mechanisms of water diffusion. Before bonding, the metallic substrates were sanded using a sandblasting machine, achieving an average roughness of 3.5 µm (± 0.5 µm). Then, they were cleaned with acetone. The bonded joints were manufactured in two different thicknesses of 1 mm (± 0.1 mm) and 3 mm (± 0.5 mm) as shown in figure 2-B. Two temporary steel wedges with these thicknesses were used to ensure a consistent adhesive thickness throughout the bonded assembly. All the bonded joints have the same length of 80 mm (± 7 mm) and the same width of 5 mm (± 0.5 mm), as shown in figure 2-A. These dimensions allow for the adoption of the assumption of 1D surface diffusion, i.e., along the width (where width <<< length).

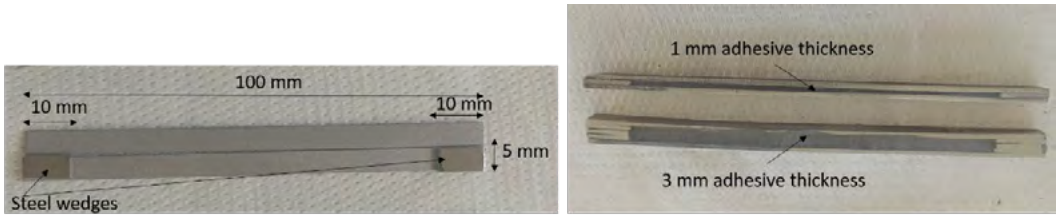

Figure 2. Dimensions of bonded assemblies: (A) 5 mm width and 80 mm length, and (B) two different thicknesses of 1 mm and 3 mm.

2.2. Aging conditions and gravimetric measurements

Before aging, methacrylate samples were dried in an oven at 50 °C until a constant mass was obtained, while the epoxy adhesives discs were placed in a desiccation chamber for 4 weeks (figure 3). No drying process was conducted for the bonded assemblies since the mass loss of E1 bulk specimens during drying was found to be minimal. Thus, the bonded joints were immediately submerged in water after curing to prevent any humidity absorption.

During drying, specimens were periodically weighed on a 10^{-3} g resolution balance (Kern PLJ 2000-3A having a maximum weighing range of 2.1 kg) for the E2 and M discs, and a 10^{-4} g resolution balance (with 610 g of maximum weighing range) was used for the bonded joints and E1 discs. The water content M_t (%) is determined using equation (1) where $m(t)$ is the mass of the sample at a time t while m_0 corresponds to the weight of totally dried specimen (i.e., for $M_t = 0$).

$$M_t\ (\%) = \frac{m(t)-m_0}{m_0} \times 100 \qquad (1)$$

Following drying, the E1 disc specimens were investigated under three different aging environments, which include immersion in demineralized water (DW), immersion in seawater (SW), and exposure to 98% relative humidity (RH) (figure 4). The bonded assemblies, E2 and M discs were placed only in DW and SW. The artificial seawater was prepared by dissolving sodium chloride (NaCl) into pure water following the reference salinity value of 3.5% provided by the ASTM D 1141 standards [8].

Figure 3. Drying process of (A) Epoxy adhesives in dessication chamber, and (B) Methacrylate adhesive in an oven at 50°C.

In each environment, a repeatability study was generated using five disc samples and five bonded assemblies (table 1). This was done to enhance confidence in the results. The total number of produced bulk adhesive discs was 45 (three adhesives, three wet environments and five specimens), while the number of bonded assemblies was 20 (two thicknesses of bonded joints, two wet environments and five specimens).

Table 1. Summary of the number of samples used for each sample type and for various aging environments

	Bulk adhesives			Bonded joints with E1 adhesive	
	E1 adhesive	E2 adhesive	M adhesive	1 mm adhesive thickness	3 mm adhesive thickness
SW	5 samples	5 samples	5 samples	5 samples	5 samples
DW	5 samples	5 samples	5 samples	5 samples	5 samples
98% RH	5 samples	5 samples	5 samples	-	-

To ensure the contact of all discs specimens' faces with water and achieve uniform diffusion, a small support (blue element in figure 3-B) was used to maintain the specimens vertically. During this wet aging process, the temperature was maintained at 50°C by placing all the specimens in a hygrothermal chamber (figure 4). This temperature is at least 20°C below the glass transition temperature Tg of all the adhesives used. The primary purpose of increasing the temperature is to accelerate diffusion, as highlighted in the study of [9].

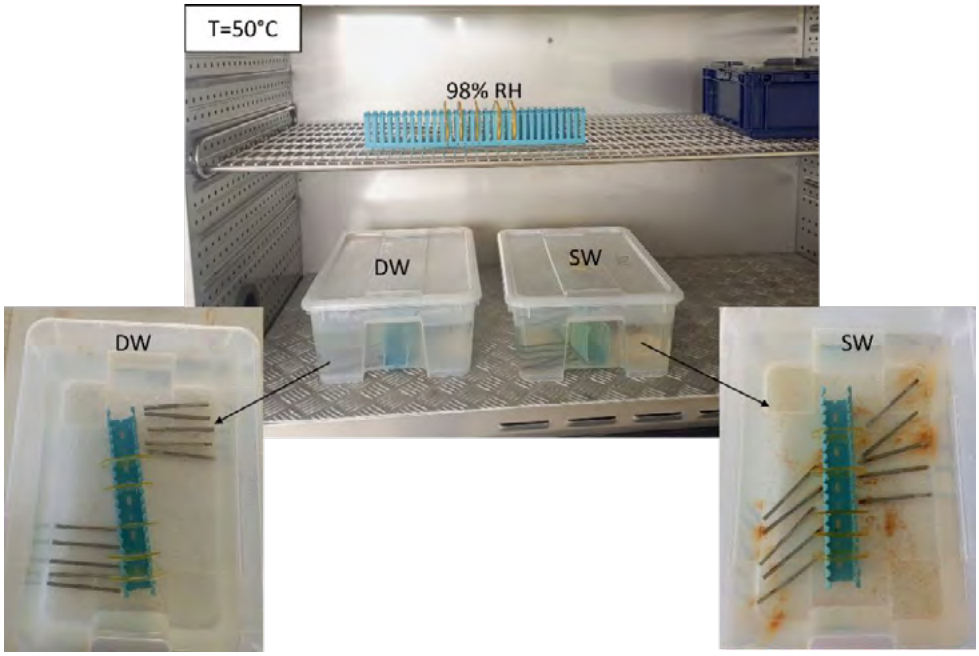

Figure 4. E1 discs and bonded assemblies placed in DW and SW, with E1 discs alone subjected to 98% RH. All the samples were in a hygrothermal chamber at 50°C.

After placing all the specimens (bulk adhesives and bonded joints) in the previously mentioned humid environments, they were taken off at different times, wiped off with tissues to dry their surfaces and weighed using the aforementioned balances. Thereby, the water gain can be calculated using equation (1) where m_0 is defined as the initial dry mass before aging. Once the saturation is reached, M_t will be equal to the saturation moisture content M_s.

Regarding the calculation of diffusion coefficient, the formula proposed by Crank [10], who defines a solution for the Fick model, is used. This formula corresponds to a 1D diffusion that takes place along the sample thickness *e* for the discs and along the sample's width for bonded assemblies.

3. Results and discussion

3.1. Gravimetric measurements for bulk adhesives

Using equation (1), the variation of the macroscopic water content *M(t)* can be graphically represented for M, E2, and E1 discs. These are respectively depicted in figures 5-A, 5-B and 6 that illustrate the evolution of weight gain with the square root of time over the adhesive thickness. Note, measurements for the E1 discs are still under progress as saturation was not obtained for the moment.

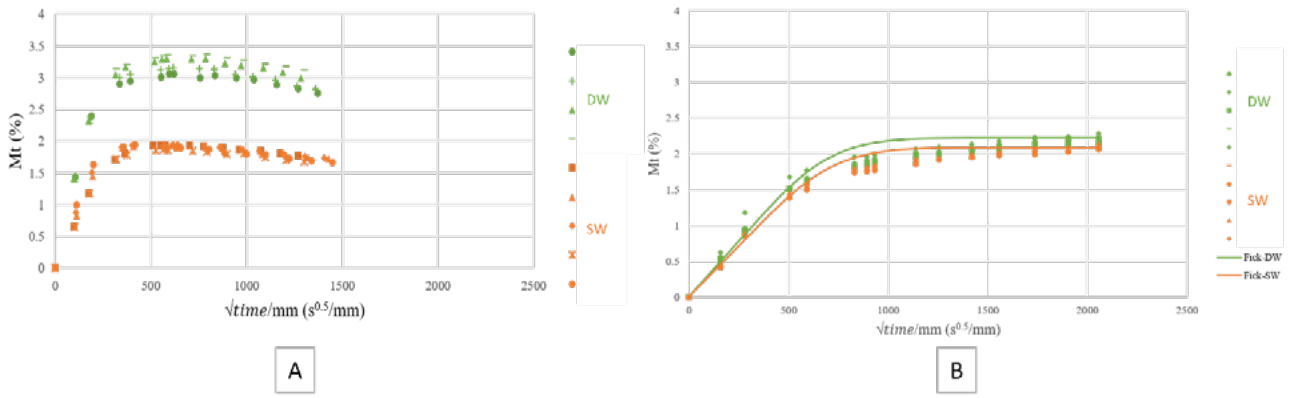

Figure 5. Sorption curves in SW and DW for the (A) M and (B) E2 discs.

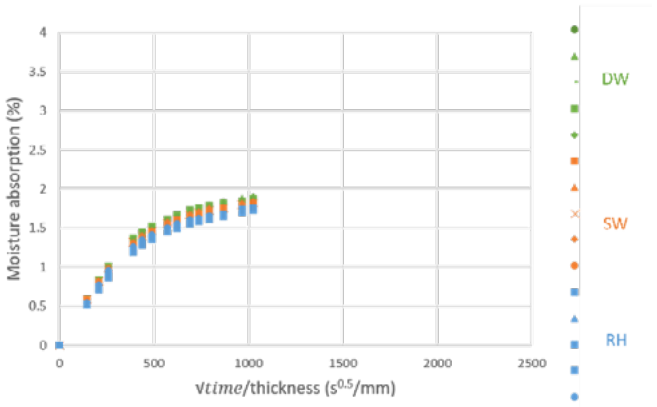

Figure 6. Sorption curves for the E1 discs under three wet conditions: immersion in SW, immersion in DW, and exposure to 98% RH.

These curves depict the absorption process for the epoxy adhesives E1 and E2, revealing two distinct stages. Initially, water uptake results in a linear increase in weight gain relative to the square root of time across the adhesive thickness. Subsequently, a plateau emerges, indicating saturation (figures 5-B and 6). For the methacrylate adhesive, the water absorption curve denotes that after immersion in water, the samples' mass increases linearly with the square root of time in the initial stage. Then, the water uptake begins to decrease after 10 days of wet aging in both SW and DW environments (figure 5-A). A small dispersion in results was obtained for all the disc adhesives.

Results of the gravimetric measurements reveal that the water uptake curves of the adhesives E1 and E2 follow Fickian diffusion, indicating non-anomalous water diffusion behavior. Indeed, the theoretical Fickian curve is distinguished by two phases: initially, a linear increase in water uptake over the square root of time is observed, succeeded by a slower absorption rate leading to a plateau, indicating saturation.

However, the water absorption profile displays a non-Fickian behavior for the M adhesive, as evidenced by a loss of mass observed after 10 days of wet aging. According to [11], this can be attributed to an initiation of material dissolution within the samples, altering the obtained weight change profile to be lower than the theoretical Fick curve. Indeed, a hydrolysis reaction occurred, causing a break in the macromolecular chain and resulting in a reduction in the rate of cross-linking. This reaction also led to the release of molecules into the water, leading to a loss of mass. This is considered as an irreversible consequence of the water diffusion within adhesives.

From the diffusion curves below, the diffusion coefficients can be calculated for the E2 and M adhesives in SW and DW. Table 2 presents the mean values of the obtained diffusion coefficients D and the mean water content at saturation M_s.

Table 2. Diffusion parameters for the M and E2 adhesives in two wet conditions (DW and SW).

	M adhesive		E2 adhesive	
Aging environment	DW	SW	DW	SW
D (mm^2/s) 10^{-7}	92.0 ± 6.20	78.1 ± 5.20	3.82 ± 0.23	3.62 ± 0.12
M_S (%)	2.92 ± 0.16	1.73 ± 0.03	2.22 ± 0.05	2.09 ± 0.03

In both SW and DW environments, the mean diffusion coefficient D of the methacrylate adhesive exceeds that of the epoxy adhesive E2. Additionally, as indicated in table 2, the diffusion coefficient is slightly larger in DW than in SW for the E2 adhesive (5.5% difference). However, a more significant contrast in diffusion coefficients between SW and DW is observed for the M adhesive, where D is 17.8% larger in DW compared to SW. For the E1, the samples are not saturated yet, but based on figure 6, it can be noticed, from a first inspection, that diffusion exhibits a slightly faster rate in DW compared to SW, with SW showing faster diffusion than in the 98% RH environment.

To summarize, the diffusion coefficient for epoxy adhesive E2 is slightly greater in DW compared to SW. A more pronounced contrast emerges with the methacrylate adhesive, consistently showing a higher diffusion coefficient in DW than in SW. It is important to note that the diffusion coefficient of these adhesives is primarily influenced by the chemical nature of these polymers. For the E1 adhesive, diffusion is ongoing, but initial findings suggest that the diffusion coefficient is higher in DW than in SW. Moreover, it appears to be greater in SW than in a 98% RH environment. These results deals with some authors in the literature who found that moisture ingress is more important in deionized water than in seawater [12].

3.2. Gravimetric measurements for bonded assemblies

The water absorption profiles for bonded assemblies, placed in SW and DW, with 1 mm and 3 mm thicknesses of adhesive, are illustrated in figures 7 and 8, respectively.

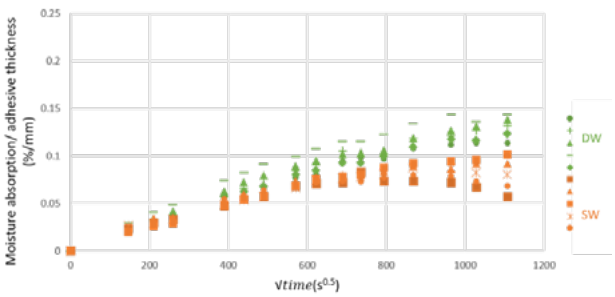

Figure 7. Water sorption curves of bonded assemblies with 1 mm adhesive thickness in SW and DW.

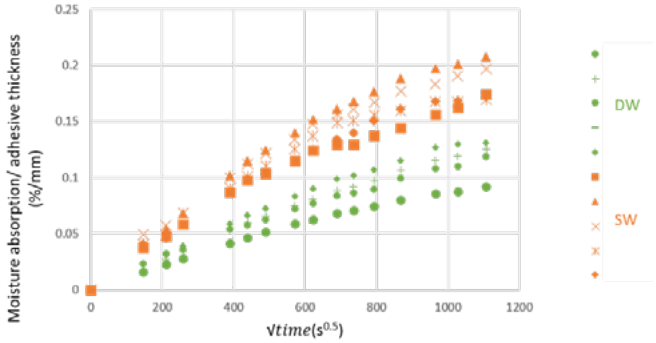

Figure 8. Water sorption curves of bonded assemblies with 3 mm adhesive thickness in SW and DW.

The stainless steel adherends of the bonded assemblies placed in SW began to corrode after 10 days of immersion (figures 7 and 8). After 25 days, corrosion became more significant, leading to a noticeable loss of mass in the water absorption profile. This loss of material due to corrosion exceeded the mass of water absorbed by the bonded joint. Consequently, it is not possible to determine a conclusive value of the diffusion coefficient for these bonded assemblies immersed in SW. However, normalization with respect to the volume of adhesive in each bonded assembly (considering the exposure surface and the primary diffusion-driving distance, which is the width for bonded joints) should be performed to be able to compare the diffusion rate between DW and SW for the 3 mm joints as well as the diffusion rate between bulk adhesives and bonded assemblies. This normalization is intended to account for uncertainties in the dimensions of the bonded assemblies.

In contrast, no corrosion was observed in the bonded joints placed in DW. Hence, only results for bonded assemblies in DW can be adopted and analyzed further. However, since diffusion is still active, the value of the diffusion coefficient for these bonded assemblies cannot be determined at this stage. The corresponding macrospcopic absorption curves are depicetd in figure 9. Nonetheless, it is evident that diffusion occurs slightly faster in the thinner adhesive joint (figure 9), despite the observed dispersion. This dispersion can primarily be attributed to uncertainties in the dimensions of the bonded joints. Further data is required for a more accurate comparison where the exact value of diffusion coefficient can be calculated.

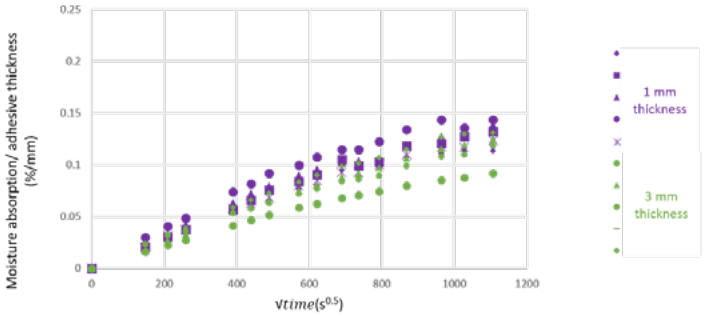

Figure 9. Water sorption curves of bonded assemblies in DW with 1 mm and 3 mm adhesive thicknesses.

4. Conclusion

In this study, the diffusion kinetics were compared at the same temperature of 50°C for three distinct adhesives: two epoxy resins, labeled as E1 and E2, and a methacrylate adhesive, labeled M. Bulk adhesives and bonded assemblies were investigated. Gravimetric measurements demonstrate that the water absorption within bulk epoxy adhesives obeyed the Fickian diffusion. This means that water sorption occurs in the polymer matrix without considering specific interactions between water and polymer chain. However, a degradation happened to the bulk methacrylate adhesive due to the water

penetration and a loss of mass initiates after 10 days of immersion. A faster diffusion is observed in the E2 bulk adhesive with respect to that of the methacrylate adhesive. Moreover, diffusion occurs more rapidly in DW than in SW for all the adhesives, consistently with existing literature.

Since adhesives are rarely used alone in real-life applications, ungoing investigations are carried out to study the diffusion process in bonded assemblies, where the interfaces (the weak points of bonded joints affecting their durability) become relevant. At this stage, slightly faster diffusion was observed in thinner joints. However, the diffusion process is still active, so further data is needed to calculate and compare diffusion rates more accurately.

The achievements of this study could be extended to predict the water uptake in bonded joints and the remaining mechanical strength in long-term aged adhesively bonded joints. For this, mechanical investigations are under investigations to correlate diffusion kinetics to mechanical degradation.

Acknowledgments

Keywords: Structural batteries, Topology optimization, Numerical modelling.

Abstract
Composite materials have drawn significant attention due to their versatility and tailored properties, offering an avenue for optimized performance in various applications. In this field, topology optimization has evidenced its capacity to provide new optimal designs, even considering the intricate interplay between material constituents, microstructure, and orientation that profoundly impact composite structures' overall behaviour and performance.
Focused on sustainability goals, structural batteries emerged as a potential solution for achieving efficient energy storage systems and increasing demand for mass electrification. Despite the novelty, interest and relevance of both these fields of research, the application of topology optimization methods to the design and development of structural batteries is still a largely unexplored field.
Therefore, this research demonstrates the possibility of applying topology optimization and novel numerical modelling approaches to the design and development of structural batteries, aiming to bridge the gap between two relevant fields of research. By delving into the methodologies of topology optimization for composite structures and fundamentals of numerical modelling in structural battery development, this study seeks to uncover unexplored synergies, identify new challenges, and pave the way for innovative opportunities in the pursuit of efficient structural battery designs aligned with sustainability goals.

1. Introduction

The successful harness and usage of renewable energy sources hold a pivotal role and contribution on the battle against climate change. Nonetheless, their effectiveness is highly dependent on the development of efficient energy storage systems, a crucial component of the future power grid that facilitates the storage of energy during off-peak periods and its release when high demand arises [1], [2]. This would enable a seamless integration of intermittent renewable sources, such as solar and wind power, enhancing energy independence and resilience.

Among the traditional electrical energy storage systems, lithium and sodium-based batteries emerged as the most used options owing to their superior energy and power densities, as well as longer life cycle [3]. However, the occurance of dendtritic growth, thermal runaway, overcharging, and the failure of individual components is a brief list of the physical phenomena that may occur during the operation of these batteries, affecting both their performance and safety [4]. These drawbacks are aggravated by the environmental impact of the extraction of essential raw-materials, such as cobalt and lithium, required for the lithium-ion batteries (LIBs) industry.
An overview of the state-of-the-art identifies the combination of the electrochemical performance of LIBs with lightweight composite engineering materials as one of the possible approaches to overcome these issues [5], [6], leading to the concept of structural batteries. The multi-functionality of having a

single component capable of simultaneously supporting mechanical loads while storing electrical energy leads to an improved efficiency, reducing raw-material consumption, carbon footprint, and fuel consumption, when applied to transportation industries, mitigates most of the drawbacks that characterize conventional batteries [7], [8].

Therefore, structural batteries are a recent development with the potential to revolutionize the design and implementation of energy storage systems, particularly in the mobility sector with focus on electric vehicles, hinging on the associated weight reduction. Fulfilling both structural and energy requirements represents a significant challenge, evidencing the need for a comprehensive understanding of the multi-physical phenomena that characterize their functioning, and that may be used to support their design and development [9].

Within the scope of this work, research on the numerical modelling techniques capable of representing the distinct physical phenomena that occur during the operation of structural batteries will be reviewed. Furthermore, their interaction with topology optimization techniques will also be explored. This possible link is justified by the similarity of objectives that usually motivate the use of topology optimization during structural design, such as the minimization of mass, and by the potential application of this method to multiple fields of research. Therefore, the following sections will provide a summarized overview of the research focused on the development of structural batteries, their associated numerical modelling techniques, and on topology optimization. Finally, a discussion on the possible interaction of these three fields will be presented and discussed, followed by the key conclusions.

2. Structural batteries

Conventional and all-solid-state batteries share a common composition: the cathode, the electrolyte, and the anode. The primary distinction relies on the type of electrolyte used. Conventional batteries use liquid electrolytes for lithium transport, requiring the inclusion of a separator to prevent short-circuiting [10], which can raise safety concerns due to inadequate thermal stability, parasitic reactions, and the flammability of organic solvents [3], [11]. As a suitable alternative, the concept of all-solid-state batteries emerged, utilizing non-flammable solid-state electrolytes to promote the movement of cations while improving the stability against dendrite formation, enhancing compatibility with high-potential electrodes, and enabling the development of higher energy-density batteries [12]. Their functioning are strongly dependent on well-designed cell configurations and comprehensive electrochemical reactions or physic interactions at the electrode/electrolyte interfaces, including physical contact and chemical and electrochemical stability [13].

One of the most promising designs, under the scope of a multi-functional composite structure, explores the potential of reinforcements, such as carbon fibres, to serve as electrodes while the matrix functions as the electrolyte [5], [14]. This dual strategy integrates both structural and energy storage capabilities, showcasing their combined potential. A key aspect of this strategy involves careful consideration of interface design to ensure that it does not compromise electrochemical performance.

In the subsequent sub-sections, a concise overview of recent research on the numerical modelling of structural batteries will be provided, with the purpose of highlighting the different physical phenomena that must be considered for their correct representation.

3. Numerical modelling of structural batteries

The state-of-the-art numerical modelling techniques used to represent structural batteries build upon the methods developed for their predecessors. Within the scope of this research, LIBs will be focused, which consist of two porous electrodes, each comprising various interpenetrating phases, such as active particles, a conductive binder matrix, and a liquid electrolyte. Their functioning relies on interplays of electrochemical reactions, ion transport, and heat generation. Therefore, to accurately capture these behaviors and battery performance, numerical modelling techniques usually address the isolated or coupled representation of chemical, electrical, and thermal physical phenomena. In research addressing the chemical behaviour of conventional batteries, it is common to focus on the representation of the

reactions occurring at the electrode/electrolyte interfaces, usually based on the Butler-Volmer equation [REF], with the purpose of determining the electrode kinetics and the movement of ions within the electrolyte, including the rate of electrochemical reactions and the distribution of ions. On the electrical behaviour, the challenge is mainly based on the accurate representation of mass transport, charge transfer, and electrical conductivity within the battery system, as the cyclic charging and discharging induces mechanical degradation, constraining the lifespan of LIBs. Finally, research on the numerical modelling of thermal phenomena with emphasis on accurately estimating the heat generation and transfer that occurs during the operation of the battery, usually oriented towards the design and development of efficient thermal management systems.

The three phenomenological fields mentioned are the common building blocks for the numerical modelling of the multi-physical nature of conventional batteries, with research commonly addressing their combination and interaction. Initial research on the numerical representation of the electrochemistry of conventional batteries dates back to the work of Newman et *al.* [15], further developed in [16], [17], with the deployment of a framework approach suitable for individual LIB cells. In this research, the authors proposed a one-dimensional (1-D) macroscopic model, where concentrated solution theory is used to describe the transport in the solution phase, while porous electrode theory is used to describe the composite positive electrode, which may consist of a solution phase, solid active-material phase, and any conductive filler or binding additives.
In addition, Golmon et *al.* [18] utilized a multi-scale approach to represent the influence of electrochemical processes on the mechanical behaviour of the battery, such as the resulting deformation, and *vice-versa*, studying also the influence of external mechanical loads on the electrical performance of the battery. A similar approach was proposed by Bower et *al.* [19] in later research, addressing the resulting stresses that may be installed during charge and discharge cycles, estimating the influence of lithiation phenomena in the electrode materials. This interaction between electrochemical and mechanical behaviour has been one of the major concerns of the research developed since then, addressing possible enhancements through the extension of the multi-scale approaches implemented [20]–[22], accounting for the material degradation during operation [23] and non-linear behaviour [24], as well as the influence of lithiation on mechanical stresses, elastic or plastic deformation, and the resulting crack initiation and propagation [25]–[33]. A similar trend is observed in the research related to the thermochemical behaviour of conventional batteries, accounting for the heat generation and resulting temperature gradients on the material thermal expansion and, consequent, mechanical stresses [34], [35].

The numerical modelling of structural batteries adds an additional dimension to the representation of these components, introducing their mechanical behaviour. Additionally, the use of materials with structural functionalities leads to slight changes in the phenomena represented. For instance, electrochemical or diffusion models add the complexity of Li (de-)intercalation with fibre reinforcements [36], the initiation and propagation of cracks due to the material dissimilarities [37]–[39], including the different thermal expansion coefficients [40]–[42], and respective extension of these phenomena into multiple scales [43], [44].

A different modelling approach that deserves to be mentioned within the scope of structural battery development is the use of Density Functional Theory (DFT). DFT explores the quantum mechanical modelling of the electronic structure and properties of materials at the atomic level. Within the scope of structural battery development, this method allows the tailoring of properties suitable for improved energy storage, which include the prediction of electronic conductivity, ion mobility, and stability. In [45], simulations were performed to predict the behavior of the employed materials for a lithium iron phosphate ($LiFePO_4$) cathode, considering the relationship between the chemical potentials, carriers density, and electronic density of states.

4. Topology optimization

Topology optimization is one of the three sub-fields of structural optimization, amongst size and shape optimization, and it is applied in the early stage of structural design, aiming to find an optimal distribution of material [46], [47]. According to an objective function and considering the division of the design domain into multiple regions, this optimization method adjusts the material density at each location, defining which regions should have material and which should not [48]. Resources efficiency and minimization of mass are objectives shared by multiple applications, motivating vast research on the use of topology optimization across diverse fields of research, which are summarily reviewed in this section.

Novel research on the field of topology optimization has focused on its synergy with additive manufacturing, specifically through the introduction of process manufacturing constraints and requirements into the formulation of the problem statement. The challenges involved in this development have been reviewed by Zhu et *al.* [49], Prathyusha and Babu [50], and Liu et al. [51] with a particular focus on either the usage of multi-scale or hierarchical structural optimization design approaches, allowing the integration of material and process limitations during the design of lightweight structures. With a similar objective, although not narrowed to additive manufacturing, Wu et *al.* [52] and Esfarjani et *al.* [53] reviewed the use of topology optimization in the design of multi-scale and metamaterial structures. In addition to classifying the optimization methods based on the use of homogenization-based, density-based, and inverse homogenization methods, these reviews highlight the diverse application of multi-scale approaches not only in structural design but also on the improvement of the thermal and electrical conductivities, thermal expansion, fluid permeability, and phononic and photonic material behaviours. The inclusion of complex material behaviour, such as buckling, geometric and non-linearities, and plasticity, is also identified as a natural development to be pursued in the field, including the introduction and refinement of the constraints associated to these physical phenomena, namely stress constraints, and adequate and failure criteria [54], [55].

Moreover, Fawaz et *al.* [56] reviewed the intrinsic limitations associated to the conventional use of topology optimization for structural design based on Finit Element Method (FEM), which may not be suitable to represent both the multi-disciplinary and -physical nature governing the functioning of a structural battery. For instance, the FEM does not consider the conservation law at each finite element [57], which may lead to numerical instabilities of the conjugate heat transfer problems [58]. The possible use of an extended FEM method (XFEM) has also been explored in combination with the level-set method for the optimization of steady-state and transient single-flow heat transfer problems [57], [59], [60], accounting for phase changes [61]. Finally, the integration of the Lattice Boltzmann method into topology optimization of flow channels in two-dimensional thermo-fluid problems has been explored in [62]–[64], allowing the use of a mesoscale method intended to solve the governing equations of transport problems at the macroscale [65], [66].

With particular concern on composite structures and their anisotropic behaviour, Gandhi and Minak [67] reviewed the use of topology optimization considering continuous fibre-reinforced polymers, adopting a simultaneous or sequential definition of both material distribution and orientation. The approach highlighted to address this issue is the use of continuous parametrization to define the fibre orientation as an angle [68], [69]. However, it faces challenges due to non-convex optimization and sensitivity to initial configurations [70], leading to suboptimal solutions [71]. In this case, further relaxing the design space, as proposed by the free material optimization process [72], [73], is suggested as a possible solution to be explored.

5. Discussion: on the topology optimization of structural batteries

The diverse range of applications studied in the literature, in conjunction with their respective multiphysical nature, demonstrates the versatility of topology optimization. Furthermore, the case studies mentioned in this article overlap with the physical nature of the phenomena used to model the behaviour of both conventional and structural batteries, suggesting the potential use of this method to support their design and development.

In recent research, topology optimization has been applied to the design of auxiliary systems, usually related to thermal management of the battery, such as cooling plates and circuits [74]–[77], to the structural design and protection of the battery against external loads, such as carrying packs and external casings [78], [79], or a combination of both structural and thermal functions combined [80]–[82].

However, scarce research can be found on the direct application of this method to design structural batteries. Mitchel and Ortiz [83] proposed the topology optimization of a silicon anode for LIBs, adopting a combined influence of electrical and structural properties in the objective function. The solution obtained allowed a material distribution capable of providing a compromise between structural performance, in terms of rigidity, and direct conduction pathways. Roy et *al.* [84] proposed the use of topology optimization framework to design porous electrodes. On one hand, the porosity of the electrode improves the electrochemical transport, while its surface area increases the electrochemical activity. This framework has been demonstrated on two applications: a porous electrode driving a steady Faradaic reaction, and a transiently operated electrode in a supercapacitor. In low-conductivity materials, the electrode designs obtained are characterized by a hierarchy of length scales and present reduced energy losses in half-cells. Pejman and Najafi [85] proposed a multi-objective multiphysics density-based topology optimization framework to design the structural battery electrolyte, considering electrochemical, thermal, and structural interactions. The objective function utilized aimed at maximizing the ionic conductivity while minimizing its compliance, imposing constraints on the volume fraction and maximum allowable temperature. In this research, Pejman and Najafi proposed as future work the inclusion of two-way coupling between the physical modules. Therefore, it would allow the damage initiated in the microstructure to have a quantified influence on the ionic conductivity and stiffness, as well as the temperature increase to influence the generated strain state due to thermal expansion.

Despite the limited research available on the junction of both fields of research, topology optimization suggests having the required versatility to cover the multiphysical domains that characterize the functioning of structural batteries.

6. Conclusions

The present article provides a summarized overview of the state-of-the-art on the numerical modelling of structural batteries, highlighting the multiphysical domains that describe their functioning, and on the field of topology optimization, showcasing its versatility and potential application in multiple fields, to draw the reader's attention to the largely unexplored potential synergies between this method and application.

Abstract
Under harsh service conditions, polymer composites can suffer damage that results in stiffness reduction. Hence it is critical to predict the damage development in composites exposed to thermal and mechanical loads. In response to this, the current paper focus on investigation and modelling of accumulation of transverse cracks in heat resistant carbon fiber cross-ply laminates subjected to mechanical loading at different elevated temperatures before and after a heat treatment. Weibull theory based modelling was applied to model transverse crack density growth in cross-ply composites subjected to static tensile loads. In the proposed two-parameter Weibull failure initiation stress approach, the shape parameter m is assumed to remain constant, but the effect of heat treatment and test temperature on local crack initiation is modelled as a scale parameter σ_0 dependency, generally described by polynomial expansion.

1. Introduction

Due to excellent mechanical and chemical properties and low density, polymer composites are favoured materials in many high-performance structural application areas e.g. aeronautics, space, sports equipment and automotive. Besides relatively high cost for materials and manufacturing, the maximum use temperature of polymer composites is often the limiting factor when determining what material to use. A possibility to extend the upper limit of the temperature use range of composites is by using temperature resistant polymers like cyanate ester, bismaleimide and polyimides, with high glass transition temperatures as matrix in the composites. A carbon fiber reinforced heat resistant polymer is employed in the presented work. The presented work, originally published and more extensively covered in recent publications [1,2], is on two temperature related phenomena that empirically was found to influence transverse crack density (= *number of cracks / unit length*) growth during thermo-mechanical tensile loading; the test temperature, and a long-term so-called Heat Treatment (HT) of the composite. Heat Treatment in this context refers to an extended exposure (500 h or more) of the test specimen to a temperature of 150°C in air without any external loading applied.

With the ambition to move from zero damage concept towards controlled progressive damage concept also at elevated temperatures, it is essential to characterise and predict the damage development. The first mode of damage during tensile loading are transverse/intralaminar cracks developed in off-axis layers with respect to the main loading direction. Typically, such transverse crack development is preceded by micro-scale debonds that coalesce to produce through-the-thickness cracks with potential to grow along fibers in the layer. With continuous loading the number of transverse cracks increases, each with further potential of initiating local delaminations growing at the interface between two layers. All the mentioned damage modes lead to degradation of thermo-elastic constants of the laminates [3,4].

Two important stages in transverse crack formation must be considered when analysing data and establishing models: a) initiation and b) propagation. Transverse crack initiation is the micro-scaled process involving coalescence of pre-existing defects, flaws or fiber/matrix debonds [5] created by in-plane stresses leading to a damage entity on a homogenized ply scale. The process of creating flaws of

sufficient size to propagate along fibers is not studied in detail in the current paper but is instead described using a failure stress distribution approach [6]. The nominal ply stress required for transverse crack initiation in the abovementioned sense only weakly depends on ply thickness and properties of adjacent plies [7,8]. Propagation of the developed mesoscale damage entity along the fiber direction is usually analysed using energy release rate (ERR) based criteria, leading to the well established $1/\sqrt{t}$ dependence of the required propagation stress on the ply thickness, t. So-called "thin" plies are defined as plies where the initiation stress is lower than the propagation stress. Conversely, for "thick" 90-layers (as considered in the current work), the nominal ply stress required for crack initiation is larger than the stress required for propagation. In "thick" plies, the initiated crack reaches a critical size in ply thickness direction and instantly grows in both ply thickness and fiber direction [9]. The transverse stress required to initiate a crack in a given position in the homogenized layer of a composite with "thick" plies consequently also will be the transverse failure stress in this position. Therefore, the failure initiation transverse stress is called in following "failure stress".

The available literature studying the influence of test temperature on damage development rates during quasi-static tensile loading are non-conclusive in the sense that some reports [10,11] showed that the elevated test temperatures reduced transverse cracking whereas few others [12] showed increase in transverse cracking tendency. This suggests that the transverse cracking characteristic depends on the used material system and the test temperature. In [13,14], the heat treatment of composites at elevated temperatures for several hours, increased the transverse cracking tendency in subsequent quasi-static tensile loading at Room Temperature (RT). To the authors knowledge, only a few studies have been performed to study and predict the crack density growth during quasi-static loading at different temperatures of heat treated composite laminates. The current work presents the systematic investigation on the effects of 1) test temperature T_{test}; 2) long term heat treatment before tensile testing, on transverse cracking in quasi-static tensile loading in heat resistant polymer cross-ply laminates. A two-parameter Weibull failure stress distribution model has been proposed to account for the temperature effects. For that, the Weibull scale parameter was assumed to be temperature dependent and defined using polynomial expression.

2. Methodology to predict crack initiation

To model crack initiation one can start by stating that fiber clusters and defects/voids are statistically distributed in the 90-layer implying that different locations within the layer has different failure stress. Such layer may be viewed as a connected chain of elements, each with certain length but with a statistically distributed failure stress. To ensure that each element will not have more than one crack, the element length can be selected based on experience as being equal to the layer thickness, t_{90}. By doing so the cumulative probability of failure P_f at transverse stress σ_T can be defined as the fraction of elements failed at that stress level or in terms of crack density,

$$P_f = \frac{\rho}{\rho_{max}}, \tag{1}$$

where ρ is the crack density at σ_T and the maximum possible crack density, $\rho_{max} = 1/t_{90}$ [15].
The distribution of failure stress in each element can also be defined using a Weibull failure stress distribution model [16,17]. Applying this methodology, consequently denoted "P_f approach" in the current paper, gives that the P_f of an element also may be expressed as

$$P_f = 1 - \exp\left(-\left(\frac{\sigma_T}{\sigma_0}\right)^m\right) \tag{2}$$

where σ_T denotes the thermo-mechanical transverse stress in 90-layer, and m and σ_0 denotes the Weibull shape and scale parameter respectively. The approach taken hereafter, also supported by findings of Sun et al [11], is to assume that the shape parameter, m, describing the variability of the failure stress in elements remains constant and is not affected by temperature effects such as test temperature or heat treatment.

The reference Weibull parameters, m and σ_0 are determined at reference conditions (as-manufactured specimens tested at RT) using data points from the low crack density region where the thermo-mechanical transverse stress is close to the stress in undamaged laminate σ_{T0}. In ln-ln axes, Eq. 2 becomes,

$$\ln\left(-\ln\left(1-P_f\right)\right) = m\, ln\sigma_{T0} + m\, ln\sigma_0 \tag{3}$$

allowing parameters m and σ_0 to be determined from a linear fit of experimental results. To address the empirically observed differences in cracking tendency at different temperatures and HT, the scale parameter is assumed to be dependent on T_{test} and HT and was defined using a polynomial expression,

$$\sigma_0^* = \sigma_0\left[1 - c\Delta T - df(T_{tr}, t_{tr}) + c_1\Delta T^2 + d_1 f^2(T_{tr}, t_{tr}) + \phi\left(\Delta T, f(T_{tr}, t_{tr})\right) + ..\right], \tag{4}$$

where ΔT is the difference between the T_{test} and a reference temperature T_R (RT in this case), T_{tr} and t_{tr} is the temperature and time of the HT and the functional dependence $f(T_{tr}, t_{tr})$ must be found experimentally. By incorporating the modified scale parameter from Eq. 4 in Eq. 2, one obtains,

$$P_f = 1 - \exp\left(-\left(\frac{\sigma_T}{\sigma_0^*}\right)^m\right). \tag{5}$$

In Eq. 4, the effects of ΔT and HT were defined separately due to the experimental time scale of those effects and also interaction between those effects were defined using the term $\phi\left(\Delta T, f(T_{tr}, t_{tr})\right)$. Definition of ϕ is suggested as, $\phi = e\Delta T\, f(T_{tr}, t_{tr})$. Parameters c, c_1, d, d_1 and e can be determined from empirical fitting.

3. Materials and conditioning

Cross-ply laminates with layups $[0/90_2]$s and $[0/90/0/90_{0.5}]$s and UD $[0_6]$, were manufactured by RTM using UD carbon fiber fabric as reinforcement to a polymer with bismaleimide formulation. Laminate properties, t_{90} and V_f, alongside with elastic constants and CTE used in the analysis are presented in Table 1 [1].

Table 1. Laminates and thermo-elastic ply constants used in stress calculations [1].

Plate	Layup	t_{90} (mm)	V_f (%)	E_1 (GPa)	E_2 (GPa)	ν_{12}	G_{12} (GPa)	α_1 (10^{-6} 1/°C)	α_2 (10^{-6} 1/°C)
Plate 1	$[0/90_2]$s	0.80	46	106.94	9.41	0.33	4.42	0.90	38.73
Plate 2	$[0/90_2]$s	0.73	52	120.08	9.92	0.32	4.96	0.60	35.88
Plate 3	$[0/90_2]$s	0.64	58	133.22	10.45	0.31	5.58	0.37	33.00
Plate 4	$[0/90/0/90_{0.5}]$s	0.16	57	131.03	10.36	0.32	5.47	0.40	33.48
Plate 5	$[0_6]$	1.00	60	137.60	10.08	0.30	5.81	0.30	30.20

The edges of samples (dimensions 180 mm and width 10-15 mm) were grinded and polished to minimize edge effects and to facilitate optical observation of edge damage development. Transverse cracks were manually counted using optical microscope (Zeiss Axioskop) either removing the specimen from the testing machine or inspecting edge replicas (Struers Repliset-T3) at RT. The crack density was calculated from the average of number of cracks over 50 mm gauge length on both specimen edges. Two specimen conditioning treatments were considered: As-Manufactured (AM) specimens with no

treatment and specimens after an extended HT. During HT, specimens taken from Plate 2, 3 and 4 were subjected to 150℃ at ambient air conditions for up to 1000 hours.

4. Quasi-static tensile test methodology

Quasi-static tensile tests were conducted on specimens where distance between grips was 100 mm at a constant cross-head displacement rate of 2 mm/min. The strain was measured using an extensometer, with gauge length of 50 mm. Tests were performed at RT, 90℃ and 150℃ using a stepwise loading procedure. Each step involves a tensile loading and unloading sequence, gradually increasing the strain level to introduce damage in 90-layer [5]. After each sequence, the edges of the tested specimen were observed for damage. Sequences were repeated until failure in or along 0-layer bundles occurred. During ET tests, the specimen was mounted in the test machine at RT. The environmental chamber, along with the specimen, was heated to desired temperature while keeping a constant, very small load (2N). Once thermal equilibrium was achieved, the specimen was loaded to the damage inducing strain level and subsequently unloaded. The specimen was thereafter allowed to slowly cool down inside the chamber to RT and observed for damage state at RT. The procedure was repeated for all incremental strain levels.

5. Results and discussion

5.1. Transverse cracking in quasi-static tensile tests

Crack density growth as a function of the calculated thermo-mechanical transverse stress in the 90-layer is shown in Figure 1. The crack density growth rate is rather similar at RT and ET, the main difference is that the stress required to reach certain crack density is lower at ET. This implies that transverse cracking initiation resistance is lower at ET. Similar observations were made for heat treated specimens. Though the crack density growth rate in heat treated specimens was similar as for AM specimens, the value of crack density at any stress level was higher for heat treated compared to AM specimens tested under same conditions. Possible reasons could be continued post curing, causing resin embrittlement [18], and/or certain extent of oxidation on specimen edges and surfaces during HT.

6. Identification of model parameters

Following sections presents a) determination of Weibull parameters at reference state, b) determination of temperature dependent model and c) applicability of the developed model, demonstrated by using independently determined parameters to predict cracking development in a laminate with same constituents but different layup and fiber content.

The reference Weibull parameters at RT of all AM (reference condition) plates are given in Table 2. They are determined using experimental data corresponding to $0.20 < P_f < 0.50$. The reason for the selected regions was a compromise between the requirement for remaining within the low crack density region ($0.05 < P_f < 0.3$) and having a statistically representative number of data points.

Table 2. Reference Weibull parameters of AM composites at RT from [1].

Plate	Shape parameter m	Scale parameter σ_0 (MPa)
Plate 1	6.18	124.01
Plate 2	3.27	141.91
Plate 3	4.71	126.99
Plate 4	4.91	191.27

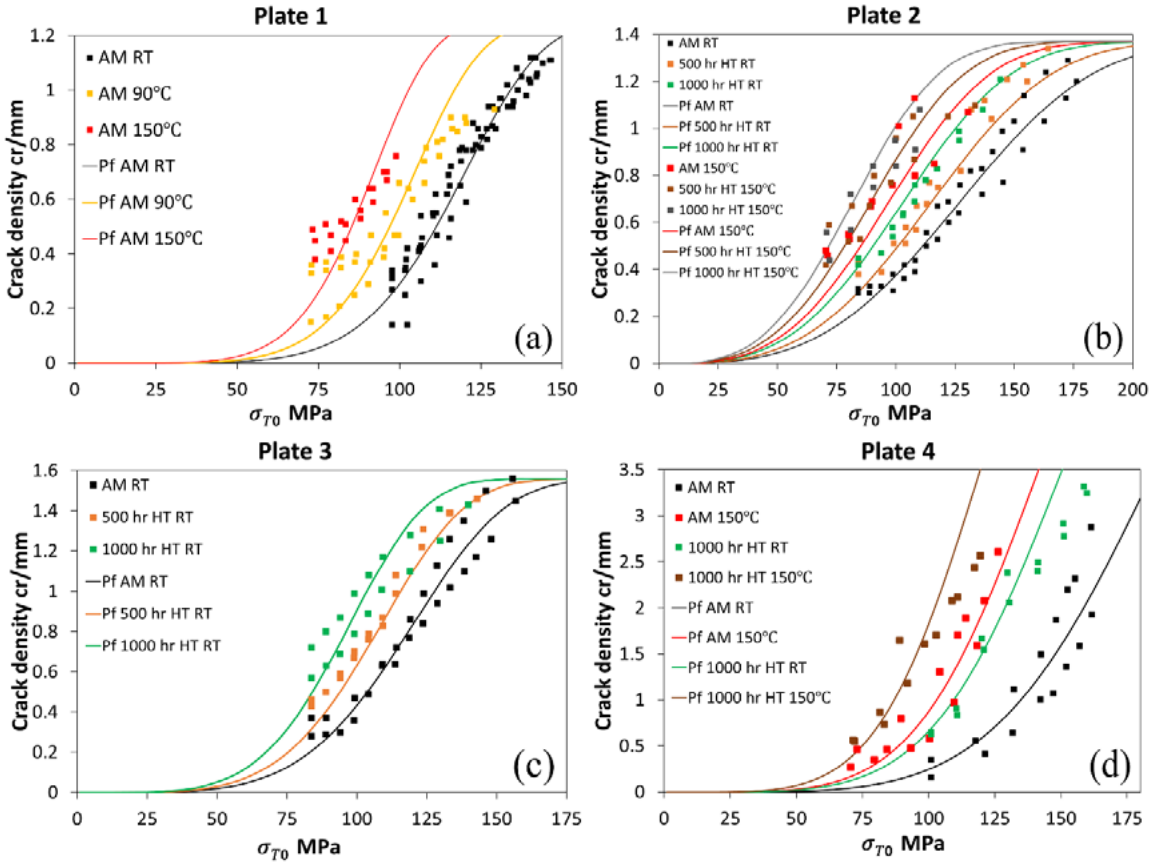

Figure 1. Crack density versus thermo-mechanical transverse stress in 90-layer. Coloured symbols are data points, solid lines are predictions. In legend, AM and HT refer to as-manufactured and heat treated specimens respectively, tested at different temperatures mentioned as RT, 90°C and 150°C. [1]

To determine model parameters only related to T_{test} effect, Eq. 4 may be written as,

$$\sigma_0^* = \sigma_0[1 - c\Delta T + c_1\Delta T^2]. \tag{6}$$

Scale parameter σ_0^* value was determined by finding a good fit for crack density growth versus σ_{T0} data of Plate 1 at elevated temperatures using Eq. 5. Determined σ_0^* showed clear reduction with increasing T_{test}. Graphical representation of the ΔT and $c\Delta T - c_1\Delta T^2$ (obtained from $1 - \sigma_0^*/\sigma_0$) relationship displays a highly linear relationship, see Figure 2a, hence $\boldsymbol{c_1 = 0}$. This suggests that including the quadratic term is not necessary for the given material. Linear fit of data gives value of $\boldsymbol{c = 0.00183}$.

In case of heat treated specimens tested at reference (RT) test conditions, Eq. 4 simplifies to,

$$\sigma_0^* = \sigma_0[1 - df(T_{tr}, t_{tr}) + d_1 f^2(T_{tr}, t_{tr})]. \tag{7}$$

The scale parameter σ_0^* dependence on HT was found by fitting crack density versus σ_{T0} at RT for Plate 2 specimens. In the current work, the only varying parameter in HT is treatment time, the temperature is constant at 150 ℃. The dependence on treatment temperature is consequently not known. Therefore, $df(T_{tr}, t_{tr})$ & $d_1 f^2(T_{tr}, t_{tr})$ in Eq. 7 becomes $d(T_{tr})t_{tr}$ & $d_1(T_{tr}){t_{tr}}^2$. Thereafter, by plotting $d(T_{tr})t_{tr} - d_1(T_{tr}){t_{tr}}^2$ (obtained from $1 - \sigma_0^*/\sigma_0$) against the t_{tr} in hours, see Figure 2b, the relationship is found to be rather linear and the quadratic term in expansion is again not required. A linear fit gives the value $\boldsymbol{d(T_{tr} = 150\,℃) = 0.000188}$.

Then the σ_0^* for heat treated specimens static tested at 150 ℃ for Plate 2 was obtained from fitting the experimental data. The interaction term between test temperature and heat treatment, $e\Delta Tf(T_{tr}, t_{tr})$ in Eq. 4 can be written as $e(T_{tr})\Delta T t_{tr}$ for cases where a single heat treatment temperature is considered. By using the σ_0, σ_0^*, c, c_1, d and d_1 values obtained, $e(T_{tr})\Delta T t_{tr}$ can be determined using Eq. 4. The obtained $e(T_{tr})\Delta T t_{tr}$ values are plotted against t_{tr} in Figure 2c. A rather linear behaviour with respect to t_{tr} is observed and linear fit gives, $\boldsymbol{e = 0.000069}$. The nonzero value of e indicates that the scale parameter reduction for heat treated specimens at elevated temperatures is more than just a sum of the HT and T_{test} caused reduction.

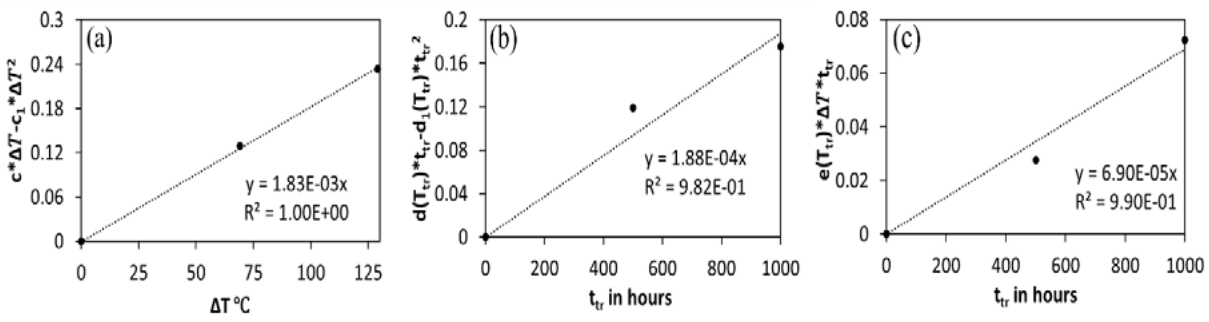

Figure 2. Graphical representation for determination of a) c b) $d(T_{tr})$ c) $e(T_{tr})$ parameters.

6.5. Verification of the HT and T_{test} dependent damage model

Simulations based on probability of failure P_f (Eq. 5) were used to produce predictions presented in Figure 1a-d. The predicted crack density using the scale parameter modified by Eq. 4 is consistent with test results. Interestingly, one can see that by using $c,\ d(T_{tr}),\ e(T_{tr})$ parameters obtained from tests on Plate 1 and 2 to predict the cracking developments of Plates 3 and 4 specimens, the crack density predictions are in good agreement, see Figure 1c and 1d. This is not surprising: all plates have the same reinforcement, interface and matrix.

7. Conclusion

Effect of test temperature and iso-thermal heat treatment on transverse cracking in 90-layer of carbon fiber reinforced polymer cross-ply laminate subjected to quasi-static tensile loading was studied. The transverse crack density growth in as-manufactured and heat treated specimens tested at different temperatures was analysed against the thermo-mechanical transverse stress in 90-layer. It was found that both elevated test temperature and heat treatment reduced the transverse cracking resistance. Methodology to predict transverse cracking was developed using a two-parameter Weibull model. In the model the Weibull scale parameter was assumed to be temperature dependent and defined using polynomial expansion. Model parameters in polynomial expansion were determined from experimental test results of Plates 1 and 2. The scale parameter was found to be linearly decreasing with the increase in tested test temperature range and heat treatment hours. The developed model to predict transverse cracking considering the temperature effects was validated against Plates 3 and 4 with same materials constituents but with different layup and fiber content.

Abstract
Fiber reinforced plastics (FRP) exhibit strongly non-linear deformation behavior. To capture this in simulations, intricate models with a variety of parameters are typically used. The identification of values for such parameters is highly challenging and requires in depth understanding of the model itself. Machine learning (ML) is a promising approach for alleviating this challenge by directly predicting parameters based on experimental results. So far, this works mostly for purely artificial data. In this work, two approaches to generalize to experimental data are investigated: a sequential approach, leveraging understanding of the constitutive model and a direct, purely data driven approach. This is exemplary carried out for a highly non-linear strain rate dependent constitutive model for the shear behavior of FRP.
The sequential model is found to work better on both artificial and experimental data. It is capable of extracting well suited parameters from the artificial data under realistic conditions. For the experimental data, the model performance depends on the composition of the experimental curves, varying between excellently suiting and reasonable predictions. Taking the expert knowledge into account for ML-model training led to far better results than the purely data driven approach. Robustifying the model predictions on experimental data promises further improvement.

1. Introduction

The stress response of FRP to shear deformation is highly dependent on both deformation state and velocity. In order to model the behavior of FRP structures and thus allow for predictive analyses, a variety of models have been published, accurately capturing this non-linear and strain rate dependent stress-strain-behavior [1, 2]. Due to the inherent complexity of these models, they, however, pose a high initial hurdle when it comes to their application to new materials. One significant aspect in that matter is the determination of governing parameters from experimental results. This typically requires in depth knowledge of the intended constitutive model and thus significantly impedes the application of novel, potentially better suited models.
A promising approach of democratizing this expert knowledge lies in the application of ML. Its application to parameter identification (PI) has recently received an increasing amount of research interest [3, 4]. Especially the field of so called direct inverse PI, in which governing parameters are directly predicted from the material behavior, i.e. stress-strain-curve, promises to facilitate the application of novel models. It has been successfully used by several authors for PI on artificial data [5, 6]. However, the application of models for direct inverse PI to experimental data remains highly challenging.

In this work two ML-based approaches to realize this goal are investigated on the example of a recently proposed highly non-linear constitutive model for the strain rate dependent shear behavior of FRP [7]: 1. A convolutional neural network (CNN) taking several stress-strain-curves as input, directly mapping them to the corresponding parameter set. 2. A sequential approach in which a rate independent parameter set is predicted for each curve and the results are passed on to a second stage of the network, extracting rate dependency parameters. Both approaches are trained on purely artificial data and the better suited one is subsequently tested on real-world experimental data. The methods are compared in terms of prediction accuracy and interpretability.

2. Methodology

2.1. Constitutive model from [7]

The material model for which parameters shall be extracted contains a direct dependency of shear stress response τ to shear strain input γ given by

$$\tau(\gamma) = G/a\ (1 - \exp(-a \cdot \gamma)) \tag{1}$$

with the initial slope G, representing the shear modulus, and the decay parameter a. Dependency of these parameters on the strain rate $\dot{\gamma}$ is modeled by a Johnson-Cook approach using the respective scaling parameters A_G and A_a:

$$G(\dot{\gamma}) = G_0(1 + A_G \ln \dot{\gamma}/\dot{\gamma}_0) \tag{2}$$

$$a(\dot{\gamma}) = a_0(1 + A_a \ln \dot{\gamma}/\dot{\gamma}_0)\,. \tag{3}$$

Using the four parameters G_0, a_0, A_G and A_a alongside the strain rate of the reference and current experiment, the stress response under out of plane shear can be accurately calculated [7].

2.1. Model setup

For the identification of the strain rate dependency of material parameters, two approaches are investigated. Firstly, a sequential one subsidizing the steps from the classical approach by models that are individually trained and ensembled afterwards. This allows for a better insight into the workings of the final model. Secondly a direct training of the ensembled model. This is done to prevent error accumulation throughout the different sub-models. The fundamental model layout and subdivisions are shown in Figure 1.

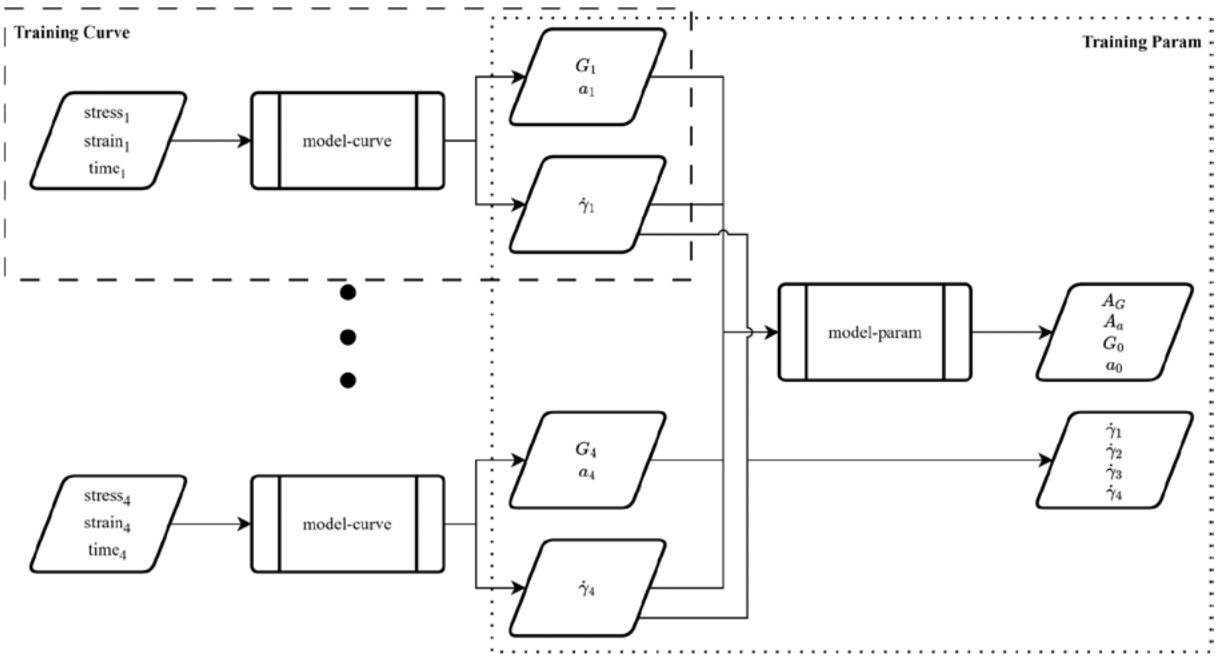

Figure 1. Fundamental layout of ensemble model

For both approaches the ensemble model takes four arrays containing time, strain and stress information as input. These are separated and each individual array is passed to `model-curve`. This maps the arrays to three scalar variables. For the first approach, this sub-step is trained a priori on a specific dataset, allowing for the interpretation of the output from `model-curve` as the governing parameters G, a and the strain rate $\dot{\gamma}$. In the second approach, this is just one of many hidden layers. The outputs of the four `model-curves` are concatenated and passed to `model-param` to extract the desired rate dependency parameters.
The fundamental architecture of `model-curve` is based on a proposition from [8], which was found in [6] to perform well for parameter identification on purely virtual data. The initial curve is first processed by two convolutional layers, each followed by max pooling. The output of this is piped through two dense layers before it is passed to the output layer. The addition of a second dense layer in comparison to [8] was found to significantly increase performance in preliminary studies. For `model-param`, a fully connected network with two hidden layers was chosen.

2.2. Creation of artificial training data

A total of three artificial datasets is required to train the full model according to the two defined approaches. All datasets are generated using the open-source Python library numpy [9]. After their creation, each dataset was split in training and test set with a ratio of 80:20.
For the sequential approach, a set of 100,000 individual time-strain-stress curves is generated, using the constitutive model from Eq. 1. Parameters G and a were drawn from a uniform distribution in the ranges 1000 to 4000 MPa and 25 to 115 respectively. For the strain rate a log-uniform distribution was used with a range 1e-4 to 5 1/s. To make the virtual data similar to the experimental ones, firstly a uniformly distributed time array was created, with the maximum time corresponding to the maximum strain of 20% at a given strain rate. From time and strain rate, strain values were calculated. These in turn were used to calculate corresponding stress using Eq. 1. To both strain and stress Gaussian noise was added. Finally, random data points from the aligned arrays were dropped until the desired input length of 201 was reached. The arrays of shape (201, 3) were used as input to predict corresponding parameters and strain rate with shape (3,).
Using Eqn. 2-3, 25,000 data points were created for training of `model-param`. The four parameters A_G, A_a, G_0 and a_0 were drawn from uniform distributions with the respective ranges 0.05 to 0.1, 0.025 to 0.05, 1000 to 2000 MPa and 25 to 75. The four strain rates were chosen from four increasing log-uniform intervals. Using Eqn. 2-3, four values for G and a were determined. Gaussian noise was added to these values. Since the number of strain rates is not suitably large to assume a zero mean of the noise values, a post hoc least-square fit is performed to determine the final set of parameters A_G, A_a, G_0 and a_0.
For the direct training, a similar approach can be taken. Notably, the individual parameters G and a used for creation of stress in step 1 of the sequential approach were not chosen randomly but taken as the values determined in step 2. However, these intermediate values were not added to the training data. To ensure comparability, a total of 25,000 series of four time-strain-stress curves were created.

3. Results

3.1. Model instantiation and training

The individual models are implemented using the open-source Python library tensorflow [10]. Well suited hyperparameters were determined on a subset of the training data using the hyperparameter optimization tool OmniOpt [11] and kept constant across both approaches. The used parameters are given in Table 1.

Table 1. Hyperparameters for models

`model-curve`				`model-param`	
filters_1	filters_2	neurons_1	neurons_2	neurons_1	neurons_2
49	24	187	172	20	20

All models were trained with an initial learning rate of 2.54e-4 using `adam` optimizer [12] and the respective dataset. The training was continued until no improvement of the mean squared error of the respective parameter predictions on the test set occurred for 50 consecutive epochs. Afterwards the best state, regarding the test set, achieved during training was restored.

3.2. Performance on virtual data

3.2.1. Sequentially trained model

To assess the final performance of the fully trained model it is evaluated on both train and test set. The parameters are used alongside the strain data from the input to obtain modeled stress responses. From this, the root mean squared error (RMSE) between input stress curve and modeled stress, hereafter referred to as "curve RMSE", is averaged across the entire data points in the dataset. The averaged curve RMSE on training and test set is 0.933 and 0.928 MPa respectively, with mean stress values of 33.2 and 32.9 MPa in the datasets.

In Figure 2 the virtual test series with overall best, median and worst curve RMSE from the test set are shown. In the best case results, the model works perfectly, despite the extremely similar stress-strain-curves at rates 1 and 2. For the median result, excellent agreement is achieved for all but the highest strain rate, at which the stress response is underestimated by 2.5 MPa. In the worst case, the model is not able to pick up on the curves' intricacies. However, the artificial input curves exhibit behavior that is not observed in the experiments described in [7]: individual curves from different strain rates intersect one another, leading to a dependency of the maximum stress with strain rate, which first increases, then plateaus and decreases and then begins to increase again. Such behavior cannot be captured by the constitutive model used here and is thus attributed to the significant noise in creating the training data.

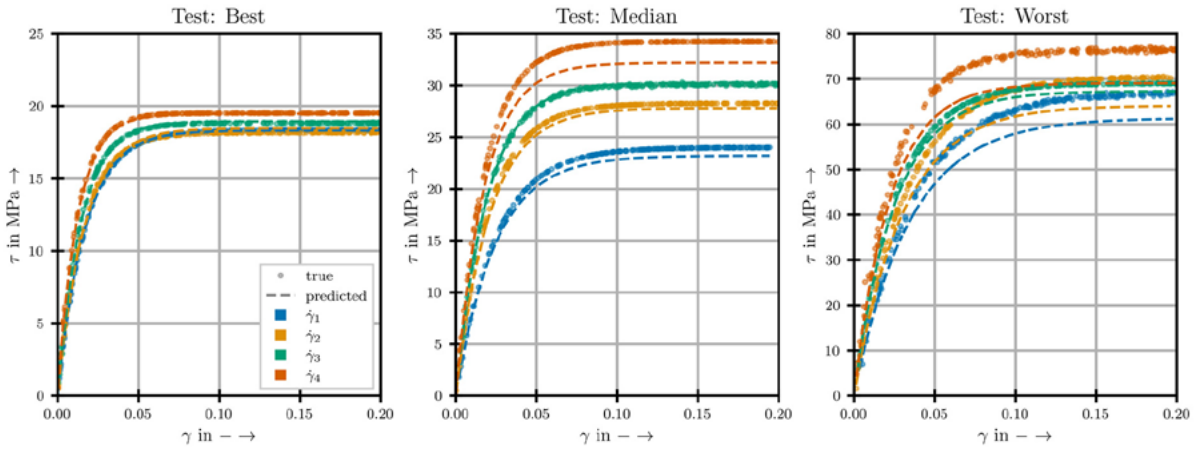

Figure 2. Resulting stress-strain-curves from predictions of the sequential model for artificial data

Given the sequential setup of the model, further insight into the models' individual performance is possible. In Figure 3 the distribution of the curve RMSEs with respect to the true parameter values is shown. From this it becomes clear that the combination of very high G values and low a values pose the highest challenge for the `model-curve`. For `model-param` no clear tendencies of the error to correlate with the input parameters was observed.

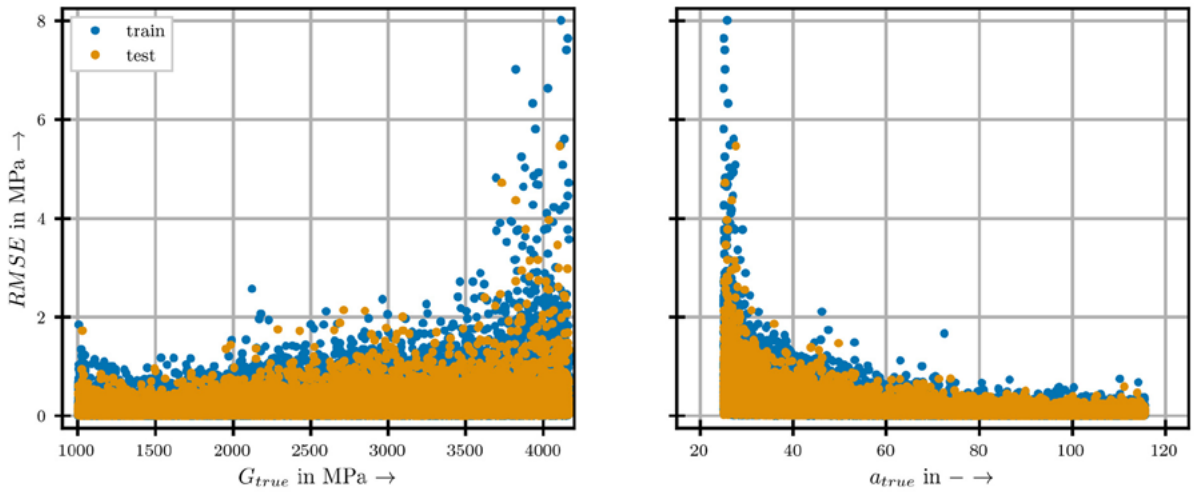

Figure 3. Distribution of error on resulting curves with respective input parameters

However, the specific input and output data of `model-param` for the three shown curves in Figure 4 show that while `model-curve` accurately extracts parameters and rate, represented by the agreement between true and intermediary values, `model-param` introduces a considerable error, leading to a significant deviation between predicted curve and input values. This is most notable at the model predictions for the G parameter of the worst example.

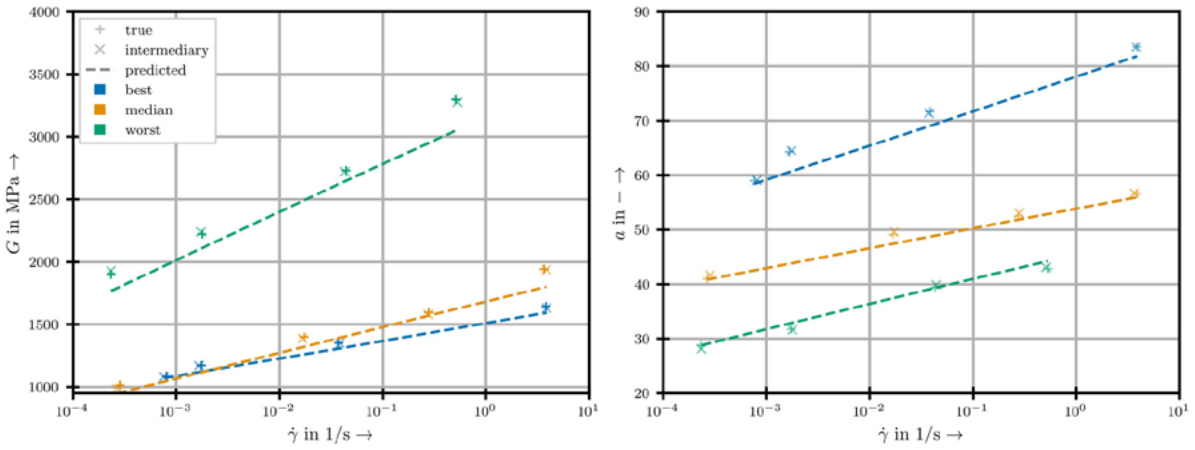

Figure 4. Predictions of sequential model corresponding to results shown in Figure 2.

3.2.2. Directly trained model

The directly trained model reaches a curve RMSE of 3.44 MPa on the training data and of 3.40 MPa on the test data. The results for best, median and worst data series are shown in Figure 5. In the best case, all four input curves lie very close together. Still, the model is not able to extract a set of parameters, leading to the excellent agreement observable with the sequential model. Already in the median case, modeling results and input stress deviate significantly. Additionally, the model does not capture the tendency of stress rising with strain rate, leading to a mismatch between input and output regarding ordering of highest stress response. This observation is strongly intensified by the worst case, where the predictions for lowest rate 1 lead to almost the maximum stress response.

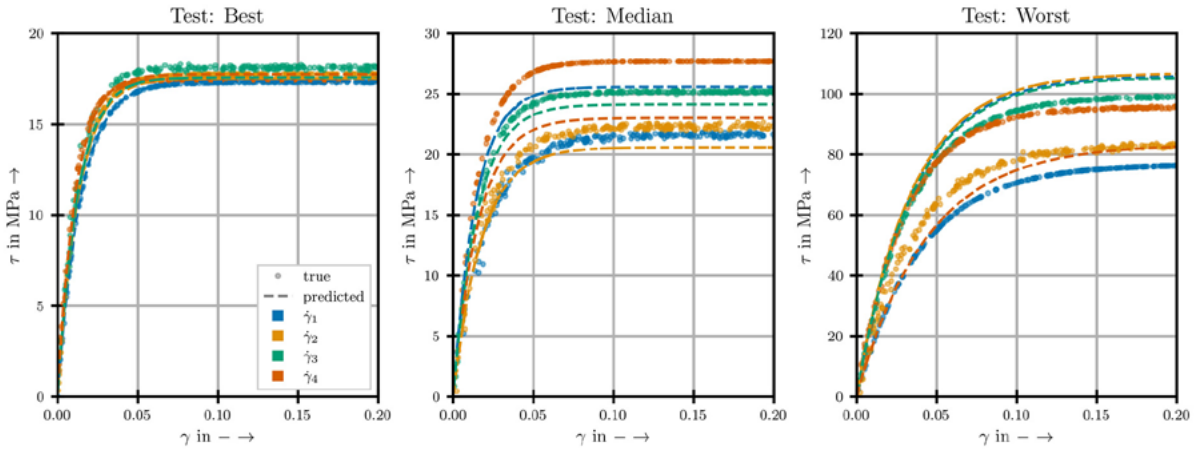

Figure 5. Resulting stress-strain-curves from predictions of the direct model for artificial data

3.2. Performance of the sequential model on experimental data

For the analysis of experimental data, existing results from [7] were used. Several individual tests across four strain rates were conducted. To evaluate them using the full model, the experiments were grouped by strain rate and then composed so that each data point contained one sample of each strain rate. Possible effects from sampling were considered by evaluating the full model on all possible combinations of experimental curves.

Similar to the behavior on artificial data, the direct model could not extract meaningful parameters from the experimental data; the tendency to mismatch rate and stress maxima persisted. Therefore, this approach is not further investigated here.

The sequential model is significantly better, achieving an average curve RMSE of 3.29 MPa at an average stress of 22.1 MPa. In these data, all test series containing one specific curve have a higher error than all others. This indicates some fundamental deficiency here. After removing this individual curve from the dataset, the average curve RMSE drops to 2.17 MPa. From the comparison of the experimental series on which the sequential model achieved the best, median and the worst performance it becomes clear that the composition of experimental curves plays a significant role in the model's predictive capabilities. On the best combination excellent agreement is achieved. On the median and worst combination, stress response is underestimated at the lowest and overestimated at the highest strain rate. For the two intermediate strain rates, good agreement can be observed.

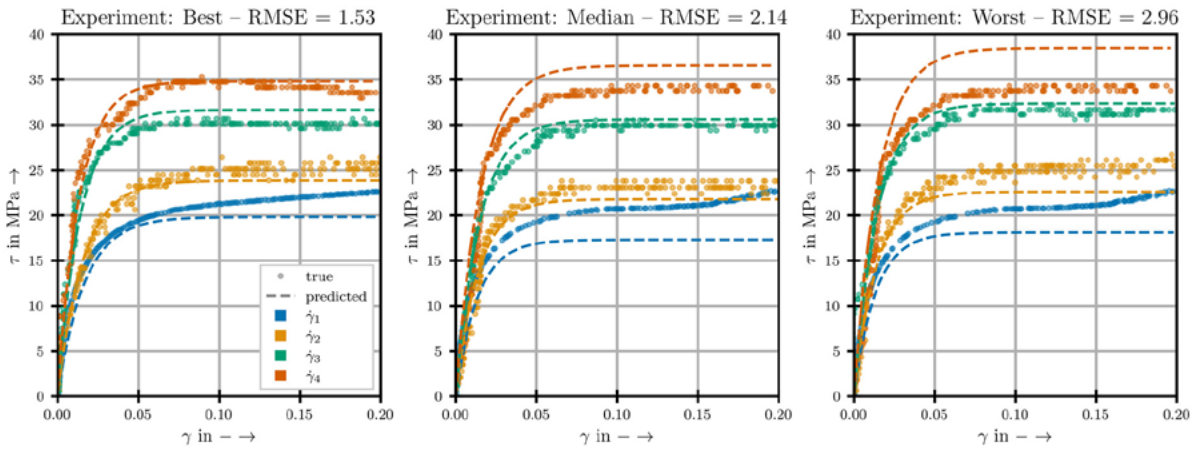

Figure 6. Resulting stress-strain-curves from predictions of the sequential model for experimental data

4. Conclusions

To alleviate the current hurdle in the form of PI for applying novel material models, the potential of two ML approaches has been investigated. Using the example of a highly non-linear, strain rate dependent constitutive model, artificial training data have been generated and used for training the ML models. In doing so, it was highly important to consider intricacies from the experimental data. Especially the inconsistent number of individual datapoints per experiment had to be considered in order to align artificial and experimental data. Additionally, several sources of noise had to be incorporated throughout the generation process to ensure applicability of the final ML model to experimental data.

By following two approaches for the model training, the importance of incorporating existing expert knowledge into the training procedure could be elucidated for the field of direct inverse PI. When pursuing the purely data driven approach, the amount of training data available did not lead to a model capable of extracting the key features from the provided data. This led to unphysical model predictions. Given the setup of the model, further insight into the cause of this problem and potential mitigations could not be obtained.

By including domain knowledge, such as the internal workings of the constitutive model, into ML-model setup and training significantly better results were achieved. The sequential training of task specific sub-models proved to be far more data efficient. Based on the same amount of data as the purely data driven training, meaningful material parameters could be extracted from the data and unphysical predictions were avoided. Furthermore, the composition of smaller expert models enabled insights into the full model's behavior. Regions in the training domain that were especially challenging for sub-models could be identified and can potentially be used to further refine training data and procedure.

Using the model sequentially trained on purely artificial data, it was possible to extract material parameters from experimental data that lead to a well fitting prediction of the stress response to a given strain load. Here, it was found that the composition of experimental data across four strain rates played a significant role in the ML model's performance. Still, the model gave reasonable predictions across all experimental data except for one individual test, that had to be removed.

Based on the presented findings, including domain knowledge into the ML model setup and training is highly recommended. Great potential for future work is expected to arise from extended ML approaches that allow for an arbitrary number of experimental curves per strain rate and should thus reduce the current dependency of prediction quality on the combination of individual curves.

Abstract
This paper presents a finite element-based warpage simulation method for carbon fibre-reinforced SMC (C-SMC) components for automotive application. In the SMC process, one of the main problems is dimensional distortion of the composite component which is an inherent response of the residual stresses that occur due to chemical and thermal shrinkage of the thermoset resin. To tackle this problem, the curing and cooling behaviour of the composite needs to be predicted in a warpage analysis. For this purpose, material characterization is performed to obtain the thermal and chemical properties, and to parametrize the material models for cure kinetics and time- and temperature-dependent resin modulus. Additionally, material properties of the resin in the glassy and rubbery state, the mechanical properties of the fibres and the fibre volume content are required as input in the thermo-mechanical simulation of warpage in Abaqus. In conjunction with the mapped fibre orientation distributions from the SMC process simulation, local homogenization of the aforementioned properties is performed to correctly define the material behaviour during warpage. The warpage of complex automotive composite structure is analysed and a comparison between the experimentally measured and the numerically predicted displacement field is provided.

1. Introduction

Sheet Molding Compound (SMC) is a ready-to-mold, discontinuous fibre reinforced polymer made from thermoset sheets under pressure and temperature by compression molding. These SMC parts offer superior weight-specific properties at relatively low cost and the ability to form complex geometries during compression molding, which is not possible with continuous reinforcement. These properties make them attractive for applications in the aerospace and automotive industries. After manufacturing, process-induced deformations such as shrinkage or warpage can occur and lead to the loss of the component's dimensional stability. Therefore, it is important to perform numerical simulations of the different process steps, including SMC process simulation, mapping & homogenization, and warpage simulation, and to combine these steps to avoid loss of information. In this way, the process-induced deformations together with the accumulated residual stresses can be predicted in advance.

Due to the reorientation of the fibres as consequence of the compression molding process, it is necessary to take the fibre orientations into account in the warpage simulation. The simulation steps of process simulation, mapping and warpage simulation must therefore be linked together. This results in a consistent CAE chain which makes it possible to transfer the information between the simulation steps [1 - 4], as shown in Figure 1. Görthofer et al. [1] and Meyer et al. [2] already present CAE chains for SMC, but warpage of SMC was not yet included. As warpage simulation generally uses a different mesh than the process simulation, the use of an intermediate mapping step is required. The fibre orientation tensor field is imported from the process simulation [5, 6] and mapped onto the warpage mesh using the

Mapping library MpCCI MabLib [7]. All necessary interface operations, such as mapping, clustering of orientation states and homogenization, are bundled in a self-developed plugin for the commercial FE tool ABAQUS. The purpose of this manuscript is to present the FEM-based warpage methodology, including flow-induced process effects, and to demonstrate its application to a complex automotive component. The methodology is explained in Section 2, followed by numerical simulation and experimental validation in Section 3. For accurately predicting the warpage behaviour of C-SMC components, an anisotropic material model which is explained in Subsection 2.2 is implemented in Abaqus using UMAT subroutine.

Figure 1. Virtual CAE chain using the example of an automotive control arm.

2. Methodology

2.1. Workflow

Warpage modelling for C-SMC requires the fibre orientation tensor distribution from moulding simulation which are mapped onto the warpage mesh [1, 4], cf. Fig. 2. The effective material properties of the composite are determined by homogenization of the mechanical, thermal and chemical properties in addition to the fibre orientation distributions from the process simulation [1, 2, 4], in order to correctly define the material behaviour during warpage. The material models and experimental characterization for cure kinetics, cure shrinkage, and cure- and temperature-dependent modulus are explained in Subsection 2.2.

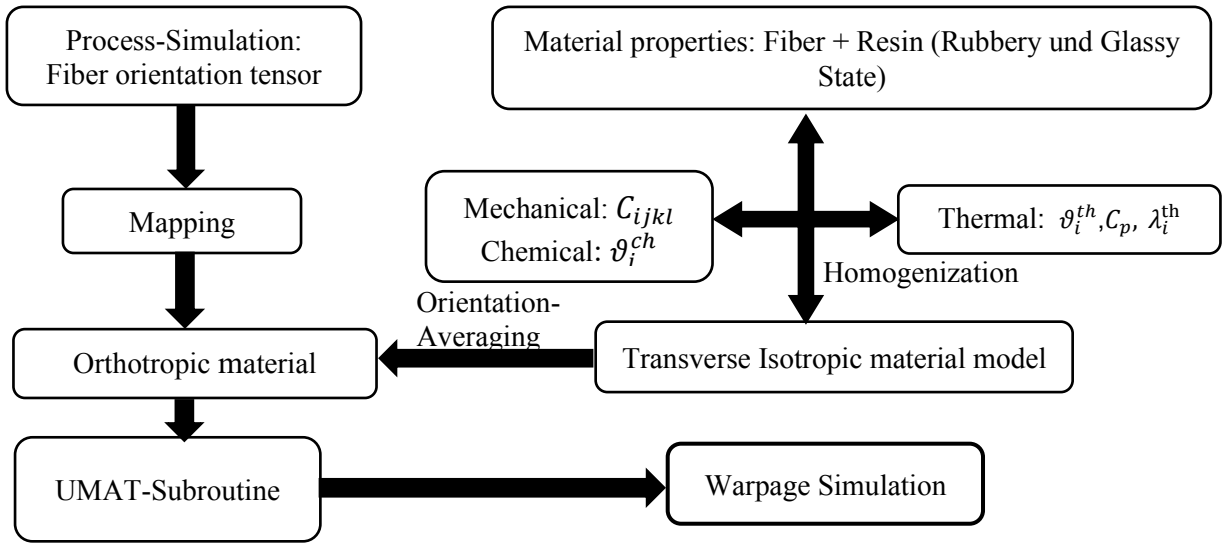

Figure 2. Workflow for the warpage modelling

In this work, the Tandon-Weng approach [8] is used for stiffness homogenization. It is based on the Eshelby tensor for unidirectional inclusions and considers the volume content of the fibres and the aspect ratio, as well as the stiffness of fibres and resin. This homogenization leads to the effective mechanical

property of the stiffness tensor C_{ijkl}. For the thermal properties, the specific heat is averaged over the volume, as it is a scalar and isotropic property. The thermal conductivity is calculated using the Clayton approach [9]. For the coefficient of thermal expansion, Schapery's energy-based approach is used [10]. Chemical shrinkage is averaged over the volume. This homogenization leads to the effective thermal properties such as the thermal conductivity ϑ_i^{th} and the specific heat C_p, as well as the coefficient vector of the thermal expansion $\lambda_i^{\text{th}}$and the chemical shrinkage ϑ_i^{ch}. The homogenized material properties are further averaged based on the fibre orientation tensor to describe the orthotropic behaviour required for SMC molded parts.

2.2. Material behaviour

The material system used for this analysis is a carbon fibre reinforced vinyl ester SMC stack with a weight percentage of 57% carbon fibres. This resin system was analysed with Toray using a differential scanning calorimeter for the cure kinetics and glass transition. A thermomechanical analysis was used for the coefficient of thermal expansion. A rheometer was used for the shrinkage measurement. Finally, a dynamic mechanical analysis was used for the elastic modulus characterization. The properties are summarized in the Table 1.

Table 1. Material Properties

	Fibre	Resin
Modulus (GPa)	250	Unrelaxed: 3.982 Relaxed: 1.125
Poisson's Ratio	0.3	0.3
Density (kg/m^3)	1800	1162

2.2.1. Cure Kinetics

The curing kinetics are calculated using the Kamal-Malkin kinetics model [11], which calculates the rate of change by

$$\frac{d\alpha}{dt} = (K_1 + K_2 \cdot \alpha^m) \cdot (1-\alpha)^n \tag{1}$$

with the empirical parameters m and n [10]. The parameters K_1 and K_2 are often specified by an Arrhenius approximation in the form.

$$K_i = A_i \cdot \exp\left(-\frac{E_i}{R \cdot T}\right) \tag{2}$$

where α is the degree of cure, $\frac{d\alpha}{dt}$ is the cure rate, E_i is the activation energy, and A_i are fitting constants. The mechanical properties of the thermoset matrix material depend on the degree of cure, due to the crosslinking in the reaction kinetics of the matrix. The cure-dependence of the glass transition temperature T_g is modelled using the DiBenedetto approach [12,13],

$$\frac{T_g - T_{g,0}}{T_{g,\infty} - T_{g,0}} = \frac{\lambda \cdot \alpha}{1-(1-\lambda)\cdot\alpha} \tag{3}$$

Here, λ is a model parameter which is 0.3. $T_{g,0}$= -44.04 °C and $T_{g,\infty}$=148.42 °C are the initial and final glass transition temperatures, respectively. $T_{g,0}$ is determined from cyclic DSC measurement, as shown in Figure 3. $T_{g,\infty}$ is the temperature at the maximum loss factor in the DMA measurement of temperature sweeps when the sample is fully cured, as shown in the Figure 4.

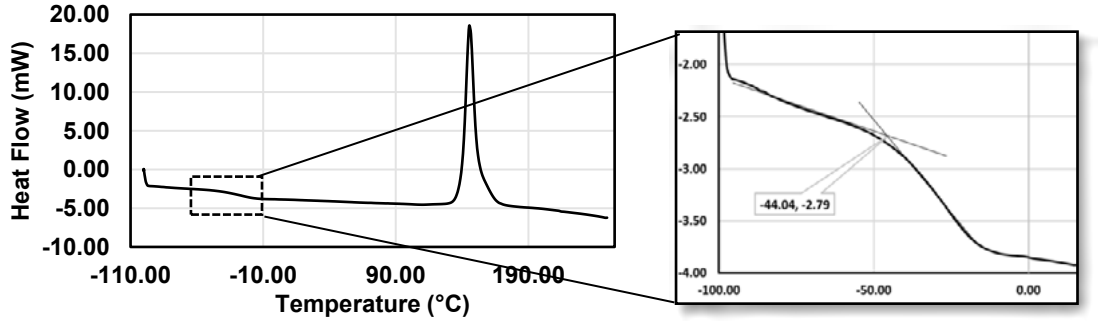

Figure 3. Cyclic DSC measurement

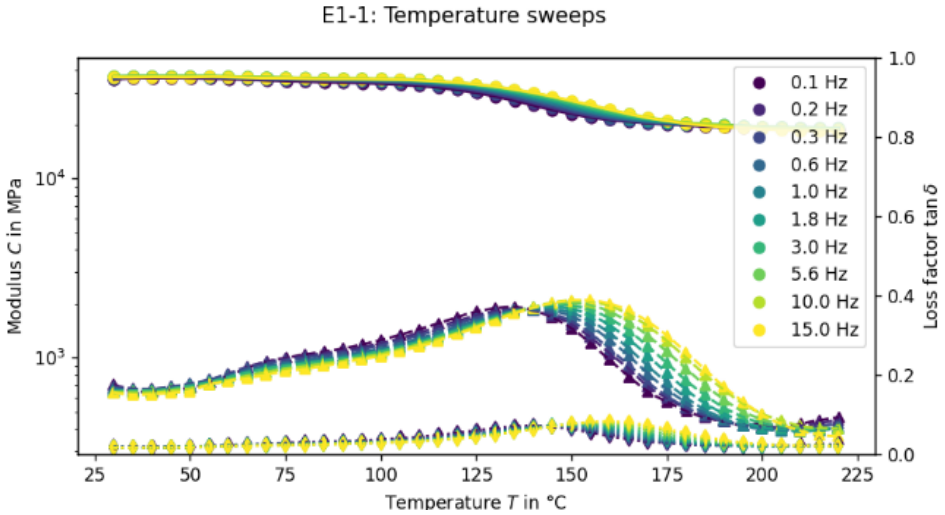

Figure 4. DMA Temperature Sweep

2.2.2. Thermal model

For the numerical simulation of the warpage of thermoset SMC components, thermal properties such as specific heat capacity, thermal conductivity, and coefficient of thermal expansion are required. These thermal properties are determined from material characterization in cooperation with Toray. The properties are given in Table 2.

Table 2. Thermal Properties

	Fibre	Resin
Coefficient of thermal expansion (1/K)	3.8×10^{-7}	3.908×10^{-5}
Specific Heat (J/Kg/K)	760	1310
Thermal Conductivity (m/W/K)	1.3	0.15

As discussed in subsection 2.2, the effective thermal conductivity is calculated with reference to Clayton [9]. For the coefficient of thermal expansion, the energy-based approach of Schapery [10] is used.

2.2.3. Chemical Shrinkage model

From PVT measurements, shrinkage is calculated to a value of -1.106% for the full cure cycle. The homogenization of chemical shrinkage is carried out using the volume averaging method, which is given by,

$$\vartheta_i^{\mathrm{ch}} = \varphi_{\mathrm{f}}\vartheta_{\mathrm{f},i}^{\mathrm{ch}} + \varphi_{\mathrm{m}}\vartheta_{\mathrm{m},i}^{\mathrm{ch}}\,. \tag{4}$$

Here $\vartheta_{\mathrm{f},i}^{\mathrm{ch}}$ and $\vartheta_{\mathrm{m},i}^{\mathrm{ch}}$ are the coefficients of chemical shrinkage for fibre and matrix, respectively. Since there is no shrinkage of the fibres, the effective shrinkage coefficient can be modified to

$$\vartheta_i^{\mathrm{ch}} = \varphi_{\mathrm{m}}\vartheta_{\mathrm{m},i}^{\mathrm{ch}} \tag{5}$$

with φ_{m}=1- φ_{f}. This is a simplified approach because the chemical shrinkage actually depends also on the fibre orientation.

2.2.4. Orthotropic CHILE Model

The Cure Hardening Instantaneously Linear Elastic (CHILE) model developed by Johnston is used to capture the stress evolution of the resin [14]. In case of C-SMC composite material, DMA experiments have shown a temperature dependency of the modulus. Therefore, the CHILE model is modified to fit a linear temperature dependency before the glass transition and used to model the cure-dependent mechanical behaviour of the composite material [14, 15, 16]. The models by Johnston [14] are extended and implemented to represent the orthotropic material behaviour for discontinuous carbon fibre reinforced vinyl ester resin SMC components. The stress evolution of the modified CHILE model is given by,

$$\sigma(t) = \int_0^t E(T,\alpha)\,\frac{\partial\varepsilon(\xi)}{\partial\xi}\mathrm{d}\xi, \tag{6}$$

where ξ is the time, $E(T,\alpha)$ is the instantaneous modulus of elasticity, which depends on the temperature T and the degree of cure $\alpha \in [0;1]$. The modified CHILE model assumes a monotonic increase in the resin modulus during curing according to

$$E(T,\alpha) = \begin{cases} E_1, & T^* < \Delta T_{\mathrm{c}_1} \\ E_2 + \dfrac{T^* - \Delta T_{\mathrm{c}_2}}{\Delta T_{\mathrm{c}_1} - \Delta T_{\mathrm{c}_2}}\,(E_1 - E_2), & \Delta T_{c_1} \le T^* < \Delta T_{\mathrm{c}_2} \\ E_3 + \dfrac{T^* - \Delta T_{\mathrm{c}_3}}{\Delta T_{\mathrm{c}_2} - \Delta T_{\mathrm{c}_3}}\,(E_2 - E_3), & \Delta T_{c_2} \le T^* < \Delta T_{\mathrm{c}_3} \\ E_3, & T^* \ge \Delta T_{\mathrm{c}_3} \end{cases}, \tag{7}$$

with $T^* = T - T_g$. The glass transition temperature T_g is calculated according to Equation (3). In DMA measurements, temperature sweep is carried out on carbon fibre reinforced SMC composite sample from 20 °C to 220 °C at frequency 1 Hz. Figure 5 reveals a tri-linear temperature dependency of the modulus of fibre reinforced vinyl ester resin. The modified CHILE model is fitted to the DMA experiments yielding the parameters: $\Delta T_{c_1} = -116.82$ °C, $\Delta T_{c_2} = -18.37$ °C, $\Delta T_{c_3} = 22.75$ °C, $E_1 = 34189.2$ MPa, $E_2 = 30906.99$ MPa, $E_3 = 16637.2$ MPa. In this model, the rubbery modulus E_3 is active as long as T_{g} has not exceeded the current temperature by a certain value ΔT_{c_3}. The stiffness is equal to the glassy modulus E_1 if the temperature T reaches a value below T_{g} - ΔT_{c_1} during cooling.

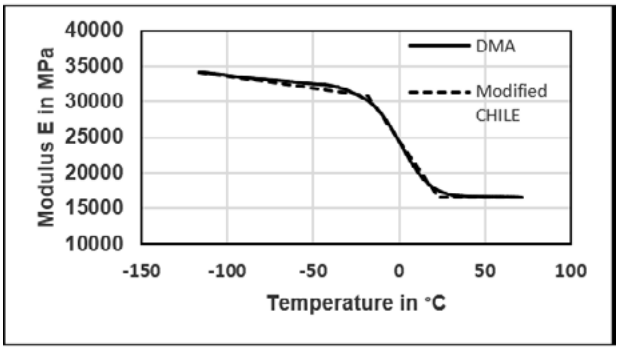

Figure 5. Temperature dependence of Modulus fitted to DMA.

2.2.5. Total strain

In the SMC process, the component undergoes chemical and thermal shrinkage in addition to the mechanical deformations, e.g. caused by the holding pressure. Thus, the complete change in elongation is given by,

$$\Delta\varepsilon_{ij} = \Delta\varepsilon_{ij}{}^{\mathrm{mech}} + \Delta\varepsilon_{ij}{}^{\mathrm{th}} + \Delta\varepsilon_{ij}{}^{\mathrm{ch}} . \tag{8}$$

The change in thermal expansion is given by,

$$\Delta\varepsilon_{ij}{}^{\mathrm{th}} = \vartheta_i^{\mathrm{th}}\Delta T . \tag{9}$$

The change in chemical elongation is given by,

$$\Delta\varepsilon_{ij}{}^{\mathrm{ch}} = \vartheta_i^{\mathrm{ch}}\Delta\alpha . \tag{10}$$

A subroutine was created for the modified CHILE model and implemented in ABAQUS. The homogenization is performed according to the method presented by Görthofer et al [1, 2] as explained in the Subsection 2.1.

2.2.6. Reverse Homogenization

The characterization is done on the C-SMC composite material. Therefore, a reverse homogenization is carried out to get the neat resin properties [18]. This is an iterative process in which the properties of the carbon fibre and the C-SMC composite material are known, and the resin properties are calculated. The workflow for the reverse homogenization is shown in Figure 6.

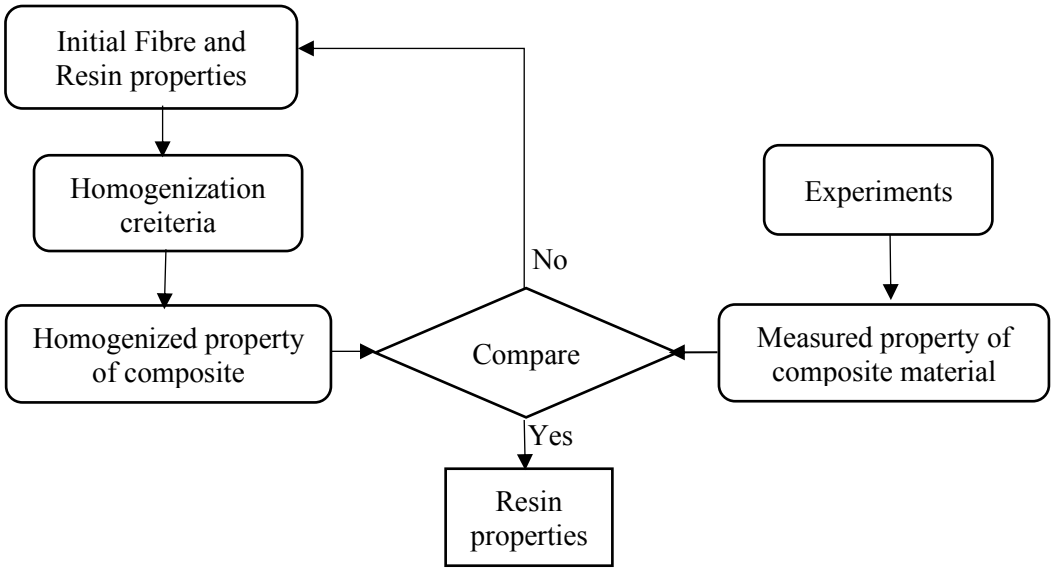

Figure 6. Reverse homogenization method

3. Numerical Simulation and Experimental Validation

The warpage analysis begins immediately after mold filling and includes the process steps of mold holding, curing, transfer and cooling outside the mold. The warpage analysis is carried out with the FE software ABAQUS 2021 (Dassault Systémes, USA). The simulation model is a section of a control arm of an automotive component, as shown in Figure 7. There are four steps in the simulations, namely mold holding, curing, transfer and cooling. During the mold holding and curing step, the displacements are blocked on the entire surface of the component, as it is still in the closed mold during the actual process. The surface temperature is set at a constant 140 °C. The curing step lasts 360 seconds, followed by a transfer step for 5 seconds and then a cooling step outside the mold. During cooling, a convection boundary condition is specified for the temperature field. The effective material properties are determined using the described schemes. For the mechanical model, the modified CHILE model is used in an orthotropic formulation. The orientation distribution is clustered into 100 sub-regions based on the fibre orientation tensors from mould filling simulation. According to the 100 material sections, 100 orthotropic materials are created that describe the thermomechanical material behaviour for the corresponding fibre orientation state.

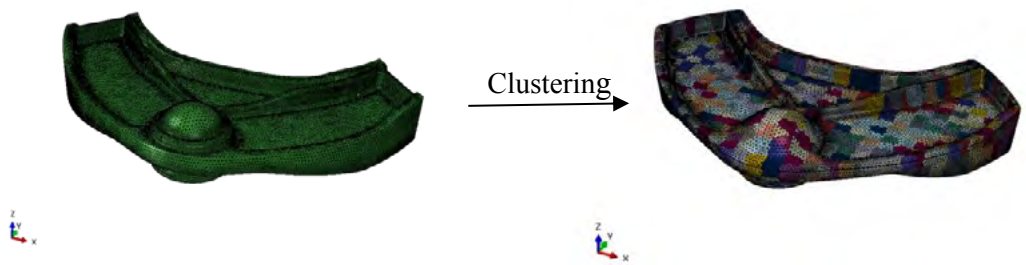

Figure 7. FE model of SMC Automotive suspension control arm showing orthotropic material clustering

An SMC suspension control arm was manufactured at Fraunhofer ICT, and measurements are conducted using GOM 3D ATOS scanner. Figure 8 shows a comparison between experimentally measured and numerically predicted displacements of the suspension control arm. The left-side figure shows the deviation of the manufactured part over the nominal geometry, and the right-side figure shows the deviation of the predicted shape of the component over the nominal geometry. The different deviation points in the figure indicate displacement values at specific locations. By comparison, it can be seen that the displacement values are qualitatively in reasonable agreement with the experimental results, but simulation underpredicts the deformation. In future work, the packing step after complete mold filling will be considered, which takes into account the additional holding pressure and may thus reduce the difference between simulation and experiment.

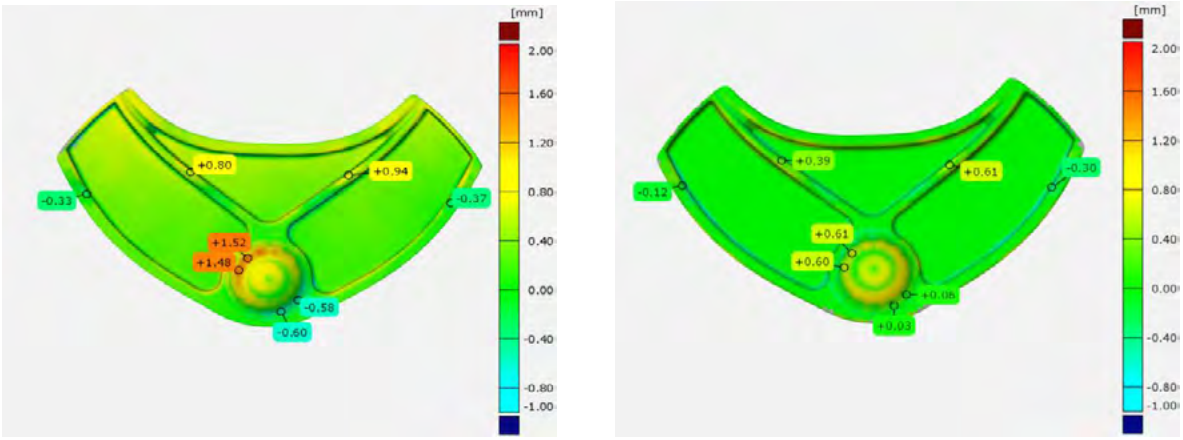

Figure 8. Comparison of experimentally measured (left) and numerically predicted (right) process-induced displacements of the SMC suspension control arm.

4. Conclusion

An orthotropic modified CHILE model has been implemented for process-induced warpage simulation of SMC components. The model is able to capture the distortion of fibre-reinforced SMC component as a function of process parameters, process-induced fibre orientation distributions and curing reaction. A consistent CAE chain approach is used to transfer the moulding simulation results onto the warpage mesh via mapping. The simulation methodology is applied for stress-deformation analysis of an automotive component suspension control arm, produced by compression molding of discontinuous carbon fibre-reinforced vinyl ester thermoset. The resulting fibre orientation distribution affects the warpage simulation results such as residual stresses and final shape of the part. The experimental results are qualitatively in good agreement with the deformations predicted by the simulations. However, the simulation underpredicts the deviation. In the future, a further developed viscoelastic material model for the matrix can also be used to capture the time-dependent behaviour of the matrix more accurately.

Keywords: Remaining useful life, flax fibre composite, creep, acoustic emission, deep learning

Abstract
This paper explores a strategy that integrates acoustic emission (AE) and deep learning techniques for the remaining useful life (RUL) prediction of flax fibre composite subjected to long-term flexural creep load. The AE and creep deformation data were acquired by monitoring the creep rupture (run to failure) tests under four different stress levels. Derivatives of cumulative AE features with respect to time, such as cumulative hit and count rates, are introduced to reflect the performance degradation rate of the materials. These proposed features appear to be more relevant for creep lifespan than traditional AE features. Long short-term memory networks and temporal convolutional networks are adopted to estimate the composite's remaining useful life. The two model's normalized root mean square errors are below 0.11, which demonstrates a satisfactory prediction accuracy in RUL of the samples subjected to different loading levels.

1. Introduction

Damage prognostics are crucial to ensure the structural integrity and reliability of natural fibre composites (NFC) during their in-service life. When subjected to long-term cyclic (fatigue) and/or constant (creep) loadings, NFC often experience a considerably dispersive lifespan due to the complex deterioration process, which is mainly caused by their non-homogenous characteristics at the composite level, coupled with the non-uniform nature of natural fibres in their micro-structure, component content, as well as the randomly distributed defects like kink bands. In this scenario, the traditional physical or empirical models can only provide a rough lifespan estimation for NFC, because most of the models are formulated in terms of the premeasured ultimate strength and predefined loading patterns [1]–[6], and overlook the impact of the uncertainty in the damage evolution and accumulation in NFC during their in-service life. Hence, it is necessary to explore a more versatile approach for damage prognostics of NFC under long-term load.

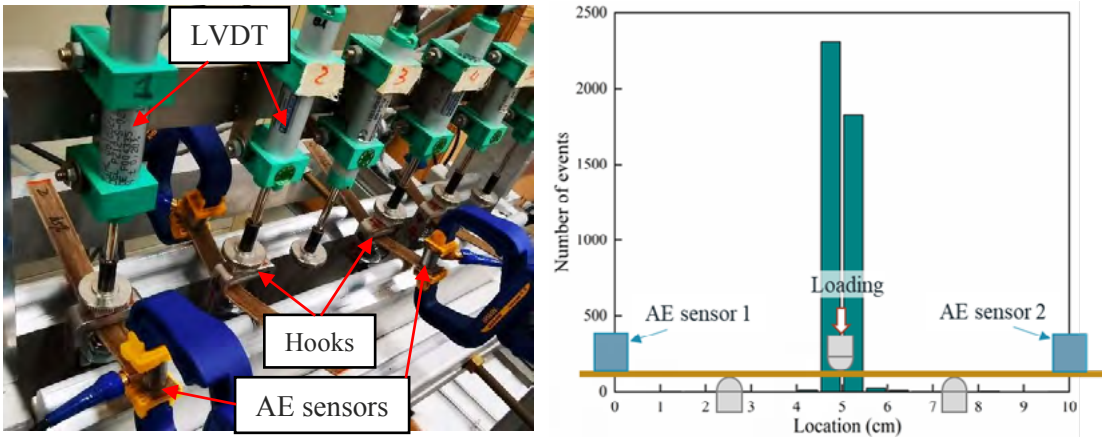
Acoustic emission (AE), a prominent technique in the domain of structural health monitoring, has been widely used in damage detection and identification of composite materials [7]–[13]. Due to increased requirements in the health management and maintenance of composite structures, efforts have also been

made in AE-based damage prognostics to predict the remaining useful life (RUL) and strength (RUS). Compared to simple empirical models considering only a single AE parameter such as energy [14], [15] or counts [16] for RUL prediction, AE-based data-driven models have been gaining increased interest due to their excellent capability of processing abundant data and mapping complex non-linear relationships. Long Short-Term Memory (LSTM) networks are a variety of recurrent neural networks (RNNs) that are capable of learning long-term dependency. They specialize in discovering the underlying patterns embedded in time series, which makes them suitable to track the degradation process and thus to predict the RUL [17]. Another popular type of neural network is the Convolutional Neural Network (CNN) which has been commonly used in Computer Vision. Motivated by its feature extraction ability and computational efficiency, 1D CNN has been introduced to signal processing in the context of structural health monitoring [18], [19]. To deal with the problem of temporal dependency existing in RUL prediction, the AE sequential data are often segmented by a time window with fixed or variable length and then fed as an input into the CNN models [20], [21]. More recently, a Temporal Convolutional Network (TCN) architecture integrated with dilated causal convolutions and residual blocks, was introduced for sequence learning tasks [22], [23] and so far has attracted considerable attention [24]–[27].

Despite the tremendous potential of data-driven models such as LSTM and TCN in damage prognostics, very few attempts have been made for RUL prediction in the field of composite materials, especially for natural fibre composites subjected to long-term creep load. In this study, AE sensors and Linear Variable Differential Transformer sensors were employed to detect damage activities and acquire creep deformation information in flax fibre composites during creep rupture tests, respectively. LSTM and TCN models were employed for RUL prediction, and the model performances were compared.

2. Materials and tests

2.1. Material system



The composites were prepared with unidirectional flax fibre (Lineo Flaxtape 110), bound by polyoxymethylene (POM) (Hostaform C2521) through a film stacking method. The composite samples have a fibre volume fraction of ~40% and dimensions of 1.5 mm thickness, 10 mm width, and 120 mm length. The properties of the fibre and matrix as well as their composite are listed in Table 1 (the longitudinal strength and modulus of the fibre and matrix were measured by tensile tests, whereas the composites were characterized through flexural tests).

Table 1 Properties of flax fibre and POM as well as their composite

Materials	Longitudinal modulus (GPa)	Longitudinal strength (MPa)
Flax fibre	68 ± 3.4	533 ± 37
POM	~2.6	~62
Flax/POM composite	19.3 ± 1.7	201± 6.5

2.2. Creep rupture tests monitored by AE

The creep rupture tests were performed using a custom-designed flexural creep set-up placed in an environmentally conditioned room (23 ºC & 50% RH) as shown in Fig. 1 (a). Six Linear Variable Differential Transformer sensors (LVDT) with a resolution of 1 μm were attached on the set-up for measuring the sample deflection during creep loading. Several stainless-steel blocks with varying dimensions were fabricated to apply the constant creep load by connecting hooks positioned in the middle of the specimens. By adjusting the number of blocks, a weight resolution of 1N could be achieved for the sustained load. Four different stress ratios (the ratio of applied stress to the ultimate strength measured by quasi-static flexural tests), namely 90 %, 85%, 80% and 75%, were used to examine the applicability of the proposed strategy to the different samples with various damage accumulation pattern. Six specimens were tested for each loading condition.

(a) (b)

Fig. 1 (a) Creep tests monitored by AE and LVDT. (b) Distribution of AE sensors along sample lengthwise direction.

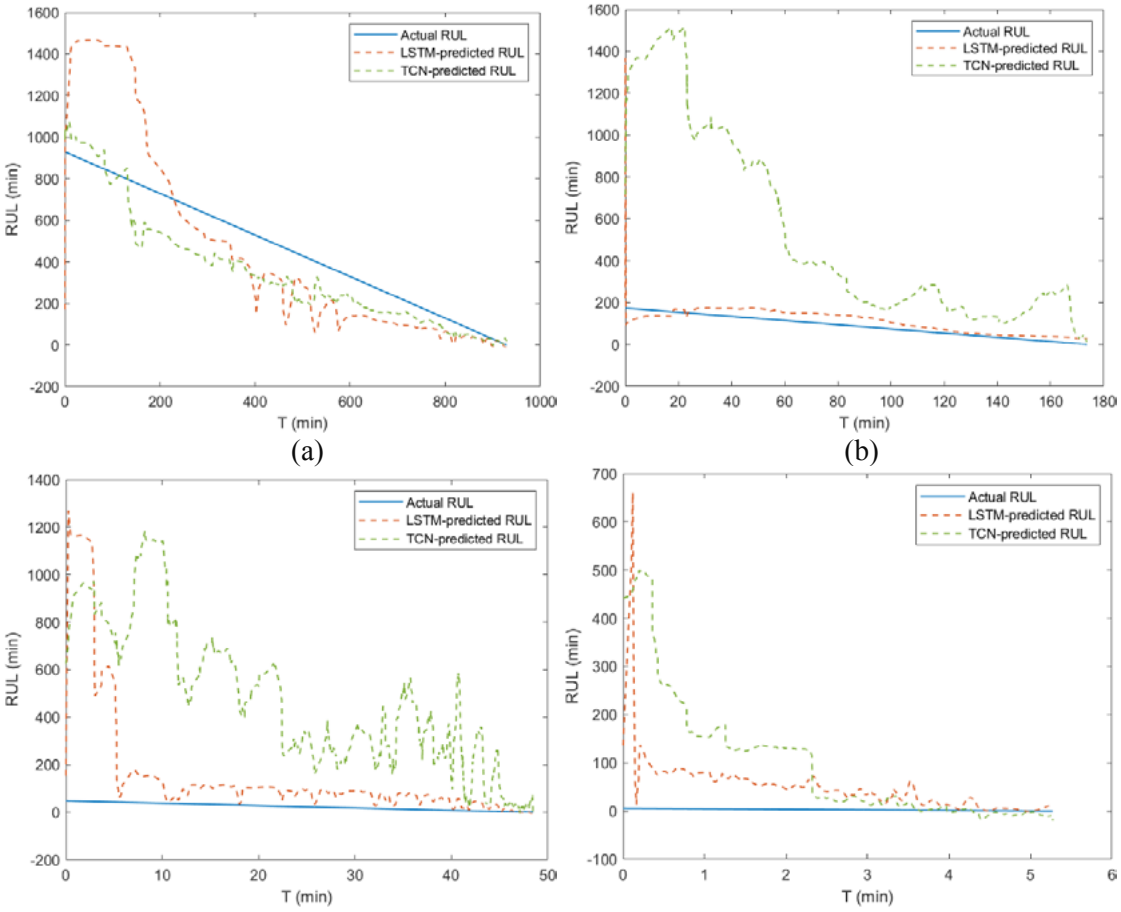
An AE device (Vallen AMSY-6 system) was used to monitor the creep rupture tests. The acoustic signal was captured by two AE-sensors Digital wave B-1025 with a broadband response from 50 - 2000 kHz, and subsequently amplified by preamplifier Vallen AEP4 with a 34 dB gain before being processed by AE-signal processor ASIP-2A. When the samples were loaded in 3-point bending mode during creep tests, the AE activities were concentrated in the middle of the sample where the damage generated, as shown in Fig. 1 (b) where two AE sensors were used for the damage localization. Only one sensor was used for each sample afterwards as the issue of disparity in detected signal energy due to varied source-detector distance (energy attenuation) caused by scattered damage locations barely existed. With four data acquisition channels configured in this Vallen system, four creep measurements could be performed synchronously, which significantly reduced the total experimental time.

3. Results and discussions

3.1. Data preparation

Unlike AE-based damage diagnostics for composite materials, where the damage modes are primarily identified by non-cumulative AE features (e.g., amplitude, rise time, counts, energy, frequency), damage prognostics rely more on cumulative features such as cumulative hits, cumulative counts and cumulative energy, which are sensitive to the damage evolution [28], [29]. Therefore, twenty-five AE features comprising thirteen non-cumulative features, six cumulative features and six cumulative features rates, were extracted based on the AE data, as presented in Table 2.

Table 2 Twenty-five extracted AE features



No.	Feature provided by Vallen system	No.	Extracted feature
1	Amplitude – A (dB)	14	Cumulative hits – Cum_Hits
2	Rise time – RT (μs)	15	Cumulative rise time – Cum_RT (μs)
3	Duration time – DT (μs)	16	Cumulative duration time - Cum_DT (μs)
4	Counts – C	17	Cumulative counts – Cum_C
5	Energy – E (eu)	18	Cumulative energy – Cum_E (eu)
6	Signal strength - SS(nVs)	19	Cumulative signal strength - Cum_SS (nVs)
7	Root mean square - RMS (μV)	20	Cumulative hits rate - Cum_Hits_rate (μs^{-1})

8	Peak frequency– FMAX (kHz)	21	Cumulative rise time rate – Cum_RT_rate
9	Frequency centroid of Gravity– FCOG (kHz)	22	Cumulative duration time rate- Cum_DT_rate
10	Cascade hits – CHIT	23	Cumulative counts rate – Cum_C_rate (μs^{-1})
11	Cascade counts - CC	24	Cumulative energy rate– Cum_E_rate (eu^{-1})
12	Cascade energy – CE (eu)	25	Cumulative signal strength rate - Cum_SS_rate (nV)
13	Cascade signal strength – CSS (nVs)		

Additionally, three creep deformation descriptors, namely creep strain, creep rate and creep ratio (the ratio of secondary creep strain to the instantaneous strain), were selected as the predictors.

3.2. RUL prediction based on LSTM and TCN

The Adaptive moment estimation (Adam) optimizer was used for training via gradient descent. All the hyperparameters of the two models were determined through a rough grid search on the data obtained from preliminary tests. In the LSTM model, 300 hidden units were set in a LSTM layer, followed by a FC layer with 50 neurons. The length of the AE sequential data is ~3500 in each measurement. To cover the complete historical data for the predictions at all timestamps, the filter size f of the TCN model was set as 5 and the number of convolutional layers (residual blocks) $K = 10$ was selected to achieve a receptive field $R = 1 + (f - 1)(2^K - 1) = 4093 > 3500$. The number of filters for each convolutional layer was set as 50. The initial learning rate was 0.01 for both LSTM and TCN models and reduced by a factor of 0.2 every 50 epochs. The maximum training epoch was set as 200 for LSTM and 100 for TCN as TCN converges more quickly. A dropout rate of 0.5 was used in both models to avoid overfitting.

(c) (d)

Fig. 2 RUL predictions of samples under four different stress levels by LSTM and TCN models based on fused data (a) Stress ratio of 75%. (b) Stress ratio of 80%. (c) Stress ratio of 85%. (d) Stress ratio of 90%.

Given the potentially consistent damage mechanisms and evolution pattern existing in the samples when subjected to different stress levels, an attempt was made to train the models using the data from twenty measurements (five out of six measurements at each stress level), whereas the remaining four measurements were held back for testing. However, poor predictions were obtained when the data from different stress levels were fused, see Fig. 2. The reason could be that the features from different stress levels vary widely with respect to time scales, from minutes (under a stress ratio of 90%) to days (under a stress ratio of 75%). The diversity of the features at different stress levels might exert a significantly greater influence on the models in training compared to the presumed consistent patterns.

Therefore, the models were trained using data from only the same stress level. A leave-one-out cross-validation method was adopted to estimate the generalization performance of the two models given the relatively small dataset (six measurements for each sample). That is, the data from five measurements of each stress level were used to train the models, and the remaining one measurement was used for testing. Each stress level sample comprises six predictions generated through the leave-one-out cross validation method.

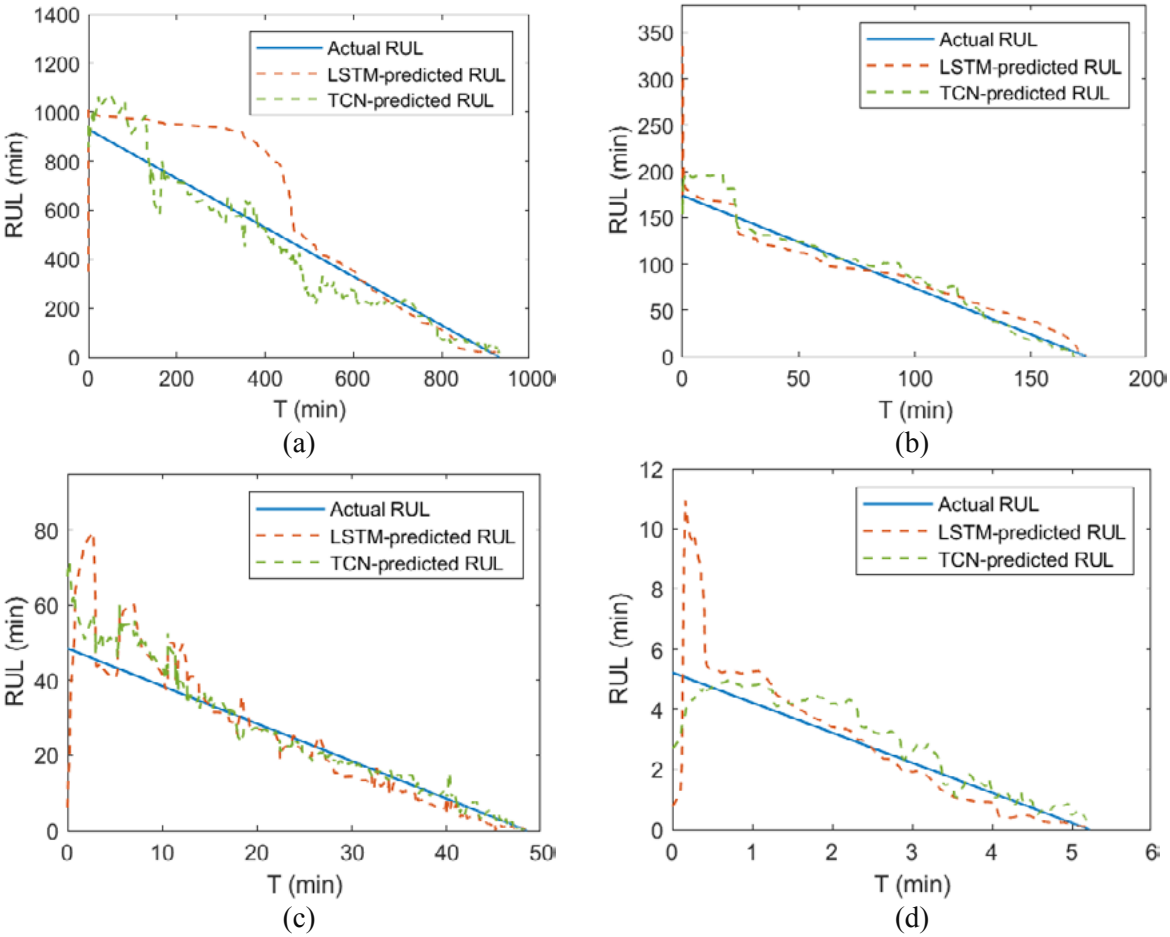


Fig. 3 Representative RUL predictions of samples under four different stress levels by LSTM and TCN. The RUL values at any moment t, were estimated based on the historical data up to t. (a) Stress ratio of 75%. (b) Stress ratio of 80%. (c) Stress ratio of 85%. (d) Stress ratio of 90%.

Fig. 3 presents the representative RUL estimations of the four samples by using LSTM and TCN (the models were trained using the data from the same stress ratio sample, respectively). In this case, the

predictions are much better than those shown in Fig. 2. It is found that the predicted values deviate noticeably from the actual RUL line in the early stage (most likely the primary creep stage) but converge to the actual RUL line when approaching the end of the creep life. The moderate performance in the early stage could be due to two reasons. Firstly, AE events generated sporadically in the early stage, leading to a relatively small number of AE events and thus limited information can be fed into the model for prediction. Secondly, the damage that occurred in the early stage when subjected to long-term creep load is mainly associated with matrix cracking based on our previous study [30]. For fibre reinforced composites, the performance degradation is less sensitive to the number of matrix failures, rather more dependent on the fibre-matrix interface and fibre failures as the load of composite materials is mainly borne by the fibres with the interface dominating the stress transfer. As the end-of-life approaches, increasing interface failures (interface debonding and fibre pull-out) as well as fibre fracture occur [30]. Consequently, better prediction results could be obtained with these more informative damage modes.

The normalized root mean squared error (NRMSE) is adopted to assess the model performance across the four samples under different stress ratios, formulated as follows:

$$NRMSE = \frac{RMSE}{T_L} = \frac{\sqrt{\frac{1}{N}\sum_{t=1}^{N}\left(\widehat{RUL_{(t)}} - RUL_{actual\,(t)}\right)^2}}{T_L} \quad (1)$$

Where $\widehat{RUL_{(t)}}$ is the estimated RUL and T_L the corresponding creep lifespan.

Each stress level sample comprises six predictions generated through the leave-one-out cross validation method. The corresponding NRMSE values are visually represented using a boxplot, as depicted in Figure 4 . It is clearly seen that the NRMSE values of the two models across all samples fall primarily within the range of 0.05 to 0.15. A minority of predictions exhibit errors exceeding 0.2. The mean NRMSE illustrated by a black dash line is used to represent the generalization performance of the two models for each sample. Notably, the mean errors of the both models for the four samples are less than 0.1. Among the four samples, the sample with a stress ratio of 80% exhibits the most favorable performance for both models, while higher mean NRMSE values are observed in samples with stress ratios of 75% and 85%, perhaps due to less patten diversity in the data of sample with stress ratio of 80%.

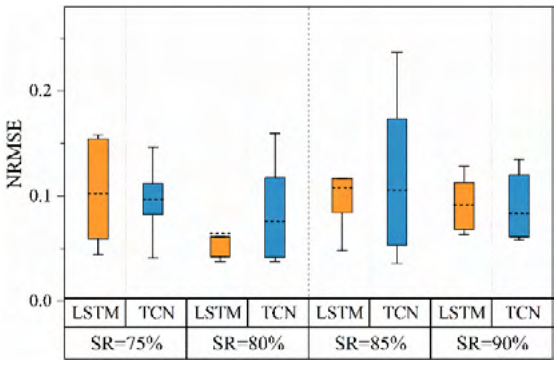

Fig. 4 The normalized RMSE of the two models for the samples under four different stress ratios.

4. Conclusions

In this study, the RUL of flax fibre composite subjected to creep load was predicted using LSTM and TCN deep learning models based on AE data and creep deformation. Cumulative feature rates, deemed crucial for RUL estimation, were proposed to reflect the performance degradation rate of the composites under creep load and were included as part of the input variables of the models. A specific evaluation metric, NRMSE, was adopted to assess and compare the model performance across four distinct samples with significantly different lifespans. Both models provided satisfactory accuracy in estimating RUL overall, with improved precision observed when more informative historical data was incorporated into the models

Keywords: glass fibre reinforced polymer, vacuum infusion, durability, thermomechanical properties, mechanical properties, hygrothermal ageing.

Abstract
The recent Technical Specification CEN/TS 19101:2022, "Design of fibre-polymer composite structures", provides moisture conversion factors for fibre-reinforced polymer (FRP) composites that were defined from data available in the literature. However, such data was found to present several limitations, namely (i) high scatter, (ii) few results for long-term exposure, and (iii) gaps for several combinations of constituent materials and manufacturing methods. In particular, very few data is available for relatively thick vacuum infused composites. This paper presents an ongoing study of the effects of hygrothermal exposure on the behaviour of glass-FRP (GFRP) composites. Relatively thick (6.5 mm) laminates were produced by vacuum infusion using (i) isophthalic polyester and (ii) vinyl ester. The laminates were immersed in water at different temperatures (20 °C, 40 °C and 60 °C) for 3, 6 and 12 months (data will be obtained for longer periods), during which water uptake measurements were conducted at regular intervals. For each period, the performance of the laminates was assessed through dynamic mechanical analysis (DMA), and tensile, compressive, and in-plane shear tests. Based on the mechanical test results, Arrhenius-type degradation models were developed and 50-year predictions were derived, later compared with the design provisions set out in CEN/TS 19101:2022.

1. Introduction

Fibre-reinforced polymer (FRP) composites offer several advantages for civil engineering applications, including lightness, high specific strength and stiffness, high resistance to corrosion and good performance under harsh environments [1,2]. Consequently, their application in the construction industry has increased in recent decades [3]. Despite their enhanced durability in service conditions, FRP composites may be susceptible to deterioration when exposed to different environmental agents, which can result in a reduction in thermomechanical and mechanical properties. These agents, acting individually or combined, include moisture [4,5], chemicals [6], ultraviolet radiation [7], thermal effects [8], thermal cycles [9], and freeze-thaw cycles [10].

Among the aformentioned environmental agents, moisture may be particularly harmful, as it can cause significant physical and chemical degradation, especially at elevated temperatures [4,5]. The physical degradation due to moisture involves phenomena such as plasticization, swelling and relaxation, and is

generally reversible upon drying. Irreversible chemical degradation mainly involves hydrolysis of the polymer matrix[11,12]. Moisture can also cause damage to the fibres and to the fibre-matrix interphace [13,14].

Several previous studies have investigated the effects of moisture exposure on the mechanical and thermomechanical properties of FRP composites [4,5]. However, several gaps exist in the literature, as noted in the test data survey that was carried out to derive a moisture conversion factor for the European Technical Specification CEN/TS 19101:2022 [5]. The following limitations in available data were then identified: (i) the FRP laminates used in previous studies are usually thinner (<4 mm) than those required for civil structural applications; (ii) few data is available for vacuum infused composites, dispite their relevance for construction; (iii) literature also lacks comprehensive comparative studies between different resin systems; (iv) the available data is often scattered and inconsistent; (v) most studies only address limited properties and short-term exposure. As a consequence, robust and validated degradation models and comprehensive design guidelines are not yet available. Addressing these literature gaps is very important to provide a solid ground for end users and engineers to make informed decisions regarding the use of FRP composites in construction and, thus, to promote the full utilization of their potential. The first step in that path is to properly and systematically measure the degradation of FRP composites exposed to different ageing conditions, including moisture.

In this context, this paper presents the results of an ongoing study about the hygrothermal durability of relatively thick glass-FRP (GFRP) composites produced by vacuum infusion using vinyl ester (VE) and unsaturated polyester (UP) resins. Both composite laminates were immersed in water at three temperatures for up to 12 months. After predetermined ageing periods, the degradation of their thermomechanical and mechanical properties was evaluated through DMA and tensile, compressive and in-plane shear tests. Additionally, the test results were used to develop Arrhenius-based models to predict the retention of selected mechanical properties after 50 years.

2. Experimental program

2.1. Materials

GFRP laminates were produced by vacuum infusion as large plates (5000 mm × 1250 mm) with a nominal thickness of 6.5 mm and subsequently cut into smaller plates with dimensions of 700 mm × 250 mm. The GFRP laminates comprise 14 layers of glass fibres (volume fraction of ~57%) and two different resin systems: unsaturated polyester (GFRP-UP) and vinyl ester (GFRP-VE). Both types of composite laminates have the same fibre architecture, thus enabling the direct comparison between them: eight layers of unidirectional fabrics (0°, 625 g/m^2), four quadriaxial fabrics (0°/+45°/90°/-45°, 835 g/m^2), and two outer layers of chopped strand mat (CSM, 300 g/m^2). Following production, both types of composite laminates were post-cured at 80 °C for a period of 12 hours. Polylite 720-691 resin (50-54% isophthalic polyester and 46-50% styrene) was used to produce the GFRP laminate with unsaturated polyester (GFRP-UP); this resin mixture included 1.5% (wt.%) of methyl ethyl ketone peroxide (MEKP, Ketanox B180). The resin used for producing the vinyl ester-based composites (GFRP-VE) was Derakane 411-200 (52% epoxy vinyl ester resin and 48% styrene), and this resin mixture included 1.5% (wt.%) of MEKP (Ketanox B180), 0.025% (wt.%) of dimethylaniline, 0.3% (wt.%) of cobalt octoate (with 1% cobalt), and 0.025% (wt.%) of 2,4-pentanodione.

2.2. Ageing procedure

The GFRP plates were immersed in demineralized water at three different temperatures of 20 °C, 40 °C and 60 °C. Water tanks with dimensions of 1000 mm × 600 mm × 500 mm were used, equipped with an electrical heater and controller to maintain the temperature at the desired level. To avoid the ingress of water along the lateral edges of the GFRP plates, they were coated with an epoxy resin (Icosit K-101 N), which promoted one-dimensional water diffusion through the composite laminates.

2.3. Test program

The initial characterization involved a series of thermomechanical (DMA) and mechanical tests, including tensile, compressive, and in-plane shear. Following a period of 3, 6 and 12 months (additional tests are

planned up to 240 months), two plates of each type of composite (GFRP-UP and GFRP-VE) were removed from the water tanks and subjected to similar tests in both wet and dry conditions. For the wet condition, specimens were tested within a short period after removal from the tanks and cutting to the appropriate size. For the dry condition, tests were carried out after 1.5 to 2 months of conditioning at room temperature, when constant mass was reached (mass change lower than 0.1% in 24 hours).

2.3.1. Thermomechanical tests

The DMA was conducted using a TA Instrument Q800 Dynamic Mechanical Analyser, in accordance with the recommendations of ISO 6721-1,5:2019. Specimens with dimensions of 60 mm × 10 mm × 4 mm (reduced thickness) were heated from 25 °C to 200 °C at a rate of 2 °C/min. During the tests, specimens were subjected to sinusoidal loading in a dual cantilever system, at a frequency of 1 Hz, with a strain amplitude of 15 μm. The glass transition temperature (T_g) was determined from the onset of the decay of the storage modulus (E') curve.

2.3.2. Mechanical tests

The tensile and compressive tests were performed according to ISO 527-4:2021 and ISO 14126:1999, respectively. Test specimens had rectangular shape, with dimensions of 300 mm × 25 mm × 6.5 mm (tensile tests) and 153 mm × 25 mm × 6.5 mm (compressive tests). Tests were performed in a universal testing machine (UTM) Instron 5989 (capacity of 600 kN), under displacement control. A video extensometer (VE, camera FLIR BFS-U3-51S5M-C; lens Fujinon HF25SA-1; software from MatchID—v2022.2) was used to measure axial strains.

The in-plane (IP) shear tests were carried out according to ASTM D5379/D5379M-19. Test specimens had rectangular shape, with dimensions of 76 mm × 19 mm, and comprised V-shaped notches at the mid-section (on both sides). Tests were performed in a UTM Instron 5982 (capacity of 100 kN), under displacement control. Strains in the notch region were also measured with the same video extensometer.

2.3.3. Mass uptake measurements

Mass uptake measurements were done in specimens immersed in demineralized water at the three different test temperatures (20 °C, 40 °C and 60 °C), following recommendations set in ASTM D5229/D5229-20 and ISO 62:1999. Squared shaped specimens of 60 mm × 60 mm were used and their lateral edges were coated with the above-mentioned epoxy resin. Prior to immersion, the specimens were dried at 40 °C until they reached constant mass (mass change lower than ± 1 mg in 24 hours).

3. Results and discussion

3.1. Initial characterization

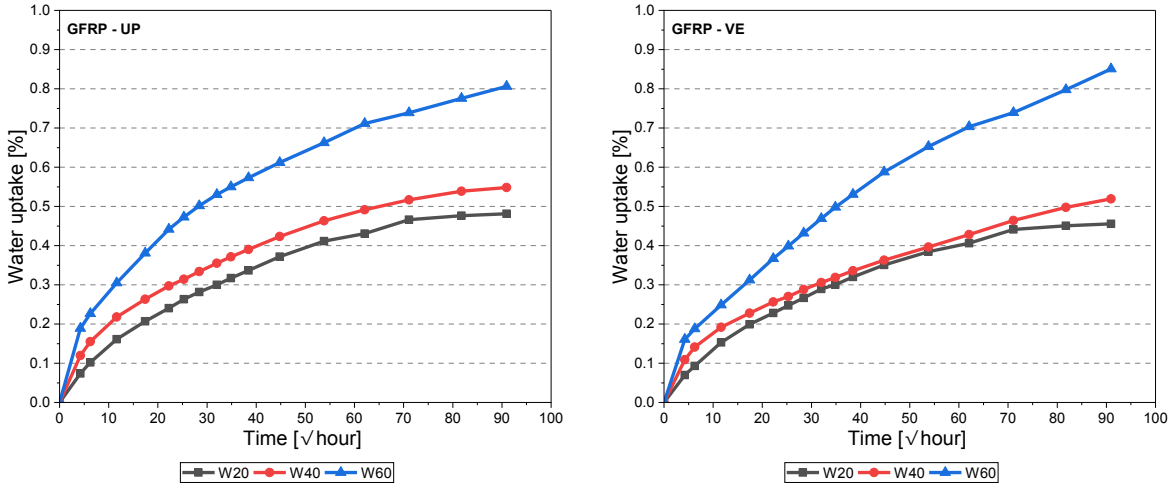

Table 1 presents the initial mechanical and thermomechanical properties of both composites, which were obtained along the main fibre reinforcement direction. For most mechanical properties, there are no significant differences between the two composites, produced with the alternative resin systems. However, with the exception of tensile strength, the mechanical properties of GFRP-VE are slightly higher, particularly in terms of compressive strength. This can be attributed to the superior performance of the VE resin in comparison to the UP resin. Also the T_g of GFRP-VE is significantly higher than that of GFRP-UP.

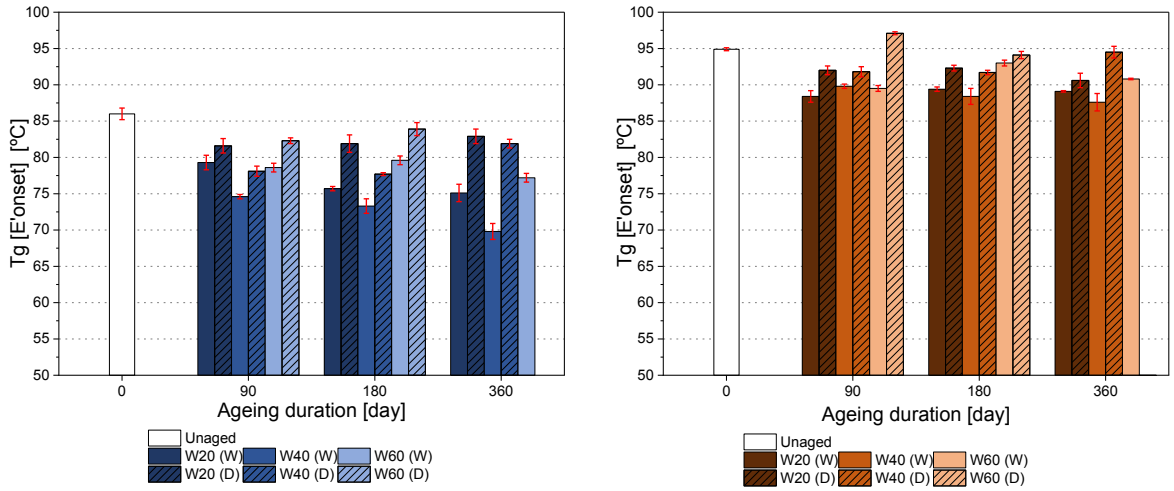
Table 1. Initial properties of GFRP composites with UP and VE resins (average ± standard deviation)

Properties	GFRP-UP	GFRP-VE
Tensile strength, σ_t [MPa]	844 ± 30	811 ± 22
Tensile modulus, E_t [GPa]	33.1 ± 0.5	35.1 ± 1.5
Compressive strength, σ_c [MPa]	470 ± 33	556 ± 45
Compressive modulus, E_c [GPa]	35.8 ± 1.9	39.2 ± 2.0
In-plane shear strength, τ [MPa]	148 ± 4	158 ± 3
In-plane shear modulus, G [GPa]	5.0 ± 0.4	5.4 ± 0.6
Glass transition temperature, T_g [°C]	86.0 ± 0.8	95.0 ± 0.2



3.2. Water uptake

Figures 1a) and 1b) present the water uptake of GFRP-UP and GFRP-VE composites over the square root of time, respectively, which prompt the following comments: (i) for both composites, as expected, mass increased with increasing immersion temperature, especially from 40 °C to 60 °C; (ii) at 20 °C and 40 °C, GFRP-VE absorbed slightly less water than GFRP-UP, while at 60 °C the opposite trend was observed; (iii) after 345 days of ageing, the water uptake curves of GFRP-UP and GFRP-VE for 20 °C are approaching a plateau (0.48% and 0.46%, respectively), while for 40 °C and 60 °C they are still increasing. Overall, the performance of both composites in terms of water uptake is fairly similar.

a) b)

Figure 1. Water uptake: a) GFRP-UP, and b) GFRP-VE

a) b)

Figure 2. Changes in T_g: a) GFRP-UP, and b) GFRP-VE (tests for W60(D) not yet completed) (error bars correspond to one standard deviation).

3.3. Glass transition temperature

Figures 2a) and 2b) ilustrate the impact of hygrothermal ageing on the T_g of GFRP-UP and GFRP-VE. In the aforementioned figure, as well as in subsequent ones, the nomenclature W20 (W) and W20 (D) represents the results of tests conducted in water at 20 °C (W20) in either wet (W) and dry (D) conditions. Other codes have similar meanings for the corresponding temperatures. Figure 5 shows that: (i) for both composites, there was an overall reduction of T_g; (ii) the reduction in T_g was generally more pronounced for GFRP-UP than for GFRP-VE, reflecting the higher hygrothermal stability of the vinyl ester resin compared to its polyester counterpart; (iii) upon drying, a moderate to significant recovery in T_g occurred in both composites (more pronounced in

GFRP-UP), which can be attributed to the reversibility of physical degradation due to plasticization; (iv) increasing immersion temperature and duration did not necessarily result in an increasing reduction of T_g, which may be partly due to competing post-curing of the resins. In fact, the maximum reduction in T_g (16.2 °C) was observed for GFRP-UP after 12 months of immersion at 40 °C (in wet condition), while the lowest reduction (2.1 °C) was observed after 6 months of immersion at 60 °C (in dry condition); the largest reduction in T_g occurred during the first 3 months of immersion, after which only a slight variation was observed. For GFRP-VE, the highest reduction in T_g (7.3 °C) occurred after 12 months of immersion at 40 °C (also in wet condition), while an increase in T_g (2.2 °C) was observed after 3 monhts of immersion at 60 °C (in dry condition). For most immersion temperatures and conditions, the T_g exhibited a tendency to stabilize after 3 months of ageing.

3.4. Mechanical behaviour

3.4.1. Tensile strength

Figures 3a) and 3b) depict the impact of hygrothermal ageing on the tensile strength of GFRP-UP and GFRP-VE composites, respectively. Figure 3 shows that, for both composites: (i) the tensile strength exhibited a general decrease due to water immersion, (ii) the magnitude of such decrease was amplified by immersion temperatures, and (iii) the highest reductions occurred in wet condition, indicateting that some degradation was reversed when tested in a dry condition. This phenomenon aligns with the observations made regarding the T_g results. For immersion at 20 °C, the reduction in tensile strength was low and after 12 months it had not yet stabilized. At higher immersion temperatures, the reduction in tensile strength was significantly higher, most of it occurring during the first 6 months, after which it appears to be stabilizing (especially for 60 °C). For immersion temperatures of 20 °C and 40 °C, the GFRP-UP exhibited inferior performance relative to its GFRP-VE counterpart, while for 60 °C the trend was opposite (in the water uptake tests, the relative performance of both composites was similar). The lowest tensile strength retentions for the GFRP-UP and GFRP-VE composites were observed after 6 and 12 months of immersion at 60 °C (wet condition), with values of 62% and 54%, respectively; after 12 months of immersion at 20 °C, those figures were 93% and 98%.

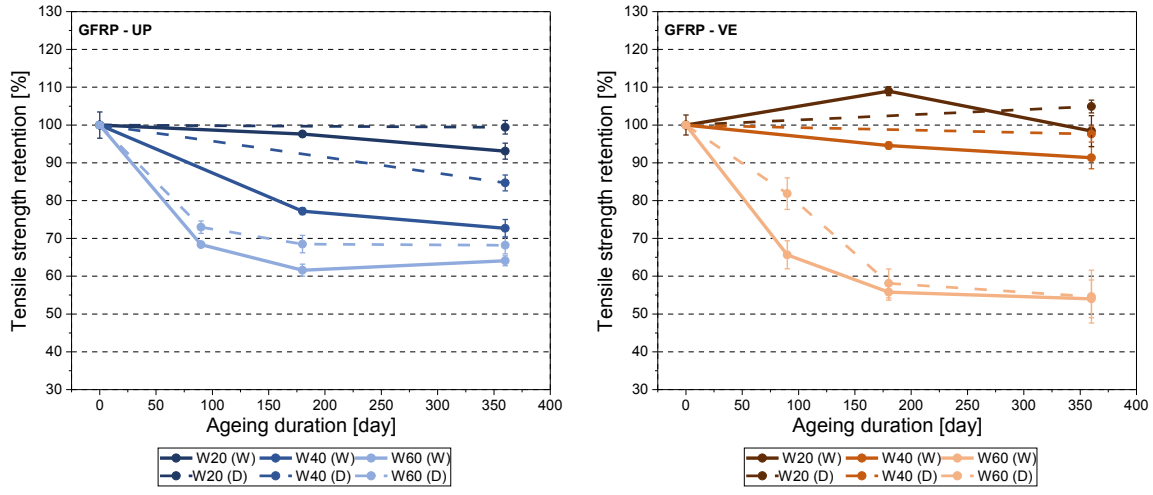


Figure 3. Tensile strength retention: a) GFRP-UP, and b) GFRP-VE (error bars correspond to one coefficient of variation (COV); some results for 3 months and 6 months of ageing are not yet available).

3.4.2. Compressive strength

Figures 4a) and 4b) illustrate the compressive strength retention of GFRP-UP and GFRP-VE composites, respectively, due to hygrothermal ageing. The impact of water immersion on compressive strength was found to be higher than that on tensile strength. This is attributed to the fact that the former property is more matrix-dominated, while the latter is more fibre-dominated. Although the scatter in compressive strength results was relatively high (due to the inherent variability of this property), similar variation trends to those reported above for tensile strength could be observed: (i) higher reductions for

higher water immersion temperature and for wet condition; (ii) partial reversibility of the degradation upon drying; (iii) larger reductions during the initial periods of ageing, especially at 60 °C; (iv) better performance of GFRP-VE for immersion at 20 °C and 40 °C and worse performance at 60 °C. The lowest compressive strength retention in the GFRP-UP and GFRP-VE composites occurred after 12 months of immersion at 60 °C (wet condition), with value of 45% and 39%, respectively; at 20 °C, those figures were 80% and 87%.

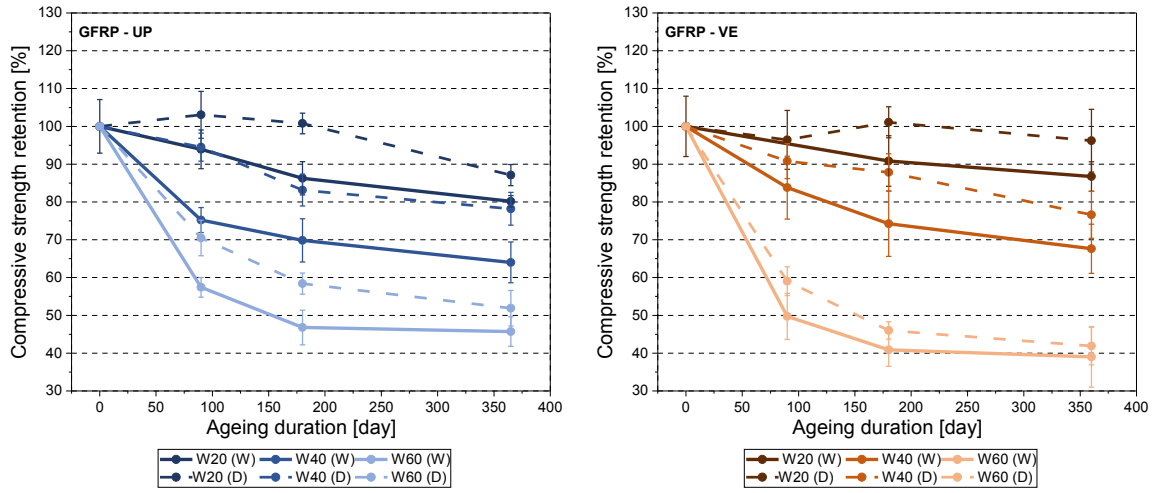

Figure 4. Compressive strength retention: a) GFRP-UP, and b) GFRP-VE (error bars correspond to one COV).

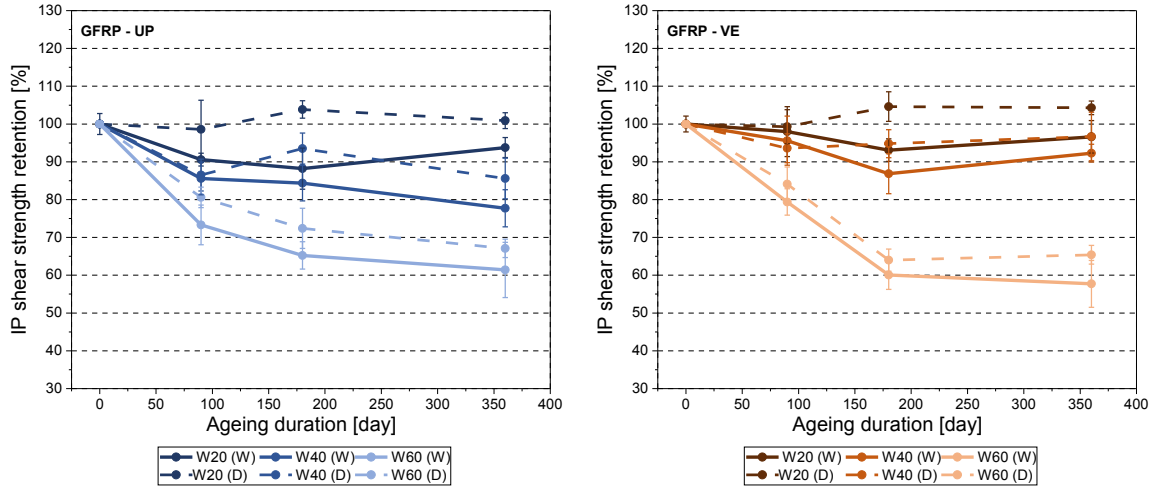
3.4.3. In-plane shear strength

Figures 5a) and 5b) present the changes in IP shear strength due to hygrothermal ageing. The overall variation trends are similar to those reported above for tensile and compressive strengths, with the IP shear strength presenting an intermediate reduction magnitude compared to those properties. As mentioned, the fibre architecture of the tested composites included quadriaxial fabrics, with significant fibre reinforcement at ±45º orientations, which resulted in a major influence of the fibre reinforcement in IP shear strength. This explains why this property was less affected by hygrothermal ageing than compressive strength. The lowest IP shear strength retention in the GFRP-UP and GFRP-VE composites occurred after 12 months of immersion at 60 °C (wet condition), with values of 61% and 58%, respectively; at 20 °C, those figures were much higher, respectively 94% and 97%.



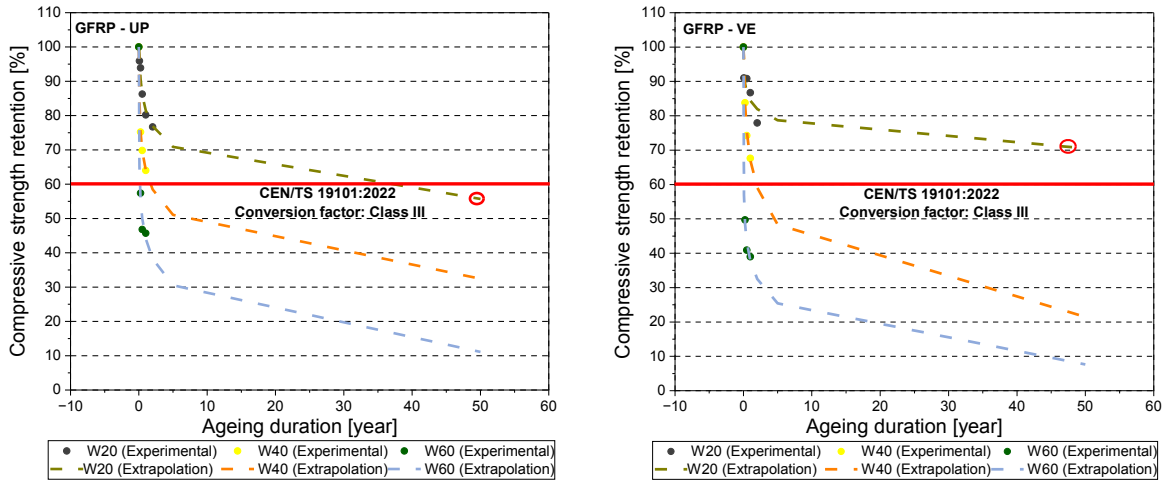


Figure 5. IP strength retention: a) GFRP-UP, and b) GFRP-VE (error bars correspond to one COV).

4. Arrhenius type degradation models

Figure 6 presents the Arrhenius-type degradation models developed for compressive strength (since this property presented the greatest depression in retention). The models were obtained by plotting property retention *versus* ageing duration (log scale) and applying curve fitting to the test data, i.e., the procedure detailed in Bank *et. al.* [15]. Using these models, 50-year predictions (extrapolations) were obtained and, for immersion at 20 °C, they (marked in red cicrcle) were compared with the conversion factor provided in CEN/TS 19101:2022. The compressive strength retention of GFRP-UP and GFRP-VE composites after 50 years was found to be 56% and 71%, respectively. These values are only slightly lower and moderately higher than the 60% retention set in CEN/TS 19101:2022 for the corresponding exposure class III (marked by a red line in Figure 6), which thus seems to cover the vacuum infused laminates used in this study.

a) b)

Figure 6. Compressive strength retention prediction: a) GFRP-UP, and b) GFRP-VE.

5. Concluding remarks

This paper presents the results of an ongoing study on the hygrothermal durability of GFRP composites produced by vacuum infusion using isophthalic polyester (GFRP-UP) and vinylester (GFRP-VE).

The results obtained so far indicate that both GFRP composites exhibited comparable performance in terms of water uptake, with slightly higher water uptake observed in GFRP-UP at 20 °C and 40 °C, and in GFRP-VE at 60 °C. A slight to moderate reduction in the glass transition temperature (T_g) was observed, with a more pronounced effect in GFRP-UP. However, upon drying, this reduction was partly recovered. For longer ageing periods and higher immersion temperatures, recovery of T_g was also observed, which may be attributed to post-curing phenomena.

The mechanical properties exhibited moderate to significant reductions, which varied according to the immersion temperature and duration, the test condition (wet or dry), and the type of resin system. Most of the degradation occurred during the initial stages of ageing, especially for higher immersion temperatures. As expected, the extent of the degradation consistently increased with the immersion temperature, e.g. the maximum reduction of compressive strength of GFRP-UP and GFRP-VE was by 55% and 61%, respectively, after 12 months of ageing at 60 °C and, upon drying, there was also significant property recovery, indicating that a part of the degradation was physical. The magnitude of the reduction in mechanical properties was found to be strongly influenced by the corresponding contribution of the fibres and polymer matrix, e.g. maximum observed reduction in tensile and compressive strengths of GFRP-VE were 46% and 61%, respectively, while the in-plane shear strength (in this case, with a relevant contribution of off-axis fibres) presented an intermediate level of degradation for most cases. In general, the GFRP-VE composite exhibited superior performance relative to GFRP-UP counterpart, namely at 20 °C and 40 °C.

Arrenhius-type models were developed based on the experimental results. These models provided 50-year compressive strength retention following water immersion at 20 °C of 56% and 71% respectively for GFRP-UP and GFRP-VE. These predicted (extrapolated) strength retentions are respectively slightly lower and moderately higher than the 60% retention set in CEN/TS 19101:2022 for exposure class III, which thus seems to cover the vacuum infused laminates used in this study.

Abstract
Fibre-reinforced polymer (FRP) composites exhibit high specific strength, lightness, high corrosion resistance, and have relatively low maintenance needs during service life, which has promoted their use in civil engineering structures. However, in the existing literature, there is limited data about the effects of dry thermal cycles (i.e., without moisture) on the degradation of FRP composites, namely those produced by vacuum infusion. To address this issue, this paper presents the findings of a study on the impact of thermal cycles on the mechanical (tensile, compression, flexure, in-plane shear and interlaminar shear) and thermomechanical (glass transition temperature) behavior of relatively thick (6.5 mm) glass-FRP (GFRP) laminates, produced by vacuum infusion, with unsaturated polyester and vinyl ester resins. The laminates were subjected to 100, 200 and 300 thermal cycles at temperatures ranging from -15 °C to 60 °C, each cycle lasting 12 hours. After each period, different tests were conducted to assess the changes in the above-mentioned mechanical and thermomechanical properties of the GFRP laminates caused by the exposure to thermal cycles. The results obtained show that the thermal cycles applied in this study caused only slight to moderate degradation of the properties of the vacuum infused GFRP laminates.

1. Introduction

The use of fibre reinforced polymer (FRP) composites in construction industry has increased over the last three decades [1], due to the advantages they provide over traditional materials, such as lightness, high specific strength and stiffness, and resistance to corrosion [2,3]. However, during their service life, FRP structures are exposed to different environmental agents that can be detrimental to them, namely moisture [4] and chemicals [5], ultraviolet radiation [6] and thermal effects [7], the latter encompassing thermal cycles [8] and, when combined with moisture, freeze-thaw cycles [9]. A thermal cycle refers to the (cyclic) change in temperature, with a given minimum and maximum temperature whose the magnitude depends on the climatic zone in which the FRP structure is located and on the specific exposure conditions for each structural component. As summarized below, thermal cycles can have different effects on FRP composites, both positive and negative.

In what concerns the exposure to the extreme temperatures of a given thermal cycle, at higher temperatures, as the glass transition temperature (T_g) of FRP composites is approached and eventually exceeded, they soften, and their mechanical properties are significantly reduced [12]. However, exposure to elevated temperatures and subsequent cooling can also promote post-cure phenomena, improving the mechanical properties and

increasing the T_g [13]. At subzero temperatures (below 0 °C), the polymer matrix hardens, causing microcracking [10]. Glass fibres and polymer matrices have different thermal expansion coefficients (e.g., 5×10^{-6} K^{-1} for E-glass and 30-200$\times10^{-6}$ K^{-1} and 30-50$\times10^{-6}$ K^{-1} for unsaturated polyester and vinyl ester resins, respectively [10,11]). Therefore, thermal cycles can cause fibre-matrix debonding due to the mismatch in expansion and contraction between the fibre reinforcement and the polymeric matrix. When the material repeatedly expands and contracts with varying temperature, cumulative damage can occur.

Several researchers have studied the effect of thermal cycles on FRP composites, namely Sousa *et al.* (2014), Grammatikos *et al*. (2016), etc. However, the available information on the effect of thermal cycles on FRP composites has several gaps: (i) the number of studies reported in the literature is still quite limited; (ii) most studies refer to FRP composites produced by pultrusion or hand layup, with very scarce data available for vacuum infusion, in spite of its relevance for civil engineering applications; (iii) comparative studies between different resin systems are also very rare, and (iv) most studies only address a limited number of properties. Therefore, an in-depth understanding of the effects of thermal cycles on FRP composites is necessary to promote their safe use in civil engineering structures, which are generally designed for 50 or 100 years.

To address the above-mentioned gaps, this paper presents a study about the effects of thermal cycles on relatively thick glass-FRP (GFPR) composites produced by vacuum infusion using two alternative resin systems, unsaturated polyester (UP) and vinyl ester (VE). Both composite materials were exposed to 300 thermal cycles and, periodically, subjected to various mechanical (tensile, compression, flexure, in-plane shear and interlaminar shear) and thermomechanical (dynamic mechanical analysis, DMA) tests to determine the impact of such exposure on their performance.

2. Experimental program

2.1. Materials

Composite laminates with 6.5 mm of nominal thickness were produced by vacuum infusion as large plates (5000 mm × 1250 mm) and later cut into smaller dimensions (700 mm × 250 mm). The composite laminates were produced using two alternative resin systems: unsaturated polyester (UP) and vinyl ester (VE). To enable a direct comparison of the two resin systems, both composites had similar fibre architecture, which included the following 14 layers of glass fibres: 8 layers of unidirectional fabrics (0°, 625 g/m^2), 4 quadriaxial fabrics (0°/+45°/90°/-45°, 835 g/m^2), and 2 outer layers of chopped strand mat (CSM, 300 g/m^2). This resulted in a fibre volume fraction of ~57%. After production, the composites were post-cured at 80 °C for a period of 12 hours. In the production of unsaturated polyester-based GFRP composites (GFRP-UP), Polylite 720-691 resin (50-54% isophthalic polyester and 46-50% styrene) was used, and this resin mixture included 1.5% (wt.%) of methyl ethyl ketone peroxide (MEKP, Ketanox B180). For vinyl ester-based GFRP composites (GFRP-VE), Derakane 411-200 (52% epoxy vinyl ester resin and 48% styrene) was used, and this resin mixture included 1.5% (wt.%) of MEKP (Ketanox B180), 0.025% (wt.%) of dimethylaniline, 0.3% (wt.%) of cobalt octoate (with 1% cobalt), and 0.025% (wt.%) of 2,4-pentanodione.

2.2. Ageing procedure

The ageing protocol used in this study was developed based on EN 13687-4:2002 and it considered the thermal variation applicable to various outdoor environments, i.e., covering a wide range of climates, for instance, in Lisbon (Portugal), Oslo (Norway) and Kuwait City (Kuwait), extreme negative air temperatures were recorded as -0.9 °C, -26.0 °C and -4.0 °C, respectively and extreme positive air temperatures were recorded as 44.0 °C, 34.6 °C and 52.1 °C, respectively. The temperature range of 75 °C (-15 °C to 60 °C) considered in this study is considerably higher, covering also the effects of temperature increase due to direct exposure to solar radiation. The thermal cycles, which were applied in a controlled environmental chamber (Aralab Testa CT 1000 EP20) are defined in Figure 1. Each cycle had a total duration of 12 hours, including (i) 1 hour of cooling from room temperature to -15 °C, (ii) 5 hours at -15 °C, (iii) 1 hour of heating from -15 °C to 60 °C (average rate of 1.25 °C/min), and (iv) 5 hours at 60 °C, with relative humidity of 50%. The composite laminates were subjected to a total of 300 thermal cycles. After each 100 cycles, batches of composite laminates were removed from the chamber and changes in their properties were assessed.

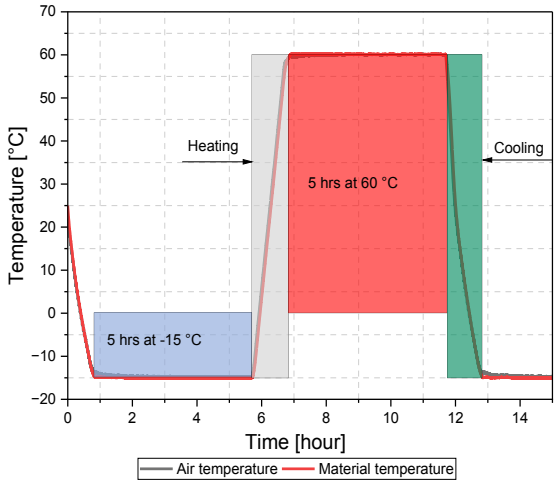

Figure 1. Phases of each thermal cycle

2.3. Test program

The test program first included tests on the unaged GFRP composites to evaluate different mechanical (tensile, compressive, flexural, in-plane shear and interlaminar shear) and thermomechanical (glass transition temperature, T_g) properties. After each 100 cycles, similar tests were repeated to assess the effects of thermal cycles in terms of retention of those properties (percentage of the initial values). For both composites, the mechanical and thermomechanical properties were determined along the longitudinal direction.

2.3.1. Thermomechanical tests

A dynamic mechanical analyser, model Q800 DMA (TA Instruments), was used to perform DMA tests, following the recommendations of the ISO 6721-1,5:2019. Each specimen had dimensions of 60 mm × 10 mm × 4 mm (thickness). During the tests, temperature ranged from 25 °C to 200 °C at a rate of 2 °C/min. Load was applied sinusoidally in a dual cantilever configuration, at a frequency of 1 Hz, with a strain amplitude of 15 µm. T_g was determined from the onset of the decay of the storage modulus (E') curve.

2.3.2. Mechanical tests

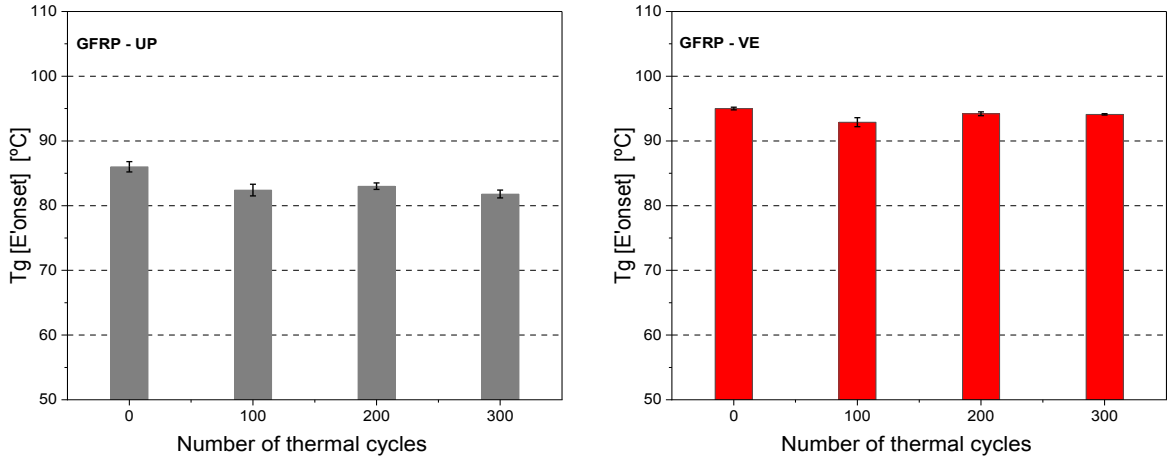
Tensile and compressive tests were performed in a universal testing machine (UTM) Instron 5989 (capacity of 600 kN), under displacement control, according to ISO 527-4:2021 and ISO 14126:1999, respectively. For both types of tests, specimens had rectangular shape, with dimensions of 300 mm × 25 mm × 6.5 mm (tension) and 153 mm × 25 mm × 6.5 mm (compression). A video extensometer (camera FLIR BFS-U3-51S5M-C; lens Fujinon HF25SA-1; software from MatchID—v2022.2) was used to measure axial strains.

Flexural, in-plane (IP) shear and interlaminar shear tests were carried out according to ISO 14125:1998, ASTM D5379/D5379M-19 and ISO 14130:1997, respectively. Rectangular shaped flexural and interlaminar shear test specimens had dimensions of 195 mm × 15 mm × 6.5 mm and 65 mm × 32.5 mm × 6.5 mm, respectively. Test specimens for in-plane shear tests also had rectangular shape, with dimensions of 76 mm × 19 mm, and comprised V-shaped notches at the mid-section section (on both sides); the main fibre direction was oriented parallel to the notch (i.e. the specimen height). Tests were performed in a UTM Instron 5982 (capacity of 100 kN), under displacement control. In IP shear tests, strains in the notch region were measured with the above-mentioned video extensometer.

3. Results and discussion

3.1. Initial characterization

Table 1 presents the initial properties of both types of composites. For most mechanical properties, differences between the two composites are relatively small. However, in general (except for tensile strength), GFRP-VE showed better performance than GFRP-UP. The most significant differences



between the two composites refer to the compressive strength, which may result from a better performance of the VE resin system compared to its UP counterpart. Also, the glass transition temperature (T_g) of GFRP-VE is significantly higher than that of GFRP-UP.

Table 1. Initial mechanical properties and T_g of GFRP composites with UP and VE resins (average ± standard deviation)

Properties	GFRP-UP	GFRP-VE
Tensile strength, σ_t [MPa]	844 ± 30	811 ± 22
Tensile modulus, E_t [GPa]	33.1 ± 0.5	35.1 ± 1.5
Compressive strength, σ_c [MPa]	470 ± 33	556 ± 45
Compressive modulus, E_c [GPa]	35.8 ± 1.9	39.2 ± 2.0
In-plane shear strength, τ [MPa]	148 ± 4	158 ± 3
In-plane shear modulus, G [GPa]	5.0 ± 0.4	5.4 ± 0.6
Glass transition temperature, T_g [°C]	86.0 ± 0.8	95.0 ± 0.2

3.2. Glass transition temperature

Figures 2a) and 2b) illustrate the changes in T_g for GFRP-UP and GFRP-VE composites, respectively, due to the exposure to thermal cycles (TC). For both composites, TC caused slight reductions in their T_g, with the effect being more pronounced in GFRP-UP than in GFRP-VE. The maximum reductions in T_g were 4.2 °C (after 300 TC) and 2.1 °C (after 100 TC), respectively. In both composites, the highest reduction in T_g occurred during the first 100 TC, followed by a slight further reduction (in the case of GFRP-UP) or recovery (in the case of GFRP-VE). TC were reported to cause similar impact on the T_g of pultruded materials, with reductions of up to 7% for GFRP-UP and 3% for GFRP-VE [8,9].

a) b)

Figure 2. Changes in T_g: a) GFRP-UP, and b) GFRP-VE (error bars correspond to one standard deviation).

3.3. Mechanical behaviour

3.3.1. Tensile strength

Figures 3a) and 3b) present the variation of tensile strength for GFRP-UP and GFRP-VE composites, respectively, as a function of the number of thermal cycles (TC). Looking at these figures, it can be concluded that: (i) TC had no significant detrimental effect on the tensile strength of both composites; (ii) increasing number of TC did not cause a higher reduction in tensile strength; (iii) for GFRP-UP, the lowest retention (96.1%) was observed after 100 TC, which corresponded to a slight decrease in tensile strength (of a similar magnitude to the experimental scatter); in contrast, the tensile strength retention for GFRP-VE did not suffer any reduction; (iv) after 300 TC, the retention of tensile strength for GFRP-UP and GFRP-VE was 97.3% and 103.6%, respectively. These results indicate that both composites exhibited

excellent tensile strength retention, suggesting that TC did not affect the fibre-matrix bonding. Previous studies on the effects of TC on the tensile strength of pultruded GFRP-UP reported varying responses, including significant increase (by 11%) [8] and decrease (by 13%) [9], while results reported for pultruded GFRP-VE [8] were like those obtained here for vacuum infused materials.

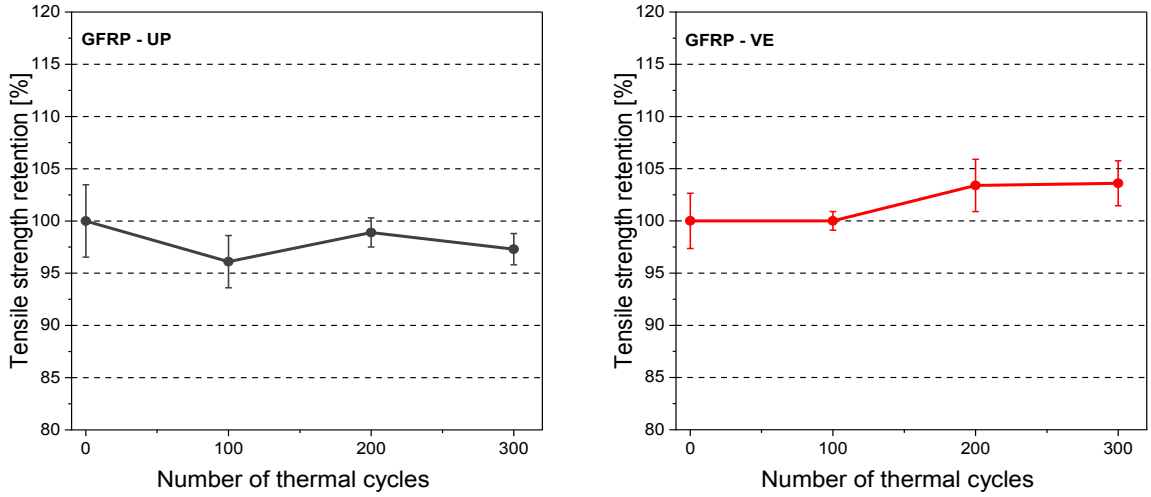


Figure 3. Tensile strength retention: a) GFRP-UP, and b) GFRP-VE (error bars correspond to one coefficient of variation, COV).

3.4.2. Compressive strength

The impact of TC on the compressive strength of GFRP-UP and GFRP-VE composites is depicted in Figure 4. The following trends were identified: (i) similar to tensile strength, the compressive strength was not significantly affected by TC; (ii) in fact, for most series, the composites showed negligible (GFRP-VE) to moderate (GFRP-UP) increase in compressive strength, which could indicate the occurrence of post-curing (although variations were of a similar order of magnitude to the experimental scatter); (iii) the maximum retention for GFRP-UP and GFRP-VE composites was 112.5% (after 300 TC) and 101.5% (after 200 TC); (iv) the lowest retention was 93.9% (after 300 TC) in GFRP-VE – again, this variation is of a similar magnitude to the experimental scatter, therefore it does not necessarily indicate the occurrence of damage such as fibre-matrix debonding or matrix micro cracking. It is worth mentioning that the compressive strength results presented relatively high scatter, due to the (well-known) inherent variability of this property.

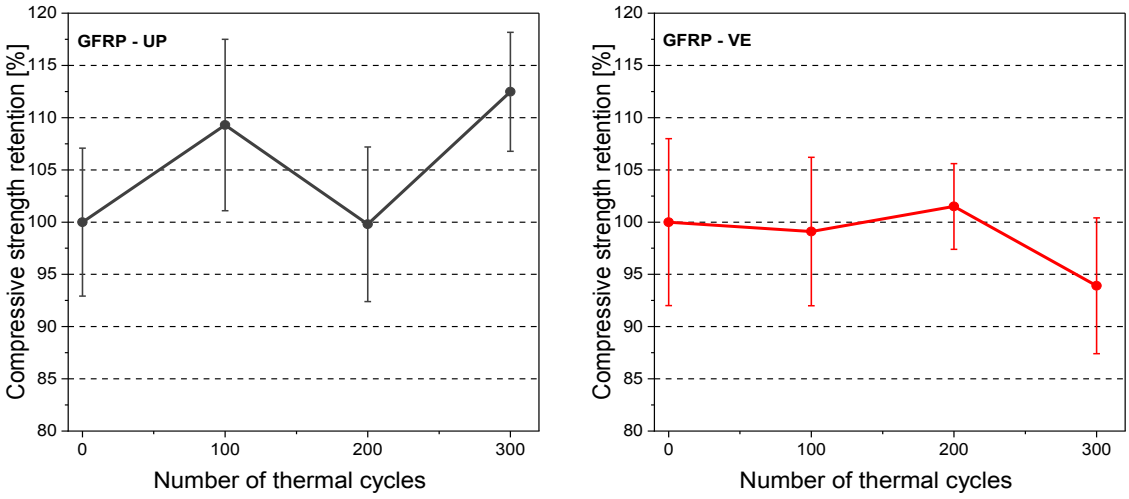

Figure 4. Compressive strength retention: a) GFRP-UP, and b) GFRP-VE (error bars correspond to one COV).

3.4.3. Flexural strength

For all number of cycles, flexural failure started at the upper laminae (in compression). Figures 5a) and 5b) show how the flexural strength varied throughout the ageing protocol, prompting the following remarks: (i) in comparison to tensile and compressive strengths, the flexural strength of GFRP-UP exhibited a more pronounced reduction, while GFRP-VE showed a similar level of retention, with only slight variations; (ii) the lowest retention values for GFRP-UP and GFRP-VE were 91% and 98%, respectively (after 200 TC), indicating that in the former composite some damage may have occurred (fibre-matrix debonding and micro cracking) – scanning electron microscopy (SEM) will be conducted to shade further light on this; (iii) the flexural strength of the composites presented moderate (GFRP-VE) to high (GFRP-UP) scatter; (iv) for both composites, the highest degradation in flexural strength was followed by an increase after 300 TC, with final retentions for GFRP-UP and GFRP-VE of 96% and 102%, respectively. Overall, these figures highlight, once again, a very good performance of both composites when subjected to TC, now in terms of flexural strength retention. Previous studies have reported much higher degradation (up to 16%) in the flexural strength of pultruded materials [8].

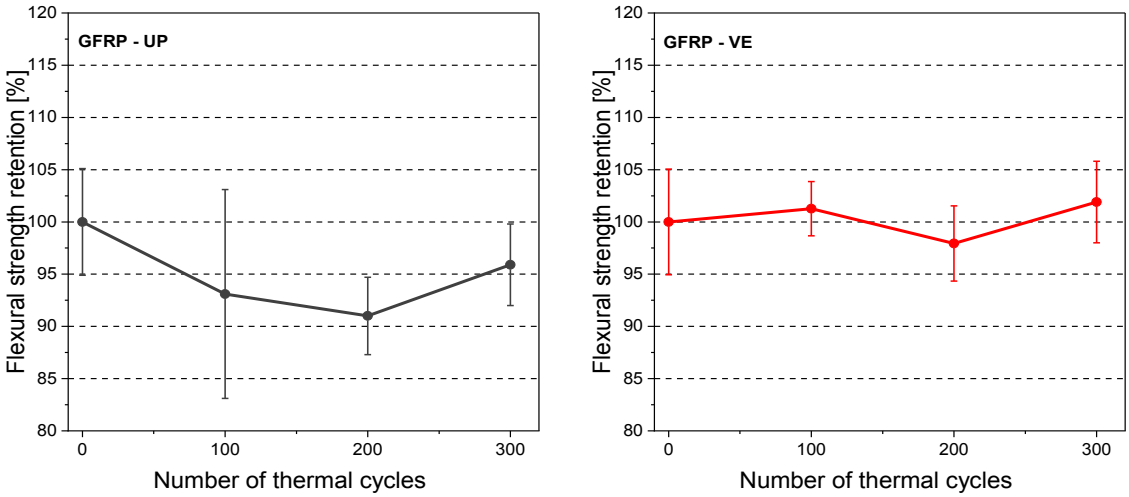

Figure 5. Flexural strength retention: a) GFRP-UP, and b) GFRP-VE (error bars correspond to one COV).

3.4.3. In-plane shear strength

The impact of TC on the in-plane (IP) shear strength is shown in Figures 6a) and 6b) for GFRP-UP and GFRP-VE composites, respectively. Here, the following trends are highlighted, largely similar to those previously mentioned for other properties: (i) both composites exhibited excellent resistance under TC, without relevant degradation of IP shear strength; (ii) retentions above 100% for various series (e.g., 104% after 200 TC for GFRP-UP and 107% after 100 TC for GFRP-VE) may indicate post-curing effects, although variations are often within the same order of magnitude as the experimental scatter. For these tests, it is worth noting the fibre architecture of the composite laminates, which included quadriaxial reinforcing mats, with fibres oriented at ±45°, thus resulting in a more fibre-dominated in-plane shear response. The excellent durability performance in terms of IP shear strength retention indicates that no relevant damage occurred in terms of fibre-matrix adhesion, even after 300 TC, in a manner similar to what was observed for tensile strength retention. Pultruded materials that were previously tested demonstrated excellent performance under exposure to TC, presenting similar retention of IP shear strength to the vacuum infused materials used in the current study [9].

3.4.3. Interlaminar shear strength

The interlaminar shear strength (ILSS) retention of GFRP-UP and GFRP-VE is presented in Figures 7. The ILSS of FRP composites depends on the adhesion at the interfaces between laminae, being also influenced by fibre bridging mechanisms. Figure 7 shows that the ageing protocol had no significant

adverse impact on the ILSS of the two composites. These results, together with the initial values of ILSS, are indicative of good fibre-matrix bonding, not significantly affected by exposure to TC, in agreement with previous observations in terms of tensile and IP shear strength retention. The changes in ILSS of GFRP-UP and GFRP-VE composites throughout the ageing protocol followed the same trend. The maximum retention was observed after 100 TC, with values of 111% and 112% for GFRP-UP and GFRP-VE, respectively. This may indicate the occurrence of post-curing. For both composites, the retention was followed by a continuous reduction until 300 FTC, for which retentions of 100% and 104% were obtained for GFRP-UP and GFRP-VE, respectively.

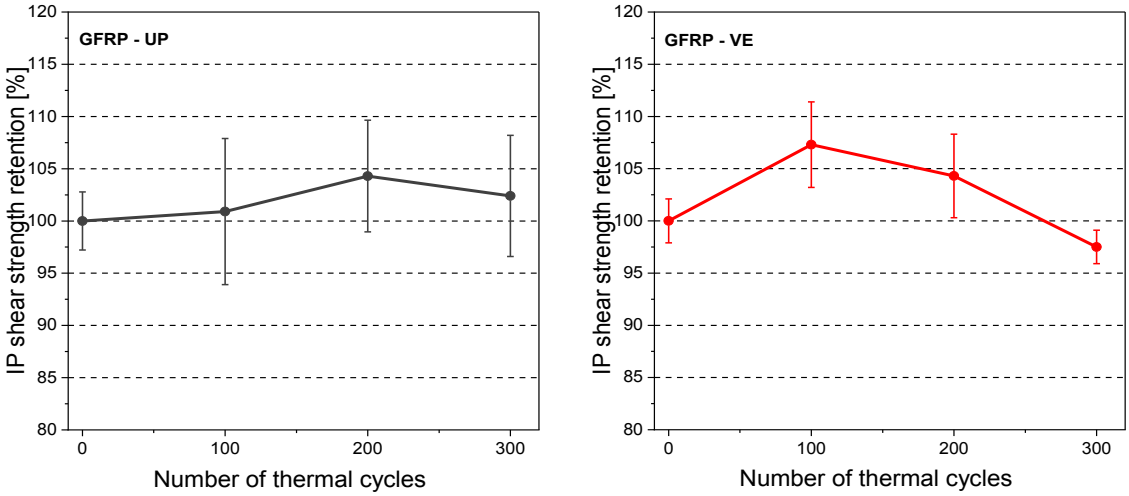

Figure 6. IP shear strength retention: a) GFRP-UP, and b) GFRP-VE (error bars correspond to one COV).

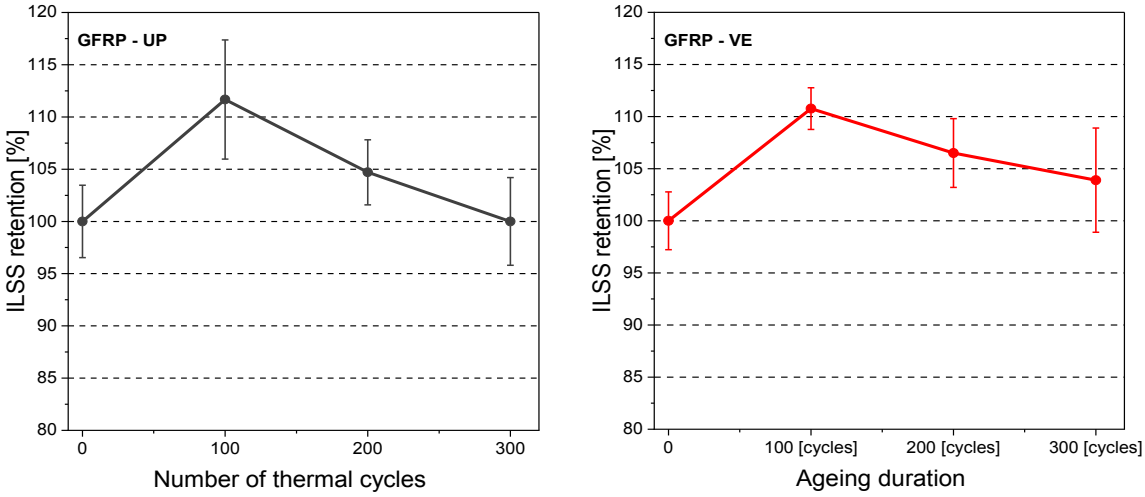

Figure 7. ILSS retention: a) GFRP-UP, and b) GFRP-VE (error bars correspond to one COV).

4. Concluding remarks

This paper presented a study about the effects of thermal cycles on the mechanical (tensile, compressive, flexural, in-plane shear and interlaminar shear strength) and thermomechanical (glass transition temperature, T_g) properties of relatively thick GFRP composites, produced by vacuum infusion, using two alternative resin systems, unsaturated polyester (GFRP-UP) and vinyl ester (GFRP-VE).

The T_g of both composites showed very slight changes due to exposure to thermal cycles, more pronounced in GFRP-UP, which exhibited a reduction from 86.0 °C to 81.8 °C. Most degradation occurred during the first 100 TC, which was followed by slight degradation (in the GFRP-UP) or recovery (in the GFRP-VE).

The mechanical characterization tests showed that exposure to the thermal cycles used in this study did not result in any significant negative impact on the mechanical properties of the composites, apart from flexural strength, for which the lowest retention for GFRP-UP was 91%. For all the other properties, the retentions were close to 100% and, some properties even increased (e.g., maximum ILSS retentions values of 112% and 111% for GFRP-UP and GFRP-VE, respectively), which may indicate the occurrence of post-curing. Overall, both composites presented excellent durability performance in response to thermal cycling, with no evidence of damage at the fibre-matrix interface or matrix micro-cracking. The variations in mechanical properties were not influenced by their inherent nature, which is to say that the properties were not influenced by whether the composite was matrix or fibre-dominated. Also, the two alternative resin systems demonstrated comparable retention of mechanical properties following thermal cycling.

Abstract
Composite materials have gained widespread use in various engineering applications due to their unique combination of high strength, good fatigue resistance, lightweight and tailored properties. The accurate prediction of the mechanical behaviour of composite structures is essential for ensuring their structural integrity and optimal performance. Finite Element Analysis (FEA) is a widely employed numerical method for simulating the mechanical response of these structures. However, the choice of finite element type significantly influences the accuracy and reliability of the predictions.

This research employs a comprehensive validation approach, including experimental testing and benchmarking against numerical solutions, to assess the accuracy of predictions obtained from different finite element types. For this purpose, a wind turbine blade has been numerically and experimentally tested, subjected to flapwise, edgewise, torsional, and a combined flapwise-torsional load case.

The comparison reveals limitations in capturing the torsional behaviour of the wind turbine blade using shell elements, while solid elements perform well. This research provides valuable insights into selecting appropriate finite element types and modelling approaches for accurate and reliable predictions of the behaviour of composite structures commonly used in aerospace, automotive, and civil engineering applications.

1. Introduction

Over the last decades, wind turbines have significantly increased in size and capacity. With the increased capacity, the wind turbine rotor dimensions have also led to greater structural flexibility with its longer and slender wind turbine blades. Consequently, larger deflections and rotations occur, which presents a challenge for the accurate aeroelastic modelling of rotor blade structures. Nevertheless, the accurate and reliable prediction of the structural response of rotor blades is crucial for predicting the power output, stability, load conditions and structural integrity of wind turbines to ensure efficient and safe operation [1].

While current aeroelastic simulation tools for wind turbine applications typically rely on beam element models, higher fidelity models, such as conventional shell elements, continuum shell elements or layered solid elements, are used to discretise these complex curved, twisted and tapered structures made of fibre composite materials during the final structural design process.

2. Methodologies

This study investigates the reliability of different finite element types for predicting the mechanical behaviour of composite structures. The analysis encompasses various modelling techniques and investigates different element types to determine the accuracy of predicting the structural performance of the DTU 12.6m wind turbine blade [2].

Four distinct finite element formulations, namely beam elements, shell elements, continuum shell elements, and layered solid elements, are compared regarding their ability to capture the intricate behaviour of the DTU 12.6m wind turbine blade at full scale and predict its structural response under various loading conditions. The study focuses on quantifying the accuracy of different modelling techniques and element types to predict the blade's displacement and the ability to calculate its torsional performance numerically.

2.1 Numerical models

The numerical discretisation of the geometry of the DTU 12.6m wind turbine blade for all numerical models is derived from a basic structural blade model defined in DTU's in-house software; Blade Modelling Tool (BMT). The BMT allows the generation of different models originating from the same source, where the geometry, material properties and layup information are stored. Thus, a high level of conformity of the different models is ensured.

The commercial finite element package Abaqus/CAE is used as a pre/post-processing software with Abaqus/Standard as a solver [3] for this study. The entire blade geometry was modelled based on input data of 99 blade cross-sections generated by DTU's Wind HawtOpt2 [4] optimisation toolchain defining the aerofoil. These cross-sections describe the outer geometry (aerofoil) of the blade. For the discretisation with conventional shell elements, the aerodynamic blade profile is used as the reference surface, with the shell normal pointing from the reference surface towards the inner part of the blade. Simultaneously, an offset of half of the shell thickness from the shell's mid-surface is applied to ensure that the aerodynamic surface is the reference surface [5]. No offset is chosen for the shear webs, meaning that the geometrical middle of the shear webs is used as the reference surface. For the modelling approaches based on a volumetric geometry representation, cross-section curves are offset from the aerofoil according to the layup definition representing the laminates' thickness [6].

Each cross-section consists of 60 regions/sections to discretise the different cross-sectional properties and possible changes in the layup of the composite structure. The composite layup consists of 6 to 54 plies through the thickness, in which the material properties, layup and ply orientations are assigned automatically by the BMT. Subsequently, the 2D cross sections, defined by their aerofoil and the shear web shape at specific positions along the wind turbine blade span, are connected via a 3D lofting feature, creating a three-dimensional blade structure.

Figure 1 shows an overlay plot of a cross-section of the DTU 12.6m wind turbine blade, where both discretisation methods, volumetric (solid) and conventional shell elements with rendered shell element thickness, are compared. The plot clearly shows that the geometric discretisation only varies in areas where the layup thickness changes due to the different approaches of both methods to discretise the transition between individual sections.

The two beam models considered in the analysis, labelled "Abaqus beam" and "HAWC2", are also generated from the previously described cross-section geometries, from which mass and stiffness properties are calculated using the cross-sectional analysis tool BECAS [7]. Both beam models are based on Timoshenko beam elements – the "Abaqus beam" model uses B31 elements, and the "HAWC2" model uses the structural formulation from DTU Wind's aeroelastic code HAWC2, consisting of linear beam elements in a multibody floating frame of reference formulation [8].

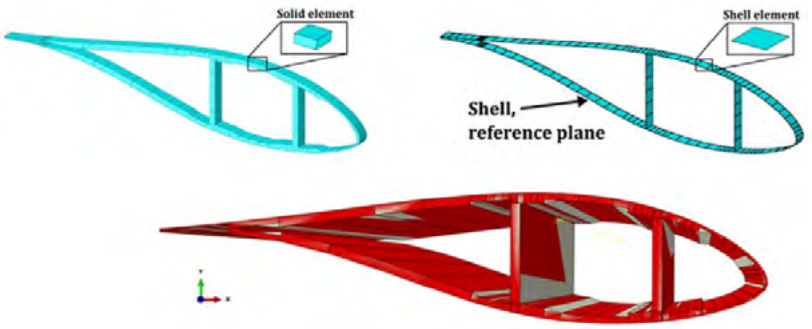

Figure 1. Cross-section of the DTU 12.6m wind turbine blade modelled with volumetric (solid) and conventional shell elements are compared by making an overlay plot of both discretisations (solid elements are grey and red, showing conventional shell elements with rendered thickness).

Figure 2 illustrates how the loads are applied to the volumetric and shell element models using coupling constraints. Here, the loads are applied to a central node (superior node) in the elastic centre calculated according to the computed elastic centre based on the strain gauge data from the Blade Property Extraction (BPE) test referring to SG (strain gauges) – explained in section 2.3 – or based on calculations according to the BECAS model (labelled BECAS) and distributed to coupled inferior nodes discretising the aerofoil geometry as shown in Figure 2. The coupled nodes' width reflects the wooden clamps used in the experimental setup to transmit the loads. The method aligns with previously conducted studies, as mentioned in [9].

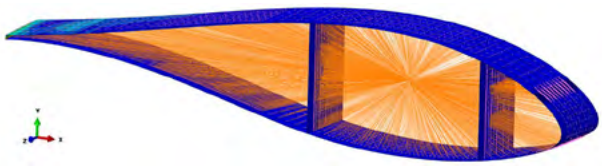

Figure 2. Blade model cross-section slice showing the coupling constraints connected to the shell nodes of the aerofoil with a central superior node in the elastic centre.

2.2 Experimental setup

The full-scale DTU 12.6m wind turbine blade experiments were conducted at the DTU Wind and Energy Systems' Large-Scale Facility at DTU Risø Campus. Here, the wind turbine blade was mounted on the test rig, as illustrated in Figure 3. Free-hanging weights were used to load the turbine blade at different locations depending on which load cases were tested. The weights were applied to metal load saddles with wooden clamps fitting the aerofoil geometry of the individual cross-sections attached to the blade, distributing the load over a cross-section. Load cells, installed between the load saddles and the weights, measured the loads applied to the blade. A digital image correlation (DIC) system based on an ARAMIS stereo camera system [10] was used to detect the translational and rotational displacement field at specific cross-sections along the blade. Moreover, strain gauges were installed to measure strains at specific locations.

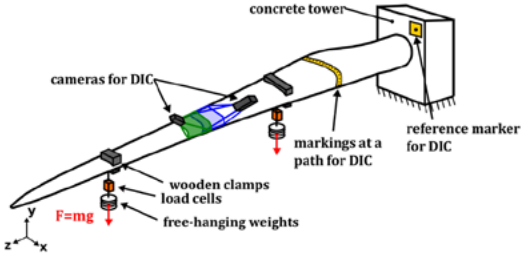

Figure 3. Illustration of the experimental setup for static test of the DTU's 12.6m wind turbine blade in suction-towards-pressure side (STP) loading (taken from [11]).

2.3 Blade property extraction method

At DTU Wind and Energy Systems, a method to determine the blade properties based on photogrammetry and/or strain measurement data has been developed. The blade property extractions (BPE) method allows for calculating the bending stiffness, the orientation of the principal axes, and the elastic centre of the wind turbine blade using standalone and combinations of different load scenarios as shown in Figure 4.

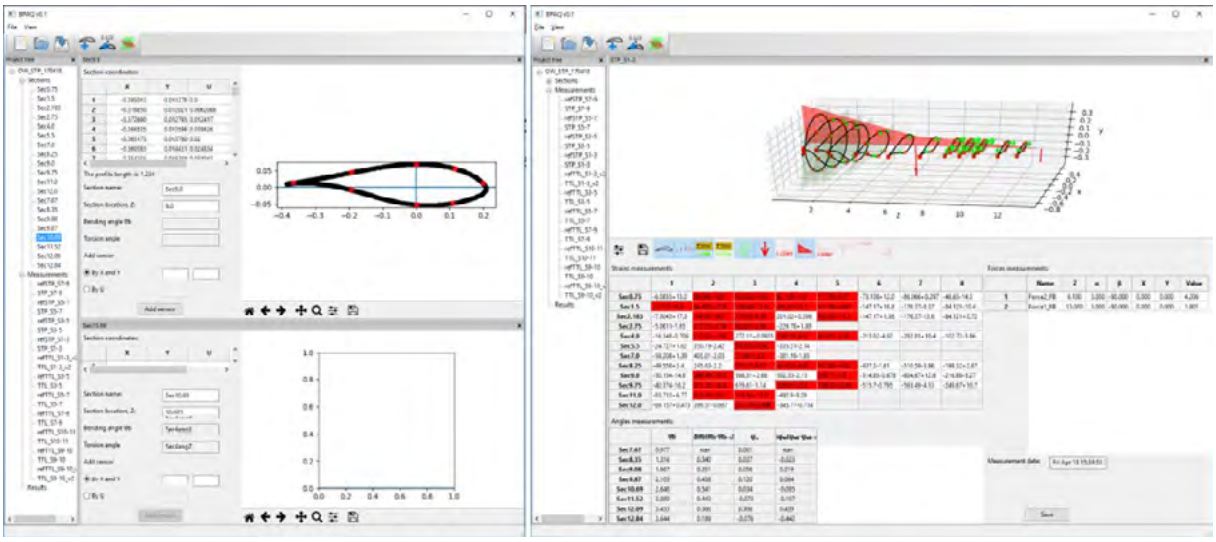

Figure 4. A Python-based code utilises cross-sectional strain measurements/displacement measurements to compute EI_x, EI_y, the principle bending axis's orientation and the elastic centre's location via the least squares method.

2.4 Test cases

A comprehensive validation approach is employed in this research, in which experimental tests are used to assess the accuracy of different finite element types to predict the response of the DTU 12.6m wind turbine blade. Various loading scenarios are considered, including flapwise, edgewise, torsional, and flapwise/torsional and combined flapwise/edgewise load cases. Some of these load cases are illustrated in Figure 5. Moreover, the eigenfrequencies/natural frequencies up to the first 10 natural modes of vibration obtained from an experimental test campaign are compared with numerical simulations of the different fidelity models, to benchmark the level of modelling/discretisation.

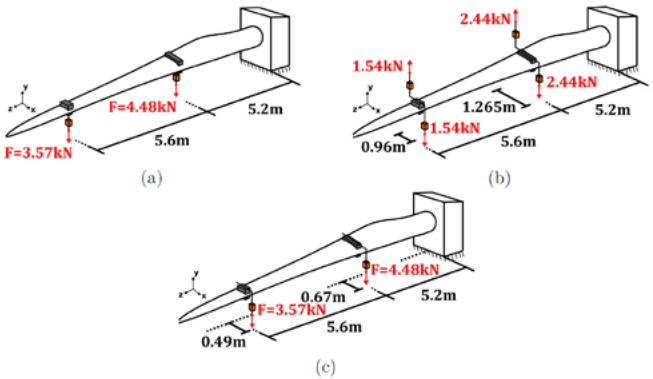

Figure 5. Illustrations of three load cases performed on the 12.6m turbine blade. (a) Suction-towards pressure side (STP) loading. (b) pure torsional (PT) loading. (c) Suction-towards pressure side with additional induced torsional (STP-tor) loading (taken from [11]).

3. Results and discussion

3.1 Blade properties:

Table 1 contains the centre of gravity and total mass of the blade calculated from the different finite element models and obtained experimentally. Here, it is evident that all numerical models deviate from the physical blade. The volumetric models underestimate the mass, whereas the conventional shell models (element type S4 & S8R) overpredict the mass. The reason for the higher mass of the shell model is inherent to the modelling approach, in which the aerodynamic blade profile is used as the top reference surface. Thus, a material overlap exists at the shear web and cap intersections, as well as in the leading and trailing edge regions, which can be visualised when rendering the shell element thickness. The beam elements underestimate the blade mass, partly because these models do not account for adhesive in the bondline of the trailing edge region (Figure 6). Due to the mass distribution difference, the centre of gravity along the blade span deviates. Consequently, the difference in centre of gravity and mass leads to differences in the eigenfrequencies, as shown in Figure 7.

Table 1: Blade properties

Element Type/Model	SC8R	C3D8R	C3D8I	S4	S8R	HAWC2/ BECAS	Abaqus beam	Test
Centre of gravity in m	3.48	3.48	3.48	3.23	3.23	3.379	3.379	3.59
Mass in kg	392.29	392.29	392.29	403.69	403.69	373.05	373.05	397.6

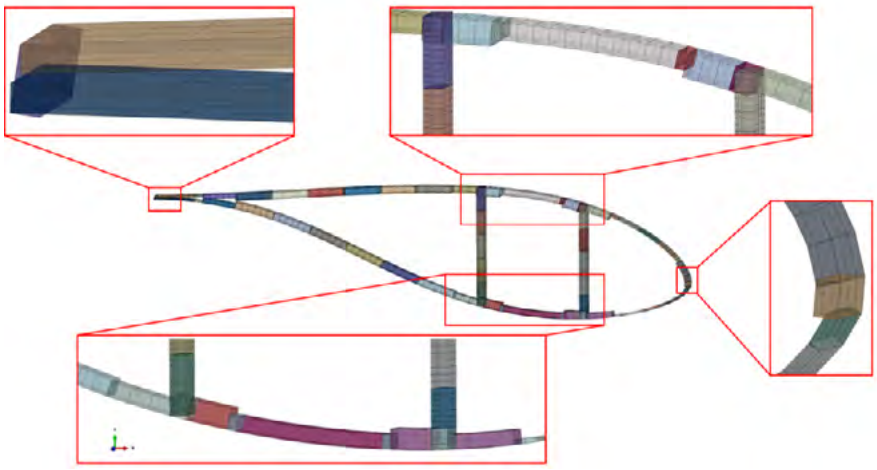

Figure 6. Blade cross-section rending of the shell element thickness visualises the material overlap at the shear web and cap intersections and in the leading and trailing edge regions.

3.2 Eigenfrequencies/natural frequencies

Figure 7 shows the eigenfrequencies of the DTU 12.6m blade based on experimental test data and numerical simulations using different element types for discretisation.

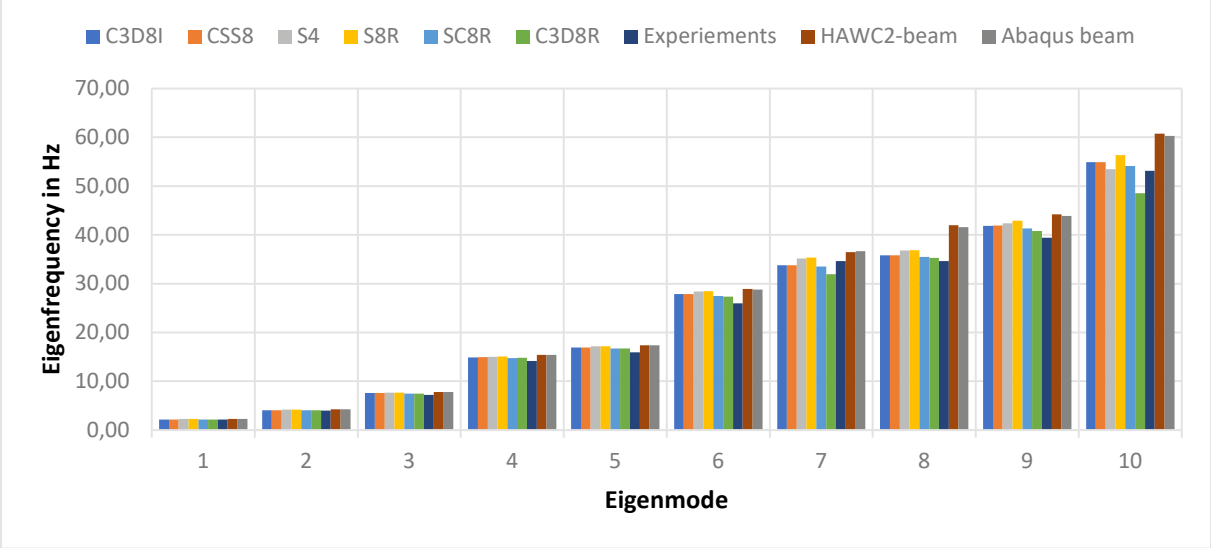

Figure 7. Eigenfrequencies of the DTU 12.6m blade based on experimental test data and numerical simulations using different element types for discretisation. Eigenmodes 1, 3, 5,6,8 and 9 have primarily a flapwise component, whereas mode 2 and partly mode 3 are edgewise mode shapes. Eigenmodes 7 and 10 are torsional modes.

3.3 Test cases

Flapwise, edgewise, torsional, and combined flapwise-torsional and flapwise/edgewise load cases have been considered numerically and experimentally. Strain gauge data and DIC measurements for the different load cases were utilised for computing the experimental cross-sectional displacements and rotations, as shown in Figure 8.

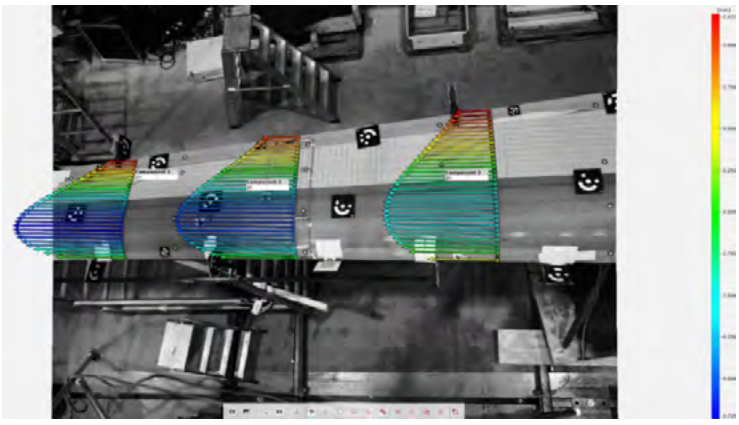

Figure 8. DIC Measurements from the STP load case utilised for computing cross sectional displacements and rotations.

The comparison study has concluded that, for predicting displacements, all numerical models show similar accuracy (see Figure 9), whereas the shell elements struggle to predict torsional response with the same accuracy as the volumetric elements do (see Figure 10). The beam elements are also less accurate than the volumetric discretisation via layered-solid or continuum shell elements.

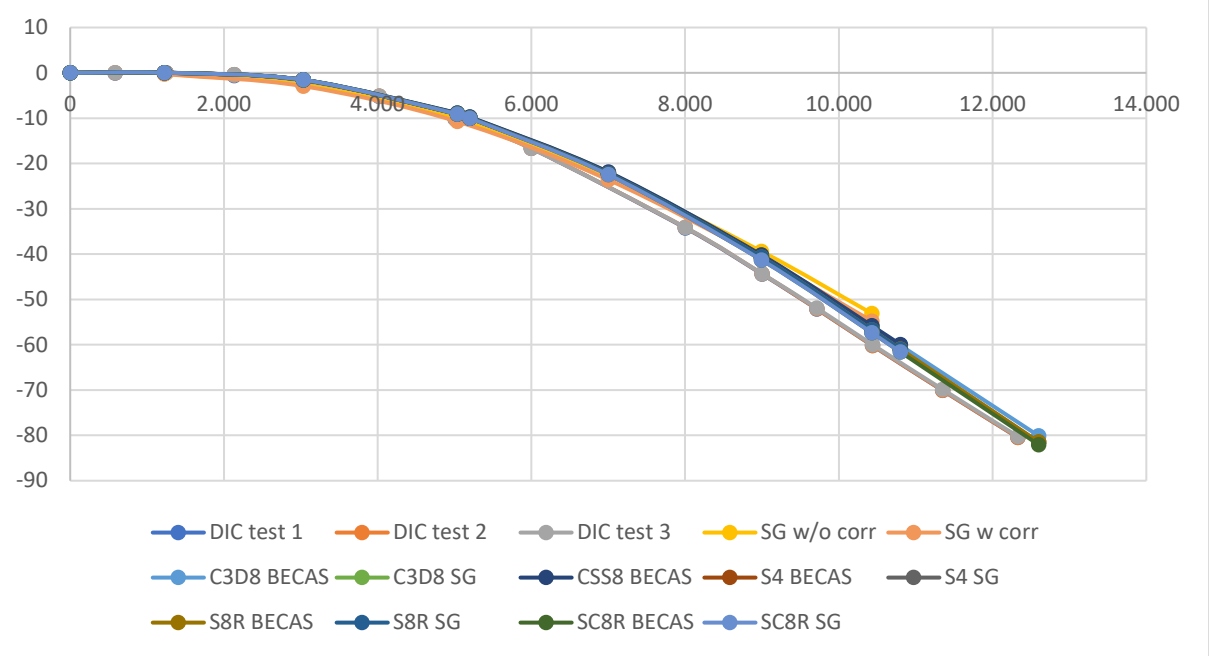

Figure 9. The depicted graphs show the displacement in y-direction in mm for the numerical predictions for different element types compared with the experimental test results for pure flapwise loading (STP load case).

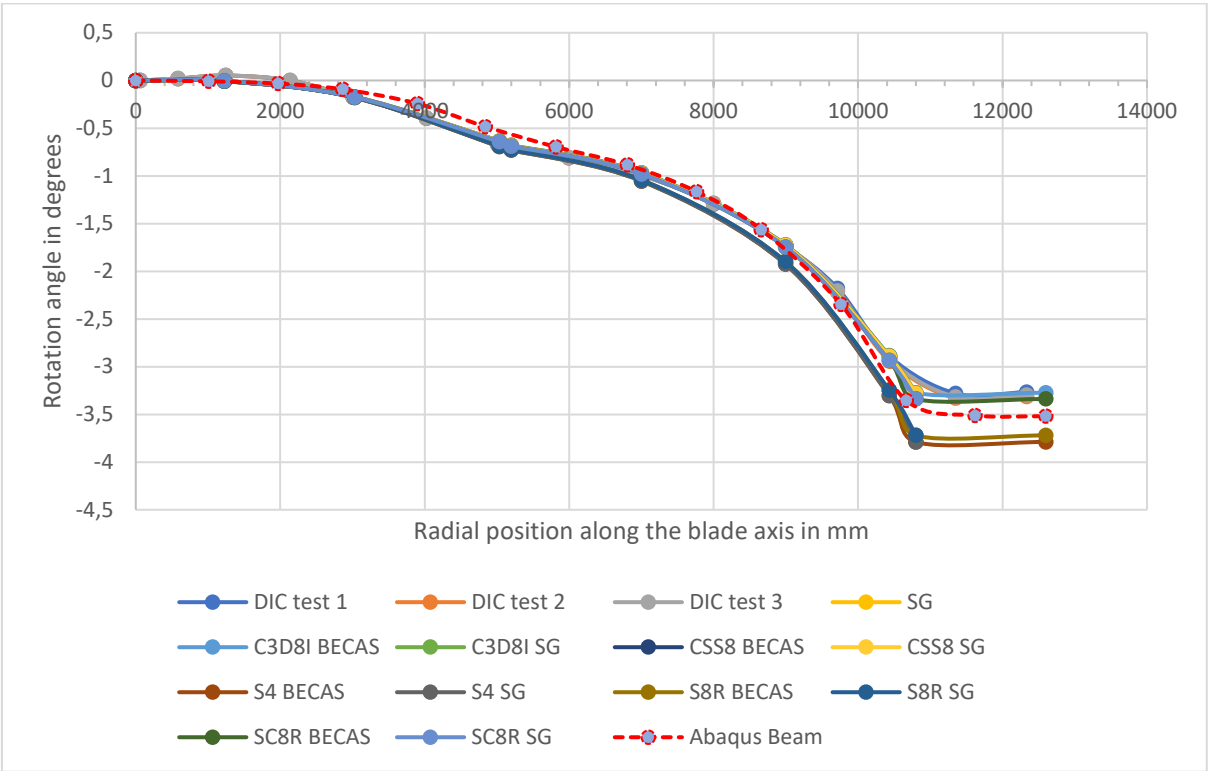

Figure 10. Rotation angle in degrees in spanwise direction (around the blade z-axis) showing numerical predictions for different element types compared with experimental for pure torsional loading (PT load case).

3. Conclusions

The comparison reveals limitations in capturing the torsional behaviour of the wind turbine blade using shell and beam elements, while solid elements perform well. These findings give valuable insights into selecting appropriate finite element types for accurate and reliable predictions of composite structures. While preliminary results have shown significant differences in computational time, more detailed and systematic investigations of factors such as mesh density and element size are needed to identify the sensitivity of each finite element type to these modelling parameters and evaluate the computational efficiency and accuracy of each finite element formulation, to provide a holistic understanding of their practical applicability.

Abstract
This study investigates the feasibility of producing composite materials by utilizing recycled plastic sourced from discarded fishing nets through a compression molding process. These composites would be further reinforced with unidirectional (UD) tape. The effects of processing parameters on mechanical properties were evaluated through tensile testing and SEM analysis. Three-layered tape composites exhibited noteworthy improvements over traditional semi-finished thermoplastics, particularly in tensile modulus and tensile strength except the elongation at break. Notable adhesion between fibers and matrix was seen even with minimal reinforcement. This finding underscores the potential for industrial application as locally reinforced plates, meeting standards in automotive or other industries. These results suggest a promising avenue for incorporating recycled plastic into composite manufacturing, offering both environmental advantages and superior mechanical properties.

1. Introduction

Environmental protection is currently a pressing concern across various industries, with a focus on curtailing carbon dioxide (CO2) emissions in order to combat climate change [1]. This is especially critical for the transportation sector, which ranks as the second largest contributor of anthropogenic greenhouse gas emissions in the European Union (EU). Road transportation alone accounts for approximately 93% of these emissions [2]. Due to recent regulations regarding CO2 emissions, the automotive sector is placing a significant focus on composite materials to further decrease the weight of the vehicle in the upcoming decade. Achieving lower vehicle mass primarily involves two key approaches: innovative design to optimize component performance and materials substitution, wherein traditional automotive materials like steel are replaced with lighter alternatives. Lighter metals such as aluminum and magnesium are increasingly utilized, along with high-strength steels in select applications. Polymer composite materials also hold promise for weight reduction in the automotive sector. Previous estimates indicate that extensive use of glass-reinforced polymers could lead to a 20–35% reduction in vehicle weight. The automotive industry has already gleaned benefits from composite materials in lower-performance applications over several decades.
Nowadays, thermoplastic matrices for semi-structural and structural applications are more and more gaining interest and material suppliers offer now a broad portfolio of semi-finished continuous fiber

thermoplastic products (organosheets, non-woven fiber consolidated sheets, unidirectional (UD) tapes...). Thermoplastic composites obviously show many advantages in several key manufacturing stages, especially a shorter processing time, easier assembly methods and good recyclability potential compared to thermoset composites. Notably, Wegmann in his study reveals that fully recycling aluminum, under ideal circumstances, yields substantial improvements in energy and CO2 balances, yielding optimal overall performance. Given the considerable energy and CO2 intensity associated with composite raw materials, integrating recycled materials into composite production is poised to reduce environmental impacts [3]. For example, repurposing old fishing nets into recycled PA6 and utilizing knitted glass fibers as fabric represent viable options [4]. So,This is our study as part of research work on composite materials.
Additionally, ongoing investigations into novel bio-based precursors for carbon fiber production and renewable resource utilization are underway within the automotive sector. Looking forward, leveraging cradle-to-cradle materials for sustainable products holds immense potential, contingent upon further advancements in recycling technologies to maximize efficacy.

2. Experimental

2.1. Materials

The tape utilized in this study consists of PA6/GF (6.35*35*0.2 mm), containing 60% weight of fibers. Table 1 presents the properties of the individual tape layer. Additionally, for purposes, a recycled PA6 derived from discarded fishing nets Fil & Fab FRANCE industry was selected to undergo processing and testing under the same conditions.

Table 1. Materials properties in this study.

Specimen Type	*E* (GPa)	*Rm* (MPa)	*A*(%)
UD Tape PA6/GF	74	2500	3.38
RECYCLED PA6	2.6	45	1.73

2.2. Compression molding

Parts were processed in an industrial way and with a large mold press with dimensions of 300x300 square meters, hrough four distinct stages:

1. Cutting the tape 35 mm.
2. Stacking and fixing the tape into the plate at 0°.
3. Transferring to press .
4. Thermoforming and part removal.

Industrial 50MT press can be observed on Figure 1 (a) and the resulting part is presented on Figure 1 (b). For each part, specimens were cut in the vertical area and prepared in the same conditions.

Figure 1. (a) Press Machine, (b) Part Molding .

13 layers of GF were 0° stacked and thermoformed (see Figure 1(b). These structures close to sandwich composite are investigated in this study. The 0° axis is defined as the main reinforced fiber axis for all composites. Then the stacked tape layers were dried by the oven for 24 h in 80°C.
The impact of molding temperature was examined while keeping process parameters and mold pressure constant (25 bars) across three distinct values: 230°C, 240°C, and 250°C. Besides, the effect of molding pressure was studied at constant process parametre and mold temperature (230°C) for 3 different values: 15, 20 and 25 bars [5]. Processing parameters of the press : heating, pressuring and thermoforming steps are summarized in Table 2.

Table 2. Processing parameters in this study

Processing Parameter	*Set-up condition*
Pre-Heat	3
Pressing Time	1
Full Pressing	2
Direct Cooling	10

2.3. Characterization

Tensile Test using MTS machine with a load cell of 5 kN. Those tests were conducted at a cross-head speed of 1 mm/min at room temperature by following the EN ISO 527 standard.
This morphological investigation is specifically centered on the SEM (Scanning Electron Microscope; Jeol JSM 6460LV) analysis applied to recycled PA6 materials reinforced with different percentages of tape. Employing SEM facilitates detailed imaging, enabling researchers to explore the subtle effects of reinforcement on the material's morphology. The specimens underwent coating with micrometer-thick layers of metallization, such as gold coating.

3. Results and discussion

3.1.Mechanical characterization

3.1.1.Effect of the process parameter on the mechanical behavior of recycled PA6

Figure 2 shows a conventional curve of recycled PA6 based on fishing nets after tensile testing [6], [7]. The x axis of this line chart represents the strain in percentage while the stress in MPa appears on the y axis. As you can see the green color indicated 230°C, the red color represented 240°C and 250°C represented by the black color. It may be clearly seen that T1 and T2 are the most successful temperatures for processing the recycled PA6 in compression molding. However T3 went up considerably then it dropped off in a weak value of stress-strain. T1 reached a peak before falling dramatically in contrast T2 continued to rising then it fell slightly.

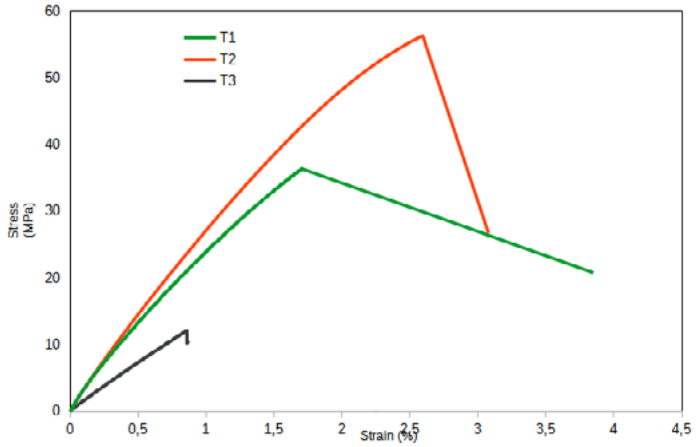

Figure 2. Effects of the temperature on the mechanical properties of the Recycled PA6 FN

Figure 3 represents the bar chart of the mechanical properties of the Recycled PA6 FN fig (a) indicating the tensile modulus, fig (b) represents the tensile strength and fig (c) shows the elongation at Break. The graph compared the different movements of the different mechanical properties. Fig 3 outlines that the best temperature for processing was the 240°C for both tensile strength and elongation at break However there's no significant difference in the modulus. Moreover, it appears that the recycled polymer is significantly affected at the temperature of T3,250°C.

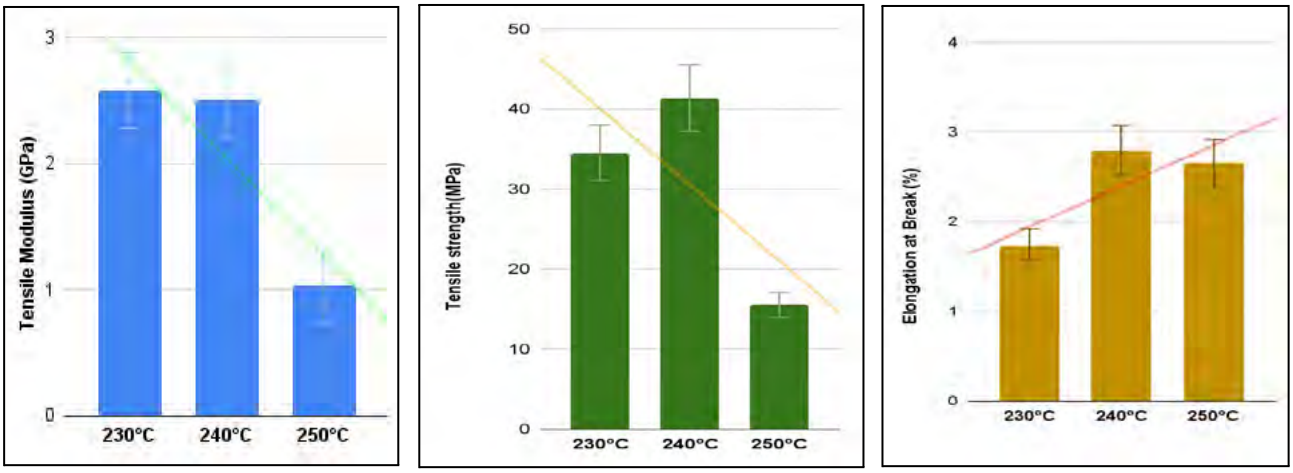

Figure 3. Effects of the temperature on the mechanical properties of the Recycled PA6 FN (a) Tensile modulus (b) Tensile strength(c) Elongation at Break

Table 2 includes the different values of modulus strength and elongation at break of the three process temperatures. As we can say 240°C is the best temperature to choose for processing a recycled PA6 with 2.51 GPa modulus, 41.38 MPa strength and 2.80 % of elongation at break. However T1 also has good properties with a slightly higher modulus (2.58 GPa) against T2.

Table 3. Effects of the temperature on the mechanical properties of he Recycled PA6 FN

Plastics	*E* (GPa)	*Rm* (MPa)	*A*(%)
Recycled PA6 FN T1	2.58 (±0.281)	34.52 (±5.65)	1.74 (±0.34)
Recycled PA6 FN T2	2.51 (±0.35)	41.38 (±11.85)	2.80 (±1.55)
Recycled PA6 FN T3	1.04 (±0.77)	15.53 (±2.,86)	2.65 (±0.392)

Figure 4 depicts a conventional curve of tensile test for a recycled PA6. It was clear to see a different behavior between the three pressure uses. At steady temperature (230°C), P2 under 20 bars of pressure increased vastly then it leveled out at a high value of stress of superior 40 MPa. However, both P1 at 15 bars and P3 at 25 bars exhibit similar behavior, they reached a peak P1 leveled out and P3 dropped off considerably Despite this, P1 is identified as the pressure level associated with a more stable behavior of recycled PA6 against P3.

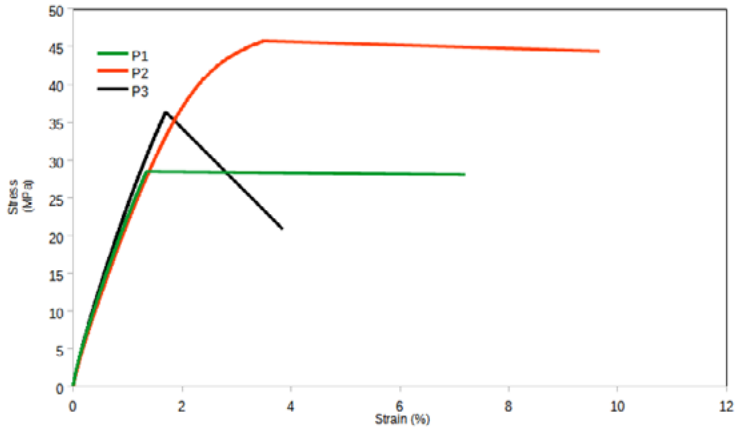

Figure 4. Effects of the Pressure on the mechanical properties of he Recycled PA6 FN

It was clearly observed (Fig 5) that 20 bars was the best pressure used in this study with a high level of strength and elongation at break against a moderate difference between the three pressure levels in modulus (see figure 5). P1 and P3 have a slight difference in modulus and strength and a considerable variation in elongation.

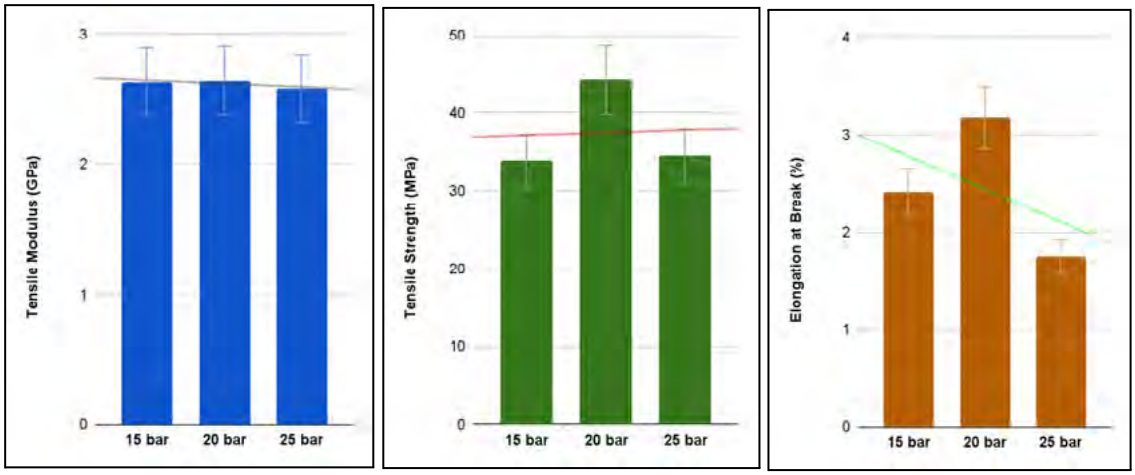

Figure 5. Effects of the pressure on the mechanical properties of the Recycled PA6 FN (a) Tensile modulus (b) Tensile strength (c) Elongation at Break.

Table 3 lists the different values of modulus strength and elongation at break of the three process pressures. It was evident that 20 bars is the best pressure for processing a recycled PA6 with 2.64 GPa modulus, 44.24 MPa strength and 3.17 % of elongation at break. However P1 has a slightly lower modulus with 2.63 GPa, strength and elongation at 33,86 MPa , 2.41 respectively. In his turn P3 has not a big difference in his mechanical properties in comparison to P1 or even P2. We can conclude that unlike temperature variation, pressure changes from 15 bars to 20 to 25 bars do not significantly affect mechanical properties. Additionally, the interval to explore lies between 20 and 25 bars.

Table 4. Effects of the pressure on the mechanical properties of he Recycled PA6 FN

Plastics	*E* (GPa)	*Rm* (MPa)	*A*(%)
Recycled PA6 FN P1	2.63 (±0.11)	33.86 (±6.13)	2.41 (±1.44)
Recycled PA6 FN P2	2.64 (±0.073)	44.24 (±4.99)	3.17 (±0.58)
Recycled PA6 FN P3	2.58 (±0.281)	34.52 (±5.65)	1.74 (±0.34)

3.1.1.Effects of continuous glass fiber incorporation to recycled PA6 polymer

Figure 6 shows a stress-strain curve of four specimens (red: tape rate 4 wt % , yellow : tape rate 8 wt %, green : tape rate 12 wt %, blue : reference with 0 wt% tape rate). the reinforced materials has increased considerably however the unreinforced material rose moderately.

It was evident that there was minimal effect, in variation of the percentage of tape, on the materials, except for a notable impact on resistance at the 12% tape level.

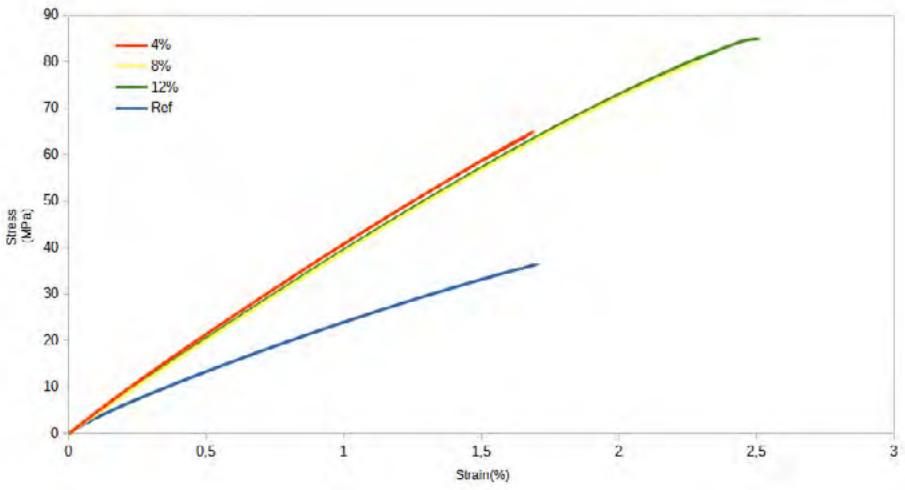

Figure 6. Effects of the tape rate on the mechanical properties of he Recycled PA6 FN

It was clear when we raised the percentage of tape there's increase in modulus and strength. However the elongation at break has different behavior. The augmentation of tape rate from 0% to 4% the elongation rose moderately. From 4% to 12% the properties have decreased significantly (see fig 7)

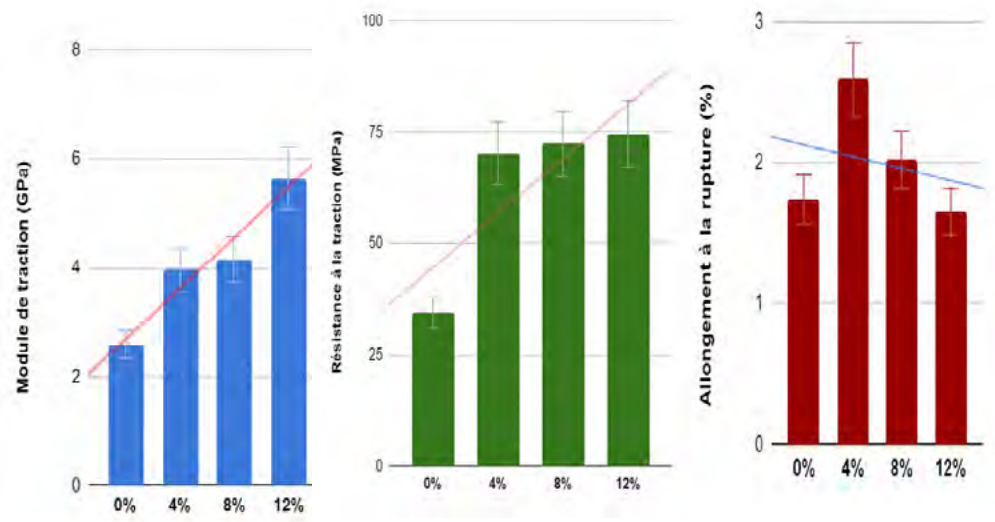

Figure 7. Effects of tape ratio on the mechanical properties of the Recycled PA6 FN

Table 4 lists the different values of the mechanical properties (E(GPa),Rm(MPa) and A(%)). The modulus and strength have increased depending on the percentage of reinforcement from 2.58 GPa to 5.64 GPa , from 34.52 MPa to 74.65 MPa respectively . However the elongation at break reached his maximum at 4 wt% by 2.59 % After that (for 8wt% and 12wt%) it declined to 1.65%. The two levels of tape reinforcement (8wt% , 12 wt%) significantly affect the modulus which increased by 118.6% , and the elongation which decreased by 5.17% respectively. However the tensile strength increased vastly for the first tape layer of 4 wt% by 103.5% and then increased a little between 4 wt % and 12 wt % with 5.7%. This may be due to the porosity and imperfection in the materials after reprocessing and manipulating the tape into plates.

Table 5. Effects of tape percentage on the mechanical properties of he Recycled PA6 FN

Plastics	*E* (GPa)	*Rm* (MPa)	*A*(%)
RECYCLED PA6	2.58 (±0.281)	34.52 (±5.65)	1.74 (±0,34)
PA6GF, 4wt%	3.96 (±0.84)	70.25 (±7,25)	2.59 (±0.3)
PA6GF, 8wt%	4.15 (±0.38)	72.26 (±6.34)	2.02 (±0.86
PA6GF, 12wt%	5.64 (±0,63)	74.65 (±7.33)	1.65 (±0.54)

3.2.SEM analysis

Fig 8 shows the SEM images of the fractured surface of the molded PA6 in different temperatures (230°C, 240°C and 250°C and different pressures (15 bars, 20 bars and 25 bars). The fractured surface of PA6 seems to be smooth and shows no apparent sign of plastics flowing, indicative to brittle failure of homogenous materials.

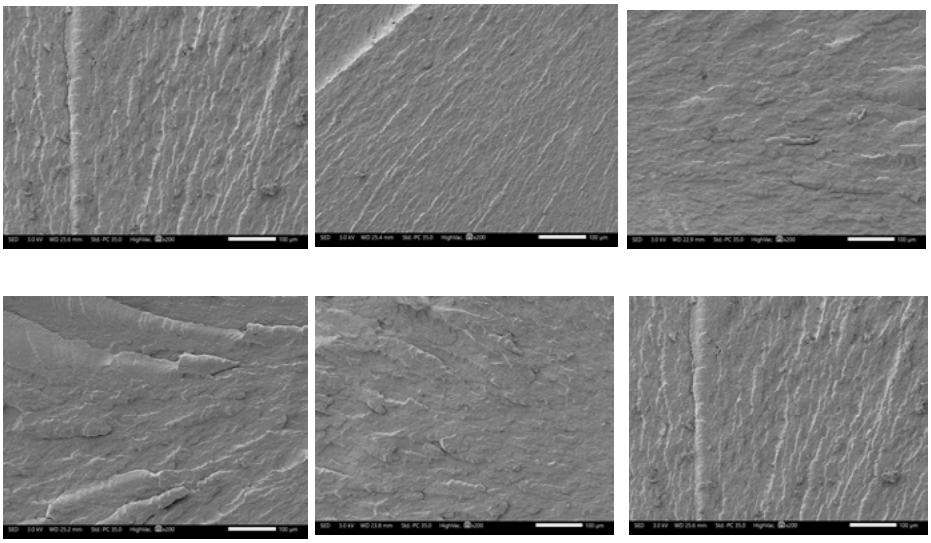

Figure 8. SEM images on Fracture surface of PA6 FN of different temperature (a) 230°C, (b) 240°C and (c) 250°C and different pressures (d)15 bars, (e) 20 bars and (f) 25 bars

To examine the microstructure and evaluate fiber-matrix adhesion, SEM examinations were conducted on tensile fracture surfaces of PA6/GF-containing specimens with varying weight percentages (4% 8% 12%) (refer to Fig.9.).
In instances of wt% PA6 reinforced with glass fiber, the matrix experienced restricted deformation, resulting in a brittle fracture.
Fiber debonding was observable (see Fig 9(a)), leaving a dark ring at the interface, consistent with findings in the study by many authors [8]. They attributed the presence of dark rings to the localized matrix deformation around fibers post-debonding. However, with most fibers being pulled out during deformation, the matrix stayed connected to the fibers, resulting in failure at the fiber-matrix interface. The surface of the fiber appeared clean and smooth , consistent with adhesion results indicating a lack of interaction between PA6-treated glass fibers. The figure 9 (b) shows the absence of the pulled-out fibers except for a few fibers. Moreover it revealed that failure predominantly took place within the matrix. Fig 9 (c) details the presence of a polymer sheath on fiber surfaces suggesting strong interactions , substantiated by differences in physical properties, notably density, in the proximity of the fiber surface compared to the bulk polymer.
The clear failure at the matrix emphasizes the importance of the interphase, highlighting a robust interfacial bond between the PA6 matrix and glass fibers in the composite material.

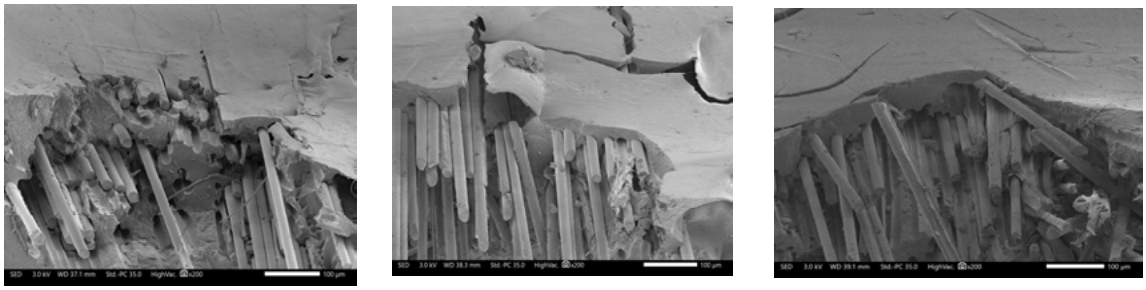

Figure 9. SEM images on Fracture surface of PA6/GF (a)at 4% , (b) 8% and (c) 12% weight ratio of reinforcement

4. Conclusions

This paper describe the main important advancement released still now for developing and characterizing a continuous glass fiber recycled thermoplastics polymers The main conclusion can be :

- There's always a big effect of the variation of temperature on the tensile properties of the recycled polymer PA6 FN
- In contrast there's no evident effect of the pressure on the recycled materials PA6 FN
- By addition of the different percentage of tape : the modulus rose slightly from 2.58 to 5.64 GPa , the strength increased significantly from 34.52 to 74.65 MPa and finally the elongation at break decreased slightly from 1.74 to 1.65%.

Acknowledgments
A paragraph (optional) at the end of the paper, before the references, can be used for acknowledgements.

Keywords: Thin-ply composites; Open-hole tension; Virtual testing, Nonlinear finite element method

Abstract
The aim of this study is to examine the effect of ply thickness and 0-degree ply ratio on the strength of the thin-ply composites in the open-hole tension (OHT) tests. To this end, we carried out OHT tests of a variety of layups having different ply thicknesses and 0-degree ply ratios. Based on the experimental results, we developed two types of high-fidelity simulation tools for the virtual testing of composite laminates; an in-house extended finite element method tool and a generic failure model implemented in the commercial software Abaqus. Two tools consider both geometric and material nonlinearities such as plasticity, non-Hookean behavior, intra/interlaminar cracking, and fiber tensile/compressive failures. Their prediction capabilities are verified against the open-hole tension experiments of several layups with a variety of 0-degree layer ratios in terms of stress-strain nonlinearity, damage propagation behavior, and ultimate strength.

1. Introduction

Due to the recent development of the spread-tow thin-ply technology [1,2], the design freedoms of ply thickness and stacking pattern per unit thickness in the composite laminated structure have been improved. Owing to this improvement, the nonconventional stacking sequence, which has never been applied to the aircraft structure so far, will be applicable. For instance, the extremely hard laminate with a high ratio of 0-degree ply can be used in the components where the loading direction is limited in a certain direction. This means that the excellent performance (specific stiffness and strength) in the fiber direction of unidirectional CFRP is able to be used more actively.

It is well known that the “in-situ” strength, which is defined as the stress and strain at ply failure within the laminates, depends on the ply thickness. Due to the high constraint from neighboring ply, the thin

ply laminates have high in-situ transverse and shear strengths [3-6]. The superior in-situ strength results in the superior laminated strength in most test cases such as non-hole tension/compression tests, open/filled-hole compression tests [7-10], and tapered laminates [11], however, it can negatively affect laminated strength in open/filled hole tention tests [7,12]. Another disadvantage to thin-ply technology is that numerous candidate stacking patterns must be reviewed in the design process. Therefore, for the optimization of the future design of CFRP laminated structures by tailoring the ply thickness and orientation, the development of a high-fidelity simulation method, which was thoroughly verified by experiments in various ply thicknesses and stacking sequences, is necessary.

This study aims to experimentally and numerically investigate the influence of ply thickness and 0-degree ply ratio on the failure mode and strength of open-hole tensile tests. Two types of high-fidelity virtual testing tools, an in-house tool and an Abaqus-implemented tool, were developed based on the experiments. In the experiment, we prepare the 6 types of CFRP laminates by changing the ply thickness from 0.05mm to 0.2mm and the 0-degree ply ratio from 10% to 67%. For all the layups, both the fracture tests and the interrupted tests are carried out to observe the progressive internal damage using X-ray radiography. These results are used to verify the prediction accuracy of the simulation tools. Based on the experimental results, we developed numerical tools considering both geometric and material nonlinearity, including plasticity, damage, and non-Hookean (NH) behavior. Using the developed scheme, the open-hole tensile strengths of the CFRP laminates are evaluated in the cases of various ply thicknesses and layups. From the sensitivity study on each model, the effects of each nonlinearity on the OHT strength are discussed.

2. Experiments

To examine the effects of ply thickness and 0°-layer ratio, five types of laminates are prepared: conventional QI laminates with three different ply thicknesses (QI50, QI100, QI200) and laminate with high and low 0°-layer ratios (H400, S400). The stacking sequences, the ratio of ply angle (0°: ±45°: 90°), and the maximum 0°-layer thicknesses of these laminates are summarized in Table 1. The material used for these laminates is thin-ply T800/epoxy unidirectional prepregs of 0.05 mm thickness (Industrial Technology Center in Fukui Prefecture). The OHT tests were carried out following JIS K7094 [32] using Instron 8802 and AG-250-X-plus (Shimadzu Corp.) under displacement control with a constant rate of 1.0 mm/min. The specimen geometry is illustrated in Fig. 1.

In order to capture damage propagation behaviors within the specimens in detail, the load was interrupted in some specimens, and X-ray inspection was conducted on them using a soft X-ray radiography system (M-100, SOFTEX, Inc.). For clear observation, the zinc iodide penetrant was immersed into the free edges including the hole edge of the specimens after unloading. The specimens were exposed to X-rays at 30kV, 1mA for 30sec.

Table 1. List of stacking sequences for OHT simulations.

Specimen ID	Layup	0°: ±45°: 90°	Max. 0° thickness
QI50	$[45/\mathbf{0}/-45/90]_{8S}$	25: 50: 25	50 μm
QI100	$[45_2/\mathbf{0_2}/-45_2/90_2]_{4S}$	25: 50: 25	100 μm
QI200	$[45_4/\mathbf{0_4}/-45_4/90_4]_{2S}$	25: 50: 25	200 μm
S400	$[(45_4/90_4/-45_4/45_4/-45_4)_2/45_4/0_4/-45_4/(45_4/-45_4)_3/\mathbf{0_4}]_S$	10: 80: 10	400 μm
H400	$[(45_2/90/-45_2/0_4)_2/(45/90/-45/\mathbf{0_4})_2]_S$	50: 37.5: 12.5	400 μm
XF600	$[45/90_2/-45/0_8/45/90/-45/0_8/45/90/-45/\mathbf{0_6}]_S$	68.75: 18.75: 12.5	600 μm

3. Numerical methods

This study developed two types of virtual testing tools; an in-house extended finite element method (XFEM) tool and a generic failure model implemented in the commercial software Abaqus. The authors have developed the former tool so far [13,14] and newly developed the latter one by implementing the models in the former to the Abaqus.

3.1. In-house virtual test tool

The in-house virtual testing tool [13,14] is based on XFEM and introduces five models for material nonlinearities; plasticity, non-hookean effect, multiple intra-laminar cracks, delamination, and fiber tensile and compressive failure. The geometrical nonlinearity is also included. Table 2 summarizes the numerical models implemented in the developed in-house tool.

Table 2. Models implemented in in-house virtual testing tool.

Phenomena	Models
Plasticity	Pressure-dependent Sun-Chen model [15,16]
Non-hookean effect	Nondlinear elastic hardening model [17,18]
Intra-laminar cracking	XFEM with enhanced cohesive zone model [13,14]
Delamination	Interface element with enhanced cohesive zone model [19,20]
Fiber tensile failure	Weibull Criteria [21]
Fiber compressive failure	LaRC03 criteria with smeared crack model [22,23]

The XFEM can handle the intralaminar cracks and resultant displacement discontinuity independent from the mesh by introducing additional degrees of freedom and enriching the interpolation function in the solid elements. Furthermore, the interface elements for delamination are also enriched to deal with interaction between intra- and inter-laminar cracks. The detailed formulations can be referred to Refs. [13, 14]. In the proposed tool, the arbitrary crack shape is defined using multiple line segments on the base surface by the two level-set functions. All the elements are classified into normal, cut, and tip elements on the base surface. Three-dimensional elements are then created by extruding the two-dimensional elements. The schematic of the crack modeling strategy in the in-house XFEM tool is illustrated in Fig. 2.

3.2. Abaqus-implemented virtual test tool

This study develops a generic failure model (GFM) by implementing material models in in-house tool listed in Table 2. This study developed a generic failure model (GFM) by implementing material models in an in-house tool into Abaqus listed in Table 2. As shown in Table 2, most material models were implemented via the user-written FORTRAN subroutine VUMAT. One exception is the Weibull criterion for fiber tensile failure. Since it is a global criterion judging the probability of survival of the entire specimen by volume integration of the stress field, it was implemented by Python script as a post-process.

Particular attention was paid to the modeling of interaction between intra- and inter-laminar cracks. To this end, the partitioned interface element strategy is developed. The details are illustrated in Fig. 3.

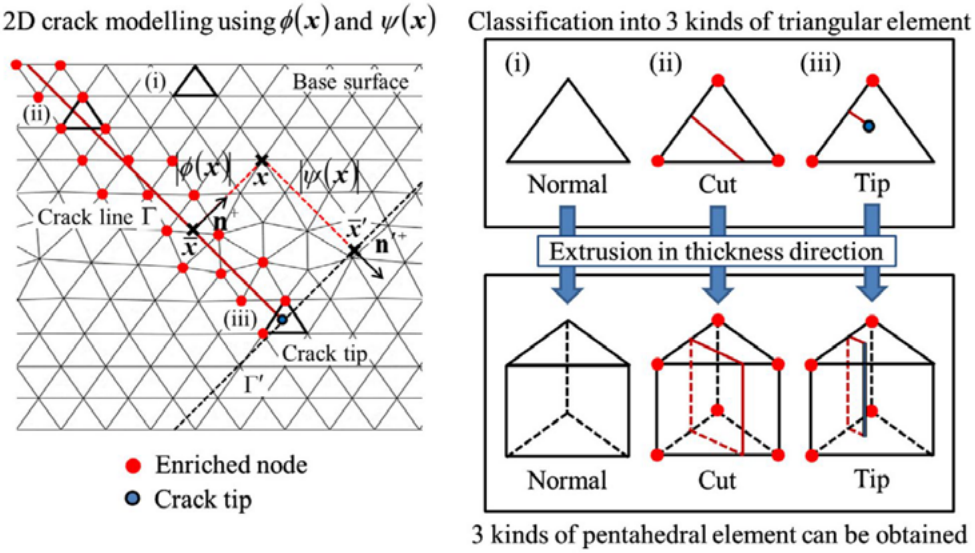

Figure 2. Schematics of intra- and inter laminar crack modeling in in-house virtual test tool [13].

Table 3. Models implemented in Abaqus virtual testing tool.

Phenomena	Models	Implementation
Plasticity	Pressure-dependent Sun-Chen model [15,16]	UMAT
Non-hookean effect	Nondlinear elastic hardening model [17,18]	UMAT
Intra-laminar cracking	Interface element with enhanced cohesive zone model [19,20]	UMAT
Delamination	Partitioned interface element with enhanced cohesive zone model	UMAT
Fiber tensile failure	Weibull Criteria [21]	Python script (Post process)
Fiber compressive failure	LaRC03 criteria with smeared crack model [22,23]	UMAT

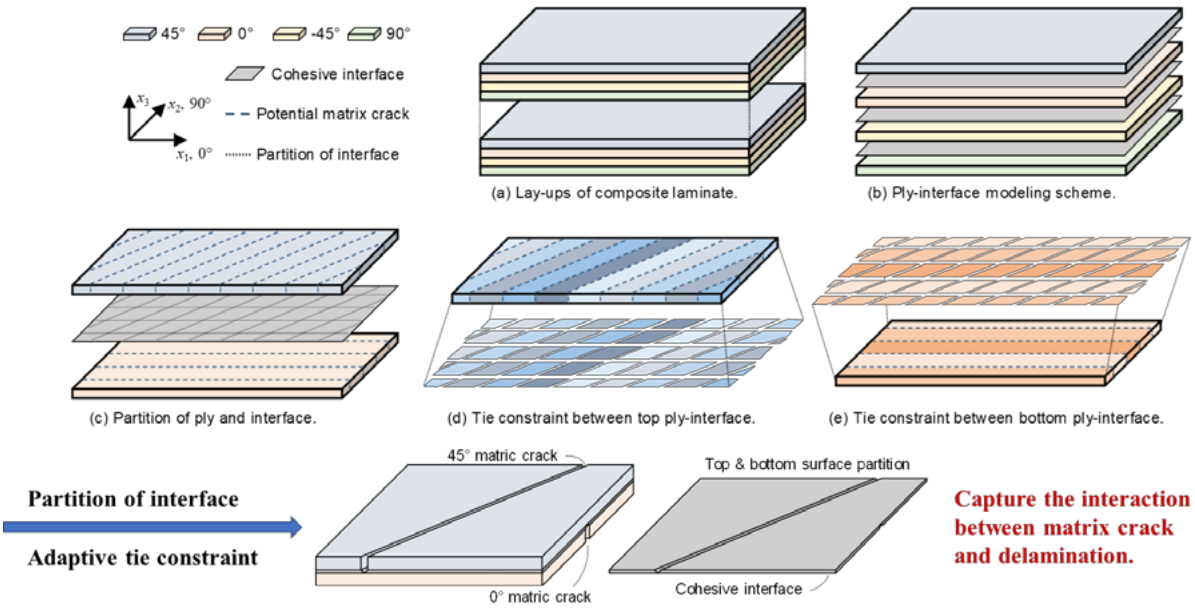

Figure 3. Schematics of intra- and inter laminar crack modeling in Abaqus virtual test tool.

Since mesh-independent crack modeling approaches such as XFFEM are hard to implement in commercial software, the developed tool employs the interface elements for intra-laminar cracks. It should be noted that such a modeling approach generally causes mesh inconsistency between the interface and neighboring plies with different fiber angles and makes it impossible to share the nodes between them. Generally, there are two ways to tackle this problem; (I) tying the ply and interface via the multi-point constraints, and (II) utilizing the surface-based interface (cohesive zone) modeling. However, they do not always provide accurate solutions for interactive propagation of intra- and inter-laminar cracks because results are dependent on the positional relationship between intralaminar crack and integration points on the interface. To tackle this problem, we proposed the partitioning of interface elements and setting tie constraints between each partitioned block of interface elements and corresponding neighboring ply elements. These procedures are automatically done by Python script as a pre-process.

4. Results and discussion

4.1. Effect of ply thickness (QI50, QI100, and QI200)

This section performs the OHT simulations in QI50, QI100, and QI200 cases using both proposed tools as the verifications of their prediction capabilities. The influence of ply thickness on the OHT strength and damage propagation behavior is also discussed via comparisons between the experimental and numerical results.

Experimental and predicted strengths and damage behaviors are compared in Table 4 and Fig. 4, respectively. It can be seen from Table 4 that the thinner ply-thickness results in lower OHT strength both in the experiment and simulation. This is because of the difference in internal damage. As shown in Fig. 4, even at 95% strength, only a few cracks happened in thin-ply laminates. In contrast, numerous cracks and delamination occurred in thick-ply even at 80% load level. In particular, these splittings in 0-degree plies can relieve the stress concentration around the hole and delay the fiber failure. By modeling these internal damages, both tools were able to capture the trend of damage behavior depending on the ply thickness (i.e., less damage in thinner ply) observed in the experiment and achieved high prediction accuracy within 15% for strength in all the cases. It should be noted that the Abaqus tool overestimated damage propagations in all the cases. This larger damage propagation caused a relaxation of stress concentration around the hole in the larger region, delayed fiber failure, and resulted in the overestimation of ultimate strength. One possible cause of the difference in prediction between in-house and Abaqus-implemented tools is the different spacing and positions of introduced cracks. Although a larger crack spacing is utilized in the Abaqus tool due to the lack of RAM, this undesirable problem will be relieved in the near future.

Table 4. Comparison of predicted and experimental OHT strength.

Specimen ID	OHT strength MPa (Error %)		
	Experiment	Sim. (in-house tool)	Sim. (Abaqus tool)
QI50	489.5	453.2 (-7.42)	554.7 (13.3)
QI100	508.4	459.2 (-9.68)	560.3 (10.2)
QI200	532.5	497.3 (-6.67)	571.2 (7.26)

4.2. Effect of 0-degree layer ratio (S400, H400, and XH600)

This section compares the experimental and numerical results of OHT tests in S400, H400, and XH600 cases. Here, sensitivity simulations were carried out using the in-house tool by omitting some material models to examine their effect on the damage and strength predictions. Comparisons of strength and stress-strain curves are provided in Table 5 and Fig. 5.

In the S400 case, significant softening happens in the stress-strain response due to the plastic behavior in the 45 plies. Therefore, both the stress-strain response and OHT strength were overestimated if the plasticity model was omitted.

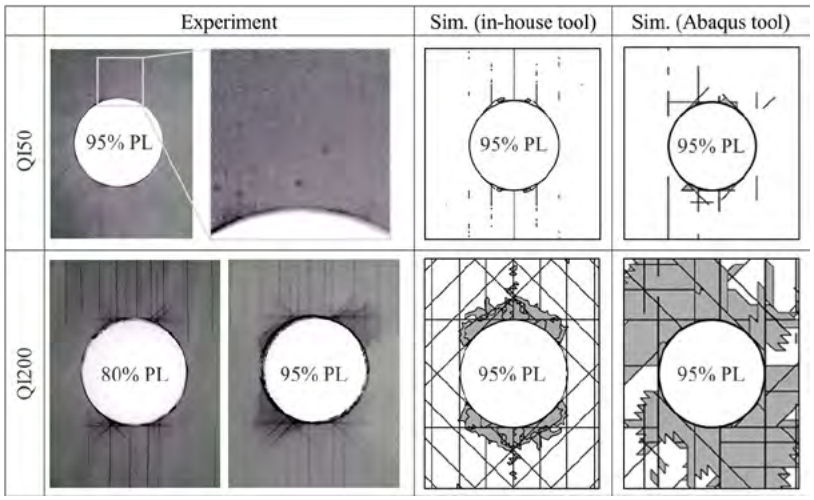

Figure 4. Comparisons of damage behaviors in QI50 and QI200 between experiment, simulation using in-house tool, and simulation using Abaqus-implemented tool.

Table 5. Comparison of predicted and experimental OHT strength.

Specimen ID	OHT strength MPa (Error %)				
	Experiment	Sim. (In-house tool)			
		w all models	w/o PLA	w/o NH	w/o GNL
S400	*313.6*	*287.0* (-8.54)	*305.0* (-1.81)	---	---
H400	673.6	695.2 (+3.20)	---	762.7 (+13.2)	---
XF600	**1363.6**	**1395.6** (+2.35)	**---**	**---**	**807.9** (-40.8)

Roman : Fiber failure mode, **Bold** : Splitting failure mode, *Italic* : Off-axis crack failure mode

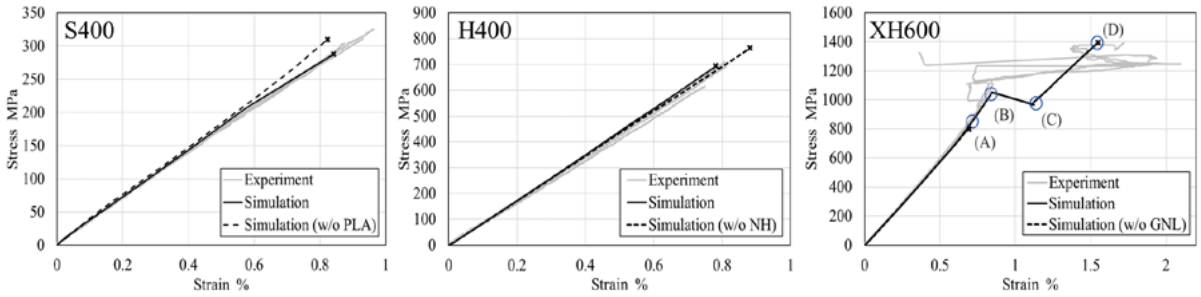

Figure 5. Comparisons of stress-strain curves in S400, H400, and XH600 cases.

In the H400 case, we compared the experiments and simulations with and without NH effect. If we neglect the NH effect (i.e., nonlinear elastic hardening in fiber direction), the stress-strain-response is underestimated, but the OHT strength is overestimated. This is because the local stress around the hole is underestimated without the NH effect. With the model for the NH effect, both the stress-strain response and OHT strength were well reproduced.

Finally, in the XH600 case, we compared the experiments and simulations with and without geometrical nonlinearity (GNL). As shown in Table 5, the strength is significantly underestimated if we neglect the GNL. In this laminate, the splittings in 0-degree layer were significantly extended with the accompanied delamination and fiber kinking (see Fig. 6). These accompanied delamination and fiber kinking highly depend on the out-of-plane deformation of the delaminated region. Therefore, without GNL, the out-of-plane deformation, delamination, fiber kinking, and the resultant ultimate failure are significantly underestimated.

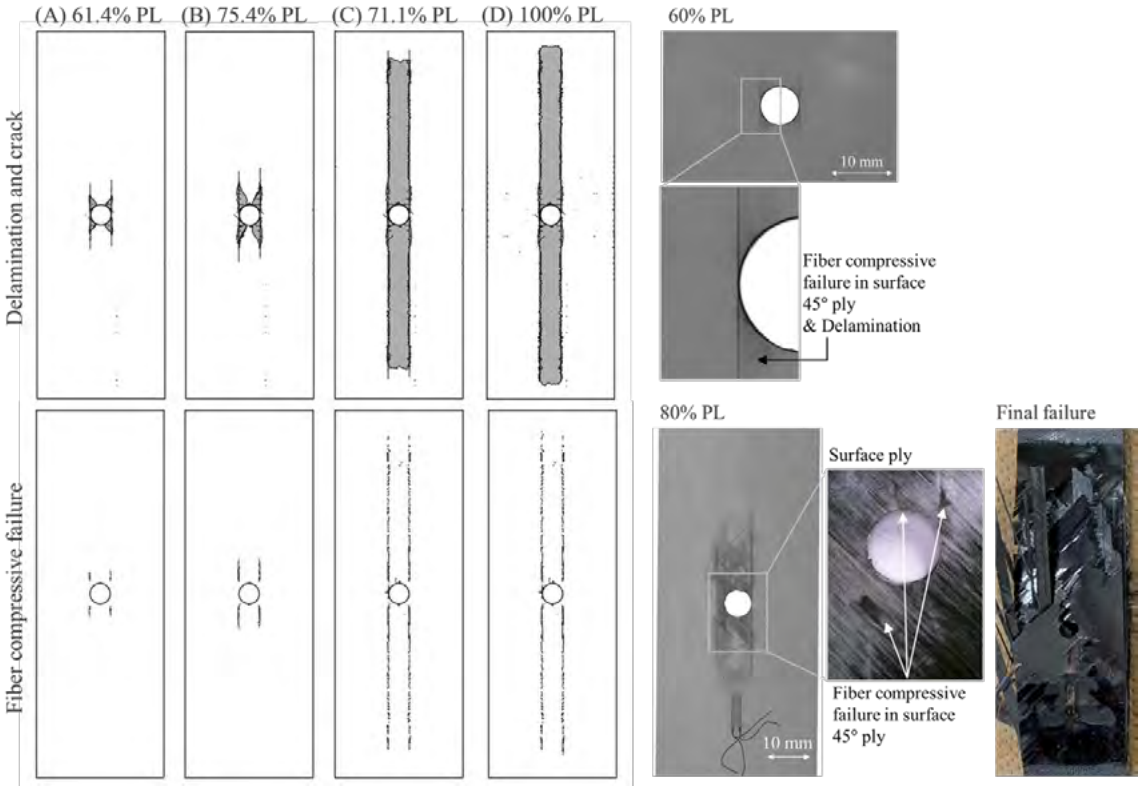

Figure 6. Comparisons of damage behaviors in XH600 case between experiment and simulation.

In summary, it was concluded that the OHT strengths of thin-ply laminate highly depend on the ply-thickness and layup, and, the proposed scheme can predict all OHT strengths very precisely by considering various material nonlinearity and GNL.

5. Conclusion

This study developed the virtual test tools for high-fidelity mesoscale simulation of composite laminates and examined the influences of ply thickness and 0-degree layer ratio on the damage behavior and the OHT strength. Two types of virtual test tools (the in-house XFEM tool and the Abaqus-implemented tool) were developed and verified in the OHT simulations of five types of layups. Based on the experimental and numerical results, we concluded that the OHT strengths highly depend on the ply-thickness and layup, and the proposed scheme can predict all OHT strengths very precisely by considering various material nonlinearity and GNL.

Acknowledgments

This study is based on the results obtained from a project, JPNP21014, subsidized by the New Energy and Industrial Technology Development Organization (NEDO).

Keywords: thermoplastic, sandwich, honeycomb, four-point bending, core shear failure, low temperature, aircraft application

Abstract
Because of the emerging need for sustainable materials in the aircraft industry a promising composite material group is remeltable thermoplastic sandwich composites. To secure the useability of these sustainable thermoplastic composite materials, it is irrevocable to gain sufficient insight into the performance of these materials under versatile environmental conditions. In this investigation, the core properties, such as the ultimate core shear strength, the shear stiffness, and the associated failure mechanisms, at different temperatures are investigated by a four-point bending test series.
This series of tests can be seen as a step towards precise material characterization to ensure the development of a sustainable material alternative for structural aircraft parts, without compromising safety and reliability. Furthermore, critical aspects could be identified for prospective investigations.

1. Introduction

In order to the challenge of improving sustainability of structural airplane parts thermoplastic composite materials are a promising material alternative. In opposite to conventionally used thermoset based materials, such as epoxy or phenolic resin, thermoplastic materials will not receive irreversible chemical reactions. Due to that, thermoplastics can be remelted or restored to the flowable state. This ability offers new methodologies regarding recycling processes as well as other process options and new maintenance possibilities.
Sandwich materials have become standard material configurations, for designing parts with excellent strength-to-weight ratios. Their low mass compared to homogenous or stiffened structures as well as their high durability and reliability keeps them attractive for different industrial applications even beside the aerospace industry.

The aerospace industry is obliged to adhere to strict safety regulations. Sandwich materials in structural airplane parts, such as the shells of the vertical rudder, are continuously researched and improved to handle all the different conditions, which can appear during operation. One of the most critical aspects is the low temperature prevailing at flight altitude. Even at temperatures down to -55°C the sandwich material needs a good mechanical performance to ensure safety and reliability. To investigate the feasibilty of replacing conventional sandwich materials with more sustainable thermoplastic-based solutions it is important to investigate differences and similarities respectively of this promising material type compared with the conventionally used.

2. State of the Art

The two shells of a conventional rudder are both sandwich panels with two corresponding skin sheets on the outer surface. These sheets, also known as face sheets, are usually made of high-performance fiber-reinforced laminate. The high performance is reached by a fabric of carbon fibers embedded in an epoxy matrix. The face sheets are supported by a low-density core material. This low density is realized by using an aramid fiber paper material (known under the trade name Nomex®) coated with phenolic resin and arranged in a characteristic honeycomb geometry. To gain the so called sandwich effect, all corresponding layers has to be connected with each other, usually by an adhesive film. A general structure of sandwich materials is shown in figure 1. The major load case a sandwich material is supposed to, is bending. The bending deflection can be separated in a pure bending-related part and shear-related part. The amount of shear related effects for homogenous materials is very small and can be neglected. By using a low-weight core material the sandwich deformation gains an increasing amount of shear-related phenomena, which have to be considered.

The simplified first order shear deformation theory is highly coupled with two assumptions. The first is that the elastic modulus of the face sheets E_f should be much higher than the one of the core material E_c.

$$E_c << E_f \tag{1}$$

The second assumption is that the height of the core material t_c should be higher compared to the thickness of the face sheets t_f.

$$t_f << t_c \tag{2}$$

If both assumptions are fulfilled the stress contribution inside the material can be approximated like it is shown in figure 2. The bending stresses are just carried by both face sheets. The bending stresses inside the core material can be neglected. The shear load is completely carried by the core material because the face sheets are thin enough to not build up notable shear forces [1].

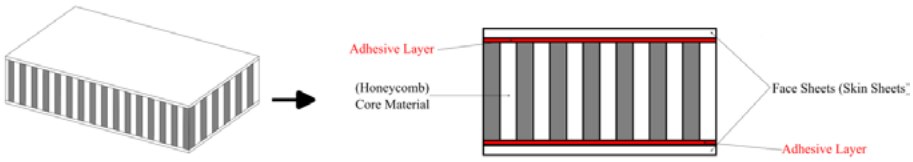

Figure 1. Sketch of general (honeycomb) sandwich structure

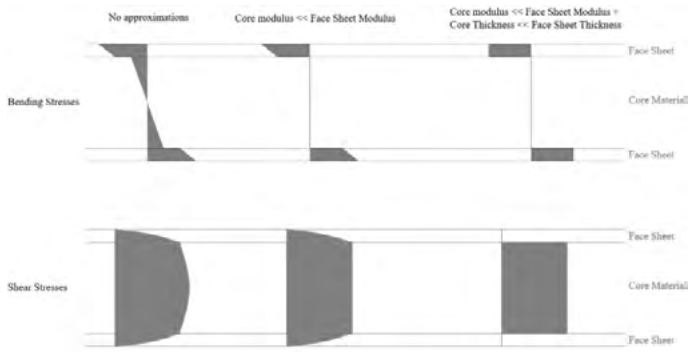

Figure 2. Approximated stress contributions

The mechanical properties of the face sheet laminate can be calculated well by using classical lamination theory (CLT). Also fiber reinforced composites consisting of thermoplastic matrix materials are already existing and are offered by the industry (e.g. by Toray Industries, Inc. or the Danish company Comfil ApS).
The honeycomb core material investigated in this approach is different from the conventional ones even beyond the material type. A specific production process also known as ThermHex process [2] realizes a semi-open folded honeycomb structure, characterized by two main differences [3]. Figure 3 shows schematically the folding process. Every row of cells obtain due to the continuous process covers, which are alternately pronounced on the upper and lower sides. This covers acting as additionally connection zones, therefore they increase the area of the core-face interface. Due to that characteristic, some known analytical calculation methods e.g. according GIBSON and ASHBY are not applicable for this core type [4]. The second difference related to conventional honeycomb cores is that the double cell walls are not connected over the complete surface. While conventionally produced cores are corrugated, stacked and connected over the full surface of double cell walls by an additional adhesive film, the folded structure just have connected zones at the upper and the lower area of the cells.
Another notable advantage of a sandwich material, which is completely thermoplastic-based, is the possibility to renounce the adhesive film for the core-face interface and realize the connection by a welding process instead.

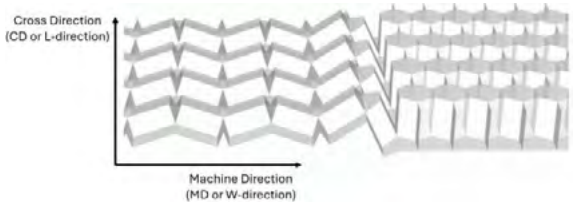

Figure 3. Process of semi-open folded honeycomb core (extracted and customized from [2])

3. Methodology

The focus for a promising material choice with respect to the use as aircraft structural part felt on two thermoplastic polymers as base material. Samples made of Polyetherimide (PEI) and Polphenylene Sulfide (PPS) were produced and provided by the company Econcore. Both polymers, regardable as high-performance thermoplastics, are characterized by a glass transition temperature, which is higher than the required operation temperature for structural airplane parts [5]. Furthermore they are less complicate to process caused by a lower melting point than other comparable high-performance thermoplastics. The core-face interface was realized in case of PPS with a welded connection. On the opposite, the PEI material is bonded together by using a thermoplastic adhesive layer.
As a first investigation to gain information about critical mechanism related to this type of sandwich materials a conventional four-point bending was chosen. In order to minimize the face sheet related proportion of the flexural rigidity and to provoce a core shear failure the decision of short sample design with a span length of 270mm was taken. The load introduction distance was 100mm. The bending test setup is located in a climatic chamber able to realize a temperature of -55°C. Tests were performed at low temperature as well as room temperature.
Three different basics are focused to compare. The first is a investigation of the failure mode, namely if the expected failure mode of core shear failure appears and if it is typically characterized. Second basic is the calculation of the ultimate core shear strength according ASTM C393 [6]. The standard prescribes a core shear failure for a properly determination. Another comparable core related property is the core shear stiffness. In order to determine it, the curvature in the area supposed to pure bending between the load introduction points was monitored by a digital image correlation system (DIC). To realize this, tracking dots are applied at the outer edges of the face sheets. With help of the curvature, the flexural rigidity can be calculated. With respect to the displacement the samples obtaining during the experiment as well as the known flexural rigidity, the shear stiffness can be calculated. Figure 4 shows the test setup inside the climatic chamber. Support point as well as load introduction points are supported by rotational bearings. To increase the load introduction surface additional load pads are applied. This helps to prevent local indentation phenomena. Figure 5 shows exemplarily a loaded test sample, where the for the DIC required tracking points as well as reference index respectively is shown.

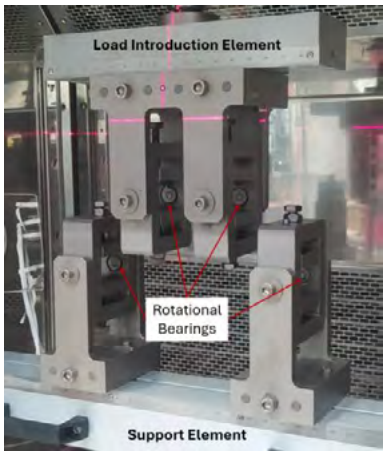

Figure 4. Four-point bending test setup

Figure 5. Loaded four-point bending test setup with PEI sample

4. Results

Figure 5 as well as figure 6 showing exemplarily the load-displacement behavior of PPS sandwichs and PEI sandwichs respectively. Due to the highly orthotropic character of honeycomb material a separation of properties with respect to the production direction and the transversal direction must be performed. The solid lines showing the low temperature tests, which can be directly compared with experimental results at room temperature visualized by dashed lines. Regarding the slopes, the curves are comparable with each other. An influence of low temperature effects the absolute force which is reached during the tests. However, all samples are subjected to a certain amount of variation, which causes that also these values are quite comparable.

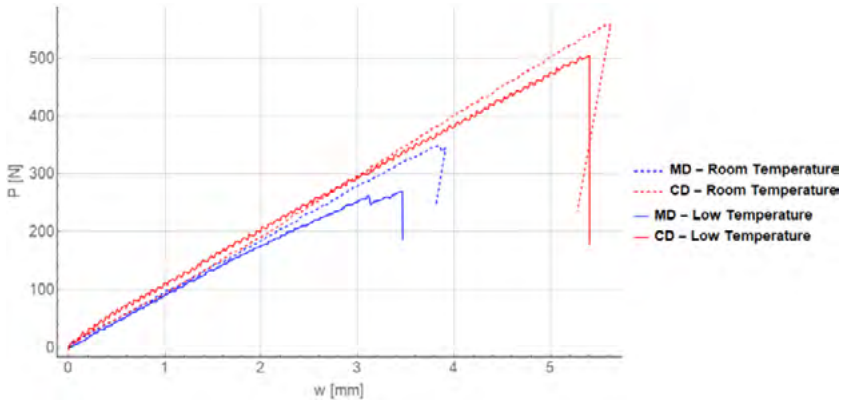

Figure 5. Exemplarily load-displacement curves of PPS

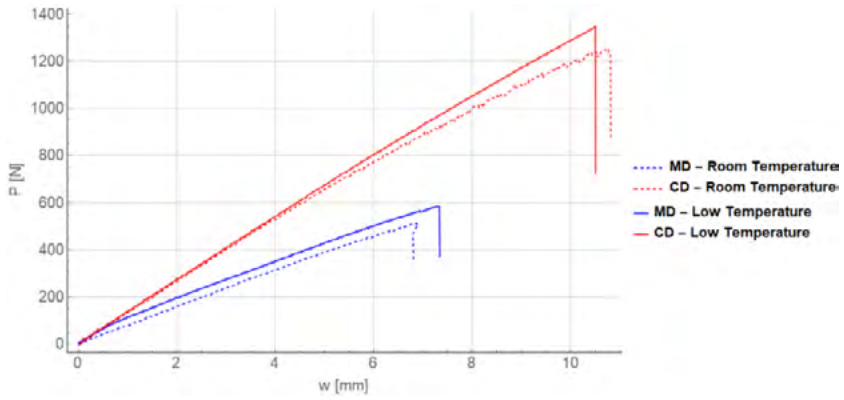

Figure 6. Exemplarily load-displacement curves of PEI

It is to note that the numerous values between both material types should not be compared directly because of differences in the geometry as well as the core density. A meaningful comparison is just possible within one material configuration between room temperature and low temperature.
In opposite to the numerous values, the failure mechanisms are representative for both material configurations and can be compared qualitatively. A buckling of the cell walls, initiating a critical failure of the core material is observable at all tested samples. The figures 7 and 8 are showing characteristic core shear failures of both material types. The shear crack is as expected in an approximate 45° angle. It is conspicuous that a development of the shear crack underneath the face sheets is observable. This phenomenon is more pronounced at low temperatures and independent of the type of core-face interface.

Figure 7. Core Shear Failure of PPS Sandwich

Figure 8. Core Shear Failure of PEI Sandwich

5. Discussion and Conclusion

The expectation of a more brittle behavior at low temperatures of -55°C was confirmed during the experiments. However, for a first investigation are these effects acceptable. All samples are supposed to a certain amount of variation, so that the results remain comparable independently of the test temperature. This also confirmes the promising character of PPS and PEI.
All in all, PPS shows a more brittle failure at lower loads than PEI, which is confirmed by lower values of the ultimate core shear strength in production direction at low temperatures. Due to increased brittleness at low temperatures, the relatively small connection zones between the double cell walls are supposed to fail earlier. A decreased shear stiffness can also be associated with this phenomena. It is planned that the PPS will additionally be modified and optimized regarding this brittle behaviour by a choice of certain additives.
The cell wall buckling as main driver of a critical core shear failure could be observed for both material types. It was observed that the failure starts in the immediate vicinity of the face sheets. The secondary source of a critical failure is the collapse of the core-face interface. Especially this phenomena will be investigated further to gain a more detailed knowledge about the failure mechanism and the associated useability of thermoplastic sandwich solutions for structural airplane parts.

Acknowledgments

Special thanks to all project partners of the work package EcoRudder of the Horizon Europe - Clean Aviation project FASTER H2 for a lot of knowledge exchange. Especially, the provision of test samples by Econcore was highly appreciated.

Keywords: Vibration, Damping, Plates

Abstract
Following the principle of constrained-layer damping (CLD), fibre metal elastomer laminates (FMELs) offer a high potential for damped lightweight structures, overcoming the undesirable vibration characteristics of conventional lightweight materials. This study investigates multiple hybrid CFRP elastomer metal laminates (HyCEMLs) regarding their damping behaviour. Following the viscoelastic material characterization of three different elastomer damping materials, different laminate lay-ups are investigated by employing a previously published analytical model based on a unified plate formulation. In particular, the free and forced vibration of simply-supported plates is investigated under consideration of the frequency-dependent material properties. The results include optimal laminate lay-ups for a maximized modal damping behaviour while maintaining a high static bending stiffness.

1. Introduction

The mechanical behaviour of fibre metal laminates (FMLs), such as glass fibre reinforced aluminium, has garnered significant attention from both academia and industry over the past decades. Their exceptional fatigue and impact resistance [1, 2] have enabled a wide range of structural applications, particularly in the aerospace sector [3]. Replacing the glass fibre-reinforced polymer (GFRP) plies with carbon fibre-reinforced polymer (CFRP) can greatly enhance mechanical properties like stiffness and strength, but it introduces corrosion issues at the aluminium interface and residual stresses due to differing thermal expansion coefficients. Incorporating elastomeric plies in these interfaces not only mitigates these issues [4] but also offers flexible options for enhancing and optimizing the vibration damping capabilities of FMLs through CLD [5]. Under bending loads, the highly compliant viscoelastic elastomer plies experience significant transverse shear deformations, allowing for substantial dissipation of vibration energy [6]. The damping behaviour of these HyCEMLs has been extensively studied in experimental studies such as [7–9], demonstrating the versatility and adaptability of the CLD mechanism in hybrid laminates. These studies also highlight the strong influence of material and laminate parameters on the achievable amount of damping in addition to cumbersome experimental characterisation procedures and thus motivate the use of computationally efficient analytical predictive models. This work employs an analytical model based on a unified plate formulation [10–12] to predict the vibration characteristics of different HyCEMLs including variations of the elastomeric damping material and overall laminate layup.

2. Materials

The HyCEMLs investigated in this contribution feature three individual constituents: CFRP, aluminum and an elastomeric damping material. The CFRP plies consist of cured unidirectionally reinforced

epoxy-based prepreg sheets HexPly M77/38/UD150/CHS-12K-70 by Hexcel with a nominal thickness of 0.15 mm. The aluminum plies are EN AW-2024 T3 ALCLAD AMS-QQA-250/5 alloy sheets with a thickness of 0.3 mm. Three different elastomeric damping materials are investigated within this study, all belonging to the KRAIBON® range of products by Gummiwerk KRAIBURG GmbH & Co. KG. An overview of the three compounds is given in Table 1.

Table 1: Properties of the three KRAIBON® compounds SAA9579/52, HAA9275/45 and HVV9632/59 studied in this work according to data sheets supplied by the manufacturer [13–15].

	SAA9579/52 (E1)	HAA9275/45 (E2)	HVV9632/59 (E3)
Base polymer	EPDM	EPDM	AEM
Mass density	$1180\,\mathrm{kg\,m^{-3}}$	$1250\,\mathrm{kg\,m^{-3}}$	$1350\,\mathrm{kg\,m^{-3}}$
Hardness	88 Shore A	98 Shore A	95 Shore A

Six different HyCEMLs, namely those listed in Table 2, are considered in this study. The laminates are manufactured as plates of dimensions 400 mm × 400 mm in a hot-mould process. The constituents are manually cut to dimensions and stacked in a heated plate tool, which has prior been treated with a release agent. The mould is heated to 150 °C and a pressure of 40 bar is applied upon closing, which is then retained for 300 s allowing for consolidation of all constituents.

Table 2: FMEL configurations and naming convention. The notation is adopted from Sessner [16]. Lower indices state the layer's thickness in mm and upper indices, if applicable, state the material orientation with respect to the x-direction. The index $(\,)_\mathrm{s}$ indicates symmetric stacks of CFRP plies.

Laminate	Abbreviation	Nominal thickness
$\left[\mathrm{A}_{0.3}/\mathrm{E1}_{0.5}/\left(\mathrm{C}^{0°}_{0.15}/\mathrm{C}^{90°}_{0.15}\right)_3/\mathrm{E1}_{0.5}/\mathrm{A}_{0.3}\right]$	A-E1-C-E1-A	2.5 mm
$\left[\mathrm{A}_{0.3}/\mathrm{E2}_{0.5}/\left(\mathrm{C}^{0°}_{0.15}/\mathrm{C}^{90°}_{0.15}\right)_3/\mathrm{E2}_{0.5}/\mathrm{A}_{0.3}\right]$	A-E2-C-E2-A	2.5 mm
$\left[\mathrm{A}_{0.3}/\mathrm{E3}_{0.5}/\left(\mathrm{C}^{0°}_{0.15}/\mathrm{C}^{90°}_{0.15}\right)_3/\mathrm{E3}_{0.5}/\mathrm{A}_{0.3}\right]$	A-E3-C-E3-A	2.5 mm
$\left[\left(\mathrm{C}^{0°}_{0.15}/\mathrm{C}^{90°}_{0.15}\right)_\mathrm{s}/\mathrm{E1}_{0.5}/\mathrm{A}_{0.3}/\mathrm{E1}_{0.5}/\left(\mathrm{C}^{0°}_{0.15}/\mathrm{C}^{90°}_{0.15}\right)_\mathrm{s}\right]$	C-E1-A-E1-C	2.5 mm
$\left[\left(\mathrm{C}^{0°}_{0.15}/\mathrm{C}^{90°}_{0.15}\right)_\mathrm{s}/\mathrm{E2}_{0.5}/\mathrm{A}_{0.3}/\mathrm{E2}_{0.5}/\left(\mathrm{C}^{0°}_{0.15}/\mathrm{C}^{90°}_{0.15}\right)_\mathrm{s}\right]$	C-E2-A-E2-C	2.5 mm
$\left[\left(\mathrm{C}^{0°}_{0.15}/\mathrm{C}^{90°}_{0.15}\right)_\mathrm{s}/\mathrm{E3}_{0.5}/\mathrm{A}_{0.3}/\mathrm{E3}_{0.5}/\left(\mathrm{C}^{0°}_{0.15}/\mathrm{C}^{90°}_{0.15}\right)_\mathrm{s}\right]$	C-E3-A-E3-C	2.5 mm

3. Methods

Experimental In order to determine, and later model, the damping behaviour of the elastomeric damping materials, dynamic mechanical analysis (DMA) is conducted for an experimental characterisation of the frequency-dependent viscoelastic materials. The DMA is conducted in tension mode with frequency sweeps ranging from 0.1 Hz to 10 Hz at discrete temperatures ranging from −80 °C to 80 °C in increments of 5 °C. Following the actual DMA experiments, time-temperature superposition (TTS) is applied, including horizontal and vertical shifts for the creation of mastercurves yielding the isothermal viscoelastic behaviour over a wide frequency range. More details on this procedure are given in Jackstadt [17].

Analytical In this study, the analytical model previously published by the authors in [10–12] is applied. Based on the Generalized Unified Formulation (GUF) by Demasi [18, 19], the Reissner's Mixed Variational Theorem (RMVT)

$$\int_\Omega \left(\delta\varepsilon_{\mathrm{pG}}^\top \sigma_{\mathrm{pH}} + \delta\varepsilon_{\mathrm{nG}}^\top \sigma_{\mathrm{nM}} + \delta\sigma_{\mathrm{nM}}^\top (\varepsilon_{\mathrm{nG}} - \varepsilon_{\mathrm{nH}})\right) \mathrm{d}V = \delta L_{\mathrm{ext}} - \int_\Omega \rho\, \delta u^\top \ddot{u} \mathrm{d}V \tag{1}$$

is considered in order to model the three displacement and three out-of-plane stress components based on the axiomatic approach

$$\begin{aligned} u_x^k(x,y,z) &= U_{x,\alpha_{u_x}}^k F_{\alpha_{u_x}}(z)\Phi_{u_x}(x,y) & \sigma_{xz}^k(x,y,z) &= S_{xz,\alpha_{\sigma_{xz}}}^k F_{\alpha_{\sigma_{xz}}}(z)\Phi_{\sigma_{xz}}(x,y) \\ u_y^k(x,y,z) &= U_{y,\alpha_{u_y}}^k F_{\alpha_{u_y}}(z)\Phi_{u_y}(x,y) & \sigma_{yz}^k(x,y,z) &= S_{yz,\alpha_{\sigma_{yz}}}^k F_{\alpha_{\sigma_{yz}}}(z)\Phi_{\sigma_{yz}}(x,y) \\ u_z^k(x,y,z) &= U_{z,\alpha_{u_z}}^k F_{\alpha_{u_z}}(z)\Phi_{u_z}(x,y) & \sigma_{zz}^k(x,y,z) &= S_{zz,\alpha_{\sigma_{zz}}}^k F_{\alpha_{\sigma_{zz}}}(z)\Phi_{\sigma_{zz}}(x,y) \end{aligned} \tag{2}$$

within each material layer k of the laminates. The simply-supported plate problem is solved using the Navier solution, yielding the in-plane dependencies Φ_i in Equation (2) as

$$\begin{aligned} \Phi_x &:= \Phi_{u_x}(x,y) = \Phi_{\sigma_{xz}}(x,y) = \cos\left(\frac{m\pi x}{a}\right)\sin\left(\frac{n\pi y}{b}\right) \\ \Phi_y &:= \Phi_{u_y}(x,y) = \Phi_{\sigma_{yz}}(x,y) = \sin\left(\frac{m\pi x}{a}\right)\cos\left(\frac{n\pi y}{b}\right) \\ \Phi_z &:= \Phi_{u_z}(x,y) = \Phi_{\sigma_{zz}}(x,y) = \sin\left(\frac{m\pi x}{a}\right)\sin\left(\frac{n\pi y}{b}\right) \end{aligned} \tag{3}$$

with a and b being the plate's in-plane dimensions. Following the layerwise assembly of the global stiffness and mass matrices as outlined in Jackstadt et al. [12], the eigenvalue problem

$$\left(\mathbf{K}_{mn}^*(\omega) - \lambda_{mn}^* \mathbf{M}_{mn}\right)\hat{\mathbf{U}}_{mn}^* = \mathbf{0} \tag{4}$$

taking into account the complex-valued stiffness matrix $\mathbf{K}_{mn}^*(\omega)$ due to the elastomer materials' viscoelasticity is solved, yielding natural frequencies

$$\omega_{mn} = \sqrt{\Re(\lambda_{mn}^*)} \tag{5}$$

and corresponding modal damping ratios

$$\xi_{mn} = \frac{\Im(\lambda_{mn}^*)}{\Re(\lambda_{mn}^*)}. \tag{6}$$

In the presence of harmonic loads, the system of equation reads

$$\left(\mathbf{K}_{mn}^* - \omega^2 \mathbf{M}_{mn}\right)\hat{\mathbf{U}}_{mn}^* = \hat{\mathbf{R}}_{mn}, \tag{7}$$

where the loads are summarized in the right-hand-side term $\hat{\mathbf{R}}_{mn}$.

4. Results

Experimental Figure 1 shows the mastercurves at room temperature of the three elastomer materials considered in this study, which have been determined from experimental DMA experiments. The three elastomers differ significantly in their stiffness as can be seen from the course of the storage modulus E'. This is particularly pronounced at lower frequency before the materials enter their glassy state. Furthermore, the materials exhibit different levels of material damping, expressed by their loss factor $\tan(\delta)$.

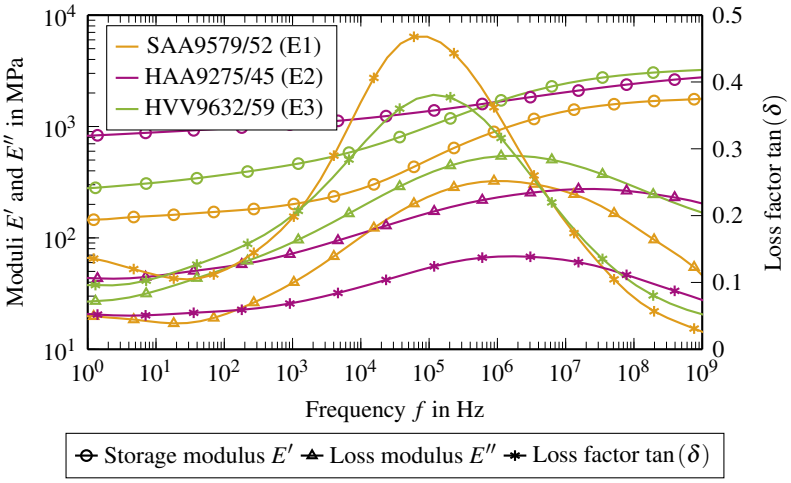

Figure 1: Master curves of the three elastomer materials at room temperature $T_R = 20\,°C$ generated from temperature and frequency sweeps in tension mode using TTS. [17]

Analytical For each of the six laminates under consideration, Figure 2 displays the natural frequencies and modal damping ratios corresponding to the first nine vibration modes of the simply-supported plates. It should be noted, that the order in which the modes occur is identical for all laminates.

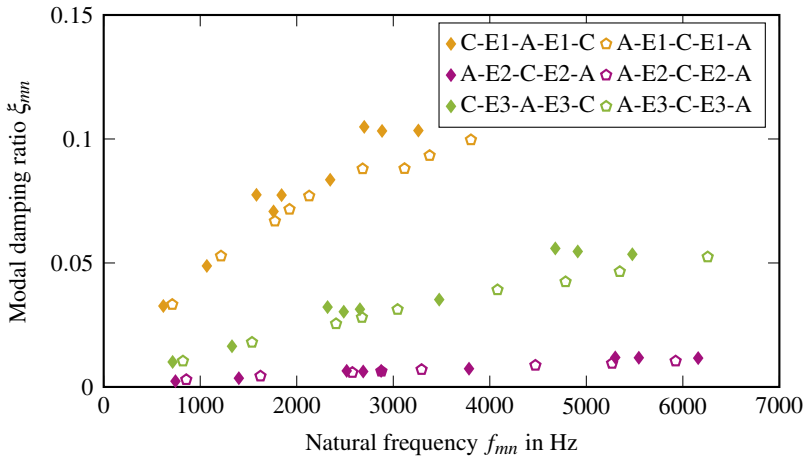

Figure 2: Modal damping ratios over corresponding natural frequencies of six different types of HyCEMLs. [17]

A clear differentiation between laminates incorporating distinct elastomer materials is evident. Specifically, laminates utilizing the same elastomer material display a consistent increase in modal damping ratios with increasing natural frequencies. Among these, the laminates incorporating the more compliant elastomer E1 demonstrate the highest modal damping ratios and relatively low natural frequencies. In contrast, the stiffer elastomer E2 results in the lowest modal damping ratios. Notably, the natural frequencies of laminates with elastomers E2 and E3 are comparable, yet the inclusion of elastomer E3 results in significantly higher modal damping ratios. These observations are consistent with the loss factors tan(δ) of the elastomer materials, as determined by DMA and depicted in Figure 1. Elastomer E1 exhibits the highest loss factor within the investigated frequency range, followed by elastomers E3 and E2. Irrespective of the specific elastomer used in the given HyCEMLs, laminates of type C-E-A-E-C show slightly higher modal damping compared to their A-E-C-E-A counterparts, albeit with a slight reduction in natural frequencies.

In order to investigate the response to forced vibration, the different HyCEMLs are excited by an harmonic force with amplitude $\hat{F}_0 = 10\,\mathrm{N}$ acting on the simply-supported plates. The structures' response is calculated as displacement amplitudes $|\hat{u}_z^*|$ and phase angles δ and shown in Figure 3 for a frequency-range of 1 Hz to 2000 Hz.

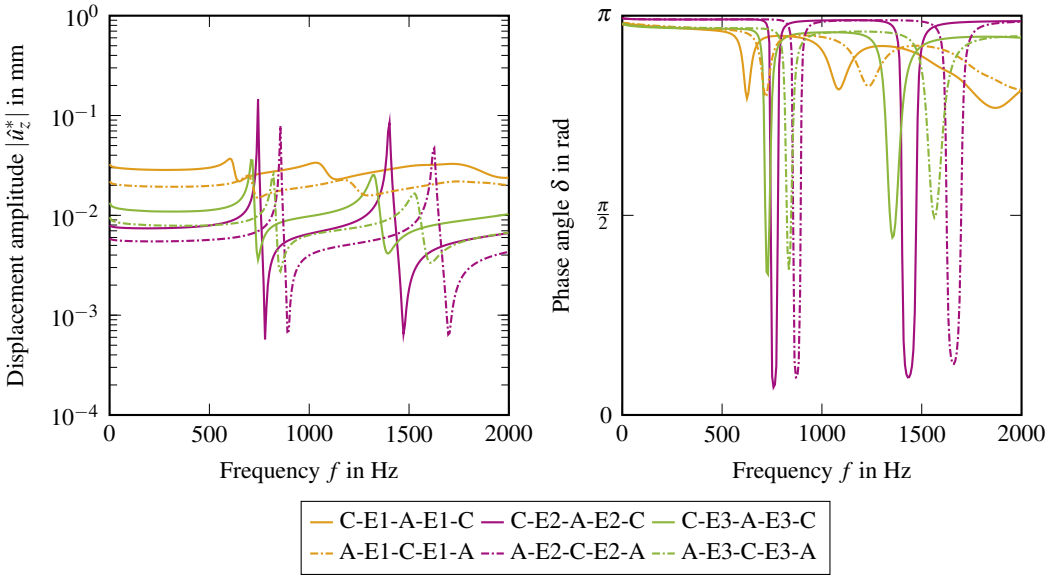

Figure 3: Frequency response to forced vibration of six different types of HyCEMLs in terms of transverse displacement amplitude and phase angle. [17]

In the left graph of Figure 3, the overall displacement amplitudes of the HyCEMLs are depicted. These amplitudes are influenced by the choice of elastomer material, with the most compliant elastomer, E1, producing the highest amplitudes. Near the natural frequency peaks on the response curve, however, laminates with stiffer elastomers, such as E2, exhibit the highest amplitudes. Additionally, these peaks are narrower compared to those of laminates with more compliant damping layers, indicating lower modal damping values. The right graph displays the phase angle between the applied oscillating force and the recorded displacement. Vibration modes can be identified by a phase angle shift δ of up to π, depending on the amount of damping featured by the mode at hand. Consequently, higher modal damping factors result in smaller phase angle shifts. At higher excitation frequencies, distinct modes become more difficult to identify, particularly for laminates with the highly compliant elastomer E1.
The results presented for the forced vibration of the six HyCEMLs are consistent with the findings from the preceding modal analyses. They confirm that the choice of elastomer material not only governs the overall level of vibration damping but also influences the structures' dynamic stiffness, as evidenced by the resulting displacement amplitudes. As elastomer materials can vary even more drastically in their stiffness, a parametric study is conducted, investigating how different laminate layups are influenced by a variation in elastomer stiffness. As an example, Figure 4 shows the influence of a variation in elastomer E1's stiffness in terms of a stiffness scaling factor κ_{E^*}, which is applied to the complex modulus

$$\tilde{E}^*(\omega) = \kappa_{E^*} E^*(\omega) = \kappa_{E^*}\left(E'(\omega) + \mathrm{i}E''(\omega)\right). \tag{8}$$

In general, the vibration characteristics of both types of laminates are influenced similarly by the stiffness variation of elastomer E1. Stiffening the damping plies in both cases leads to higher natural frequencies, with the higher modes experiencing more significant shifts. Conversely, reducing the stiffness decreases this mode dependency. Both increasing and decreasing the stiffness of the damping layers affect the

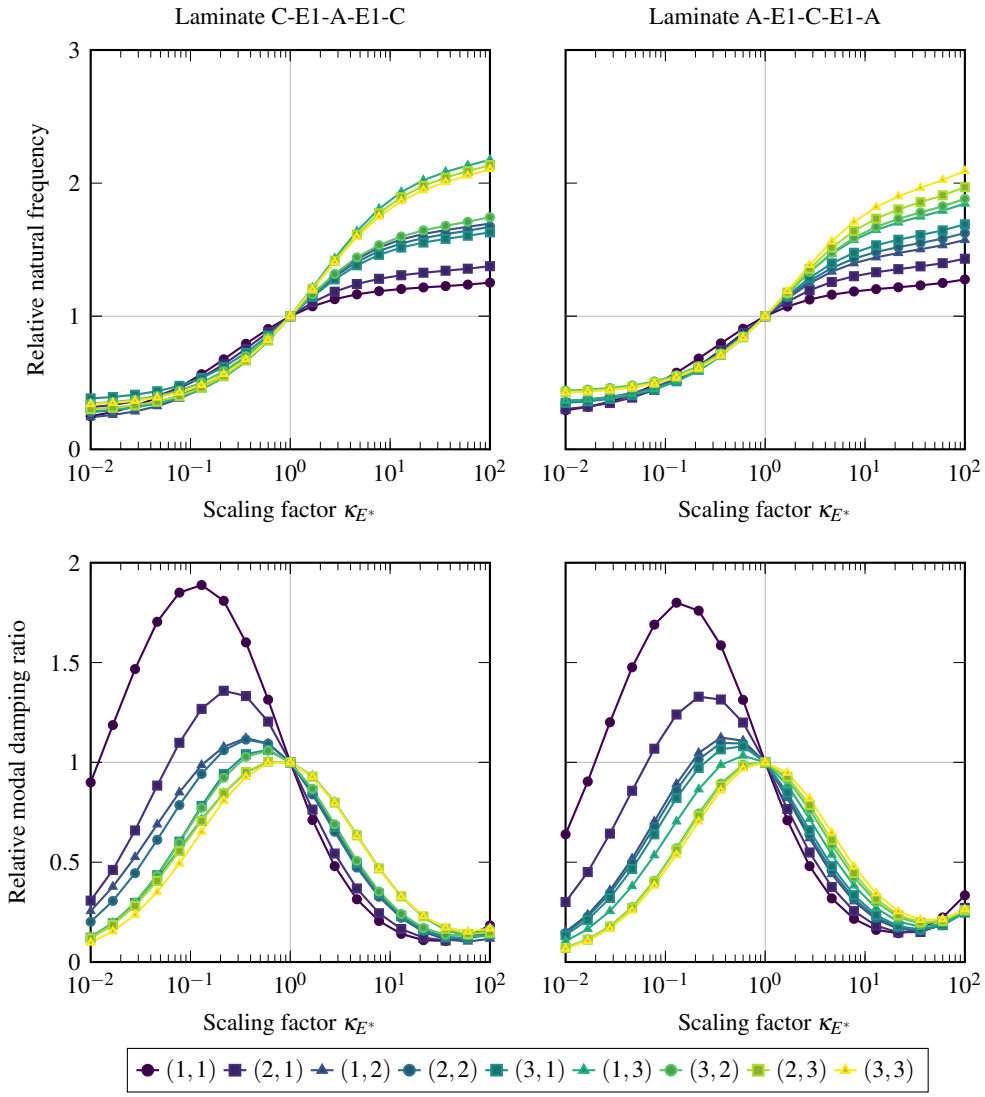

Figure 4: Relative natural frequencies and modal damping ratios for laminates C-E1-A-E1-C and A-E1-C-E1-A with varied complex stiffness in terms of κ_{E^*}. [17]

system within a specific range, showing convergence towards a plateau in both directions.
A different pattern emerges when considering the modal damping ratios in the graphs on the bottom of Figure 4, which also behave similarly for both types of laminates. Each of the nine modes examined exhibits a distinct maximum in their modal damping ratio within the range of the scaling factor κ_{E^*}. The peak modal damping for each mode occurs at different values of κ_{E^*}. While the higher modes do not surpass the damping achieved in the reference configuration ($\kappa_{E^*} = 1$), a significant increase in modal damping can be obtained for the first two vibration modes by using a more compliant elastomer. For the given plate dimensions and elastomer E1, an optimal modal damping appears to be achieved for the higher vibration modes, largely independent of the specific laminate layup.

5. Conclusion

In this study, an analytical model is employed to determine the vibration characteristics of different types of HyCEMLs. The findings indicate that the choice of elastomer material used largely dictates the resulting dynamic behaviour, whereas the overall laminate layup has a smaller influence. This correlation is confirmed under forced vibration and offers the possibility of designing CLD laminates, which offer high

bending stiffness under static loading while also being highly damped under vibration. A variation of the elastomers' complex stiffness whilst maintaining a constant loss factor shows the occurrence of a mode-dependent optimal elastomer stiffness for maximum damping, which is consistent with other reports in literature. Finally, the strong laminate and material dependencies illustrated in this study underline the necessity of efficient predictive models complementing experimental characterisation methods in the design phase of damped lightweight materials.

Acknowledgments

This work has been funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) within the SPP1897 "Calm, Smooth, Smart – Novel approaches for influencing vibrations by means of deliberately introduced dissipation", project KA 4224/3-2 "HyCEML – Hybrid CFRP/elastomer/metal laminates containing elastomeric interfaces for deliberate dissipation" (Karlsruhe Institute of Technology). The work is also part of the Heisenberg project "Digitalization of fiber-reinforced polymer processes for resource-efficient manufacturing of lightweight components", funded by the DFG (project no. 798455807141). Furthermore, the authors would like to acknowledge Gummiwerk KRAIBURG GmbH & Co. KG for providing the elastomer material.

Keywords: Polymer composites, Flammability, Combustion, Fireproofing, Mycelium

Abstract
This study investigates the influence of deacetylation and hollow glass microsphere incorporation on the thermal stability and fire reaction properties of mycelium. Deacetylation, achieved through alkaline treatment of mycelium, enhances thermal stability and char formation by increasing chitosan content. Thermogravimetric analysis revealed improved char yields with increased deacetylation, correlating with enhanced fire reaction properties of mycelium. Microscale combustion tests using pyrolysis-combustion flow calorimetry revealed decreased heat release rates in deacetylated mycelium. Cone calorimeter tests simulating real-world fire scenarios, demonstrated superior fire performance in deacetylated mycelium, with delayed ignition and reduced flaming intensity. Incorporating deacetylated mycelium as fireproofing mats in glass fiber-reinforced polymer laminates improved fire safety by forming carbonaceous char at the heat-exposed surface. This research highlighted the potential of deacetylated mycelium as a sustainable fireproofing material for lightweight polymer composites in fire-prone environments, paving the way for effective bio-derived fireproofing solutions.

1. Introduction

Fibre-reinforced polymer (FRP) composites are increasingly used in engineering design, including civil infrastructure, where weight minimisation is a critical objective [1]. FRP composites have excellent structural efficiency making them desirable for applications requiring lightweight materials. Despite their adoption in various engineering fields, the use of FRP composites in fire-prone applications remains a significant challenge. In the event of exposure to high heat flux or radiant heat from a fire, the polymer matrix within the composites volatilizes into combustible gases, leading to ignition and flaming combustion [2]. A major issue during the flaming combustion of FRP composites is the emission of highly toxic gases, fumes, and sometimes heavy smoke due to incomplete combustion [2]. This issue is particularly critical in civil infrastructure, where fatalities and serious injuries in building fires are often caused by entrapment due to smoke-induced vision impairment or inhalation of toxic gases. Recent tragic examples, including the 2017 Grenfell Tower fire [3], where 72 people lost their lives, and 2010 Shanghai, China, apartment fire that killed at least 58 people and injured more than 70 others [4], highlight the risks posed by the use of flammable materials in civil structures.

The flaming combustion intensity for FRP composites, along with the amount of toxic volatiles or smoke produced, can be controlled by modifying the flammable polymer matrix using fire retardant additives [5]. These additives can be applied in the form of fire retardant nano- or microparticles incorporated into the polymer matrix, used for fibre treatment, or as fireproofing materials on the heat-exposed surface of the composite [6]. Generally, fire retardant additives for FRP composites involve materials that promote surface char formation reduce free radicals and fuel load thereby precluding fire propagation.

Currently, state-of-the-art fire retardant technology involves the use of phosphorous and nitrogen-based fire retardants, which, unfortunately, have been linked to reproductive and developmental issues, environmental persistence, and harm to aquatic organisms [7]. Therefore, it is imperative to develop new, biodegradable and environmentally sustainable fire retardants and fire proofing systems that are just as effective as their synthetic counterparts. Several bio-derived materials have potential for use as fire retardant additives or fireproofing systems for FRP composites. Some of these biodegradable fire retardants include dopamine, tannin, phytic acid, casein and mycelium [8]. Mycelium is particularly promising due to its high chitin content, which has been demonstrated to promote surface char formation, thereby insulating the underlying flammable composite. Additionally, mycelium can be grown from recovered organic waste, diverting waste from landfills. It also grows in the dark, without need for energy to support growth, further enhancing its sustainability and eco-friendliness.

Mycelium, the thread-like hyphae filaments of fungi, has chitin-constituted cell walls that exhibit promising fire-retardant properties. When exposed to heat, mycelium decomposes into a consolidated char. This surface char can slow down heat transfer to the flammable substrate and prevent the release of combustible volatiles into the combustion zone. When mycelium is treated with an alkaline medium such as sodium hydroxide (NaOH), deacetylation occurs, converting chitin into chitosan. Additionally, the alkaline-induced degradation of β-1,4-glycosidic chemical bonds produces low molecular weight hydroxyl-terminated polymer segments, which promote char formation [9]. The elevated char production underscores the potential of mycelium as an effective fireproofing material.

Limited research has focused on assessing the flammability characteristics of mycelium and its derivatives. This study investigated the correlation between thermogravimetric analysis (TGA) char yields and the flammability properties of mycelium. Micro-scale combustion properties of unmodified and deacetylated mycelium were evaluated using pyrolysis-combustion flow calorimetry (PCFC), while the flammability characteristics of mycelium were analyzed using a cone calorimeter. Additionally, the study explored the influence of hollow glass microspheres (HGM) on the thermal stability and flammability characteristics of mycelium. At high temperatures, HGM particles melt, forming viscous and potentially thermal insulative SiO_2 micro-architectures on the heat-exposed surface.

UL-94 flammability tests evaluated the flame spread characteristics of mycelium. Various parameters, including the duration of flame persistence, dripping behavior, and burning rate, were measured. The effectiveness of unmodified and deacetylated mycelium in fireproofing glass fibre-reinforced epoxy polymer (GFRP) composites was assessed using a cone calorimeter. Microstructural characterization of the char was conducted using scanning electron microscopy (SEM) to elucidate the mechanisms responsible for variations in char yields and the fire response of mycelium and its derivatives.

2. Methodology

A brief description of the materials and methodology followed in preparing the materials for experimental analysis is provided in this paper. For a detailed overview of the methodology, the reader is referred to a previous publication [10]. An isolated culture of mycelium fungi, *Ganoderma australe*, growing on malt extract agar was sourced from RMIT University's Fungal Culture Collection (Australia) and used as an inoculum. All materials used for cultivating mycelium were sterilised at 121°C for 30 min to prevent pathogenic or bacterial contamination. Blackstrap molasses (E&A Salce, Australia) was diluted to a 10 wt.% molasses/water solution using ionised water. A 3 cm-diameter circular disc of the fungal culture cut from the agar plate using the tip of a sterilised 50 mL centrifuge

tube was transferred to the centre of the PP container containing 350 mL diluted molasses. In the case of HGM-containing mycelium, 10 mL of HGM particles were sifted over molasses using a sieve. The PP container was sealed and incubated (temperature 25°C; white light) for 60 days. In the case of HGM-reinforced mycelium, 10 mL of the West System 411 HGM particles (ATL Composites, Australia) were sifted over molasses using a sieve. The residual molasses on mycelium biomass was rinsed with deionised water. Deacetylation was conducted at 40°C to preserve the microstural integrity of mycelium.

Some mycelium sheets were deacetylated using 2M reagent-grade sodium hydroxide, NaOH (Sigma Aldrich, Australia) at 40°C for 2 or 8 hr. Another batch of mycelium was deacetylated using 4M NaOH at 40°C over 2 hr. A standard nomenclature, concentration/temperature/time, was used to identify deacetylated mycelium. For example, mycelium deacetylated using 2M NaOH at 40°C for 2 hr was identified as 2M/40°C/2h. The unmodified (as-grown) and deacetylated mycelium sheets incorporating HGM particles were identified as Control-HGM and 2M/40°C/8h-HGM, respectively. Table 1 shows the deacetylation conditions, along with the identities of the mycelium samples. The calculation of the degree of deacetylation, DD, is explained in our previous publication [10].

Table 1. Deacetylation conditions (NaOH concentration and incubation time), biomass yields and the degree of deacetylation for mycelium sheets treated at 40°C.

Sample	[NaOH] (M)	Time (hr)	HGMs	[a]Biomass (%)	[b]DD (%)	[c]DD* (%)
Control	-	-	-	-	45 ± 3	48 ± 2
2M/40°C/2h	2	2	-	74 ± 4	56 ± 4	54 ± 4
2M/40°C/8h	2	8	-	62 ± 3	84 ± 2	83 ± 3
4M/40°C/2h	4	2	-	66 ± 1	75 ± 3	77 ± 2
Control-HGM	-	-	Yes	-	49 ± 1	46 ± 4
2M/40°C/8h-HGM	2	8	Yes	65 ± 3	86 ± 3	81 ± 2

[a]Biomass (%) is percent ratio of dry mass yield of a deacetylated to the unmodified mycelium.
[b]DD: degree of deacetylation (absorption peak intensity ratio of the C=O to OH bands).
[c]DD*: degree of deacetylation (integrated area ratio of the C=O and OH absorption bands).

Mycelium sheets were dried at 60°C over 3 hr and stored in hermetic plastic bags to prevent moisture absorption. Dry mycelium was used for microstructural characterization, thermal stability evaluation and microscale combustion calorimetry. For cone calorimetry tests, mycelium sheets were stacked and hot-pressed to form multi-layer laminates as described later.

The microstructure and morphology of both pristine mycelium sheets and residual char collected during TGA experiments at 600 or 850°C were characterised using the SEM (FEI Qanta 200) equipped with an Energy Dispersive X-Ray Spectrometer (SEM-EDS) and operated by the Aztec software. Mycelium sheets or residual char powder were bonded to an electrically conductive carbon tape which was then affixed to a sample holder. The sample was coated with iridium in a Leica ACE600 sputter coater operated at 8×10^{-3} mbar to achieve a coating thickness of ~5 nm.

The thermal stability of mycelium derivatives was evaluated using the Perkin Elmer STA 6000. Mycelium flakes (~12 mg) were placed into an alumina crucible which was then inserted into the TGA furnace. The furnace temperature was increased from 35 to 850°C at a rate of 30°C/min (flowing N_2 gas; 20 mL/min). A minimum of three repeat experiments were conducted for each mycelium sample. Microscale combustion properties of mycelium were evaluated using the Fire Testing Technology (Gosport, UK) supplied PCFC in accordance with the ASTM D7309-21 standard [11]. Mycelium flakes ~5 mg) were placed into the sample holder which was then inserted into the PCFC chamber. The chamber temperature was increased from 75 to 850°C at a rate of 1K/s under an N_2 (80 cm^3/min) and O_2 (20 cm^3/min) atmosphere. The combustion chamber temperature was maintained at 900°C.

Wet unmodified or alkaline-treated mycelium sheets were stacked to create multilayer mycelium only laminates. Mycelium laminate layups were hot-pressed at 60°C under 0.25 MPa compressive pressure for at least 3 hr, resulting in denatured and consolidated laminates of ~4.5 mm thickness. Mycelium laminates were transferred to a compression-loaded jig and further dried at 60°C in a conventional oven. Two mycelia only laminates were manufactured: unmodified (Control-Lam) and deacetylated (2M/40°C/8h-Lam). Fire reaction properties of the Control-Lam and 2M/40°C/8h-Lam mycelium only laminates were evaluated using the cone calorimeter operated at an incident heat flux of 35 kW/m^2. Consolidated mycelium-only laminates (unmodified and deacetylated) measuring 125 × 13 × 2 mm were evaluated under the UL-94 vertical flame test according to ASTM D3801-20 guidelines [12].

To assess their fireproofing efficacy, mycelium derivates were bonded onto the heat-exposed surface of the GFRP laminate. Due to their fragility, mycelium sheets required reinforcement prior to integration onto GFRP laminates. Two hot-pressed mycelium sheets (Control or 2M/40°C/8h) were bonded between 35 gsm chopped strand glass fibre veils (Glass Fibre Tissue & Veil, Australia) using epoxy. The glass fibre veil/mycelium/epoxy fireproofing mat was cured at ~23°C for 24 hr and post-curing at 60°C for 8 hr. The respective weight fractions of the glass fibre veil, mycelium, and epoxy matrix were 5, 31, and 64%. A baseline glass fibre veil/epoxy mat without mycelium was manufactured in the same way.

Eight-ply GFRP composites were manufactured via vacuum-assisted resin infusion using plain woven glass fabric (570 gsm) (Colan, Australia) and epoxy resin/amine hardener (West System 105/206) (ATL Composites, Australia). The glass fibre to epoxy weight ratio in the GFRP-Laminate, was 40:60. Fireproofing glass veil/epoxy mats with or without mycelium were then bonded onto the heat-exposed surface of the GFRP laminate. Fireproofed GFRP laminates were vacuum-bagged, cured at ~23°C for 24 hr and post-cured at 60°C for 8 hr. GFRP-Glass veil, GFRP-Control, and GFRP-2M/40°C/8h respectively refer to a GFRP laminate incorporating: a two-layer glass veil without mycelium; unmodified mycelium (Control); and deacetylated (2M/40°C/8h) fireproofing mats..

Fire properties of mycelium only laminates and the GFRP-Laminate were evaluated using square (85 × 85 mm) specimens in accordance with ISO 5660 [13]. Cone calorimeter specimens were wrapped in thin aluminium foil and horizontally mounted ~25 mm below the radiant cone heater, which was operated at 35 kW/m^2. Fire reaction properties of fireproofed GFRP laminates (100 × 100 mm) were evaluated under cone calorimeter conditions in accordance with ISO 5660 [13]. At least three experiments were conducted for each configuration.

3. Results and discussion

Mycelium-only laminates and mycelium fireproofed GFRP laminates are shown in Figure 1. A sideview image of the mycelium-only laminate revealed a consolidated structure layup suggesting strong bonding between mycelium in the absence of a binder. The two-layer mycelium/veil system bonded well to the GFRP laminate as shown in Figure 1(B).

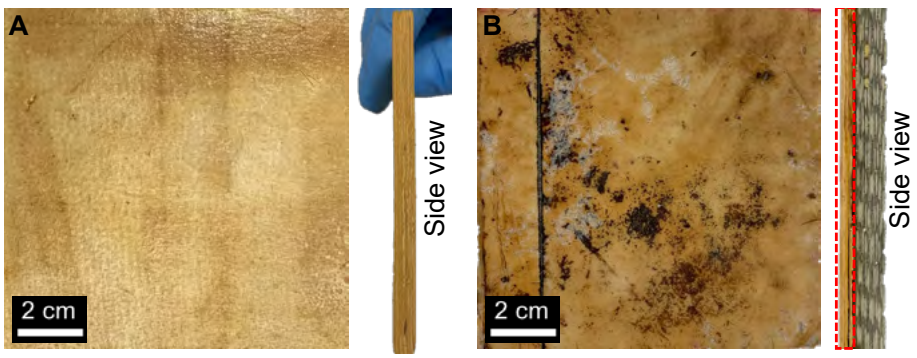

Figure 1. Top and side-view of (A) mycelium-only laminate and (B) mycelium fireproofed GFRP laminate. Dashed red lines in (B) indicate the fireproofing mycelium bonded to the GFRP laminate [10].

Figure 2(A) shows that under the mildest deacetylation conditions of 2M NaOH at 40°C for 2 hr, the filamentous hyphae network was preserved. Sample 2M/40°C/2h, had the highest biomass retention of 74% among all deacetylated mycelium samples. Increasing the deacetylation time from 2 to 8 hr or elevating the NaOH concentration from 2 to 4M caused the hyphae strands to fuse into micro-globular features, as revealed in Figures 2(B, C). Degree of deacetylation increased with time or NaOH concentration. However, harsher deacetylation conditions further reduced biomass yields. The reduction in biomass yields upon deacetylation was attributed to deproteinization caused by the cleavage of chemical bonds between chitin and proteins [14].

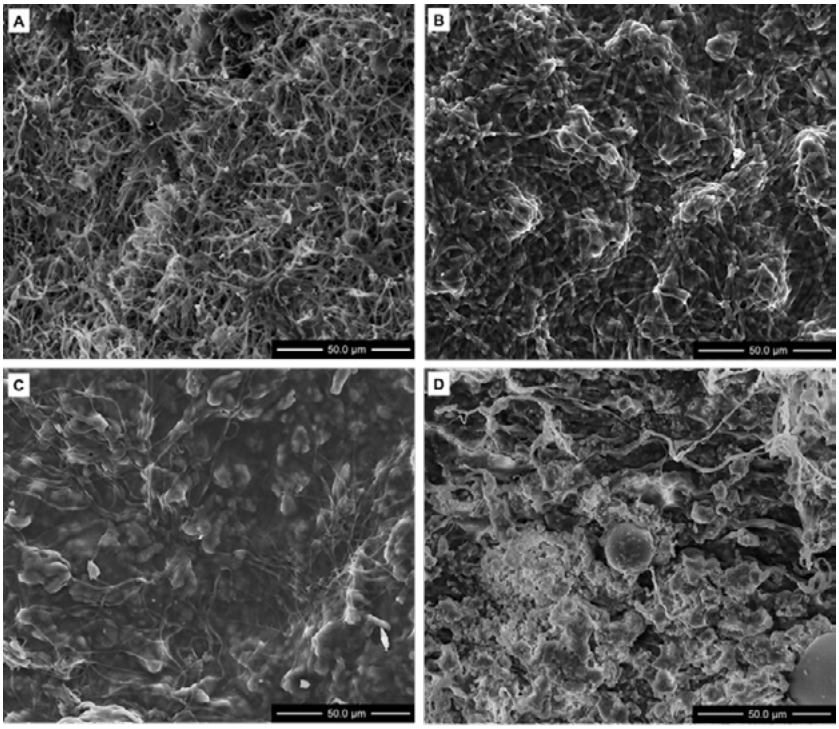

Figure 2. SEM images of deacetylated mycelium (A) 2M/40ºC/2h, (B) 2M/40ºC/8h, (C) 4M/40ºC/2h and (D) 2M/40ºC/8h-HGM. Spherical particles in (D) indicate HGM particles [10].

Deacetylation converted chitin components into chitosan, which has unique thermal degradation properties including the ability to form large quantities of surface char. TGA experiments revealed how different alkaline treatment conditions affected the thermal stability of mycelium. The TGA mass-temperature and derivative thermogravimetry profiles, Figure 3, showed five distinct mass loss events for unmodified mycelium, attributed to the decomposition of hydrophobins, dehydration, and the breakdown of fungal cell wall components [15]. The primary thermal degradation stage resulted in significant mass loss due to the decomposition of chitin, amino acids, and polysaccharides, followed by the formation of primary and secondary char.

Deacetylation had minimal impact on the thermal degradation temperatures and mass loss rates for the first two stages. However, the third mass loss event showed significant differences; for example, in the 2M/40°C/8h sample, the peak thermal degradation temperature occurred about 70°C earlier than in unmodified mycelium, indicating an earlier onset of primary thermal decomposition. Additionally, the mass loss during this stage was lower in deacetylated mycelia. The fourth and final mass loss events were largely similar across all samples, with the final event occurring between 600 and 835°C. These results suggest that while the overall thermal degradation mechanisms remain consistent, deacetylation particularly affects the primary thermal degradation stage and improves the primary char yield.

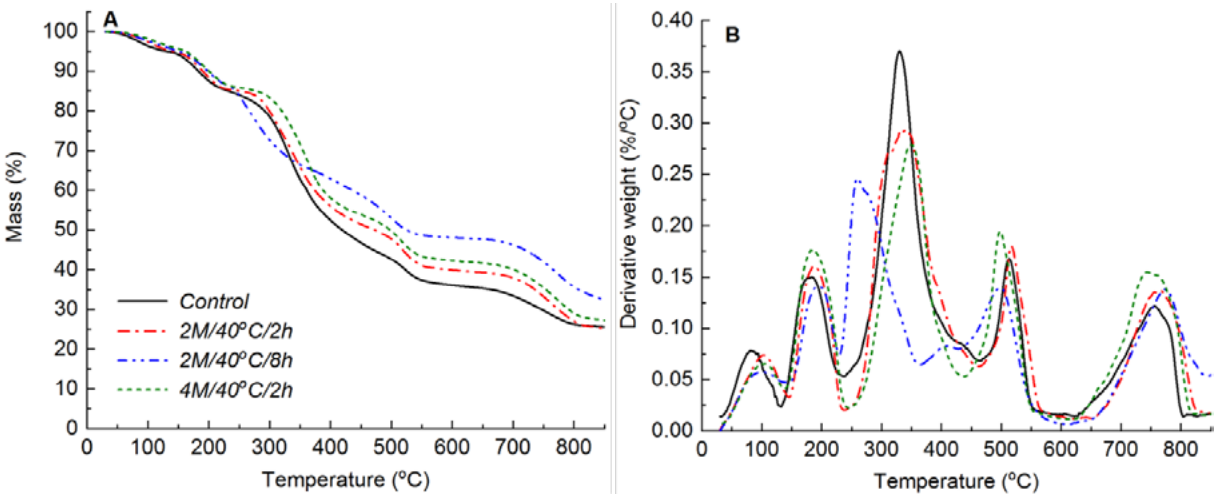

Figure 3. (A) Mass-temperature and (B) mass loss rate profiles for unmodified and deacetylated mycelium without HGM particles [10].

There were no significant differences in the TGA evaluated thermal stability of mycelium with and without HGM particles [10]. This was attributed to the relatively low content of HGM particles embedded in mycelium. However, microstructural analysis of residual char collected at 600°C revealed the presence of SiO_2 which later formed an integrated porous network at 850°C as shown in Figure 4.

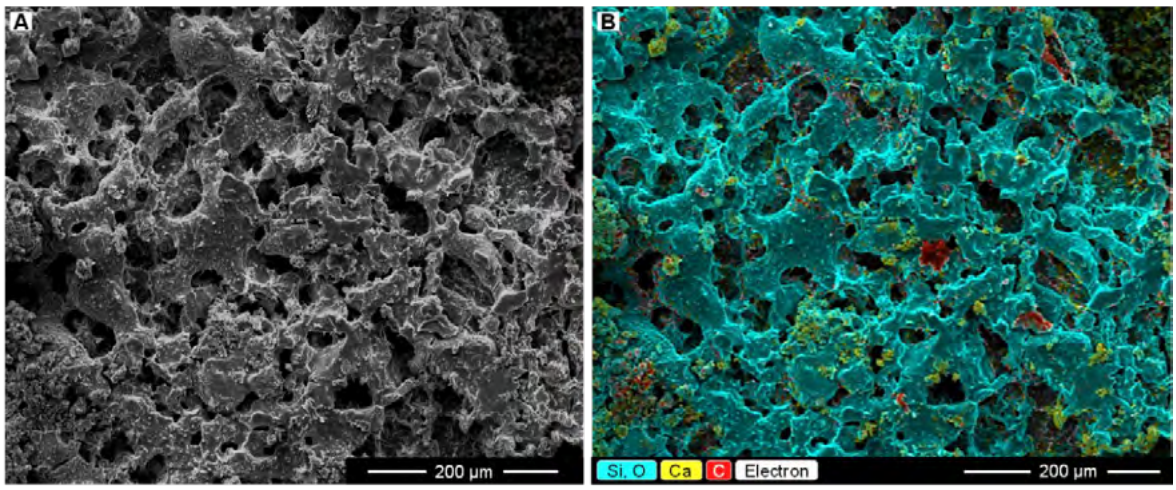

Figure 4. SEM (left) and EDS (right) image of the residual char for 2M/40°C/8h-HGM at 850°C [10].

The specific heat release rates (HRR) measured by PCFC for unmodified and deacetylated mycelium samples, shown in Figure 5(A), indicated lower HRRs for deacetylated samples. Five distinct combustion stages were identified, except for the 2M/40°C/8h sample, which exhibited unique thermal degradation pathways. The HRR-temperature profiles for samples under mild deacetylation conditions resembled that of unmodified mycelium, while harsher conditions significantly altered the profiles, particularly for 2M/40°C/8h, which had a notably lower peak HRR (pHRR). The TGA mass loss rate and PCFC HRR profiles for unmodified mycelium matched despite different heating conditions. While reductions in specific pHRR, shifts to higher peak HRR, and relatively lower heat release capacity indicate improved flammability for deacetylated mycelium, these metrics alone do not fully capture the material's combustion behavior. Consequently, cone calorimeter tests were necessary to evaluate the fire reaction properties of mycelium-only laminates and subsequently GFRP fireproofing efficacy of mycelium under conditions simulating a real fire.

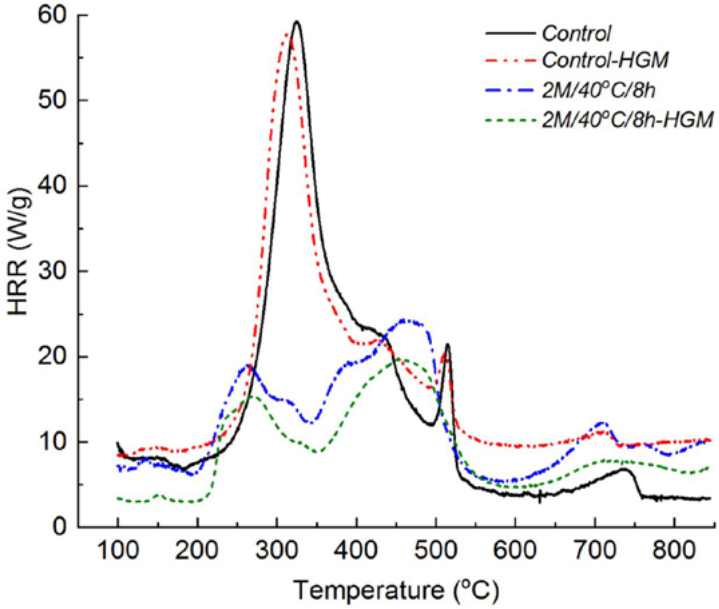

Figure 5. PCFC-measured specific HRR profiles of unmodified and deacetylated mycelium with (Control-HGM and 2M/40°C/8h-HGM) and without HGM particles (Control and 2M/40°C/8h) [10].

The cone calorimeter flammability characteristics of GFRP-Lam are compared to those of Control-Lam and 2M/40°C/8h-Lam in Figure 6. Sample 2M/40°C/8h-Lam was selected for fire reaction evaluation based on its high TGA char yield and lowest PCFC specific HRR. Control-Lam exhibited a sharp HRR spike shortly after ignition, reaching an average peak value of 149 kW/m^2 within 10 s, followed by a secondary peak event at around 50 s post-ignition. In contrast, 2M/40°C/8h-Lam showed no sharp HRR spike, maintaining HRR values below 50 kW/m^2 with broad peak events recorded at approximately 185 s and 398 s. Despite the greater total heat release from 2M/40°C/8h-Lam compared to Control-Lam, its flaming intensity was significantly lower due to enhanced char-forming characteristics. Further, both Control-Lam and 2M/40°C/8h-Lam exhibited substantially lower HRR profiles compared to GFRP-Lam, demonstrating mycelium as a potential fireproofing material for flammable composites. The deacetylated mycelium achieved UL94 V-0 rating suggesting superior resistance to flame spread [16].

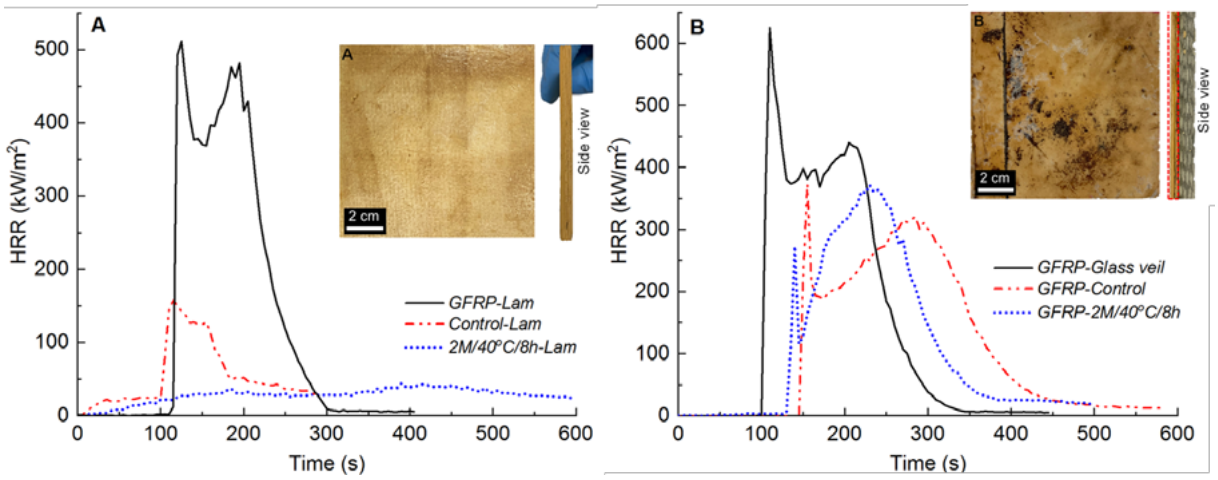

Figure 6. Cone calorimeter HRR profiles for (A) mycelium-only (Control-Lam and 2M/40°C/8h-Lam) and GFRP-Lam and (B) GFRP laminates fireproofed using the glass veil (GFRP-glass veil), unmodified (GFRP-Control) and deacetylated mycelium (GFRP-2M/40°C/8h) at 35 kW/m^2 [10].

4. Conclusions

This study investigated the impact of deacetylation on mycelium's fire reaction properties, correlating thermal degradation profiles with char yields. Increasing the degree of deacetylation through alkaline treatment enhanced thermal stability and char formation of mycelium. PCFC tests indicated improved combustion properties in deacetylated mycelium, with decreased heat release rates and combustion capacities. Cone calorimeter tests simulating real-world fire scenarios, revealed superior fire performance in deacetylated mycelium, particularly delaying ignition and reducing flaming intensity. Incorporating deacetylated mycelium as fireproofing mats in GFRP laminates improved fire safety by forming carbonaceous char at the laminate surface, suggesting its potential for protecting flammable polymer composites in fire-prone environments such as transport vehicles and buildings.

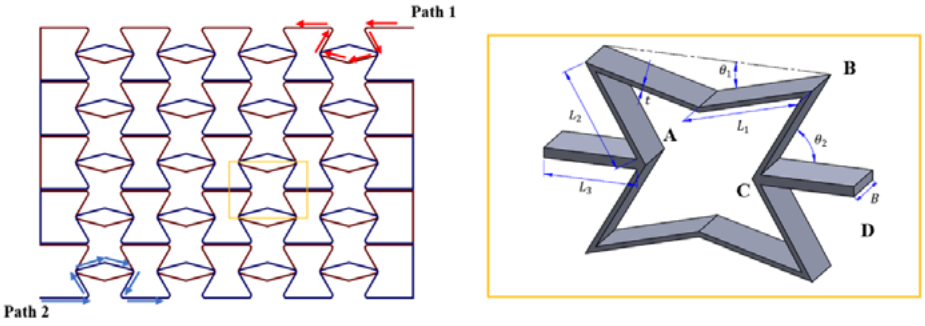
Abstract
In this study, a novel combined auxetic honeycomb structure, featuring both star and hourglass shapes, is introduced. Experimental evaluations of quasi-static compressive loading applied to these structures in the vertical orientations are encompassed by the research. For specimen preparation, the manufacturing process involved fused filament fabrication, commonly known as 3D printing. During the test, the nonlinear response of the star-hourglass-shaped auxetic lattice subjected to compressive loading is analyzed at stepwise quasi-static tests. At each step, the send and receive signals are measured using the ultrasound sensor. The variation and reflection of the ultrasonic wave signals are used to evaluate the health status of the star-hourglass-shaped auxetic structure, as signal alterations are typically associated with damage. The performed experimental procedure is employed to assess the influence of damage and plasticity modes on wave response under compressive loading of the star-hourglass-shaped auxetic structures, which were fabricated with both pure and reinforced PLA materials. The findings indicate that in structures printed with pure PLA, plasticity dominates as the primary nonlinear phenomenon. Conversely, in lattice structures fabricated with reinforced PLA, damage events and fracture phenomena take precedence, outweighing the nonlinear response attributed to plasticity. Furthermore, it is demonstrated by obtained results that the energy absorption capabilities of composite structures surpass those of structures made exclusively with pure PLA.

1. Introduction

Cellular structures display several noteworthy characteristics, such as a robust strength-to-weight ratio, enhanced mechanical properties, effective energy absorption, sufficient fracture toughness, and heightened resistance to impacts [1]. Due to these benefits, cellular structures find widespread application across diverse industries including transportation, medical engineering, automotive production, and civil engineering [2]. An efficient strategy to alter the equivalent mechanical properties in different directions [3, 4] is to corrugate the cellular structures. The structures of this type are flexible along a corrugated wall (in the longitudinal direction) and provide the capability of adapting to deformations. Meanwhile, they exhibit stiff responses perpendicular to the corrugated wall (transverse directions) and provide a high load-bearing capacity [5]. Researchers have suggested several approaches to improve stiffness and boost energy absorption capacity within cellular structures [6]. Choudhry et al. [7] introduced innovative re-entrant auxetic honeycombs featuring vertical ribs and investigated their nonlinear responses under compression loads. Their findings revealed that these novel honeycombs exhibited superior energy absorption compared to traditional re-entrant honeycombs. Li et al. [8] conducted in-plane quasi-static compressive tests to explore the mechanical behavior and energy absorption capabilities of their honeycomb structures. They discovered that incorporating a variable cross-section design in the width direction boosted both compressive strength and energy absorption. Wang et al. [9] proposed a novel hierarchical lattice design by replacing the main straight beams of the face-centered cubic lattice with a string of higher-level circular beams to enhance energy absorption

capacity. Their results indicated that this hierarchical design, with an appropriate number of higher-level circular beams, could simultaneously improve specific energy absorption and crushing force efficiency. Reviewing the literature reveals that one of the critical issues about the behavior of cellular structures for real application is the scanning of the response of these structures for possible damage formations that are prone to them. Structural health monitoring (SHM) is a powerful approach to identifying structural damages and forecasting their remaining lifespan. By doing so, it ensures safety, reduces maintenance costs and downtime, evaluates the durability of structural components, and enhances the reliability and safety of structures [10]. The signals of guided wave propagation obtained by sensors include damage-sensitive information that can be exploited for damage detection [11]. Current methods for inspecting the structural health of lattice structures often rely on analyzing vibration signals [12]. Jose et al. [13] proposed using vibration parameters, such as natural frequency, damping ratio, and mode shapes, as inputs for a neural network model. The target output of this model was to predict the centroid coordinates of removed members in Cartesian space and to locate damage in lattice structures. Thankachan et al. [14] utilized vibrational modal frequencies or the first mode shape as inputs, and the Cartesian coordinates of the centroid of damaged members, along with the percentage reduction in cross-section, as outputs for a combination of an artificial neural network and a Cuckoo search algorithm. This was used to predict both the location and severity of damage in lattice structures. The review of existing literature reveals a gap in research concerning damage detection in lattice structures using ultrasound methods. Thus, this study introduces a novel combined auxetic honeycomb structure, incorporating both star and hourglass shapes. This innovative lattice design can be produced using 3D printing techniques, offering the flexibility to utilize either pure or reinforced filaments integrated with continuous fibers. The research encompasses experimental assessments of quasi-static compressive loading applied vertically to these structures. Specimen preparation involved fused filament fabrication, commonly referred to as 3D printing. During testing, the nonlinear response of the star-hourglass-shaped auxetic lattice under compressive loading is analyzed through stepwise quasi-static tests. At each step, ultrasound sensors measure both the transmission and reception of signals. Variations and reflections in these ultrasonic wave signals are utilized to assess the structural health of the star-hourglass-shaped auxetic lattice, as changes in signals typically indicate damage. The experimental procedure is employed to evaluate how damage and plasticity modes influence wave responses during compressive loading of the star-hourglass-shaped auxetic structures. These structures were fabricated using both pure and reinforced PLA materials.



2. Star Hourglass Honeycomb structures

The star-hourglass honeycomb structure, illustrated in Figure 1, draws inspiration from a fusion of star-shaped and hourglass honeycomb configurations. Among the array of auxetic designs, star-shaped honeycombs stand out for their exceptional energy absorption capability, attributed to their remarkable flexibility and hinge movement during compression, resulting from plastic deformation angles. Similarly, hourglass honeycombs exhibit a notably high equivalent elastic modulus compared to other structures. This study introduces a pioneering combined star-hourglass honeycomb, which inherits the outstanding energy absorption and elastic modulus characteristics of both star-shaped and hourglass honeycombs simultaneously. The innovative structure aims to enhance equivalent material properties and plateau strength while maintaining a low weight compared to traditional materials like foam and honeycomb fillings. A crucial aspect of this proposed lattice structure is its compatibility with fabrication using 3D printing technology, utilizing either pure or reinforced filaments with continuous fibers, as depicted in Figure 1, enabling the creation of various automobile components. This structure holds potential for application in load-bearing engineering contexts, as well as in scenarios requiring energy absorption and crashworthiness, depending on the specific application requirements of this type of cellular structure.

3. Experimental methodology

3.1. Material properties of parent materials

To improve the energy absorption capacity of star-hourglass honeycomb structures composed of biodegradable thermoplastic PLA, polymers are reinforced with chopped carbon using the Fused Filament Fabrication (FFF) method. These fibers serve to enhance the mechanical properties of the 3D printed components. Tensile and compression test specimens are prepared according to ASTM D638 and ASTM D695 standards, respectively. These specimens undergo uniaxial tension and compression tests to characterize the properties of the materials utilized in this research.

(a) (b)

Figure 1. Configuration of star hourglass honeycomb structure (a) Printing paths, (b) Definition of geometrical parameter on an extracted unit cell.

3.2. 3D Printing of specimens

The specimens were manufactured using an FDM 3D printer, specifically the Quantum-2020 model, which utilizes standard 1.75 mm PLA filament as the substrate. The 3D printing G-Codes were generated using Simplify 3D software.

Table 1. General settings of the 3D printing process.

Parameter	Nozzle diameter	Air gap	Layer thickness	Bed temperature	Printing speed	Nozzle temperature
Value	1 mm	0.02mm	0.3 mm	65°C	10mm/s	210°C

Table. 1 summarizes the overall settings of 3D printing. Table. 2 also represents the geometrical parameters of the star hourglass honeycomb structure.

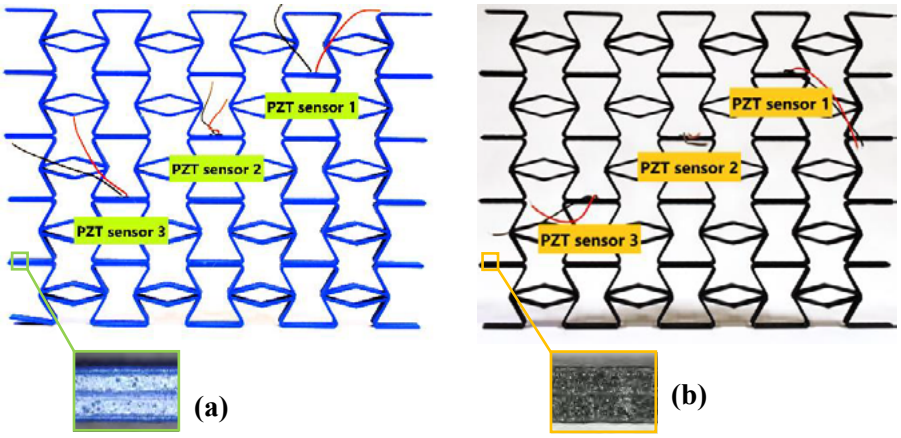


Figure 2. (a) star hourglass honeycomb structure fabricated by pure PLA, (b) star hourglass honeycomb structure fabricated by PLA reinforced by chopped carbon fibers.

Three specimens were prepared using the FDM process, which involves feeding filament through an extruder into a heated chamber. Within this chamber, pressure is applied to extrude the molten polymer through a nozzle. After each layer is deposited, the nozzle moves upward, allowing the adjacent layer to be placed atop the preceding one. The layer height for printing each specimen was set at 0.3 mm, and the thickness of the cellular wall remained consistent at 0.9 mm for all structures. Fig. 2 illustrates the 3D printer and the created cellular structures. Each structure is equipped with three PZT, arranged diagonally at equal distances, to coverage of the received ultrasonic waves throughout most structure areas, rather than just in a local area, enhancing the ability to monitor more structural paths. Furthermore, the use of multiple sensors enhances system redundancy, ensuring that even if one sensor fails or delivers poor-quality signals, other sensors can continue to provide critical monitoring data.

Table 2 Considered geometrical parameters for 3D printing structures.

L_1 (mm)	L_2 (mm)	L_3 (mm)	θ_1 (deg)	θ_2 (deg)	t (mm)	B (mm)	Total dimension (mm^3)
12.85	12.35	12	15	45	0.9	10	144×120×10

It should be noted that the measured mass of star hourglass honeycomb structures printed by pure PLA, and reinforced PLA by chopped carbon fibers are 32.66 gr, and 28.53 gr respectively.

4. Results and discussion

4.1. Characterization tests

To assess the material properties of the raw PLA material, specimens in both dog bone and cylindrical shapes are 3D printed using FDM technology. Tensile tests, following ASTM-D638 standards, and compression tests, following ASTM-D695 standards, are conducted on these specimens. A minimum of three samples are tested for each test category. The tests are performed using an Instron 5500R machine at a fixed crosshead speed of 5 mm/min. It is important to highlight that loading-unloading-reloading tests are conducted on both tensile and compression coupon tests to extract the necessary damage parameters and inelastic strains. The stress-strain responses of standard coupon tests for pure PLA and PLA reinforced with chopped carbon fibers are depicted in Figure 5. The material properties of PLA obtained from the conducted tensile tests are summarized in Table 3.

Table 3. Obtained material properties of Pure PLA and reinforced PLA by chopped carbon fibers using standard tensile and compression tests.

Material	***E*** **(GPa)**	***ν***	σ_{yt} **(MPa)**	ε_t **(%)**	σ_{ut} **(MPa)**	σ_{yc} **(MPa)**	ε_c **(%)**	σ_{ut} **(MPa)**
Pure PLA	$2.22^{\pm 0.1}$	0.3	$25.5^{\pm 1.2}$	$23.5^{\pm 0.01}$	$18.5^{\pm 0.5}$	$36.5^{\pm 1.1}$	$60\pm^{0.01}$	$60.42^{\pm 0.3}$
Chopped Carbon PLA	$3.1^{\pm 0.12}$	0.3	$62.8^{\pm 1.1}$	$10^{\pm 0.05}$	$58^{\pm 1.5}$	$79.1^{\pm 1.21}$	$55^{\pm 0.03}$	$86^{\pm 1.6}$

4.2. Compression tests

Typically, the energy absorption capacity of a specific structure is assessed through compression testing. This test generates a force-displacement curve, which serves as a representation of the structure's energy absorption characteristics. In this study, as depicted in Figure 3, the specimens underwent in-plane compression testing using the INSTRON-5500R compression test device. The velocity of the upper jaw displacement, applying quasi-static load, was set at 5 mm/min. Force-displacement curves were then obtained from the device, serving as the basis for further analysis and evaluation. For each material of the star-hourglass honeycomb structures, two specimens were tested. The specimens were compressed until they reached approximately 50% of their initial height. Figures 3 to 4 present the compression force-displacement curves obtained from both experimental and numerical testing of the star-hourglass honeycomb structures with various parent materials. In the results obtained, efforts were made to illustrate the different stages of structural deformation. Following compression loading in the y

direction, data from all three-star-hourglass honeycomb structures were recorded step by step to analyze the force behavior of the structures at different displacement rates.

4.2.1. Star hourglass honeycomb structure fabricated by pure PLA

According to the diagram depicted in Figure 3, for the star-hourglass honeycomb structure fabricated from pure PLA, the force initially increases from zero to 4 mm in the first elastic interval, indicating the structure's ability to withstand the applied load until signs of damage emerge at a displacement of 8 mm, leading to a notable reduction in force. The force remains relatively constant until reaching a displacement of 33 mm, where plasticity and damage become evident in the oblique struts. From the displacement range of 35 mm onwards, an upward trend in force is observed, continuing until all rows of the structure are compressed together.

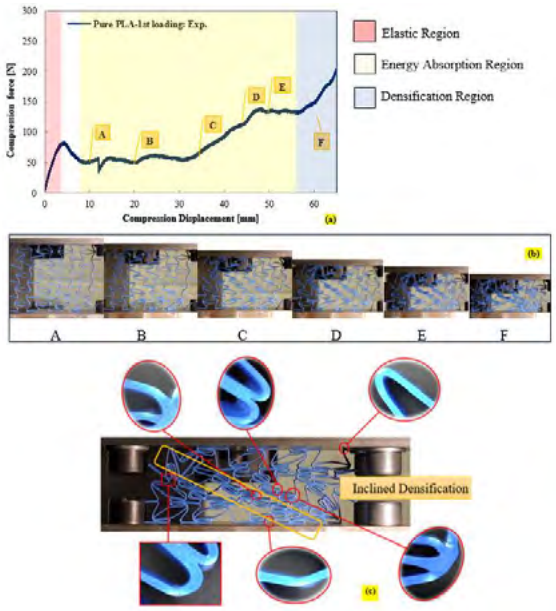

Figure 3. (a) Load- displacement and energy absorption diagram of compression test of star hourglass honeycomb structure sample fabricated by pure PLA in the y direction (b) deformation of star hourglass honeycomb structure at different displacement stage, (c) plasticity and damage phenomena (u_y=60 mm).

In the experimental test illustrated in Figures 3(a) and 3(b) A to F, the first zone represents the elastic response under the applied compressive load. As the oblique struts undergo compressive deformation, the star-shaped walls are compressed row by row, augmenting the load capacity of the structure. The second zone denotes the absorption zone, characterized by the appearance of inclined deformation zones. Plastic deformation and microcrack damage occur at the hinge connections of the inclined unit walls and horizontal struts. Deformation not only occurs within the deformation zone but also spreads obliquely to adjacent structural units as compression progresses, gradually widening the deformation zone. The layer-by-layer compression deformation characteristic of the inclined walls maintains stress at a constant level, resembling a shear zone until partial densification is reached within the inclined zone. Deformation outside the shear zone tends to be more homogeneous. Increasing compression distance leads to the piling up of unit walls, resulting in an expanding densification region until the entire structure is gradually compressed to a dense state at fixed ends. Force partially increases at locations where oblique struts are jointed, and the middle rows of the structure become densified. Once the middle rows of the structure are sufficiently densified, the structure's stiffness increases negligibly, while stress begins to rise continuously until the entire structure collapses, representing the third zone of the curve. Microcracks form in the tension side of the struts of the star-hourglass honeycomb structure at the last level of applied compression load for the first loading stage, as observed in Figure 3(c). While severe

failure at the hinges is not experienced, the formation of microcracks results in local stiffness reduction at the damaged location, which can affect the structure's response after recovery.

4.2.2. Star hourglass structure fabricated by reinforced PLA by chopped carbon fibers

According to the diagram depicted in Figure 4, during the first loading stage, the force initially rises from zero to 5 mm in the first elastic interval. The structure withstands the applied load until signs of damage emerge at a displacement of 9.5 mm, leading to a significant reduction in force. Subsequently, the force level remains relatively constant until reaching a displacement of 37 mm, where plasticity and damage occur in the oblique struts. Force begins to increase within the displacement range of 39 mm, and this upward trend continues until all rows of the structure are fully compressed together. In the experimental test response illustrated in Figure 4(a), the first zone highlighted in pink represents the elastic response under the applied compressive load. As shown in Figure 4(b), when the oblique struts undergo compressive deformation, the star-shaped walls are compressed row by row, resulting in an increase in the structure's load capacity. The second zone highlighted in white denotes the absorption zone, where the oblique struts are partially bending, but the horizontal struts of the cells are not yet deformed. Force increases partially at locations where oblique struts are jointed, and the middle rows of the structure become densified. Once the middle rows of the structure are sufficiently densified, the structure's stiffness increases negligibly, while stress begins to rise continuously until the entire structure collapses, representing the third zone of the curve.

4.3. Ultrasonic tests

Ultrasonic-guided waves are one of the most common inspection tools for collecting valuable data in engineering based on the SHM system. The damage will affect the material or structural properties, impacting wave propagation characteristics and showing a particular wave response [15]. In undamaged structures, ultrasonic waves propagate at a speed specific to their material characteristics. The waveform displays specific patterns influenced by the material's properties, such as density and elastic modulus. Damage such as cracks, voids, or corrosion alters these physical properties, thus impacting the speed and path of the sound wave propagation. During propagation, ultrasonic waves undergo absorption and scattering within the material, leading to attenuation of wave energy. When damage occurs within the structure, increased absorption and scattering in the affected area further intensify the attenuation of the waveform. Monitoring the extent of signal amplitude attenuation allows for an estimation of structural health. To evaluate the health of 3D printed auxetic structures under compression load, ultrasound signals of auxetic structures are obtained under different deformation levels. These signals are then analyzed, and the damage-sensitive features envelope and phase are extracted. The two auxetic structure samples connected to three PZT sensors are shown in Fig.2. The ultrasonic test is conducted as follows: a laptop is used to control the excitation signal. A Hanning windowed sinusoid with a frequency of 100 kHz and a duration of 6 cycles was applied as the excitation signal. The wave generator produces the excitation signal, which is displayed on the oscilloscope. The signal is then amplified by the signal amplifier and subsequently connected to the PLA auxetic structure through PZT sensor 1. Both PZT sensors 2 and 3 are utilized to capture the response signal. The ultrasonic signals at 100kHz response from PZT sensor. 3 (chopped carbon PLA) and sensor 2 (pure PLA), corresponding to the initial 35mm of deformation that includes key structural deformation stages and exhibits relatively better signal quality, were utilized as the raw wave signal. The two types of damage-sensitive features have been used to analyze the signal changes [15], which are the local envelope and phase, both are extracted from raw wave signal by using the Hilbert transform. Two sets of envelope and phase data vary with the deformation, with each deformation corresponding to a different distribution of the respective envelope and phase. The probability density function (PDF) distributions of envelope and phase with deformation ranging from 0 to 35 mm (chopped carbon PLA) and 0 to 34 mm (pure PLA) are shown in Fig. 5. It can be seen that the data distributions of the different envelopes (Fig. 5 (a) and (c)) and phases (Fig. 5 (b) and (d)) vary from each other, as they correspond to different levels of damage states. Theoretically, a greater disparity in the distribution shape indicates a larger deviation from the structure's initial health status. During the elastic phase, the PDFs of both the envelope and phase are similar, suggesting minimal

changes in the structure's properties. However, with increasing deformation, the PDFs of the envelope and phase for the two materials begin to exhibit significant fluctuations, particularly in the envelope. This often indicates that the structure is experiencing damage or the onset of plasticity. From compression tests, notable fluctuations in data distribution become apparent after the first peak on the force curve. Thus, we define the deformation at this first peak as the critical deformation.

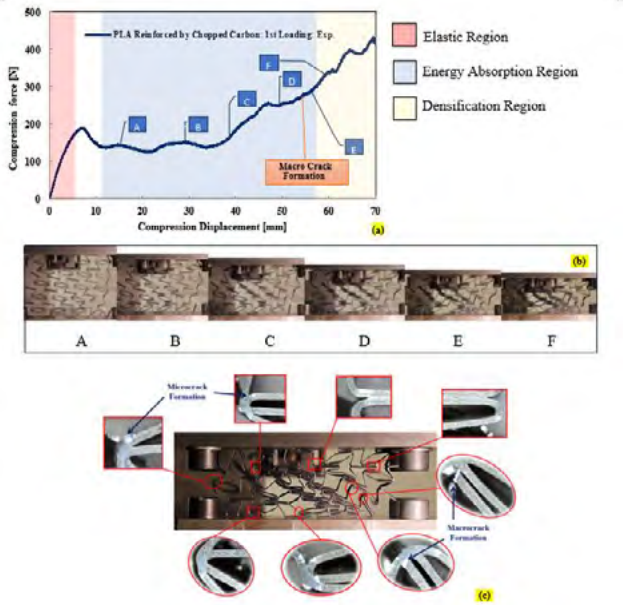

Figure 4. (a) Load- displacement and energy absorption diagram of compression test of star hourglass honeycomb structure sample fabricated by PLA reinforced by chopped carbon fibers (b) deformation of star hourglass honeycomb structure at different displacement stage, (c) plasticity and damage phenomena (u_y=62 mm).

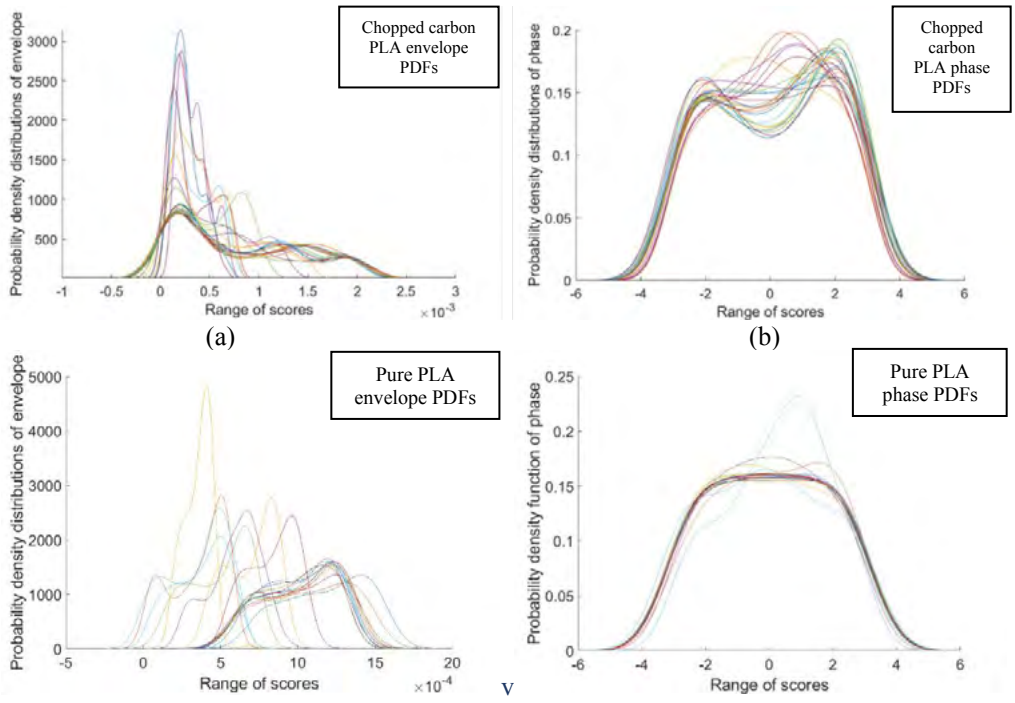

Figure 5. Two hourglass honeycomb structures' probability density distributions of the envelope (a) and (c), and phase (b) and (d).

Between reaching the critical deformation, the shape change of the distribution is minor, and after the critical deformation, significant changes in the PDFs' shape are observed. Specifically, the critical deformation for the hourglass honeycomb structure fabricated with pure PLA and chopped Carbon PLA

is 4.5 mm and 7.5 mm, respectively. Based on this way, a relatively conservative assessment of structural health status can be determined.

5. Conclusions

This paper represented the nonlinear response of an innovative lattice structure which was manufactured using 3D printing techniques. Experimental evaluations of quasi-static compressive loading applied to these structures in the vertical orientations are encompassed by the research. During the test, the nonlinear response of the star-hourglass-shaped auxetic lattice subjected to compressive loading is analyzed at stepwise quasi-static tests. Ultrasonic tests were conducted to obtain ultrasonic signals under various deformation states of two star hourglass shaped honeycomb structures. The Hilbert transform was employed to extract two damage-sensitive features: envelope and phase from ultrasonic signals. Based on the PDFs of the respective envelope and phase, along with the force curve, the critical damage or plasticity deformation was determined to assess the structural health status.

Keywords: fibre-reinforced composite, tubular joint, adhesive bonding, finite element modelling

Abstract
Reliable joining of fibre-reinforced polymer-matrix composites to metals remains one of the technological challenges to overcome when developing multi-material structures and components. In this paper, 2D (axisymmetric) finite element models of bio-inspired tubular metal-composite single lap adhesive joints are developed to study the effects of stiffness variation in the adhesive on joint performance. Axial tension, torsion and internal pressure are considered. Stiffness variation in the adhesive is implemented via the user defined field subroutine. Comprehensive parametric studies are facilitated via Python scripting. The developed models were extensively validated for different loading scenarios using results in the literature. Several profiles of stiffness variation in the adhesive have been examined and compared with a reference joint configuration without stiffness variation. Investigated stiffness variation profiles have been shown to reduce asymmetry of stress distributions in the adhesive and reduce maximum stresses in comparison with the reference joint configuration. The results demonstrate that a combination of overlap length and stiffness variation profile in the adhesive can reduce stresses and improve joint performance.

1. Introduction

Successful development of multi-material structures and components depends on reliable joining of fibre-reinforced polymer-matrix composites to metals, which remains one of the key technological challenges to overcome. Adhesive bonding has many advantages over other joining methods including lower fabrication costs, lower structural weight, better cost-effectiveness, unparalleled ability to join dissimilar materials such as metals and composites, and potential to disassemble them for recycling at the end of their service life [1, 2]. Stress distribution in adhesive joints, especially in lap joints, is non-uniform, with stress concentrations due to stiffness mismatch observed at the ends of the bonded area which often lead to premature failure of the joint. To eliminate these stress concentrations, several techniques have been proposed in the literature, either focusing on the adhesive, the adherend, or both. Several bio-inspired concepts such as functional grading [3], mechanical interlocking through surface patterning [4], adhesive patterning [5] and 3D metal pins [6, 7], to name but a few, are currently actively explored in metal-composite joint design with the view to achieve enhancements in joint performance and maximise recyclability.

Functional grading found in natural materials such as bones and teeth has evolved as a response to stress concentration at material interfaces and allows for a more balanced stress distribution across the joint. Inspired by nature, the concept of functional grading has been applied to the metal-composite adhesive joint design, pre-dominantly focusing on the adhesives [8]. Extensive analytical, numerical, and experimental studies of flat single lap joints with graded adhesives have been performed, demonstrating that varying stiffness properties of the adhesive with the overlap length along the bond line can reduce peak stresses at the overlap ends and improve performance of the joint. To achieve stiffness variation in the adhesive, several methods have been proposed, including adding microparticles such as glass beads or nanoparticles such as carbon black to the adhesive, using graded curing processes and/or adhesive mixes [8].

In this study, 2D (axisymmetric) models of bio-inspired tubular metal-composite single lap adhesive joints have been developed in Abaqus to study the effects of stiffness variation in the adhesive on the joint performance. Axial tension, torsion and internal pressure are considered. Stiffness variation in the adhesive is implemented via the user defined field subroutine. Python scripting is used to facilitate comprehensive parametric studies. The developed models have been extensively validated for different loading scenarios using results in the literature, including [9, 10]. Several profiles of stiffness variation in the adhesive have been examined and compared with a reference joint configuration without stiffness variation. Investigated joint configurations have been shown to reduce asymmetry of stress distributions in the adhesive and reduce maximum stresses in comparison with the reference joint configuration.

2. Methodology

Figure 1 shows a tubular single lap joint (TSLJ) comprising inner metal pipe of length L_t, radius R_i and thickness t_t, outer composite pipe of the same length and thickness, bonded together through a thin adhesive layer of thickness t_a and overlap length L_o. The joint is subjected to internal pressure P, axial load F and torsion T.

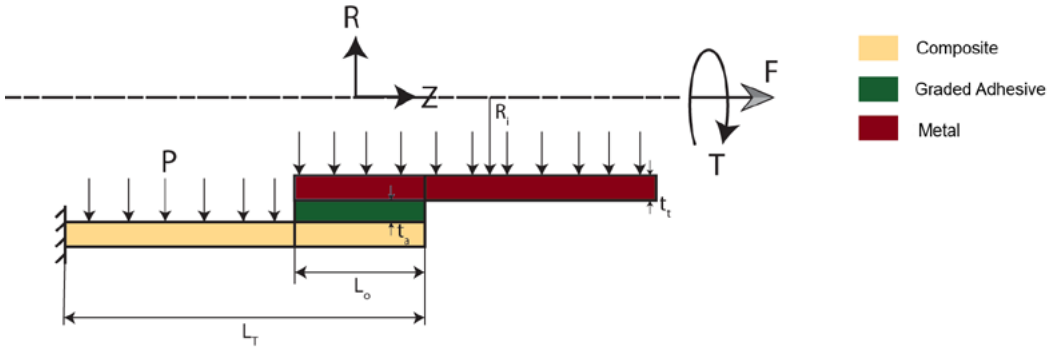

Figure 1. Tubular Single Lap Joint subjected to internal pressure axial loading and torsion

Young's modulus of the adhesive was assumed to vary with the axial coordinate z along the overlap length according to one of the five profile functions [11] given below by Eqs. (1)-(5), with Profile 5 taken as a reference configuration.

Profile 1 $$E_{f1} = E_{max} \exp\left[-4\ln\left(\frac{E_{max}}{E_{min}}\right)\left(\frac{z}{L_o} - \frac{1}{2}\right)^2\right] \quad (1)$$

Profile 2 $$E_{f2} = 4(E_{min} - E_{max})\left(\frac{z^2}{L_o^2} - \frac{z}{L_o}\right) + E_{min} \quad (2)$$

Profile 3 $$E_{f3} = 8(E_{max} - E_{min})\left(2\left(\frac{z}{L_o} - \frac{1}{2}\right)^4 - \left(\frac{z}{L_O} - \frac{1}{2}\right)^2\right) + E_{max} \quad (3)$$

Profile 4 $$E_{f4} = 12.8(E_{min} - E_{max})\left(\left(\frac{z}{L_o} - \frac{1}{2}\right)^6 + \left(\frac{z}{L_o} - \frac{1}{2}\right)^4\right) + E_{max} \quad (4)$$

Profile 5 $$E_{f5} = E_{max} \quad (5)$$

Figure 2 shows the above five stiffness variation profiles in the adhesive as a function of the normalized overlap length $\eta = z/L_o$. Out of the four grading profiles, profiles 1 and 3 are the least steep, profile 2 is moderately steep and profile 4 is the steepest.

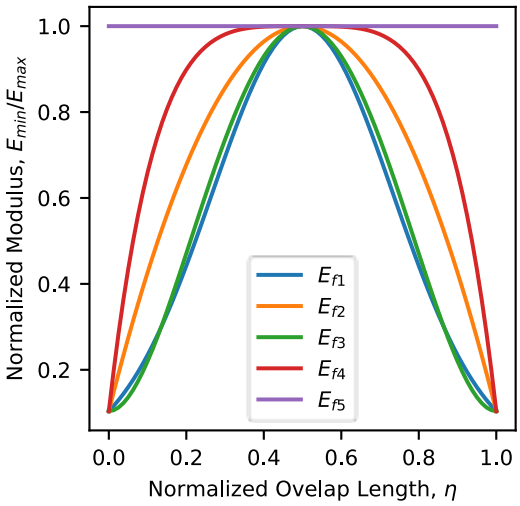

Figure 2. Normalized Young's modulus of the adhesive as a function of the normalized overlap length for five considered stiffness variation profiles.

Finite element (FE) modelling of the joint is performed in Abaqus [12] using four-node axisymmetric quadrilateral elements CAX4 for simulations involving axial tension and internal pressure and four-node generalized bilinear axisymmetric quadrilateral elements with twist CGAX4 for simulations involving torsion. Stiffness variation in the adhesive is implemented via the used defined field subroutine (USDFLD). Python scripting is used to facilitate comprehensive parametric studies. The developed FE model of TSLJ has been extensively validated for different loading scenarios using results in the literature, including [9, 10].

3. Results and discussion

Geometry of the joint is defined by the inner pipe radius $R_i = 8\,mm$, inner and outer pipes wall thickness $t_t = 2\,mm$, and adhesive layer thickness $t_a = 0.2\,mm$. A range of the overlap lengths was considered, taking values of $L_o = 10; 25; 50; 100; 200\,mm$, while the pipe lengths were taken as $L_t = L_o + 30\,mm$. Material properties of the metal pipe are taken as $E = 200\,GPa, \nu = 0.28$. The GFRP composite pipe was modelled as a unidirectional transversely isotropic GFRP material with the following material properties [13]: $E_1 = 20\,GPa$, $E_2 = E_3 = 5\,GPa$, $\nu_{12} = 0.3$, $\nu_{13} = \nu_{23} = 0.28$, $G_{12} = 2\,GPa$, $G_{13} = G_{23} = 1.5\,GPa$. Elastic properties of the adhesive are taken as [11]: $E_{min} = 0.280\,GPa$, $E_{max} = 2.7\,GPa$, $\nu = 0.35$. A displacement of 0.2 mm was applied to the metal end for tension cases, a rotation of 0.15 radians about the axis for torsion cases and a pressure of 10 MPa for internal pressure cases.

Figure 3 shows variation of shear stress τ_{rz} in the adhesive of a composite-metal tubular joint subjected to tensile loading as a function of the normalized overlap length. For all considered overlap lengths, the shear stress variation is strongly influenced by the stiffness variation in the adhesive, and the maximum stresses in the graded adhesives are reduced compared to the constant stiffness adhesive. Stiffness variation profiles 1 and 3, given by Eq. (1) and (3) respectively produce greater stress reduction compared to stiffness variation profiles 2 and 4, given by Eq. (2) and (4) respectively, but at the expense of slightly increasing stress values in the middle portion of the overlap length. For smaller overlap lengths of $L_o = 10\,mm$ and $L_o = 25\,mm$, the effect of stiffness grading in the adhesive on shear stress variation is felt throughout, however for longer overlap lengths of $L_o = 50;\ 100; 200\,mm$, stress variation away from the edges is largely unaffected by adhesive grading.

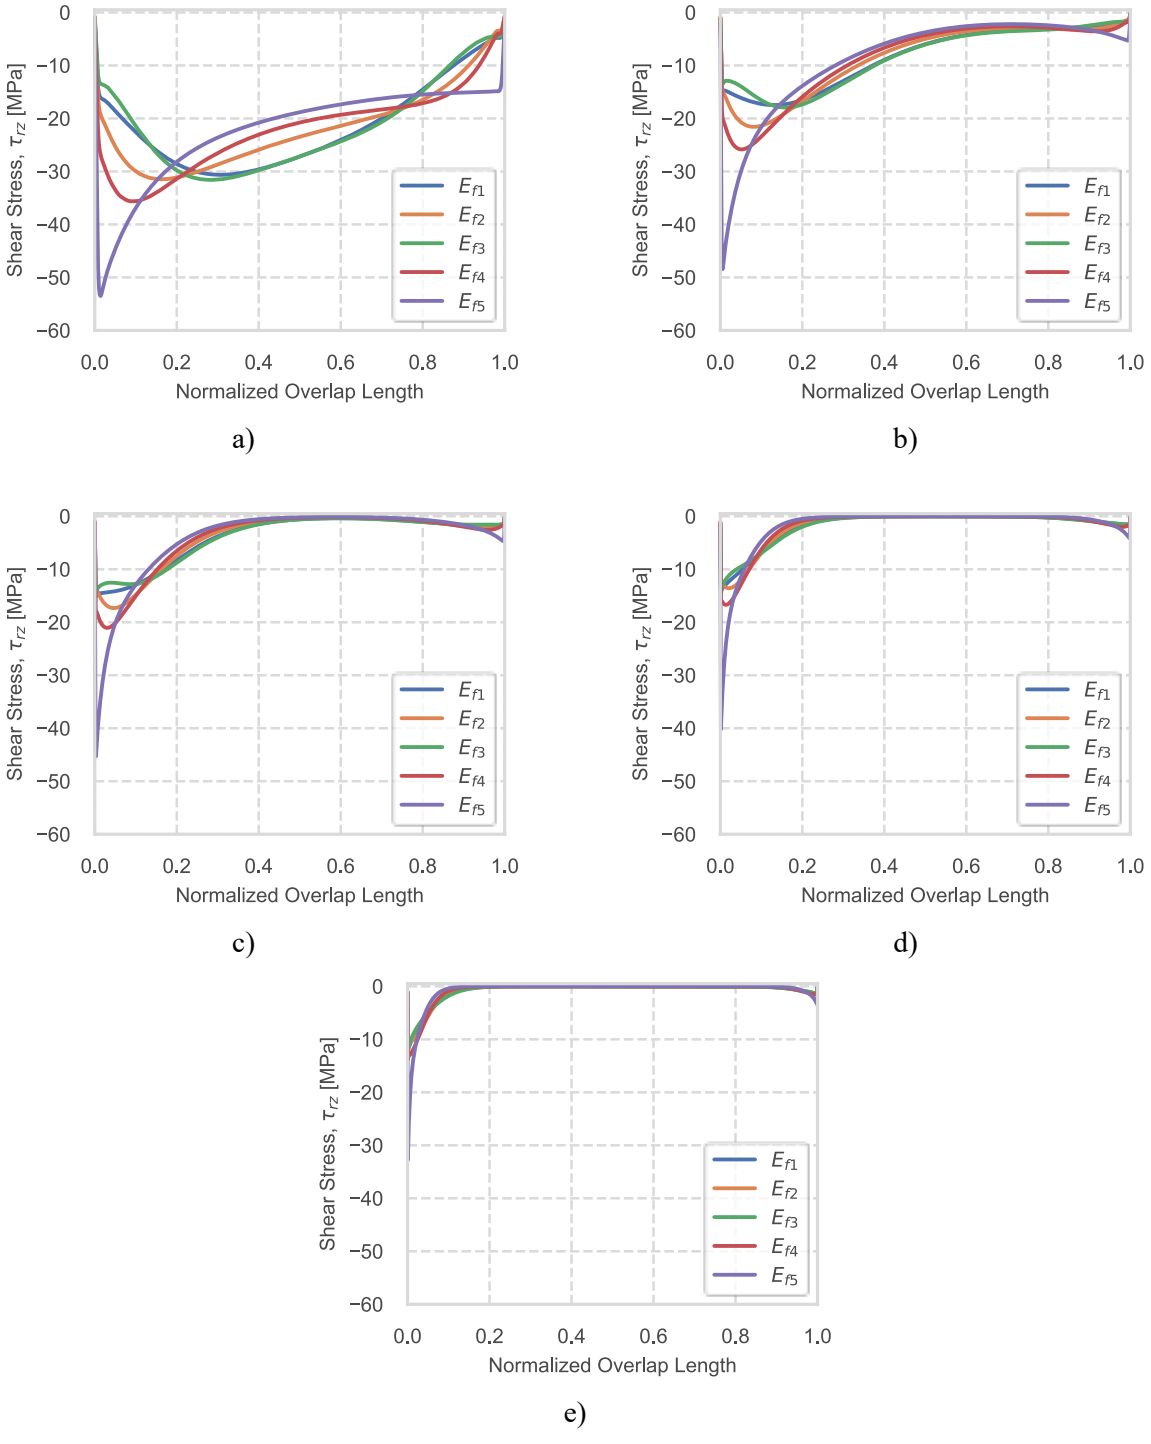

Figure 3. TSLJ under axial tension. Shear stress variation in the adhesive for five stiffness variation profiles and different overlap lengths: a) 10 mm; b) 25mm; c) 50 mm; d) 100 mm; e) 200 mm.

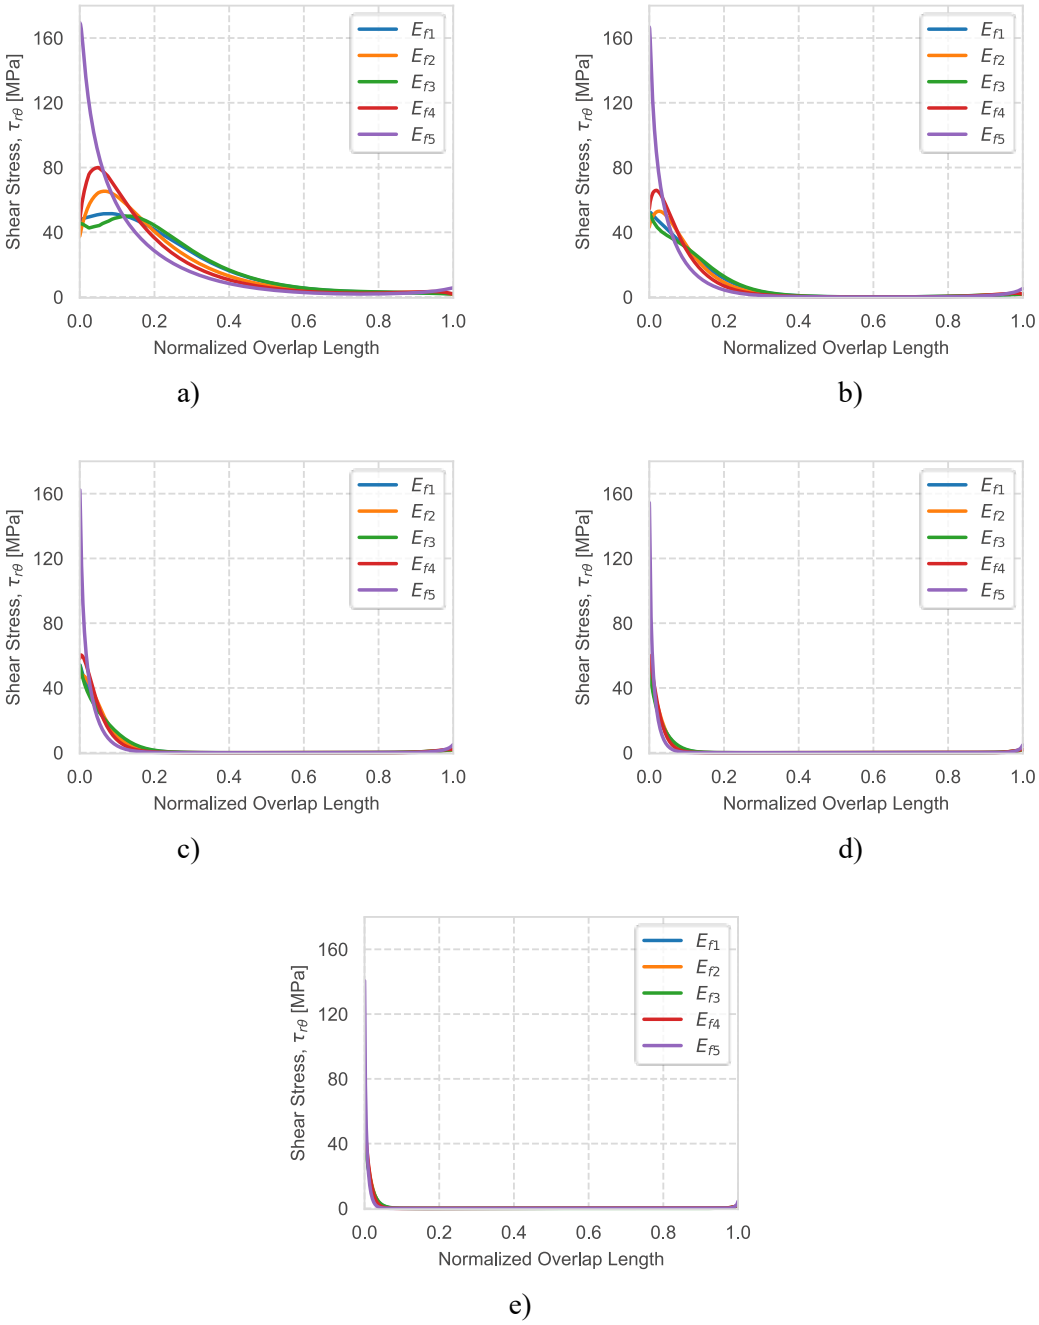

Figure 4. TSLJ under torsion. Shear stress variation in the adhesive for five stiffness variation profiles and different overlap lengths: a) 10 mm; b) 25mm; c) 50 mm; d) 100 mm; e) 200 mm.

Variation of shear stress τ_{rz} in the adhesive of a composite-metal tubular joint subjected to torsional loading is shown in Figure 4 as a function of the normalized overlap length. It is evident from Figure 4 that for all considered overlap lengths, stiffness grading in the adhesive significantly reduces the maximum shear stress compared to the reference configuration, and stiffness variation profiles 1 and 3 again perform better than stiffness variation profiles 2 and 4. For longer overlap lengths, shear stresses away from the internal edge $\eta = 0$ are largely unaffected by the grading profile and are similar to those in the reference case of the constant stiffness adhesive.

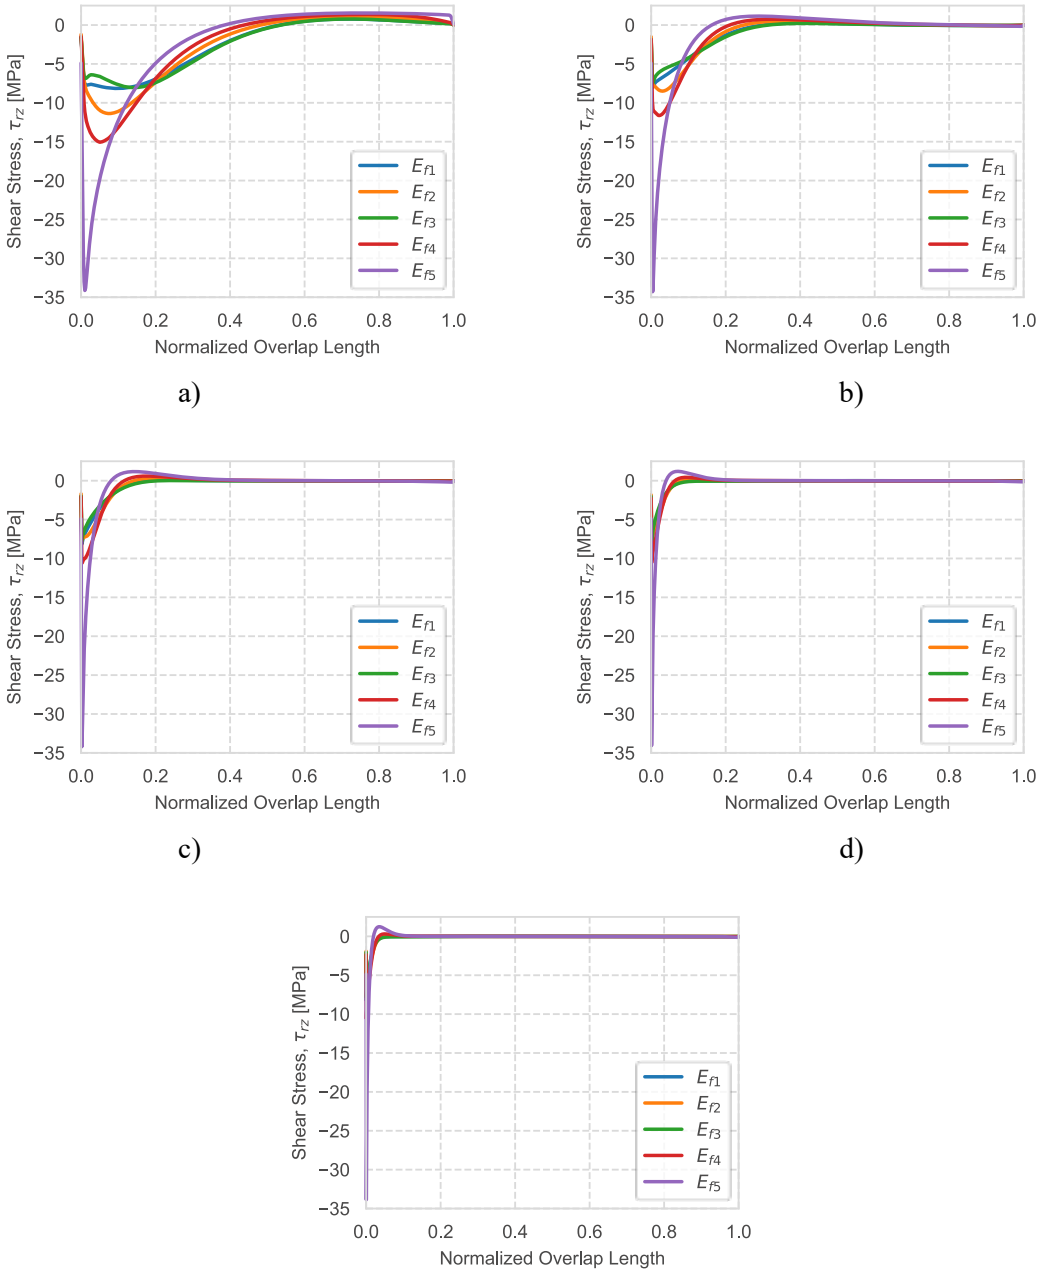

Figure 5. TSLJ under internal pressure. Shear stress variation in the adhesive for different stiffness variation profiles and different overlap lengths: a) 10 mm; b) 25mm; c) 50 mm; d) 100 mm; e) 200 mm.

Variation of shear stress τ_{rz} in the adhesive of a composite-metal tubular joint subjected to internal pressure is plotted in Figure 5 as a function of the normalized overlap length. Again, adhesive stiffness grading profiles 1 and 3 perform better at reducing the maximum shear stress in the adhesive than grading profiles 2 and 4. For longer overlap lengths, shear stresses away from the internal edge $\eta = 0$ are largely unaffected by the stiffness grading in the adhesive and are similar to those in the reference case of the constant stiffness adhesive.

4. Conclusions

In this study, finite element modelling of tubular single lap metal-composite adhesive joints has been performed with the view to study the influence of stiffness variation in the adhesive on joint performance. Several U-shaped profiles of stiffness variation in the adhesive have been examined and compared with a reference joint configuration without stiffness variation. All investigated stiffness profiles have been shown to reduce asymmetry of stress distributions and the maximum shear stress value in the adhesive layer under tensile loading, torsional loading and internal pressure. Stiffness variation profiles 1 and 3 were found to be more effective at reducing the maximum shear stress value in the adhesive than profiles 2 and 4. The results demonstrate that a combination of overlap length and stiffness variation profile in the adhesive can have beneficial effect on stresses in the adhesive and thus improve joint performance.

Abstract
Environmental aging significantly impacts composites, introducing uncertainty in material durability and compromising physico-mechanical properties, rending reliable prediction of a service life crucial. Experimental validation procedures for composites entail expensive and time-demanding testing programs bottleneck for innovation, thus turning modeling into an economically viable alternative capable of partially replacing extensive testing. A combination of accelerated testing methodologies alongside qualification by modeling, based in fundamental scientific principles, is seen as a viable long-term solution. Multiple approaches have been suggested to forecast long-term properties based on short-term measurements, aiming to streamline the assessment process by minimizing time and associated costs.

A modular lifetime prediction framework is presented herein, including insights into the environmental aging mechanisms of composite (micro-)constituents. Influence of factors on degradation rates, such as chemical composition, sizing quality, temperature, acidity, and mechanical stresses are considered. Lifetime is predicted by a diverse set of modeling tools, including degradation rate modelling, superposition principles, and parametrization techniques. The modular framework serves as a potentially valuable resource for both industry and academia, offering insights into predicting the lifetime of fiber-reinforced polymers. In addition, the duality of lifetime prediction is briefly discussed, presenting distinction in the definitions of integrity, failure criteria and end-of-life scenarios. Consequently, similar aging phenomena and modeling methodologies apply, whether prioritizing "safety" or "decomposition".

1. Introduction

Fiber-Reinforced Polymers (FPR) are used as structural materials due to their light weight and increased mechanical properties. During their service lifetime, exposure to environmental aging is common. Aqueous and humid environments, impacts of temperature, pH, and mechanical stresses result in the structural weakening of FRPs. The superior physico-mechanical properties of FRPs, such as strength and stiffness, are then compromised by the uncertainty of the material-environment interaction [1]. The presented modeling framework provides means of predicting the extent of such deterioration, and thus the expected lifetime.

Modeling emerges as an economically feasible alternative, complementing testing with simulation and accelerated testing methodologies, based on fundamental physico-chemical principles [2].

There are three microconstituents in an FRP, namely a polymer matrix, fiber reinforcement, and a multi-component sizing-rich interphase/interface. The interphase originates from the sizing (coating applied to the fiber surface), and is formed between the reinforcing fibers and the matrix polymer during the FRP manufacturing process. What complicates the prediction of composite aging is that each of the three microconstituents ages differently and may also affect the degradation rates of each other (coupling effects) [1]. Since the FRP composition is modular in its nature, a necessity for a modular modeling approach is called for, based on the understanding of the molecular mechanisms and kinetics of environmental aging of individual microconstituents [1]. The multiscale nature of lifetime prediction is shown in Figure 1.

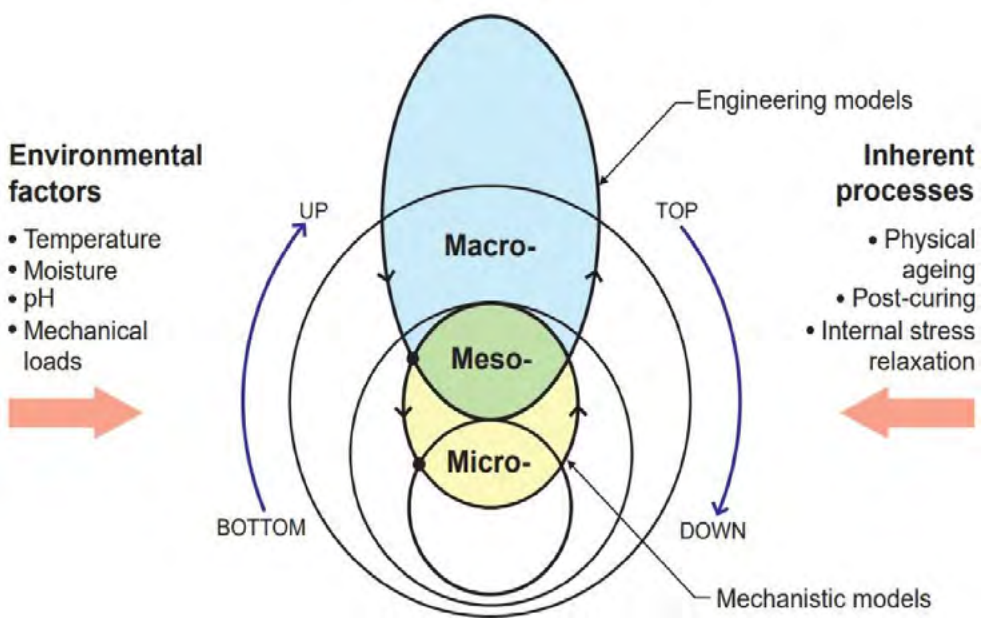

Figure 1. Multitude of scales involved in the Lifetime Prediction Modeling [3].

Many approaches have been proposed for predicting the long-term properties of polymers and FRPs based on short-term tests allowing for reduction of the time scales and costs required to obtain long-term data [4]. Accelerated testing methodologies enable the simulation of natural exposure effects within relatively short time frames [3]. The state-of-the-art modeling methodologies for predicting the lifetime of polymers and FRPs under environmental impact include the rate models (Arrhenius, Eyring, and Zhurkov); superposition principles (Time-Temperature, Time-Moisture, Time-Stress, and Time-Aging Time); Plasticity-controlled failure modeling methods and parametric methods (Larson–Miller, and Monkmann–Grant) [3]. The Modular framework presented herein is a multiscale modeling approach.

2. Methods

2.1. Modular Framework

The modular framework is a step towards the multiscale lifetime prediction and understanding of the composite aging phenomena [4]. The modular approach is schematically shown in Figure 2. Red colored modules are under development. QSPR stands for Quantitative Structure-Property Relationships.

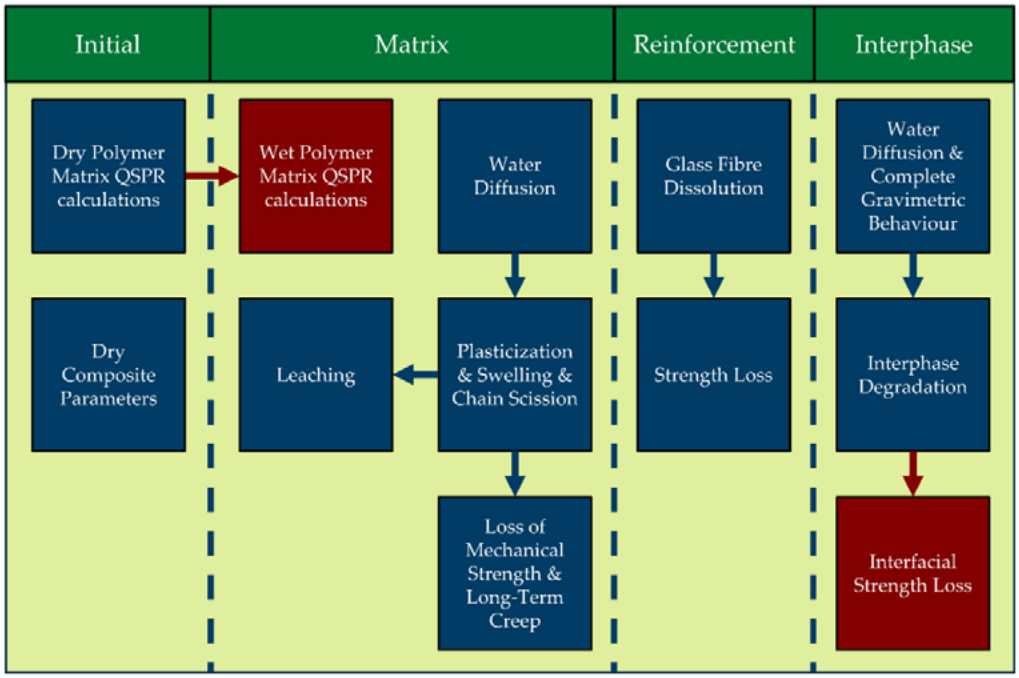

Figure 2. Modules of the framework for lifetime prediction of composite materials affected by humid/water environment [5].

As shown in Figure 2, modules are divided in four sections that relate to the overall composite configuration and modeling of environmental degradation of individual micro-constituents (polymer, fibers and interphase). Initial section covers such properties as volume and mass fiber fraction, the total number and surface area of fibers inside a composite, and the amount of sizing. Detailed instructions for determination of all these parameters can be found in [1]. More directions are provided in the following respective chapters.

2.2. Lifetime of Polymer Matrix

Service lifetime of polymers and polymer mixes are impacted by aging process. State-of-the-art multiscale and modular approaches of predicting environmental aging of polymeric and composite materials have been systematized and discussed, with this study providing a comprehensive overview of the broad possibilities and present limitations of the currently available models.

Polymer aging degradation rate is mainly influenced by factors like chemical formulation, environmental and material composition, acidity, mechanical stresses and temperature. Utilizing a spectrum of modeling tools, from simplified correlations to advanced simulations, enables lifetime prediction of polymer materials. Service life is forecasted using degradation rate models, superposition principles, and parametrization techniques, offering valuable insights for both the industry and academia [3].

The diffusion and leaching modules can employ both Fickian or non-Fickian diffusion [3]. As a result of diffusion and absorption of plasticizing molecules, e.g. water, plasticization and hygroscopic swelling may occur [2]. More detailed description can be found in [1].

Some polymers undergo irreversible degradation due to chain scission or hydrolysis, for example, polyamides. Such hydrolysis kinetics were described in detail in works by Mazan et. al. [6]. They developed a multiscale model for predicting the mechanical properties after hydrolytic degradation. The methodology described should apply to other thermoplastics that undergo hydrolysis. Mazan et al. have

reported that hydrolysis induced chain scission and chemicrystalization were the two main mechanisms of property change [7].

One of the promising methodologies to access the lifetime of polymers and the deterioration of properties, e.g. due to recycling and aging, has been identified to be the Quantitative Structure-Property Relationship (QSPR) approach for predicting properties of matrix polymers. Physical and chemical properties of the matrix polymer can be calculated as regression functions of the connectivity indices, based on the topological graph theory and Jozef Bicerano's QSPR approach [8]. Connectivity indices are derived from the chemical Lewis diagrams. Physical meaning of the connectivity indices is the description of electronic environment and the bonding configuration of atoms in the molecule, thus linking the microscale with the engineering properties on the macroscale, as shown in Figure 3.

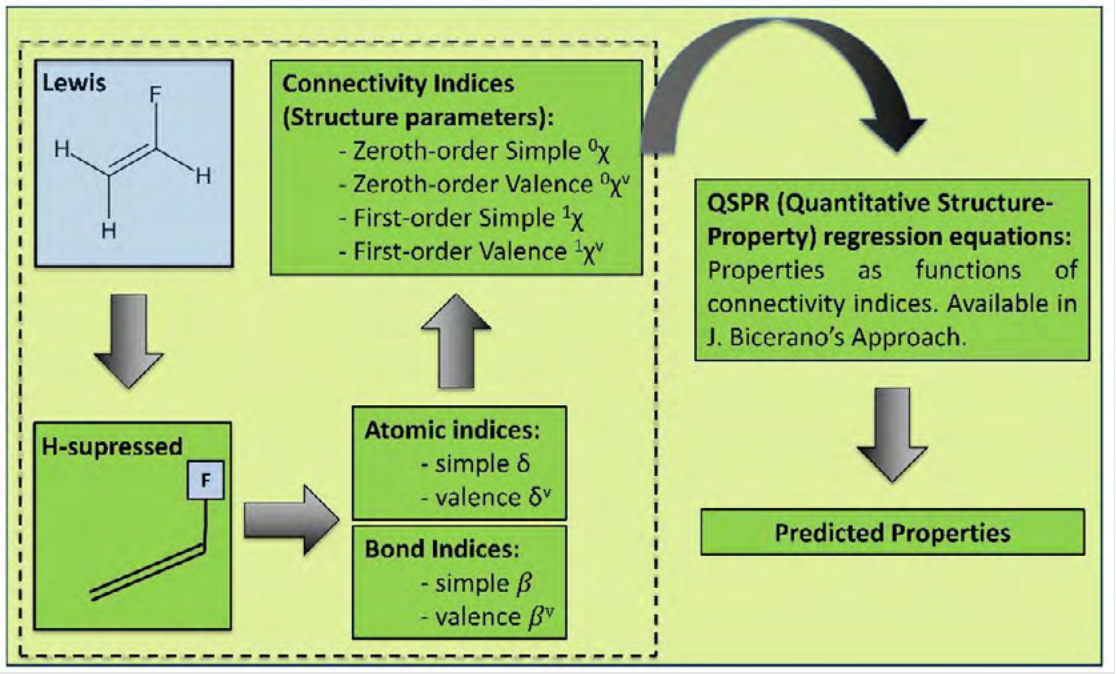

Figure 3. Quantitative Structure-Property Relationship (QSPR) approach; topological method and connectivity indices, reproduced from [5].

The method is based on the idea of a topological graph theory, allowing to describe a polymeric system as a number of parameters – connectivity indices, which are derived from the chemical Lewis diagrams. Physical meaning of the connectivity indices is the description of electronic environment and the bonding configuration of each non-hydrogen atom in the molecule. This approach should be considered as potentially useful for building the link from the microstructure up to the macro properties [2].

In addition, a variety of models can be employed in the above-mentioned modules. Rate Model such as Arrhenius is widely used when temperature is the dominant accelerating factor in aging. The Arrhenius relationship is widely used for lifetime predictions of polymers and composites through monitoring ultimate mechanical properties and their retention, e.g., tensile strength, interfacial shear strength, creep strength, and fatigue strength. However, the durability prediction methodology in most studies is based on the time shift concept [3]. For instance, for some polymers, time-temperature and time-temperature-plasticization superposition approaches might be considered and involved in evaluating the effect of physical effects on the polymers [9].

Finally, some multiscale approaches may be applied to study the complex nature of degradation of polymers, such as the Data-Driven Approach to Elucidate Degradation Trends described in [10]

2.3. Lifetime of Reinforcement

Carbon Fibers (CFs) are typically chemically inert in water, not showing any mechanical strength and stiffness changes. However, it was reported that some CF bundles had a water- and toluene-soluble binder [11]. Moreover, environmental degradation kinetic reaction models for aramid fibres have been presented by Horta et. al. in 2000 and 2003 [12,13]. Natural fibres on the other hand, are mainly affected by plasticization, hygroscopic swelling and biodegradation with microorganisms [14]. Lastly, Glass Fibers (GFs), the most common type of fiber reinforcement [15], are hydrophilic and hence susceptible to degradation when exposed to humid environments [16]. The fact that GFs degrade in aqueous environments has been known at the least since the 1970s [17,18]. However, the rates of hydrothermal degradation vary depending on the material grade and the sizing.

To predict lifetime of glass FRPs, an analytical toolbox consisting of seven modeling modules was presented in a recent work (2021) on the Modular Paradigm for GFRPs [19]. The seven developed modules of the Reinforcement Modular Group within the Modular Paradigm are shown in Figure 4.

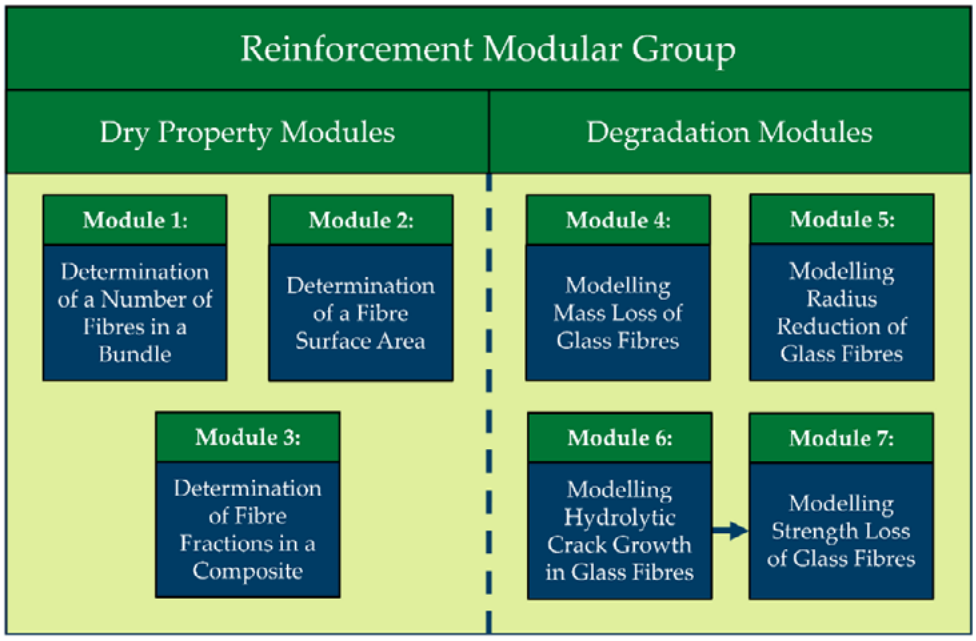

Figure 4. The seven developed modules for Reinforcement lifetime prediction within the Modular Toolbox [19].

Models that predict mass loss and radius reduction are the Contracting Cylinder model [20], the Shrinking Cylinder model [21] and the Dissolving Cylinder Zero-Order Kinetic (DCZOK) model [22].

The crack growth evolution can be modelled by micromechanical models that were proposed by Wierderhorn and Bolz in 1970 [18] and by Sekine and Beaumont in 1998 [23]. The modeling link between the dissolution chemistry-based kinetic models (DCZOK model) and the hydrolytic crack growth in GFs was only recently developed by Echtermeyer and Krauklis et al. in 2019 [11], even though it was initially proposed by Charles back in 1958 for bulk glass [24]. The established link enables prediction of the long-term deterioration of mechanical properties of the GFs due to hydrolytic crack growth by modeling the dissolution kinetics [11]. For FRPs, environmental parameters, such as pH, temperature, availability and composition of the environmental solution, and presence of mechanical stress, as well as fiber orientation play significant roles affecting the dissolution kinetics of GF in polymer composites [25].

2.4. Lifetime of the Interphase

The quality of the interfacial interaction is dependent on the adhesion and present flaws [26]. The FRP interphase may degrade due to hydrolysis, forming interphase flaws. These flaws may further develop into fiber-matrix debondings, matrix cracks and splittings along the fibers [27].

A mass balance approach has been proposed to deduce the hydrothermal aging of the interphase. Mass balance enabled deduction of the kinetics of the hydrolytic degradation of the sizing-rich composite interphase, the rate of dissolution being comparable to that of GFs hydrolytic dissolution [27].

There have been some attempts to quantitatively link the mass loss and the composite interfacial strength loss, but the proper model is yet to be established [28].

3. Discussion

Lifetime prediction modelling is complex due to the duality present in the definitions of failure criteria, integrity, and end-of-life, prioritizing either "safety" or "decomposition" scenarios, shown in Figure 5.

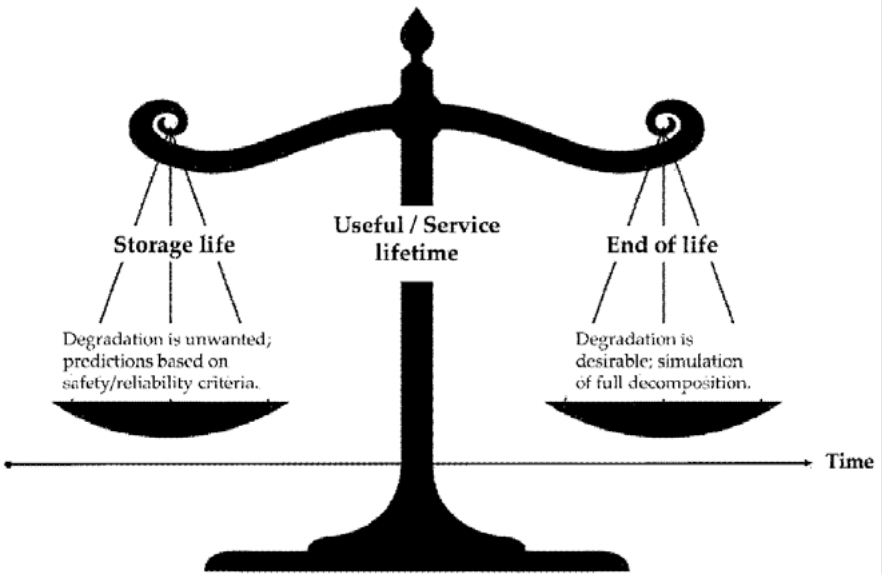

Figure 5. The complexity of Lifetime Prediction modelling is due to necessity to prioritize either “safety” or “decomposition” scenarios [2].

In other words, there are applications where degradation is unfavorable ("safety": structural polymers and FRPs) and is favorable ("decomposition": biodegradable plastics). In conventional structural applications, the aim is to ensure the integrity of the material within a valid lifetime safely, whereas in biodegradation tests (e.g., in compost or soil), the end of life (EoL) is defined by the "decomposition" criteria. While the criteria differ, the modelling approaches could be essentially the same in both scenarios. Future work should consider improvement of the individual modules [28], as well as their interconnectivity in the Lifetime Prediction Framework. For example, the missing link is the lack of understanding how the time-dependent aging of the interphase results in the deterioration of the FRP interfacial strength.

4. Conclusions

An overview of the state-of-the-art related to a modular framework for lifetime prediction of FRPs affected by the environment, has been presented. The underlying physical and chemical principles of the methodology were described. The modeling framework is able to account for the influence of various environmental factors such as pH, temperature, and mechanical stresses, as well as the effects of sizing protection and chemical composition.

Keywords: Metal-composite joints, Textile composites, Mechanical testing, Finite element modeling, Damage development

Abstract
Joining of dissimilar materials such as metals and polymeric composites using bolting, riveting or adhesive joining results in abrupt change in mechanical properties at the joints causing stress concentration. Structural health of a hybrid metal-composite structure can be compromised by factors such as environmental degradation of adhesive or galvanic corrosion at the metal-composite joints. To solve these issues, metal-composite joints with textile mesostructure have been developed with hybrid carbon/steel fiber textile composites. The hybrid composites are tested under quasi-static tensile loading to study macro-mechanical properties and evolution of microdamage. Two configurations of woven hybrid composites are chosen for FE modeling of damage development. 3D representative volume elements are built such that resin-impregnated yarns are modelled as homogeneous orthotropic materials, and yarn/matrix-interface behavior is characterized by cohesive zone material modeling. During mechanical test simulation, stress-strain curves are plotted and damage schematics inside yarns and matrix are obtained. The FEM predictions match the experimental results of microdamage evolution, but they underestimate the experimental tensile strength values for hybrid composite configuration with stainless steel-fiber yarn in the warp-direction and carbon-fiber yarn in the weft-direction.

1. Introduction

Recent efforts to combine the use of metals and polymer-matrix composites in aerospace structures have led to the necessity of suitable metal-composite joining techniques. Jahn et al. [1] and Pramanik et al. [2] have reviewed the existing metal-composite joining techniques, among which the most common techniques are adhesive bonding and mechanical joining (bolting, riveting etc.). Although these techniques are effective in joining metal- and composite-parts, they have some serious drawbacks in terms of mechanical properties of joints. Adhesive metal-composite bonding results in an abrupt change of mechanical properties from the metal-side to the composite-side and the progressive environmental degradation of adhesive joints over time can be an issue [2]. In case of mechanical metal-composite joining using bolts or rivets, in addition to the abrupt change of mechanical properties and consequently high stress concentration at the joints, very poor notched strength of composite laminates as compared to their unnotched strength poses a serious threat to structural integrity of hybrid metal-composite structures [3].

While joining two dissimilar materials, their galvanic corrosion potential is an important factor which needs to be taken into consideration. This is critical while designing a metal-composite joint. In the case

of joining Al-alloys with carbon-fiber reinforced polymers (CFRP), Al-alloys must be coated at the joints, as the two materials have high galvanic corrosion potential [2,4,5]. On the contrary, alloys such as stainless steel are compatible with CFRP [5], and they can be joined together without any need of surface coating. In literature, there are multiple studies regarding CFRP-stainless steel hybrid stack-up or sandwich structures [6-8], where excellent joining is achieved using methods such as co-curing and weld-bonding.

In a similar study, Pupurs et al. [9] have recently developed CFRP-stainless steel hybrid joints with textile meso-structure. It is shown that epoxy-based hybrid composites with interwoven carbon-fiber yarns and stainless steel-fiber yarns possess mechanical properties intermediate to non-hybrid epoxy-based carbon-fiber and steel-fiber composites. The assembly of hybrid carbon/steel fiber textile composite with non-hybrid composites on either sides can act as a suitable metal-composite joint with gradual property change from the metal-side to the composite side.

In a follow-up study, Kulkarni et al. [10] have analyzed micro-damage evolution in hybrid carbon/steel fiber textile composites using experimental approach. A detailed description of possible damage modes in non-hybrid textile composites can be found in [11]. Similar damage modes have been reported in [10] for hybrid textile composites. Numerical study of mechanical behavior of hybrid carbon/steel fiber textile composites has been conducted in [12], where finite element models of the hybrid composites are developed, and their elastic properties are compared with the experimental values reported in [9].

The present work focuses on finite element modeling of microdamage in hybrid carbon/steel fiber textile composites. To evaluate damage inside fiber yarns and matrix, strength-based criteria are used. The yarn/matrix-interface is modelled with contact elements and yarn-matrix debonding is studied using cohesive zone material (CZM) modeling.

2. Materials and methods

Fabric reinforcements for the hybrid carbon/steel fiber textile composites were manufactured using T300 carbon-fiber yarns from Toray (Japan) and SY 11/1 stainless steel-yarns from Fujibo (Japan) and Bekaert (Belgium). The carbon-fiber yarns had a tow size of 1K with 7 μm individual filament diameter. The stainless steel-fiber yarns were 91 tex with 12 μm individual filament diameter. Two types of fabrics were manufactured - i) woven fabrics with plain weave pattern using manual weaving loom, and ii) knitted fabrics with plain weft knit pattern using manual knitting machine. Composite manufacturing was carried out using vacuum infusion of epoxy LY1564 resin (with XB 3404-1 hardener) into stacked dry fabric layers. The composite plates were oven-cured at 80 ^{o}C for 8 hours. Multiple configurations of knitted and woven composites with different meso-structures were manufactured. Composite specimens were tested under quasi-static tensile loading according to ASTM D3039 standard, and properties such as elastic modulus, tensile strength and strain-to-failure were obtained for each hybrid configuration. Additionally, micro-damage evolution with increasing level of applied strain was also studied. A detailed list of woven and knitted hybrid composite configurations, along with their mechanical properties obtained using experimental methods, can be found in [10].

For numerical analysis of mechanical properties and micro-damage evolution, two configurations among woven hybrid composites were chosen, namely, i) H5, with steel-fiber yarn in weft-direction and carbon-fiber yarn in warp-direction, and ii) H6, with carbon-fiber yarn in weft-direction and steel-fiber yarn in warp-direction. A schematic representation of the meso-structures of the two configurations is given in Fig. 1.

For FEM analysis, 3D representative volume elements (RVEs) for H5 and H6 were constructed in SolidWorks software and were imported in ANSYS Mechanical FEM software to generate element mesh and to apply boundary conditions. The curvature of warp yarns was modelled using a simple sine-wave function, whereas weft yarns were assumed to be straight. The yarns were embedded in a cuboidal matrix block, on which the relevant boundary conditions were applied. As shown Fig. 2, uniform displacement U_x along warp yarn-direction (X-axis) was applied on the right-face of the matrix block.

Symmetry boundary conditions were applied on the top-, bottom-, front- and left-faces, and U_z displacement coupling was applied at the back-face of the matrix block, allowing free contraction according to Poisson's effect along weft yarn-direction (Z-axis). Warp yarn-curvature and yarn cross-sections were calibrated according to optical microscopy images from the experimental results. Additional calibrations were performed by comparing elastic properties of the RVEs with the elastic properties obtained from the experimental results. The resin-impregnated carbon-fiber and stainless steel-fiber yarns were considered as homogeneous orthotropic materials with properties given in Table 1. Epoxy matrix was modelled as an isotropic material with Young's modulus $E = 3\ GPa$ and Poisson's ratio $\nu = 0.29$.

(a) (b)

Figure 1. Schematic representation of (a) H5 and (b) H6. Carbon-fiber yarns are shown in black, and steel-fiber yarns are shown in white. Yarns along X-axis are warp yarns and yarns perpendicular to X-axis (along Z-axis, not shown in the figure) are weft yarns.

Table 1. Material properties of resin-impregnated fiber yarns.

Material property	Notation	Unit	Carbon-fiber yarn	Stainless steel-fiber yarn
Longitudinal modulus	E_L	GPa	139.21	105.00
Transverse modulus	E_T	GPa	7.52	105.00
Longitudinal Poisson's ratio	ν_{LT}	-	0.22	0.30
Transverse Poisson's ratio	ν_{T3}	-	0.40	0.30
In-plane shear modulus	G_{LT}	GPa	3.43	40.38
Out-of-plane shear modulus	G_{T3}	GPa	2.69	40.38

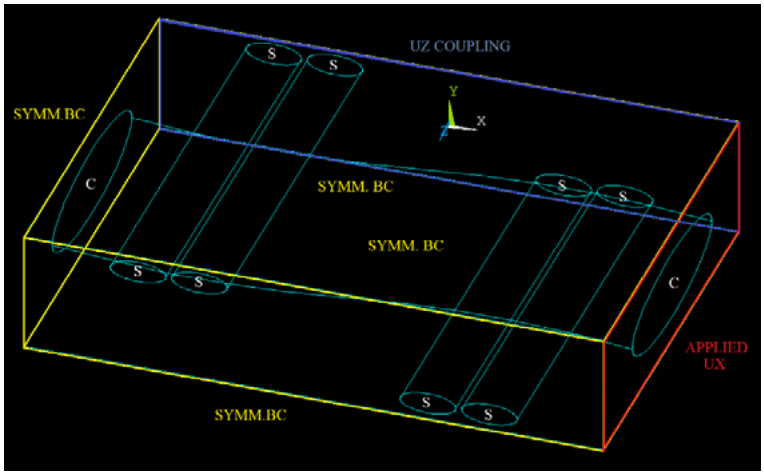

Figure 2. Representative Volume Element (RVE) of composite configuration H5. 'S' denotes steel-fiber yarn and 'C' denotes carbon-fiber yarn. Similar boundary conditions were applied for RVE of composite configuration H6.

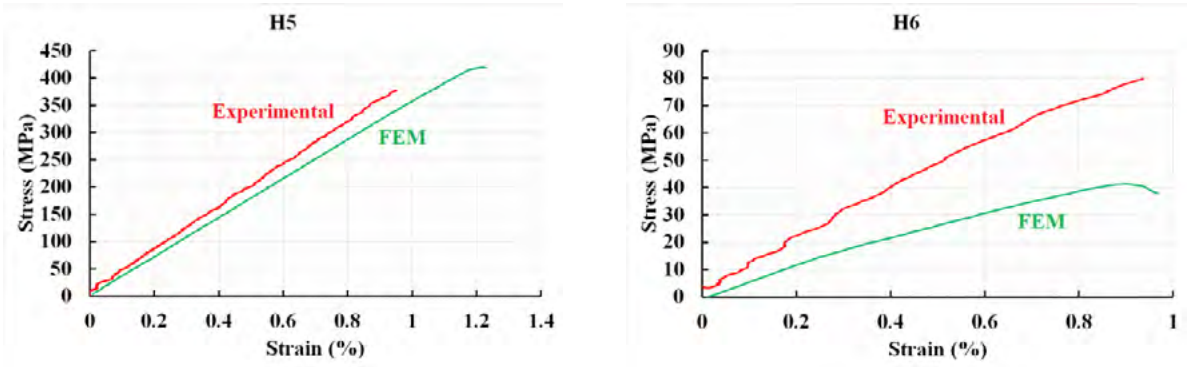
During FE simulation, displacement U_x corresponding to 0.01% strain was applied at first time step. To study the quasi-static tensile test response of the FE model, value of applied strain was incremented by 0.01% at each subsequent time step until the model underwent final failure. To identify damage initiation sites inside fiber yarns and matrix, material strength limits were defined, and maximum stress criterion was used. To simulate progressive damage evolution, instant material stiffness reduction method was used such that material stiffness was reduced by 5% at every damage initiation instance. For analysis of yarn/matrix-interface debonding, contact elements were applied at the interface and CZM modeling was used. Bilinear material behavior with linear softening in the cohesive zone was defined by the values of maximum traction and critical energy release rates for normal separation and tangential slipping. Using the FEM solutions, stress-strain curves for H5 and H6 were plotted, and the schematics of i) damage status inside yarns and matrix and ii) contact status at yarn/matrix-interface were obtained.

3. Results and discussion

3.1. Stress-strain curves

To study mechanical behavior of FE models at the macro-scale, stress-strain curves were plotted for the two chosen composite configurations, and they were compared with the experimental results. Fig. 3 shows the comparison between experimental- and FEM stress-strain curves for H5 and H6.

In the case of composite configuration H5, FEM predictions for tensile strength and strain-to-failure in the warp direction are higher than the experimental values. The FEM model of H5 shows lower stiffness than experimental observation, but the difference in modulus values is small compared to the difference in FEM- and experimental modulus values for H6. For the FEM model of H6, the discrepancy in the use of input material properties for warp yarn (in this case, resin-impregnated stainless steel-fiber yarn) might have caused such a large difference in FEM- and experimental elastic modulus and tensile strength values along the warp-direction. Here, factors such as yarn twist, irregular fiber shapes and non-uniform fiber volume fraction should be considered, which cannot be replicated in the FEM analysis.



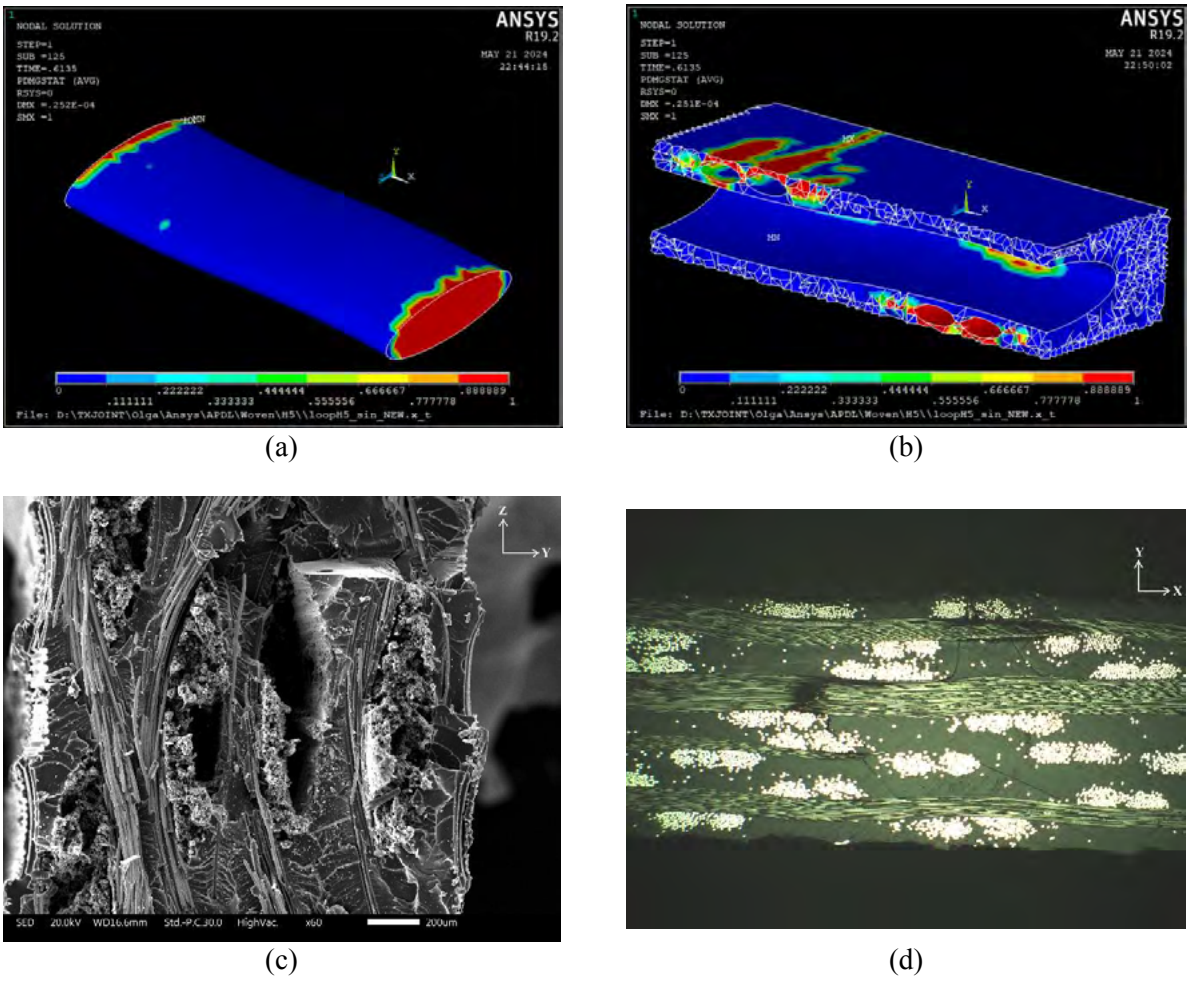


Figure 3. Stress-strain curves for composite configurations (a) H5 and (b) H6.

3.2. Microdamage studies

During quasi-static tensile loading simulation, microdamage inside yarns and matrix and debonding at the yarn/matrix-interface was monitored at each time step until final failure. Figs. 4 and 5 compare FEM damage status for yarn and matrix with experimental observations at the instance of final failure for H5 and H6. In composite configuration H5, the irregular damage of carbon-fiber warp yarns can be seen in Figs. 4(a) and 4(c). The matrix damage around weft yarns in FE model (refer Fig. 4(b)) is comparable with the matrix damage in optical microscopy image shown in Fig. 4(d). In composite configuration H6, partially damaged warp yarn/matrix-interface seen in Fig. 5(a) can be correlated with the yarn/matrix-interface in SEM fracture surface image in Fig. 5(c). The matrix damage surrounding warp yarns i.e.,

delaminations, can be seen in FE model (refer Fig. 5(b)) as well as in optical microscopy image (refer Fig. 5(d)). In terms of yarn/matrix-interface strengths, Figs. 4(c) and 5(c) depict that carbon-fiber yarn/epoxy-matrix interface is much weaker than the stainless-steel fiber yarn/epoxy-matrix interface.

(c) (d)

Figure 4. Schematics of microdamage (at the instance of final failure) for composite configuration H5, (a) FEM warp-yarn damage, (b) FEM matrix damage, (c) SEM image of fracture surface, and (d) Optical microscope image of polished edge (For FEM damage schematics, 0 = No damage, 1 = Full damage).

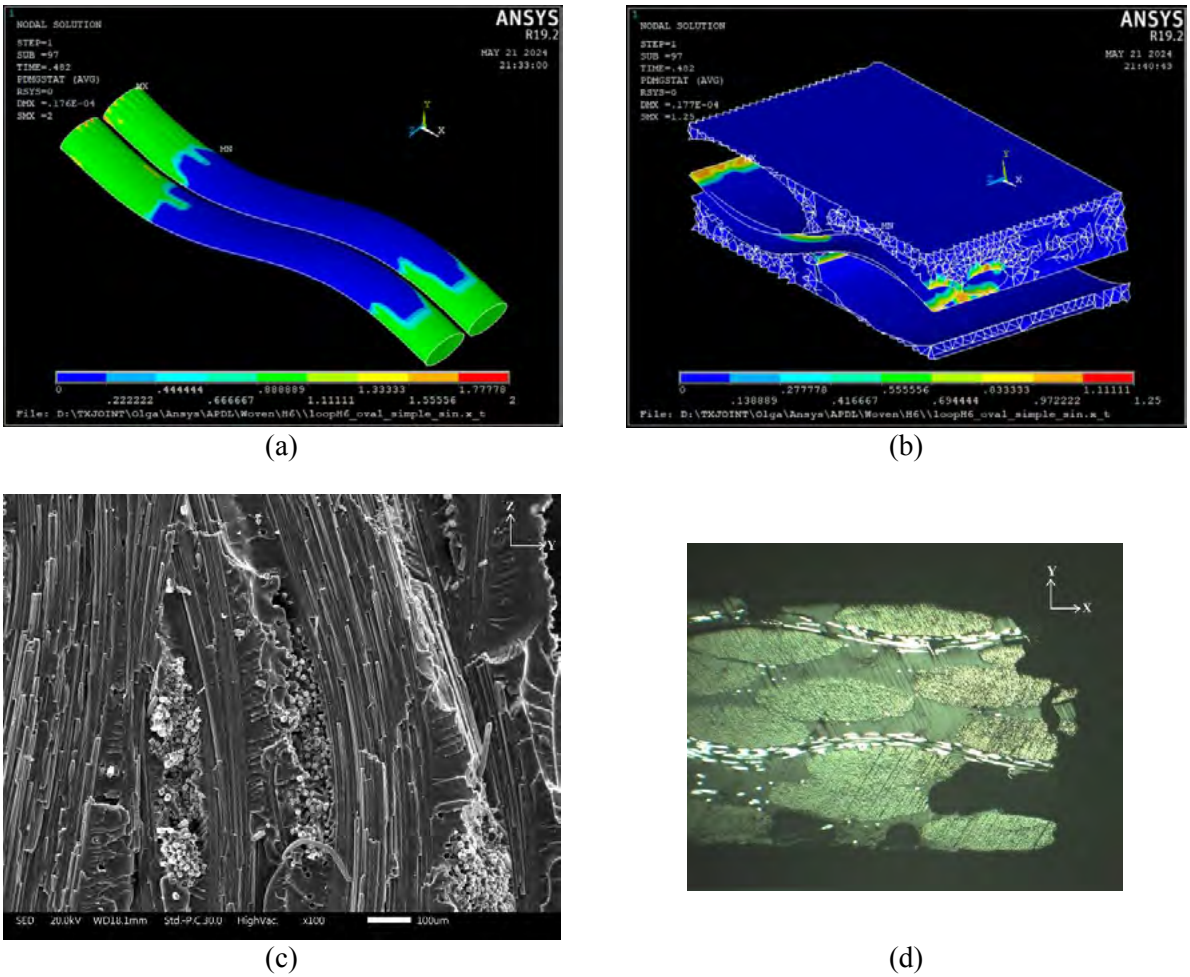

Figure 5. Schematics of microdamage (at the instance of final failure) for composite configuration H6, (a) FEM warp-yarn damage, (b) FEM matrix damage, (c) SEM image of fracture surface, and (d) Optical microscope image of polished edge (For FEM damage schematics, 0 = No damage, 1 = Partial damage, 2 = Full damage).

4. Conclusions

Damage development in hybrid carbon/steel fiber textile composites was studied using FE modeling. Representative volume elements were constructed for two configurations of hybrid woven composites and their mechanical response under quasi-static tensile loading was studied. To identify damage initiation sites inside fiber yarns and matrix, strength limits were defined, and maximum stress criterion was applied. Yarn/matrix-interface debonding was simulated by defining contact elements at the interface and by applying cohesive zone properties with bilinear material law. The macro-mechanical response of the hybrid composite FE models was captured by plotting stress-strain curves. For hybrid composite with stainless-steel fiber yarn in warp direction and carbon-fiber yarn in weft direction, FE model underestimates the experimental stiffness and strength values along warp direction by 50%. In terms of micro-damage evolution, FE models give accurate prediction of damage initiation sites and damage in fiber yarns and matrix at the instance of final failure.

Keywords: fatigue, creep, SFRT, microstructure, load ratio

Abstract
This work contributes to a more accurate prediction of the fatigue behaviour of structures, while reducing the number of characterisation tests on specimens for Short Fibre Reinforced Thermoplastic (SFRT) composites, based on nylon and short glass fibres. To achieve this, a more profound understanding of the oligocylic fatigue and creep damage mechanisms is required, both from a microstructural and a macroscopical perspective. Microscopically, no differences in fracture surfaces are observed. Macroscopically, a straightening of the S-t (Stress-time) curves is observed as the loading ratio increases. This relationship, highlighted by [5] through a strain-based criterion, paves the way for the development of a simplified fatigue model, suitable for use in the industrial world, based on creep calculation.

1. Introduction

1.1. Generalities

In order to address the challenges posed by global warming, there is a pressing need to enhance the energy efficiency of vehicles. This can be achieved by taking greater advantage of composite materials with an organic matrix, in particular a thermoplastic one. These materials are easily moldable and can significantly reduce structural weight, while offering good recyclability and high production rates. Initially intended for low-stressed components, thermoplastic composites, such as **PA66GF50**, are now well-suited to meet the requirements of parts subject to severe stresses and harsh environments. In order to guarantee user safety and to optimise maintenance, it is essential to effectively predict the service life of components under operating conditions.

Fatigue characterisation is a complex process: PA66GF50 is highly sensitive to external parameters such as **temperature**, **ambient humidity**, and **cyclic load ratio** [1], as well as intrinsic parameters such as **injection orientation** or **product thickness**. Numerous criteria have been proposed in the literature to predict component life [8]. These criteria establish a mathematical relationship between the **presumed life** (number of cycles or time to failure) and one or more observable or deducible quantities (strain, stress, energy, etc.) at the material's local scale. Prior to modelling and simulating the behaviour of a structure, it is essential to scale up to the representative specimen level. A robust criterion can predict and unify specimen life for a wide range of external and intrinsic parameters. Building upon this criterion, micromechanical models for life prediction have been developed [2,3]. These models enable the determination of the local life of a part without requiring the use of a complex and time-consuming damage model.

1.2. Criteria

In the work of [4], a criterion based on the mean strain rate (**2CMeanE**) was employed to estimate the life expectancy of representative specimens (**oligocyclic fatigue** and **creep)**. This criterion demonstrated satisfactory performance for cyclic load ratios between 0 and 1. Subsequently, a criterion based on the maximum strain rate (**2CMaxE**) was developed for load ratios between -1 and 1 [5]. This criterion is slightly more effective than energy-based criteria, such as **AED** [6], or **mixed criteria** (strain-energy) [7]. Indeed, it successfully grouped the results from 433 fatigue tests on representative specimens, with 86% of predicted life spans falling within a dispersion range of two. Furthermore, in comparison to more complex criteria [7,8], this criterion requires only two parameters and a single physical quantity for implementation, thus offering a simpler and more straightforward approach. Moreover, in contrast to the AED criterion [6], the 2CMaxE criterion is applicable to **creep** [5]. This requires the creep and fatigue deformation data to be expressed in the **time domain**. These results show the **link** between creep and fatigue.

To enhance the reliability of the 2CMaxE criterion [5], a range of load ratios and parameters related to environmental conditions are considered and incorporated into an experimental database.

1.3. S-t curves

From a macroscopic perspective, an upturn in the logarithmic **Wöhler curve** has been observed previously as the load ratio increases and approaches 1 (**pure creep**) [4]. It should be noted that the curves are time dependent, as the fatigue number of cycles is equal to the creep lifetime for our **1 Hz** frequency. An experimental campaign was conducted at room temperature for two conditions (**configuration 1**: 0% humidity and 0° orientation, **configuration 2**: 50% humidity and 90° orientation) to deepen the understanding of this phenomenon. Log-linear regressions for each curve are plotted according to the following law (Eq.1):

$$S_{max} = \sigma_{UTS} - b \log(t_f). \quad (1)$$

S_{max} represents the maximum applied stress, σ_{UTS} denotes the ultimate tensile stress (**NF EN 12003**), b is the slope of the curve et t_f fatigue life to failure. Given the significant uncertainties arising from the variability in fatigue life during tests, a correlation coefficient is provided for indicative purposes.

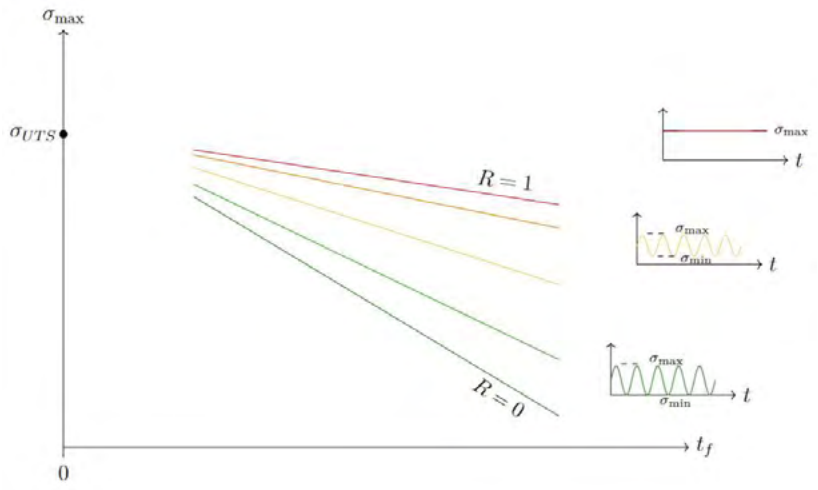

Figure 1. Illustration of the maximum stress - life curve for various load ratio values (R ranging from 0 to 1).

Under these conditions and for an identical lifespan, it is assumed that as one approaches a creep loading scenario, the maximum stress to be applied increases (Figure 1).

One author in the literature demonstrates a different behavioural pattern. Two distinct slopes are observed for fatigue loading, as evidenced by [9]. Other authors present an increase in fatigue strength with an increase in load ratio, although the softening of the slope is far less noticeable [7,10].

2. Methods

2.1. Material and conditioning

The material under study is a **polyamide 66** reinforced with **short glass fibres** with a fibre content of 50% by weight (**PA66GF50**), in the form of injection-molded plates with a thickness of 3 mm. The PA66 matrix is a semi-crystalline thermoplastic with visco-elasto-plastic mechanical properties. The material is conditioned at two **humidity levels**: **0%RH** and **50%RH**. The first conditioning involves heating the material to 80°C in an oven until mass stabilization is achieved. The second involves conditioning at 62%RH and 70°C until mass stabilization is achieved. **Dogbone-shaped** specimens used for fatigue tests were cut from the injection-molded plates with two different **angles** θ relative to the injection direction: 0° and 90°. Six specimens were cut from each plate.

2.2. Mechanical tests

Fatigue tests under load were conducted using an INSTRON 8801 hydraulic fatigue machine. All tests were performed at **room temperature** (T=23°C). Mass measurements indicated that the humidity variation during the test was negligible. The fatigue tests were conducted using a sinusoidal signal at a constant frequency of **1 Hz** to avoid **self-heating** and with a constant stress amplitude. Five load ratios were considered in this study, defined as the ratio between the maximum applied stress and the minimum stress: **R = 0** (R0), **R = 0.2** (R02), **R = 0.5** (R05), **R = 0.8** (R08), **and R = 1** (R1). For each load ratio and maximum applied stress level, a minimum of three tests were conducted. Furthermore, each curve includes a minimum of four levels of maximum applied stress.

3. Results

3.1. Microscopic observations

A microscopic investigation was conducted using a **Scanning Electron Microscope (SEM)** to analyse the fracture surfaces of various specimens. Thus, the objective was to gain insight into the observed decrease in fatigue life compared to creep loading (with identical maximum stress). A comparison of **fracture surfaces** obtained from fatigue (R0) and creep (R1) was performed, showing **no significant differences**, in accordance with the literature [2,11], whether under 0%RH and 0° conditions or at 80%RH (Figure 2a and b) and for orientations of 0° or 90°. At 0%RH, the surfaces only exhibit a **brittle looking zone** with numerous **pores** (micro and nanopores). At 80%RH, both ductile and brittle zones were observed in both cases, with no significant differences between fatigue and creep. **Extended plastic zones**, fibre-matrix interface debonding, and fractures were observed in both fatigue and creep conditions (Figure 2).

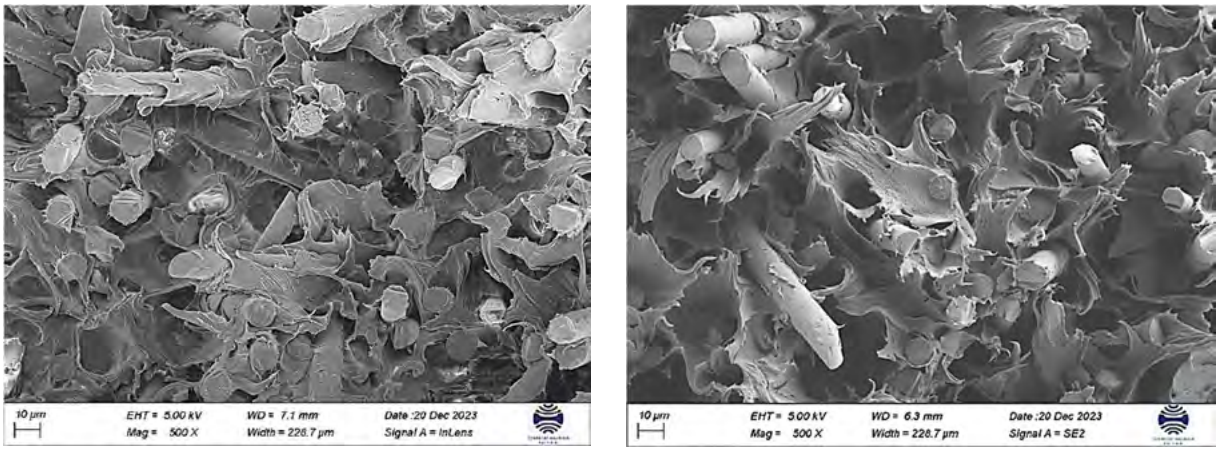

Figure 2. SEM images of ductile fracture surfaces. Fatigue (left), creep (right).

3.1. Macroscopic comparisons

The maximum stress, expressed as a percentage of the UTS stress, is plotted against time to failure. The parameters of the log-linear regressions are provided in Table 1. The **correlation coefficient** r^2 is also given, calculated using the formula (Eq.2):

$$r^2 = 1 - \frac{\sum_1^n \left(y_i - y_i^{pred}\right)^2)}{\sum_1^n (y_i - \bar{y_i})^2)} \quad (2)$$

The y_i values represent the values for point i, y_i^{pred} predicted value for point i calculated using a **log-linear regression** method. The $\bar{y_i}$ empirical mean is derived from the data. As expected, we observe an increase in the slope of the S-N curve as R increases from 0 to 0.2 and 0.5. However, as R approaches 1, a decrease in fatigue strength is observed, contrary to what was expected (Figure 1), for both conditioning levels. For the 0%RH conditioning, the upward trends cease beyond R05, with the R08 and R1 curves nearly overlapping.

With regard to the 50%RH conditioning (Figure 3), the curves from R0 to R08 exhibit a discernable **upward trend**. However, the creep curve shows a steeper slope and a considerably lower level than expected.

Table 1. Fatigue interpolation parameters, S-t curves, 50%RH, 90°

R	$\%\sigma_{UTS}$	b/σ_{UTS}	r^2
1	0.94	0.025	0.77
0.8	0.93	0.009	0.54
0.5	0.96	0.020	0.89
0.2	1.01	0.037	0.86
0	1.04	0.048	0,86

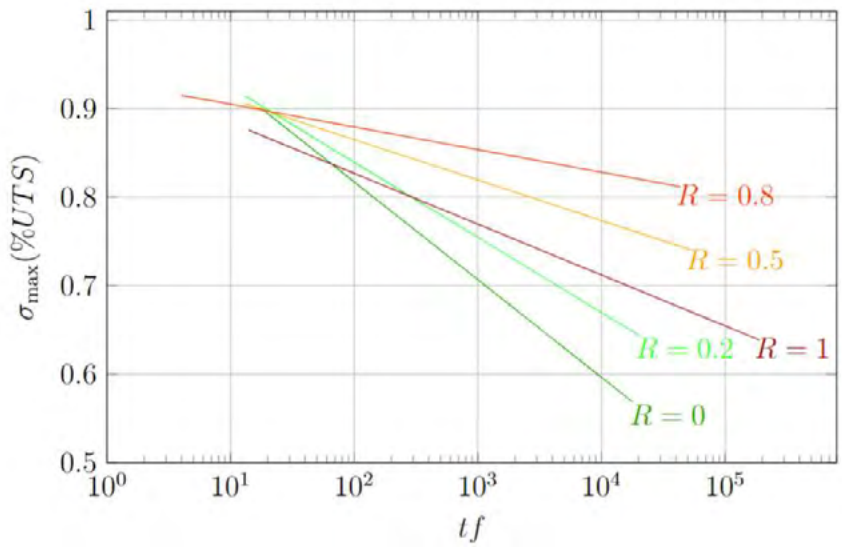

Figure 3.S-t curve (%UTS) – lifetime for several R values (R between 0(dark green) end 1 (dark red)), 50RH / 90°.

4. Discussions

A high degree of **dispersion** is observed, particularly evident in the creep curves, which introduces uncertainty into the analysis of the results, especially as R increases (highest for the creep curves) (Table 1).

While an upward trend in the slope can be confidently observed, it is more challenging to assert that the creep resistance level is below the other curves. To increase certainty regarding the slope and position of the curves, a new test campaign will be conducted.

5. Conclusion

The relationship between fatigue and creep is complex, both at the macroscopic and microscopic levels. From the microscopic perspective, **no significant differences** were observed in the fracture surface observations. Based on the similarity of the fracture surfaces between fatigue and creep, it can be inferred that similar damage mechanisms occurred. A **micro-tomography** observation campaign is planned to observe and quantify real-time differences in **damage mechanisms** between the two loading types (porosity rate, percentage of broken fibres, etc.), which may not be observable on fracture surfaces. From a macroscopic perspective, a **softening** of the S-t curves is observed for R ranging from 0 to 0.5 or 0.8 depending on the specimen type. However, the creep curve does not align with the expected level, which could indicate differences in damage mechanisms or simply the high measured dispersion. A similar test campaign at 80%RH is also planned to highlight the effect of ductile specimen behaviour on the curves' upward trend. Additionally, extra creep tests will be conducted to reduce **statistical uncertainty** regarding the obtained levels. A comparison of surface deformation fields between creep and fatigue will also be carried out using Digital Image Correlation (DIC).

The 2CMaxE criterion supports an **innovative numerical approach** to fatigue design (**oligocyclic**), leveraging insights gained from creep tests. These efforts contribute to better predicting the fatigue behaviour of structures while significantly reducing characterisation tests on specimens. Creep models capturing maximum average strain rate will be established. Post-processing using the experimentally determined criterion will predict the lifespan of complex components.

Acknowledgments

The authors would like to express their gratitude to the teams at the **ESTACA Laval laboratory** and the **Centre des Matériaux** of Mines Paris - PSL. In particular, they would like to acknowledge the invaluable assistance of **Raphaël DEFOSSEZ** during experiments.

Keywords: Numerical modeling, Behavior law, Flax roving

Abstract

Today, environmental considerations are leading manufacturers to integrate more and more composites based on plant fibre reinforcements, particularly from flax, into their production. However, predicting the behavior, mechanical characteristics and feasibility of parts remains complex. The step of shaping the dry reinforcement during the LCM (Liquid Composite Moulding) process is for example fundamental for the service life of the composite part. However, it is still difficult to accurately predict the final shape and integrity of the reinforcement. In order to study the behavior of a dry reinforcement under different stresses during shaping, this study proposes to carry out a numerical simulation on a mesoscopic scale of a 500tex flax roving supplied by the company Depestele in the context of tensile solicitation and to compare this simulation to the result of the associated experimental test. For this, a highly representative geometric model, taking into account the geometric variability of the roving and an adapted transverse isotropic hypoelastic behavior law are implemented. The comparison of the tensile curves shows a good correlation with the expected result.

1. Introduction

1.1. Context

The integration of composite parts based on fibrous reinforcement with natural fibers is increasingly popular with manufacturers, particularly for their damping properties. However, there is a major obstacle to the integration of this type of part, particularly in technical applications, which lies in the difficulty of having an efficient and controlled manufacturing process.

Indeed, the development of this type of part is carried out by LCM type processes which require imposing strong stresses on the dry reinforcement, particularly in tension, shear, and compression to keep it in the mold. However, to avoid damage to the reinforcement at this stage of the process, it is important to be able to characterize and predict the behavior of the dry reinforcement for this type of stress. The complexity of the implementation of reinforcement tests and the multiplicity of architectures lead to the desire to set up numerical simulations predictive of mechanical behavior. In order to accurately characterize the behavior of the reinforcement while guaranteeing reasonable calculation times, we place ourselves at the mesoscopic scale, i.e. the interlacing of the strands (here a linen roving)

modeled by an equivalent homogeneous material is considered. The implementation of the numerical simulation thus consists of determining and identifying the behavior of the equivalent homogeneous material of the strands and modeling the ERVs (Representative Elemental Volume) of the reinforcement from the strands. To do this, it is therefore necessary to have a geometry of the reinforcement, the strands, and an adapted law of behavior.

In this study, the strands are linen rovings. Rovings are assemblies of thousands of long staple fibers arranged in an almost parallel manner and held together in the transverse direction by a cohesive agent. The behavior law must therefore make it possible to model the behavior of the homogeneous material equivalent to a flax roving. An hypoelastic transverse isotropic law behavior already used by the team in the case of roving of synthetic fibers [1] will be adapted in this study to take into account the specificities related to flax.

Among these specificities is the high geometric variability of flax rovings (Figure 1) related to its structure and manufacturing process. Indeed, several categories of fibers can be identified within a flax stem. Inside the stems, bundles of fibres develop, which are aggregations of unitary fibres connected to each other by a membrane called the middle lamella [2]. Unit fibers are the shortest fibers that can be extracted from the stem and are the most studied because they have mechanical properties compared to their density comparable to glass fibers [3]. However, the difficulty of extraction without damage of this type of fiber and their short length (of the order of a few millimeters) do not make them good candidates for the manufacture of roving. However, the fibre bundles with the party lamella prevent good impregnation [4] for composite manufacturing. Thus, the fibers within the rovings are so-called technical fibers and are bundles that are not completely dissociated up to the unit fibers. However, for the manufacture of rovings, this incomplete dissociation, added to the initial variability of the cross-sections of the unit fibres, does not homogenize completely [5] and at the end of the chain creates the high cross-section variability of the flax rovings. However, the number of fibers in the transverse section varies little, since the linear mass is controlled and not very variable along the wire [5], so the variability of cross-section depends mainly on the internal arrangement. But in the case of a homogenization of a material by the apparent cross-section, this is not negligible.

Figure 1. Example of geometric variability observable on 20mm roving specimens

In addition to the geometric variability, we must add the variability of the mechanical properties of the natural fibers [6] and the various factors that can influence the results [7–10]. Although manufacturers homogenize the batches with fibres from different plots and years, which allows a certain reproducibility of the mechanical properties, there is still a certain variability in the mechanical properties that is difficult to link to the elements mentioned earlier. In addition, the particular structure of the rovings does not allow for extrapolation of the properties that will be obtained from the data on the unit fibres and the strength of the roving. These specificities make mechanical tests on the roving essential to obtain properties but also the exploitation of these tests difficult. The possibility of carrying out simulations considering these two types of specificities will make it possible to carry out more detailed inverse identifications to understand and interpret the behavior of this type of material. This is all the truer when certain quantities related to the properties of the materials will be strongly influenced by these variations in geometries during compression loading.

The aim of this study is to determine the tensile behavior of the equivalent homogeneous material to be implemented in the mesoscopic model. To do this, in order to overcome geometric effects and go back to the real behavior of the fibrous assembly, it is necessary to set up a numerical simulation taking into account the apparent geometric variability at the initial instant of the flax roving in the context of a uniaxial tensile test. A specimen is made from a roving and tested experimentally. A digital twin with the geometric variability of the specimen is recreated at the same time. The hypoelastic behavior law is modified to adapt to changes in geometries and the simulation results are compared to the experimental results.

1.2. Traction behaviour of flax roving

The study of the behavior of rovings is complex and this is why few studies are directly interested in the tensile behaviors of rovings, preferring to directly identify the behavior of reinforcements [11] or study the properties of unit fibers [3,12–14]. Nevertheless, it appears that the tensile loading curve of flax rovings has a typical shape (3 types appear in the literature [19] but type III is preponderant). Three phases during loading can be identified for type III, two non-linear phases which frame a linear phase from which the maximum stiffness K is extracted and for which an apparent modulus reported for the purpose of the roving can be identified. The initial non-linear phase is due to both the internal reorganization of the unit fibers and the structure within the roving (realignment in the direction of traction). The final nonlinear phase is due to fiber breaks and can be described by Weibull-type modeling [10].

It is found in the literature that the length of the gauge of the specimen influences both the breaking force and the stiffness. Concerning the breaking force, this result is classic and comes from the probability of the appearance of critical defects within a specimen which increases with the length of the gauge. In the case of stiffness, this result is less expected and comes from the internal organization of the roving and in particular from the role of the cohesive agent in the transmission of force between the technical fibers. For some rovings, it has been established that the shorter the gauge length, the closer the stiffness is to what is found for unit fibers. On the other hand, for longer gauge lengths, the stiffness decreases to a threshold value. As the influence of the gauge length is not implemented at this stage in the behavior law, the reconstruction length used here is the same as that used for the tests. Then there is the influence of various external factors such as the temperature and humidity of the test conditions, which are therefore controlled in our case.

1.3. Numerical modeling

The long-term objective of this mesoscopic modeling is to study the behavior of dry reinforcements. The variability in the cross-section of the rovings observed as soon as the coil comes out is also visible in the reinforcement and can be accentuated along the roving by the successive interlacing of the reinforcement patterns. However, in the case of rovings, tensile stiffness depends only on the number of technical fibers in tension in the roving. Thus, by the method of manufacture and the management of the titer in the rovings, it can be considered that each section of the roving is crossed by the same number of technical fibers. Therefore, if the shapes and sizes of the cross-sections change due to the different organization of the bundles, the tensile strength being carried by the number of technical fibers is not modified by these cross-section changes, which therefore requires an adaptation in the assignment of mechanical properties in the finite elements.

The behavior law used in this study is a transverse isotropic hypoelastic behavior law allowing to relate the stress increments to the increments of deformation in the base oriented by the fibers Here the base of the fibers is oriented in such a way that the longitudinal direction of the roving is in direction 1 and the transverse directions of the roving are in directions 2 and 3 (thickness and width of the roving respectively). This behavior law is implemented in a Vumat Abaqus.® for an explicit scheme and

elements of type C3D8R. The Vumat makes it possible to monitor the evolution of the material orientation of the fibers in the element being calculated [1]. Among the hypotheses for establishing this law, the absence of interaction between direction 1 and the transverse directions in the case of tensile stress implies the determination of a single coefficient (C1111). This coefficient is expressed by dividing the stiffness of the roving by the cross-section [1].

As explained above (I.1.1), the equivalent homogeneous material of a roving is modelled by the external roving shape (i.e. the apparent section of the roving) but as the variability of cross-sections is not due to a variation in the number of local technical fibres but to an internal arrangement linked to the architecture of the technical fibres (Figure 2), the difference in the size of the sections in the longitudinal direction should not lead to a variation in tensile stiffness at the level of the different sections. It will obviously be very different in compression.

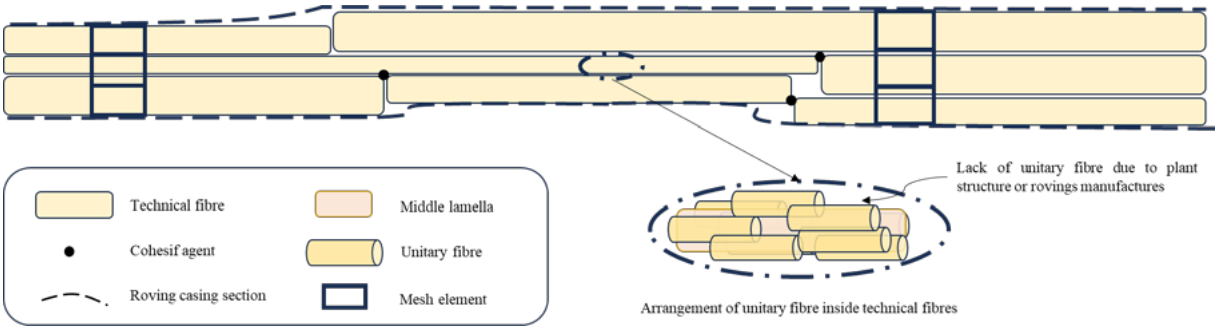

Figure 2. Schematic diagram for assigning element properties in the case of variable geometry section of the model.

The meshing made by the specific tool for fibrous reinforcement [15] requires that the model has the same number of elements in each section but with elements of different sizes between the sections. To obtain the same stiffness between sections of different sizes, the tensile modulus for each element must be related to the size of the section. This assignment of homogenized stiffness per section must be carried out both for the initial state and during the deformation of the sections. Thus, the allocation of the initial surface to which the elements belong at the beginning of the test is carried out and updated in the VUMAT and makes it possible to homogenize the resulting stress in each section. It should be noted that, while cross-section variations remain modest for tensile test, being able to manage the assignment of properties according to cross-section size will be all the more important for simulations of compression tests where the volume fractions of fibers and cross-section shapes vary greatly.

The adaptation of the hypoelastic behavior law to the geometric specificities of flax rovings is therefore possible by controlling the assignment of the properties of the elements according to the section to which they belong. Concerning the adaptation of this behavior law to the response of the tensile loading curve, this will be carried out in several steps. The first step, which is the one used for this study, consists in modeling the loading curve only by a linear approximation of stiffness K' without taking into account the nonlinear initiation of the breaking phase of the roving. The next steps will aim to integrate the two nonlinearities of the loading curve. To carry out this numerical simulation, it is therefore necessary to model a representative sample of the geometric variability of a flax roving and to carry out a uniaxial tensile test from which the stiffness on the loading curve will be recovered.

The numerical modeling of the tensile behavior of a flax roving requires both a precise geometry to reproduce the variability of the samples and a behavior law that allows to reproduce the behavior of the equivalent homogeneous material.

2. Material & Methods

2.1. Material of the study

A roving sample supplied by the company Depestele with a linear density of 500tex (kg/m) is prepared for tensile testing. The manufacturing protocol is similar to that used by Moothoo [16]. For the purpose of a 3D reconstruction using a digital microscope, the gauge length of the specimens is 20mm. The manufacturing protocol consists of gluing aluminum plate using Araldite to the sample. The length of the gauge is ensured by means of a template. A pre-tensioning force of 0.3 N is applied at the same time to each end of the specimen to ensure that the strand is straight and to ensure good repeatability of the initial state. After the manufacture of the specimen, a 24-hour drying period of the adhesive is necessary before the tensile test can be carried out. A 3D image of this specimen (Figure 3) is obtained using a Keyence digital microscope (VHX-5000) with a resolution of 2.21µm (XY plane) to obtain the geometric characteristics of our sample and allow the reconstruction of the model in numerical simulation.

2.2. Methods

2.2.1. Experimental tensile test

The test is carried out using a Zwick traction machine with a capacity of 5kN. The test is piloted in displacement with a crosshead travel speed of 6.66.10-5 $^{s-1}$. Before the test, a pre-tensioning of 2N is applied to the specimen. As the length of the gauge tested is small, a Sony α1 ILCE-1 camera with an RGB sensor, size 5760x5760 (pixels), is used to obtain the average deformation of the test specimen. The camera is placed in such a way that the resolution of the images is about 0.01mm/pixel. The synchronization between the camera and the traction machine is achieved with the timestamp of the images. The exploitation of the images by a Matlab code makes it possible to trace the loading curve of the test and to obtain the information necessary for the numerical simulation.

2.2.2. Numerical tensile test

The digital model of the specimen is obtained from a 3D image (Figure 3), reconstructed using Matlab. A preliminary study has determined that the roving sections shape are rectangular. The reconstruction therefore requires the ability to extract the thickness and width of sections from the specimen while maintaining geometric variability while smoothing the profile and eliminating artifacts from the image. For example, by eliminating groups of fibers that are not attached from one end of the specimen to the other and will therefore not participate in the tensile test. The selected cross-section profiles (1 per 0.8mm length) are then injected into CatiaV5 to reconstruct a volume model, which is itself reinjected into Abaqus®. Once the mesh has been obtained, the coordinates of the integration points (1 per C3D8R element) and the sections of the associated model are computed using a Matlab code and transcribed into a file allowing the reading by the Vumat during the calculation.

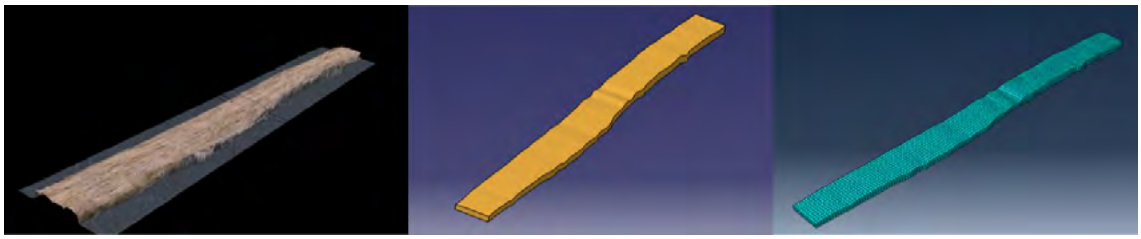

Figure 3. Reconstruction of the geometric model of the specimen from the 3D image of the digital microscope to the mesh model in Abaqus.

The material orientation of the elements is determined in the initial state using the GEOFAB software, which is a tool for modeling and meshing woven strands and reinforcements [1,15]. The material parameters used in the simulation are the flax density (1.4.10-9 t/mm2), the stiffness K' (in N) extracted from the tensile test and the value of the cross-sections (in mm2) calculated at the integration points. Displacement is applied to the nodes at the end of the model in the direction of pull. The total displacement is carried out in one step, from the preload to the length for which the non-linear failure of the roving is initiated. A damping of 10^4 as well as a shear modulus of 120MPa are applied for the stability of the calculation.

To illustrate the impact of taking into account the geometry of the roving, on the identification of the tensile property of the equivalent homogeneous material, two models are tested in simulation. A model with a behavior law (LDC1) that does not take into account the section variation, and which assigns to all the elements a stiffness dependent on the average cross-section of the specimen, and a modeling with a behavior law (LDC2) which allows to assign the initial stiffness of each element according to the size of the section to which it belongs.

3. Results & Discussions

The use of the camera images makes it possible to measure the length of the specimen after preload at 48.44mm. The exploitation of the 3D image under the microscope gives an average thickness of 0.59 ± 0.08 mm and an average width of 2.49 ± 0.2 mm. The test was conducted with an ambient temperature of 22°C and a humidity of 42.4%. The tensile curve obtained after the test has been used is given below (Figure 4).

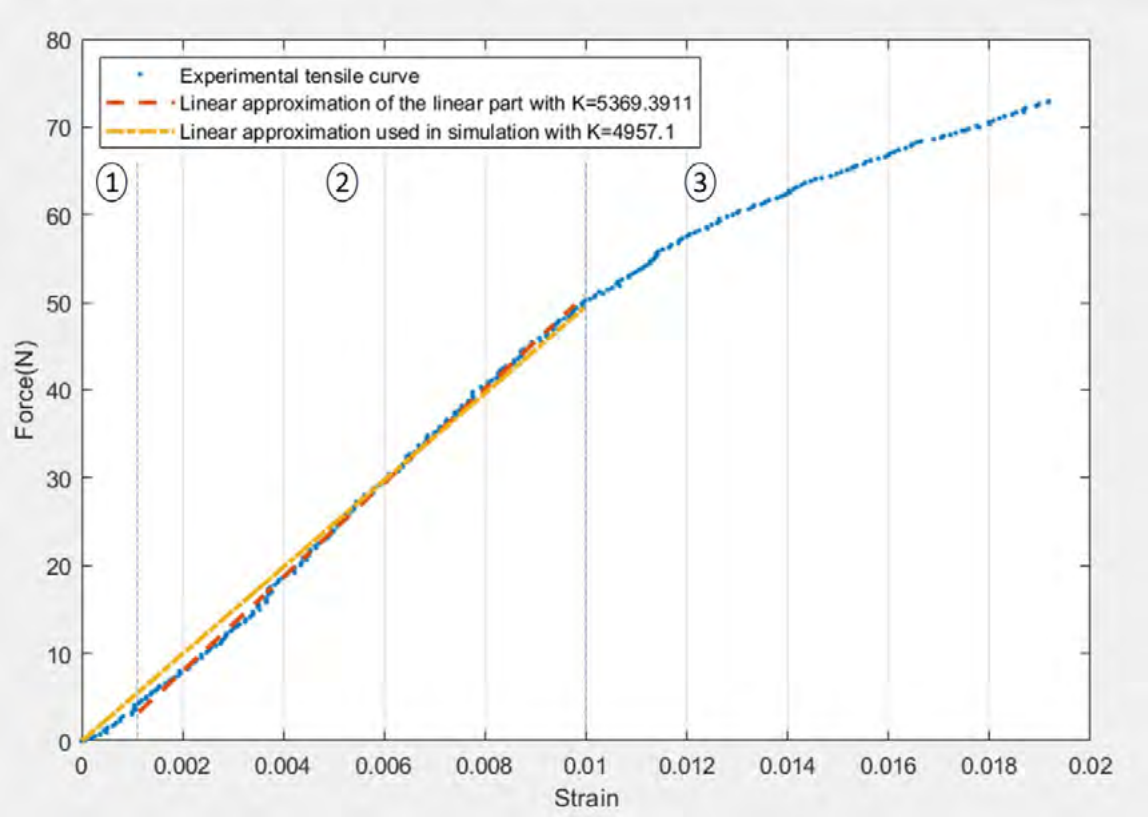

Figure 4. Experimental tensile curve obtained after exploitation of the test images.

The stiffness in the linear zone (2) is ... N and the linear approximation of the stiffness K' which was injected for the numerical test is 4957.1N. The simulation with a ... hours with LDC1 modeling and .. hours for modeling with LDC2. The tensile curves obtained are compared to those of the experimental test (Figure 5).

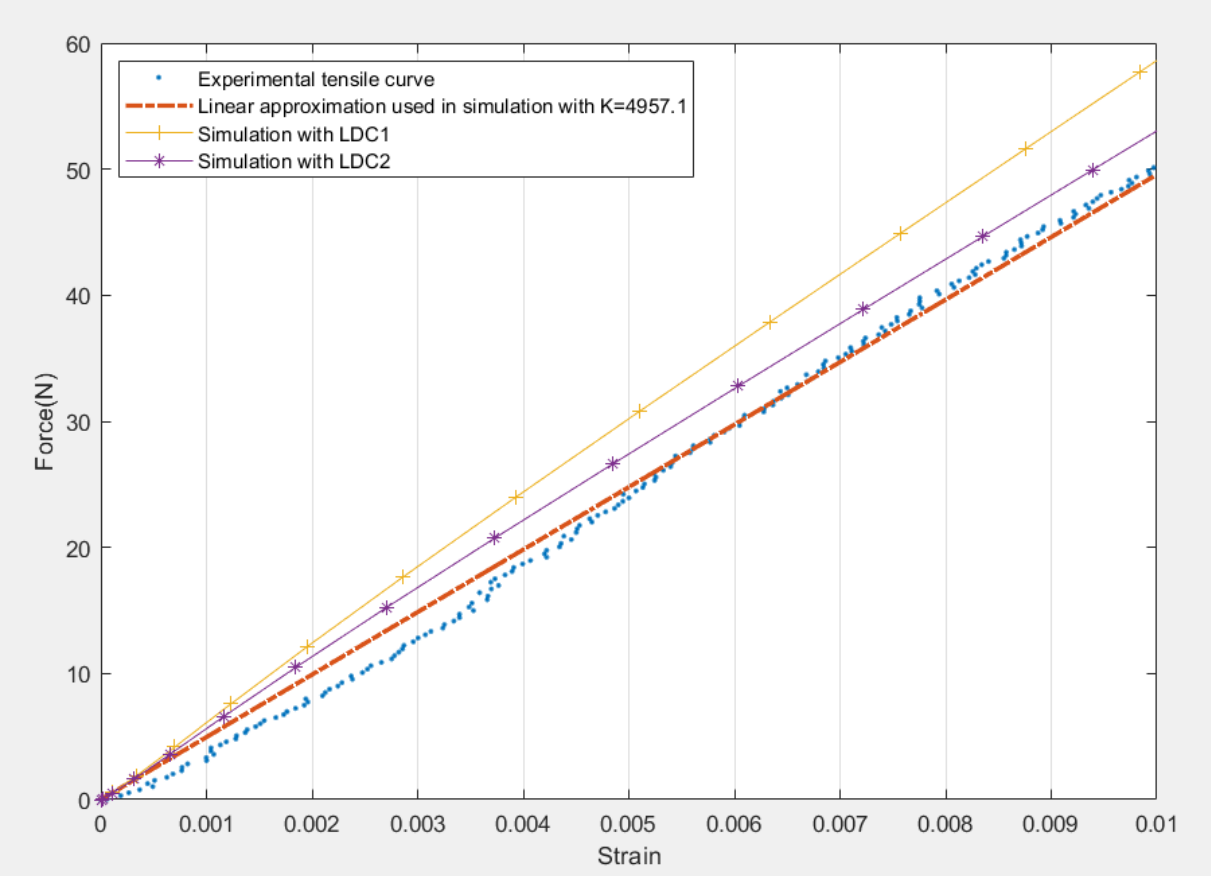

Figure 5. Comparison of experimental and numerical tensile curves

The figure shows a deviation in stiffness of 19.7% with the desired result for the modeling with LDC1 and a deviation of 8% with LDC2. The deviation obtained with the LDC2 modeling is due to the fact that the strand is slightly curved (Figure 3) and that the bending stiffness that comes into play is driven by the shear coefficient which has not been specifically identified for this material. This will therefore have to be taken into account in future modelling.

4. Conclusions and perspectives

The objective of this study was to have a numerical model of a flax roving to take into account the cross-sections variability, thus making it possible to identify more realistically the tensile behavior of the equivalent homogeneous material. A transverse isotropic hypoelastic behavior law that has already been used in the modeling of synthetic roving behavior has been used and adapted to the flax specificities. The tensile loading curve has been approximated linearly and the response of the numerical simulation is satisfactory from this point of view considering the future implementation of the realignment of the strand with the tension load. In the perspective of being able to achieve a fine inverse identification of the roving behavior, the realization of this step is encouraging. It is now necessary to tackle the modeling of the non-linear parts of the loading curve.

This first step paves the way for the modeling of a primary stress for LCM-type processes, compression loading.

Keywords: CFRP, delamination, Non-Destructive Testing, Lamb Waves, Thermography

Abstract
Despite having excellent mechanical performance and resistance to corrosion, Carbon Fibre Reinforced Composites are also particularly sensitive to delamination which may lead to their failure, and therefore represent a risk for their use. In order to prevent delamination, detecting and understanding them has been widely investigated by industrials and researchers. In this study, two types of delamination, one type induced by lightning strike test and one induced by impact test, are investigated by various classic and advanced NDT methods. Different features can therefore be extracted from healthy and delaminated zones, such as thermal propagation characteristics, ultrasonic wave attenuation or Lamb Wave propagation modes. The results allowed to emphasize the structural differences between lightning strike induced and impact induced delamination and to correlate various NDT techniques and their measured material features. This type of data fusion is partucilarly promising for improving the efficiency of defects detection by combining various methods, compensating for their respective weakness while emphasizing their strengths, and finally reduce the false positives and negatives.

1. Introduction

Carbon Fibres Reinforced Plastics (CFRP) have been increasingly attracting interest, particularly in the fields of aeronautics, aerospace and automobile, due to their outstanding mechanical performances combined with low weight. However, one of the main limitations to their use is their susceptibility to delamination, which present an important risk of structure failure. Delamination can be induced by various solicitations on the material, including mechanical solicitations (shock, fatigue, vibrations) but also thermal and even chemical solicitations [1–4].

The understanding of delamination generation, propagation or structure is an important area for research in order to prevent them. To detect delamination at any stage of the material fabrication and service, industrials and researchers developed Non-Destructive Testing (NDT) methods which have the ability to provide information on the inner structures while leaving them intact. Depending on their nature or the method involved, NDT techniques provide different aspects of the material characteristics. For example, Ultrasonic Testing (UT) provides information on the propagation of ultrasonic waves through the material, such as the waves dB attenuation or the presence of backwall echoes. InfraRed Thermography (IRT) provides information on the thermal propagation characteristics through the material. Radiographic Testing provides information on the material capacity to attenuate gamma rays, exactly in the way medical radiographies do with human body [2,5,6]. A very immediate but sometimes misconsiderated NDT method is visual inspection, which provides many information by just observing material surfaces state such as surface porosity, thickness variations, changes of colour, etc. Visual inspection can be assisted with more advanced methods such as 3D Optical Profilometers or Scanning Electron Microscopes (SEM), and many others [2,7].

In this research, CFRP samples which have been subjected to lightning strike in their centre are investigated using various NDT methods in order to collect a wide range of material characteristics in the healthy and defected zones. The comparison and correlation of these various material data, also called data fusion, allows to record particular features characterizing the lightning-strike induced delamination by selecting the best abilities of each NDT technique.
In the second part of this article, the experimental samples and the different NDT inspections are presented. The third part describes the analysis of the experimental data and the data fusion, with discussion points. The fourth and final part of this document gives a conclusion.

2. Experiment

2.1 Specimen preparation

In this experiment, two CFRP samples sized 150 per 150 mm have been used. The manufacturing was handmade in the Yokozeki laboratory at the University of Tokyo, Japan, by applying the resin on wowen carbon fibre fabric (TR3110M, TR30-3K, 200 GSM, Mitsubishi Rayon Co. Ltd.), stacking the prepregs in 0°/90° direction and then curing in hotpress. Instead of classic epoxy resin, the polyaniline-based resin PANI-DBSA/Phenol-DVB (PDPD) as described by Zhou and al. in [8] has been used in order to limit the damage from lightning strike test.
The two samples (respectively called LS-1 and LS-2) have been tested with a simulated Lightning Strike using the high impulse current generator (Otowa Electric Co.) at the National Composite Center at Nagoya University, Nagoya, Japan with a peak current at -40 kA [8]. The lightning strike induced a visible deformation of the samples surface, shown in figure 1.

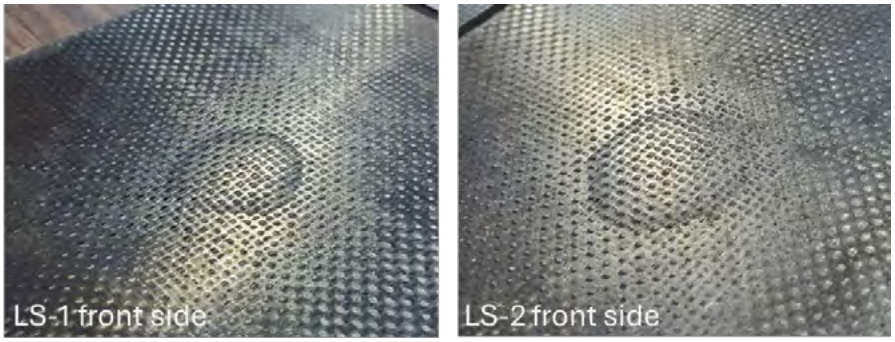

Figure 1: Visible deformation of the surface induced by the lightning strike

2.2 Visual Inspection

In addition to the eye inspection as shown in the figure, a 3D profilometry as also been performed on the 100 per 100 mm square at the centre of all samples using the Keyence VR-6000 profilometer located at the Chofu Aerospace Center Aerodrome Branch of the JAXA. The top and bottom surfaces thickness cartographies of all samples are shown in figure. It is to be noted that the back side results of LS-1 and LS-2 show a regular thickness difference, this is in fact due to the large surface deformation on the other side which unbalances the samples when set on this side. No deformation induced from the lightning strike is however detected. Some small small points are visible on all cartographies, they are surface irregularities also observable by eye and are attributed to the handmade resin application during the manufacturing. The Visual Inspection results are shown in the figures 2 and 3 where the color scale represents the thickness of every surface point. In the figure 3, the color scale has been replaced in order to allow a better visualization of the surface deformations induced by low velocity impact test.

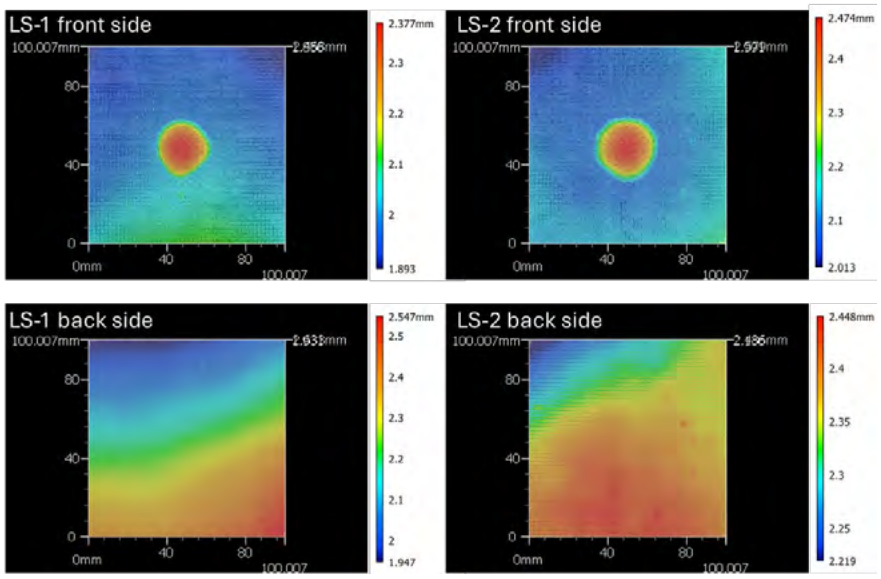

Figure 2: Profilometry measurement results in colour scale

2.3 Thermographic inspection

A thermographic inspection is performed on the four samples using the Thermal Wave Imaging system Echotherm coupled with MOSAIQ 4.0 analysis software located at the Chofu Aerospace Center Aerodrome Branch of the JAXA. The Echotherm system consists of a disposable hood containing an InfraRed camera and a flashlamp, connected to a display screen. The measurement is set to 10 to 18 seconds after flash. The video of thermal propagation recorded by the system shows a specific structure on the defected zone of LS-1 and LS-2 with three different zones: a dark ring on the periphery of the defect, a white ring inside the black ring, and a grey zone at the centre. These zones are shown in the parts a) of figures 3 and 4. The parts c) and b) of the figures 3 and 4 show respectively the log-log cooling plots at different points of the samples surface and the localization of these points.

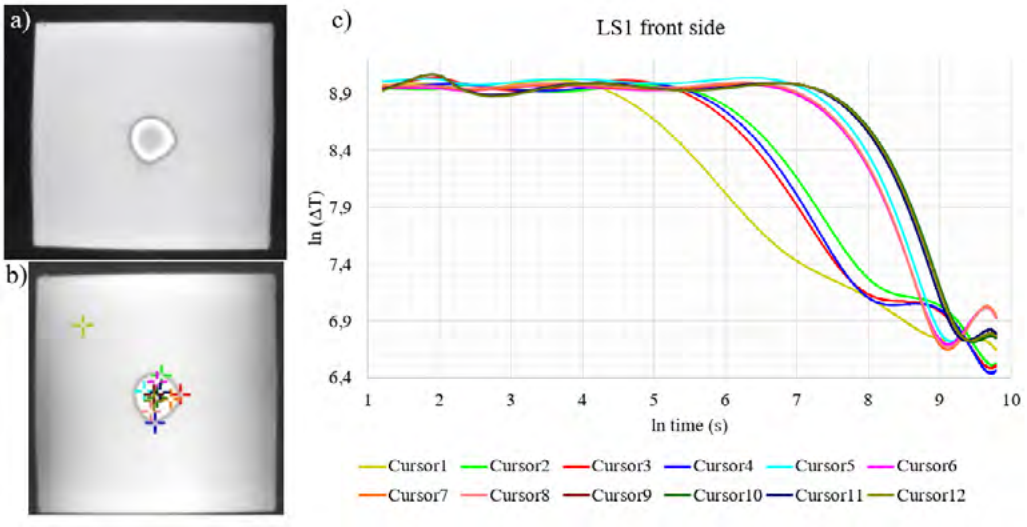

Figure 3: Thermographic Inspection results on LS-1 with a) the different aspects of cooling shown at the thermal video, b) localisation of the cooling curves cursos, c) cooling curves

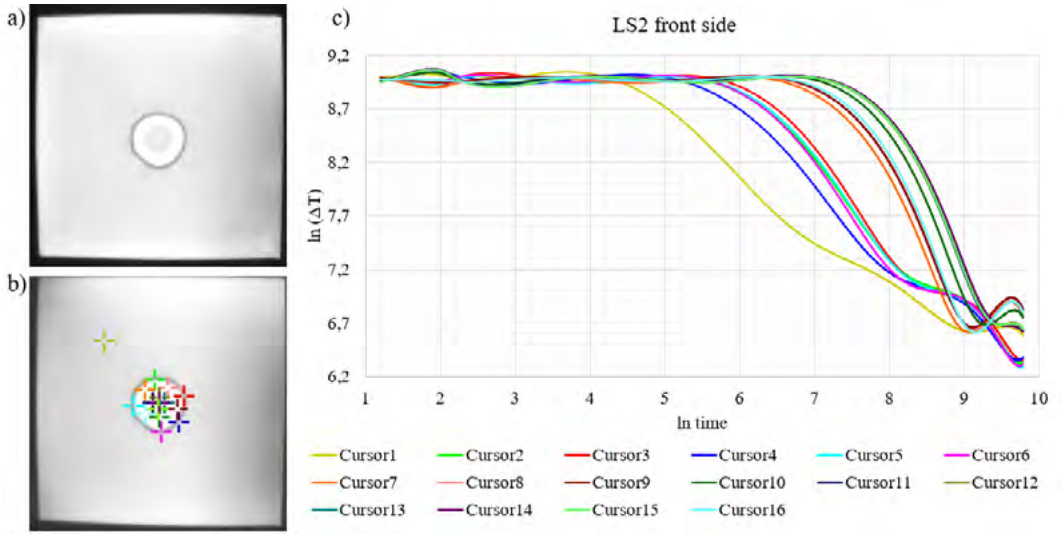

Figure 4: Thermographic Inspection results on LS-1 with a) the different aspects of cooling shown at the thermal video, b) localisation of the cooling curves cursos, c) cooling curves

2.4 Ultrasonic Testing inspections

Two methods have been used for Ultrasonic Inspection of the samples: a classic method consisting of a manual A-scan directly in contact with the samples using an Omniscan SX with an Olympus V201-RM 5 MHz delay line transducer located in Yokozeki Laboratory at the University of Tokyo, Tokyo, Japan. A-scan signals have been directly observed at different zones of the front and back sides of the samples. The second method, which is more innovative, uses Lamb Waves control with a fully non-contact system base on a Laser Induced Plasma Shock Wave (LIPSW) developed by Hosoya et al. [9,10]. Using sophisticated signal processing algorithm, this method is able to investigate various features of the Lamb Waves propagation through the specimen.

A-scan measurements shown that the backwall echo was detectable in all flat zones but not detectable in the thicker zone of the LS-1 and LS-2 samples. Therefore, measuring a thickness of delamination from this side was impossible. However, by measuring the signal on he back side, backwall echoes were found in the defected zone at respectively 1.79 mm and 2.02 mm for LS-1 and LS-2. Considering the thickness observed in the defected zone in figures , the defected zone is therefore estimated to be about 0.4 to 0.6 mm depth in both samples.

The LIPSW system method allows to record the Lamb Waves propagation field measured in the out-of-plane direction at the top surface. The Root Mean Square (RMS) of signals is shown in the left side of the figure 5 for LS-1 and LS-2. The cartography can be improved by measuring Damage Indexes from the algorithm. As an example, a Root Mean Squared Error (RMSE) cartography is shown in the right side of figure 5 for LS-1 and LS-2. The algorithm and the method for extracting RMSE cartography are described in [10].

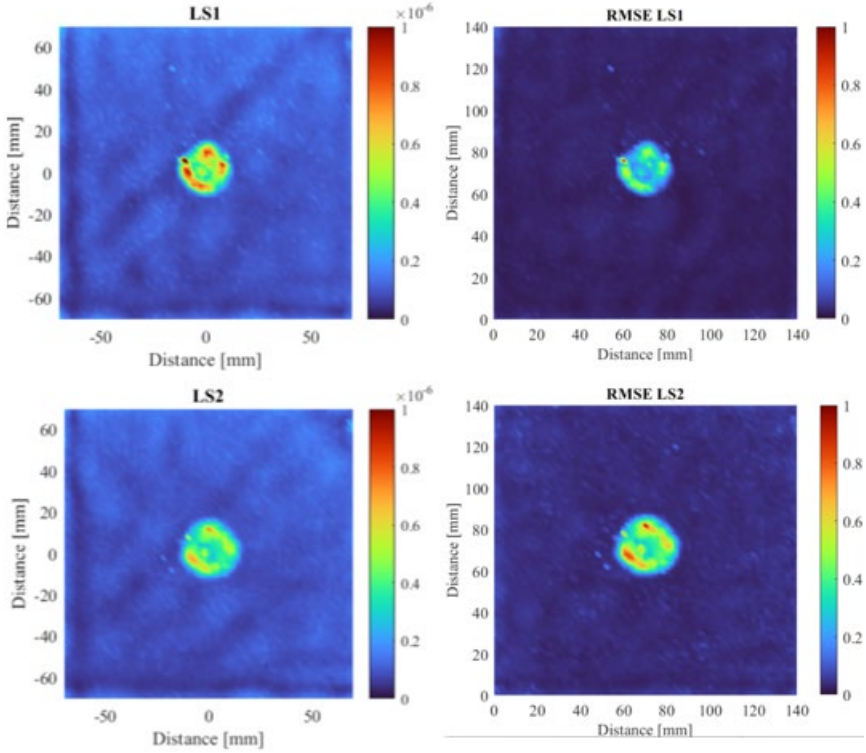

Figure 5: Lamb Waves measurement results shown as Damage Indexes cartographies with Root Mean Square on the left side and Root Mean Squared Error using a Wavelet Transform based algorithm on right side

3. Data fusion and discussion

The localization, size and shape of the defected zone are confirmed by Visual Inspection, Thermographic Inspection and LIPSW Inspection. For more quantitative study, quantitative data from Thermographic Inspection and LIPSW Inspection are calculated and compared.
Using the cooling curves, it is possible to measure the cooling slope and the breaking time which reflect the diffusivity of the heat through the sample. The thermal diffusivity α is calculated from the breaking time with the following equation:

$$\alpha = \frac{L^2}{\pi t^*} \quad (1)$$

Where α is the thermal diffusivity in mm²/s, L is the thickness in mm and t* the breaking time of the cooling curve.
The figure 6 shows the data fusion between the thermal diffusivity calculated in the four different zones: healthy, the black ring zone, the white ring zone and the grey centre (respectively represented in green, black, light blue and grey), and the RMSE value measured by LIPSW method for the same points. The LS-1 and LS-2 samples are fusionned for this figure as they are directly comparable and in order to increase the dataset. The four different zones are clearly visible on the graphe. It is to be noted that if considering only the thermal characteristics (looking at the x-axis), the healthy, grey and white zones may be difficult to distinguish. In a similar way, if considering only the LIPSW results (by looking at

the y-axis only), the white ring and the grey centre are difficult to distinguish, such as the healthy zone and the black ring.

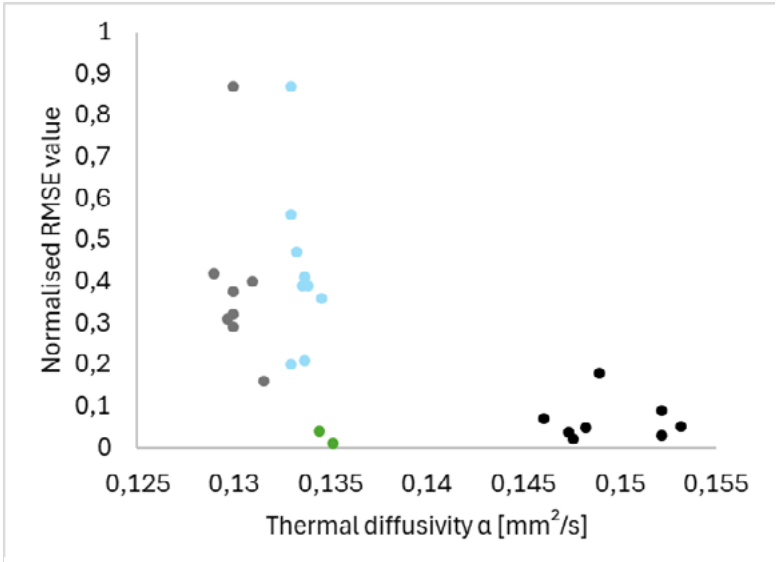

Figure 6: Classification of all LS-1 and LS-2 measurement points from LIPSW results (RMSE) and Thermographic results (thermal diffusivity)

4. Conclusions

In this study, several Non-Destructive Testing methods are used in order to investigate lightning strike induced delaminations in Carbon Fibre Reinforced flat samples. Visual Inspection using 3D optical profilometry, Ultrasonic Testing using manual A-scan and an innovate non-contact Lamb Waves method and Thermographic Inspection have been combined in order to characterize the delamination with various material features. The combination of Visual Inspection with manual Ultrasonic A-scan allowed to obtain good evaluation of the depth of the damage zones. Secondly, by combining quantitatively the Thermographic Inspection and the Lamb Waves Inspection results, interesting visualization of the different samples zones have been obtained. The thermal diffusivity calculated from Thermographic Inspection cooling curves and the Root Mean Squares Error of the Lamb Waves signals obtained from the Lamb Wavew Inspection, alone, do not give a clear representation of the different damaged zones. However, their combination allowed to obtain a better visualization of these zones. This shows the very promising outcomes that can be obtained by combining different characterization methods.

For further investigation, we are aiming to use similar methods using delaminations induced by impact. The data fusion of several Non-Destructive Testing characteristics may be able to give interesting information about the difference of delamination structure depending on their origin (thermal or mechanical), which is particularly useful for understanding the delaminations and therefore work for preventing them.

Keywords: FML, Low-velocity impact, Elastomer, Energy dissipation, Impact energy

Abstract

This study investigates the low-velocity impact responses and damage mechanisms of HyCEMLs compared to conventional FMLs by considering variations in impact energy levels. Impact behavior with impact energies ranging from 3 J to 30 J is evaluated for FMLs and HyCEMLs by numerical and experimental methods. The force–time and energy-time histories are compared and discussed. Furthermore, damage mechanisms including metal plasticity, metal failure, delamination, and CFRP failure are revealed. The energy dissipation due to each mechanism is further quantified with regard to different impact energies. In addition, the energy release ratio of each component of the hybrid laminates after impact is evaluated in order to determine the recovery state of materials in potential applications. It is found that the initial damage force of HyCEML is increased, while the peak force and structural stiffness are reduced. The observed damage mechanism of FML and HyCEML are in competition during the impact and make different contributions to the total energy dissipation. The relation of those contributions varies with different impact energies. Additionally, the elastomer changes the damage mechanisms each component of the hybrid laminate which is useful to improve usage efficiency of hybrid materials. The findings of this work will assist in the assessment of impact damage resistance of hybrid laminates and provides added value for composite design engineers to design specific mechanisms for optimal energy dissipation based on given requirements.

1. Introduction

Fiber-metal laminates (FML) are a combination of sheets of fiber-reinforced polymer and metal, and can be found in various aerospace applications nowadays[1]. Carbon laminate aluminum reinforced epoxy (CLARE) is relatively new compared with glass laminate aluminum reinforced epoxy (GLARE), which is commonly used in the industry. CLARE shows even higher specific mechanical properties [2]. However, the combination of aluminum sheets with carbon fibers often leads to galvanic corrosion in the interface [3]. The big mismatch in thermal expansion coefficients between these materials leads to high residual stresses after curing in a hot mold [4]. One possible way to solve this problem is to introduce an elastomeric interlayer between the aluminum sheet and carbon fiber reinforced polymer (CFRP) ply. In addition, galvanic corrosion can be prevented [5], but also the damping behavior [6] and impact performance can be adjusted [7].

Impact response, damage mechanism and extent of damage change with the impact energy. Mohotti et al. [8] investigate the impact behavior of polyurea (rubber-like material) coated aluminum plates impacted at about 10 m/s. The introduction of polyurea is beneficial in reducing the permanent deformation of the aluminum. Sarlin et al. [9] conduct end notch flexure and single cantilever beam tests on three-layer steel-rubber-composite hybrid laminates and find that the interface strength between steel and rubber is higher than that of composite and rubber. Li et al. [10] investigated the impact behavior of hybrid CFRP-elastomer-metal laminates (HyCEML) and have reported how the elastomer influences the energy distribution and damage mechanisms under one specific impact energy.

There is insufficient literature on the impact behavior and particularly on the associated damage mechanisms of hybrid laminates with elastomer under LVI conditions to the authors' knowledge. The published literature shows that elastomers play an essential role in impact behavior, and the damage mechanisms of hybrid laminates are complex under dynamic loads. Impact energy has a strong influence on the response of the specimen. The damage mechanisms, including metal plasticity, CFRP failure, and delamination inside hybrid laminate, are competitive damage mechanisms that are changed by impact energies. It is also valuable to vary impact energy in the research for automotive applications, such as a stone impacting the battery container and pedestrian impacting the engine front hood.

This work investigates the low-velocity impact response of FML and HyCEML impacted with a wide range of energies. Impact responses, including force-time (*F-t*), energy-time (*E-t*), and critical characteristic parameters, are quantified and compared. The energy dissipated by aluminum plasticity, delamination, CFRP failure, aluminum failure, and viscosity is revealed. The contribution of each mechanism to the total energy dissipation of laminates impacted with different energies is quantified. It is found that each mechanism is a competitive failure mechanism. A comparative investigation of FML and HyCEML reveals the role of elastomer layers in changing the energy dissipation mechanism under different impact energies.

2. Materials and methods

A brief description of the materials and methods used in this work is presented here. Details can be found in the authors' previous work [10].

2.1. Materials

The configuration of the HyCEML plate investigated in this work is $\left[A_{0.3}/E_{0.5}/\left(C^{0°}_{0.15}/C^{90°}_{0.15}\right)_3/E_{0.5}/A_{0.3}\right]$ (A: aluminum; E: elastomer, C: CFRP) according to the nomenclature for hybrid laminates based on VDI 2014. Figure 1 illustrates the layup of HyCEML under investigation in this study. The metal layer used in this work is the aluminum alloy AL 2024-T3 with a thickness of 0.3 mm. The batch number of the elastomer is SAA9579-52 by KRAIBURG GmbH & Co. KG with a density of 1180 kg/m3, and the thickness of the elastomer layer is 0.5 mm. The CFRP prepreg named HexPlyM77/38/UD150/CHS-12K-70 by Hexcel is used and the nominal thickness of a single ply is 0.15 mm.

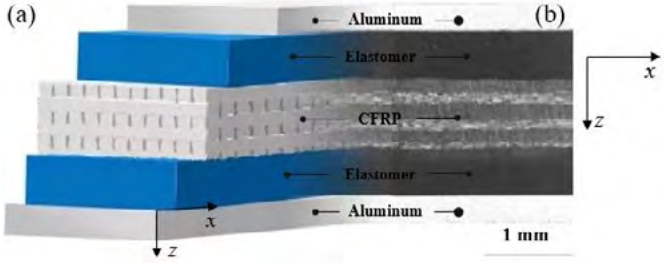

Figure 1. Hybrid CFRP-elastomer- metal laminates: (a) schematic cross-section of layup [10] (b) micrograph of cross section [11].

2.2. Methods

Drop weight impact tests are carried out referring to ASTM D7136 to investigate the dynamic response and damage mechanism of hybrid laminate subjected to out-of-plane LVI loading. A drop-tower machine Coesfeld Magnus 1300, Figure 2. (a), with the support fixture shown in Figure 2 (b) is employed. The specimen size is 150 mm × 100 mm, and the opening dimensions of the supporting window are 125 mm and 75 mm. The boundary conditions of the tests are shown in Table 1. The impactor's displacement over time and the contact force between the impactor and laminate are recorded during the impact. The absorbed energy during the impact is obtained by the continuous integration method on the force-displacement curve.

Table 1. Test parameters of HyCEML impact tests.

Impact energy (J)	Impactor mass (kg)	Impactor diameter (mm)	Impact velocity (m/s)
10	5.25	20	1.883
30	5.25	20	3.350

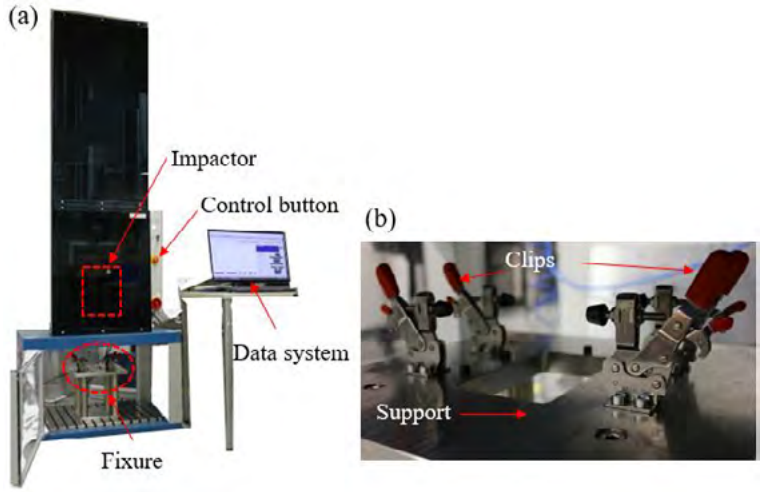

Figure 2. Drop weight testing equipment: (a) drop-weight tower (b) fixture for specimen.

The commercial finite element software Abaqus 2020, with explicit time integration, is adopted to investigate the impact behavior of HyCEML. The finite element (FE) model consists of an impactor with an initial velocity and a HyCEML plate with the dimensions 150 mm × 100 mm × 2.5 mm. The configuration of the plate is $\left[A_{0.3}/E_{0.5}/\left(C^{0°}_{0.15}/C^{90°}_{0.15}\right)_3/E_{0.5}/A_{0.3}\right]$. The details about the numetricla model are described in [10].

3. Results and discussion

In this section, the impact response for both, conventional FML and HyCEML, plates subjected to different impact energies is analyzed. The change of damage mechanisms and energy dissipation with the impact energy are investigated.

3.1. Impact history

The *F-t*, *F-u*, and *E-t* curves of hybrid laminates with elastomer and conventional FML subjected to different impact energy levels are analyzed. The impact behavior is compared for FML $\left[A_{0.3}/\left(C^{0^\circ}_{0.15}/C^{90^\circ}_{0.15}\right)_3/A_{0.3}\right]$ without elastomer and HyCEML $\left[A_{0.3}/E_{0.5}/\left(C^{0^\circ}_{0.15}/C^{90^\circ}_{0.15}\right)_3/E_{0.5}/A_{0.3}\right]$.

3.1.1. Force-time curves

The *F-t* curves of the HyCEML and FML plates subjected to impact energy levels ranging from 3 J to 30 J are shown in Figure 3. The *F-t* curves have a similar shape for the two laminates impacted with different energies. Up to 24 J, the *F-t* curves are almost symmetrical in ascending and descending parts. It is a typical curve under non-penetration condition [12]. The symmetry of the curve is not as pronounced as in the condition of 3 J, when the laminates are impacted with energies of more than 10 J and 15 J for FML and HyCEML, respectively. The oscillations represent progressive damage inside the laminates. Especially for the FML under impact energy of 30 J, the load drops dramatically. It is caused by partial penetration.

The value of F_{inc} (incipient damage force) is one important measure for the ability to impact resistance. The load drops at F_{inc}, cf. Figure 3, and the stiffness of the laminate decreases. This is caused by delamination inside the laminate. More damage modes will occur afterwards, such as the extension of delamination, matrix failure, fiber breakage and aluminum cracks. The curve fluctuates until it reaches the value of F_{max}.

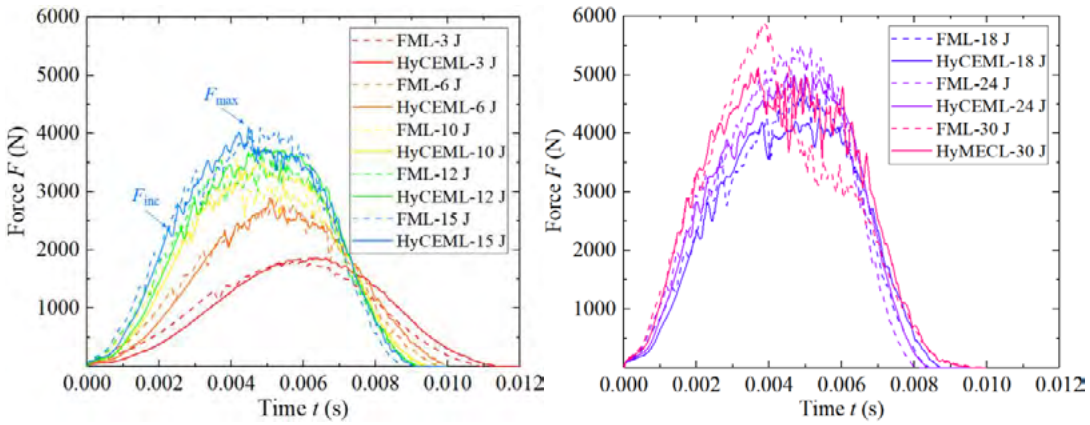

Figure 3. Force-time curves of FML and HyCEML impacted with energies ranging from 3 J to 30 J.

3.1.3. Energy-time curve

The *E-t* curves of FML and HyCEML impacted ranging from 3 J to 30 J are shown in Figure 4. The energy ascends to the maximum value E_{imp} (initial impact energy). Then it descends to the final value E_{abs}. The difference between the Eimp and Eabs is related to the elastic strain energy. It is found, that the dissipated energy of HyCEML is slightly lower than that of the FML. Especially at 12 J and 30 J levels, the final energy absorption is reduced by about 15% and 10%, respectively, compared with FML. This is mainly due to the stress and damage mechanism changes inside HyCEML.

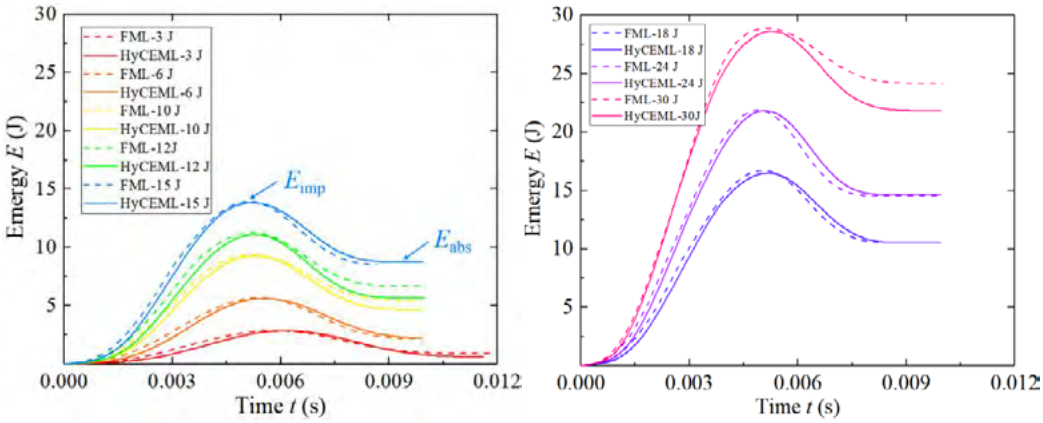

Figure 4. Energy-time curves of FML and HyCEML impacted with different energies.

3.2. Damage assessment

The main reason for the difference in impact behavior of FML and HyCEML is the changes in the internal damage mechanism after introducing the elastomer layer. This section will investigate the damage mechanism differences of these two laminates impacted with different energies. It should be noted that the interfaces between aluminum and elastomer and between CFRP and elastomer do not delaminate in this work. As seen in the *F-u* curves, the load oscillates significantly. This is mainly caused by four damage modes, namely aluminum yielding, aluminum crack, matrix failure, and delamination. Delamination includes interfaces between 0° and 90° CFRP and interfaces between CFRP and aluminum (only for FML).

3.2.1. Damage modes

This section investigates the differences in damage modes between FML and HyCEML impacted with energy from 3 J to 30 J. Plasticity and crack of the aluminum, delamination, and matrix failure are considered. Matrix failure is the primary intra-ply damage mechanism inside the CFRP under rebound conditions in this study.

Figure 5 shows the plastic strain (PEEQ) of the aluminum layers in hybrid laminates under different impact energies. It is found that the plastic strain of the aluminum layer increases with the impact energy. The difference in plastic strain between FML and HyCEML impacted with 3 J is small. However, there is a noticeable difference for 30 J conditions. Cracks occur in the bottom aluminum layer of FML due to the enormous plastic strain. There is no fracture in HyCEML, which shows that elastomer layers play an essential role in protecting the aluminum layers under high-energy impacts.

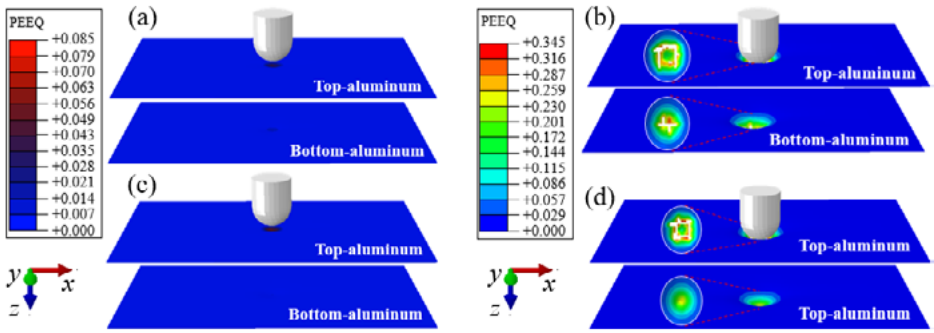

Figure 5. The plastic strain of aluminum layers in hybrid laminates subjected with different energies: (a) FML impacted with 3 J (b) FML impacted with 30 J (c) HyCEML impacted with 3 J (d) HyCEML impacted with 30 J.

Figure 6 shows the delamination between aluminum and CFRP and between 0° and 90° CFRP inside the laminates impacted with different energies. The degree of delamination damage (SDEG) varies from

0 to 1, with 0 representing no damage and 1 representing complete delamination. The delaminated area in FML and HyCEML increases with impact energy. The introduction of elastomer layers protects interfaces between aluminum and CFRP and interfaces between 0° and 90° CFRP. Tension failure is the primary damage mode for matrix failure. Figure 7 shows the matrix failure in the CFRP layers inside laminates impacted with different energies. The degree of tensile failure in the matrix (HSNMTCRT) varies from 0 to 1, with 0 representing no damage and 1 representing complete damage. The damaged area in HyCEML is larger than that in FML. This is caused by the elastomer layers, which increase the proportion of CFRP involved in the load-bearing, avoiding increased damage in the aluminum layers.

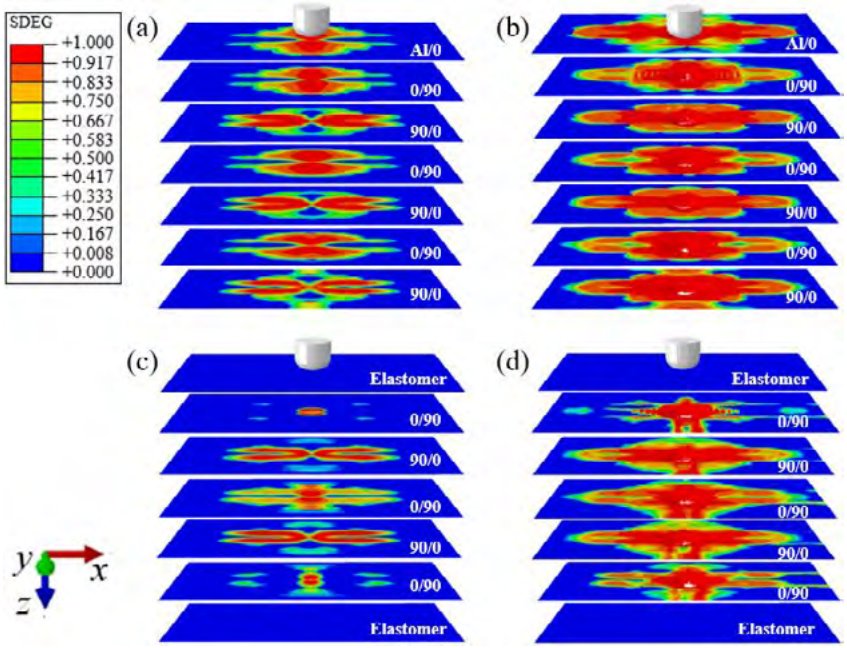

Figure 6. Delaminated area inside laminates impacted with different energies: (a) FML impacted with 3 J (b) FML impacted with 30 J (c) HyCEML impacted with 3 J (d) HyCEML impacted with 30 J.

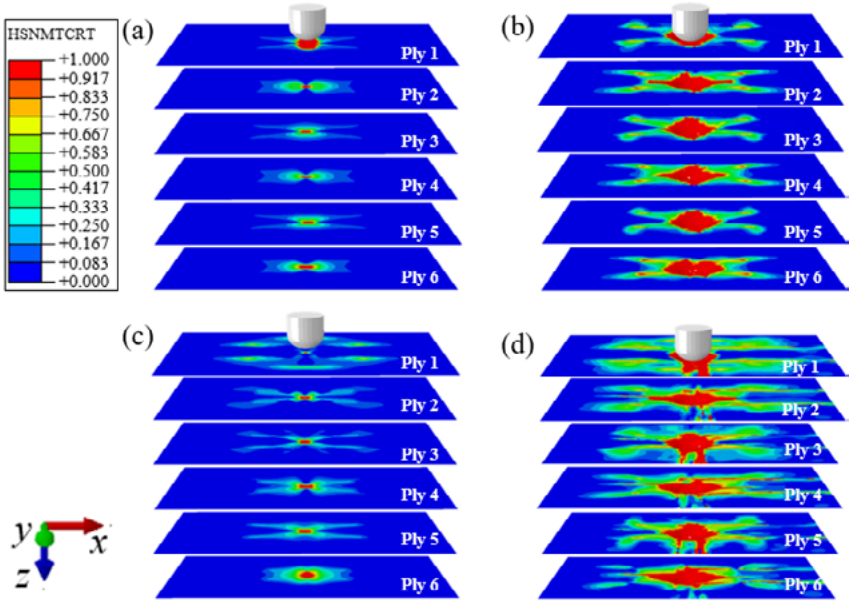

Figure 7. Matrix failure inside laminates impacted with different energies: (a) FML impacted with 3 J (b) FML impacted with 30 J (c) HyCEML impacted with 3 J (d) HyCEML impacted with 30 J.

3.2.2. Energy dissipation

In this section, five dissipative mechanisms and the total energy dissipation are quantified and compared for HyCEML and FML, impacted with different impact energies. The energy dissipated by the aluminum plasticity, delamination between 0° and 90° CFRP, and intra-ply failure of CFRP changes with the impact energy, cf. Figure 8. (a) - (c). The delamination between aluminum and CFRP (only in FML), and the viscosity of elastomer (only in HyCEML) is illustrated in Figure 8. (d). The energy dissipated by aluminum fracture is shown in in Figure 8. (e). Figure 8. (f) displays the total energy dissipation of FML and HyCEML under different impact energies. The proportion of each mechanism in the total energy dissipation in different impact conditions is quantitatively analyzed. The ratio of energy dissipated by each mechanism to the total energy dissipation is plotted in the form of a line chart, cf. Figure 8. (a) - (e).

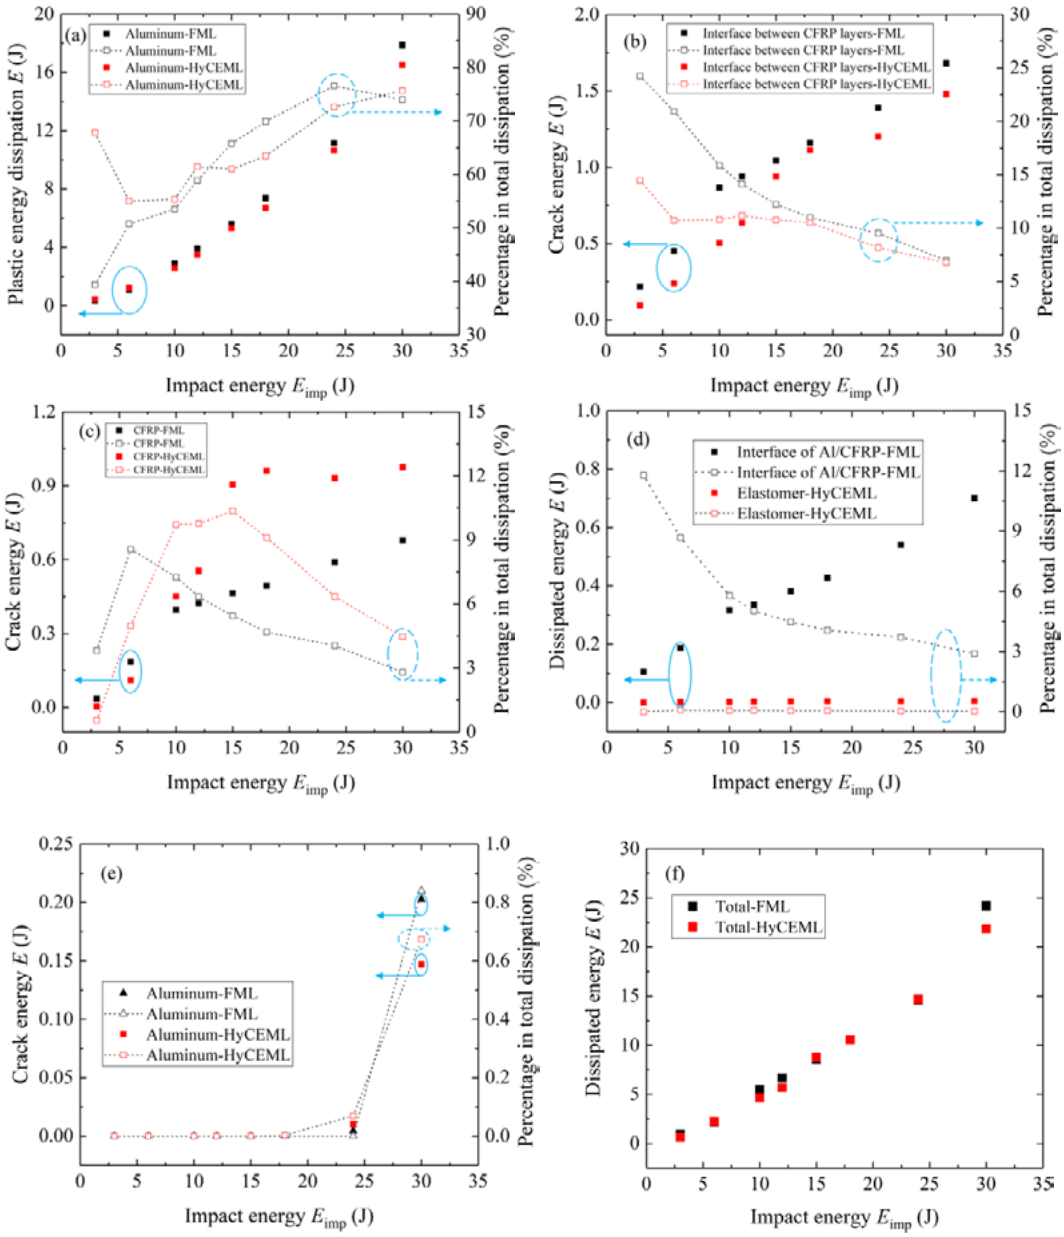

Figure 8. Energy dissipation comparison of FML and HyCEML under different impact energies.

Figure 8. (a) shows the relationship between the energy dissipated through plastic deformation of aluminum and the overall impact energy in FML and HyCEML. It is found that the energy dissipated

by aluminum plasticity in HyCEML is less than that in FML when the impact energy is greater than 10 J. Compared with Figure 8. (c), the energy dissipated by intra-ply failure of the CFRP, including matrix and fiber failure, in the HyCEML exceeds that in the FML. It shows that the elastomer layers make the impact energy more evenly distributed in the aluminum and in the CFRP. The energy dissipated by aluminum plasticity accounts for more than 50% of the total energy dissipation, even up to 77% at the impact energy level of 24 J. It is thus the most important energy dissipation mechanism. The energy dissipated by intra-ply failure of CFRP accounts for less than 12% of the total energy dissipation. The energy dissipation is more evenly distributed in these two primary mechanisms due to the introduction of the elastomer. The hybrid materials are efficiently taken advantage of. The overall load-bearing capacity of the hybrid laminate is improved.

The inter-ply damage of CFRP layers is the second most important energy dissipation mechanism in hybrid laminates. Figure 8. (b) shows the relationship between the energy dissipated by inter-ply damage of CFRP layers and impact energy in FML and HyCEML. Similarly, introducing elastomer layers also effectively reduces the delamination between 0° and 90° CFRP. It is due to the redistribution of impact energy among different dissipative mechanisms such as the aluminum plasticity, intra-ply damage of CFRP layers, and inter-ply damage of CFRP layers. In addition, the introduction of elastomers makes the in-plane dynamic load more uniform in every single ply, which is another crucial reason for the protection of the aluminum and the interfaces between CFRP layers.

The line charts in Figure 8. (a) - (e) describe the relationship of each dissipative mechanism and the impact energy. It is found that the proportion of energy dissipated by the aluminum increases with the impact energy. The proportions of delamination between 0° and 90° CFRP, between aluminum and CFRP gradually decreases with the impact energy. However, this does not occur monotonously. The energy dissipation due to the intra-ply damage of CFRP layers accounts for about 10% of the total dissipation of HyCEML at impact energy levels ranging from 10 J to 18 J, which is similar to the dissipated energy from inter-ply damage of CFRP layers. The introduction of elastomer layers changes the contribution of each damage mechanism to the total energy dissipation.

The energy dissipated by delamination between aluminum and CFRP is lower than that dissipated by delamination between 0° and 90° CFRP, cf. Figure 8. (d). However, considering that there are only two layers in FML, the damage degree of interfaces between aluminum and CFRP is also severe. The material corresponding to this interface is the elastomer in HyCEML. It can be found that the energy dissipated by viscosity is relatively small. The key role of the elastomer in HyCEML, thus, appears not to be dissipation by itself but rather as the distribution of load in order to enable other mechanisms to dissipate more energy.

Figure 8. (f) shows the total energy dissipation of FML and HyCEML impacted with different energies. It is found that the introduction of elastomer protects the hybrid laminate, especially at impact energies of 12 J, 10 J and 30 J. Under the other impact energy levels, even the total energy dissipation does not change much after the introduction of the elastomer, but the energy dissipated by each mechanism is changed concluded from Figure 8. (a) - (e). This is significant for the design of structures in which certain dissipative mechanisms are to be favored above others.

4. Conclusions

In this work, the impact behavior of hybrid CFRP-elastomer-metal laminates (HyCEML) and conventional fiber-metal laminates (FML) are compared in a wide range of impact energies by experimental and numerical methods. The damage modes of the hybrid laminate under low-velocity impact conditions are determined, and the energy dissipated by each mechanism under different impact energies is quantified.

The damage mechanisms of FML and HyCEML include metal plasticity, metal failure, delamination, CFRP failure. Each mechanism is a competitive failure mechanism and contributes a different proportion to the total energy dissipation under different impact energies. The elastomer layers change

the energy distribution in each component of hybrid laminates. The damage of the aluminum and delamination between 0° and 90° CFRP are reduced, and the usage efficiency of hybrid materials is improved due to the elastomer layer. The initial damage force of the laminate is increased, while the peak force and structural stiffness are reduced. The total energy dissipation decreases under large-energy impacts. Even if the total energy dissipation does not change under some impact energies, each mechanism's proportion of energy dissipated is changed.

Keywords: Optimisation, Biaxial Loading, Failure Criteria

Abstract
Failure Criteria (FC) are commonly employed for the prediction of various forms of failure in Fibre Reinforced Polymers (FRP). However, they are usually extensions of criteria designed for isotropic materials and can struggle to accurately predict failure for FRP [1], [2]. Numerable factors, such as stacking sequence, loading direction, material characterization and the definition of failure significantly affect the accuracy and therefore the reliability of most common FC, particularly in complex load states [3], [4]
A testing apparatus and a cruciform specimen are developed for experimental in-plane biaxial testing at a lab-scale. The new biaxial testing apparatus is used to assess the accuracy of five common FC in terms of their predictions of failure load and their suitability within the objective function of a coupled FEA-GA optimisation approach.
Each FC is used to design an *optimal* cruciform specimen by specifying the stacking sequence of a laminate such that the highest load is carried by the specimen at failure.
Analysis of the results and comparison with earlier works suggest the Puck failure criteria is the most accurate and the most conservative, so, it is suggested as the most suitable.

1. Introduction

For a structural design object to efficiently perform its task, its allowable working loads must be based on some prediction of the limits of material strength [5]. This is true regardless of material or application. Well-established means of failure prediction for Fibre Reinforced Polymers (FRP) utilise Failure Criteria (FC), but previous works suggest they are not always reliable for multiaxial failure prediction [4], [6], [7], [8], [9], [10], [11]. Resultingly, in industry, FC are commonly only used as an initial sizing tool due to their inaccuracy, report Hinton et al. [12]. If the conditions under which a part might fail are not reliably identifiable, how can a designer hope to generate efficient responses to loading conditions? Structural Safety Factors (SFs) will need to include enlarged redundancy; thus, optimal structural efficiency cannot be achieved; Something which is crucial in high-performance applications, or more generally where structural mass affects energy efficiency.

Early work on biaxial testing by Hannon and Tiernan [13] investigated sheet metal specimens that exhibited anisotropy due to their manufacturing processes. Their review discussed developments in specimen and Biaxial Testing Apparatus (BTA) design and stressed the importance of testing materials in biaxial loading scenarios. Crucially, it was recognised that anisotropic materials would exhibit unique behaviour only captured by testing in multiaxial loading scenarios [13]. This behaviour is also observable in FRP laminates failure given the severely anisotropic nature of the uniaxial plies [14], [15]. Just as for metals, characterising FRPs using standard uniaxial tensile testing is insufficient to

reveal their true behaviour in biaxial and multiaxial loading [13], [16], [17]. However, FRP laminates strengths are often measured using individual coupon tests, the data from which is used to set global design allowables. This approach fails to characterise responses to biaxial loading or the effects of laminate configuration and can lead to failure in components expected to withstand loading according to their uniaxially loaded behaviour [13].

Despite the inaccuracy of FC, they still hold an important place in the design process for Large Composite Structures (LCSs), especially so in high-performnace applications. Testing full-scale LCSs is often too slow or expensive, so, considering and understanding the response of FRPs subject multiaxial loads is necessary [16], [18], [19]. Implementing FC into design and optimisation procedures is critical to estimating performance. Choosing the best FC for a high-performance structural optimisation case is essential as the better optimsed a structure can be, in terms of it strength to mass ratio, the better the structure can perform in a competitive setting.

This work investigates the effect of FC choice on optimised laminate specimens. Five FC; Puck (P) [20], Hashin (H) [21], Maximum Strain (MS) [22], Tsai-Hill (TH) [23], and Tsai-Wu (TW) [24] are substituted into the objective function of a Genetic Algorithm (GA) based optimisation approach for laminate stacking sequence and ply orientations. Each FC is used to optimise a newly developed biaixial cruciform specimen, tested to failure in a newly developed BTA. Test results are compared with simulated optimal laminate performance, and conclusions regarding the reliability of the investigated FC are drawn

2. Methodology

Following a review of literature looking at the application of multiple techniques for testing FRPs and other materials biaxially, a linkage-driven BTA has been chosen as the most suitable method for the testing in this work. This choice is made because of the relative inexpense of this type of apparatus compared to the independently actuated types and the ease of adaptation to the research centre's existing Instron 1185. Figure 1 shows the BTA built for this testing. It is a development of the linkage-driven design proposed by Ferron and Makinde [25].

The accompanying cruciform specimen (Figure 2) was developed concurrently with the BTA and was originally based on an optimised specimen designed by [26]. Specimen designs present in the literature usually target a gauge zone with as uniform a biaxial stress state as possible. However, the objectives of this work are to analyse the effects of FC choice in the context of LCS design where complex geometry and loading states are usually present, achieved by the addition of a central hole. Several design iterations were required, but the final specimen reliably fails in the gauge section and produces repeatable failure.

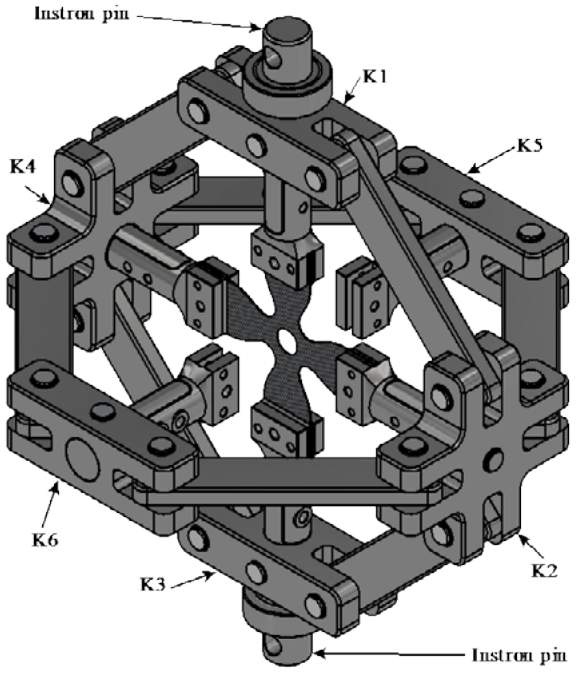

Figure 1: Illustration of the biaxial testing apparatus

For the specimen optimsation, a previously developed GA-based approach [27] has been coupled with an FEA solver (ABAQUS 2022). Five-layer laminates subjected to equal 1% tension-
