Our model is founded on fundamental thermodynamic principles and addresses the complex interplay between various physical phenomena occurring during hot forming. The framework simultaneously accounts for work hardening, dynamic recovery, recrystallization, and grain growth through a physics-based approach. A key strength of our methodology lies in its ability to couple microstructural evolution with thermo-mechanical material behavior, enabling accurate predictions of local microstructure development throughout the entire forging process.

We have implemented the model within the FORGE finite element software environment, facilitated by the DynamiX GUI, which allows for practical industrial applications. The simulation framework has been specifically calibrated for turbine shaft steels containing critical elements such as Mo, Nb, and Ni. Our validation approach combines extensive thermo-mechanical experiments with detailed metallographic analyses performed on industrial-scale components, ensuring robust and reliable predictions under various processing conditions.

The model demonstrates particular strength in optimizing process parameters while considering the desired microstructural and mechanical properties. Our results show that the implementation successfully predicts local microstructure evolution across multiple length scales, from grain interactions to macroscopic property development. This capability enables more efficient process design and optimization, potentially reducing the material and energy consumption associated with traditional trial-and-error approaches in large-scale forging operations.

Furthermore, our work provides a foundation for sustainable manufacturing practices in the energy sector. By enabling precise prediction of microstructure evolution based on varying process parameters, the model supports the development of optimized processing routes with reduced energy consumption and more efficient use of critical raw materials. The methodology significantly reduces the time and resources required for process design through numerical simulations, representing a substantial improvement over conventional approaches in the forging industry.

This research contributes to the ongoing digital transformation of the metallurgical industry by providing a robust, physics-based tool for process and material optimization. The developed framework represents a significant step toward more sustainable

Multiscale modeling of microstructure formation in re-heating and quenching process for understanding creep related properties of large shaft

Dr. Aarne Pohjonen, Finland

Oral Presentation (20')

Abstract

Microstructure is the key for understanding the mechanical properties of a steel product. Microstructure formation can be simulated using models at different length scales that can include the desired level of resolution and physical phenomena involved in the manufacturing process. For example, the formation of microstructure during thermomechanical processing requires larger scale model which can simulate the conditions relevant to industrial operations and then provide the boundary conditions for the smaller scale models.

We apply heat transfer and conduction finite element simulations coupled with mean field phase transformation model to calculate the cooling of macroscopic objects. Phenomenological Cellular Automata (CA) models are used to calculate nucleation, growth and impingement of phase regions, as well as grain growth phenomena. Physically based phase field / level-set model is used for simulating partitioning diffusion, transformation strains, elasticity and plasticity associated with microstructure formation during cooling.

By combining the models with different length scales, we aim to bridge the industrial scale down to microstructure length scale. The aim of the microstructure formation model is to complement the experimental investigations and to provide relevant information for understanding the creep related properties of a large scale shaft.

Paper 32 4

Heat Treatment Simulation of Normalized Steel 9310

Prof. Jeongho kim, United States

Oral Presentation (20')

Abstract

This presentation addresses a computational approach to simulate the heat treatment process of Steel 9310. The aim is to validate the heat treatment process with experiments and use that validation to help to create a digital twin of the heat treatment process, which can be used to mimic the heat treatment of any new steel alloy. Heat treat process includes copper plating, stress relieving, vacuum carburizing, annealing, copper plate stripping, hardening & quenching, cold treat, and temper. First, the finite element model is validated with experiments, and then a parametric study is carried out to identify the critical process parameters. Then, the results of the parametric study are used to establish a relationship between the critical process parameters and the output hardness, residual stress, and distortions. This research also aims to find the effects of critical process parameters on the final hardness, residual stress and distortions during heat treatment of Steel 9310. The usage of virtual but validated physics-based models in the steel gear manufacturing drastically reduces cost and time and saves energy.

Data driven reduced order modelling of metal casts with induction-heated feeders and a parameterized geometry

Mr. Florian Arbes, Norway

Oral Presentation (20')

Abstract

Energy efficiency and innovation are key drivers in the energy intensive metal casting industry. Conventional casting processes rely on oversized feeders to prevent defects, leading to significant energy waste and additional work for handling, sawing, and re-melting of metal. Therefore, the Norwegian company EFFEE develops an induction-heated feeder that can be dimensioned much smaller. Early tests show induction-heated feeders can cut energy use by 30%, with feeder size reduced by 40% (e.g., 800kg to 100kg for a 1000kg casting), lowering overall variable costs by 3%.

With the innovation comes a need to understand the impact on material properties and to optimize the processes. Preventing potential issues and identifying opportunities where induction feeders can actively enhance the casting process are critical to build confidence in the casting industry. Current simulation software cannot effectively and accurately predict the effects of induction heating and Lorentz force stirring caused by electromagnetic fields on molten metal solidification process during casting, leaving unanswered questions about heat transfer, material structure, and defect prevention. To fill this gap, IFE is developing the Induction Feeder SIMulator (IFSIM) to get deeper insights and to analyze the new technology systematically. With the help of COMSOL and the in-house software Alsim, IFSIM provides predictions of melt levels and flow underneath the feeder, essential for optimally controlling induction heat input.

Detailed simulations can take hours, making parameter studies and automated optimizations expensive. We have developed a data driven surrogate model based on Non-Intrusive Reduced Order Modelling. It allows accurate predictions in split seconds even when training data is sparse. A given cast geometry is quickly approximated by a representative, simplified and parameterized geometry for which we have precomputed snapshots. The snapshots are reduced with a proper orthogonal decomposition (POD), and interpolation or machine learning in the reduced space allows to predict the reduced coefficients for new inputs in real time. The full system response can be obtained through a simple linear projection, and it is used to optimize the input of induction heat.

However, the mesh changes with time to account for solidification shrinkage, and because of the parameterized geometry, the mesh changes in the parameter domain too. The fact that spatial locations of the snapshot data don't match introduces significant challenges. Moreover, moving discontinuities such as the melt surface in the feeder are known to be difficult to represent with linear subspaces. We employ novel smoothing and desmoothing techniques to address this.

Machine learning approaches for the determination of liquidus and eutectics

Ph.D. Katarina Firdova, France

Oral Presentation (20')

Abstract

Knowledge of the liquidus is crucial for designing and processing a wide range of materials. Local minima in the liquidus correspond to the composition of the eutectics which are particularly important for the design of alloys such as metallic glasses, solders, cast alloys, or phase change materials for energy storage [1] due to their properties such as low melting points and the absence of a solidification range. Liquidus data can be obtained from Calphad-based thermodynamic calculations, however, two challenges arise. The first is to be able to efficiently screen for eutectics in the immense compositional space offered by multicomponent alloys, since Calphad databases can include dozens of elements. The second is the lack of liquidus data to improve and enlarge the reliability of the calculations, starting with the binary systems that are the building blocks of Calphad databases.

In recent years, machine learning (ML) algorithms have demonstrated their power in various applications. In our work, we examine how liquidus determination can benefit from ML's ability to extend the information gained from the training sample to new observations.

In the first part we focus on exploitation of the Calphad databases guided by active learning and the subsequent interpolation of retrieved data in order to accelerate acquisition of the liquidus. Eutectics are then identified as local minima in the liquidus representation. Benchmark of different approaches for eutectic identification is performed.

The second part of work addresses the challenge of shortage of liquidus data in many binary systems. Using properties of the pure elements as well as thermodynamic properties of mixing that were also obtained by ML models [2], a model is developed to predict the liquidus in binary systems generated by 70 elements.

Paper 1304 7

Effect of microsegregation on phase transformation behaviour and microstructural evolution in a continuously cooled 1CrMoV bainitic steel

Mr. Rishabh Bharadwaj, Finland

Oral Presentation (20')

Abstract

This study aims to understand the effect of microsegregation on phase transformation behaviour and the corresponding microstructural evolution at different cooling rates in an oil-quenched 1CrMoV bainitic steel used for turbine applications in power plants. Samples for dilatometer measurements were subjected to heat treatment in a Gleeble 3800 thermomechanical simulator, where the samples were heated at 5 °C/sec to 950 °C and held at this temperature for 30 minutes to achieve an austenite grain size comparable to that of industrial conditions. Following this, the samples were continuously cooled at different linear cooling rates in the range 0.03 – 50 °C/sec. The Ar₃, Ar₁, Bs, and Ms temperatures were identified as a function of cooling rate based on the inflexions in the dilatation curves, and a continuous cooling transformation (CCT) diagram was constructed. Presence of microstructural features such as quasipolygonal ferrite, lath bainite/upper bainite, coalesced bainite, and lath martensite were confirmed using both confocal laser scanning microscopy (CLSM) and scanning electron microscopy (SEM). Due to the effect of microsegregation in the steel, the impact on austenite grain size and phase transformation behaviour differed between prior alloy-rich (interdendritic) and alloy-lean (dendritic) regions. To identify bainite and martensite phase constituents more comprehensively in these complex microstructures, electron backscattered diffraction (EBSD) technique was utilized to construct band contrast maps. Phase fractions were measured in both alloy-rich and alloy-lean regions, which revealed discernible variances. The high-hardenable alloy-rich regions were more prone to the formation of harder martensite phase, compared to the significant formation of bainite along with martensite in the alloy-lean regions. The microstructural observations corroborated the result of the dilatation tests over a broad cooling range between 2.5 and 50 °C/sec. Additionally, the electron probe microanalyzer (EPMA) was utilized to confirm the microsegregation pattern in the steel. Elements such as Cr, Mo, V, Mn, and Ni were found to be enriched in the alloy-rich (originally interdendritic regions), whereas the alloy-lean dendritic regions were depleted of these elements. The EPMA results further corroborated the predictions of the thermodynamic modelling. The partition coefficients measured using the EPMA further verified the thermodynamic predictions.

Machine Learning Approaches for Predicting Engineering-relevant Material Properties

Dr. Pascal Salzbrener, United Kingdom

Oral Presentation (20')

Abstract

AI and machine learning (ML) are playing an increasingly important role in materials science, offering new ways to accelerate discovery and optimize material properties. Much of the focus has been on applications such as crystal structure prediction and the development of ML interatomic potentials; however, these techniques are largely limited to idealized or simplified systems. In contrast, despite their practical significance, AI/ML applications to real engineering materials have received less attention. With the rapid expansion and democratization of AI/ML tools in recent years, it can be difficult to select the most suitable approach for the intended application, as often best practices from more established fields, e.g. finance, do not fully translate to the world of materials. Engineering materials, with their complex microstructures and processing-dependent properties, present unique challenges that require specialized ML methods. This work explores AI/ML techniques for predicting the properties of real materials, addressing key challenges such as data scarcity, microstructural effects, and the influence of state and environmental variables. We discuss strategies including validation, uncertainty quantification, and the integration of domain knowledge to improve predictive accuracy and reliability. This will be illustrated using a number of examples. By adapting ML methods to the specific challenges of engineering materials, this research aims to support their broader adoption in materials design and development.

Paper 1769 1 Advances in Modelling, Simulation, and Digitalization for Material and Process Design of Metallic Materials

Dr. Dirk Helm, Germany

Highlight (Oral Presentation 20')

Abstract

The manufacturing of materials and their transformation into products in a sustainable and environmentally friendly manner is one of the major challenges currently facing industry in order to enable a greener society. In the fields of materials science and the mechanics of materials, the last few decades have been dominated by innovations in modelling and simulation as well as characterisation techniques. The determination of process-structure-property relationships plays an increasingly important role. Notably, the chemical composition and the microstructure of materials is identified as a pivotal factor, with the potential to markedly accelerate the design of materials, processes, and products while substantially minimizing experimental requirements. The talk proposes a paradigm shift, advocating for an integrated approach underpinned by the Integrated Computational Materials Engineering (ICME) framework, the digital transformation of diverse data into knowledge, and the strategic application of artificial intelligence to expedite processes and generate actionable recommendations. The digital representation of materials and processes by using semantic technologies to enable FAIR (Findable, Accessible, Interoperable, Reusable) data as well as the solving material and process design challenges via machine learning are key elements of the change of paradigm. The talk will demonstrate how the three central elements will be linked to accelerate the material and process design.

Paper 1758 2 **Advancing Interoperability and Digitalization in Materials Science and Manufacturing: A Semantic Workflow Module for Standardized Data Management**
Mr. Yoav Nahshon, Germany
Oral Presentation (20')

Abstract

Inconsistent experimental procedures, diverse modelling methodologies, and insufficient protocol reporting present significant challenges in materials science, hindering reproducibility and data validation. The standardization of data offers a promising approach to addressing these issues; however, integrating data from disparate sources, a common scenario in the field of materials science and manufacturing, introduces complexities. While applying ontologies facilitates data harmonization and interoperability, the associated overhead can be substantial. Moreover, effective tools for managing these challenges are scarce and often inadequate for production environments.

This talk introduces a novel semantic workflow module, developed as part of the Dataspace Management System (DSMS) technology stack, to address critical gaps in managing material-related processes such as manufacturing and characterization. A key challenge we address is that users are typically not ontology experts, which can hinder efficient interaction with complex data. The intuitive interface of the module simplifies this process, enabling users to easily engage with the system without requiring deep knowledge of the underlying ontologies.

We illustrate the module's powerful and user-friendly approach with a practical use case derived from the ongoing AID4GREENEST project. There we leverage the CHADA (CHAracterization DAta) framework for standardizing characterization workflows as well as its ontological representation, the CHAMEO ontology, a module of the European Multiperspective Material Ontology (EMMO). We assert that this development contributes to the critical effort of optimising product development in the manufacturing industry.

- Paper 1538 3** **A common workflow description for experimental and computational materials science**
Dr. Steffen Brinckmann, Germany
Oral Presentation (20')
- Abstract**
- Workflows in experimental materials science often rely on informal, textual descriptions with minimal standardization, which limits their machine-readability and interoperability. Typically, these workflows are structured in two layers: the top layer provides an abstract description, while the bottom layer details the technical aspects of the operating procedure. Similarly, also computational workflows follow a two-layer structure, with the top layer commonly represented by a Jupyter script that chains function calls, and the bottom layer comprising individual functions.
- This presentation introduces a workflow description concept designed to support both experimental and computational materials science, facilitating interoperability. The pyiron workflow software enables users to graphically combine building blocks. Experimental scientists can access instrument operating procedures via custom workflow software on various devices. Despite the use of different software, the workflow descriptions remain consistent, allowing execution on a single engine. We will present various workflows and illustrate how experimental and computational scientists can collaborate using shared workflows, thereby bridging different materials science disciplines.
- Paper 2120 4** **nanoHUB services for FAIR simulations and data: ResultsDB, Sim2Ls, and AI research assistant**
Prof. Alejandro Strachan, United States
Oral Presentation (20')
- Abstract**
- nanoHUB is an open cyber platform for online simulation, data, and education that seeks to make scientific software and associated data widely available and useful. This presentation will describe recent developments in our infrastructure to address modern data needs. nanoHUB's Sim2Ls (pronounced sim tools) make simulation, modeling, and data workflows discoverable and accessible to all users for cloud computing using standard APIs. In addition, published tools are findable (with digital object identifiers), reusable (via documented requirements and services), and reproducible via containerization. In addition, all Sim2L runs are automatically cached, and their results are indexed in a global and queryable database (ResultsDB). We believe this infrastructure significantly lowers the barriers to making simulation/data workflows and their data findable, accessible, interoperable, and reusable (FAIR). These information resources can be easily invoked as needed by domain experts to advance their fields. I will demonstrate the use of the ResultsDB and Sim2Ls as information sources to power an autonomous research agent based on a large language model for end-to-end scientific discovery.

Machine Learning Approach in Aluminium Melt Quality Control

Ph.D. Mona Khodabakhshi, Italy

Oral Presentation (20')

Abstract

To support sustainability, industries aim to reduce energy use and emissions. Primary aluminium production is energy-intensive and relies on bauxite, facing strict regulations. Achieving high-quality aluminium casting relies significantly on melt preparation, influencing the occurrence of wide variety of casting defects. While traditional methods face challenges in assessing melt quality online due to time and energy constraints, recent innovations present a practical evaluation system. This advancement holds promise for improving final product quality and operational efficiency by minimizing suboptimal molten material and subsequent scrap. A patented system offers real-time insights during alloy solidification, reducing the carbon footprint and enhancing casting quality. When combined with advanced machine learning algorithms, this system rapidly detects impurities, improving production processes and alloy reliability. This research explores the integration of machine learning (ML) methodologies to revolutionize melt quality assessment. By establishing correlations between rapidly obtainable non-equilibrium thermodynamic data and critical melt parameters, predictive models will enable estimations of chemical composition and solidification processes. Leveraging fundamental melt composition data and cooling regimes, these models aim to predict diverse solidified part characteristics, aiding process engineers. This project aims to elucidate crucial connections between cooling curves and solidified part characteristics using predictive models, thus advancing melt quality control. Integration of various ML techniques such as simple linear regression, Multiple Linear Regression, Lasso regression, Elastic Net regression, Ridge Regression, Polynomial, SVR, Random Forest, Decision tree and Gradient Boosting regression represents a significant step forward, promising rapid, real-time estimation of melt quality parameters. Results obtained from the evaluation of the mentioned models highlighted the higher accuracy of the Gradient Boosting Regression model followed as the best candidates to be used for the prediction of magnesium content during aluminium alloy preparation because magnesium is the main alloying element for alloy 5754.

MicrostructureDB: An AI-Powered Open Data Platform for Materials Characterization

Dr. Daria Tomecka, Belgium

Oral Presentation (20')

Abstract

We present MicrostructureDB, a new platform that demonstrates how AI can enhance metallurgical data analysis and laboratory management. This beta release introduces practical tools for automating common challenges in materials characterization: identifying experimental anomalies, filling missing data, and finding related samples across datasets. The platform includes an integrated metallurgical AI assistant that helps researchers interpret results and maintain consistent documentation standards. Using our curated steel microstructure collection, we demonstrate how these tools can streamline laboratory workflows, improve data quality, and accelerate the analysis of experimental results. Through practical examples, we showcase the platform's capabilities in enhancing materials research while maintaining rigorous scientific standards, illustrating the potential of AI-assisted materials characterization.

Enhanced osteogenic differentiation and extracellular matrix formation by mechanically stimulated electroactive scaffolds

Prof. Maria Chatzinikolaïdou, Greece

Oral Presentation (20')

Abstract

Background

Mechanical stimulation applied on cell-loaded scaffolds in in vitro cultures recapitulates the physiological bone tissue and effects the osteogenesis. Poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) is a electrically conductive polymer that responds to mechanical stimulation producing an electrical signal that promotes the osteogenic differentiation of pre-osteoblastic cells by opening the voltage-gated calcium channels. The aim of this study was to examine the biological behavior of pre-osteoblastic cells when seeded onto electroactive PEDOT:PSS-containing scaffolds applying uniaxial compression as mechanical stimulation relevant to physiological body movements.

Methodology

PEDOT (0.15 % w/v and 0.10 % w/v) was combined with 5 % w/v poly(vinyl alcohol) (PVA) and 5 % w/v gelatin, casted into wells, freeze dried and crosslinked. The scaffolds were physicochemically, mechanically and biologically characterized. Scaffolds seeded with pre-osteoblastic cells were subjected to uniaxial compression by means of a bioreactor with a frequency of 1 Hz and a strain of 10% for 1 h every day for 21 days. The loading parameters resemble the in vivo loading situation. Cell viability and morphology of the pre-osteoblastic cells seeded onto the scaffolds was determined. The alkaline phosphatase (ALP) activity, the collagen and calcium production were quantified. Determination of the calcium and phosphorous mineralization through atomic-resolution mapping and Energy Dispersive Spectroscopy (EDS) was carried out, as well as X-ray diffraction (XRD) analysis, aiming to detect biomineralized matrix.

Results

Elastic moduli ranged between 1 and 5 MPa. The degradation rates indicate a mass loss of 15% after 21 days. Scanning electron microscopy images displayed strong adhesion of well-spread cells, while the cell viability increased over time. The ALP activity at days 3 and 7 was significantly higher in the dynamic culture compared to the static one. Increased collagen and calcium secretion validate osteogenic response and extracellular matrix formation. Moreover, EDS and XRD analysis revealed the presence of bone-like apatite formation on scaffold surfaces after 21 days.

Conclusion

The results indicate that the PEDOT:PSS/PVA/gelatin scaffolds support the adhesion, proliferation, and osteogenic differentiation of the pre-osteoblastic cells under mechanical stimulation. Furthermore, the development of a comprehensive 3D mechano-active model establishes an innovative platform for studying osteogenesis under conditions closely resembling the body natural state. This approach contributes to advancing in vitro evaluation but also significantly reduces the need for in vivo experimentation.

A Microfluidic Model to Evaluate the Proangiogenic Effects of Biomaterials

Dr. Oscar Castaño, Spain

Oral Presentation (20')

Abstract

Vascularization is critical for the successful integration of biomedical implants, as a sufficient blood supply is essential for their functionality. To promote revascularization, various strategies have been explored, including the incorporation of angiogenic factors. However, these approaches are hindered by challenges such as the limited stability of the factors and their high production costs. As an alternative, optimizing the physicochemical properties of biomaterials to stimulate vascularization has been actively investigated.

Current models used to assess implant vascularization exhibit significant limitations, including the difficulty in isolating the effects of individual material parameters. Furthermore, traditional assays often fail to accurately replicate in vivo conditions. Microfluidic platforms have emerged as a promising solution, providing precise control over the cellular microenvironment, mimicking physiological conditions, and enabling more efficient and cost-effective studies.

In this work, we introduce a 3D model utilizing microfluidic technology that addresses the limitations of traditional methods, providing a more biomimetic tissue environment. This platform allows for the evaluation of how bioactive biomaterials, releasing signaling molecules like ions or proteins, modulate angiogenesis. The model was validated through computational simulations and experiments assessing cell migration [1].

This compact microphysiological platform enables the investigation of interactions between biomaterials and endothelial cells to evaluate their capacity to promote vascularization. Its application could accelerate preclinical testing of biomaterials and enhance the understanding of the mechanisms underlying vascular formation, addressing the shortcomings of traditional models. This innovation provides a reliable and efficient alternative for tissue regeneration research and the development of novel biomaterials.

Paper 1459 4 Multifunctional copper-containing mesoporous glass nanoparticles for wound healing in bone infection treatment

Dr. Isabel Izquierdo- Barba, Spain

Oral Presentation (20')

Abstract

The prevalence of chronic wounds in bone infections is a key factor to take into account since they hinder the regeneration of the damaged tissue. This situation leads to a continuous proinflammatory state and a decrease in the level of stem cells. Although the management of these wounds focuses on applying passive protective barriers that keep the wound environment away from external agents, often infections cannot be prevented, leading to ischemia and necrosis.

This research work reports the design and development of innovative nanosystems based on biocompatible and multicomponent radial mesoporous glass nanoparticles (RNPs), in the SiO₂-CaO-P₂O₅ system, for wound healing in bone infection treatment. The combination of the antibiotic rifampicin (RIF) and reparative metal ions (Cu²⁺) in a unique nanosystem, allows the incorporation of antimicrobial and regenerative agents to combat wound healing, infection and promote bone regeneration.

Rifampicin-loaded radial mesoporous glass nanoparticles in the SiO₂-CaO-P₂O₅ system (RNPs) containing Cu²⁺ in the outer shell were synthesized by a simple and versatile method. RNPs were externally functionalized with a third-generation polypropylene dendrimer (PPI-G3), which allows the complexation of metal ions through its tertiary amines and, moreover, favors bacterial internalization via its protonated primary amines. The nanosystem promoted fast wound closure (98.1%), high biocompatibility (>70%) and a great capacity for migration and invasion. The versatility of the nanosystem obeys its capacity to load any antibiotic and its ability to complex any therapeutic metal ion according to clinical needs. These results envision the possible development of personalized therapies for wound healing in bone infection treatments.

Paper 1478 5 **Impact of synthesis method, coating, and functionalisation on the cellular internalisation and efficacy of superparamagnetic iron oxide nanoparticles for bone tissue engineering**
Ph.D. Manuel Estévez, Spain
Oral Presentation (20')

Abstract

Superparamagnetic iron oxide nanoparticles (SPIONs) have emerged as versatile tools in a variety of biomedical applications, including bone tissue engineering. Their ability to induce specific cellular responses and facilitate bone regeneration makes them promising candidates for bone repair therapies [1]. In turn, the method of synthesis of SPIONs influences the structural and magnetic properties of the nanoparticles, which affects their efficacy in biomedical applications [2]. In addition, the size, coating and functionalisation of SPIONs are determining factors in their interaction with cells. Smaller nanoparticles may facilitate greater cellular internalisation, but may also present toxicity risks. On the other hand, specific coatings and functionalisations can enhance biocompatibility and direct cellular activity [3]. Therefore, in this work SPIONs have been synthesised by different methods: i) thermal decomposition of an organometallic precursor, ii) flame spray pyrolysis and iii) polyol-mediated liquid phase thermal decomposition. The SPIONs were then coated with dimercaptosuccinic acid or citric acid depending on the synthesis method, functionalised with an RGD peptide for targeting to cellular integrins and extensively characterised. Subsequently, a comparative internalisation study of SPIONs was carried out. For this purpose, bone marrow-derived human mesenchymal stem cells (hBM-MSCs) were used and flow cytometry assays with different endocytosis inhibitors, transmission electron microscopy, iron quantification and cytocompatibility analysis were performed. The results showed different internalisation dependent on SPION type, dose, coating and functionalisation, as well as different endocytosis mechanisms involved in nanoparticle uptake. In addition, different cellular localisation was observed depending on the time of study. These results are crucial to evaluate their role in different biomedical applications such as bone tissue engineering through mechanotransduction processes.

Advanced Nanoindentation Approaches to Assess the Mechanical Behavior of Dental Composites

Mr. Krisztián Bali, Hungary

Oral Presentation (20')

Abstract

Nowadays dental composites are mainly reinforced with quartz particles, often called conventional, and polymerized in layers or in bulk-fill mode. A modern approach is to reinforce the composite with short optical fibres (SFRC). The optical fibres can enhance the polymerization process and improve mechanical behaviour.

In this study we tested 5 groups of dental composites, where the samples were standardized in a 5x5x5 mm geometry. In total n=18 samples were produced, the groups were the following: group 1: (control) conventional layered composite in 2+2+1 mm, group 2: layered SFRC in 2+2+1 mm, group 3: bulk-fill SFRC, group 4: bulk-fill conventional, group 5: layered in 2+2 SFRC and 1 mm conventional. After the polymerization the hardness of samples were measured with the nanoindentation technique both on the top, side and bottom along with creep measurement on the top. After the measurements the samples were stored in water for 30 days and finally the mechanical behaviour and parameters were measured once again. During the 30 days the water absorption of each sample were measured.

The conventional bulk-fill dental composite (group 4) showed significantly lower mean hardness ($p < 0.001$). The SFRC did not show statistically significant difference in the hardness. Bulk-fill SFRC and conventional showed significant difference in the mean elastic modulus ($p = 0.005$). The creep behaviour showed a significant difference as well, especially the time behaviour parameters (retarded modulus and viscosity in the standard linear model). The water absorption showed significant difference between the groups, the SFRC bulk-fill showed a significant less mean water absorption. The groups also showed a linear correlation between the water absorption and time passing ($p < 0.001$, $r = 0.71-0.85$).

The SFRC samples showed similar hardness while the bulk-fill conventional composite had less hardness.

Characterization of the deformation and damage behavior of fiber-reinforced ceramics in bending test

Mrs. Natalia Nier, Germany

Oral Presentation (20')

Abstract

Fiber-reinforced ceramics exhibit higher fracture toughness and damage tolerance than monolithic ceramics and can therefore be used as a construction material in a wide range of applications. This behavior is caused by additional microstructural mechanisms (crack-stop mechanisms) such as crack deflection, crack branching, crack bridging and fiber pull-out. For these mechanisms to be effective, the fiber and matrix properties have to be matched to each other. In particular, a sufficiently weak fiber/matrix bond is required. The three-stage liquid silicone infiltration (LSI) process is a cost-efficient method for production of fiber-reinforced ceramics (C/C-SiC). A carbon fiber-reinforced plastic is converted into a ceramic matrix composite via pyrolysis and siliconization. By varying the starting materials and process parameters used, it is possible to develop different material qualities with a different range of properties.

The aim of this article is to describe the deformation and damage behavior of selected short-fiber and continuous-fiber-reinforced C/C-SiC ceramics. For this purpose, quasi-static bending tests were carried in-situ in a scanning electron microscope (SEM). Images were taken at defined stopping points during the test for documentation. Crack initiation, crack propagation and failure of the C/C-SiC ceramics were recorded and subsequently discussed. Conclusions were drawn for suitable material design.

On the contribution of zirconia phase transformation on fracture properties and crack propagation at the interface of nacre-like alumina composites

Ph.D. Benjamin Bert, France

Oral Presentation (20')

Abstract

In recent decades, researchers developed composite mimicking natural nacre “brick-and-mortar” microstructure. Nacre-Like Alumina (NLA), with a fully dense structure composed of alumina platelets in a glassy phase, garnered the most attention due to their good tradeoff between strength and toughness [1]. The main reinforcement mechanism involves crack deflection at the platelet interfaces resulting in a significant increase of the material toughness [2].

Even if NLA toughness in the specific ‘across’ direction [3] is already optimized, solutions can be envisioned to enhance their flexural strength. It may be done by modifying the interface between the platelets, e.g. incorporating tetragonal zirconia at the interface to leverage tetragonal to monoclinic phase transformation. Specifically, under tensile stress—typically at a crack tip—tetragonal to monoclinic zirconia transformation occurs, inducing compressive stresses, delaying crack propagation and thereby improving fracture toughness. This phenomenon was studied by Henry et al. [4], who incorporated yttria-stabilized zirconia into NLA composition. They revealed a notable increase in NLA flexural strength while not reducing the toughness. However, the study did not definitively establish whether this improvement was directly due to the phase transformation of tetragonal zirconia.

To sum up, zirconia-based NLA demonstrate a real potential for strength improvement. Therefore, the present study investigates several stabilization levels and amounts of zirconia to identify compositions with optimal fracture properties, with the primary aim to confirm or refute the existence of stress-induced phase transformation in these composites.

Laser structuring of ceramic endoprosthesis and its influence on the strength, aging behavior and tribological properties of ATZ ceramics

Mr. Axel Hartmann, Germany

Oral Presentation (20')

Abstract

Ceramic resurfacing is emerging as a viable alternative to total hip replacement for young and active patients experiencing osteoarthritis. This approach utilizes monolithic, thin-walled implants characterized by large articulation diameters. Despite the excellent material properties, these large bearing surfaces are expected to cause increased wear. Critical factors include significantly increased friction torques during dry friction and high starting torques after long periods of inactivity. The rise in friction coefficients can result in micromovements at the bone-implant interface, potentially leading to implant loosening and the consequent need for premature revision.

One potential solution to this problem is to utilize an ultrashort pulse laser to structurally modify the articulation surface. This method creates defined microstructures (dimples), which serve to reduce the contact surface, thereby decreasing the frictional torque that occurs. The dimples also function as a microreservoir for synovia, helping to prevent the breakage of the lubricating film.

In order to identify the ideal dimple geometry for the applications mentioned above, a series of tests were conducted on dimples with varying aspect ratios and textured areas. The resulting dimple quality was evaluated by scanning electron microscopy (SEM) and tribological measurements. Furthermore, the impact of the laser structuring on the mechanical and microstructural characteristics of the Alumina-Toughened-zirconia (ATZ) ceramic is of significant importance. Therefore, the flexural strength was determined, and an analysis was conducted on the phase composition and aging behavior of the microstructured ceramic.

The results presented in this lecture were obtained within the BMBF-funded research project Self-X-For-Implants (funding programme: Biologization of Technology, FKZ: 13XP5209A).

Behavior of Ceramic Oxides in Durability Tests for High-Temperature Solar Receivers

Dr. M-Magdalena Lorente-Ayza, Spain

Oral Presentation (20')

Abstract

Thermochemical processes utilizing solar energy and other high-temperature solar applications require a significant concentration of solar radiation, often exceeding 100 W/cm². In this context, advanced ceramics are an ideal choice, as these materials can withstand temperatures of up to 1400 °C or higher, maintaining stability against detrimental morphological changes. Additionally, the selected materials must be capable of withstanding high flux densities and temperatures over thousands of cycles, given that these systems operate daily with start-up and shutdown procedures.

In this study, materials and operational procedures have been developed using concentrated solar energy for the characterization of materials intended for solar volumetric receivers, which can also serve as supports for solar catalysts. Various testing campaigns have been conducted in the SF40 Solar Furnace at CIEMAT-PSA for the aging of advanced ceramic specimens under concentrated solar radiation, using a specific test bench. Different ceramic materials formed by uniaxial pressing and sintered under various conditions have been evaluated. The objective is to compare their behavior under real conditions of high energy fluxes and elevated temperatures, assessing their properties in a Concentrated Solar Thermal (CST) operational environment.

The work has been carried out thanks to the project "Boost to the solar thermal H₂ production via the development and validation of new materials for ceramic solar receivers with improved durability (HIDROFERR)", with project reference PID2020-118599RB-I00, funded by Ministerio de Ciencia e Innovación, Agencia Estatal de Investigación, with Digital Object Identifier 10.13039/501100011033, and FEDER Funds.

Paper 1660 1 Development and Integration of Novel Ultra-High Temperature Ceramics

Dr. Peter Tatarko, Slovakia

Oral Presentation (20')

Abstract

This work presents the development of high-purity single phase high entropy carbides, such as (HfZrTaNbTi)C and (MoNbTaVW)C, and high entropy diboride, such as (HfZrTaNbTi)B₂ by Spark Plasma Sintering (SPS). The main aim of this study was to develop an appropriate approach to join this novel class of Ultra-High Temperature Ceramics (UHTC). The presentation will be divided into three parts. The first part will focus on wetting and joining of (HfZrTaNbTi)C and (HfZrTaNbTi)B₂ with a commercially available AgCuTi alloy. The apparent shear strength of HEC and HEB joints was 176 ± 39 MPa and 116 ± 38 MPa, respectively. In all cases, the failure occurred in base materials, which fragmented into many small pieces, indicating that the shear strength of both joints was predetermined by the intrinsic properties of base materials. The second part will describe the joining of (MoNbTaVW)C with a NiTa eutectic alloy. The addition of 17.2 at.% Ta to Ni significantly reduced interfacial reactions and dissolution of HEC, while maintaining excellent wetting behaviour with the final wetting angle of $\leq 150^\circ$. Successful joining of HEC ceramics was achieved using a NiTa interlayer, demonstrating a high shear strength of 220 ± 17 MPa. The last part of the presentation will focus on the joining of (HfZrTaNbTi)C and (HfZrTaNbTi)B₂ with the high entropy alloy containing the same transition metals, i.e. HfZrTaNbTi. Microstructural and interfacial characterizations of the joint revealed a homogeneous, crack-free, and well-bonded interfaces. The effect of joining temperature on the mechanical strength was evaluated, revealing the strength exceeding 350 MPa for the joints made at 1800°C. High-temperature bending tests revealed no significant strength deterioration up to 1000°C.

Paper 1839 3 Microstructural evolution and mechanical properties of ultra-high temperature binary carbides

Dr. Alexandra Kovalčíková, Slovakia

Oral Presentation (20')

Abstract

This study investigates the microstructural evolution and basic mechanical properties of high-temperature binary carbides. Transition metal elements of group IV and V of PTP, namely Ti, Zr, Hf, V, Nb, and Ta were selected to prepare a combination of 15 binary carbides. The rationale to select these chemical compositions is due to higher thermal stability of their mono carbides, oxides or borides, known as UHTC ceramics. Binary carbides, for example (TiZr)C, (ZrHf)C, (HfV)C, (VNb)C, (NbTa)C etc. were prepared using ball milling for 4 hours of starting powder of monocarbides. The samples were spark plasma sintered at 2100°C for 10 or 20 minutes at 70MPa in argon atmosphere, respectively. Almost fully dense single phase carbides were prepared. However, the XRD confirmed low amount of oxide phases as ZrO₂, TiO₂ or HfO₂. Longer time of sintering has not changed the grains size of binary carbides significantly. The basic mechanical and tribological properties as nano/micro hardness, Elastic modulus, fracture toughness, and coefficient of friction were measured and the influence of chemical composition of carbides on mechanical properties was studied.

Acknowledgements: This work was supported by the Slovak Research and Development Agency under the contracts APVV-22-0493, by Scientific grant agency VEGA 2/0107/24, and by the project of Slovak Academy of Sciences IMPULZ IM-2022-67.

Paper 1666 4 High Entropy Ceramics with Improved Oxidation Resistance

Dr. Monika Tatarkova, Slovakia

Oral Presentation (20')

Abstract

The present work reports the development of novel high entropy ceramics with improved mechanical properties, and dynamic oxidation resistance. Highly dense high entropy diboride (Ti_{0.2}Zr_{0.2}Hf_{0.2}Nb_{0.2}Ta_{0.2})B₂-SiC composites with different β -SiC content (5, 10, 15, 20 and 25 vol.%) were synthesized using ball milling followed by Spark Plasma Sintering (SPS) at 1900°C. High-purity high entropy diboride (HEB) powder was synthesized using boro/carbothermal reduction of oxide precursors at 1800°C. X-ray diffraction patterns of the synthesized powders and sintered compacts of HEB showed a single solid solution with hexagonal AlB₂ structure without any residual oxide impurities. X-ray energy dispersive Spectroscopy (EDS) mapping results indicated the uniform elemental distribution of transition metals in the HEB phase. The addition of SiC improved the densification of HEB-SiC composites. The composite with 20 vol.% SiC exhibited a unique combination of mechanical properties, such as superior Vickers hardness (22.28 ± 0.25 GPa), flexural strength (750. 21 ± 43.23 MPa), indentation fracture toughness (4.12 ± 0.2 MPa.m^{1/2}), Young's modulus (495.3 ± 0.3 GPa) and dynamic oxidation resistance (0.02 mg.cm⁻².s⁻¹).

Acknowledgment: This work was supported by the projects VEGA 2/0145/25 and SAS-TUBITAK/JRP/2023/807/ HiTemCom (No. 720464). The support of Slovak Research and Development Agency under the Contract no. APVV-21-0402 is also acknowledged.

Paper 139 **1** **CABLE Twitchalloy: Design of a High Strength, High Electrical Conductivity and High Thermostability Aluminum Alloy**
Dr. Maria Ioanna Tzini, United States
Oral Presentation (20')

Abstract

Recycling of aluminum alloys is the best practice to reduce the carbon footprint of automotive aluminum products, however the aluminum scrap, “twitch”, is contaminated with impurity elements such as Fe and Si, and the cost of recycling techniques is significantly high. In parallel, the U.S. electricity delivery system undergoes changes to improve its reliability and resilience to extreme weather conditions. The design of a novel thermostable aluminum-based cable conductor for overhead transmission lines utilizing high volumes of aluminum twitch is a promising solution and a cost competitive way to recyclability. In the present study, CALPHAD-based ICME tools are employed for the design of an aluminum cable conductor with high strength, high electrical conductivity, and high thermostability via melt-spinning and high-temperature aging. A hierarchical system-based approach is adopted, and the thermodynamic calculations are aided by high-throughput DFT databases to design novel intermetallic compounds supporting new classes of aluminum alloys compatible with recycling of automotive scrap. The main design objectives are to maximize the electrical conductivity through the complete gettering of the impurity elements and maximize the precipitation strengthening through the formation of Q phase and the elimination of Si phase. Rapidly solidified specimens that utilize aluminum twitch were prepared, and electrical resistivity measurements using the 4-point probe method were carried out at room temperature. The calculations were validated experimentally, and the microstructures of the specimens were characterized via STEM and APT analyses.

Prediction of Porosity in CFRP Ultrasound Testing Using Deep Learning and X-ray CT

Mr. Alberto Vicente Del Egido, Spain

Oral Presentation (20')

Abstract

Fast and reliable nondestructive testing (NDT) is critical for the carbon fiber reinforced polymer (CFRP) industry. NDT covers a range of techniques and plays a pivotal role in the development of novel materials by enabling the assessment of their properties and verifying the reliability of new manufacturing methods. During production, NDT is essential for quality assurance, ensuring that manufactured samples comply with required specifications. Additionally, NDT is invaluable for maintenance applications, allowing for the detection of defects caused by operational use. One key defect in CFRPs that can significantly influence mechanical performance is porosity. Porosity can lead to degraded mechanical properties and cause early catastrophic failure of parts, making its precise evaluation essential. The void volume fraction, which quantifies the percentage of a sample's volume occupied by voids, is a widely recognized metric for assessing porosity. Accurately measuring void volumetric fraction requires NDT techniques capable of high-resolution 3D data acquisition, such as X-ray Computed Tomography (XCT). While lab XCT offers unparalleled micron up to submicron resolution and detailed internal structure visualization, it is expensive, time-consuming, and demands strict experimental conditions. In contrast, ultrasonic testing (UT) is a highly efficient NDT method extensively used in the CFRP industry for its rapid diagnostic capabilities across varying sample sizes. However, UT faces limitations in resolution and clarity of internal structural representations compared to XCT. To bridge this gap, our research focuses on combining the efficiency of UT with the precision of XCT through artificial intelligence (AI). Specifically, we aim to leverage UT data to predict porosity metrics equivalent to those derived from XCT. We developed an end-to-end data pipeline, including automated data preprocessing and registration, and several deep learning models designed to predict the void volumetric fraction from UT measurements. So far, the best model has reached a R^2 score of 0.68. In this study, we present the comparison between model prediction and XCT data, to investigate the extent to which porosity prediction captures relevant porosity-related information. This allows to evaluate the potential of AI to enhance the precision of UT-based NDT.

Paper 687 3 Quantitative analysis on ML-DIC patch for daylight and dark mode strain measurement

Mr. Youn Woo Shin, South Korea

Oral Presentation (20')

Abstract

The Al-Zn-Mg-based 7xxx series aluminum alloy is widely utilized in aircraft as a structural material due to its excellent strength-to-weight ratio, fatigue properties, and superior corrosion resistance compared to the 2xxx series alloys. The A7050 alloy, known for its high strength, resistance to stress corrosion cracking, and fracture toughness, can be produced in rolled sheet form due to its low sensitivity to heat treatment, making it suitable for various aircraft structural components.

Detecting internal cracks within aircraft structures made from such materials poses a challenging task and overlooking them during inspections can lead to catastrophic accidents. To address this issue, various non-destructive testing methods have been investigated, among which the use of mechanoluminescent (ML) materials has been chosen. ML materials, a type of luminescent substance, can convert the luminescent intensity induced by mechanical stimuli such as tension, compression, torsion, and friction into measurable stress, which can then be further translated into strain by employed to perform comparative analysis between ML materials and strain.

Therefore, in this study, specimens fabricated from A7050-T7451 were intentionally introduced with randomly positioned, angled, and sized defects to simulate real-world conditions. ML and DIC images were captured during tensile testing, and each obtained image was meticulously examined and evaluated to analyze the presence of defects at the rear surface of the specimens.

Paper 967 4 Alloy design of γ' -strengthened CoNi-based superalloys with low crack susceptibility suitable for additive manufacturing

Lu Song,

Oral Presentation (20')

Abstract

γ' -strengthened CoNi-based superalloys are more suitable for additive manufacturing (AM) than γ' -strengthened Ni-based superalloys due to their narrower freezing range and better weldability. In this study, a design methodology for CoNi-based superalloys suitable for additive manufacturing was developed by integrating machine learning (ML) with calculation of phase diagrams (CALPHAD) approach. This methodology comprehensively accounted for critical factors, including phase equilibrium, γ' volume fraction, γ' size, γ' solvus temperature, oxidation resistance, alloy density, and sensitivity to strain age cracking of CoNi-based superalloys. This approach enables an effective design of CoNi-based superalloys for additive manufacturing with low crack sensitivity. The results show that the designed alloy exhibited exceptional printability, minimal compositional segregation, and the ability to produce crack-free components with a relative density exceeding 99.99% on non-preheated substrates by selective laser melting (SLM). Furthermore, the designed alloy demonstrated an exceptional outstanding strength–ductility synergy. This study provides valuable technical insights for the engineering application of additively manufactured CoNi-based superalloys.

Paper 1982 6 **Machine-learning the thermodynamics of multi-principal element structural alloys through chemically embedded cluster expansions**
Mr. Yann Müller, Switzerland
Oral Presentation (20')

Abstract

Multi-principal element alloys are an emerging class of materials that are attractive candidates for structural, electronic and electrochemical applications. A systematic investigation of chemical space in such alloys is however untenable. Computational techniques, such as the cluster expansion methods, have proven to be useful tools in discerning alloy compositions with favorable properties and enabling a fundamental understanding of phase stability in multi-component alloys. However, the cluster expansion method remains difficult to deploy in alloy systems containing several chemical components. In conventional cluster expansions, the number of features scales polynomially with the number of alloying elements. The rapid increase in the number of features causes difficulties in parameterizing and evaluating conventional cluster expansions. Here, we introduce the embedded cluster expansion (eCE) formalism that mitigates this rapid growth in the number of features. Chemical similarities between elements are simultaneously learned during training to reduce the number of site-basis functions. We will then describe how eCE models can be deployed to build accurate thermodynamic models of refractory alloys containing up to 9 elements. We show that the eCE model can successfully reproduce ordering energetics of the alloy, requires a limited amount of data, and can robustly extrapolate ordering energies.

Hydrogen-Enhanced Entropy (HEENT) Mechanism For Hydrogen Embrittlement in Metals: An Umbrella Over HELP, HEDE and HESIV Mechanisms

Prof. Masoud Moshtaghi, Finland

Oral Presentation (20')

Abstract

One of the most serious challenges in materials science is hydrogen embrittlement (HE). It mainly concerns structural elements that are cyclically loaded in an environment rich in hydrogen, such as in a pressure vessel. Though Paris' law and Coffin-Manson laws are fundamental models for estimating the propagation of fatigue cracks and the lifetimes in low-cycle fatigue, their conventional forms are not able to capture the rather complex hydrogen/material interactions. This study attempts to bridge this fundamental gap by addressing the hydrogen effects on the fatigue performance, proposing new versions of the Paris' and Coffin-Manson laws, and validating these modifications via numerical simulations and experimental data.

The law of Paris was used to analyse the rates of crack growth (da/dN) under variable hydrogen concentrations, pressures, and cyclic loading conditions. A new modified model was developed to include hydrogen-specific parameters associated with the crack tip such as the hydrogen concentration, activation energy for embrittlement, and those environmental factors such as temperature and pressure. The Coffin-Manson law, on the other hand, was modified to incorporate a direct account of reduced ductility and accelerated initiation associated with hydrogen embrittlement effects. Important parameters such as fatigue ductility coefficient (ϵ_f) and exponent (c) were determined experimentally for high-strength steels and aluminium alloys in hydrogen environments. Further, the work focuses on the impacts of hydrogen on threshold stress intensity factors (ΔK_{th}) and fatigue limit, providing more insight about the environmental sensitivities of these parameters.

Finite Element Simulations with the Aid of Abaqus for verification of revised laws. The model considered hydrogen diffusion, a localized plasticity, and crack development for analysing crack propagation under simultaneously applied mechanical and environmental stress. The comparative exercise indicated the extent to which the revised laws significantly improve prediction accuracy for materials undergoing hydrogen embrittlement. This shows that hydrogen increases the rates of crack growth and shortens the fatigue lifetimes, thereby underlining the need for incorporating hydrogen-sensitive factors in models.

This research addresses a significant gap in the literature by presenting a cohesive framework for predicting fatigue life in environments rich in hydrogen, integrating experimental findings with computational modelling. It presents practical consequences for sectors like aerospace, automotive, and energy, where hydrogen embrittlement threatens the integrity of components. Upcoming research will concentrate on broadening the material database and investigating multiscale modelling techniques to enhance the predictive abilities of these adjusted laws.

Effect of Ti and Nb on hydrogen trapping in welded S690 HSLA steel and effect on delayed cold cracking

Dr. Michael Rhode, Germany

Oral Presentation (20')

Abstract

Fine-grain, high-strength, low-alloy (HSLA) structural steels with yield strengths > 600 MPa are now the state of the art in construction applications such as mobile cranes and civil engineering. HSLA grades derive their strength from a combination of specific heat treatment and the underlying chemical composition. In this context, Ti or Nb are essential to obtain a fine-grained microstructure as well as the necessary carbides or nitrides for precipitation strengthening. In this context, the specific effect of Ti or Nb-rich compounds on hydrogen trapping and diffusion is well known for special laboratory cast alloys, but unknown for realistic steel compositions. For this reason, a series of S690Q-based alloys were synthesized, close to a real steel composition, but with well controlled Ti or Nb additions in different amounts. Specimens were obtained from these alloys by electrochemical discharge machining (EDM). The specimens were tested using the well-established electrochemical permeation technique. From the experimental results, the hydrogen diffusion coefficients and the analytical subsurface hydrogen concentration were calculated. In addition, the hydrogen trapping behavior at elevated temperatures was interpreted by thermal desorption analysis (TDA) using different heating rates of hydrogen charged samples. The results showed that in contrast to metallurgically "pure" laboratory cast alloys, realistic chemical compositions were similar in their hydrogen trapping behavior, despite some small differences. All investigated steel grades exhibited shallow and reversible hydrogen trapping, regardless of their chemical composition. Of course, the experiments only allowed the calculation of effective diffusion coefficients and trapping energies, which represent an average of the entire microstructure. Nevertheless, HSLA steels are typically joined by arc welding, which includes the risk of delayed hydrogen assisted cracking. From the point of view of welding practice, however, a more or less identical hydrogen diffusion behavior means that no special "metallurgically specific", justifiable measures need to be considered, despite the well-established processes such as "soaking" or dehydrogenation heat treatment. Of course, a closer look at the heat-affected zone (HAZ) or the weld metal of the specific welds is necessary. However, especially in the case of thick-walled welds, it is assumed that the weld metal and HAZ are similar to the base material due to the multi-layer welding, which results in multiple annealing cycles of the weld metal and HAZ.

Hydrogen compatibility of internal combustion engine components

Prof. Giorgia Ghiara, Italy

Oral Presentation (20')

Abstract

In the broader context of the transition from fossil fuels to cleaner and renewable energies, the introduction of hydrogen in the transport field necessitates the testing of metallic components that are compatible with hydrogen-powered vehicles. Numerous studies have been conducted to address the question of whether hydrogen embrittlement affects hydrogen-powered vehicles. The results of these studies have indicated that the answer to this question is in the affirmative. This conclusion is based on the composition, manufacturing procedure and mechanical properties of the component in question, as well as the hydrogen partial pressure and operating conditions. Several prominent private enterprises (for instance, Toyota, Hyundai, Honda, BMW, GM) have directed their research and development departments to explore the potential compatibility of internal combustion engines (ICEs) with hydrogen-based fuels. The selection of materials is therefore a pivotal consideration, with particular attention to the operational conditions to which they are exposed.

In accordance with this trend, the present study constitutes a component of a project promoted by the Italian company Dumarey Automotive Italia S.p.A., the objective of which is to ensure full compatibility of internal combustion engine (ICE) components in the context of a transition from hydrocarbon to hydrogen engines. A primary objective of the project is the identification of hydrogen embrittlement-(HE)-resistant alloys, with a focus on the selection of components, including but not limited to pistons, engine heads, and engine blocks, deemed suitable for these applications.

A series of experiments were conducted on a set of alloys (comprising various aluminium alloys and cast irons) in order to evaluate their mechanical performance and susceptibility to hydrogen degradation. Slow strain rate testing (SSRT) of hydrogen-charged samples was performed on selected alloys. In addition, fractographic analyses were carried out to identify characteristic fracture features connected to hydrogen embrittlement (HE).

Comparison of hydrogen embrittlement fractures of tempered martensitic steel obtained by various test methods

Mr. Ryoto Tokizaki, Japan

Oral Presentation (20')

Abstract

Conventionally, slow strain rate test (SSRT) and constant load test (CLT) have been widely used to evaluate the hydrogen embrittlement susceptibility of high-strength steels. High-strength bolts are typically subjected to a constant displacement tensile load under actual service conditions. However, there are few reports on evaluating hydrogen embrittlement susceptibility using constant displacement tensile test (CDT). Furthermore, differences in hydrogen embrittlement susceptibility obtained by SSRT, CLT, and CDT have not been clarified. In the present study, we compared the fracture strength and fracture morphology of hydrogen-charged tempered martensitic steel using SSRT, CLT, and CDT. Tempered martensitic steel specimens with a tensile strength of 1530 MPa were prepared as smooth round bars with a gauge length of 30 mm and a diameter of 6 mm. Specimens were charged with hydrogen in a 0.1N NaOH aqueous solution containing 1.0 to 3.0 g·L⁻¹ NH₄SCN at a temperature of 30 °C for 96 h using the constant current cathodic electrolysis at a current density of 20 to 50 A·m⁻². Following hydrogen precharging, three types of tensile tests were conducted. For SSRT, tensile tests were performed at strain rates of 5.56×10⁻⁶ to 5.56×10⁻⁷ s⁻¹. For CLT, the load was applied at a rate of 3.33 MPa·s⁻¹ until reaching a predetermined stress value in the range from 400 to 1200 MPa, after which the constant stresses were applied for up to 48 h. For CDT, the load was applied at the same rate as CLT, but displacement was fixed upon reaching the predetermined stress value in the range of 500 to 1200 MPa, and held constant for up to 10 h. The critical fracture strengths were determined for each test method, and fracture surfaces were observed using a scanning electron microscope. Under low amount of hydrogen, the critical fracture strengths for SSRT, CDT, and CLT were 1420 MPa, 1400 MPa, and 1350 MPa, respectively, which were no significant differences among the three testing methods. Fracture surfaces obtained by three testing methods commonly exhibited quasi-cleavage facets initiating from the base material at the edge on the circumference of the specimens. Under high amount of hydrogen, the critical fracture strengths for SSRT, CDT, and CLT were 900 MPa, 500 MPa, and 400 MPa, respectively, indicating significant differences between SSRT and the other two testing methods. Fracture surfaces for all three methods showed a mixture of quasi-cleavage and intergranular fractures, where the crack initiation occurred around the internal precipitates.

Influence of environment and crystallographic factors and on hydrogen embrittlement in Al-Zn-Mg alloy

Dr. Hiro Fujihara, Japan

Oral Presentation (20')

Abstract

Al-Zn-Mg alloys possess high strength but also exhibit high sensitivity to hydrogen embrittlement. Hydrogen embrittlement occurs not only by hydrogen present within the material but also by external hydrogen from the environment (e.g., through corrosion). To develop materials with high resistance to hydrogen embrittlement, it is crucial to identify the microstructural features that are most susceptible and most resistant to hydrogen embrittlement. In a previous study, we proposed a method for identifying the strongest and weakest grain boundaries with respect to internal-hydrogen-induced intergranular cracking using three-dimensional (3D) image-based statistical analysis. However, the effect of external hydrogen is known to be higher in promoting hydrogen embrittlement than that of internal hydrogen. Therefore, this study investigated the dominant factors influencing external-hydrogen-induced fracture behavior in an Al-Zn-Mg alloy by analyzing hydrogen embrittlement under controlled environmental conditions using multi-modal 3D image-based analysis.

Al-9.6%Zn-1.8%Mg ternary alloy was prepared. Specimens for in-situ tensile testing were prepared using electrical discharge machining in water, which resulted in hydrogen charging during the cutting process. The in-situ tensile tests were conducted in both water and a pure argon atmosphere. X-ray computed tomography (CT) and diffraction contrast tomography (DCT) experiments were performed at BL20XU in SPring-8 to visualize the 3D microstructure and hydrogen embrittlement behavior.

On the fracture surface, ductile fracture was dominant in the argon atmosphere. On the other hand, intergranular and quasi-cleavage fracture surfaces were observed in the water environment. This result clearly demonstrates that the external environment promotes hydrogen embrittlement. Crack initiation sites were identified by superimposing 3D crack and grain images. Design parameters representing the shape and size of grains and grain boundaries were determined for all grains and grain boundaries. Principal component analysis (PCA) and global sensitivity analysis (GSA) were employed to select the design parameters that had the greatest influence on hydrogen embrittlement.

Using the selected design parameters, metamodeling analysis was used to predict the weakest microstructures, i.e., those with the highest probability of cracking, for both transgranular and intergranular cracks. Intergranular cracks initiated at grain boundaries where three constituent grains at a triple junction exhibited different shapes and high Schmid factors. These grains are likely to undergo plastic deformation more readily, which facilitates the reaction between external water and aluminum, leading to localized hydrogen enrichment and promoting early initiation of intergranular cracking. Eliminating grains and grain boundaries exhibiting these weakest microstructural characteristics represents an effective approach to designing materials resistant to external-hydrogen-induced fracture.

Effect of hydrogen on the passivity of steel: investigating the role of the surface and interfaces

Mrs. Chiara Menegus, Switzerland

Oral Presentation (20')

Abstract

In the context of a growing hydrogen economy, we must confront a relevant number of challenges arising from hydrogen interaction with steel across various stages of production, storage, transportation, and utilization. While extensive research has been conducted on hydrogen embrittlement, the role of the passive oxide layer, which naturally forms on steel surfaces in both natural and controlled atmospheres, has received little attention. This layer serves a dual function: protecting against corrosion and potentially acting as a barrier to hydrogen ingress.

To investigate this, the interaction of hydrogen with the main components of steel oxides, namely Fe and Cr oxides, was studied. Fe-Cr alloys at different relative amounts are prepared by magnetron sputtering and subsequently in-situ thermally oxidized to simulate different steel oxides. Electrochemical hydrogen charging was performed using a custom flow cell within a glovebox, allowing hydrogen exposure on one side of the sample while maintaining an inert argon atmosphere on the other. This setup minimizes surface polarization and unintended modifications on the surface of interest, enabling the evaluation of hydrogen's effects on the oxide layer.

Post-charging, the samples are transferred under ultra-high vacuum conditions for analysis using both soft and hard X-ray photoelectron spectroscopy (XPS and HAXPES). The analysis focuses on determining the oxide layer thickness, composition, oxide/hydroxide phase distribution, the Fe³⁺/Fe²⁺ ratio within the oxide films, and the chemical states of elements at and near the oxide/alloy interface.

Additionally, hydrogen quantification and depth distribution within the thin passive layers were studied using Elastic Recoil Detection Analysis (ERDA). A custom electrochemical cell was designed for in-operando ERDA analysis during hydrogen charging, enabling measurements throughout the permeation transient.

This integrated approach offers new insights into hydrogen penetration, diffusion, and solubility mechanisms within steel surface layers, enhancing our understanding of hydrogen-steel interactions, contributing to the development of more durable materials for hydrogen-related applications.

Evaluation of the hydrogen embrittlement index for a martensitic advanced high strength steel using ex-situ tensile tests

Mr. Carlo Maria Belardini, Italy

Oral Presentation (20')

Abstract

Car body-in-white lightweighting is a pathway to improved sustainability of the automotive industry due to the following increased fuel efficiency. For this reason, ever higher-strength steels with moderate ductility are being actively developed in the field. Hydrogen does interact with steels in multiple ways, in a series of phenomena collectively known as hydrogen embrittlement. Even low amounts of hydrogen can significantly impact ductility of automotive high strength steels, which is required both for sufficient formability and crashworthiness.

A commonly used technique for better performing such risk assessment is the identification of an hydrogen embrittlement index, which correlates loss of mechanical or technological properties of the steel to hydrogen content. In this work an advanced characterization of the hydrogen embrittlement index for a martensitic advanced high strength steel is performed. To that aim, ex situ electrochemically charged tensile specimen are tested in the slow strain rate regime and the effects of hydrogen on the tensile curve are evaluated. The interpretation of the tests is aided by their FEM simulations which allow for a better understanding of the stress and strain conditions in the specimen at fracture nucleation conditions. Further, a simulation of hydrogen diffusion and trapping considering its outgassing kinetics at room temperature allows for a better understanding of the hydrogen concentration present in the specimen. Correlation of both the concentration data and the stress-strain state at fracture nucleation may provide a better formulation of the hydrogen embrittlement index.

H4_4 - Aluminum Recycling

Chair: Park, Prof. Joohyun

Paper 771 1 **Science of Dirty Alloys: improving the recyclability of Al alloys**

Mr. Paul Chatron-Michaud, France

Highlight (Oral Presentation 20')

Abstract

Theoretically, aluminum alloys, like most metallic alloys, are infinitely recyclable. In the case of aluminum alloys, the energy involved in the recycling process represents only 5% of the energy required for primary production. However, recycling presents some difficulties, as alloying elements from certain series are poisons to be avoided for others. Therefore, their mixing in the recycling process must be strictly limited, as such contamination leads to a reduction in the properties of so-called secondary aluminum, particularly ductility, which in turn reduces the potential applications for the use of this recycled aluminum. This decrease is usually attributed to the presence of Fe-rich brittle intermetallic compounds (IMC). The objective of this work is to improve the recycling sector's ability to produce alloys of interest for a wide range of applications, in particular by closing the loop on wrought grades such as 5xxx and 6xxx alloys without any downgrade to casting alloys. To do so, the methodology relies on a combination of experimental approaches and thermodynamic calculations to better understand the impact of impurities on the microstructure and improve the predictive capacity of numerical simulation tools in compositional spaces they were not optimized for, to assess the impact of composition shift on the formation of detrimental IMC. To reproduce the consequences of recycling on the composition of secondary aluminum, industrial alloys have been enriched to reach up to 0.5w% Fe, 0.9w% Si, 1.0w% Mn and 4.7w% Mg. The nature, size, shape and distribution of IMC have been successfully investigated by advanced techniques such as EDS, EBSD and XRD. Both massive samples and isolated IMC have been studied, thanks to a new take on a matrix selective dissolution technique (so called "Sibut" technique). This technique allowed a precise quantification of the different IMC in the enriched alloys through XRD and Rietveld refinement. The influence of several processing parameters on IMC such as cooling rate or homogenizing heat treatment have been studied. Experimental results have been also compared with numerical phase transformation models and thermodynamical calculations in order to challenge and optimize current databases.

2

Circular economy of aluminium alloy to extrusion process: From dismantled batteries to batteries.

Ph.D. Sylvia Cruz, Spain

Oral Presentation (20')

Abstract

The automotive industry has played a decisive role in the economy and it has been the responsible of important advances in new materials, processes and designs. In the last years the huge increment in the use of electrical vehicles has lead to the increase on the amount of aluminium employed in each vehicle. At the same time, the bauxite, principal source of primary aluminium is considered a Critical Raw Material since 2020, open the opportunity to increase and approach one of the most relevant properties of the aluminium alloys, their recyclability.

Aluminium alloys can be recycled infinitely without losing their properties, with a clear tendency to increase the use of secondary alloys. Unfortunately, the scrap is usually mixed and contaminated, restricting the use of secondary alloys until the present days to low performance applications. The most common and undesirable impurity in recycled Al-Si alloys is Iron. Due to the low solubility of Fe in Al, secondary phases are usually formed in Al Alloys, decreasing the mechanical properties and increasing their porosity. The light alloys research group of Eurecat is focused on the research and development of high-performance aluminium alloys with high scrap ratio, evaluating the effect of the principal impurities and alloying elements on alloy properties and their effect in an extrusion process, in this case. Eurecat leads the research in this area, thanks to the participation in different European projects. In particular, FREE4LIB project has allowed the demonstration the possibility of closing the cycle of extrusion aluminium alloys used in the battery of electrical vehicles.

The dismantled batteries were supply by ACCUREC. The sorting of the scrap was made depending on the Si content. The scrap with more than 1% of Si, was used to produce casting alloys and the scrap with less than 1%, to produce extrusion alloys. The extrudability of the secondary alloys obtained 100% from dismantled batteries were studied with an special extrusion device developed by EURECAT. The microstructure and mechanical properties of the extruded profiles obtained were also analysed. The extrusion alloy obtained directly from the battery scrap, has a chemical composition similar to 6082 but with a higher Cu content, however, the results suggest than a Cu level near to 0,2% do not have a detrimental effect in the mechanical properties or alloy extrudability, allowing the use of aluminium alloys with higher Cu contents to produce extruded profiles for high performance applications.

Paper 911 **3** **Methodology to design a new high performance HPDC aluminium alloy with a high recycled content**
Ph.D. Manel da Silva, Spain
Oral Presentation (20')

Abstract

The European Green Deal generates to the automotive industry a need to evolve towards a greener and more sustainable system for achieving a net-zero emission of Greenhouse Gases (GHG) in Europe by 2050, and to secure itself a stable future. In order to achieve this objective, the materials have been improved and new developments performed over the last years. In order to reach this target, the vehicles have to be as light as possible and, of course, there is the necessity to move towards a global electrification of the road transport. Both solutions involve the use of innovative and light materials for improving energy efficiency and aluminium alloys are the core of this material evolution. Structural parts require high mechanical properties, as 10% elongation at fracture and, at least 100 MPa yield strength, as they have a crash-relevant function. For this kind of applications, the automotive sector has always used primary alloys, while secondary alloys only for non-structural parts as engine blocks or housings. The reason behind this is the detrimental effect that iron and other impurities, commonly present in the aluminium scrap, have in the alloy castability and mechanical properties.

In this study, the effect that different elements have in the most common alloy used for HPDC structural applications, AlSi10MnMg alloy have been investigated. Relevant alloy properties, such as alloy flowability, and mechanical properties after T5 and annealing heat treatments were analyzed. The effect of different levels of the main alloying elements (Si, Mg and Sr), as well as the main impurities commonly present in the scrap (Fe and Cu), were investigated. The results show that, while the Mg level has a strong influence in the hardening achieved after a T5 heat treatment, it does affect very little the yield strength and maximum strength achieved after an annealing. Alternately, the Cu level does not significantly affect the alloy strength after a T5 heat treatment, but highly affect the alloy strength after the annealing.

Solid-state recycling of AA6006 via chips compaction and hot rolling

Mr. Pietro Cetto, Italy

Oral Presentation (20')

Abstract

Solid-state recycling techniques for aluminum have been studied for years as a potential alternative to conventional recycling methods that rely on remelting, due to their lower energy consumption and reduced environmental impact. This study explores the solid-state recycling of AA6006 chips through compaction and consequent hot rolling, with the aim of producing a continuous bulk material. The focus has been set on the effects on material properties of different process parameters, including compaction pressure, rolling temperature and rolling reduction ratio. The final mechanical properties were defined through tensile and hardness tests. Microstructural evolution was monitored throughout different process steps involving optical microscopy, Scanning Electron Microscopy (SEM) and Electron Backscattered Diffraction (EBSD). Correlations have been found between microstructural features and mechanical properties. Preliminary results indicate that this approach has potential for producing high-density materials with promising mechanical properties, providing a viable alternative for more sustainable aluminum recycling in a circular economy perspective aimed at minimizing wastes.

Solid-state recycling of aluminium AA6060: effect of thermomechanical coupling on oxidation during extrusion

Ph.D. Théo Duchateau, France

Oral Presentation (20')

Abstract

The electrolysis of alumina to obtain aluminium from ore requires a lot of electricity. Recycling avoids electrolysis by reusing waste in its metallic form. Wrought aluminium, approximately 40% of recycled aluminium in 2007, undergoes a remelting process and is then shaped through plastic deformation. Hot extrusion is a commonly used process to produce wrought aluminium profiles.

In the solid-state recycling process, to reduce energy consumption, waste is shaped without a remelting step. The studied process is divided into three stages: industrial AA6060 chips are compacted to form a chip billet, the billet is heated to the forming temperature, and it is hot extruded. However, during the process carried out at 450 and 550 °C, magnesium oxides grow on the chips surface and form a network in the extrudates [1]. This network, at prior chip boundaries, leads to mechanical losses in directions normal to the extrusion direction [2]. An acceleration of the kinetics is measured during extrusion, making this stage the main source of oxides. The purpose of this study is to understand the effect of the thermomechanical coupling on oxidation during extrusion.

First, to reproduce the extrusion ex-situ, massive samples and aluminium chips compressed at 450 and 550 °C with a Gleeble3500 are analysed. Then, a study is conducted on samples taken during the extrusion process and on the extrudates. Two heat treatment conditions are compared: 450 °C and 550 °C for 45 minutes, together with two extrusion temperatures: 380 and 450 °C. To quantify and/or describe the nature of the oxide, a multi-technique and multi-scale approach is used. The oxygen concentration is measured by inert gas fusion (IGF) at each stage, the nature of the surface oxides is determined by X-ray photoelectron spectroscopy (XPS), and the dimensions and nature of the oxide network in aluminium are measured using transmission electron microscopy (TEM) coupled with energy dispersive X-ray spectroscopy (EDS). The microstructural evolution due to hot deformation is followed by electron backscatter diffraction (EBSD). These chemical analysis results and oxide quantification, coupled with microstructural evolution, allow to describe the acceleration of oxidation kinetics during extrusion and determining its causes in order to suggest ways of optimizing the process.

Paper 1409 1 **Unravelling the copper precipitation mechanism at the grain boundaries and intergranular cementite in copper alloyed ferritic steels: steps towards enhanced understanding and use of copper in steel scrap.**

Mrs. Asmaa Elbeltagy, Germany

Highlight (Oral Presentation 20')

Abstract

The need to accommodate copper in steels is becoming increasingly important due to the rising accumulation of copper in steel scrap, driven by the transition from fuel combustion vehicles to electric vehicles. This shift is a necessary step toward circularity and reducing carbon dioxide emissions from the steel industry.

Copper precipitation is one of the most promising strengthening mechanisms in steels, offering enhanced fatigue resistance, ductility, and strength. These benefits contribute to improved lifespan and weight reduction in ferritic steels. While copper precipitation within the matrix is well understood and extensively studied, its behavior at grain boundaries and intergranular carbides has not been studied, investigated, or considered in the design of copper-alloyed steels. This is despite its critical influence on grain boundary strength, material properties, crack initiation and propagation resistance, and, ultimately, structural integrity and fatigue life.

This study presents novel findings on the accelerated precipitation mechanism of copper at intergranular cementite. Using a combination of transmission electron microscopy (TEM), atom probe tomography (APT), and in-situ small-angle X-ray scattering (SAXS), along with MatCalc© simulations, we systematically investigate medium- and ultra-low-carbon copper-alloyed ferritic steels. The study examines the effect of carbon content and reveals an accelerated Cu-precipitation mechanism at grain boundaries during austenite decomposition and isothermal aging.

Unravelling this unique mechanism—its relation to austenite decomposition, cementite formation, and varying carbon content—provides valuable insights for optimizing copper-containing ferritic steels and potentially leveraging intergranular Cu precipitation for grain boundary engineering to enhance mechanical properties. By refining heat treatment processes, chemical composition design, and product development, these findings contribute to extending product lifespan and increasing the viability of higher copper concentrations in steel recycling, making sustainable steel production more feasible.

2

Life cycle assessment for a holistic approach to sustainable steel design

Mrs. Hannah Naber, Germany

Oral Presentation (20')

Abstract

Steel production is undergoing a significant transition toward a circular, recycling-based process, leading to changes in chemical composition. This shift is driven by the presence of contaminated scrap fractions, introducing impurities such as copper, and an increasing emphasis on the environmental impact of raw materials. To enhance circularity, the recyclability and reusability of steel depends on the controlled mixing of different iron sources and scrap, as well as the selection of alloying elements.

In addition to physical material optimization, integrating materials into the digital representation of production processes is crucial. The Digital Material Shadow provides a standardized approach to material digitalization, enabling more accurate and efficient process modeling.[1]

When developing alloy concepts, the focus must extend beyond cost and material properties to include environmental impact. A holistic optimization approach is essential, as the environmental footprint arises not only from raw materials but also from production processes.[2] Alloy composition can influence production parameters and even modify entire process steps. For instance, air-hardening steels form a martensitic structure through air cooling alone, eliminating the need for downstream heat treatment. This process modification significantly reduces energy consumption and emissions.[3]

To assess the environmental impact of steel grades, Life Cycle Assessment (LCA) is applied in accordance with DIN EN ISO 14040/14044 standards. The analysis follows a “cradle-to-gate” approach, evaluating aspects such as CO₂ footprint, toxicity, energy, and water consumption. [4]

Building on this foundation, a holistic analysis concept incorporating the Digital Material Shadow was developed and implemented. Individual steels were assessed up to the industrial semi-finished product stage through an ecological evaluation of melting processes. By integrating environmental impact, costs, and material properties, a comprehensive assessment was conducted, enabling a data-driven and sustainable decision-making process for alloy design.

TiC-Containing Ferritic Steels: A Path Toward Lightweight, High-Performance, and Sustainable Vehicles

Mrs. Asmaa Elbeltagy, Germany

Oral Presentation (20')

Abstract

Future vehicle designs prioritize weight reduction to lower carbon dioxide emissions while maintaining maximum safety, including high shock absorption capacity. While high- and medium-manganese steels offer excellent strength-ductility combinations, they present industrial challenges and do not fully align with sustainability standards due to their high environmental impact. This makes the optimization of ferritic steels a crucial and more sustainable alternative.

Titanium carbides (TiC) as precipitating phases provide a promising approach to enhancing ferritic steel through precipitation strengthening while simultaneously controlling recrystallization degree. However, despite their potential for achieving the desired mechanical properties, the complex interaction between precipitation and recrystallization—depending on temperature, annealing time, and Ti content—poses significant challenges in optimizing steel design.

This study aims to unravel the complex relationship between Ti content, recrystallization mechanisms, and precipitation formation. A combination of advanced characterization techniques—including scanning transmission electron microscopy (S-TEM), atom probe tomography (APT), electron backscatter diffraction (EBSD), and in-situ small-angle X-ray scattering (SAXS)—is employed to investigate the interplay between processing parameters, precipitation behavior, recrystallization degree, and their collective impact on mechanical properties.

The insights from this study enable a more effective utilization of TiC to optimize precipitation strengthening while achieving the ideal recrystallization degree and optimal mechanical properties. This understanding contributes to the development and optimization of TiC-containing ferritic steel grades as environmentally friendly alternatives, meeting the evolving demands of the automotive industry and aligning with standards for sustainable steel production and use.

Sustainable manufacturing of FeCrCoMnNi high-entropy alloy (HEA) using ferroalloys feedstock via slagging methods

Mr. Yao Su, South Korea

Oral Presentation (20')

Abstract

Ferroalloys play an indispensable role in the materials world, especially in the steelmaking process. In the current study, commercial ferroalloys, such as high-carbon ferromanganese (HCFMn), low-carbon ferrochromium (LCFeCr) and ferronickel (FeNi), are utilized in the manufacturing of the ultra-clean FeCrCoMnNi-based high-entropy alloy (HEA) in view of the cost-effectiveness and the sustainability of manufacturing process. However, elemental impurities such as carbon, oxygen, sulfur and other trace elements in ferroalloys can affect the mechanical and corrosion properties of HEA.

The present study explores the deoxidation and desulfurization behaviors of FeCrCoMnNi HEA with varying carbon content (0.3, 0.7, and 1.8 at%) using a CaO-Al₂O₃-MgO slag in an induction melting furnace at 1773 K. The results indicate that different carbon levels significantly affect the grain size, nano twinning, and carbide size, as observed through EBSD and SEM analyses. These microstructural changes influence mechanical properties, including yield strength, ultimate tensile strength, and elongation, as revealed by tensile testing.

Additionally, the corrosion properties of the three types of C-alloyed HEA were examined in 0.1 mol H₂SO₄, with corrosion film composition characterized using XPS method. The study discusses the effects of carbon content on microstructure development, strengthening mechanisms, and corrosion resistance.

Paper 1184 5 **Solvometallurgical process for copper and cobalt extraction from DRC oxide ores using Di-(2-ethyl hexyl)phosphoric acid**
Mr. Heritier Tshipeshi Makina, Belgium
Oral Presentation (20')

Abstract

Conventional metallurgical process of metals like copper and cobalt from their primary resources are often energy and emissions intensive. Herein we report an alternative solvometallurgical process to extract copper and cobalt from Kamwale ore site in Democratic Republic of Congo. Copper and cobalt bearing minerals were found as malachite and heterogenite, respectively. In this study, di-(2-ethyl hexyl)phosphoric acid (D2EHPA) diluted in kerosene was used for selective Cu and Co dissolution. To reduce Co (III) to Co(II), sodium metabisulfite or copper were studied separately. The influence of leaching parameters like the extractant and reducing agent amounts, solid-to-organic ratio, leaching temperature and time were investigated. Under optimal conditions, >98% of Cu and >87% of Co can be leached with no Fe extraction. While Co dissolution is chemically controlled, Cu dissolution is also impacted by diffusion control. The speciation of dissolved Cu and Co in D2EHPA by UV-Vis spectroscopy showed the formation of Cu(II) and Co(II)-D2EHPA complexes. Following the leaching, the loaded organic phase was stripped using diluted sulfuric acid solution. Several stripping parameters were optimized including pH, organic-to-aqueous ratio and contact time. This way, >93% Cu and >99% Co can be stripped from the organic phase which effectively regenerates consumed D2EHPA for reuse as confirmed by FTIR analysis.

Paper 2179 1 Hidden insights of Friction Welding Processes - Linking material behaviour to process performance

Prof. Chris Bennett, United Kingdom

Keynote (Oral Presentation 40')

Abstract

Friction welding is a group of high-integrity, solid-state joining processes that are widely used in the joining of advanced materials employed in the aerospace industry. These processes use mechanical friction to generate heat at the interface between two workpieces, followed by the application of pressure to forge them together. These processes are highly dynamic in nature, with materials experiencing both high heating and deformation rates, leading to complex material evolution. While these techniques offer numerous advantages over traditional fusion welding processes, they also present several material-specific challenges that engineers must address to achieve successful welds, for example, material flow behaviour represents a significant challenge as during friction welding, materials must undergo plastic deformation to create intimate contact at the interface. Materials with high flow stress or low ductility at elevated temperatures can be difficult to process.

Throughout his career, Prof. Chris Bennett has been dedicated to understanding the detail of these processes and his talk will cover a range of experimental and modelling techniques that have been employed to develop a deeper understanding of the processes, revealing their effects on the material both during the process and the characteristics of the joints and properties of the resulting material. The talk will include both experimental and modelling characterisation approaches, residual stress prediction and measurement, and the characterisation of mechanical material properties of the resultant material. Through this work, new insights and a holistic understanding of the processes have been gained, and suggestions for further work to further enhance the understanding and optimisation of processes for existing and new materials will be presented.

Paper 694 **2** **Secondary Grain Boundary Dislocations Modulate Segregation Energy Spectra in Fe-W Alloys**
Dr. Xinren Chen, Germany
Highlight (Oral Presentation 20')

Abstract

Grain boundaries (GBs) are key sites for structure-specific chemical segregation of solute atoms. While traditionally defined as planar defects, GBs inherently exhibit curvature due to the three-dimensional (3D) topology of grains, necessitating the formation of secondary grain boundary dislocations (sGBDs). In this study, we demonstrate that these topologically necessary sGBDs have a significant impact on segregation energy spectra, often surpassing the effects of defect-free GBs. Using advanced nanoscale correlative tomography, which integrates crystallographic and chemical analysis, we establish a direct quantitative relationship between sGBDs and segregation energy in a model Fe-W alloy. Our findings introduce an additional degree of freedom for tailoring segregation behavior, presenting new opportunities for microstructural engineering and the development of next-generation materials.

Effect of humidity on the wear behaviour of a medium carbon high silicon nanostructured bainitic steel

Ph.D. Chiara Soffritti, Italy

Oral Presentation (20')

Abstract

Nanostructured bainitic steels (NBSs) have attracted significant attention due to their exceptional combination of strength, ductility and wear resistance. These materials exhibit ultimate tensile strengths exceeding 1.5 GPa alongside fracture elongations of approximately 20%. Additionally, their chemical composition requires limited amounts or even the complete absence of expensive alloying elements such as Cr, V, Mo, and Nb, making them highly attractive for various industrial applications, particularly in the transportation sector.

The mechanical performances and wear resistance of NBSs under dry sliding conditions align with the transportation industry's current demands for reduced CO₂ emissions and improved passenger safety. The high strength of these materials enables the production of thinner, lighter components, leading to lower fuel consumption without compromising intrusion resistance. Moreover, their remarkable durability reduces maintenance costs and enhances vehicle safety. As a result, significant research efforts have been dedicated to comprehensively understanding the in-service properties of NBSs.

While numerous studies have explored the wear behaviour of NBSs under dry sliding conditions, focusing on the influence of heat treatment parameters, applied forces, sliding speed and

lubrication, the impact of environmental humidity remains poorly understood.

Investigating the role

of humidity is crucial to accurately describing material degradation under real-world operating

conditions, considering that a large part of the technological applications operate in the open air.

Indeed, a potential shift in the wear mechanisms at different humidity levels due to the lubrication

effect of moisture and the modification of the oxide layer that covers the steel can occur.

This study

examines a 0.45C-2.8Si-2.7Mn-0.56Al nanostructured bainitic steel under three humidity levels:

low (<25 %), medium (~50%), and high (~90%). The microstructural characterization was carried

out by SEM, XRD, Vickers microhardness before and after wear tests. The tribological tests comprised ball-on-disc configuration (ASTM G99-17 standard) using nanostructured bainitic steel

discs 45 mm in diameter and 5 mm in thickness and a 100Cr6 steel ball 6 mm in diameter as

counter-body material. The obtained wear tracks were analyzed by optical profilometer to evaluate

the wear rates and by SEM to analyze the wear mechanisms. The results showed that relative

Federico García Lorca Auditorium (Level 0)

humidity has a noticeable effect on wear damage and oxide layer formation with significant modification of the wear rate with the humidity level. These outcomes enable to describe the effects of environmental conditions and oxide layers on the wear performance of NBSs and so to predict the behavior in different practical applications.

Copper-Free, Eco-Friendly, Composite Brake Linings: Optimization of Manufacturing Parameters

Mr. Abduselam Abubeker Issa, Turkey

Oral Presentation (20')

Abstract

Brake pads are critical for the safety of vehicles, ensuring reliable performance on speed control. The frictional behavior of automotive brakes is defined by the active surfaces of the disc, pad, and particles between them, making this a complex tribological system. There are several criteria that have to be met. First of all, the coefficient of friction should remain as stable as possible with time, temperature, erosion, etc. In addition, the optimization of wear performance is crucial to maintain a long service life of the pad while not damaging the opposite surface, the disc. Moreover, the particles generated as a result of wear should not harm the environment. It was found that the copper particles, which is one of the primary constituents of the brake pads, had toxic effects on aquatic life. As a result, in 2010, U.S. Environmental Protection Agency initiated a phase-out of copper in brake pads. Accordingly, this study focuses on the production of an eco-friendly, copper-free brake pad. A phenolic resin is used as the binder of the lubricants, friction modifiers, abrasives, fillers and the copper-replacement material. Hot-pressing technique is employed in the production of brake pad samples. The effects of processing parameters (pressure, temperature and time) on the friction and wear performance were analyzed within the scope of this study. The thermal transitions of the resin were characterized with thermogravimetric analysis (TGA) while pin-on-disc wear tests according to ASTM G99 were employed for measuring the coefficient of friction (COF) and wear rates at a temperature range of 100°C-350°C. The wear surfaces were examined with both stereo and scanning electron microscopes.

Paper 1804 6 **Effect of Surface Defects and Oxide Layers from Different Stages during Hot Rolling on the Bendability of Martensitic Wear-resistant Steel**
Mr. John Joy, Sweden
Oral Presentation (20')

Abstract

During hot rolling of steel, various defects are introduced on and below the surface of the steel strip. These defects will propagate and evolve through the different stages of the hot rolling process and may finally affect the material performance during subsequent manufacturing processes when components are produced. In forming operations, the bending behaviour of high-performance steel is critical to ensure an efficient and robust production process. Understanding the connection between surface defects and oxide layers and the bendability of high-performance steels is critical for forming process optimisation. The aim of this study is to investigate the surface/near surface defects and oxide layers for a high-performance martensitic wear-resistant steel at different stages of the hot rolling process (roughing mill, finishing mill, and after the final processing stage) and correlate these to the bendability. Pre- and post-bend test analysis was performed using scanning electron microscopy with energy dispersive spectroscopy, 3D white light interferometry, X-ray diffraction, and microhardness measurements. Friction free standard bend tests VDA 230 were conducted at a 90° bend angle with the bend axes parallel and perpendicular to the rolling direction. In general, the bendability of samples in levelled condition after finishing process is less compared to as-rolled condition. The results show that the formation of red scale between the steel substrate and primary oxides significantly affects the bendability of the martensitic wear-resistant steel in both as-rolled and levelled conditions. Red scale is a type of oxide rich in silicon called fayalite, which is formed during the hot rolling process and was found to be embedded non-homogeneously across the surface. Detailed characterisation indicated that crack initiation during bending was primarily concentrated at the red scale region. The presence of sub surface cracks parallel to the bend axis in this area further shows that presence of red scale negatively affect the formability. Abrasive wear grooves that are formed during the finishing process have also been found to affect the bendability.

Residual Stress Analysis for Aluminum Cast Alloys

Mr. Lukas Helml, Austria

Oral Presentation (20')

Abstract

The measurement of residual stresses in aluminum castings is a challenging task due to the coarse grain microstructure. The small number of large grains that can be analyzed is a limiting factor for X-ray based analysis methods such as the $\sin^2(\psi)$ method. In addition, if the microstructure is too coarse, it can be difficult to interpret the results from the drilling method.

To address this challenge, in the present work we use a wrought alloy with comparatively small grains and produce parts with similar geometry to the cast part. The heat treatment process of the wrought alloy is analogous to that of the cast alloy, involving solution annealing followed by water quenching and subsequent artificial aging. During the quenching process, residual stresses are induced which are subsequently relieved during aging. Accurate knowledge of the material behavior during all stages of heat treatment is critical to predicting the residual stress state. The microstructural state of the alloy is analyzed metallographically, and the mechanical behavior of the material is characterized using a dilatometer.

In addition to the experimental characterization, a state parameter based material subroutine called Simple-MSE is employed in a finite element simulation, which takes into account the temperature and strain rate dependent mechanical properties of the material. The subroutine is implemented in ANSYS-Mechanical. To verify the simulated results, the residual stresses of the wrought alloy parts are measured using the hole-drilling method and the $\sin^2(\psi)$ method. The results of both methods are compared with the simulation and the advantages and challenges are discussed.

Paper 951 1 **Tensile deformation behavior of CoNi-based single crystal superalloys at different temperatures**

Lu Song,

Highlight (Oral Presentation 20')

Abstract

γ' -strengthened Co-based superalloys have been considered as the candidate for high-temperature applications due to their analogous $\gamma+\gamma'$ configuration and higher melting temperature compared to the widely used Ni-based superalloys. Moreover, the compositions have been optimized into CoNi-based superalloys to obtain good comprehensive properties, such as microstructural stability and environmental resistance. To further enhance the mechanical property of CoNi-based superalloys, a high-Cr CoNi-based single crystal was developed, and its tensile deformation performance at different temperatures was investigated by analyzing the featured deformation substructures and their elemental segregation. The 0.2 % yield strength initially decreases up to 650 °C. Subsequently, the yield strength anomalously increases at 760 °C before abruptly dropping off at higher temperatures. At 760 °C, the deformation behavior is characterized by continuous strain hardening with increased plastic strain. The plastic deformation is initially dominated by forming anti-phase boundary (APB)-coupled dislocation pair shearing γ' precipitates. With the increase of strain, the leading partial dislocations of stacking faults (SFs) shear γ' precipitates. Subsequently, the interactions of SFs further enhance the deformation resistance due to the formation of sessile stair-rod dislocation and coherent SF interfaces preventing further expansion of other SFs. Different from 760 °C, with the increase of temperature, the flow stress decreases first and increases with the increasing strain during the yield process. The initial decrease of flow stress is mainly ascribed to the formation of SFs inside the γ' precipitates. A similar strengthening mechanism of SF interactions was observed for the increase of flow stress. Interestingly, APB-related complex deformation substructures, such as APB-SF, were also observed up to a strain of 2%, and its interaction with SFs is responsible for the further strain hardening process. The Co and Cr segregation at SF was investigated to be associated with the formation of APB-related complex deformation substructures. In addition, a comparison of the deformation mechanism was made among the Co-Al-W, CoNi and Ni-based single crystal superalloys to further understand the strengthening mechanism of γ' -strengthened superalloys, which is also meaningful for enhancing the mechanical properties of CoNi-based superalloys.

Paper 2006 2

Advanced quenching of steels for controlled and improved properties

Prof. Mattias Calmunger, Sweden

Oral Presentation (20')

Abstract

Proper and precisely controlled heat treatment of steel components can significantly enhance their mechanical properties. Processes like hardening of carbon steels or quench annealing of duplex stainless steels involve specific phase transformations that must be accurately controlled during quenching. The cooling rate directly influences the final microstructure of the steel, which in turn determines its mechanical properties. Improper cooling can lead to insufficient hardening, undesired residual stresses, or even cracks, resulting in premature failure of the component.

As the complexity of steel component geometries increases and the demand for tailored mechanical properties grows, traditional quenching methods often fall short. There is a need for advanced quenching techniques that can provide tailored or uniform and precise control over cooling rates and subsequently microstructures. These techniques must be adaptable to various component sizes and shapes, ensuring desired properties throughout the material.

One promising approach is the use of impinging jet quenching. This technique provides high quenching rates and the ability to create tailored microstructures within a single component. By varying parameters such as jet location, number, spacing, and flow rate, impinging jet quenching can be customized to meet the specific needs of different steel components.

This study investigates carbon steels and super duplex stainless steels (SDSS), focusing on creating microstructure gradients and optimizing mechanical properties using the Impinging Jet Quenching Technique (IJQT).

For steel with varied hardenability, the quenching process resulted in a transition from a fully martensitic state to a softer ferritic/bainitic condition. This gradient was confirmed through microscopy, tensile tests and hardness measurements. The steel with higher hardenability predominantly remained in a fully hardened martensitic state with slight ferritic and bainitic features. Temperature evolution during quenching was recorded and used to predict phase transformations, final hardness, and residual stresses, showing good correlation with experimental results.

For the SDSS results showed a consistent decrease in impact toughness with decreasing cooling capacity, although intermetallic precipitation was observed only in some locations. Bars cooled with higher air flow rates met toughness and precipitation quality criteria, making air cooling with IJQT applicable for 80 mm and smaller diameters.

These results highlight IJQT's potential to precisely control the quenching process, optimizing mechanical properties in both boron-containing carbon steels and SDSS, enhancing their durability and performance in various industrial applications.

Paper 1383 3 **Wire-arc directed deposition of Ti-6Al-2Sn-4Zr-2Mo: insights on mechanical behavior and high temperature creep dynamics**
Mr. José L. Neves, Austria
Oral Presentation (20')

Abstract

Ti-6Al-2Sn-4Zr-2Mo (wt.%) was developed in the late 1960s as a high-temperature alloy, known for its excellent tensile and creep strength, with long-term service capability at temperatures up to 425°C. It is widely used in aerospace applications, including compressor blades, impellers, and engine exhaust nozzle structures. Despite its established role in industry, its application in wire-arc directed energy deposition (waDED) has remained largely unexplored. To date, only one study has examined Ti-6242 in this context, focusing on microstructural details and dissimilar alloy bonding. The present study investigates the feasibility of processing Ti-6242 using cold metal transfer-based waDED. Deposited samples were heat-treated following industry recommendations and mechanically tested. Room-temperature mechanical properties were evaluated through hardness measurements and tensile testing, while high-temperature behaviour was assessed using full-scale tensile creep tests under varying temperatures and constant loads. After a two-stage heat-treatment, a solution heat treatment at 955°C for one hour and aging at 650°C for eight hours (both cooled to room temperature using air cooling), the deposited material, achieved a yield strength of 922.01 ± 22.4 MPa, 1023.1 ± 16.8 MPa ultimate strength and an elongation to fracture of 7.3 ± 1.8 %. The microstructures of the deformed and crept samples were further characterized using scanning electron microscopy and electron backscatter diffraction to evaluate the deformation mechanisms under different loading modes and temperatures. The results demonstrate that, despite its limited prior exploration, this process is capable to produce Ti-6242 samples with mechanical properties that meet industry standards. These findings provide a basis for expanding the use of the wire-arc DED process for high-temperature alloy applications.

Paper 829 4 Influence of the Pt addition on the primary microstructure of heat-resistant Ni-based superalloy for aerospace applications

Dr. Lukasz Rakoczy, Poland

Oral Presentation (20')

Abstract

Single crystal (SX) Ni-based superalloys are currently utilized in civil and military aeroengines at temperatures up to 1100–1150°C. This is due to their excellent combination of environmental resistance to corrosion and oxidation, along with superior mechanical properties, particularly under creep conditions. A distinguishing characteristic of Ni-based superalloys is the high volume fraction of γ' precipitates, which remains stable up to 1000 °C. However, their strength diminishes rapidly beyond 1000 °C, primarily due to a reduction in precipitate volume fraction, accelerated diffusion rates, and directional coarsening. To develop Ni-based superalloys capable of maintaining microstructural stability at operating temperatures of approximately 1150–1200 °C, it is essential to explore new compositional domains. The intermetallic γ' phase is key in strengthening the γ matrix and its chemical composition, distribution, morphology, size and volume fraction determine the stability of turbine blades during service.

In this work, the SX Ni-based superalloy René N5 (Ni-7.0Cr-8.0Co-2.0Mo-3.0Re-5.0W-6.2Al-7.0Ta-0.2Hf) has been subjected to chemical composition modifications with platinum (Pt). Observations and analyses of five variants were carried out using thermodynamic simulations, differential scanning calorimetry (DSC), X-ray diffraction (XRD), light microscopy (LM), scanning electron microscopy (SEM), and X-ray spectroscopy (EDX). Thermodynamical simulations showed that the Pt addition effectively influences the stability of γ' and increases its volume fraction. Pt is partitioning mainly in the γ' not γ matrix. Microstructure of produced castings characterized by a typical dendritic structure with a dominant amount of cubic-like intermetallic γ' phase.

This work was supported by the National Science Center (Poland) under project “Monocrystalline Ni-based superalloys modified with platinum for the production of critical rotating turbine components of aircraft engines” (2023/51/D/ST11/00945).

Paper 576 **5** **The use of High Temperature Profilometry-based Indentation Plastometry (HT-PIP) for the Rapid Characterisation of High Temperature Alloys**
Dr. James Miller, United Kingdom
Oral Presentation (20')

Abstract Profilometry-based indentation plastometry (PIP) is a technique that enables the rapid characterisation of the stress-strain curve of a material. It combines experimental readings of the residual profile from indentation testing and an iterative inverse FE model to extract plasticity characteristics, such as yield stress and work hardening rates, more rapidly than tensile testing.

A recently developed hot stage now allows PIP to be performed at temperatures up to 800°C. The low thermal inertia of this stage and small material volume requirements offers advantages in terms of minimising heating times and time at temperature. The effects of oxidation and oxygen uptake are monitored for several alloys. The short time at high temperatures has prevented the formation of oxides thick enough to change the indent profile significantly.

A wide range of materials - including steels, nickel superalloys, aluminium, tungsten, niobium and copper – have been tested. Results across the materials spectrum are aligned with high temperature tensile testing in cases where the mechanical behaviour is not significantly affected by creep.

This advancement should enable high-throughput, high temperature mechanical testing, offering a faster and more efficient alternative to conventional methods.

Impact of the initial HAZ microstructure of low alloy steels on intergranular embrittlement due to thermal ageing

Mrs. Apolline Bouyer, France

Oral Presentation (20')

Abstract

The reactor vessel, the pressurizer and the steam generators used in nuclear power plants are fabricated from low alloy steels. Due to their large size, each component is made of smaller parts, that are welded together. The area where two steel pieces are welded together is composed of the weld metal, the Heat Affected Zone (HAZ) and the base metal.

These components are exposed to temperatures up to 345°C, during long period of time, leading to thermal ageing. Current norms define HAZs to be the most susceptible regions to thermal ageing. Indeed, it is commonly assumed that the shift of their ductile-to-brittle transition temperature (DBTT) upon ageing is three times larger than that of the base metal.

Under these conditions, thermal ageing is due to Reversible Temper Embrittlement (RTE) or intergranular embrittlement, which is a non-hardening thermal ageing mechanism. This mechanism is characterized by impurities segregating to grain boundaries (mainly phosphorus). The phosphorus segregation at prior austenite grain boundaries reduces grain boundaries cohesion, which lowers the critical intergranular fracture stress, resulting in an increase in DBTT. Consequently, a ductile fracture at a given temperature before thermal ageing can switch to a brittle fracture at the same temperature after thermal ageing.

This study aims to understand how the initial HAZ microstructure influences the embrittlement due to thermal ageing. While the base metal microstructure of low alloy steels is mainly bainitic, HAZ gather many different microstructures, each with their own susceptibility to thermal ageing. In this study, a variety of simulated HAZ microstructures was generated using a Gleeble thermomechanical simulator. After performing a post-welding heat treatment, half of the specimens created were aged using an accelerated ageing heat treatment. Instrumented Charpy V-notch impact tests were conducted on the different microstructures, both in the initial and aged conditions, to build DBTT curves. The 'load diagram' method was applied to analyze the force-displacement curves measured during the Charpy tests, to estimate the critical cleavage fracture stress for each microstructure before and after thermal ageing. The intergranular segregation was measured by Auger Electron Spectroscopy (AES). According to the first AES results, it seems that the HAZ microstructure has little influence on the phosphorus concentration at grain boundaries after thermal ageing, although it significantly affects the shift in DBTT.

Paper 2180 1 **Damage tolerance of nanostructured thin films during multiaxial deformation using polymer supported tensile tests**

Dr. Barbara Putz, Switzerland

Keynote (Oral Presentation 40')

Abstract

Brittle layers are often dominating the fracture behavior of flexible thin film nanolaminate structures through stress concentration, whereby the modulation period ($t_{\text{brittle}} + t_{\text{ductile}}$, film thickness t) and the modulation ratio ($t_{\text{brittle}}/t_{\text{ductile}}$) influence the extent of embrittlement. Atomic layer deposition (ALD) holds enormous potential to design nanolaminates with tailored mechanical properties, due to the unique way in which materials are built in an atomic layer-by-layer fashion. When combined with other thin film techniques, such as magnetron sputtering (PVD), without breaking vacuum, the layer-by-layer nature of ALD can be harvested to design (sub)nanoscale interface and nanolaminate architectures with extremely good control over the layer thicknesses. For metal-oxide interfaces (Al/Al₂O₃), the minimum ALD layer thickness of one monolayer (nominal thickness 0.14 nm) far exceeds the thickness restrictions of natural oxidation of Al (2-10 nm¹). The mechanical behavior of resulting nanolaminates consisting of Al (10-150 nm, PVD) and Al₂O₃ (0.1-10 nm, ALD) is studied in-situ under uni- and biaxial tensile loading using polymer substrates. Ultrathin oxide layers confine the grain growth of the metallic thin films, creating sub-layer architectures with unique properties. In-situ film stress and electrical resistance measurements as a function of varying oxide and metal layer thickness show that brittle failure of the nanolaminates can be avoided for oxide thicknesses ≤ 2 nm and the maximum strength is obtained with 25 nm Al layers. In the second part of the talk, the potential of modifying the deformation behavior of metallic thin films via incorporated nanoparticles will be discussed, produced via combined magnetron sputtering and a nanoparticle source. The thin films contain nanoparticles with a tailored size, shape, distribution and volume density without precipitation-related restrictions concerning phase diagrams and solubility. Their microstructures and nanoparticle concentrations were confirmed and characterized by TEM. For inherently brittle films (200 nm Mo), suffering from through-thickness crack formation at low applied strains, incorporating various amounts of Al nanoparticles (20 nm diameter) can significantly improve the electro-mechanical behavior. The observed changes in the developing crack pattern, through crack deflection at nanoparticles, correlates well with a lower electrical resistance at equivalent strains and changes in the stress-strain curve. For ductile films (50 - 200 nm Cu and Au) the observed influence of nanoparticles (W, 4 nm diameter and Co, 10 nm diameter) strongly depends on the grain size and film thickness, whereby both softening and strengthening mechanisms have been observed.

Paper 1228 2 **The potential of Scanning Microelectrochemical Techniques to monitor chemical activity across surface layers and coatings on metals**
Prof. Ricardo M. Souto, Spain
Highlight (Oral Presentation 20')

Abstract

Advanced methodologies for protection against material degradation aim at the design, development and synthesis of new materials and characterization procedures operating at the micro and submicrometer scale of complex microstructures. Environmentally induced degradation of a material involves chemical reactions initiated at the micrometer and submicrometer scales. On the other hand, the choice of protection strategies for a specific surface depends on a judicious choice of surface layers and coatings as well as active molecules (such as corrosion inhibitors). Unfortunately, very often the limiting step for the development of effective functionalized anticorrosion coating systems is the lack of information on the local dissolution rate as a function of physicochemical characteristics, such as pH, aggressive ion concentrations and dissolved oxygen for a given metal/coating system, as to properly design the triggering condition for the smart release of active protective agents from the functionalized material. Therefore, to properly design and fabricate a functionalized surface layer or coating suitable for a certain metal-environment combination, it will be necessary to address information on the chemical changes occurring in the corroding substrate, and the actual surface protection mechanism at the micrometer scale in situ, that is, at finer levels of spatial resolution and time scales that can facilitate advances in lifetime prediction compared to conventional macroscale corrosion monitoring strategies.

The recent application of new characterization techniques based on electrochemically sensitive scanning probe methodologies, which are an extension of local probe techniques originating from the use of microelectrodes as probes in near-field microscopic techniques to operate inside a small electrochemical cell, has found potentially-broad applicability in Corrosion Science. Among them, scanning electrochemical microscopy (SECM) takes advantage of the successful combination of chemical and/or electrochemical selectivities provided by microelectrode probes with the fine spatial resolution of the scanning microscopies to probe reaction dynamics in the complex environments and microstructures of alloys and composite materials, creating new opportunities to explore the design of materials and tailored corrosion protection methods (including inhibitors, coatings and smart materials) and to achieve a link between micrometer- and submicrometer-level processes and macroscopic behaviors. In this work we report our new advances in the monitoring of the chemical reactivities of surface layers and coatings applied on metal substrates exposed to humid environments by using scanning microelectrochemical techniques in situ with spatial resolution.

Characterization of the fracture toughness of material interfaces

Mr. David Miñón, Spain

Oral Presentation (20')

Abstract

The study of fracture modes is essential for the characterization of fracture toughness of material interfaces, whether adhesive or chemical. This work presents a methodology for the experimental measurement of fracture modes. The experimental setup includes standardized mechanical testing procedures, such as double cantilever beam (DCB) and end-notched flexure (ENF) tests, to quantify mode I and mode II fracture toughness, respectively. Additionally, specimens have been designed whose constitutive laws facilitate the characterization of the mechanical properties of the interface. Furthermore, the study incorporates a numerical correlation that enables the validation of experimental results through finite element analysis (FEA). The numerical simulations employ cohesive zone models (CZM) based on the traction-separation law.

4

Adhesion properties of carbide-rich nano-coatings produced by ion irradiation

Dr. Adel Sarolta Racz, Hungary

Oral Presentation (20')

Abstract

The good adhesion of coatings to the substrate is essentially important in various applications e.g.: catalysis, protective coatings etc. By applying ion irradiation, it is possible to improve the adhesion of coatings due to the ion mixing of coating to the substrate. Herein, carbide-rich nano-layers are formed by means of noble gas irradiation. Various multilayer structures (C/Mo and C/W with individual layer thicknesses of 10-20 nm) on a silicon substrate were irradiated by argon and xenon ions with energy in the range of 40-120 keV and fluences between $0.25 \cdot 10^{16}$ ions/cm². At the interfaces molybdenum-carbide and tungsten-carbide were formed. The carbide in-depth distributions have been detected by XPS depth profiling [1]. The adhesion of the coating has been tested by ramped load scratch test in a nanoindenter with a spheroconical diamond tip. The critical loads for the coating delamination were obtained from the optical microscopic images of the individual scratches. Depending on the irradiation conditions the adhesion of the coatings has been increased. The structural changes along the scratches were investigated extensively by cross-sectional transmission electron microscope. Serious changes were observed (amorphization, crystallization) in the coating and the silicon substrate due to scratching.

5

Damage and delamination behaviour of oxide scale layers

Mr. Simon Peddinghaus, Germany

Highlight (Oral Presentation 20')

Abstract

In hot bulk forming processes of steel, oxide scale layers are formed in dependence of the occurring process conditions. As remaining oxide scale can weaken the formed workpiece, it has to be removed at the end of the process. Through this, the oxide scale formation can lead to a mass loss of up to 3 % in addition to influencing the forming process for example by affecting the friction conditions or increasing the die wear [1]. However, oxide scale layers can protect against further oxidation and limit the mass loss as long as they are not damaged, for example through cracks [2]. For the precise numerical description of a forming process using a finite element simulation, it is therefore necessary to model the formation and damage behaviour of the oxide layer. This paper presents a characterisation and modelling approach to describe the damage behaviour depending on the process conditions as well as the alloy composition.

Procedure

The properties and layer structure of the oxide scale was characterised through nanoindentation. The damage behaviour was investigated by means of compression and tensile tests with oxidated specimens. The tests were carried out at varying oxidation and testing conditions such as the forming temperature or strain rate. In addition, the occurring oxide layers and their properties for multiple steel alloys, with different contents of carbon and chromium, were compared.

The experimental data was used to develop a numerical modelling approach for finite element simulations. A mesh splitting algorithm was applied to describe the damage behaviour of the oxide scale layers in forming processes through the occurring stresses.

Key findings

- The damage behaviour of oxide scale layers is dependent of the oxidation parameters, the occurring stresses and the particular alloy contents of chromium and carbon.
- Oxide scale failure can be modelled in dependence of the process parameters and stress state using a mesh splitting algorithm.

Abstract

The addition of metal components into dielectric matrices is an interesting way for increasing the effective permittivity. Recently other interesting electromagnetic properties have been reported in such composites, which make them attractive for microwave absorption, electromagnetic shielding, filters, capacitors, etc. [1]. This work investigated Ag-BaTiO₃ composites, in which optimum compositions and phase arrangements are searched to find: (i) giant permittivity in the dielectric state below the percolation, or (ii) metacomposite properties, above the percolation (near-zero or negative permittivity). To produce different types of microstructures after sintering, Ag-BaTiO₃ composite powders were prepared by mixing BaTiO₃ with Ag micropowders or by precipitation of Ag nanoparticles from AgNO₃ onto BaTiO₃ grains. The composites were sintered in the range of Ag melting temperature (960°C). The resulting ceramics have grain sizes in the range of 350 nm – 3µm and bi-modal distribution of silver filler, with both fine Ag inclusions and large agglomerates embedded into the ceramic matrix. The frequency and temperature dependence of the dielectric, conductive and electromagnetic properties are discussed in function of Ag filler addition and the microstructural characteristics. Different types of microstructures were generated by the interplay between Ag melting/infiltration/recrystallisation processes taking place simultaneous with the ceramic consolidation. In-situ monitoring of these processes allowed to identify the optimum sintering strategy in order to derive different types of microstructures and related properties.

Modeling by 3D finite element calculations (FEM) demonstrated that dielectric, ferro/piezoelectric and tunability properties can be tuned through inhomogeneous field distributions at the interfaces between metal-ferroelectric, thus subjected some regions to higher fields and generating enhanced electrical responses [2]. Three percolation ranges (see Figure) with substantial permittivity increase are found experimentally and described by FEM modeling, as resulted from specific microstructural metallic configurations. As resulted from calculations, the frequency ranges for the metacomposite properties can also be tuned by composition and microstructural design.

Paper 826 2 **Enhancement of Corrosion Resistance of MAO/Polydopamine/Poly(lactic Acid)-Coated AZ31 Magnesium Alloy for Biomedical Applications**

Dottorato di Ricerca Fulvia Desiderio, Italy

Oral Presentation (20')

Abstract

This paper aimed to investigate the enhancement of the corrosion resistance of a protective system applied on the AZ31 magnesium alloy to be used as an orthopedic biomedical device, composed of three different superimposed layers: (a) magnesium-based oxide, (b) polydopamine, and (c) poly(lactic acid). Specifically, morphological and chemical analyses, crystallographic, roughness, and micro-hardness were carried out. The electrochemical measurements were performed in Hanks' Balanced Salt solution at 37 °C. The micro arc oxidation (MAO) treatment involved the classic pancake structure of the oxide with a consequent high extension of the real area. The sealing of its pores via the polydopamine was well highlighted through the surface roughness analysis. As expected, the magnesium oxide layer reduced the degradation rate. The presence of polydopamine on the oxide layer improved the corrosion resistance of the alloy, showing a pseudo-passivity range in the potentiodynamic polarization curve, due to the filling of oxide pores. The highest impedance modulus in the electrochemical impedance spectroscopy analysis during the temporal observation of 168 h was observed when all coatings were applied on magnesium substrate, due to a synergetic action. Thus, the multilayers should represent a protective system to control the degradation process.

Ultrafast Laser Functionalization of Doped Zinc Oxide Films

Mr. Gonzalo Gomez-Munoz, Spain

Oral Presentation (20')

Abstract

Zinc oxide (ZnO) is a large-bandgap semiconductor with n-type conductivity due to natural oxygen vacancies. It has additionally very interesting properties (such as biocompatibility, piezoelectricity or antibacterial activity [1,2]) which makes it a good candidate as active material for photocatalysis, gas sensing and other environmental applications [3]. ZnO can be doped to enhance its conductivity and light absorptance [4] by introducing shallow levels in the bandgap which increase the carrier density at room temperature and reduces the minimum energy required for a photon to be absorbed. Fs-laser texturing is an excellent functionalization tool for all type of materials. It has already been used to increase silicon absorptance by generating high aspect-ratio structures [5], to generate electrical anisotropies in ITO [6] or to enhance the wettability of marble surfaces [7]. By altering the topography of a material, it is not only possible to increase its active surface, something of primary importance for gas sensing and photocatalysis applications, but also to induce optical and electrical anisotropies while triggering a redshift of its transparency window [8], which can be beneficial for photovoltaics and TICs applications. In this work, doped ZnO films have been processed with ultrashort laser pulses ($\lambda = 1030$ nm, $\tau = 350$ fs) to generate Laser Induced Periodic Surface Structures (LIPSS) [9]. The films were grown by sputtering or pulsed laser deposition (PLD) using different amounts of Al_2O_3 and Yb_2O_3 as dopants. Coherent LIPSS propagation has been successfully induced for doping levels above a certain threshold. The optimization of the laser conditions for generating morphological, optical and electrical anisotropies in the doped films will be presented while the potential use of the laser generated structures in emerging applications will be discussed.

Paper 2020 5 **Novel Sulfur-rich polymers from inverse vulcanization as functional materials for all-polymer photonic structures and metamaterials**
Dr. Paola Stagnaro, Italy
Oral Presentation (20')

Abstract

Low materials costs, ease of fabrication and scale-up are making all-polymer photonic structures increasingly researched for light control applications. However, in their transparency region most of processable polymers have relatively low and similar refractive indices, this hindering strong light confinement effects [1]. In this regard, a new class of amorphous polymers with high content of S-S bonds, named inverse vulcanized polymers (IVPs) from the inverse vulcanization (IV) reaction they are obtained [2], promise photonic building blocks with very high refractive index and excellent transparency in the near infrared region (NIR), that is the telecommunication window.

The solvent-free IV process represents indeed an efficient and green method of up-cycling waste elemental Sulfur, abundant and ubiquitous by-product of gas and oil industry, to obtain sustainable polymeric materials with unique functional properties. IV process takes advantage of Sulfur's ring-opening and linear chain-forming tendency at high temperatures to bind hydrocarbon comonomers to the Sulfur radicals being formed. Due to their nature consisting of polysulfide chains cross-linked typically by divinyl moieties, IVPs exhibit dynamic covalent and self-healing behaviour. Moreover, the high content of easily polarizable S-S bonds endows IVPs with high refractive index and excellent NIR transparency.

Here, novel IVPs with outstanding refractive index were prepared from purposely designed cross-linking comonomers, namely isopropenyl aromatics synthesized through a single-step Suzuki-Miyaura cross-coupling reaction [3,4]. Comonomer type and amount were varied to address both the optical behaviour and filmability of the ensuing IVPs, that is the technologically relevant properties for application and industrial scale-up. Achieved IVPs were employed to fabricate all-polymer photonic structures, such as distributed Bragg reflectors (DBRs) and imprinted metasurfaces. Gathered results open the way to a variety of applications for light emission control, spanning from free-standing, high-reflectance DBRs and microcavities for NIR emitting lasers, to fabrication of metamaterials for advanced nanophotonics.

Multifunctional composites based on covalent adaptable networks modified with recycled carbon fiber

Prof. Alberto Jiménez Suárez, Spain

Highlight (Oral Presentation 20')

Abstract

The development of covalent adaptable networks (CANs) is crucial for advancing composite materials, particularly in enhancing their recyclability and self-healing capabilities. CANs, which incorporate dynamic covalent bonds, allow for the reconfiguration of the polymer network under specific conditions, enabling repair and recycling. This adaptability is essential for extending the lifespan of composite materials and reducing waste.

In parallel, the recycling of carbon fiber composites (CFRPs) is gaining attention due to the high value and performance of carbon fibers which had led to their introduction in several applications such as aerospace industry. This industry makes use of preimpregnated products which cannot be easily recycled, which is a problem due to the large amount of scrap and expired products. Mechanical recycling of this scrap has been previously studied by the research group with extraordinary good results obtaining multifunctional composites with high added value.

In this work the combination of CANs and recycled carbon fibers has led to the development of multifunctional composites with enhanced mechanical properties, self-healing and shape-memory abilities, as well as reduced environmental impact. A commercial imine-based CAN has been modified by the addition of different contents of rCF to reach the percolation threshold and allow Joule effect heating. In this way, the material was heated by Joule effect to temperatures above the T_v and T_g of the material (previously measured) to allow dynamic behaviour of the thermoset resin. Nevertheless, the presence of rCF affected the shape memory behaviour and the capability to change the shape of the materials with temperature. In the same way, rCF affected the flowing capabilities of the material thus affecting the self-healing capabilities, so the rCF content was optimized in the study to allow keeping these functionalities and the capability of reaching the temperature required by Joule effect. Additionally, the self-sensing capabilities and the effect on the mechanical properties of the rCF in the polymer matrix were also studied.

Sustainable Thermosets with Dynamic Covalent Bonds: From Lignin-Derived Aldehydes to High-Performance Epoxy Materials

Dr. Sandu Cibotaru, France

Oral Presentation (20')

Abstract

The escalating urgency of global environmental issues has spurred a transformative shift in chemical research. The widespread use of bisphenol A (BPA), a recognized endocrine disruptor, in conventional petroleum-based epoxy resins has necessitated the exploration of bio-derived alternatives to mitigate potential health and environmental risks [1, 2]. In the pursuit of sustainable and eco-friendly alternatives to traditional epoxy resins, Schiff-based epoxy thermosets have emerged as a promising strategy. These materials leverage the inherent dynamic and reversible nature of imine functional groups, enabling thermal reprocessability and chemical recyclability [3, 4].

This study explores the synthesis of Schiff-based epoxy thermosets using sustainable approaches, starting from lignin-derived aldehydes such as vanillin and syringaldehyde. Starting with these compounds, we synthesized Schiff base monomers which were subsequently glycidylated to create novel epoxy thermosetting resins. A novel self-polymerization strategy is employed, eliminating the need for additional curing agents and resulting in thermosets with high material properties.

The Schiff-based epoxy thermosets developed in this study exhibit impressive performance characteristics. They demonstrate high mechanical properties, with storage moduli at room temperature ranging from 1.5 to 2.2 GPa. The materials also show excellent thermal stability, with glass transition values between 138 °C and 249 °C, significantly higher than traditional DGEBA-based epoxies. Thermogravimetric analysis revealed high thermal stability, with T5% values of 310-350 °C in air [5]. The thermosets also display excellent flame-retardant properties, with Limiting Oxygen Index (LOI) values between 33% and 36%. Notably, these bio-based materials have a lower apparent density (0.74-1.09 g/cm³) compared to DGEBA references, making them suitable for lightweight applications. Additionally, the thermosets demonstrate the ability to be chemically recycled in acidic conditions and thermally reprocessed, highlighting their potential for sustainable and circular material applications.

Smart Polymer Coatings for Safety Applications in Battery Systems: Exploiting Click Chemistry and Diels-Alder Reactions

Mr. Bautista-Anguís Daniel, Austria

Oral Presentation (20')

Abstract

In the last decade, the production of electric vehicles (EVs) has increased with the aim of reducing CO₂ emissions from traditional internal combustion engine vehicles. The transition to EVs is critical for addressing environmental challenges and promoting sustainable transportation solutions. Therefore, ensuring the optimal functioning of their components is paramount to safeguarding passenger safety. Special attention must be given to monitoring and detecting potential overheating events, particularly within battery systems, to prevent irreversible damage. A promising and cost-effective solution involves the use of temperature-responsive polymers combined with low-cost metal oxide (MOx) gas sensors. When certain critical temperatures are reached, the polymer releases detectable gases, which are captured by MOx sensors connected to an alert system. The use of polymer coatings enables a more thorough and accurate assessment of temperature across the entire surface.

To enable the controlled release of tracer gases at critical temperatures, our work was divided in two different approaches:

In the first approach, short-chain thiols with low boiling points were chosen as tracer gases. Blocked model compounds were synthesized through a click reaction between the short-chain thiols and 4,4'-Methylenebis(phenyl isocyanate) (MDI). The unblocking temperatures of these compounds were determined using different thermal techniques such as differential scanning calorimetry (DSC) or thermogravimetric analysis (TGA) among others. This unblocking reaction, occurring at temperatures above the boiling point of the thiols, results in their release in the gas phase. The released gases were characterized by evolving gas analysis coupled with mass spectrometry (EGA-MS). The most promising thiol, 1-propanethiol, was covalently bonded into a polyurethane matrix made from a polymeric MDI and polyol. The reusability of the polymer coating after releasing the gas was also evaluated, ensuring the reusability of the matrix for different applications or allowing the introduction of more 1-propanethiol.

In the second approach, the focus was on the covalent bonding between thiophene molecules and a thiol-ene network. This method uses the reversibility of the Diels-Alder (DA) reaction between a commercial bismaleimide (BMI-689) and thiophene, also offering a novel strategy for developing functional coatings. The retro Diels-Alder (rDA) reaction enables the recovery of reactants at specific temperatures. The test results proved that the rDA reaction temperature is higher than the boiling point of thiophene, allowing the release of thiophene groups as a tracer gas, easily detected by various sensors. The aforementioned characterization methods for the first approach were used to determine the rDA reaction temperature and identify the released components.

[d] Institute for Building Energetics, Thermotechnology and Energy Storage (IGTE), University of Stuttgart, Stuttgart, Germany

[e] Institute of Engineering Thermodynamics, German Aerospace Center (DLR), Stuttgart, Germany

Carbon aerogels have a great potential to be used in applications like adsorption, catalysis, supercapacitors, fuel cells or batteries based on their unique properties such as well-controlled pore size distribution, high porosity, large specific surface area, high electrical conductivity and low envelope density.[1] They have a three-dimensional, open porous structure and are produced via carbonization of organic aerogels based on e.g. resorcinol-formaldehyde polymers.

Polymer electrolyte membrane fuel cells are a very promising technique for converting hydrogen into electrical energy. But until now, one major problem for large-scale application are the high platinum catalyst costs. A suitable alternative to the critical raw materials are iron-nitrogen (Fe-N_x) complexes embedded in a porous, carbonaceous structure.

For the application as a catalyst, the carbon matrix has to be modified in order to incorporate the active Fe-N_x sites into the carbon structure. Therefore, the carbon is treated with different synthesis steps to introduce nitrogen and iron into the carbon structure.[2] Prior nitrogen doping of the carbon aerogel, oxygen doping was identified as a crucial step. To introduce nitrogen and iron, the oxidized carbon aerogel is mixed with nitrogen and iron precursors and thermally treated to obtain Fe-N-C materials.

The presentation will focus on our recent studies showing different synthesis techniques and the results of physicochemical and electrochemical characterization of the doped carbon aerogels using physisorption measurements, scanning and transmission electron microscopy, X-ray photoelectron spectroscopy, electrical conductivity measurements and rotating ring-disk electrode measurements.[3]

Electrodeposited CuNiCo Ternary Alloy Films as High-Performance Electrocatalysts for Nitrate Reduction

Mrs. Salbin Sediqi, Germany

Oral Presentation (20')

Abstract

Electrodeposition offers a scalable and versatile method for fabricating catalytic surfaces tailored for specific electrochemical applications. This study presents the synthesis of a ternary CuNiCo thin alloy film on a graphite substrate via electrodeposition, optimized for the nitrate reduction reaction (NO_3^- RR). A Hull cell was utilized to gain insights into current density effects, aiming for uniform deposition and improved catalytic performance. Additionally, the influence of precursor concentrations, pH, additives, and current density was systematically analyzed to determine the optimal alloy composition and deposition conditions.

The deposited CuNiCo alloy was characterized using techniques such as scanning electron microscopy (SEM) and energy-dispersive X-ray spectroscopy (EDS), with X-ray absorption near-edge structure (XANES) analysis offering valuable insights into the alloy's chemical composition and electronic structure. Electrochemical performance was evaluated through cyclic voltammetry (CV), linear sweep voltammetry (LSV), and chronopotentiometry in nitrate-containing electrolytes. Preliminary findings suggest that the ternary alloy offers promising activity and selectivity for NO_3^- RR, with indications of higher nitrate conversion rates compared to monometallic and bimetallic counterparts. Furthermore, the catalyst demonstrated promising potential for CO_2 reduction reactions, highlighting its versatility in various electrochemical applications. This work underscores the synergistic effects of the ternary CuNiCo system, offering a pathway for the development of advanced catalysts for environmentally critical reduction reactions.

Paper 900 1 Novel Printable Microwave Metasurfaces for Energy Harvesting Applications

Dr. Zacharias Viskadourakis, Greece

Highlight (Oral Presentation 20')

Abstract

Metamaterials are artificially constructed materials, which exhibit tailored interaction with incident electromagnetic radiation, enabling extraordinary functions and properties. Up to now metamaterials and metasurfaces (2D version of metamaterials, consisting of a single plane of meta-atoms) have been realized for a great variety of electromagnetic applications. Among them, metamaterials for energy harvesting gain lately great interest. In this context, most efforts are focusing in the microwave frequency range in the last decade. Reasons for such an attention include the tremendous evolution of wireless communications, resulting to an incredible increment of microwave emitting and receiving, including telecommunication antennas, wi-fi hubs etc.

Conventionally, metasurface units, are constructed employing the printed circuit (PCB) technology, which permits the high printing resolution and the consequent high quality of the produced metamaterial unit. Although PCB technology exhibits some severe drawbacks i.e., it is a multi-step, long-time procedure, complex infrastructure is needed, highly dedicated personnel is required, etc. During the last years, construction of complex objects is being achieved employing additive / subtractive manufacturing technologies. In principle, during an additive / subtractive manufacturing process, a 3D structure is developed by stacking/removing material layers, until the desired object is grown. Such technology exhibits distinct advantages (i.e., it is a quick, cost-effective and user-friendly method) while it allows the large-scale production of objects, reducing their consequent cost and production time.

To date, additive/subtractive manufacturing technology has been successfully used in constructing metasurfaces for applications in the microwave regime. In this context, we hereby present the fabrication of stand - alone metasurface units, of the cut-wire topology, employing the FFF method. In addition, we also employ the CNC engraving method to develop complementary metasurfaces, of toroidal topology. Both metasurfaces were thoroughly studied, regarding their energy harvesting capability in the microwave regime. Experimental results evidently show that they both can effectively absorb electromagnetic energy and transform it to DC electric signal, through a simple rectification circuit. Therefore, they can efficiently be used as energy harvesters, mining energy from surrounding microwave signals.

Nest we present, preliminary results about the combination of metamaterial harvesters with other kind of harvesting devices, such as photovoltaics. Corresponding experimental data show that combination of metasurface with photovoltaic panels could be feasible, resulting in a harvesting system which could continuously provide low -power systems and devices with electrical power.

Thermomechanical response and microstructural characterization of Nitinol alloy produced by laser powder bed fusion

Dr. Maria Beatrice Abrami, Italy

Oral Presentation (20')

Abstract

Nitinol (NiTi), a nearly equiatomic nickel-titanium alloy, is the most extensively used shape memory metallic material due to its peculiar smart features, good corrosion resistance and biocompatibility. Thanks to a low temperature phase transformation, known as martensitic transformation, it can exhibit the shape memory effect, which leads to shape recovery after deformation upon heating, or superelasticity, which allows the recovery of large deformations upon stress removal. These properties make it particularly attractive for a wide range of applications, such as in the biomedical, robotics or aerospace fields.

In recent years, several studies have investigated the additive manufacturing (AM) of NiTi to better exploit and expand its application potential, leveraging design freedom and the capability to produce complex shape components offered by these techniques. Laser powder bed fusion (L-PBF) is one of the preferred AM methods due to the finer microstructure and better surface finishing achievable. To optimize the functional properties of L-PBFed NiTi, numerous research efforts are currently focused on developing tailored heat treatments.

In the present work, various aging heat treatments were performed on NiTi samples produced by L-PBF. Specifically, aging treatments were carried out for 15 minutes at 400 °C and 500 °C, both directly after production (direct aging) and after solution annealing. The thermomechanical behavior was examined by performing cyclic compression tests at different temperatures and compression tests up to failure. Temperature-stress diagrams were experimentally determined, establishing the overall behavior of the alloys. Results of mechanical tests were correlated with the transformation temperatures of the alloy, measured by means of differential scanning calorimetry (DSC) analyses, and to the microstructure of the alloy. Precipitates formation was characterized through transmission electron microscopy (TEM) and texture analysis was carried out via electron backscattered diffraction (EBSD).

3

Process parameters optimization for L-PBF of a NiTi alloy: a combined analytical and experimental investigation

Michele Gragnanini,

Oral Presentation (20')

Abstract

Additive manufacturing (AM) technologies have revolutionized the fabrication of biomedical devices, finding extensive applications in orthopedics, orthodontics and cardiovascular implants. Among the materials employed, Shape Memory Alloys (SMAs), particularly NiTi alloys, are prominent due to their superelastic mechanical properties, functional capabilities and biocompatibility. Their limited machinability through traditional methods has driven increased interest in using AM techniques to address these limitations and enable the production of customized biomedical components. This study aims to analyze the printability of a Ni50.8Ti49.2 alloy produced through the Laser Powder Bed Fusion (L-PBF) technique. The optimal L-PBF printing conditions were estimated using an analytical model that predicts the temperature field generated by a moving point heat source in steady-state. This model guided the design of an experimental campaign through a full factorial design of experiments (DOE) to determine the printability region to avoid the presence of lack of fusion- or keyhole-induced defects. Material samples were fabricated using a Renishaw RenAM 500S printer with a maximum laser power of 500 W, operating in continuous or pulsed mode. Based on the insights from the DOE, several printing parameters combinations, including laser power, scanning speed, hatch distance, and scanning strategy, were tested to evaluate the material's feasibility region. Material cubic samples with an edge length of 5 mm were produced and analyzed to correlate the printing conditions with the resulting microstructural characteristics and process-induced defects. Standard microstructural characterization techniques (optical and scanning electron microscopy, OM and SEM) and differential scanning calorimetry (DSC) were employed to assess the microstructural features and transformation temperature ranges (TTRs). The OM and SEM analyses showed that the detected percentage porosity of the samples was consistent with the predictions provided by the analytical model. In terms of the feasibility of the process parameter, ten parameter combinations were identified within the predicted region, which enabled the production of samples with porosity below 0.2 %. The DSC, performed after a solution treatment conducted at 850 °C for 15 min, revealed transition temperatures comparable to those of the virgin powder. These findings suggest that the adopted L-PBF printing parameters did not alter the alloy's chemical composition, preserving its original transition temperatures and confirming its suitability for biomedical applications. By minimizing porosity and aiming for a defect-free microstructure, this study underscores the potential of L-PBF in overcoming the challenges associated with the traditional machining of NiTi alloys, supporting the production of NiTi-based biomedical components with enhanced functional performance.

Paper 1365 4

Ultrafast-laser powder bed fusion of Nb₂O₅-TiO₂ mixtures for emerging environmental applications

Mr. Gonzalo Gomez-Munoz, Spain

Oral Presentation (20')

Abstract

Transition metal oxides (TMOs) are materials whose properties can be tuned through their structure and composition. This makes them particularly interesting for energy applications, as battery electrodes [1], and various environmental applications including gas sensing or photocatalysis for water purification and water splitting [2]. Nb₂O₅-based TMOs are interesting candidates for these applications due to their tunable electrical and optical properties. In Nb₂O₅ oxygen content plays a major role in determining its electrical properties. The stoichiometric oxide is insulating, which limits its use in the energy applications. In addition to this low conductivity, Nb₂O₅ has a large bandgap which limits its performance in fields such as photocatalysis, because only ultraviolet light can effectively induce electron-hole pair formation, limiting its utility under visible light. However, the introduction of a metallic doping in the TMO structure allows the formation of shallow levels in the oxide's electronic bandgap, which contribute with carriers to the conductivity and enable the absorption of longer wavelengths, making doping an effective strategy to overcome the inherent limitations of the pure oxide. In the case of Nb₂O₅, conductivity is mediated by oxygen vacancies, but doping also induces oxygen defects that may strongly increase the conductivity of the material [3]. In this context, we have focused our studies on titanium niobates (Ti_xNb_yO_z or TNOs) a class of ternary oxides, with TiNb₂O₇ and Ti₂Nb₁₀O₂₉ being among the most stable ones [4]. Recently, we optimized an ultrafast-laser powder bed processing technique to produce uniform and compact sintered conductive layers of a monoclinic oxygen-deficient Nb₂O₅ phase [5], where the conductivity of the layers was determined by their microstructure and oxygen-deficiency. In this work, we have followed a similar approach, irradiating a mixture of high-purity TiO₂ and Nb₂O₅ powders, to optimize the ultrafast-laser powder bed processing technique to produce continuous TNO layers (with the mentioned targeted stoichiometries). As a result of the optimization process, continuous and compact layers of TNO have been successfully sintered. The effect of the laser processing parameters on the sintering of the layers will be described, as along with the post-processing treatments applied to functionalize them for emerging applications.

SELF-HEALING HYDROGELS PRINTED BY PHOTOINDUCED 3D PRINTING TECHNIQUES FOR BIOMEDICAL APPLICATIONS

Mrs. Maria D'Aloia, Italy

Oral Presentation (20')

Abstract

Light-induced 3D printing is becoming increasingly important in various research fields due to its advantages over other additive manufacturing methods, such as higher resolution and printing speed. In this work, we want to exploit light-induced 3D printing and, in particular, Digital Light Processing (DLP) to make a biocompatible and self-healing hydrogel for application in tissue engineering. Self-healing hydrogels (SHHs) with appropriate properties, in fact, can mimic the biomechanical characteristics of biological tissues and self-repair when damaged, acting as ideal three-dimensional scaffolds for cell proliferation and differentiation. So far, such hydrogels have been processed mainly through extrusion-based technologies, limited in design and resolution(1); to obtain more complex objects with better resolution, we will exploit DLP.

Light-induced 3D printing is becoming increasingly important in various research fields due to its advantages over other additive manufacturing methods, such as higher resolution and printing speed¹. In this work, we want to exploit light-induced 3D printing and, in particular, Digital Light Processing (DLP) to make a biocompatible and self-healing hydrogel for application in tissue engineering. Self-healing hydrogels (SHHs) with appropriate properties, in fact, can mimic the biomechanical characteristics of biological tissues and self-repair when damaged(2), acting as ideal three-dimensional scaffolds for cell proliferation and differentiation(3). So far, such hydrogels have been processed mainly through extrusion-based technologies, limited in design and resolution¹; to obtain more complex objects with better resolution, we will exploit DLP.

The hydrogel is fabricated using water-soluble, commercially available materials, such as polyethylene glycol diacrylate (PEGDA), hydroxyethyl methacrylate (HEMA), dithiothreitol (DTT) and borax. We successfully printed complex 3D objects using a commercial DLP printer, and we evaluated the ability of self-repair by cutting the specimens and bringing the two ends together, without any other stimuli: after 72h, the specimen is able to self-standing and resist tension and can be subjected to several cycles of breakage and repair. We then characterized the hydrogels in terms of chemical, rheological and mechanical properties, and finally we performed cytocompatibility tests to verify applicability in tissue engineering.

Paper 427 **6** **Novel air-jet spinning-assisted 3D printing of porous scaffolds for tissue engineering applications**
Prof. Muammer Koc, Qatar
Oral Presentation (20')

Abstract

The fabrication of porous scaffolds with controlled architecture and enhanced bioactivity remains a critical challenge in tissue engineering. Conventional 3D printing techniques, while offering high precision, often struggle to achieve the microporosity and surface topography required for optimal cell attachment, proliferation, and tissue integration. To address these limitations, we introduce a novel air-jet spinning-assisted 3D printing (AJS-3DP) approach for fabricating porous scaffolds with tailored microstructural properties. This hybrid technique combines the advantages of air-jet spinning, which generates ultrafine fibers, with extrusion-based 3D printing, ensuring hierarchical porosity and an interconnected network structure.

In this study, we optimized key processing parameters, including air pressure, polymer solution viscosity, and fiber deposition rate, to achieve uniform and reproducible fiber deposition within the 3D-printed scaffold matrix. The resulting scaffolds were characterized for their morphological, mechanical, and biological properties using scanning electron microscopy (SEM), mechanical compression testing, and in vitro cell studies. The integration of air-jet spun fibers into the printed scaffold significantly enhanced the surface roughness and porosity, promoting cell adhesion and proliferation. Furthermore, the hierarchical porous structure facilitated nutrient and oxygen diffusion, critical for tissue regeneration. In vitro biological assays confirmed superior cell attachment, viability, and spreading on the air-jet spun fiber-enhanced scaffolds. The controlled fiber deposition further enabled the tuning of pore size distribution and scaffold permeability, demonstrating the potential of this technique for designing patient-specific tissue scaffolds.

The novel AJS-3DP method presents a promising strategy for fabricating next-generation biomimetic scaffolds for bone and soft tissue engineering applications. By leveraging the synergistic effects of air-jet spinning and 3D printing, this approach offers a scalable and customizable solution for producing scaffolds with enhanced bioactivity and mechanical performance. This research highlights a significant advancement in scaffold fabrication technology, providing a versatile platform for engineering functional tissue constructs.

Paper 1825 1 **Exploiting the potential of Metal-Organic Frameworks to improve the therapeutic efficiency of Glycodrugs**

Prof. Carolina Carrillo Carrión, Spain

Keynote (Oral Presentation 40')

Abstract

Glycomimetics have attracted much interest as therapeutic agents for a wide variety of diseases; however, their optimal delivery in cells is still a major concern. The therapeutic potential of many bioactive glycomimetics is often limited by poor biodistribution due to issues such as quick degradation or clearance, or low solubility or aggregation in biological media. The latter is the case of sp2-iminoglycolipids, a family of glycolipids endowed with immunomodulatory capabilities but requiring high doses (in the micromolar range) to exhibit an effective cellular response.

In this context, the use of nanosized metal-organic frameworks (MOFs) has been recognized as a promising strategy to achieve more efficient delivery of small bioactive compounds; however, the efficient encapsulation of large biomolecules such as carbohydrates is not trivial, and probably for that reason has been little investigated until now. Our group has recently optimized a synthetic procedure for the encapsulation of a variety of glycolipids within a zeolitic-imidazolate framework-8 (ZIF-8) nanostructure, giving rise to several GlycoZIFs with distinctive therapeutic potential depending on the specific glycolipid encapsulated. We have performed computational studies to disclose the favorable glyco-ZIF interactions and propose a plausible mechanism of formation of these GlycoZIFs.

From the application point of view, the therapeutic activity of two different GlycoZIFs have been evaluated in in vitro and ex vivo experiments. These works demonstrate the potential of GlycoZIFs to: (1) modulate the oxidative stress in endothelial cells, by exploiting the antioxidant properties of a GlycoZIF that encapsulates Se-glycolipids, and (2) treat diabetic retinopathy, thanks to the anti-inflammatory effect exerted by a GlycoZIF that contains SO2-glycolipids. In conclusion, these examples serve to illustrate the promising future of carbohydrate/MOF-hybrid materials in the biomedical field.

Paper 1025 2 Smart food packaging based on Metal-Organic Frameworks: one platform with multiple possibilities
Mrs. Miriam Abán, Spain
Oral Presentation (20')

Abstract

Reducing food loss is a major global challenge, approximately 30% of the food is wasted throughout the supply chain. In this context, packaging plays a fundamental role by helping to minimize waste, protecting food during production, transport and storage and ultimately extending its shelf life. Smart packaging technologies are being explored for their ability to prevent contamination (mainly water sources), regulate the internal conditions of packaged products, and preserve food quality through the incorporation of active components.¹

Here, we propose two strategies for integrating metal-organic frameworks (MOFs) into smart packaging to avoid contamination and increase the food shelf-life: use of intrinsically active MOFs, or encapsulation of active ingredients in porous frameworks. For the first strategy, a new MOF, IEF-32 ([CaC₂₄H₂₂N₃O₉P₃]) based on the micronutrient Ca and a triazine derivative ligand with potential antimicrobial properties, has been synthesized and fully characterized. IEF-32 demonstrated high preservation capacity in grapes for one month. A second strategy is the encapsulation of eugenol, a natural essential oil with remarkable antifungal and antimicrobial activities,² in the microporous Zn bispirazolate MOF ZnBDP ([ZnC₁₂H₈N₄]; SBET ≈ 2000 m²/g; square channels of 1.1 nm).³ The successful encapsulation of eugenol was performed using two different approaches (vapour and liquid phase), achieving significant cargoes of 22 and 60 wt.%, respectively. Further, eugenol was slowly and progressively released in water (60% in 2 weeks), demonstrating its efficient preservation against fungal infections in strawberry and grape fruits. These results highlight the potential of MOFs in preservation of foodstuffs.

Paper 1040 3 **Synthesis of novel porphyrin-based MOFs for environmental remediation**

Mr. Guillermo Gortázar, Spain

Oral Presentation (20')

Abstract

The increase in atmospheric CO₂ concentration due to the combustion of fossil fuels is one of the major environmental challenges of the 21st century. In pursuit of a total decarbonization, a key research focus is the development of advanced technologies for CO₂ utilization. Metal Organic Frameworks (MOFs) have emerged as promising candidates for CO₂ capture, owing to their high specific areas, remarkable sorption capacities and tuneable physicochemical features [1]. However, their industrial implementation remains limited due to relevant drawbacks, i.e., the lack of stability and catalytic efficiency. In this context, the development of new MOFs based on highly conjugated linkers and high-valence metals is particularly encouraging. The combination of abundant and non-toxic cations, such as Ti(IV), Zr(IV) or Fe(III), which exhibit hard Pearson acidic behaviour, with polydentate linkers (e.g. porphyrins), presenting hard Pearson basic coordinating moieties (e.g. carboxylates) is expected to yield highly conjugated and stable coordination polymers [2]. Furthermore, the use of these macrocyclic linkers also allows the generation of dual-site catalysts by introducing additional, non-structural metal ions into the coordination network through ligand metalation. This enhanced stability, combined with the optoelectronic properties ascribed to the selected linkers [3] and the synergetic effects of simultaneous metal sites, is expected to improve the catalytic performance of these materials towards a more efficient CO₂ conversion.

Herein, we report the synthesis of two novel MOF families based on the combination of two carboxy-substituted trans A2-B2 porphyrins (i.e., 5,15-(di-4-carboxyphenyl)-10,20-(diphenyl)porphyrin (DCPP) and 5,15-(di-4-carboxyphenyl)porphyrin (BDP), both barely described in the literature, and three M(III) lanthanides (Dy, Nd, Y). These materials were prepared through both solvothermal and MW-assisted methods leading to different porous isostructural series (BET surface areas up to 700 m²/g). Materials were physicochemically characterized with a broad palette of techniques, including X-ray diffraction, infrared and UV-Vis spectroscopies, elemental analysis, gas sorption studies (affinity towards CO₂), electron microscopy, and thermogravimetric analysis, among others, and their chemical/structural stability evaluated under different conditions (aqueous media at different pH, different organic solvents). These novel MOFs are currently being tested as potential CO₂ catalysts and luminescent sensors.

Covalent Organic Frameworks for the Efficient Adsorption and Detection of Contaminants of Emerging Concern in Runoff Waters

Dr. Monica Quarato, Portugal

Oral Presentation (20')

Abstract

Urban runoff is widely recognised as an important pathway for pollutants released in the urban environment.¹ Common contaminants include sediments, heavy metals, pesticides, fertilizers, oil, and bacteria from urban, industrial, and agricultural areas. Although the toxicological profile of some of these pollutants remains poorly characterized, they can exhibit biological activity even at very low concentrations, potentially harming non-target organisms. Additionally, they can persist in the environment, leading to long-term ecological damage.²

Many pesticides classified as Highly Hazardous Pesticides (HHPs), along with tire wear particles, and other emerging contaminants, are frequently detected in runoff waters.^{3 4} Under the European Water Framework Directive (WFD), the EU Commission regulates surface water quality to preserve, protect and improve the aquatic ecosystem and human health by setting environmental quality standards (EQS) for surface waters.⁵ Within this framework, the Horizon Europe project D4RUNOFF focuses on contributing to the development of innovative detection methods and sensors for characterizing runoff pollutants and enabling rapid in-situ monitoring. It aims to support the implementation of cost-effective hybrid mitigation solutions that integrate nature-based strategies with water infrastructures.

Innovative nanomaterials, such as covalent organic frameworks (COFs), have been explored as adsorbents for the efficient removal of micropollutants from water and wastewater.⁶ COFs are a class of crystalline porous organic polymers composed entirely of organic building blocks. Thanks to their tuneable functionality and pore aperture sizes, as well as structural stability under various conditions, they are widely favoured for adsorbing various molecules. This study assessed COFs as alternative adsorbents to solid-phase extraction (SPE). Several COFs (i.e., TpBD-(CF₃)₂, TpBD-(CH₃)₂, TpBD-DMTP) were tested for the extraction of different triazines and 6-PPD-quinone. Results demonstrated that TpBD-(CF₃)₂ and TpBD-(CH₃)₂ show strong potential as alternative SPE adsorbents for these substances. Subsequently, contaminant detection was achieved using the Surface-Enhanced Raman Scattering (SERS) technique. Furthermore, the combination of COFs for contaminant adsorption and concentration with a microfluidic device for detection enables real-time runoff water monitoring, ensuring a rapid and in-situ response.

Sustainable water purification using UiO-66 MOF gels for PFAS remediation

Prof. Joerg Jinschek, Denmark

Oral Presentation (20')

Abstract

Perfluoroalkyl substances (PFAS) or "forever chemicals" pose significant concern regarding their impact on the environment and overall health due to their toxicity and long-term durability. Among them, perfluorooctanoic acid (PFOA) is responsible for various complications in malignant diseases and developmental disorders, and its long-term persistence with respect to degradation processes in nature makes its removal from water particularly challenging.

This study investigates the use of zirconium terephthalate metal-organic framework (MOF) gel UiO-66 to extract PFOA from contaminated water using powder X-ray diffraction (PXRD), scanning / transmission electron microscopy (STEM & TEM) imaging and energy dispersive X-ray spectroscopy (EDS), as well as nuclear magnetic resonance (NMR) spectroscopy.

The gel form of UiO-66 exhibits a similar structure to the powder form of UiO-66, but has improved processing and usability capabilities. PXRD and TEM analysis confirmed the nanocrystalline character (with an average size of about 20 nm) and the hierarchical porous structure of the gel. Quantitative evaluation using ¹⁹F-NMR showed an extraction efficiency of 96% for PFOA, while solid-state NMR confirmed the interactions between the fluorine groups in PFOA and the carbonyl groups in the gel network. In addition, STEM-EDS analysis showed a homogeneously dispersed distribution of PFOA in the gel and thus confirmed its efficient absorption mechanism. In addition, satisfactory performance in its membrane form, with a harvesting efficiency of over 95%, was displayed through successive membrane filtering processes. Notably, the filtering process did not require any external pressure, and it relied purely on gravity, providing a cost-effective and efficient alternative to traditional water purification processes.

Given these findings, the use of UiO-66 MOF gels for water ultrafiltration is very promising as a feasible and scalable process for PFAS remediation and, more generally, for environmental pollution control with an effective and environmentally-friendly approach.

Paper 1856 7 **Nanosized Porphyrinic Metal-Organic Frameworks for the Construction of Transparent Membranes as a Multiresponsive Optical Gas Sensor**
Dr. Francisco García Moscoso, Spain
Oral Presentation (20')

Abstract

The well-known and excellent colorimetric sensing capacity of porphyrins, along with the exceptional structural properties of metal-organic frameworks (MOFs), make porphyrin-based MOFs, such as PCN-222, ideal candidates for the generation/construction of a chemical sensor based on absorbance. However, there are two key requirements for this end which remain challenging: (i) the synthesis of nanoscale PCN-222 in order to minimize/avoid scattering in the absorbance measurement, and (ii) the deposition/integration of the PCN-222 into thin transparent membranes/films in an homogeneous manner without compromising the performance of the PCN-222 (i.e., accessible porosity to interact with analytes and distinctive optical response as a function of the analyte). Fortunately, using an optimized microwave-based synthetic method, we were able to prepare high-quality PCN-222 nanoparticles with a rod-shape and lateral size of ca. 100 nm, and almost negligible scattering in the absorbance spectrum when dispersed in water solution, thanks not only to the small size of the particles but also to their high colloidal stability. Moreover, using poly(dimethylsiloxane) (PDMS) for the formation of flexible and transparent membranes, we have proposed a simple method for the integration of the PCN into the membrane resulting in a multi-responsive optical gas sensor with excellent sensitivity, capable of discriminating between different VOCs through pattern recognition identification.

Paper 908 1 Metal-Organic Frameworks for the Production of Radionuclides of Medical Interest

Dr. Pablo Serra Crespo, The Netherlands

Highlight (Oral Presentation 20')

Abstract

Metal-Organic Frameworks (MOFs) have emerged as promising materials for various applications, including the production of radionuclides for medical imaging and therapy. In this study, we demonstrate the potential of MOFs as:

- i) Adsorbents in the $^{99}\text{Mo}/^{99m}\text{Tc}$ generator, a device used in over 80% of diagnostic nuclear imaging procedures, accounting for the diagnosis of 30-40 million patients every year. Our results show that MOFs can achieve high adsorption capacities, exceeding 500 mg/g, and exhibit excellent radiation stability, making them suitable candidates for replacing traditional adsorbents in the $^{99}\text{Mo}/^{99m}\text{Tc}$ generator. The molybdenum adsorption performance of MOFs, including adsorption kinetics and isotherms, was determined, and the adsorption mechanism was studied using various analytical techniques, such as X-ray photoelectron spectroscopy, Raman spectroscopy, zeta potential, and density functional theory calculation.
 - ii) Radiation targets for the production of ^{51}Cr , a radionuclide with applications in labelling red blood cells, diagnosing gastrointestinal bleeding, and assessing the life span of red cells. The radiation stability of these MOFs is assessed using two different facilities, and the results show that MIL-100 (Cr) and MIL-101 (Cr) exhibit excellent radiation stability after exposure to gamma radiation doses up to 5 MGy, without showing a dose rate dependency. The Cr-MOFs were irradiated in a nuclear reactor, and the ^{51}Cr yield and specific activity were determined at different irradiation times, extracting agents, and extraction times. The most optimal results show that high enrichment factors (>500) and yields (>50%) can be achieved, appearing to be a promising ^{51}Cr production route for nuclear medicine.
 - iii) Precursors to produce materials containing mono-atomically dispersed molybdenum which can be utilized for producing molybdenum-99 with high specific activity. This approach enables the selective isolation of molybdenum-99, enhancing its specific activity and ultimately yielding a product with a purity and quality comparable to that obtained through traditional fission-based methods, thereby providing a viable alternative for the production of this crucial medical isotope.
- Our research highlights the potential of MOFs in the production of radionuclides for medical applications, and we believe that these emerging porous materials will play a crucial role in the development of innovative technologies for the healthcare sector.

Paper 2039 2 **Improving the electrocatalytic behaviour of ZIF-67 nanomaterials via fast eco-friendly cold plasma treatments**
Dr. Víctor Karim Abdelkader Fernández, Spain
Oral Presentation (20')

Abstract

Coordination polymers, known as metal-organic frameworks (MOFs), exhibit remarkable properties such as high crystallinity, well-defined porosity, large surface areas, and great structural and compositional versatility. Moreover, the metal nodes forming the 3D frameworks —together with the organic linkers— are homogeneously distributed at the nanometric scale, providing numerous active sites for (electro)catalysis in various energy-related processes. However, these promising nanomaterials face several challenges, including limited accessibility to active sites, low electrical conductivity, and moderate stability under working conditions. In this context, advanced cold plasma treatments (highly reactive, non-equilibrium systems formed by the partial ionization of a gas or gas mixture) emerge as a powerful and environmentally friendly tool to enhance the electrocatalytic performance of MOFs. These treatments enable precise modifications of their nanostructures—through functionalization, nanoparticle formation, defect engineering, etc.—with a high degree of control over the extent of these alterations. Recently, our research group has begun exploring the compositional and structural modification of ZIF-67-based materials (a MOF composed of Co^{2+} ions and 2-methylimidazole ligands) using plasmas derived from different precursors. We have observed that short treatments —on the order of minutes— can significantly improve the electrocatalytic activity of these nanomaterials toward the oxygen evolution reaction (OER), a key process for green hydrogen production in electrolyzer devices.

Accelerating MOF Synthesis Through AI: Building the Lab-of-the-Future

Dr. Manuel Tsotsalas, Germany

Highlight (Oral Presentation 20')

Abstract

Metal–organic frameworks (MOFs) present a vast chemical landscape, offering diverse structures and exceptional tunability for applications ranging from catalysis to sensing. While computational tools have long guided MOF discovery and design, recent advancements in Artificial Intelligence (AI) are transforming their experimental realization—potentially accelerating R&D by up to tenfold. However, technology alone will not suffice; to unlock AI's full impact, we must integrate data-driven methodologies into everyday lab practices.

In this presentation, I will provide an experimentalist's perspective on merging AI with established laboratory routines. Drawing on examples from our work at the Karlsruhe Institute of Technology (KIT), we have successfully leveraged closed-loop AI systems to optimize growth conditions for Surface-anchored MOFs (SURMOFs), achieving improved crystallinity, uniform orientation, and minimal surface roughness. I will further illustrate how automated data extraction and machine learning predict initial synthesis conditions for new MOF structures, which can be refined through iterative, AI-guided cycles. The second part of the presentation focuses on our journey toward the "Lab-of-the-Future," facilitated by Aixelo Inc.—a KIT spin-off dedicated to AI software, strategy consulting, and professional services. Our EDISON-4.0™ platform empowers chemists to adopt AI without specialized coding or data science expertise, much like using apps on a smartphone. Key capabilities include:

1. Automated Data Extraction & Machine Learning – Rapid predictions for optimal synthesis conditions and reduced trial-and-error.
2. Adaptive Experimental Planning – Autonomous optimization that continually refines parameters based on real-time feedback.
3. Integration of Large Language Models – Streamlined data management and accelerated knowledge extraction across experiments.

By bridging AI innovation with practical application, our platform lowers barriers to AI adoption and fosters significant productivity gains. Ultimately, this presentation underscores how AI-driven strategies can fast-track MOF research, transform traditional workflows, and pave the way for a more efficient, data-centric era in materials science.

Paper 2022 4 **Covalent Organic Framework in combination with Surface-enhanced Raman scattering for Ultrasensitive Antibiotic Detection**
Mrs. Ana Vieira, Portugal
Oral Presentation (20')

Abstract

In modern days, antibiotics are indispensable in human and animal therapy. However, their rapid and accurate detection is crucial in environmental and biological samples for contamination monitoring and antimicrobial resistance control [1]. Surface-enhanced Raman Scattering (SERS) is a powerful tool that benefits from signal enhancement caused by plasmonic metallic nanostructures, enabling fast and highly sensitive detection of different molecules, including antibiotics.

A pre-concentration step is needed due to the very low concentration of the target compound found in the environment and food matrices. A covalent organic framework (COF), a crystalline porous material, was selected as pre-concentrator since these materials have been demonstrated to adsorb pharmaceuticals efficiently. [2]

In this study, sulfonamides were chosen as the target antibiotic family to test the COF's pre-concentration efficiency and the SERS strategy's performance due to the special interest and urgency of their monitoring. In particular, sulfamethoxazole, a widely used antibiotic to treat gram-positive and gram-negative bacteria, is an emerging contaminant of concern in groundwater worldwide. The EU has established a detection limit of 10 ng/L for sulfamethoxazole in surface water [4] and a maximum residue limit of 100 µg/Kg for total sulfonamides in milk [5].

Our results demonstrate that our COF-SERS combinative strategy enables the detection and differentiation of at least sulfamethoxazole, sulfathiazole and sulfapyridine (also in mixture) at 0.1 µg/L. This is achieved through spectral pre-processing, followed by artificial intelligence (AI)-driven analysis. Combining material-enhanced SERS performance and AI, this platform represents a promising tool for on-site antibiotic detection with high sensitivity and selectivity.

Immobilization of Lipase on Hafnium based MOF for heterogenous biocatalysis

Ph.D. Carlotta Pontremoli, Italy

Oral Presentation (20')

Abstract

Most transport fuels and chemicals are currently derived from fossil resources but concerns about depletion and pollution have driven interest in renewable alternatives. Biomass offers a sustainable carbon source for biofuels and valuable chemicals, and specifically 5-Hydroxymethylfurfural (HMF), a versatile platform molecule derived from hexoses can be reduced to 2,5-bis(hydroxymethyl)furan (BHMF) followed by the esterification of BHMF for its potential use as alternative to petroleum-derived phthalates [1,2]. To date, metal catalysts effectively facilitate this transformation, however, often require severe conditions and suffer of metal leaching and deactivation. Here, we propose a heterogeneous biocatalyst based on the enzyme lipase immobilized on a hafnium-based Metal-Organic Frameworks (MOF), capable of performing a cascade reaction to obtain BHMF-DE.

Pure microporous UiO-66(Hf) and hierarchical HPUs-(X), where X indicates the volume of water added on the synthesis, were prepared following a procedure reported in the literature [3]. Since the pore size of the materials plays a critical role in enzyme immobilization efficiency, according to lipase from *Candida Rugosa* diameter (5 nm [4]), the MOFs' cavities have been rationalized to have different size and thus different degree of lipase immobilization. Moreover, to increase the possibility of immobilization, MOF's surface has been functionalized with proline. Lipase was loaded according to the adsorption method [3]. All the materials were characterized by means XRD, N₂ physisorption, and FE-SEM while the amount of immobilized lipase was determined using the hydrolysis reaction of 4-nitrophenyl palmitate catalyzed by the enzyme.

In all the tested materials, lipase retained the catalytic activity after immobilization, with a slower kinetics compared to the free enzyme. The cascade catalytic reaction from HMF to BHMF-diester as well as the reusability of the bifunctional material were finally studied. The MOF catalyzes the Meerwein-Ponndorf-Verley reduction of HMF to BHMF, while lipase is involved in the transesterification step to produce BHMF-diester. A full cascade reaction test achieved a 57% yield for BHMF-diester with the most promising material, confirming the catalyst's efficiency. Recycling tests showed that the lipase remained stable over three cycles, and enzyme immobilization improved its stability at higher temperatures, supporting the enzyme's potential for extended use in catalytic processes.

Paper 558 **6** **Investigation of phase transformation in zeolitic imidazolate frameworks (ZIFs) under operating conditions using in-situ TEM**
Dr. Pritam Banerjee, Denmark
Oral Presentation (20')

Abstract

Zeolitic imidazolate frameworks (ZIFs), an intriguing class of metal-organic frameworks (MOFs) with zeolite-like topologies and composed of metal ions connected by imidazolate linkers, have attracted great attention due to their promising applications in gas separation and catalysis. To gain important insights into their behavior and performance when 'in use,' in-situ transmission electron microscopy (TEM) has shown great potential to study the structural evolution of ZIFs under such operating conditions. However, investigating such delicate soft materials by TEM is challenging due to potential radiation damage by the TEM's electron probe.

In our study, we systematically investigated the stability and phase transformation of ZIFs under different temperature and gas environments using advanced in-situ environmental TEM techniques. First, we evaluated the stability of ZIF crystals under electron beam exposure using electron diffraction, i.e. by measuring the attenuation of relative intensities in Bragg planes over time as a function of the applied total electron dose. We established a critical electron dose threshold of $30 \text{ e-}\text{\AA}^{-2}\text{s}^{-1}$ at room temperature for ZIF-8 and ZIF-L. If a larger electron dose than this critical total dose is applied during any TEM experiment, electron-beam-induced structural degradation will occur. Further, we investigated the effect of elevated temperature and found that at temperatures above 550°C , ZIF-L undergoes a structural collapse and amorphization. Using EDX and EELS mapping in STEM, changes in composition and chemical state have been tracked. Now controlling the electron beam effects, we then investigated the pyrolysis of ZIF-L at temperatures between 700°C and 1100°C to establish a structure-property correlations for its performance in oxygen reduction reaction (ORR). We found that nitrogen-doped graphitic carbon, formed during pyrolysis, is a key factor in improving the properties of pyrolyzed ZIF-L.

Furthermore, we investigated the stability of ZIF-8 in an oxygen atmosphere. Under 2.7 mbar O_2 pressure and temperatures ranging from 350°C to 550°C , we studied the transformation of ZIF-8 into ZnO nanoparticles, identified by contrast changes in TEM bright-field images and confirmed by selected area diffraction (SAED) patterns. Our comprehensive study demonstrates the power of in-situ TEM techniques in elucidating structure-property relationships when overcoming the challenges associated with electron-beam experiments on beam-sensitive MOFs. Our findings provide valuable insights into the behavior of ZIFs under realistic operating conditions and contribute to developing more efficient and stable MOF-based materials for various applications.

Paper 1256 2 **Electrospun Lignin/ZIF-8 Hybrid Nanofibers for Sustainable Catalysis and Environmental Applications**

Señora. Linet Hernandez Gil, Spain

Oral Presentation (20')

Abstract

Metal-organic frameworks (MOFs) are highly attractive due to their structural and chemical tunability, electrical insulation properties, adjustable pore size, and chemistry, which allow specific interactions with ions. Recent advancements in processing have enabled the synthesis of self-supporting membranes [1]. Additionally, MOFs exhibit stability in aqueous environments, making them suitable for water capture in aggressive or toxic conditions. Their production can also be cost-effective using low-cost metal precursors and organic building blocks. Among MOF materials, zeolitic imidazolate framework (ZIF) structures stand out for their exceptional properties, such as high thermal and chemical stability. ZIF-8, with the molecular formula $\text{Zn}(\text{2-methylimidazolate})$, is one of the most studied.

Nevertheless, the inherent fragility of MOF crystals hinders the fabrication of membranes composed solely of MOFs, requiring their integration with polymeric substrates to enhance their flexibility and handling. Recently, the electrospinning route has revealed as an efficient process for incorporating MOFs into polymeric nanofibers, combining porosity and high surface area with additional functionality. This advancement expands their applicability in fields such as energy and environmental science [2].

The increasing demand for sustainable materials in energy and environmental applications has intensified the search for non-fossil alternatives to conventional polymers. In this context, lignin, an abundant biomass-derived biopolymer, has emerged as a promising candidate for hybrid nanofiber fabrication. In this work, electrospun lignin/ZIF-8 hybrid nanofibers were developed. Lignin was blended with polyethylene oxide (PEO) to optimize electrospinnability and nanoscale ZIF-8 particles were integrated, which improves catalytic activity due to its high surface area and tunable porosity. This combination enhances catalytic performance, enabling applications in energy storage (dye-sensitized solar cells, batteries, capacitors, and supercapacitors) and environmental remediation. Moreover, the nanofibers serve as efficient catalyst support for various catalytic processes, including photocatalysts, and as adsorbents for water purification and volatile organic compound (VOC) removal, providing a sustainable approach to advanced catalysis and environmental protection. [3]. The hybrid nanofibers of ZIF-8/lignin, after thermal treatment, were analyzed in terms of morphology (SEM and TEM), enabling a detailed assessment of nanoparticle incorporation and distribution within the fibers. Their structural integrity was verified through XRD and FTIR analysis, while textural properties were also assessed using N_2 adsorption isotherms (BET), pore size distribution, and CO_2 sorption and co-sorption capacities (DVS and BTA).

MOF-Polymer Composites for Enhanced Atmospheric Water Harvesting

Dr. Alessandro Sinopoli, Italy

Oral Presentation (20')

Abstract

The development of highly efficient sorbent materials is crucial for advancing atmospheric water harvesting (AWH) technologies, particularly in arid and semi-arid climates. In this work, we report the synthesis, characterization, and performance evaluation of novel MOF-polymer composites designed for efficient water capture. A series of zirconium-, iron-, and chromium-based MOFs were synthesized and functionalized with hydrophilic linkers to optimize water uptake under low relative humidity conditions. The resulting MOFs demonstrated water adsorption capacities exceeding 45 wt.% at 70 % RH, with rapid adsorption kinetics and excellent structural stability over multiple cycles. Novel more sustainable solvothermal synthesis routes were optimized to minimizing energy-intensive processing and reduce the environmental impact, while maintaining high yield and good crystallinity. To enhance scalability and mechanical stability, these MOFs were incorporated into polymeric matrices, including alginate and polyvinylpyrrolidone, forming robust and versatile composite structures. The polymer integration preserved MOF adsorption efficiency while increasing the mechanical integrity and processability of the materials. The MOF-alginate composites were prepared as beads. Beads provide better mechanical stability than powders, maintaining structural integrity over multiple cycles. Their uniform packing ensures consistent moisture distribution, preventing aggregation and improving sorption kinetics. Additionally, beads are also easier to handle, transport, and reuse, making them ideal for scalable and sustainable AWH applications. On the other side, MOF-PVP composites have been used as coatings to enhance the performance of sorption-based thermal energy storage (TES) and AWH systems. These composites exhibited an improvement in long-term cycling stability. The coating plays a vital role in improving heat and mass transfer efficiency between the sorbent material and the heat-exchanger, ensuring material stability, and enabling scalability. Further performance enhancement was achieved through the incorporation of carbon-based photothermal harvesters, enabling solar-driven water desorption. Spectroscopic and thermal imaging analyses confirmed an increase in surface temperature upon solar irradiation, facilitating efficient moisture release at low energy inputs. This study highlights the potential of engineered MOF-polymer composites as next-generation materials for sustainable AWH. Ongoing work focuses on refining composite formulations, optimizing photothermal efficiency, and scaling production methodologies to further enhance their viability for real-world applications. and solar-driven desorption.

Paper 2124 4 **Exploring CO₂ capture dynamics in CALF-20 using positron annihilation lifetime spectroscopy**
Dr. Ahmed Gamal Attallah, Germany
Oral Presentation (20')

Abstract

Reducing atmospheric CO₂ levels is crucial to mitigate climate change. This study investigates the effectiveness of the zinc-based metal-organic framework CALF-20 (Zn) for CO₂ capture across varying temperatures. The unique structure of CALF-20 allows it to maintain high CO₂ selectivity and efficiency in a broad range of temperatures. Positron annihilation lifetime spectroscopy (PALS) played a crucial role in this research, providing detailed insights into the CO₂ adsorption dynamics within CALF-20. The variable temperature PALS experiments demonstrate that CO₂ molecules are spatially localized within the CALF-20 cages, leaving temperature- and pressure-dependent gaps between them. PALS results indicate that CO₂ initially spreads across cage centers, 1D chains, and ultimately adheres to pore walls. Interestingly, positronium intensity, which increases with CO₂ adsorption pressure, closely aligns with the Langmuir-Freundlich isotherm and reflects gas uptake behaviour. These findings highlight CALF-20's potential for effective CO₂ capture and storage, demonstrating its capability to perform well across a range of temperatures. The study underscores the vital role of PALS in investigating and understanding the structural and functional characteristics of CALF-20 for CO₂ capture applications.

- Paper 1329** **5** **Design and optimization of zeolite-CZA tandem catalysts for CO₂-to-ethylene conversion: towards green polymer production**
Mrs. Natalia Spera, Portugal
Oral Presentation (20')

Abstract

As the demand for sustainable carbon sources grows, carbon dioxide (CO₂) has emerged as a promising feedstock. Its catalytic conversion can yield valuable chemicals, offering both environmental and industrial benefits. One exciting possibility is the production of light hydrocarbons (C₂–C₄), which are essential for the energy, chemical, and manufacturing sectors, through a carbon-negative approach. Ethylene (C₂H₄), a major contributor to the olefin market, is traditionally derived from high-energy processes involving naphtha and ethane, which emit harmful pollutants. Developing sustainable, economically viable production routes has therefore become a key focus. The direct catalytic hydrogenation of CO₂ to ethylene faces challenges due to C–C coupling barriers. A promising alternative is using tandem heterogeneous catalysts for sequential reactions, with methanol as an intermediate. In the first step, CO₂ is hydrogenated to methanol using Cu- and Zn-based catalysts. In the second step, methanol is converted into ethylene via a methanol-to-olefins (MTO) process, typically using zeolite catalysts with acidic sites to facilitate C–C bond formation. Herein, we explored a tandem catalytic approach with porous materials, combining Cu/ZnO/Al₂O₃ (CZA) catalyst for CO₂ hydrogenation to methanol and a zeolite-based catalyst for methanol-to-olefins (MTO) conversion. The zeolite-CZA composite catalyst was synthesized via coprecipitation in an automated synthesis system (Atlas Potassium, Syrris) to facilitate the scale-up process. Zeolites were either used as received or surface-functionalized. Structural, textural, and compositional characterization studies are being performed to understand how synthesis processes and material selection influence its catalytic properties. Powder X-ray diffraction (PXRD) confirmed the retention of crystalline CuO and ZnO phases in both the CZA and zeolite-CZA samples, indicating preservation of the crystallinity of both catalysts. Scanning electron microscopy (SEM) analysis revealed that CZA had an irregular morphology, while the zeolites displayed well-defined crystalline structures. Additional textural studies, including N₂-physisorption, are being conducted to assess the surface area and pore size distribution, crucial factors influencing catalytic performance. Furthermore, inductively coupled plasma (ICP) spectroscopy is being utilized to determine the elemental composition of the catalysts. Future work will focus on fine-tuning synthesis parameters and evaluating the material's efficiency as a tandem catalyst for ethylene production from CO₂. This study highlights the significance of porous materials in CO₂ valorisation. We aim to demonstrate the potential of zeolite-CZA as an efficient tandem catalyst for real-world industrial applications, particularly for ethylene production, supporting global carbon-neutral efforts through the production of green polymers.

Paper 1949 6 **Synthesis and characterization of hybrid composites for marine biotoxins by surface-enhanced Raman scattering (SERS)**
Dr. Bernardo A. Nogueira, Portugal
Oral Presentation (20')

Abstract

The efficient, rapid, and cost-effective detection of marine biotoxins remains a critical scientific and technological challenge, exacerbated by the increasing prevalence of harmful algal blooms (HABs). These blooms, driven by excessive algal accumulation in aquatic ecosystems, can produce toxins that pose serious risks to human health. The rising frequency and intensity of HABs, further amplified by ocean warming and climate change, highlight the urgent need for innovative detection strategies. Beyond health concerns, HABs also have substantial economic consequences, particularly for marine-related industries such as aquaculture. Hence, developing advanced, rapid, and selective detection methods is essential to mitigate these risks, ensuring both public safety and the resilience of marine economies [1].

To address this challenge, we have developed a microfluidic system for surface-enhanced Raman scattering (SERS)-based detection of marine biotoxins. This innovative platform integrates an organic-plasmonic hybrid composite designed for high-affinity, selective toxin adsorption. The composite consists of covalent organic polymers (COPs) or covalent organic frameworks (COFs) as chemoreceptor with high-affinity, preferential toxin adsorption [2,3] and gold nanoparticles (GNPs) as optical enhancer, which allow the SERS detection, enabling selective trace-level detection. In this communication, the exploration of different COPs and COFs, their different structures (e.g., bulk, core-shell, and surface-functionalized forms) alongside various GNPs morphologies (spherical particles, aggregates and anisotropic gold nanostars) will be discussed. Preliminary assessments of these hybrid composites demonstrate promising sensitivity for trace toxin detection, laying the groundwork for an integrated detection system optimized for aquaculture farms in open-sea environments.

Additionally, the designed system leverages on density functional theory (DFT) calculations, to validate the resulting SERS signals, ensuring precise toxin identification and quantification, and will incorporate automated detection powered by chemometrics and machine learning algorithms, enhancing efficiency, accuracy, and real-time monitoring capabilities.

Paper 1232 1 Real-Time Insights into Microstructure Evolution in Laser Powder Bed Fusion Using Operando Neutron and X-ray Diffraction

Dr. Steven Van Petegem, Switzerland

Keynote (Oral Presentation 40')

Abstract

Additive manufacturing (AM) has transformed modern materials processing, enabling the fabrication of highly complex structures with remarkable efficiency. Among the various AM techniques, laser powder bed fusion (LPBF) is particularly notable for its ability to produce intricate metallic components. The process relies on a high-energy laser to selectively melt fine metal powders, followed by rapid solidification. However, the extreme thermal gradients and fast phase transformations inherent to LPBF present challenges in controlling microstructural development, residual stress distribution, and defect formation. Gaining a deeper understanding of these evolving phenomena is key to optimizing processing conditions and enhancing material properties.

In recent years, operando neutron and synchrotron X-ray diffraction have emerged as powerful methods for capturing real-time microstructural changes occurring within and around the melt pool during laser-based AM processes. These advanced techniques offer crucial insights into phase transitions, thermal effects, and stress evolution—factors that ultimately dictate the final performance of AM-produced materials.

Achieving meaningful operando measurements requires specialized experimental setups that not only mimic industrial AM conditions but also integrate seamlessly with synchrotron and neutron beamlines. This presentation showcases the developments at the Paul Scherrer Institute (PSI) aimed at overcoming this challenge. A series of miniaturized, AM-compatible setups have been designed and implemented at beamline facilities, enabling real-time studies of LPBF processes.

Demonstrations of these setups include case studies where operando X-ray diffraction provides detailed tracking of phase evolution and thermal behavior across various alloys and multi-material systems. Neutron diffraction and Bragg edge imaging reveal critical insights into the development of residual stresses in bulk components. Fast X-ray imaging provides insight into cracking mechanisms and chemical mixing at the interface of multi-materials.

By directly observing transient phenomena as they occur, these techniques not only enhance our understanding of LPBF process dynamics but also generate valuable experimental datasets for refining computational models. Ultimately, these findings contribute to improving AM process control, optimizing material properties, and increasing the reliability of additively manufactured components.

Paper 1530 2 **Microstructure, mechanical and thermal properties of copper – steel multimaterials fabricated by laser direct energy deposition**
Mr. Tobia Romano, Latvia
Oral Presentation (20')

Abstract

Copper – steel multimaterials combine the excellent electrical and thermal conductivity of copper with the high mechanical properties of steel. Compared to conventional joining techniques, additive manufacturing enables the fabrication of complex multimaterial components with precise control over internal material distribution. However, the manufacturing of copper – steel parts presents significant challenges due to the poor solubility between Cu and Fe and the large discrepancy in thermal conductivity and expansion coefficients, often leading to the development of large thermal stresses and the formation of solidification cracks.

This investigation is focused on the characterization of copper – steel multimaterial parts produced via laser direct energy deposition, using a system equipped with multiple hoppers for the simultaneous deposition of different powders in controlled weight ratios. Pure copper and AISI 4130 low-alloy steel powders were used for the in-situ fabrication of distinct blend compositions, which serve as the building blocks for a possible functionally graded structure: 100% 4130, 75% 4130 – 25% Cu, 50% 4130 – 50% Cu, and 25% 4130 – 75% Cu. The samples were characterized through X-ray fluorescence and diffraction, optical and scanning electron microscopy, microhardness, indentation plastometry, and laser flash analysis to determine their chemical composition, microstructural features, and mechanical and thermal properties.

As-built parts exhibited peculiar macrostructure morphologies resulting from Fe-Cu liquid phase separation and Marangoni effect. A recursive macrostructure comprising Cu and Fe regions alternating as matrix and dispersed phase at different length scales was observed for 50% 4130 – 50% Cu composition. Large thermal stresses and scarce terminal liquid at the end of solidification led to the formation of cracks in the samples with 75% 4130 – 25% Cu composition, whereas the abundant terminal liquid in 50% 4130 – 50% Cu and 25% 4130 – 75% Cu allowed microcrack backfilling, resulting in sound parts.

The formation of interconnected Cu regions in 50% 4130 – 50% Cu and 25% 4130 – 75% Cu samples led to ~50% and ~200% higher thermal diffusivity compared to the base steel, respectively. Fine martensitic constituents, supersaturated solid phases with finely dispersed precipitates, and the interaction between hard Fe and soft Cu domains contributed to high strength and ductility in 50% 4130 – 50% Cu parts. Heat treatments improved the strength and hardness of 100% 4130 samples due to the formation of tempered martensite, while 50% 4130 – 50% Cu samples softened due to Cu recrystallization and Cu/Fe diffusion from supersaturated phases.

Paper 1544 3

Additively manufactured high-strength and heat-resistant eutectic aluminum alloys

Mr. Feng Li, The Netherlands

Oral Presentation (20')

Abstract

Aluminum alloys are widely utilized in lightweight structural applications due to their favorable strength-to-weight ratio and excellent corrosion resistance. However, in additive manufacturing, conventional high-strength aluminum alloys exhibit a pronounced susceptibility to solidification cracking, significantly limiting their processability and applicability. Moreover, these alloys suffer from severe mechanical degradation at elevated temperatures, as the precipitate phases undergo rapid coarsening and lose their strengthening efficacy. Consequently, there is a pressing need to develop novel alloy design strategies that mitigate cracking susceptibility while ensuring superior thermal stability and mechanical performance in high-temperature environments. This work presents a novel Al-Ni-Fe-Zr eutectic alloy, designed using thermodynamic principles and non-equilibrium solidification modeling to optimize both printability and mechanical performance. Fabricated via laser powder bed fusion, the alloy with finer grains in the horizontal and vertical planes, refined by Zr-induced nucleation, significantly reduces microstructural anisotropy. The alloy achieves an as-built yield strength of 339.9 MPa and ultimate tensile strength of 560.9 MPa, attributed to its refined ~300 nm cellular microstructure with high-volume fractions of stable Al₃Ni eutectics. Thermal exposure at 350 °C for 100 h demonstrated the alloy's excellent resistance to coarsening, indicating its thermal stability. In-situ synchrotron X-ray diffraction, analyzed via the Williamson-Hall method, revealed significant dislocation accumulation in the as-built state. Aging led to partial dislocation recovery, suggesting a moderate relaxation of internal stresses. Nanosized L1₂-Al₃Zr precipitates with coherent interfaces further enhanced the yield strength to 391.4 MPa after aging at 300 °C for 6 h and contributed to high-temperature interface stability. These findings highlight the potential of the Al-Ni-Fe-Zr alloy for high-performance applications in environments where long-term thermal stability and mechanical integrity are crucial.

Microstructural Evolution and Mechanical Performance of Heat-Treated LPBF 17-4PH Stainless Steel:

Prof. Marialaura Tocci, Italy

Oral Presentation (20')

Abstract

Additive Manufacturing (AM) processes, particularly Laser Powder Bed Fusion (LPBF), have revolutionized the production of complex metallic components. Among various materials, 17-4PH stainless steel has gained significant attention due to its excellent combination of strength, hardness, and corrosion resistance. However, the rapid solidification conditions typical of LPBF processes lead to unique microstructural features that differ from conventionally manufactured parts, requiring specific post-processing treatments to achieve optimal properties.

This study investigates the influence of various heat treatment parameters on the microstructural evolution and mechanical properties of LPBF-manufactured 17-4PH stainless steel. Despite significant research in this field, contradictory results are often reported in literature regarding microstructural features obtained under as-built condition and optimal post-processing conditions. The inert gas used during the manufacturing process has been also reported to affect microstructural features under as-built condition. A comprehensive experimental campaign was conducted combining multiple characterization techniques, including optical microscopy, Scanning Electron Microscopy (SEM) and X-Ray based techniques to analyze the phase transformations and precipitation phenomena. Mechanical properties were evaluated through Vickers microhardness measurements. Different heat treatment cycles were tested to identify the optimal processing window for achieving desired microstructural features and mechanical performance.

Building upon the optimized heat treatment parameters, lattice structures were fabricated and mechanically characterized through compression testing. This application-oriented phase of the research demonstrates the potential of properly heat-treated LPBF 17-4PH for lightweight structural applications. The results provide valuable insights into the relationship between processing parameters, microstructural evolution, and mechanical behavior of LPBF 17-4PH, contributing to a better understanding of this widely used but complex material system.

Paper 1637 5 **Design of thermal treatments and composition evaluation of bio-compatible HEA Ti 3DP alloys based on computational thermodynamic approach**
Ph.D. Vasilis Loukadakis, Greece
Oral Presentation (20')

Abstract The design of titanium-based high-entropy alloys (HEAs) for biomedical applications presents a significant challenge, particularly when considering the complex thermal histories associated with additive manufacturing (AM) processes. This work leverages advanced computational tools to investigate the microstructural evolution and mechanical properties of a range of Ti-HEA compositions subjected to diverse AM thermal cycles. By integrating computational modeling with experimental validation, this study aims to establish a robust framework for selecting optimal HEA compositions and developing tailored post-AM heat treatments to achieve the desired combination of biocompatibility, strength, and ductility for demanding biomedical applications.

Paper 1753 6 **Innovative FeCr alloys SOFC/SOEC Interconnectors processed by advanced processing technologies leveraging master alloy concept**
Dr. Javier Hidalgo, Spain
Oral Presentation (20')

Abstract This study assesses innovative FeCr alloys designed for interconnectors in solid oxide fuel cells (SOFC) and solid oxide electrolyzer cells (SOEC). Using Crofer22 APU as a reference, novel alloys were developed for powder injection molding (PIM) and material extrusion (MEX) additive manufacturing, seeking improvement in performance with scalable and cost-effective processing routes. These alloys incorporate controlled additions of cobalt, manganese, and copper into a Fe-30Cr matrix using the master alloy approach to optimize thermal expansion, oxidation resistance, and mechanical strength. Both PIM and MEX processing were optimized to ensure defect-free fabrication of complex interconnectors. The feedstock formulation was carefully adjusted to achieve homogeneous powder dispersion and optimal flowability. Injection parameters were refined to minimize defects such as warping and residual stresses. Similarly, MEX processing involved fine-tuning extrusion parameters, including temperature, layer adhesion, and infill density, to enhance shape retention and reduce porosity. For both techniques, debinding strategies were optimized to prevent carbon residues, employing a two-step thermal and solvent-based approach that ensured complete binder removal without compromising dimensional stability. Sintering was conducted at 1320 °C, leading to near-full densification and a uniform microstructure with finely dispersed precipitates. The impact of exposure to in-service conditions, including high temperatures and oxidizing/reducing atmospheres, was evaluated through detailed microstructural characterization and phase analysis using scanning electron microscopy (SEM) and X-ray diffraction (XRD). Mechanical performance was assessed via microhardness and bending tests, comparing as-sintered specimens with those subjected to simulated operating environments. By addressing critical manufacturing challenges this research enhances the viability of advanced FeCr alloys for interconnector applications, supporting the development of more efficient and durable components for sustainable energy technologies.

Paper 1602 7

Microstructure Analysis and Micro-Mechanical Properties of Cu-based Metallic Glass between Different Scanning Strategies by Laser Powder Bed Fusion

Mr. Hsuan-Min Lin, Taiwan

Oral Presentation (20')

Abstract

With advancements in additive manufacturing (AM) technology, researchers have identified that the high cooling rates and small-scale molten pool characteristics inherent to this process offer a viable pathway for fabricating bulk metallic glasses (BMGs). By precisely controlling processing parameters based on the energy density equation, molten pools in the Laser Powder Bed Fusion (LPBF) process can be systematically stacked, enabling the formation of fully dense final components.

Despite the theoretical advantages of LPBF for BMG fabrication, two primary challenges remain. First, the densification of printed structures is highly sensitive to process parameters, including laser power (P), scanning speed (v), hatch distance (h), and layer thickness (t). These four parameters collectively define the energy density, which governs molten pool behavior. Optimizing these parameters is critical to achieving a homogeneous arrangement of molten pools within the material, thereby maximizing densification. Second, the formation of a heat-affected zone (HAZ) due to heat conduction around the molten pool poses a significant risk to maintaining the amorphous structure. If the printed amorphous alloy is reheated beyond its glass transition temperature (T_g), crystallization may occur, compromising the material's desirable properties.

To address these challenges, this study introduces a repetitive scanning strategy. In the initial scan, a lower energy input partially melts the metal powders, creating a porous structure that enhances heat dissipation and mitigates the impact of the HAZ. A subsequent scan with higher laser energy then fully melts the porous structure, ensuring densification while minimizing crystallization risks.

Microstructural analysis revealed that the two scanning strategies produced distinct phase separation morphologies. Furthermore, nano-indentation testing demonstrated that these variations in scanning strategy led to differences in micro-mechanical properties across different regions within each molten pool. In conclusion, this research focuses on comparing the effects of single-pass and repetitive scanning strategies on microstructural evolution and micro-mechanical performance, providing insights into optimizing LPBF parameters for BMG fabrication.

Highlight (Oral Presentation 20')

Abstract

Molten Metal Deposition (MMD) is a novel 3D printing approach that enables the fabrication of intricate geometries by continuous volumetric controlled stream of molten metal, such as aluminum, without the need for structural supports or post-processing operations like debinding and sintering. This method offers significant advantages in terms of efficiency and design flexibility. In this study, a 4xxx aluminum alloy, known for its combination of lightness properties and mechanical strength, was used as raw material. The inclusion of silicon plays a critical role in improving the molten metal's workability by reducing its viscosity, which facilitates the deposition of uniform layers, a key factor for achieving high-quality, intricate geometries. This study investigates the influence of process parameters on the defect formation and on the microstructure of single-wall rectangular samples in the as-built state. A Design of Experiment (DOE) approach was developed to assess the effect of variables such as nozzle temperature, substrate temperature, print speed, layer height, and trace width on defect formation and the microstructure of two different sample types with varying dimensions. The samples were subjected to conventional metallographic preparation followed by chemical etching with the Keller reagent to reveal their microstructural characteristics, which were then analyzed using Optical Microscopy (OM), Scanning Electron Microscopy (SEM) and Energy Dispersive Spectroscopy (EDS) to further assess chemical composition and morphology. Stereomicroscopy was then used to perform a surface analysis of the samples, including the characterization of surface waviness, aimed at understanding the quality of the material deposition process. Waviness between layers was examined to evaluate the cohesion between successive layers and to identify any interlayers defects. In addition, a detailed roughness analysis, both within each layer and between adjacent layers, was performed to further evaluate the surface quality and material behavior during the printing. Vickers microhardness tests were also conducted in order to investigate the mechanical properties along the growth direction of the samples. The results of this study provide crucial information on the potential of the innovative additive technology provided by ValCUN, highlighting the essential role of process parameters and their direct influence on the quality and performance of the final parts.

Correlation between Process Parameters and Microstructure of Nano- to Micro-Particle-Reinforced 3D Printed Aluminum Matrix Composites

Prof. Che-Nan Kuo, Taiwan

Oral Presentation (20')

Abstract

Lightweight materials are widely applied in aerospace, construction, and automotive applications. Introducing high specific strength materials is a promising way to achieve weight loss. Meanwhile, the 3D printing process is equally important due to its capability to realize complex lightweight designs. However, aluminum alloys such as Al-6061 and Al-7075 are challenging to be printed due to the hot cracking issue. Among the aluminum alloys, scalmalloy (Al-4.49Mg-0.71Sc-0.51Mn-0.27Zr-0.07Fe-0.03Si alloy, Al-Sc alloy) was developed to overcome the hot crack issue during the laser powder bed fusion (LPBF) process. In our previous study, the nano to micron-sized defects, such as the precipitate-free zone or unmelted powders, were successfully eliminated with the assistance of Al/MgI. In this study, in-situ synthesis and ex-situ addition were introduced to accomplish the simultaneous strengthening of precipitation and dispersion. Sc was added to the Al-Mg alloy to precipitate the Al₃Sc nanoparticles during the solidification. At the same time, SiC particles were mixed with the Al-based alloy powders and would remain after 3D processing due to the higher melting temperature of SiC. The relationship between the microstructure evolution and process parameters, including the 3D printing process and heat treatment, was explored.

Paper 2094 3

Coupling a continuous wave laser with a scanning electron microscope; use to improve mechanical behaviour of additive manufacturing 316L stainless steel

Ph.D. Juan Guillermo Santos Macías, Spain

Oral Presentation (20')

Abstract

Novel and vanguard fields like additive manufacturing (AM) require dedicated solutions to reach their full potential. In order to research the extreme heat processes involved in metal AM, a new coupling between a continuous wave laser and an environmental scanning electron microscope (SEM) was developed [1]. The laser parameters can be varied in a wide range that includes those used in metal AM techniques like laser powder bed fusion (LPBF) and laser-based direct energy deposition (LDED). The SEM allows to characterise in situ the processed materials in vacuum or controlled atmosphere.

This device was used to study the effect of lasering the surface of an LDED 316L stainless steel with LPBF parameters [1]. The state before and after lasering was characterised with SEM (secondary electrons, backscatter electron, electron backscatter diffraction), transmission electron microscopy and mechanical testing (static and fatigue). A one order of magnitude microstructural refinement was achieved, with significant mechanical behaviour improvement. These results showcase the capabilities of the laser SEM device, that also include great prospects for simulation research, which can gain significantly from the data provided by it [2,3].

Effect of build orientation on the microstructure and corrosion properties of additively manufactured SS316L

Dr. Arshad Yazdanpanah, Italy

Oral Presentation (20')

Abstract

This study investigates the effect of build orientation on the microstructure and corrosion behaviour of stainless steel 316L fabricated utilizing laser powder bed fusion (LPBF). Samples were produced at various inclination angles (40°, 50°, 60°, 70°, 80°, and 90°) using gas-atomized SS316L powder under an inert argon atmosphere. Microstructural analysis was performed using optical microscopy and scanning electron microscopy (SEM) to examine grain size, sub-grain cellular structures, and melt pool morphology. Residual stresses were measured via X-ray diffraction (XRD), while Vickers microhardness tests evaluated the mechanical properties. Corrosion performance was assessed through electrochemical impedance spectroscopy (EIS) and potentiodynamic polarization (PDP) in borate buffer solution. Results show that build orientation strongly influences thermal gradients, leading to variations in microstructure, residual stress, and corrosion resistance. The 60° orientation demonstrated the best performance with fine, uniform columnar grains, minimal elemental segregation, and the highest charge transfer resistance (R_{ct}), indicating superior corrosion resistance. Conversely, orientations such as 50° and 90° exhibited high residual stress and greater susceptibility to localized corrosion. This research underscores the critical role of build orientation in optimizing the properties of LPBF-manufactured SS316L components for corrosion-resistant applications.

Paper	1588	6	Influence of laser powder bed fusion on the microstructure and thermoelectric properties of CuNi Mrs. Karolin Amstein, Germany Oral Presentation (20')
Abstract			Thermoelectric materials enable the direct conversion of thermal energy into electrical energy and vice versa, offering a promising approach for energy harvesting and active cooling in various applications. However, the conventional manufacturing of such materials restricts the geometrical complexity, involves long process chains and leads to significant material losses. Additive manufacturing offers a solution for a potential broader application of thermoelectric devices, by enabling the direct fabrication of complex, customized structures. At the same time a reduction of material consumption and production time can be achieved as well as controlling the microstructure. However, applying additive manufacturing to synthesize thermoelectric materials still requires considerable research regarding processability and material properties. Furthermore, developing eco-friendly, non-toxic and earth-abundant thermoelectric materials that are competitive for specific applications are becoming increasingly important. The present contribution investigates the additive manufacturing of an earth abundant CuNi alloy by laser powder bed fusion (PBF-LB/M). Through optimized process parameters development, highly dense bulk samples were successfully produced. Furthermore, PBF-LB/M enables specific tailoring of the microstructure, i.e. regarding grain size and morphology, by adjusting the process parameters as detected by optical microscopy, scanning electron microscopy (SEM), electron backscatter diffraction (EBSD) and X-ray diffraction (XRD). This process optimization enables the modification of thermoelectric properties, such as electrical and thermal conductivity as well as the Seebeck coefficient, to meet the demands of advanced applications.

Blown-Powder Directed Energy Deposition (DED) of Inconel 625: process simulation and experimental validation

Dott. Alberto Santoni, Italy

Oral Presentation (20')

Abstract

Blown-Powder Directed Energy Deposition (DED) is an advanced Additive Manufacturing (AM) technique widely used for producing complex, high-performance components, particularly in aerospace applications. The use of Inconel 625, a nickel-based superalloy, is essential for components subjected to extreme conditions, including high temperatures, mechanical stresses, and corrosive environments. Inconel 625 is known for its outstanding high-temperature strength, oxidation and corrosion resistance, and excellent fatigue and creep resistance, making it ideal for critical aerospace components like turbine blades and exhaust systems. However, the effectiveness of DED with Inconel 625 relies heavily on the properties of the powder feedstock, including granulometry, flowability, and interactions with the deposition nozzle. These factors are essential for ensuring uniform material delivery and precise deposition, which directly impact the quality and performance of the final parts.

This study investigates both virgin and recycled Inconel 625 powders, characterized through Scanning Electron Microscopy (SEM), Energy Dispersive Spectroscopy (EDS), and X-ray Diffraction (XRD). The primary focus is on the impact of powder characteristic, such as particle size distribution and flowability, on the efficiency and quality of the deposition process. These properties were analysed in relation to the nozzle's performance, specifically how the powder's flowability affects deposition consistency and dimensional tolerance during DED processing. The correlation between the powder feedstock and the resulting mechanical and microstructural properties of thin-walled components was examined. Microstructural analysis, conducted via Optical Microscopy (OM) and SEM, were employed to assess key features such as grain structure, porosity, and phase formation and distribution. These characteristics are critical for ensuring the performance and reliability of the produced parts. To optimize the DED process, Finite Element Method (FEM) simulations were conducted on CAD models prior to printing to predict deformations and residual stresses that occur during deposition. The simulation results facilitated the optimization of component geometry to enhance printability and minimize distortions, with the methodology tailored for scalability to more complex geometries. The simulation accuracy was validated by comparing the virtual model with the printed geometry, using stereomicroscope measurements, which confirmed the FEM model's reliability in forecasting distortions.

The findings of this study emphasize the critical role of powder properties in the DED process and their direct influence on the quality and performance of additively manufactured aerospace components. By integrating powder characterization, process simulation, and microstructural analysis, this work provides valuable insights into optimizing material feedstock and process parameters, enhancing the efficiency and quality of components produced via additive manufacturing.

Paper 782 3 **Effect of substrate preheating on repairing Inconel 718 parts by Cold Spray Additive Manufacturing**
Ph.D. Vicente Albaladejo, Spain
Oral Presentation (20')

Abstract

Cold Spray Additive Manufacturing (CSAM) is a promising solid-state repair technique for high-performance materials such as Inconel 718® (IN718). However, the influence of substrate preheating on the deposition quality of IN718 coatings remains not completely explored. This study investigates the effect of substrate preheating on the microstructure, adhesion, and bonding mechanisms of cold-sprayed IN718 deposits, providing a viable alternative for repairing damaged IN718 components without altering their original microstructure.

Thick IN718 deposits were fabricated on IN718 substrates at three preheating temperatures: room temperature (RT), 250°C, and 400°C. The coatings were analyzed for porosity, microhardness, phase composition, and adhesion mechanisms at the splat-substrate interface. Bonding strength was also evaluated at varying deposit thicknesses and preheating conditions.

The results confirm that CSAM can effectively repair IN718 components without requiring bond coatings or extensive pre-processing, maintaining the feedstock's microstructure and phase composition. Substrate preheating significantly enhanced deposit density through two mechanisms: (i) increased plastic deformation due to substrate softening in the initial layers and (ii) the peening effect from subsequent particle impacts. Preheating also improved adhesion and cohesion, with the highest density (>99.9%) achieved at 400°C. Despite these improvements, microhardness remained unaffected by substrate temperature or deposit thickness.

These findings provide critical insights into optimizing CSAM processing parameters for IN718 repairs, reinforcing its potential as a sustainable and efficient alternative for restoring high-value aerospace and industrial components.

Innovative chemically-assisted mass finishing processes for additively manufactured metallic components

Mr. Matteo Pozzi, Italy

Oral Presentation (20')

Abstract

Additive manufacturing (AM) is an emerging manufacturing technology allowing for the production of customized parts characterized by complex geometries, often presenting cavities and channels. Poor surface finishing of as-built components is an issue that frequently limits the applicability of this technology: the presence of surface defects and high roughness (average roughness Ra usually ranging between 5 and 30 μm) make surface post-processing necessary.

This study focuses on chemically-assisted mass finishing as effective process to polish AM components. Conventional mass finishing is a widely applied technology that promotes surface smoothing through the mechanical action of abrasive media that remove surface asperities. Chemically-assisted mass finishing is a newly developed approach relying on the combination of the mechanical action of media and the chemical action of etching solutions, allowing to increase material removal rate, treat highly rough surfaces and reach cavities and recesses poorly accessible by media. The effect of printing parameters, surface orientation, properties of the abrasive media, process time and composition of the etching solutions on surface roughness and morphology was investigated on samples with increasing geometrical complexity.

Tests were performed on AISI 316 L and Inconel 718 samples produced by Laser Powder Bed Fusion technology. Polishing processes were run in vibrating machines in wet conditions with ceramic or polymeric abrasive media characterized by different cutting efficiency. Chemical solutions composed by oxidizing species, pH regulators, passivating and complexing agents were added. Surface roughness was assessed by optical and by contact profilometry; surface morphology was observed by means of optical and electronic microscopy; 3D optical scans were used to evaluate material removal homogeneity. Treated components underwent compositional analysis (Energy Dispersive X-ray Spectroscopy and Glow-Discharge Optical Emission Spectroscopy) and corrosion tests.

Considering external surfaces, initial roughness (initial Ra ranging between 6 and 32 μm according to surface orientation) was reduced by more than 80% regardless printing orientation, reaching values lower than Ra = 1,0 μm in most favorable printing conditions. On inner surfaces (inside the channels), roughness homogeneously decreased by about 60% along the entire length of the component. In both cases, chemically-assisted processes have proven to be more effective than conventional mass finishing and chemical polishing, resulting in lower roughness and more homogeneous surfaces. Based on corrosion tests, the investigated chemically-assisted mass-finishing processes did not alter the corrosion behavior of the components.

Paper 1097 5 Tensile and Low-Cycle Fatigue Behavior of Laser Powder Bed Fused Inconel 718 at Room and High Temperature
Dr. Leonardo Agudo Jácome, Germany
Oral Presentation (20')

Abstract

The nickel base superalloy Inconel 718 (IN718) is the most commonly used Ni-based superalloy for high temperature structural applications for its remarkable strength, as well as creep, fatigue, and corrosion resistance up to 650 °C. While IN718 has traditionally been employed as cast or wrought material, is difficult to machine because of its high strength and toughness. The additive manufacturing of IN718 components made by metal AM has thus gained extensive attention to produce expensive near-net shaped components of high-temperature alloys such as IN718 for it saves material and costs in processing and machining steps.

Among all metal additive manufacturing (AM) technologies, laser powder bed fusion (PBF-LB/M) is the most widespread, IN718 being one of the most common alloys produced. However, high cooling rates associated to the PBF-LB/M process, hinders the primary strengthening phases γ'' and γ' to form, as these cooling rates induce a dislocation cellular substructure at which walls forming Laves phases bind segregating Nb, Ti and Mo. Many of the therefore needed heat treatment strategies can then promote Laves phase transformation into the stable δ phase along the cell and grain boundaries. Laves and δ phases, as well as grain boundary primary carbides may have adverse effects on mechanical properties. The mostly needle-shaped δ phase was namely found to have a detrimental effect on creep rupture life while no direct effect on LCF fatigue life was evident.

In this work room- and high-temperature (650 °C) tensile and low-cycle fatigue behaviors of PBF-LB/M IN718 is investigated in the four-step heat treated state and compared wrought IN718. The microstructure of both materials is characterized across length scales via microscopy methods. The elastic and yield properties are comparable at both test temperatures while tensile strength, ductility, and strain hardening capacity are lower for the PBF-LB/M IN718 material. Its fatigue life at room temperature is slightly lower than that for the wrought material, which is reversed at 650 °C. The cyclic stress response for both materials is marked by cyclic softening that is more pronounced at higher test temperatures. Multiple secondary cracks form at high strain amplitudes, at both room and high temperatures. High testing temperatures specially enhance crack formation at the transitions of regions between elongated grains and columns of stacked grains with ripple patterns in the PBF-LB/M material. Additional to this behavior, pronounced crack branching and deflection indicate that the cracks are controlled by sharp micromechanical gradients.

Paper 261 **1** **Enhancing Lithium-Ion Batteries: Advanced Architectures for High-Performance LiFePO₄ Cathodes**

Dr. Carolina Lara, Chile

Keynote (Oral Presentation 40')

Abstract

The increasing demand for sustainable energy solutions and the rapid expansion of the electric vehicle (EV) market have placed significant focus on lithium-ion batteries as a critical enabler of these technologies. Among the various cathode materials, lithium iron phosphate (LiFePO₄, or LFP) has emerged as a compelling option due to its superior thermal stability, inherent safety, and cost-effectiveness. LFP's long cycle life and resistance to thermal runaway make it an ideal candidate for large-scale applications, including EVs and renewable energy storage systems. Moreover, its reliance on abundant, non-toxic raw materials positions it as a sustainable alternative to nickel- and cobalt-based chemistries. However, despite these advantages, LFP suffers from kinetic limitations that hinder its performance under high-power and fast-charging conditions, restricting its broader adoption in energy-intensive scenarios such as electromobility.

The primary objective of this study is to overcome the kinetic limitations of LFP by designing and optimizing a novel cathode architecture. This approach aims to enhance the transport of lithium ions and electrons, thereby improving the electrochemical performance of LFP-based batteries at high current rates.

To achieve this, the research focused on combining the morphology of LFP particles with conductive additives to act synergistically, enhancing ion and electron transport. Through the optimized manufacturing and drying process of the cathode film, the alignment of internal structures was achieved, resulting in highly interconnected networks. The microstructural characterization of the cathodes and their components was conducted using advanced techniques, revealing improved structural connectivity and alignment. Electrochemical characterization, including rate capability tests and cycling stability, demonstrated the superior performance of the proposed architecture compared to alternative designs.

The results showed that the aligned cathode architecture significantly improves energy transfer efficiency, enabling enhanced performance under high current rates. Additionally, this design mitigates traditional kinetic challenges while improving durability and energy efficiency. These findings highlight the scalability and practicality of the proposed approach, offering a promising pathway for industrial-scale production of fast-charging LFP-based batteries.

This study presents a significant advancement in LFP cathode engineering by integrating material design with alternative and low cost manufacturing techniques. Unlike prior studies, which often focus on improving either the material properties or the electrode structure in isolation, this work demonstrates the transformative impact of aligning both aspects. The resulting architecture not only bridges the gap between material

Intercalation-Conversion Hybrid Cathode Enabled by MXene-Driven TiO₂/TiS₂ Heterostructure for High-Energy-Density Li-S Battery

Prof. Seung-Mo Lee, South Korea

Oral Presentation (20')

Abstract

A dense electrode with high sulfur loading is a straightforward approach to increasing the energy density of lithium-sulfur battery (LSB), but the development of dense electrodes suffers from both fabrication challenges and electron/ion transport limitations. In addition, the shuttle effect of soluble lithium polysulfides and sluggish reaction kinetics cause declined utilization efficiency of the active material and poor cycling stability. Herein, a dense intercalation-conversion hybrid cathode is prepared using MXene-driven TiS₂ nano-needles decorated with TiO₂ nanoparticles. The TiO₂/TiS₂ heterostructure simultaneously possessing a high adsorption capability (TiO₂) and bidirectional electrocatalytic effect (TiS₂) is observed to effectively suppress lithium polysulfide shuttling and facilitate the sulfur conversion reactions. Furthermore, it is believed that TiS₂ provides additional capacity from the intercalation reaction and functions as a multichannel network to feed both Li⁺/e⁻ to the active sulfur material due to its high electronic and ionic conductivities. Thanks to these synergistic effects, the LSB assembled using the TiO₂/TiS₂ heterostructure exhibits high gravimetric and volumetric energy densities of 331 Wh kg⁻¹ and 730 Wh L⁻¹, respectively, as well as superior cyclability at a high sulfur mass loading of 7.5 mg cm⁻² and lean electrolyte of 2.5 μ L mg⁻¹.

Paper 1015 3 **Novel Polyperyleneimide-Based Organic Cathodes with Graphene-Like Structures for Calcium Multivalent Secondary Batteries.**
Señora. Belén Martínez, Spain
Oral Presentation (20')

Abstract

The green and digital transition, as well as the associated transformation of our economy, industry and society to achieve climate neutrality in Europe by 2050 is a challenge, which cannot be faced without considering the development of new energy storage technologies, as crucial components in promoting alternative and sustainable energy strategies, including wind or solar energy harvesting. Traditionally, the energy storage systems are based on lithium materials and transition metals, whose extraction and use are associated with a high environmental, social and economic impact. For this reason, it is vitally important to find new energy alternatives that are ecologically, socially and environmentally sustainable. Among these new energy alternatives are calcium batteries, which are part of the group called transition-metal-free energy storage systems, and although they are expected to be safe, efficient and economically viable, its application is limited due to the difficulty of finding efficient cathodes for calcium-type batteries.

Numerous studies have evaluated the electrochemical properties of Organic Electrode Materials (OEMs), including conductive polymers, organosulfur compounds, and carbonyl compounds. While strategies such as structural engineering, polymerization, hybridization, and amorphization have been employed to enhance cathode performance, the use of OEMs in multivalent batteries remains limited. Challenges such as low cell voltage, reduced specific power/energy, poor electrical conductivity, and dissolution in electrolytes continue to hinder their practical application.

In this study, we present our latest advancements in developing organic cathodes based on polyperyleneimide redox-active materials integrated with graphene-like structures. Utilizing directed methodologies, we achieved highly conductive hybrid cathodes with a redox-active molecule content of 90%-95% and capacities reaching 2-3 mAh/cm². These innovative cathode materials were synthesized using a novel, cost-effective, reproducible, and sustainable approach, eliminating the need for expensive and environmentally harmful solvents such as DMF and DMSO. Thus, the developed polymer synthetic strategy is straightforward, scalable to gram quantities, and without complex purification or isolation processes.

The developed hybrid materials were structurally characterized using a combination of techniques, including nuclear magnetic resonance (NMR), differential scanning calorimetry–thermogravimetric analysis (DSC-TG), and infrared spectroscopy (IR), among others. Upon confirming their structures, their electrochemical properties were analyzed using electrochemical techniques such as cyclic voltammetry and impedance spectroscopy, and others related methods, which provided promising properties as efficient a stable organic cathodes for calcium batteries.

Finally, they were studied in symmetric calcium cells, yielding promising results.

Novel Na_{0.75}(Ni_{0.2}Co_{0.2}Mn_{0.2}Fe_{0.2}Ti_{0.2})O₂ high entropy cathodes for sodium-ion batteries with superior capacity and stability

Prof. Mauro Coduri, Italy

Highlight (Oral Presentation 20')

Abstract

The great abundance of sodium, its low cost and the similar chemistry to lithium, makes sodium-ion batteries (SIBs) a promising alternative to traditional lithium-ion batteries. However, the development of sustainable, low-cost, high-capacity, and stable cathode materials is still an open challenge for the SIBs technology. Layered oxides (Na_x(TM)O₂, with TM being a transition metal ion) are among the most promising candidates. They can exhibit a set of flexible crystallographic structures, differing on the layer stacking and the metal connectivity, which proved to be efficient with respect to Na reversible insertion and extraction. A critical aspect of layered oxides is that high specific capacity can be achieved at the expense of cycling stability. The latter can be improved by exploiting the high entropy concept, i.e. by designing materials with a large configurational entropy, characterized by more cations sharing the same crystallographic site. Indeed, the combination of different transition metals helps to increase the reversibility of the phase transitions occurring during the charging/discharging cycles.

Here we report on a novel composite cathode active material (CAM) with composition Na_{0.75}(Ni_{0.2}Co_{0.2}Mn_{0.2}Fe_{0.2}Ti_{0.2})O₂ produced with a homemade spray pyrolysis setup, which led to well separated grains with submicrometric size. The CAM is composed for three parts of a mixture of two layered oxides, and for one part of some residual rock salt and spinel phases. The electrochemical performance combine high capacity and stability: the cathode reaches initial discharge capacities of approximately 180 mAh g⁻¹ (0.08C, 15 mA g⁻¹) and exhibits capacity retention of 69% after 300 cycles at a current density as high as 200 mA g⁻¹ (1C). The post mortem analysis revealed no major changes in microstructure and phase composition.

To assess the impact of the microstructure, we prepared a CAM with the same chemical composition using a more conventional synthesis method, specifically sol-gel. This approach yielded a nearly phase-pure material with smaller and more irregular grains. In comparison to the CAM produced via spray pyrolysis, it exhibited electrochemical performance consistent with existing literature, with reduced capacity and stability.

Paper 1606 5 DFT calculations of the electrochemical curve of LiMn_{1.5}Ni_{0.5}O₄: influence of the functional and comparison with experiments

Ph.D. Nicolas Emery, France

Oral Presentation (20')

Abstract

Nickel and manganese spinels are widely studied for their high application potential [1]. The electrochemical behavior of these materials, such as the voltage difference between the Ni²⁺/Ni³⁺ and Ni³⁺/Ni⁴⁺ redox couples, is influenced by the nickel content and structural defects [2-4]. Detailed characterizations of the lithiated materials, combined with theoretical methods, have provided insight into these defects [2,3]. However, these coupled studies do not fully describe the influence of these defects on the shape of the electrochemical curve of the Li_xMn_{1.5}Ni_{0.5}O₄ system ($0 \leq x \leq 1$): either they are limited to the influence on the mean operating voltage [3], or the question is not addressed [2]. A literature review shows that, for the ideal case of the perfectly ordered P4332 group structure, only two DFT studies address the description of the electrochemical curve, one with the PBE functional [5] and the other with the same PBE functional with the Hubbard correction [6]. In the first, the curve is qualitatively reproduced with an underestimated mean voltage, whereas in the second, if the mean voltage is like the experiment, the intermediate phase Li_{0.5}Mn_{1.5}Ni_{0.5}O₄ is not supposed to be unstable and not observed. Thus, before tackling the fine description of the influence of these defects, it is necessary to have as good as possible reproduction of the galvanostatic curve. In this communication, we will compare four different functionals to describe the Li_xMn_{1.5}Ni_{0.5}O₄ ($0 \leq x \leq 1$) system and check the result with various experimental results. We employed the PBE and PBE+U (adding the Hubbard correction), R²Scan and HSE06 functionals as implemented in VASP [7]. Thus, using a set of experimental/theoretical comparisons, we will describe the Li_xMn_{1.5}Ni_{0.5}O₄ ($0 \leq x \leq 1$) system more or less accurately depending on the functional used. At the end of this work, the best functional identified to describe the Li_xMn_{1.5}Ni_{0.5}O₄ ($0 \leq x \leq 1$) system will be used to study lithium diffusion, the effect of stoichiometry, structural defects, etc.

Paper 1832 7

Operando analysis of lead batteries by wavelength-selective neutron imaging

Dr. Angel Larrea, Spain

Highlight (Oral Presentation 20')

Abstract

We have explored the use of wavelength-selective neutron imaging and Bragg edge analysis to carry out non-destructive studies of working lead batteries fabricated with three commercial electrodes, giving a total battery size of ~15 cm x 10 cm x 1 cm. Due to the high average atomic number of the constituent materials and the large electrode thickness (~3mm), neutron scattering is the only technique that allows the behaviour of these devices to be studied under real operating conditions.

In this technique the concentration of a crystalline phase can be determined by comparing images taken at close neutron wavelengths near a diffraction Bragg edge. This technique offers promising temporal and spatial resolutions and has been applied for the first time to electrochemical storage devices. We will present the first results from experiments carried out at the Paul Scherrer Institut (PSI, Switzerland). These experiments include the analysis of single-phase powders, dry electrodes and operating cells during charge-discharge cycles.

Paper 521 1 **Development of Silicide Thermoelectric Devices for Energy Harvesting based on Recyclable Silicon from PV industry**

Dr. Panagiotis Mangelis, Cyprus

Highlight (Oral Presentation 20')

Abstract

Taking into account that ca. 66% of global energy consumption is emitted to the environment as waste heat, thermoelectric (TE) devices can offer a promising approach for waste heat recovery and energy savings when applied in combustion engines and industrial processes. Solid-state TE Generators (TEGs) are able to provide great advantages since they directly convert heat into clean electrical power through the Seebeck effect, and operate without any CO₂ or toxic emissions, vibration, or noise. Silicide thermoelectrics have attracted considerable attention because these compounds consist of earth-abundant and eco-friendly elements, combining good TE properties and suitable stability for mid-temperature TE applications. From the point of view of materials, the TE efficiency is determined by the dimensionless figure of merit, ZT, depending on the Seebeck coefficient, the electrical conductivity, the absolute temperature, and the thermal conductivity.

In an effort to establish a circular economy approach and provide a cost-effective solution for the manufacturing of high-performance TEGs, the European program ICARUS attempts to utilize effectively recycled Si from PV manufacturing industry for the development of silicide thermoelectrics. Two types of recycled Si kerf are used for the synthesis of n-type Mg₂Si_xSn_{1-x}, (0.6 ≤ x ≤ 1.0) solid solutions and p-type Higher Manganese Silicide (HMS) MnSi_x phases. The investigated materials are developed by Mechanical Alloying (MA) which is an energy-efficient, straightforward and scalable method. Material characterization is carried out by using X-ray diffraction and the crystal structure of final products is confirmed through the Rietveld method, while SEM analysis is also performed to study the micro-structure of developed phases. Promising TE efficiencies are achieved for the kerf-based materials which are used for the fabrication of TE modules (TEM). The developed devices are characterized using a TEM testing apparatus. High power density is achieved for the Si-kerf-based TEM devices, and a good agreement between experimental and simulated performance is observed. The aforementioned results validate that this research work is a successful paradigm of circular economy approach, providing sustainability and a strong silicon recycling solution in the field of green energy technologies.

This work is part of ICARUS project funded by Horizon 2020 research and innovation programme under grant agreement No 958365. ICARUS project aims to process and refine secondary raw materials from silicon PV manufacturing.

Paper 190 **2** **The discovery of Ta₂Ni₃S₈: a new fiber-like crystal structure with promising thermoelectric properties**
Dr. Radoslaw Chmielowski, France
Highlight (Oral Presentation 20')

Abstract

Our quest for new materials for thermoelectric applications has led to the discovery of a completely new material, previously undescribed in any material database. The novel compound, Ta₂Ni₃S₈, was synthesized in a quartz ampoule in the form of low-dimensional fibrous grains, making the determination of its crystal structure highly complex. Conventional X-ray diffraction tools were insufficient for resolving its structure. Consequently, the precession electron diffraction tomography method [1-3], combined with dynamical calculations [4-5], was employed to solve and refine the structure on an individual fiber isolated on a carbon grid. The material is characterized by the space group I4/m (No. 87), with unit cell parameters $a = 23.853(4) \text{ \AA}$ and $c = 3.2962(4) \text{ \AA}$. The evaluation of the transport properties was carried out on pellets fabricated by spark plasma sintering. However, due to its fibrous nature, the material exhibits strong anisotropy (up to 6x between along and across fibers) in transport properties. Intrinsically, Ta₂Ni₃S₈ shows n-type conductivity, with a Seebeck coefficient ranging from -100 to -150 $\mu\text{V/K}$. To assess the thermoelectric potential of this material, several doping trials were performed using W, Cu, Cl, Ni, and Sb. Notably, Ta₂Ni₃S₈ doped with Cu demonstrated a power factor along the fibers of 700 - 1200 $\mu\text{W}\cdot\text{K}^{-2}\cdot\text{m}^{-1}$ from RT to 460°C making this material an interesting candidate for further optimization.

High Thermoelectric Performance of Copper Selenide and Silver Selenide electrodeposited films

Mrs. Elena Pérez-Picazo, Spain

Oral Presentation (20')

Abstract

The growing interest in thermoelectric applications has driven a shift towards affordable, sustainable and easily scalable materials that continue to offer high performance, such as copper selenide (Cu₂Se)[1-2] and silver selenide (Ag₂Se)[3]. In this work, copper selenide and silver selenide films with different compositions were grown by electroposition using new optimized solutions. The structural, morphological and compositional characteristics of the films were analyzed by X-ray diffraction (XRD), scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDX) and X-ray fluorescence (XRF). The thermoelectric properties, such as electrical conductivity (σ), Seebeck coefficient (S) and thermal conductivity (k) of the films were also measured. Maximum power factors ($PF=\sigma S^2$) of $912 \pm 188 \mu W/m \cdot K^2$ and $3464 \pm 714 \mu W/m \cdot K^2$ were obtained for the copper selenide and the silver selenide films, respectively, surpassing all previous records reported in the literature for films[4-5]. These results set a new benchmark for electrodeposited Cu₂Se and Ag₂Se films, advancing high-performance thermoelectric materials.

Paper 516 4 Use of fast preparation method to produce n- and p- thermoelectric legs and their integration into a thermoelectric module for power generation

Prof. Andres Sotelo, Spain

Oral Presentation (20')

Abstract

It is well known that the massive use of thermoelectric generators (TEG) requires not only high-performance p- and n-type thermoelectric materials, but also good compatibility among the different elements used to build the TEG. Moreover, the highest output power, low cost per watt, and long life span are other features that should be achieved in these TEG. Based on previous works, $\text{Ca}_{0.91}\text{Y}_{0.03}\text{La}_{0.03}\text{Yb}_{0.03}\text{MnO}_3$, and $\text{Ca}_{2.93}\text{Sr}_{0.07}\text{Co}_4\text{O}_9$ materials were prepared as n- and p-type legs. The stoichiometric amounts of precursors were attrition milled for 2h, dried and manually milled. The mixtures were calcined at 1100, and 850°C for 1h, for the n-, and p-type, respectively, and cold uniaxially pressed. The pellets were sintered at 1310°C for 6h, and 900°C for 12h for the n-, and p-type materials, respectively. Powder XRD patterns showed that the thermoelectric phase is the major one in both cases, accompanied of small amounts of secondary phases. Microstructural studies confirmed the XRD data, and showed much lower porosity content in the n-type material than in the p-type one. Electrical resistivity showed semiconducting-like behaviour for both types of samples, and the values at 800°C are 5.7, and 17mΩ cm for the n- and p-type legs, respectively. Seebeck coefficient is negative for the n-type, and positive for the p-type. Furthermore, the absolute value is increased with temperature in both cases, reaching 190, and 290μV/K for the n-, and p-type legs, respectively. Thermal conductivity decreases with temperature for the p-type material reaching 1.60W/K m at 800°C, while it is approximately constant for the n-type (1.20W/K m). These results lead to ZT values of 0.56, and 0.53, for the n-, and p-type materials, respectively. Once the materials have been fully characterized, a large number of p-, and n-type legs were prepared, and their resistance at room temperature has been determined, followed by Ag paint of their ends and sintered at 900°C for 2h to assure good adhesion. At the same time, Ag has been used to design the electrical circuit on the top and bottom alumina layers, and sintered at 900°C for 2h. Finally, the thermoelectric legs were integrated in the TEG using Ag paint and the whole system has been sintered at 900°C for 2h, and the final prototype has been characterized with a cold side temperature fixed at 16°C, while the hot side has been heated at temperatures between 100 and 900°C.

Paper 254 **5** **Intrinsic Plasmonic Heating in Bismuth Telluride Nanostructures: Enhancing Thermoelectric Performance through Geometric and Nanostructure Modifications**
Dr. Olga Caballero Calero, Spain
Oral Presentation (20')

Abstract

This study explores the potential of plasmonic heating in bismuth telluride (Bi_2Te_3) nanostructures as a pathway to enhance their thermoelectric performance without the need for external metallic plasmonic nanoparticles. By harnessing surface plasmon resonances inherent to nanostructured Bi_2Te_3 , we demonstrate localized temperature increases that improve thermoelectric efficiency. Utilizing template-assisted electrochemical deposition, we fabricated 1D nanowire arrays and 3D nanowire networks, systematically evaluating their plasmonic heating performance through Raman spectroscopy under various excitation wavelengths. Our results reveal that 3D nanowire networks exhibit significantly higher plasmonic resonance intensities compared to 1D arrays, leading to more pronounced localized heating. This enhanced thermal gradient, driven by plasmonic heating, can improve energy conversion efficiency in thermoelectric applications. Unlike traditional approaches that rely on metallic nanoparticles to induce plasmonic effects, our findings underscore the capability of Bi_2Te_3 nanostructures to independently generate and optimize plasmonic heating through geometric and structural modifications. The unique plasmonic properties of Bi_2Te_3 , a topological insulator, stem from its topological surface states, which enable visible-range surface plasmon resonances. These resonances can be tailored by engineering the size, shape, and arrangement of nanostructures, offering a versatile platform for enhancing both plasmonic and thermoelectric functionalities. The 3D nanowire networks, in particular, demonstrate superior plasmonic heating capabilities due to their increased surface area and enhanced light-matter interactions, highlighting their potential for next-generation thermoelectric devices. This work not only advances the understanding of plasmonic interactions in topological insulators but also opens new avenues for the design of sustainable energy technologies. By strategically optimizing Bi_2Te_3 nanostructures to exploit plasmonic heating mechanisms, we provide a pathway for developing high-efficiency thermoelectric devices. These findings emphasize the importance of integrating plasmonic and thermoelectric properties at the nanoscale, offering a transformative approach to energy conversion and thermal management in advanced material systems. In summary, our study establishes the foundation for leveraging intrinsic plasmonic heating in Bi_2Te_3 nanostructures, paving the way for innovative applications in thermoelectric energy conversion. Future research can build upon these insights to further enhance device performance through precise nanoscale engineering of plasmonic and thermoelectric interactions.

ALL-PRINTED, ORGANIC THERMOELECTRIC GENERATORS ON FLEXIBLE SUBSTRATES

Mr. Loup Chopplet, France

Oral Presentation (20')

Abstract

To meet current environmental challenges, researchers are looking to develop new methods of energy production that would provide an alternative to fossil fuels, while also reducing the greenhouse gas emission. Within this context, thermoelectric materials, i.e. materials capable of converting heat into electricity, have been arousing growing interest over the last twenty years, as they could help to meet the quest for energy.¹ The many advances on organic semiconductors (OSCs) are showing ever better conductive properties, in addition to their improvable high electrical conductivity, and an intrinsic low thermal conductivity, which is in line with the optimisation of the figure of merit quantifying thermoelectric efficiency, namely zT . This makes OSCs ideal candidates for thermoelectric devices. Compared with inorganic semiconductors, OSCs offer several advantages, such as their better processability in the liquid phase (enabling the use of printing techniques), their flexibility, their mechanical robustness and their competitive cost². In this work, we will present the fabrication and characterisation of fully printed thermoelectric generators on flexible polyimide substrates. These generators are composed of two legs, electrically connected in series. The first leg is made using a p-type OSC, namely poly(3,4-ethylenedioxythiophene) polystyrene sulphonate (PEDOT: PSS), in the form of a commercial ink deposited by ink-jet printing. The second leg is made using an n-type OSC, namely poly(3,7-dihydrobenzo[1,2-b:4,5-b']difuran-2,6-dione) (PBDF) synthesised from protocols described in the literature³ and deposited here by ink dispensing. We will present the formulation of the inks, the characterisation of their rheological properties and the electrical properties of the printed layers. Then, we will describe the fabrication of the full generators and their complete thermoelectric characterisation (I/V and V/T curves, output power measurements). While exposed to a temperature gradient of 13K/cm, our generators exhibit a Seebeck coefficient as high as 35 $\mu\text{V/K}$ and an output power of 2 nW for a p-n pair measuring 6 cm^2 and approximately 1 μm thick. Finally, we will present the outcome of the mechanical tests of these flexible thermoelectric generators, in order to investigate the impact of flexibility on their thermoelectric performances.

Effect of Deposition Temperature on the Thermoelectric Properties of MnFe_2O_4 Thin Films

Prof. Paolo Mele, Japan

Highlight (Oral Presentation 20')

Abstract

This study investigates the influence of deposition temperature in the pulsed laser deposition (PLD) process on the structural and thermoelectric properties of manganese ferrite (MnFe_2O_4) thin films. Deposition temperature plays a crucial role in determining crystallinity and preferential growth orientation, with higher temperatures enhancing crystallinity and promoting growth along the [311] crystallographic direction. These trends were confirmed through X-ray diffraction (XRD) analysis and morphological examination via scanning electron microscopy (SEM) and transmission electron microscopy (TEM), which revealed well-defined crystalline structures at elevated deposition temperatures.

To further optimize the thermoelectric performance, post-deposition annealing was carried out under different atmospheric conditions, including air, oxygen, argon, and a reducing environment ($\text{Ar} + 1\% \text{H}_2$). The thermoelectric properties were characterized in terms of the Seebeck coefficient (S) and sheet resistance (R_s) at room temperature, revealing significant anisotropy effects influencing charge transport. Among the investigated samples, the highest Seebeck coefficient was observed for the film deposited at 700 °C, with a value of $-665 \mu\text{V/K}$ at room temperature, indicating n-type semiconductor behavior.

However, thermoelectric measurements conducted over a temperature range from room temperature to 350°C exhibited variations, suggesting a complex interplay between crystallinity, grain orientation, and charge transport mechanisms. Notably, the highest power factor of $6.5 \mu\text{W}/(\text{m}\cdot\text{K}^2)$ was achieved at 350°C for the film deposited at 200 °C, despite its lower crystallinity at room temperature. This finding suggests that thermally activated charge transport mechanisms significantly contribute to the overall thermoelectric performance.

Post-deposition annealing played a crucial role in modifying the film structure and transport properties. Annealing in oxidizing atmospheres (air or O_2) led to phase transformations into hematite, drastically reducing electrical conductivity. In contrast, reducing conditions ($\text{Ar} + 1\% \text{H}_2$) altered the preferential crystal orientation from [311] to [111], introducing an additional unidentified phase. Annealing in pure argon at 300°C successfully preserved the [311] orientation while maintaining favorable electrical conductivity, highlighting the importance of controlled thermal treatments for optimizing thermoelectric performance.

This work demonstrates that both deposition temperature and post-deposition annealing significantly affect the crystallographic orientation and thermoelectric behavior of MnFe_2O_4 thin films. The findings provide valuable insights into tailoring the structural and electronic properties of spinel ferrites for thermoelectric applications.

Paper 480 **2** **High Power Factor Silver Selenide thin films deposited at low temperature by pulsed hybrid reactive magnetron sputtering (PHRMS)**
Mr. Jose María Domínguez Vázquez, Spain
Oral Presentation (20')

Abstract

Thermoelectric materials convert a thermal gradient into a voltage difference. This quality makes them candidates for increasing the efficiency of energy generation, through the harvest of waste heat. Thermoelectric generators (TEGs) can be applied for waste heat recovery, like is the case of human heat harvesting, which can be useful for powering wearables and Internet of Things (IoT) devices (1). Thermoelectric efficiency is evaluated with the figure of merit zT , defined as $zT = S^2 \sigma T / \kappa$, being S the Seebeck coefficient, σ the electrical conductivity, κ the thermal conductivity and T the temperature. Therefore, materials with high power factor ($PF = S^2 \sigma$) and low thermal conductivity are highly interesting.

Silver selenide (Ag_2Se) is a high-performance thermoelectric material near the room temperature range (2,3). Although this material has been widely studied in bulk form, thin film works remain scarce in comparison, due to its fabrication complexity. To fabricate these films our group developed pulsed hybrid reactive magnetron sputtering (PHRMS) (4,5). In this technique, Ag is deposited by DC magnetron sputtering and Se is added using a pulsed flux effusion cell. This technique avoids Se overpressure or high substrate/cell temperatures to obtain Ag_2Se films with good thermoelectric properties, therefore, it is totally compatible with the use of polymer substrates, also flexible ones, for producing wearable devices. The PHRMS process is implemented in EUOPHAS, a newly developed semi-industrial multi-chamber deposition system, designed for the fabrication of 2" size samples.

In this work, we present our first experimental results of Ag_2Se thin films grown on amorphous borosilicate glass substrates at room temperature by PHRMS in the EUOPHAS system where we obtain thin films showing α -phase crystallization and a PF around $4000 \mu W / (m \cdot K^2)$, surpassing actual values from the literature (4,6). The structural and thermoelectric characterization are shown and discussed as well as the effect of stoichiometry variation on the properties of the films.

Evolution of defects for high thermoelectric power factor in copper iodide films

Dr. Peter Paul Murmu, New Zealand

Oral Presentation (20')

Abstract

Copper iodide (CuI) is a wide-bandgap semiconductor and a sustainable thermoelectric material suitable for transparent thermoelectric and smart window applications[1]. However, it suffers from poor electrical transport properties due to its low electrical conductivity (σ), which leads to a low power factor ($\alpha^2\sigma$), where α is the Seebeck coefficient, thereby reducing its thermoelectric energy conversion efficiency. Defect engineering is an effective method for tuning its electronic band structure and modifying defect complexes to improve the power factor[2]. Ion implantation is a versatile microfabrication doping technique that allows for controlled introduction of suitable dopants and modulation of point defects[3].

In this paper, we report on the defect engineering by implanting noble gas ions (Ne, Ar, and Xe)[4] or chalcogen ions (S, Se, and Te)[5,6] into cubic zinc blende γ -CuI films[7] using a GNS low-energy ion implanter. Density functional theory and Monte Carlo calculations revealed that the substitution of chalcogen elements (Ch) at the iodine site (ChI) and the copper vacancy (VCu) defect complex exhibited a shallower acceptor transition than isolated ChI and VCu defects. Noble gas ions led to the abundant production of Frenkel pairs, which suppressed compensating donors in CuI and increased hole density. The implantation generated point defects favored formation of defect complexes with the dopants, simultaneously increasing α and σ , resulting in a high power factor. Our results demonstrate that defect engineering via implantation is an effective strategy for enhancing the power factor and achieving high thermoelectric efficiency.

Paper 1783 4 **Thermomagnetic properties of multi-principal elements Cu-Fe-Mn-Ni-Sn-Ti alloys for waste heat recovery**
Dr. Leandro Santos Silva, Brazil
Oral Presentation (20')

Abstract

The study of multi-principal elements alloys (MPEA's) can be a useful approach for the obtention of magnetic materials with tunable properties. A good example of that is the addition of Sn to the CuFeMnNiTi alloy, which increases the magnetic response from an initial paramagnetic to a ferromagnetic behavior with a magnetization saturation of ~15 emu/g at room temperature [1]. Among several magnetic applications, the tunable properties of MPEA's can be applied as thermomagnetic materials in the recovery of low-grade waste heat. The low-grade waste heat is 70% of the energy lost as heat in the transformation industry. Nonetheless, this type of energy source is usually below 230°C, cannot be recovered by conventional methods and requires thermomagnetic materials with Curie temperature near room temperature [2]. In this study, the effects of the Ti content on the microstructural and magnetic properties of CuFeMnNiSnTi alloys were verified using scanning electron microscopy, energy-dispersive X-ray spectroscopy, X-ray diffraction, thermogravimetric analysis in the presence of a magnetic field, and magnetization measurements at room temperature. The as-cast CuFeMnNiSnTi0.8 alloy was composed of four phases: a Heusler-Ti(Fe, Ni)2Sn phase, a δ -(Cu, Mn)4Sn phase, Fe-fcc, and the Laves Fe2Ti compound. The highest saturation magnetization at room temperature, 44.4 emu/g, was achieved in the CuFeMnNiSn alloy with 74.0 wt.% of δ phase and 5.4 wt.% of an iron solid solution with a bcc structure. Besides that, the Curie temperature was reduced in lower Ti contents from 450 K to 350 K. The reduced phases and a lower Curie temperature are desired in thermomagnetic devices, and these results may be useful for the design of new thermomagnetic materials.

Hydrophobic materials and treatments for outdoor electrical insulation

Dr. Athanasios Milonitis, Switzerland

Oral Presentation (20')

Abstract

Outdoor electrical insulation materials are of fundamental importance for electrical distribution systems and related devices, such as instrument transformers, sensors, and embedded poles. On top of good electrical insulation, to withstand the outdoor environmental conditions, hydrophobic properties and UV protection contribute substantially to achieve good, long-time performance. Essentially, hydrophobicity is crucial for outdoor electrical insulation for several reasons:

Prevents water tracks: Hydrophobic surfaces resist the formation of water tracks, which can conduct electricity and increase leakage currents. Therefore, hydrophobicity helps in reducing the probability of flashovers and other deterioration effects.

Self-cleaning property: Outdoor insulators are often exposed to pollutants. Hydrophobic surfaces prevent contaminants from adhering, maintaining the insulator's electrical performance and reducing maintenance needs.

Improves longevity: Some self-healing hydrophobic materials can recover their hydrophobicity even after exposure to harsh conditions. This self-healing property extends the lifespan of the insulators by retaining self-cleaning properties and preventing water tracks.

These properties make hydrophobicity a key factor in ensuring the reliability and durability of outdoor electrical insulation devices. On top of their surface performance requirements, the material composition of outdoor insulation systems needs to comply with current and future regulations. Therefore, we are looking at sustainable material solutions with good hydrophobic properties, while at the same time, we investigate the possibilities of having a circular approach for the end-of-life products. Given the fact that these insulating materials are typically thermosetting polymers in their nature to survive the long-term exposure to outdoor conditions, their recyclability is an additional challenge.

In this work we are exploring 3 pathways to find alternative, more eco-friendly materials for serving the needs of outdoor electrical insulation. Specifically, we look at 1) bulk composition modification, 2) coatings, and 3) physical surface roughening towards the enhancement of hydrophobic performance. We discuss the advantages and disadvantages of these approaches, and we show a few examples. We also discuss methods for characterizing their performance which includes the evaluation of static and dynamic wetting properties, as well as more specific to the application tests, such as the measurement of leakage currents, tracking and erosion, etc. Based on such measurements we define what experimental outcomes are desired for a material to be considered as a good performing outdoor electrical insulator.

Finally, we also analyze potential recycling strategies of decommissioned products, that so far are typically sent for landfilling or being incinerated. We discuss how this could contribute towards a circular economy and responsible waste management.

Paper 201 1 **Functional coatings: from gas phase synthesis to applications**

Prof. Dr. Franz Faupel, Germany

Keynote (Oral Presentation 40')

Abstract

Functional coatings based on highly filled particulate metal-dielectric nanocomposite films exhibit unique properties with a wide range of applications. To explore collective interactions between the particles, we control particle separation at the nanometer scale using vapor phase deposition, a scalable approach that offers excellent control over the filling factor and other properties. For the deposition of functional polymer thin films, we employ initiated chemical vapor deposition (iCVD) to prevent the decomposition of functional groups. Examples include highly stable electrets for electret microphones and magnetoelectric sensors, 3D superhydrophobic coatings, nanoscale gradient copolymers, and strain-invariant conductors for soft robotics.

In fabricating nanocomposites, nanoparticles can form during gas phase co-deposition via self-organization or through high-rate gas aggregation cluster sources, which provide independent control of filling factor and size, as well as in situ monitoring and control of alloy nanoparticle composition. Recent examples of nanocomposites include plasmonic meta-materials, photoswitchable molecular plasmonic systems, memristors, memsensors, and self-organized nanogranular networks for neuromorphic electronics. Additionally, we have explored nanoscale synergistic effects of plasmonics and photocatalysis, such as photoinduced enhanced Raman spectroscopy (PIERS).

Paper 109 2 **Hydrophobic and Ice Adhesion Properties of Aluminium Samples with Surface Modification Mimicking Scallop Shell Structures**
Mr. Chenglin Li, Germany
Oral Presentation (20')

Abstract

With the rapid rise in heat pump installations in recent years, the issue of icing on aluminum samples used in air sourced heat pump systems has gained significant attention. Ice formation on the heat exchanger located on the outside of the building reduces the efficiency of heat transport; moreover, it results in increased energy consumption and maintenance costs. Thus, developing aluminum samples with anti-icing properties has become an important research direction. Inspired by the surface structure of scallop shells, we propose using laser technology to create scallop shell-like structures on aluminum sheet surfaces to optimize their hydrophobic properties, so that the ice on the sample surface can be easily separated or slide off more easily after melting.[1]

In this study, we first measured the surface characteristics of untreated aluminium samples, including ice adhesion, as well as static and dynamic contact angles. These initial results served as a baseline for comparison. Subsequently, we applied Direct Laser Interference Patterning (DLIP) to replicate the ridged structures of scallop shells on the aluminium surface and conducted the same tests on the laser-treated samples. The results demonstrated that the static contact angle of the aluminium samples significantly increased after laser treatment, indicating a notable enhancement in hydrophobicity. The ice adhesion force varied depending on the laser treatment method and showed a consistent decrease with repeated measurements.

To better understand the impact of laser treatment on surface morphology, detailed observations were performed using scanning electron microscopy (SEM). Furthermore, we applied a dip-coating process with a PDMS solution to fill the cavities within the DLIP-generated ridges. This approach not only reduced ice adhesion by minimizing the anchoring points between the ice and the DLIP-structured surface but also maintained high contact angle values. Our findings revealed that the laser-treated aluminium surfaces exhibit regular ridged structures that closely mimic the surface features of scallop shells.

This study verifies the effectiveness of bioinspired structures in enhancing the hydrophobic surfaces and demonstrates the great potential of laser technology in surface engineering. It expands the boundaries of biomimetic materials science and provide a basis for optimizing heat pump performance with potential for widespread industrial application.

Paper 1252 3 **Design of superhydrophobic transparent surfaces by laser and fluorine-based functionalization with anti-fogging and anti-icing responses**

Dr. Carmen Lopez-Santos, Spain

Oral Presentation (20')

Abstract

Glass surfaces used for outdoor applications are partially hydrophilic, making them particularly susceptible to ice-accretion, fog, and contaminants. These events hamper maintaining long-term transparency and an easy cleaning of architectural and cover elements, such as glazing, photovoltaic panels, outdoor optical systems and sensors. This makes the control of the wetting properties of structural glass a topic of the utmost importance and high interest for many industrial applications. However, surface modification procedures such as functional coatings and/or the microscale surface texturing for controlling the wetting behavior inevitably entails optical changes and possibly transmittance losses. Therefore, keeping a high transparency while providing a robust water repellence to transparent systems is a key challenge for the surface engineering community. The endeavour is even more demanding for situations and systems operating in harsh environments at low temperatures and high humidity conditions.

In this work, we present a new strategy to get a precise control over the hydrophobicity of transparent substrates, while preserving as much as possible their optical properties. The approach combines laser patterning with a mild chemical surface functionalization to achieve superhydrophobicity, anti-icing, and anti-fogging responses. A precise parametrization of the femtosecond UV laser treatments on borosilicate glass, whereby pattern geometry, scanning cycles, and motif dimensions, have been systematically changed, lead to a controlled variation of surface morphology, as characterized by the resulting percentage of the laser-treated area and surface roughness. The developed microstructure proved suitable for hosting fluorinated molecules devoted to the enhancement of the hydrophobicity while preserving the optical transmittance. Moreover, superhydrophobic laser-patterned transparent glass has been shown to have an anti-fouling behaviour upon interaction with biological simulating agents. Water condensation experiments carried out by environmental scanning electron microscopy have confirmed a remarkable anti-fogging performance of the laser-treated glass surface, whereas freezing delay time measurements, as well as ice adhesion tests in a pull-off configuration, have demonstrated the extraordinary anti-icing capacity of the laser patterned transparent substrates and their stable behaviour even after 5 freezing/thawing cycles.

Paper	2072	5	From passive to active structurally controlled optical coatings for energy and eyewear applications Prof. Ludvik Martinu, Canada Oral Presentation (20')
Abstract			Control of energetic interactions at the surface of the growing thin films allows one to selectively adjust their micro- and nanostructure. This is particularly important when synthesizing optical films by vapor-based techniques such as reactive sputtering (including HiPIMS), evaporation (including Glancing Angle Deposition), Plasma-Enhanced Chemical Vapor Deposition, Atomic Layer Deposition and Gas Agglomeration Cluster formation. As a result, this has become increasingly attractive for judicious fabrication of nanostructured optical filters with controlled film porosity, crystallinity, anisotropy, plasmonic effects and other features of both passive as well as active (dynamic – e.g., electrochromic or thermochromic) coating materials with new functionalities. This presentation will illustrate the progress and new opportunities in structurally controlled optical coating systems such as high-performance low-emissivity and smart windows for energy saving in the building sector, energy control in satellites, ophthalmic lenses and enhanced vision, and other optical coating devices.

Paper 795 **6** **Biocompatible multilayer system for the degradation control of an additively manufactured WE43 alloy**
Mrs. Esther Lopez, Spain
Oral Presentation (20')

Abstract

Mg alloy WE43 is one of most relevant alloys for bioimplants due to its good mechanical properties and biocompatibility. Additive manufacturing (AM) techniques such as powder bed fusion (PBF) have paved the way for fabrication of orthopaedic implants with complex internal and external geometries with excellent mechanical properties, unachievable by other means. However, the main problem that prevents the wider use of Mg-based implants is the control of their degradation rate. Plasma electrolytic oxidation (PEO) is based on the growth of an oxide layer by means of high voltages (300V – 600V) and eco-friendly electrolytes that can improve the corrosion resistance and enhance the bioactivity of the structure. The combination of PEO with other coatings in a hybrid system can be employed to control the degradation rate of biomedical devices. This study focuses on the development of a multilayer system on an AM WE43 scaffold comprising a PEO layer in combination with hydroxyapatite (HAp) and polycaprolactone (PCL). The role of HAp is to promote bone growth and PCL is used as a carrier of a fluoroquinolone that exhibit antibiotic and corrosion inhibition properties. The scaffolds were characterized by optical and scanning electron microscopy (SEM), X-ray diffraction (XRD), energy dispersive X-ray spectroscopy (EDS) and transmission electron microscopy (TEM). The drug-loaded coating was characterized by SEM, EDS, XRD and their roughness was measured using optical profilometer. Electrical impedance spectroscopy (EIS) measurements on drug-loaded coated scaffold in Hank's solution at 37°C were performed up to 3 days. The fluoroquinolone release into Hank's solution was measured by means of ultraviolet-visible spectroscopy (UV-VIS) and correlated with corrosion resistance of the coated system. The corrosion of a bare alloy in the presence of fluoroquinolone was also studied. The results revealed that both PEO and HAp layers were able to uniformly cover the struts of the scaffold even within the recesses of difficult access. The role of the coating in corrosion modulating effect of quinolone on AM WE43 Mg alloy scaffold is highlighted.

Paper 1374 1 A Materials Science Approach to the Analysis of Ion Diffusion Effects in Barley Seed Surfaces Treated with an Air Plasma Discharge

Dr. Carmen Lopez-Santos, Spain

Oral Presentation (20')

Abstract

Plasma in agriculture is a current application area of surface engineering which is generating much interest from both fundamental and applied perspectives and because of its high impact on seeding efficiency and environmental sustainability. Plasma treatment of seeds contributes to enhance the germination rate, promoting early plant deployment, and providing protection against pathogen detrimental actions. Current studies often link these positive effects to biochemical alterations affecting seed metabolism and genetic factors controlling seeds germination and young plants growth. In this study, we focus on the analysis of the redistribution of ions in the interior of barley seed surface layers when they are subjected to a cold air plasma treatment. For this purpose, we apply a Materials Science approach involving the use of scanning electron microscopy combined with Energy Dispersive X-ray spectroscopy and depth profiling analysis using X-ray photoemission coupled with gas cluster sputtering. Moreover, we have developed a Monte Carlo model accounting for the positive ion migration in the interior of seeds upon their exposure to a plasma. These tools are compatible for the description of similar ion migration effects taking place during the processing and use of a large variety of materials (e.g., membranes, ionic solids, etc.). Additionally, we explore the impact of plasma exposure on the lixiviation of ions through the seeds' hull when they are immersed in water. The findings reveal that the superficial layers of the seed hull (up to approximately ~100 nm in depth) exhibit a notable enrichment of K⁺ and Ca²⁺ ions, accompanied by alterations in the O/C and N/C atomic ratios. These observations were further corroborated by electron microscopy and fluorescence analysis of seed cross-sections. Meanwhile, the Monte Carlo model, which simulates the electrostatic interactions between the negative charge accumulated at the seed surface due to plasma exposure and the positive ions present within the seed interior has provided some clues to understand the migration mechanism in this system. It has been also demonstrated that plasma-treated seeds exhibit more efficient ion lixiviation when immersed in water compared to untreated seeds. Notably, a significant concentration of NO₃⁻ anions was detected in the leachate, which is attributed to secondary reactions between nitrogen species incorporated into the seeds during the air plasma treatment and reactive oxygen species generated at the seed surface. These findings are discussed in the context of their potential use to improve seed germination capacity and a more robust plant growth.

Paper 794 2 Kinetics and Mechanisms of Stripping HVOF Coatings (Inconel 625 and Inconel 625 + 40% CrC) Using Drylyte® Technology
Ph.D. Raúl Adad Ruesca, Spain
Oral Presentation (20')

Abstract

The stripping process and kinetics of two high-velocity oxy-fuel (HVOF) coatings—Inconel 625 and Inconel 625 + 40% CrC—were studied on carbon steel and AISI 316 stainless steel substrates using Drylyte® Technology. The removal rate, surface morphology evolution, and electrochemical behavior during the stripping process were analyzed. The Drylyte electrolyte-based process demonstrated effective material removal, with significant differences observed between the two coatings. Inconel 625 exhibited a higher removal rate than the composite Inconel 625 + 40% CrC due to the presence of chromium carbide, which increased coating hardness and reduced dissolution kinetics. For both coatings, the stripping rate was higher on carbon steel compared to stainless steel, attributed to the different electrochemical behavior of the substrates. Kinetic analysis revealed that the stripping rate followed a mixed mechanism involving electrochemical dissolution and mechanical particle detachment. The activation energy for material removal was estimated to be higher for the Inconel 625 + 40% CrC coating, confirming its greater resistance to stripping. Surface characterization after stripping showed minimal substrate damage, confirming the selectivity of the Drylyte process. In conclusion, the Drylyte® Technology presents an efficient and controlled method for stripping HVOF coatings, with stripping kinetics strongly influenced by coating composition and substrate type. The findings provide valuable insights for optimizing the removal of thermally sprayed coatings in industrial applications.

Optimizing the heat treatments for electroless Ni-P nanocomposite coatings: the impact on mechanical properties and tribological behavior

Dr. Giulia Pedrizzetti, Italy

Highlight (Oral Presentation 20')

Abstract

Electroless Ni-P coatings with high phosphorus content (≈ 11 wt.%) are widely used in the energy production industry to protect steel components from extreme environmental attack. However, the deposition process can lead to hydrogen entrapment within the coating, causing significant embrittlement and reducing mechanical resistance. Improvement of properties and durability of coatings can be achieved by two approaches: (i) incorporating functional second-phase particles and (ii) applying heat treatments for dehydrogenation and crystallization. This study investigates the manufacturing and characterization of Ni-P nanocomposites reinforced with Al_2O_3 and ZrO_2 nanoparticles and subjected to various heat treatment schedules, focusing on how dehydrogenation affects coating microstructure and protective properties. Coatings were reinforced with varying concentrations of nanoparticles and underwent dehydrogenation at 200°C for 2 hours and annealing at 400°C for 1 hour, applied individually or in sequence to assess their effects on coating performances. Microstructural changes were analyzed by SEM and XRD. Hardness, elastic modulus and fracture toughness were evaluated through instrumented indentation tests, wear resistance and mechanisms were investigated by ball-on-disc tests with an Al_2O_3 counterpart. Microstructural analysis revealed that the amorphous structure of the coatings remained unaltered with nanoparticle inclusion, although ZrO_2 provided better dispersion than Al_2O_3 and, accordingly, higher microhardness. Dehydrogenation improved coating hardness by facilitating initial grain growth, while annealing at 400°C induced the formation of nanometric Ni_3P precipitates, resulting in +120% hardness compared to unreinforced Ni-P coatings. Nanocomposite coatings exhibited higher fracture toughness compared to unreinforced Ni-P due to the crack deflection mechanisms. No detectable differences in hardness and microstructure were detected after heat treatment at 400°C for 1h with or without prior dehydrogenation and, as expected, fracture toughness dramatically decreases; however, the dehydrogenated coatings exhibited higher KI and lower Young's modulus. ZrO_2 -reinforced coatings exhibited enhanced wear resistance, with wear tests highlighting the critical role of dehydrogenation in reducing both the coefficient of friction ($\sim 14\%$) and the wear rate ($\sim 97\%$) when performed prior to annealing at 400°C for 1 hour. Wear track analysis revealed that non-dehydrogenated samples primarily failed by complete coating delamination, with abrasion identified as the dominant wear mechanism. In contrast, dehydrogenated samples displayed significantly improved durability, attributed to the formation of a protective oxide layer, which effectively enhanced the overall wear resistance of the coatings. The present findings underscore the synergistic benefits of nanoparticle reinforcement and tailored thermal treatments, highlighting the critical role of dehydrogenation and offering practical solutions for improving the durability in demanding engineering applications.

Paper 2002 4 **MECHANICAL AND WEAR PERFORMANCE OF HYBRID POWDER COATINGS: THE ROLE OF CURING CONDITIONS**
Mrs. Nataly Elizabeth Calderón Perea, Spain
Oral Presentation (20')

Abstract Keywords: Powder coatings, curing conditions, epoxy-polyester, mechanical properties, wear resistance.

Powder organic coatings have gained significant attention as a sustainable alternative to conventional liquid coatings due to their solvent-free formulation, which eliminates volatile organic compound (VOC) emissions [1]. In addition to their environmental benefits, these coatings exhibit high efficiency, durability, and excellent corrosion resistance. Most of them are composed of thermosetting resins (epoxy, polyester, hybrid, polyurethane, or acrylic), curing agents, pigments and performance-enhancing additives, which collectively determine their mechanical and chemical properties [2]. The curing process is one of the most important factors in achieving a high-performance painted system, as it directly influences the adhesion, hardness, and flexibility of powder coatings, wear resistance and environmental degradation [2]. Improper curing, whether under-curing or over-curing, can lead to inadequate mechanical integrity and reduced protective capabilities. To date, some studies have investigated the curing behavior of nanoparticle-functionalized epoxy or polyester [3] powder coatings; however, no studies on epoxy-polyester hybrid coatings have been reported in the literature. Therefore, this study aims to systematically evaluate the influence of temperature and curing time on the properties of a hybrid epoxy-polyester organic powder coating applied to carbon steel substrates.

The curing process was carried out at 4 different temperature-time combinations: 160 °C for 18 min, 170 °C for 10 min, 180 °C for 10 min, and 180 °C for 15 min. The effect of these curing conditions was analyzed focusing on polymer crosslinking (measuring the glass transition temperature, T_g), aesthetic properties (gloss), roughness, hardness and wear resistance.

The main results indicate that lower curing temperatures with longer curing times lead to a decrease in T_g and hardness, as well as reduced wear resistance, suggesting incomplete crosslinking. On the other hand, high-temperature curing results in a higher T_g, hardness and wear resistance. Regarding the aesthetic properties, high temperature enhances the gloss. Based on the results, the optimal curing range for the studied coating was determined to be 180 °C for 10–15 min, achieving a balance between mechanical performance and wear resistance, due to optimized crosslinking. These results contribute to the optimization of curing processes in powder coatings to enhance their durability and protective capabilities in different applications.

Paper 1709 6 **Electrodeposition of nickel-matrix nano-composite coatings for tribological applications from REACH compliant electrolytes**
Mr. Filippo Zoia, Italy
Oral Presentation (20')

Abstract

For years, chromium trioxide CrO_3 has been used for hard chromium plating, guaranteeing wear resistance due to its outstanding tribological properties. However, the use of highly concentrated CrO_3 solutions and the formation of hexavalent chromium species is hazardous for human health. In fact, chromium trioxide is classified as carcinogenic (category 1A) and mutagenic (category 1B). Since 2013, it has been listed as a Substance of Very High Concern (SVHC) in Annex XIV of the REACH authorization list by European Chemicals Agency (ECHA) [1].

The most recent achievements in new tribo-coatings suggest that nickel-based layers constitute a viable alternative to hard chromium plating, both in the form of alloys (NiP, NiW) and nickel-matrix nano-composites. Regarding the latter, two types of particles can be embedded within the nickel matrix: hard ceramic particles (B_4C , Al_2O_3) and solid lubricant particles (graphene, MoS_2), which confer high hardness and low friction coefficient, respectively [2].

Nickel plating, nevertheless, introduces safety issues that must be addressed. Boric acid (H_3BO_3), routinely added to the plating solution as a pH buffer, must be replaced since it has been nominated as a SVHC candidate. According to the harmonised classification and labelling (ATP20) approved by the European Union, boric acid may damage fertility and the unborn child [1] and can be potentially substituted with different organic compounds, such as citric, succinic or malonic acid.

The need to operate in a more sustainable and human-centred way, following Safe and Sustainable by Design (SSbD) principles, brings to the development of REACH compliant formulations for the electrodeposition of functional coatings based on nickel. In this context, the MOZART project, founded by the European Union, has the ambitious purpose of assisting the fulfilment of REACH requirements to deposit nickel-matrix nanocomposite coatings for wear reduction or self-lubrication [3].

In the framework of the MOZART project, the present research aims at developing a nickel nano-composite coating deposited from an innovative boric acid-free REACH compliant solution. Hard nanoparticles are dispersed in such electrolyte in order to improve the wear resistance of the electrodeposited material. The morphological and tribological properties of the resulting composite coatings are characterized and compared to those of typical hard chromium layers.

Paper 2135 1 **Dual pH-responsive and shrinkable Mesoporous Silica Nanoparticles for Pancreatic Ductal Adenocarcinoma**
Dr. David Sánchez-García, Spain
Keynote (Oral Presentation 40')

Abstract

Pancreatic ductal adenocarcinoma (PDAC) is the most prevalent form of pancreatic cancer (PanCa), accounting for 95% of cases and ranking as the third deadliest cancer in 2023.¹ Despite advances in oncology, PDAC remains highly lethal due to its dense desmoplastic stroma and complex tumour microenvironment (TME), which hinder the penetration and efficacy of conventional drugs and nanocarriers. Numerous drug delivery systems (DDS) have been explored as potential strategies to improve PDAC therapeutic efficacy.² However, significant challenges remain, particularly, the internalization of the DDSs into the tumor and the rapid immune clearance of the nanocarriers from the bloodstream, which drastically reduces their accumulation at the tumor site, resulting in less than 5% reaching the target cells.³

To improve the efficiency of the present treatments, our group have developed a dual pH -sensitive, shrinkable DDS based on mesoporous silica nanoparticles (MSNs) for combination chemotherapy against PDAC cells. To do so, MSNs are loaded with a gemcitabine-camptothecin conjugate and coated with a poly(β amino ester) polymer via a novel dual-sensitive linker. The incorporation of an electrostatic albumin corona further improves the stability of the system at physiological conditions, while endowing the system with an active targeting to the TME. This design allows for controlled stepwise disassembly under acidic conditions corresponding to the ECM and lysosomal environments and presents significantly reduced uptake in macrophage cultures. The high initial hydrodynamic size of the carrier would permit the retention within the TME via the EPR effect, strengthened by the albumin-mediated targeting. Upon exposure to the mildly acidic ECM, partial degradation of the coating enables size reduction, facilitating tumour penetration to PanCa cells. Furthermore, the biological activity of the nanoparticles was evaluated in advanced 3D culture models, designed to closely mimic the TME of PDAC.

Paper 1363 2

Mesoporous silica nanoparticles carrying an iron chelator for the treatment of iron overload diseases. Proof of concept.

Ph.D. María-José Morán-jiménez, Spain

Highlight (Oral Presentation 20')

Abstract

Iron is a trace element essential for cellular metabolism, but it is toxic when present in excess. Hereditary hemochromatosis is a primary iron overload disease. Other disorders have a secondary iron overload due to frequent blood transfusions. The common form of iron removal therapy is periodic bleeding, but this is not feasible for β -thalassemia, and the alternative is the use of iron chelating agents, such as deferoxamine (DFO), deferiprone and deferasirox. These treatments are effective but suboptimal, either in their effectiveness in depleting iron from the liver, or in their safety due to side effects. During the last decades, notable achievements have been obtained in the field of nanotechnology for biomedical applications.

Aiming to create a safer and more effective way to administer iron chelators, we have designed mesoporous silica nanoparticles (MSNP ~200 nm in diameter) to which DFO has been covalently linked (MSNP-DFO). We have performed in vitro studies in human hepatocellular carcinoma HepG2 cells with MSNP-DFO, and in vivo studies are being performed in a murine model of hemochromatosis.

In vitro studies show that cultured HepG2 uptake MSNP, without loss of cell viability at any of the concentrations tested (50-500 μ g/ml) at 24-72 hours of treatment.

Nevertheless, when incubated with MSNP-DFO there is a decrease in HepG2 viability, especially at higher concentrations and longer treatments, similar to what is observed with DFO at equivalent concentrations (10-100 μ M), indicating that the chelating capacity of MSNP-DFO is similar to that of DFO. Certainly, 72-hour treatments with MSNP-DFO or DFO decrease cell viability, but when treatments are removed after 24 hours and cells are kept in fresh medium for an additional 48 hours, DFO-treated cells do not lose as much viability as MSNP-DFO-treated cells, suggesting that MSNP-DFO retains its chelating capacity for longer. Furthermore, HepG2 cells have been iron overloaded with 100 μ M ferric ammonium citrate for 18 hours, and then treated with MSNP-DFO (200 and 400 μ g/ml) or equivalent doses of DFO (40 and 80 μ M) for 24 and 72 hours. Measuring intracellular iron levels show that DFO loses its chelating capacity over time, while MSNP-DFO retains its chelating capacity for at least 72 h.

The results obtained so far suggest that these MSNP-DFO could constitute a valuable strategy to improve the efficiency of the chelator, and that they could be considered as a future treatment of iron overload disorders.

Paper 1482 3 **Mucolytic and antibiotic combination therapy through silica-based nanocarriers to eradicate *Escherichia coli* biofilms**
Dr. Montserrat Colilla, Spain
Oral Presentation (20')

Abstract

Escherichia coli (*E. coli*) is one of the species most frequently involved in biofilm-associated infections. Biofilms hinder the penetration of conventional antibiotics, making them highly resistant to these drugs and rendering their treatment and eradication of biofilms extremely difficult.

Herein, we designed a novel, easy-to-synthesize and versatile biocompatible nanosystem to eradicate mature *E. coli* biofilms by using a unique nanoplatform based on mesoporous silica nanocarriers to co-deliver a mucolytic agent, N-acetylcysteine (AC), and an antibiotic, levofloxacin (LVX), as combination therapy. We demonstrate that, through a relatively simple synthetic approach, enhanced antibacterial efficacy is achieved by improving the penetration of the antibiotic LVX into the biofilm through the mucopolysaccharide matrix disruptive action of the mucolytic AC. The strengths of this basic research are based on the precise design and exhaustive characterization of the developed nanomaterials, together with the in-depth evaluation of the in vitro disrupting effect on mature *E. coli* biofilms. The great versatility of MSNs allows loading the different antimicrobial agents into well-defined compartments of these nanocarriers. For this purpose, LVX was loaded into the mesopores of MSNs and then coated with a gelatin layer containing AC alone or a mixture of AC and LVX. In this way, the antibiotic levofloxacin was loaded into the mesoporous silica structure, while N-acetylcysteine, as a mucolytic agent, was embedded in the outer gelatin layer. The sequential co-delivery of antimicrobial agents from the compartmented nanocarrier allows the release of N-acetylcysteine at the earliest stage, followed by the sustained release of levofloxacin. The aim was to achieve a sequential delivery of the different antimicrobial agents placed in the different compartments. A thorough characterization of the developed nanosystems was carried out and the kinetics of molecular release from the different compartments were determined.

Moreover, the antimicrobial effect of these nanosystems against mature *E. coli* biofilms was valuated in vitro by confocal laser scanning microscopy and biofilm viability assays. The release behavior produces an enhanced antimicrobial effect, allowing for approximately 99.8% reduction of mature *E. coli* biofilm. Furthermore, preliminary biocompatibility studies were performed with preosteoblastic cells showing good biocompatibility and no changes in the different phases of the cell cycle after treatment with the nanosystem.

Modification of microemulsion-assisted sol–gel method to control the composition of multi-ion-doped mesoporous bioactive glass particles

Prof. Rada Petrovic, Serbia

Oral Presentation (20')

Abstract

The microemulsion-assisted sol–gel method, combined with a cationic surfactant, is widely used to synthesize spherical mesoporous bioactive SiO₂–CaO glass particles (MBGs), which have various biomedical applications owing to their biocompatibility, bioactivity and mesoporous structure with surface properties suitable for drug loading. The biological properties of MBGs can be tailored by optimizing the calcium content, as calcium plays a critical role in MBGs bioactivity and pro-osteogenic properties. Additionally, incorporating an optimal quantity of so-called therapeutic ions promotes specific biological responses upon release, such as: osteogenic (Mg²⁺ and Sr²⁺), angiogenic (Cu²⁺ and Mg²⁺) and antimicrobial (Cu²⁺ and Zn²⁺) effects. Previous investigations have shown that the incorporation of high amounts (>20 mol%) of calcium, as well as strontium, into highly dispersed MBGs is challenging, resulting in a significant discrepancy between the nominal and actual composition. The problem stems from the synthesis process itself, as insufficient amounts of the ions are adsorbed on the surface of the silica particles, which initially form within oil droplets in water. The aim of this study was to optimize or modify microemulsion-assisted sol–gel synthesis to better control the content of Ca, Mg, Sr, Cu and Zn in multi-ion-doped spherical MBGs. The main parameter varied was the pH value, specifically the ammonia content, which influences hydrolysis and condensation rates of tetraethyl orthosilicate (the silica precursor), as well as ions adsorption. The synthesis modification involved impregnating pure silica particles with ions after synthesis rather than relying on adsorption during the synthesis. The morphology and chemical composition of MBGs were analyzed by FESEM and EDS analysis, while an MTT assay was performed on mouse bone marrow-derived stem cells (mBMSCs) to assess in vitro biocompatibility. The specific surface area was determined by BET method. The results indicate that pH variations slightly influence MBGs size and composition. Furthermore, ions whose hydroxides are poorly soluble (Cu, Zn, Mg) were found to bind much better to silica than ions whose hydroxides are more soluble (Ca, Sr). The synthesis modification demonstrated a much greater potential for controlling the composition of MBGs compared to pH adjustments.

Paper 1443 5 **Design, synthesis and optimization of ion-doped mesoporous bioactive glass nanoparticles with large pore size: A promising platform in bone tissue regeneration**

Dr. Sandra Sanchez-Salcedo, Spain

Oral Presentation (20')

Abstract

Nanotechnology is in full swing in the field of medicine. Researchers are developing nanoparticles both for the diagnosis of diseases through biosensor devices and for the treatment of pathologies through the controlled release of therapeutic ions and biomolecules.

Here, we show a facile synthetic approach based in the sol–gel method in the presence of structure directing agents to fabricate monodisperse mesoporous bioactive glass nanoparticles with large radial pores (LP-RMBGs) adapting the recipe of Liang et al. 2015. Nanospheres were synthesized using cetyltrimethylammonium bromide (CTAB), as a template agent, and trimethylamine (TEA) as a hydrolysis catalyst. The reagents tetraethylorthosilicate (TEOS), triethyl phosphate (TEP), calcium nitrate tetrahydrate ($\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$) and $\text{Zn}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ were used as the silicon, phosphorus, calcium and zinc sources, respectively. These reagents were sequentially added under magnetic stirring to an aqueous solution of CTAB and TEA at 30 min intervals, and allowed to react overnight. LP-RMBGs Nominal compositions of $79.5\text{-SiO}_2\text{-}18\text{CaO-}2.5\text{P}_2\text{O}_5$, $79.5\text{-SiO}_2\text{-}18\text{CaO-}2.5\text{ZnO}$ and $79.5\text{-SiO}_2\text{-}15.6\text{CaO-}2.5\text{P}_2\text{O}_5$. The resulting nanoparticles suspension were centrifuged and washed twice with absolute ethanol and twice with milli-Q water at 11,000 rpm for 12 minutes. Then, the solid was collected and allowed to dry at 60°C in the oven for 24 h. Finally, the organic matter was extracted by calcination at 600°C for 4 hours with a ramp up of 1°C/min and a ramp down of 10°C/min.

The study of different concentrations of CTAB, TEA, temperature and stirring, the homogeneous size of the LP-RMBGs as well as the expansion of their pore size have been controlled. The effects of the presence of ZnO and P_2O_5 precursors on the porosity, surface area and size of the nanoparticles were also investigated. Among the different kinds of nanoparticles, large pore radial mesoporous bioactive glasses have become the subject matter due to their excellent textural and morphological features, as well as their ability to include therapeutic ions into their composition.

With these nanospheres combined therapies for bone tissue regeneration are envisioned. These nanosystems would allow for releasing therapeutic ions and co-deliver nucleic acids and other bio macromolecules hosted in the large pores. These nanoparticles can be administrated by intraosseous injection or incorporated into 3D-scaffolds to promote osteogenesis and osteogenesis in the management of bone pathologies.

Paper 1414 1 **In situ TEM tensile testing of small-scale model systems to study the effect of ordering and interfaces**

Dr. Peter Schweizer, Germany

Highlight (Oral Presentation 20')

Abstract

Size effects decisively influence the properties of materials at small length scales. In the context of mechanical properties, the trend of 'smaller is stronger' has been well established. However, to this day it remains challenging to find suitable testing geometries and setups to test mechanical properties on small scales while avoiding pitfalls such as preparation or testing artefacts. Therefore, certain aspects of small-scale mechanics have barely been explored. Here we use in situ TEM tensile testing to study the effect of interfaces and atomic-scale ordering on mechanical properties. We use a flexible copper nanowire platform as a small-scale model system which allows us to test different aspects of materials on the nanoscale. The nanowires are alloyed with gold and the ordering is tuned using different heat treatments. Tensile testing of wires with different degrees of ordering (as inferred from 4D-STEM) reveals a transition from twin to slip-based plasticity and a change in yield strength. Besides studying ordering we test ALD based Aluminum oxide films coated onto our nanowire platform. This gives us the possibility to test the mechanical properties of ultrathin coatings and understand the role interfaces play in the deformation process.

Paper 1912 2 **Effect of temperature, strain rate and grain size on the strain partitioning in the Alloy 718 up to 650 °C: A HR-DIC investigation**

Mr. Damien Texier, France

Highlight (Oral Presentation 20')

Abstract

The Ni-based superalloy Alloy 718 (Inconel 718) is an excellent alloy candidate for structural components operating at intermediate temperatures. In the past decades, its mechanical behavior and damage behavior has been intensively investigated at high temperature to establish a relationship between its strain-rate sensitivity and its oxidation-assisted intergranular cracking (OAIC). The present study focuses on the effect of the temperature, the strain rate and the grain size effects on strain localization partitioning at grain boundaries (GBs), twin boundaries (TBs) and intergranular from room temperature up to 650 °C, in the Portevin-Le-Chatelier (PLC) and non-PLC domains. HR-DIC analysis and out-of-plane measurements were performed to quantify plasticity distribution and preferential cracking site at the microstructure scale depending on the strain rate. Changes in strain localization with the grain size and strain rate demonstrated the concomitant action of strain localization and environmental degradation on the OAIC.

Elastic Microstructures in Bulk Metallic Glasses — Are They Real?

Mr. Reza Rashidi, Germany

Oral Presentation (20')

Abstract

Abstract

Amorphous metallic alloys, known as metallic glasses (MGs), are distinct from conventional crystalline alloys due to their unique disordered structure. Unlike crystalline alloys with an ordered, periodic atomic arrangement, MGs appear homogeneous and monolithic when studied at meso- and macroscopic length scales. Compatible with atomistic simulations and not unsurprisingly, they exhibit structural heterogeneity at the lower nanometer scale, as observed experimentally with AFM techniques. However, elastic property mapping by nanoindentation revealed elastic fluctuations at length scales about an order of magnitude larger (~ 100 nm) - their origin is still under debate.

Our previous work identified an elastic correlation length of around 150-200 nm in a Zr-based alloy (Materials & Design 229 (2023) 111929). It ruled out chemical fluctuations as the underlying origin, suggesting that cooling constraints during solidification may be a contributing factor. This hypothesis can be seen as the local microstructural manifestation of cooling-induced internal residual stresses known to exist in MG rods and revealed by focused ion beam-digital image correlation ring-core milling (Materials & Design 104 (2016) 235-241).

Here, we further investigate this idea by examining various casting geometries and thermal histories, tracking how elastic decorrelation lengths change with sample size and position within the MG samples. We find that thermal annealing reduces decorrelation length-scale gradients and reduces the position-dependence of the elastic fluctuations (Scripta Materialia 255 (2025) 116380). As a new step in our nano-elastic property assessment, we leverage spatially-resolved scanning nanobeam diffraction to narrow down the possible structural origin of these elastic signatures.

In-situ SEM micro-shear experiments to evaluate the failure modes of metallization interfaces in electronics

Dr. Andre Clausner, Germany

Oral Presentation (20')

Abstract

In the rapidly evolving field of microelectronics, the reliability of metallization stack interfaces is critical for the performance and longevity of devices. This study focuses on the measurement of shear strength of an interface between a copper (Cu) metallization and a thin (<50nm) dielectric cap, meant to prevent metal oxidation. Depositing a thicker, service dielectric (Silicon nitride, SiN, 500nm) and milling prismatic test structures with an in-plane footprint visible at an optical microscope (10x10µm) enabled relocation and successful shear interface tests using a bi-directional nanoindentation device, which served as a preliminary step to rank the strength of two cap recipes under comparison. While testing on standalone nanoindentation platforms is convenient in terms of throughput and has the potential to be partially automated, the assessment of failure modes relies on ex-situ observation methods, lacking deep insights into the origins of different kind of failures. But these insights are necessary to understand the root-cause of the failures and, potentially increase the system robustness as well as formulate life-time models, which is essential for designing more reliable microelectronic devices. Therefore, this research aims to deepen our understanding of these interface fracture phenomena through in-situ micro-shear experiments conducted within a Scanning Electron Microscope (SEM), allowing for a quantitative real-time observation of the shear behavior and interface failures.

Utilizing nanoindentation techniques within the SEM, we examined the cross-section of the Cu/cap interface upon shear, enabling the observation of failure modes as they occur under applied stress.

We distinguished between ductile and brittle failure modes, providing a comprehensive analysis of the conditions that led to each type of failure. Through meticulous observation and analysis, we aim to establish a clearer correspondence between the observed failure behavior and the signatures of failure in the load/displacement signal, being the latter the only link between insightful in-situ experiments and higher throughput standalone shear experiments.

To further enhance our understanding, a thorough root cause analysis of both ductile and brittle failure modes was conducted. By identifying the underlying causes of these failures, we hope to provide valuable insights that can improve material selection and interface engineering in microelectronics.

In conclusion, by combining standalone nanomechanical testing with validation by in-situ SEM experimentation, this research contributes to the ongoing efforts to improve the reliability of metallization interfaces in microelectronics. The findings from this study will enhance our understanding of interface behavior and pave the way for more robust microelectronic devices.

In-Situ TKD Tensile Testing Reveals Complex Nanoscale Deformation Twinning in Rhenium

Mr. Philipp Kroeker, Switzerland

Oral Presentation (20')

Abstract

Deformation twinning (DT) plays a central role in the plastic deformation of hexagonal close-packed (HCP) metals, due to their insufficient amount of slip systems. DT can enable plasticity along the c-axis when pyramidal slip is not possible. However, DT has also been associated with reduced ductility, high residual stresses, and the promotion of fracture. As a result, DT complicates the broader adoption of HCP metals in industry. While DT has been extensively studied, fundamental questions persist regarding twin nucleation, growth mechanisms, and the interaction of twins with surrounding microstructural features, such as grain boundaries and other twins.

This study employs a novel in-situ transmission Kikuchi diffraction (TKD) methodology developed in-house at EMPA Thun, which is capable of sub-10 nm resolution orientation mapping during micro tensile testing [1]. Applied to single-crystal Rhenium under c-axis tension, we reveal previously unobserved mechanisms relating to the commonly observed $\{112\}\{112\bar{6}\}$ extension twin (ET), specifically the formation of secondary ETs within primary ETs. Together with interactions between intersecting primary twin variants, the secondary ETs lead to the formation of an apparent nanogained microstructure. Based on the insights gained into the fundamental deformation mechanisms of Rhenium, implications for its accommodation of plastic strain are discussed. This includes the effect of secondary ETs on twin thickening mechanisms and fracture behavior, particularly considering the expected intense shear localization at the interfaces of matrix and secondary ET.

Paper 1087 6 **Mechanistic Insights into Strengthening via Precipitate Assemblies Using In Situ Micropillar Compression of Ni-Cr-Al-Nb Alloys**
Dr. Ujjval Bansal, Germany
Oral Presentation (20')

Abstract

Ni-base superalloys, such as Inconel 718 or 625, achieve precipitate hardening primarily through the metastable, ordered γ' phase, unlike most superalloys that rely on $L1_2$ -ordered γ'' phase [1]. The addition of Nb with traces of Ti, promotes γ'' formation (stable variant: δ -phase), which can precipitate on pre-existing γ' phase within the γ -matrix, creating γ - γ' - γ'' composite precipitate assemblies [2]. Such microstructures are proven effective in enhancing strength, for instance, a Ni-Cr-Al-Nb alloy shows a strength increment of ~15% compared to Rene88 at 700 °C [3-4]. However, the underlying strengthening mechanisms and the quantitative role of composite precipitate assembly to the overall strength remain unexplored. In this study, we aim to enhance the mechanistic understanding of induced strengthening due to composite precipitate assemblies by examining the dislocation interactions with such assemblies. To achieve this, variations in the γ - γ' - γ'' microstructure are induced by heat-treating Ni-16Cr-4Al-6Nb(at%) alloy. Micropillars of diameter 1 μ m were fabricated using FIB and yield strength at room temperature was measured through in situ SEM micropillar compression test using diamond flat punch under displacement control mode at a strain rate of $1/10^3$. The measured yield strength (2% offset) after 700 °C for 1000 h was approximately 1146 ± 41 MPa, consistent with literature [4]. At 800°C for 100 hours, there was a 1.4-fold improvement, while a short-duration annealing at 700°C for 100 hours followed by 800°C for 100 hours resulted in a strength enhancement of 1.5-fold. The critical resolved shear stress (CRSS) was then calculated from the yield strength by considering the highest Schmid factor. A cumulative distribution function (CDF) of CRSS from different heat treated samples was analyzed to elucidate the impact of microstructure post heat treatment. The 3D-APT analysis of γ' - γ'' -precipitates in Ni-Cr-Al-Nb alloy post heat treatment revealed the presence of δ -phase in addition to γ - γ' - γ'' microstructure after heat treatment at 800°C for 100 hours. Given that the pillars were fabricated within the similar grain orientation, two potential strengthening mechanisms are postulated: solid-solution strengthening and precipitate strengthening. TEM investigations of deformed pillars were conducted in aberration-corrected TEM to comprehend the deformation behavior. This talk will show and discuss the factors contributing to the strength in Ni-Cr-Al-Nb alloys post heat-treatment.

Paper 1352 7

The impact of grain boundary states on mechanical failure in nanocrystalline materials

Dr. Markus Alfreider, Austria

Oral Presentation (20')

Abstract

Nanocrystalline materials exhibit increased strength due to the structural constraint on dislocation mobility. However, severely inhibiting dislocation mobility can lead to high local stress concentrations and subsequently localized early failure, i.e. low toughness and ductility. In the case of nanocrystalline systems processed by severe plastic deformation the grains get fragmented by formation of new boundaries through dislocation entanglements, leading to high contents of extrinsic grain boundary dislocations as opposed to conventional materials. These materials even exhibit a counterintuitive 'hardening-by-annealing' phenomenon, opposed to the 'softening-by-annealing' through recovery processes in coarse grained materials. This change in behavior originates from the fact that, at such

small grain sizes, dislocation sources in the grain interior are considerably rare and necessitate a high activation stress due to geometric constraint, leaving the dislocation source structure/density at grain boundaries as the governing factor for plasticity.

The present work showcases a single phase equiatomic Fe-Cr alloy processed by high pressure torsion to obtain a system with sub-100 nm grain size, which was deliberately altered using sequential heat treatments to modify the local grain boundary state at constant grain size (300°C), as well as to investigate the grain size influence via moderate grain growth to approximately 300 nm (500°C). Due to the limited specimen size during high pressure torsion (<0.5 mm) the material was investigated using in situ micromechanical testing techniques, ranging from tensile testing with additional point feature tracking to obtain detailed information on strain localization to continuous J-integral measurement to determine elastic-plastic fracture characteristics. Furthermore, the correlative (non-)equilibrium nature of grain boundaries was elucidated by damping measurements using micromechanical spectroscopy as well as correlative Synchrotron X-Ray investigations.

This multitude of data allows us to fully capture the changes in strength, ductility, strain localization, fracture toughness and anelasticity within one material system, with only the grain boundary structure/area as the main factor of change. The obtained correlations between these parameters will be discussed in detail to elaborate a pathway for structural grain boundary engineering without the necessity of chemical modifications.

Paper 827 8 **DVC-Driven Analysis of Mechanical Deformation in SLM WE43 Scaffolds with In Situ X-ray Characterization**
Ph.D. Maria-Dolores Martin-Alonso, Spain
Oral Presentation (20')

Abstract

Porous magnesium scaffolds produced via laser powder bed fusion (LPBF) show great potential for bone regeneration due to their ability to support tissue ingrowth and enable fluid transport. Magnesium implants also possess mechanical properties closely matching those of bone, thereby minimizing stress shielding effects. Understanding the load-bearing capacity and mechanical behavior of these scaffolds is crucial for optimizing their performance and ensuring a uniform stress distribution that promotes a controlled failure mode.

Cubic scaffolds ($10 \times 10 \times 10 \text{ mm}^3$) of WE43 magnesium alloy with open porous structures, designed with different lattice geometries (BCC, FCC, TPMS) and an average strut diameter of $500 \mu\text{m}$, were fabricated using LPBF. Their mechanical properties and failure mechanisms were investigated through in situ synchrotron X-ray microtomography compression tests under varying mechanical loading conditions. This study explores the application of Digital Volume Correlation (DVC) to analyze the mechanical behavior of magnesium scaffolds. DVC provides a detailed assessment of localized deformations and strain fields across the scaffold structure under mechanical loading. By examining the evolution of these parameters, this work aims to enhance the understanding of the mechanical response and failure mechanisms in magnesium scaffolds.

We will address the complete DVC workflow, encompassing uncertainty analysis, residual examination, and the evaluation of displacements and strain fields. This comprehensive approach provides valuable insights into the mechanical behavior of Mg scaffolds for bone regeneration applications.

Paper 1264 1 In situ Transmission Kikuchi Diffraction (TKD) Tensile Testing

Dr. Tijmen Vermeij, Switzerland

Oral Presentation (20')

Abstract

We present a novel methodology for in situ Transmission Kikuchi Diffraction (TKD) tensile testing that enables nanoscale characterization of the evolution of complex plasticity mechanisms. By integrating a modified in situ Scanning Electron Microscope (SEM) nanoindenter with a microscale push-to-pull device and a conventional Electron Backscatter Diffraction (EBSD) detector, we achieved TKD measurements at high spatial resolution during mechanical deformation. A dedicated focused ion beam procedure was developed for site-specific specimen fabrication, including lift-out, thinning, and shaping into a dog-bone geometry. The methodology was demonstrated on several case studies: (i) a metastable β -Ti single crystal, on which we quantified the initiation and evolution of nanoscale twinning and stress-induced martensitic transformation, (ii) an HCP Re single crystal loaded along the c-axis showing complex nanoscale twinning and twin-to-twin interactions, and (iii) a CuAl/Al₂O₃ nanolaminate, which exhibited nanoscale plasticity and twinning/detwinning in a complex microstructure. Furthermore, we explore the possibilities for performing elastic and plastic strain measurements using HR-TKD and SEM-DIC, respectively, alongside regular TKD mapping. Overall, this approach provides a robust alternative to in situ EBSD and transmission electron microscopy testing, with the potential of providing local stress-strain data, facilitating detailed analysis of deformation mechanisms at the nanoscale.

Metal-Ceramic Nanolaminate Design for Enhanced Mechanical Properties

Dr. Xavier Maeder, Switzerland

Oral Presentation (20')

Abstract

Metal-ceramic multilayer composites exhibit improved strength, ductility, and toughness due to the synergistic effects of their differing properties and characteristics. In such composites, interface strengthening and microstructural control through grain size and layer refinement play a crucial role in determining mechanical properties. In this study, we present experimental data on the fabrication and mechanical behavior of nanolaminates composed of metallic alloy layers with thicknesses ranging from 30 to 120 nm, alternating with thin amorphous Al₂O₃ interfaces measuring 2 to 5 nm. The metal and oxide are deposited using physical vapor deposition (PVD) and atomic layer deposition (ALD), respectively, in a hybrid deposition chamber without breaking the vacuum.

The incorporation of these thin amorphous oxide interfaces between the metal layers serves several purposes: a) it disrupts the columnar growth of the metal alloy film, allowing for a smaller and more controlled grain size, b) it regulates diffusion, c) it inhibits the propagation of dislocations and twins, and d) it controls grain boundary migration and recrystallization during annealing.

As a model system, we fabricated Cu_{1-x} – Al_x (where X represents 0, 5, and 12 at.%) multilayers and subjected them to micropillar compression, micro-tensile mechanical testing, nanoindentation, in situ tensile transmission Kikuchi diffraction (TKD), and 4D-STEM experiments. By varying the aluminum content, we can precisely control the stacking fault energy within the interlayer, thereby influencing the formation and size of nano-twins. The roles of various small-scale mechanisms, such as Hall-Petch strengthening, solid solution effects, and interface strengthening, will also be discussed.

Creep Dominated High Cycle Fatigue of Freestanding Gold Thin Films: Microstructure and Temperature Dependent Deformation Mechanisms

Prof. Benoit Merle, Germany

Oral Presentation (20')

Abstract

Freestanding metallic thin films experience cyclic loading conditions when they are used in flexible electronic devices, e.g. as interconnects. While supported thin films have been extensively studied, comparatively little is known about the fatigue behavior of freestanding films, largely due to experimental challenges. In addition to sharing unique PVD microstructures, freestanding films stand out due to the ubiquitous presence of a free surface, which likely further alters the classical fatigue mechanisms known from their bulk counterparts.

Using bulge testing, we investigated the widespread columnar ultra-fine grained and nanocrystalline microstructures by conducting a comprehensive investigation of the high cycle fatigue behavior of gold thin films over a temperature range of 20 to 100°C, closely reflecting operational conditions in microelectronic devices. Interrupted testing, coupled with transmission electron microscopy, was used to monitor the microstructural evolution. Through analysis of activation parameters and comparisons to reference creep bulge tests, we demonstrated that the cyclic behavior is dominated by creep mechanisms. Cyclic creep was evidenced for all microstructural conditions and temperatures. At 100°C, nanocrystalline films exhibited an unexpected fatigue limit. The distinct behaviors of columnar ultrafine-grained and nanocrystalline samples will be discussed in detail during the presentation.

In situ TEM investigation of fracture growth in novel nanolaminate thin films

Dr. Vivek Devulapalli, Switzerland

Oral Presentation (20')

Abstract

In-situ transmission electron microscopy (TEM) provides unprecedented opportunities to directly observe and understand deformation mechanisms in advanced materials, making it an invaluable tool for developing tougher nanostructured systems. This study presents atomically resolved insights into the fracture behaviour of Cu-Al multilayer thin films incorporating ultrathin amorphous Al_2O_3 interlayers. Through in-situ TEM tensile testing, we directly observed the dynamic interplay between crack propagation and microstructural evolution. The multilayer system, consisting of 30-120 nm thick Cu-10% Al layers separated by 2 nm Al_2O_3 interlayers deposited via atomic layer deposition (ALD), demonstrated remarkable toughness through multiple mechanisms. Our real-time observations revealed that void nucleation preferentially occurred at interfaces between the ALD layer and high-angle grain boundaries, forcing cracks to follow tortuous paths and thereby enhancing the material's overall toughness. The investigation uncovered several concurrent deformation mechanisms operating ahead of the crack tip, including dislocation glide, grain boundary sliding, detwinning, and grain rotation. Notably, we observed a significant reduction in twin fraction from 30% to 20% during crack growth, indicating that plasticity at the crack tip is partially accommodated through detwinning. Perhaps most remarkably, the amorphous Al_2O_3 interlayers exhibited unprecedented ductility, thinning from 2 nm to approximately 500 pm before failure. This exceptional behaviour in an otherwise brittle ceramic material, combined with the complex crack propagation pathways and multiple operative deformation mechanisms, contributes to the enhanced mechanical performance of these multilayer systems. These findings provide crucial insights for the design of damage-tolerant metallic thin films and demonstrate the potential of engineered interfaces in achieving superior mechanical properties in multilayer materials.

Paper 1297 5 High-strength and non-brittle crystalline-amorphous PVD-ALD nanolaminates of amorphous alumina and AlCoCrFeNi high-entropy alloy

Mr. Samuel Bojarski, Switzerland

Oral Presentation (20')

Abstract

Over the past few decades, there has been extensive research interest in reducing characteristic length-scales in materials in order to achieve high strengths without compromising ductility. One popular strategy has been the refinement of grain size through "nanolaminate" architectures: alternating layers of two different materials with sub-micrometre thicknesses. For most material pairings deposited by physical vapour deposition (PVD), the alternating layers disrupt columnar grain growth, retaining sub-micrometre in-plane grain size through the thickness of sample. In parallel, a new approach to metallurgy emerged: the idea that near-equiatomic mixes of five or more elements should be stabilised in a single phase by their high entropy of mixing, rather than decomposing into intermetallic phases. This field of "high-entropy alloys" (HEAs) has produced some of the strongest metals ever reported, without compromising on ductility or toughness. We have combined these two strategies to create nanolaminate films using the AlCoCrFeNi HEA: both metal-metal fcc/bcc multilayers (exploiting the dependence of phase on Al content in this alloy); as well as metal-ceramic nanolaminates with 2 nm atomic layer deposition (ALD) amorphous alumina interlayers. Microstructural analysis confirms that the ALD layers effectively disrupt out-of-plane grain growth and retain small in-plane grain size. Micropillar compression experiments show that this system is exceptionally strong for a metal, and still plastic in its deformation. Through post-deformation TEM imaging, we show that the amorphous alumina interlayers deform in a ductile manner co-operatively with the metal layers, remaining continuous even under significant local strains. We discuss possible mechanisms capable of explaining the co-operative non-local deformation of the amorphous layer, and how these layers contribute to the nanolaminate's high strength.

Paper 2038 6 Influence of material properties on the mechanical behavior of architected structures

Mrs. Chloé Fouqué, France

Oral Presentation (20')

Abstract

Metamaterials enable the achievement of exceptional mechanical properties that are unattainable with conventional materials, primarily through the tailored geometry of their unit cells. In particular, combining high stiffness with significant elastic recovery—two typically conflicting properties—can be realized by leveraging structural instabilities such as elastic buckling and snap-through effects. While it is well established that unit cell's geometry plays a dominant role in determining metamaterial effective properties [1], the influence of the constitutive material remains less explored. This study aims to quantify and rank the impact of the constitutive material on the mechanical response of metamaterials, with a focus on rigidity and elastic recovery.

A combined experimental and numerical approach was used to investigate this influence. Additive manufacturing via the Laser Powder Bed Fusion (LPBF) process was employed to produce metamaterial structures incorporating instability-based deformation mechanisms. Compression tests were conducted with in situ Digital Image Correlation (DIC) [2] to capture local constitutive material behavior. Experimental results were compared with finite element simulations incorporating material laws that account for non-uniform plastic deformations. Additionally, the influence of different constitutive materials was analyzed on an identical unit cell geometry to validate the findings. The study provides new insights into the role of the base material in metamaterial performance, offering valuable guidelines for optimizing material-geometry interactions in the design of high-performance structures.

Paper 1767 1

Statistics of micro-deformation mechanisms of HCP zinc coatings quantified by SSLIP analysis of in-situ EBSD-SEM-DIC testing

Prof. J.P.M. (Johan) Hoefnagels, The Netherlands

Highlight (Oral Presentation 20')

Abstract

HCP plasticity is complex due to the high anisotropy, apparent brittleness, and the alternative plasticity mechanisms that often activate, such as twinning, grain boundary sliding, and/or grain boundary migration, alongside plasticity of multiple active HCP crystallographic slip families. Detailed understanding of HCP plasticity is important for many applications, such as zinc corrosion coatings for steel. In this study, a range of novel methodologies for high-resolution and robust measurement and identification of micromechanical deformation mechanisms are applied to identify all the different plastic mechanisms. The methodologies are based on in-situ EBSD-SEM-DIC testing [1,2], capable of obtaining strain fields with a ~40nm spatial resolution aligned to EBSD microstructure maps [3], with recently developed advanced EBSD-SEM-DIC analysis routines to quantify all HCP slip system activity maps as well as the activity maps of twinning, grain boundary sliding, and grain boundary migration [4,5]. A detailed statistical analysis has been conducted of these different plasticity mechanisms and their mutual interactions in zinc coatings, including >300 grains, corresponding to a total grain boundary length of ~2.9 mm. This huge statistical analysis resulted in a detailed hypothesis that tries to explain the activation of the 4 active zinc slip families, the occurrence of twinning, and the statistical analysis between the various identified GB properties of each GB segment, including the identified in-plane sliding and/or apparent opening kinematics, its angle with the loading direction, the crystallographic misorientation angle. Additionally, the interaction between these plasticity mechanisms has been studied, as will be presented at EUROMAT 2025.

Paper 784 2 **Mechanical properties of RE-Ni₂ Laves phases and effect of vacancy on partial dislocation motions**
Mr. Sang-hyeok Lee, Germany
Oral Presentation (20')

Abstract

Laves phases, one of the largest intermetallic groups, are promising candidates for hydrogen storage alloys and economically viable superalloys. However, their inherent brittleness has limited widespread industrial application.

A deeper understanding of their deformation mechanisms could help overcome this limitation. Recent advancements have elucidated the role of antisite substitution and alloying as crucial factors in enhancing the ductility of Laves phases. However, the influence of vacancy defects remains unclear due to their rarity owing higher formation energy compared to antisite defects, despite predictions that vacancies strongly influence dislocation mobility.

To this end, the mechanical properties of rare-earth Laves (RNi₂) phases were investigated to understand the effect of vacancy-type defects on dislocation motion, with both experimental and computational approaches. The hardness and reduced modulus of RNi₂-Laves phases (R=Er, Y, Sm, and La) were evaluated by the correlative nanoindentation technique, which provides orientation-dependent mechanical properties. Additionally, the mechanisms of partial dislocation motion under influence of vacancies were explored with atomistic simulations using machine learning interatomic potentials.

Paper 451 3 **Investigations of Solute Segregation on Grain Boundaries and Their Role in Deformation Mechanisms of Mg Alloys**
Mr. Hexin Wang, Germany
Oral Presentation (20')

Abstract

Grain boundaries (GBs) and their migration play a significant role in the deformation and texture modification of magnesium (Mg) alloys [1]. However, their response to deformation, particularly their interaction with moving dislocations, remains incompletely understood. This study investigates the properties of GBs and dislocations in Mg and its alloys through nanomechanical testing and atomic-scale modeling [2]. The tendency for solute segregation at representative GBs is characterized using atom probe tomography, while micropillar compression tests on bi-crystalline Mg and Mg-X alloys (where X = Zn or Y) are conducted to explore the effects of solute segregation on GB properties. The atomistic mechanisms underlying interactions between dislocations and GBs in Mg and its alloys were elucidated. This study provides valuable insights into interfacial segregation at GBs in Mg alloys and its implications for plasticity.

Paper 1449 4 A novel 3-electrode-based backside H-charging setup for in-situ micromechanical study: Development and demonstration

Dr. Bathini Lavakumar, France

Oral Presentation (20')

Abstract

Hydrogen (H) is leading the global campaign in search of sustainable energy materials to replace conventional fossil fuels. However, due to hydrogen embrittlement (HE), materials can experience a significant shift in their mechanical properties and undergo brittle failure in the presence of hydrogen. Conventional ex-situ testing methods suffer from hydrogen outgassing and concentration gradients during the testing. Furthermore, large specimens require longer charging cycles, making sample preparation a time-consuming process. In pursuit of deconvoluting the specific interactions between hydrogen and individual microstructural features, novel in-situ electrochemical deformation techniques involving simultaneous H-charging and micromechanical testing, have been recently developed at our laboratory. To integrate the three key aspects of HE studies (H-charging, micromechanics, and microstructural investigation) into one single platform, an in-situ 3-electrode-based back-side H-charging cell will be presented, that is designed to be compatible with scanning electron microscope-based analytics. Continuous H-charging is therefore performed on thin samples subjected to external loading (nanoindentation and micropillar compression) to study the stress-strain behaviour of a low alloy cast steel (G20Mn5, A. Yaktiti et al. Corrosion Science 199 (2022) 110208) and a Ni bicrystal at various deformation rates ($10^{-4} \text{ /s} < \dot{\epsilon} < 10 \text{ /s}$).

Paper 1646 **5** **Hot-Working Characteristics and Microstructural Evolution of INCONEL 625 Multiphase Superalloy**
Prof. Nicolae Șerban, Romania
Oral Presentation (20')

Abstract

Nickel-based superalloys, such as INCONEL 625, are widely used in various industrial sectors, including chemical, petrochemical, energy, and aerospace, where they operate under demanding conditions requiring exceptional mechanical strength and corrosion resistance at high temperatures. The combination of Ni and Cr gives these superalloys exceptional properties in severe operating environments, such as remarkable oxidation resistance, superior to stainless steels, especially at temperatures above 650°C, as well as high resistance to stress corrosion cracking and localized corrosion, including pitting and crevice corrosion, in aqueous environments, even those containing sulphides and chlorides. Optimal mechanical properties at high temperatures are achieved by controlling all parameters of thermomechanical processing, especially during hot-working, a control that is often difficult to achieve. This study examines the hot-working behaviour of INCONEL 625 superalloy by evaluating its deformability and microstructural evolution within the 1050 – 1200°C temperature range. The microstructural changes were analysed using X-ray Diffraction (XRD) and Scanning Electron Microscopy with Electron Backscatter Diffraction (SEM-EBSD), while deformability was assessed through the upsetting method with a gravity-drop hammer. The following structural characteristics were analysed: constituent phases, lattice strain, crystallite size, phase morphology. Experimental data on deformation resistance, specific mechanical work, and plasticity were collected and analysed based on deformation temperature and impact energy. The findings indicate that increasing the deformation temperature improves plasticity, and a detailed analysis of plasticity's growth rate as a function of impact energy revealed that higher impact energy results in a more pronounced increase in plasticity. Additionally, deformation resistance was found to decrease with rising temperature across all impact energies. Likewise, specific mechanical work followed a decreasing trend with increasing deformation temperature, irrespective of impact energy.

Keywords: deformability; microstructural evolution; deformation resistance; plasticity; nickel-based superalloys.

Paper 1498 1 **Dynamical studies (liquid/gas/corrosion strain & crystalline- amorphous- phase maps) using in situ 4D-SPED in advanced materials**

Dr. Stavros Nicolopoulos, Belgium

Keynote (Oral Presentation 40')

Abstract

Automatic crystal orientation & phase mapping (ASTAR technique) can be applied in a variety of materials [1,2] using 4D-SPED (scanning Precession Electron Diffraction), where beam precession (to improve ED patterns quality [3,4]) in TEM is used in synchronization with beam scanning. ASTAR technique has significant spatial resolution down to 1-3 nm (in case of FEG-TEM).

In situ methods have been extensively applied towards dynamical studies. The combination of 4D-SPED ASTAR with the new generation of pixelated detectors allows the use of extremely low electron dose with significantly fast acquisition times (500-1000fps). For example, we have obtained orientation /texture maps on Au colloidal nanoparticles in water by monitoring local orientation changes over time.

Another in-situ study, regards Zirconium- (Zr-) based alloys, that utilized as cladding material for nuclear reactor fuel, are susceptible to oxidation under harsh reactor operation conditions. Using a MEMS-based environment holder, we have studied Zr metal oxidation mechanism by monitoring local orientation/phase changes using ASTAR and strain mapping by integrating four-dimensional scanning transmission electron microscopy (4D-STEM), ambient pressure gas-cell holder, precession electron microscopy (PED), and direct electron detector (DED). This type of setup can be used to conduct in situ/ in operando corrosion studies across a broad range of materials.

Again, the recent development of e-PDF mapping analysis (pair distribution function by electron diffraction) in TEM enables the study of amorphous materials at nm scale resolution and distinguish between various complex amorphous phases (e.g. phase separated glasses for industrial use, semiconductor thin amorphous layers, etc.)

Chiral Nanomaterials

Prof. Iouri Gouko, Ireland

Highlight (Oral Presentation 20')

Abstract

Symmetry and chirality are properties commonly found throughout the natural world. Chirality is one of the most important factors in molecular recognition, with chiral compounds having a major role in chemistry, biology and medicine. Chirality has also been envisaged to play an important role in nanotechnology. Over the last years the area of chiral nanoparticles has received a great deal of attention due to the range of potential applications offered by these materials. The main aim of our work is to develop new types of technologically important inorganic nanoparticulate materials possessing optical activity and chirality, study their properties, investigate their nature and explore their applications. We have developed a range of new chiral nanomaterials including chiral ternary silver indium sulfide and selenide based semiconducting nanoparticles (quantum dots). In addition, we started to explore the properties of new anisotropic chiral 2D nanostructures. The new nanomaterials have shown a very interesting optical activity and unusual chiral morphologies which were confirmed by various instrumental techniques. Several critical aspects on the nanocrystals growth, characterization, and the optimisation of the surface passivation by the chiral ligand in order to optimize the nanoparticle chirality are thoroughly investigated. Optical spectroscopy as circular dichroism and luminescence are exploited to analyze the coordination processes leading to the formation of the ligand-nanocrystal chiral interface. The study highlights the dynamic nature of the interaction between the nanocrystals surface and the chiral ligand and clarify some fundamental aspects for the transfer and optimization of the chiroptical activity. We have also explored potential applications of chiral quantum dots for chiral recognition and luminescent chemo- and bio- sensing. Finally, we overview chiral nanomaterials within the framework of synthesis-structure-property-application relationships and provide insights on how to leverage machine learning for the study of these complex relationships.

The phase diagram of colloidal nanostructures sensitizing rare-earth photoluminescence

Dr. Guillaume Gouget, France

Oral Presentation (20')

Abstract

To improve photoemission conversion yield of rare-earth (RE) emitters, one strategy is to host them in semiconducting nanocrystals. From the pioneering work of the field in 2005, innovative reaction pathways toward colloidal nanocrystals have increased emitter loading content from 0.6% in 2013 to 5% in 2021. Improvements were incremental, by choosing pertinent RE cationic sites and anionic environments, following the hard-soft acids and bases rule proposed by Ralph Pearson in the 60s. The most recent results consist of 5% Er-doped La_2S_3 nanophosphors we obtained in oleylamine at 220°C during 1h. They display near-spherical shapes, $3.9 \pm 0.7 \text{ nm}$ diameters, and so-called “ γ ” cubic phase. In the bulk, γ RE sulfides are stabilized only at 2000°C or by mechanical milling. We investigate erbium solubility in the cation network of nanocrystalline La_2S_3 , (i) looking for the best E(3+) content for Er(3+) photoluminescence, and (ii) with special care on phase identification.

Probing several $x = \text{Er}/(\text{Er} + \text{La})$ molar ratios, we combine pXRD, SAXS, TEM, HRTEM, HAADF-STEM and TEM-EDX mapping with sub-nanometer scale resolution to identify nanocrystals' structure, morphology and RE content. As x increases, three domains are observed, with only partial solubility of Er(3+) in La_2S_3 , up to $x = 0.25$. A second population of $\text{La}(3+):\text{Er}_2\text{S}_3$ nanocrystals appears for $x \geq 0.25$. Both populations display the same γ -phase, but with distinct morphologies: cubic-like shapes for Er-poor nanocrystals versus plate shapes for Er-rich ones. Er(3+) photoemission is detected only for $x = 0.05$. The oral presentation will discuss the peculiar behaviors of colloidal nanocrystals $\text{Er}(2x)\text{La}(2-2x)\text{S}_3$ ($0 \leq x \leq 1$) obtained by wet colloidal synthesis. First, we identify a limit of solubility for Er(3+) insertion in La_2S_3 . Still, the 25% solubility represents a 5-fold increase compared to our previous work. Considering photoluminescence of $\text{Er}(2x)\text{La}(2-2x)\text{S}_3$ nanocolloids, $x = 0.25$ shall not be exceeded for future studies.

Second, higher loadings ($0.25 \leq x \leq 0.75$) lead to two populations with distinct shapes, and same crystal structure. Motivations for the system to favor such an atypical shape segregation will be discussed, in regard of the elemental environments and morphological differences.

Completing the $\text{Er}(2x)\text{La}(2-2x)\text{S}_3$ ($0 \leq x \leq 1$) series with a single-phase domain of nanoplates for $x > 0.75$, we propose a methodology to study full series of ternary, mixed RE chalcogenide nanocrystals. The methodology is inspired from phase diagram studies historically ran for compositions from the bulk. Additional examples will be provided for europium and lanthanum sulfides. The study emphasizes the need for in-depth, adapted characterizations to combine the structural, morphological, compositional and surface characteristics of nanocrystalline colloids.

FeCoNi nanowires as candidates for 3D magnetic memory units

Dr. Malgorzata Kac, Poland

Oral Presentation (20')

Abstract

Nanomaterials have been among the most studied objects in the last few decades. Their unique electrical, optical and magnetic properties make them attractive for various applications from biomedicine to environmental protection and consumer electronics. A particularly interesting aspect is connected with spintronic applications, where one-dimensional magnetic objects such as nanowires may be promising materials for a new type of three-dimensional magnetic memory units called racetrack memory. In this study, FeCoNi nanowires (NWs) will be presented as a candidate for magnetic memory in a 3D approach. To meet the required criteria, they should demonstrate well-defined morphology, chemical composition, structure, and magnetic properties. Thus, nanowires with a diameter of 40 and 100 nm and a length of 6 μm were electrodeposited in polycarbonate membranes using a template-assisted method. Their chemical composition was modified by an appropriately selected cathodic potential and resulted in an increase in Ni content while decreasing Fe and Co concentrations when the applied voltage was shifted towards more cathodic values. These nanowires crystallized in the fcc structure with significant changes in the lattice parameters and crystallite size associated with various elemental content and different current density. The geometry, chemical composition, and structure of nanowires influenced their magnetic properties. All samples showed an easy magnetic axis along the NW axis due to the dominant role of shape anisotropy. The coercivity and squareness values decreased for 40 nm diameter nanowires with increasing cathodic potential, but showed an opposite relationship for nanowires with a diameter of 100 nm because of dominant contribution of dipolar interactions. Studies of angular coercivity dependence exhibited the vortex domain wall propagation at the angles close to the easy direction and switching of the magnetization reversal mechanism to coherent rotation or transverse domain wall movement at the angles close to the hard directions. First-order reversal curve analysis together with Lorentz TEM observations revealed the single-domain structure of both nanowire diameters and confirmed non-interacting system in the case of 40 nm diameter nanowires. Segmented nanowires composed of FeCoNi alloys with different concentrations showed domain walls located at the segment boundaries. Therefore, the obtained nanowires meet the criteria required for 3D racetrack memory applications.

Solution growth of one-dimensional wide bandgap semiconductor nanostructures

Dr. Jan Grym, Czech Republic

Oral Presentation (20')

Abstract

One-dimensional wide-bandgap semiconductor nanostructures have garnered increasing attention in recent years, due to their promising potential for future electronic and optoelectronic devices. While the growth of these nanostructures from the vapor phase has been extensively investigated both experimentally and theoretically, the growth from solutions is predominantly addressed through empirical methods, without a fundamental understanding of the growth phenomena. In its basic form, growth is conducted in batch reactors, where reactants are introduced to induce supersaturation by controlling the thermodynamic properties of the system. However, these simple reactors exhibit poor control of supersaturation and its temporal dependence.

We introduce the concept of continuous-flow reactors and demonstrate that supersaturation can be precisely controlled in these reactors. In conjunction with lithographic techniques, growth in continuous flow reactors enables the elucidation of fundamental growth phenomena by combining experimental results with theoretical modeling. The significance of understanding the fundamentals of growth is demonstrated on (a) the growth of ZnO nanowires (NWs) by chemical bath deposition (CBD) with controlled morphology on p-type GaN epitaxial layers and on GaN NW arrays grown by plasma-assisted molecular beam epitaxy (PAMBE) for UV light sources and (b) on NW networks for gas sensors. The electrical properties of the individual NW heterojunctions and the fundamental building blocks of their networks were investigated within the chamber of a scanning electron microscope equipped with nanomanipulators.

ALIAS: an Atomistic Local Identification of Stiffness method

Ph.D. Fabrice Detrez, France

Highlight (Oral Presentation 20')

Abstract

This study tackles the problem of identification of elastic continuum model by atomistic simulations for graphene polymer nanocomposite. The Atomistic Local Identification of Stiffness method, so-called ALIAS method, is developed to estimate the local stiffness tensor at all points of polymer graphene laminate nanocomposite. Results suggest that the graphene can be modeled at continuum scale by a general imperfect interface with zero thickness. Moreover, the identification procedure reveals the existence of interphase on either side of the graphene with a thickness of 1 nm, which is one and a half times stiffer than the polymer bulk matrix. The identified continuum model is used to study the effective elastic properties of nanocomposites with sandwich microstructure. This study at continuum scale reveals a softening effect due the very low stiffness of slip along graphene plane. The softening due to the interfaces is preponderant in relation to the interphase stiffening. Finally, the continuum model also suggests that the wrinkling of graphene increases the stiffness of nanocomposites.

Advances in supported 1D organic nanowires growth as soft-templates for conformal multifunctional coatings by vacuum and plasma deposition techniques

Dr. Víctor López-Flores, Spain

Oral Presentation (20')

Abstract

Surface nanoarchitectures exhibit optical, electronic, and chemical properties that can be exploited in a myriad of applications. Among these, supported one-dimensional (1D) nanostructures are of relevance in notable areas such as energy (nanogenerators, batteries, solar cells and hydrogen), microelectronics, catalysis, photonics, biomaterials and biomedicine, and nanosensors.

Our approach to produce these 1D nanostructures is to grow single crystalline organic nanowires (ONW) by organic physical vapor deposition of planar molecules. These molecules adhere to the substrate in preferential spots that elongate when more molecules arrive and attach to themselves by π - π stacking. The control of the deposition parameters and surface structure and chemistry provides the ability to regulate density, thickness and length to the one suitable for the required application. By using vacuum deposition, this method avoids organic solvents and hazardous reagents, therefore being clean, reproducible and industrially scalable. During the last years, we have demonstrated the compatibility of the protocol with relevant substrates ranging from polymers (PDMS, PET, EcoFlex) to metal meshes, cellulose, graphene and carbon paper, including on-device formation on silicon wafers and TCOs.

Furthermore, these ONWs can be used as soft templates for coatings to be deposited conformally by a range of vacuum and plasma deposition techniques. Being organic, the ONWs can be easily removed after the coating by sublimation or plasma treatment, leaving a nanotube of the coating material behind. In addition, the space between the nanotubes can be filled with a soluble material by solution processing. This allows for a wide collection of materials, both organic and inorganic, and thus of possible applications to profit from the 1D nanoarchitecture.

This communication reports our recent advances in the growth of several supported 1D ONWs for energy, optic, electronic and sensing applications. We will specifically cover the use of non-planar molecules, the benefits of growing ONWs with a low sublimation point, the control of ONW density and length, the variety of suitable substrates, and the possibility of producing complex 3D nanoarchitectures. We will also examine a diversity of materials that can conformally coat these ONWs. Finally, we will present a few examples of applications of these surface nanoarchitectures.

Computational design of new electrolytes for supercapacitors

Dr. Mauro Francesco Sgroi, Italy

Poster Presentation

Abstract

One of the key challenges in developing safe and efficient batteries and supercapacitors lies in designing electrolytes with a broad electrochemical stability window. Achieving this requires a combination of experimental synthesis, characterization, and theoretical modelling. Accurate prediction of the electrochemical stability of new electrolytes is essential to accelerate the optimization of electrochemical energy storage systems. Although conceptually straightforward, determining the electrochemical stability window (ESW) of ionic liquid-based electrolytes is a computationally intensive and complex task. Various quantum theory approaches exist, each differing in accuracy and computational cost. The simplest method, albeit the least precise, involves correlating the ESW to the energy difference between the HOMO (Highest Occupied Molecular Orbital) and the LUMO (Lowest Unoccupied Molecular Orbital) [1]. A more advanced technique calculates the energy difference between ions and their oxidized/reduced forms, considering both vertical and adiabatic transitions. This approach can also account for implicit solvent effects and zero-point energy, though it still has limitations [1]. Another approach factors in a surrounding shell of counter-ions for the ion under study, addressing long-range electrostatic effects while using an implicit solvent model [2]. However, this method requires arbitrary decisions about the number of counter-ions included and does not accurately simulate Coulombic interactions between them. We propose a novel method to estimate ion energies using a multiscale QM/MM approach. In this framework, the ion of interest is treated using an accurate quantum mechanical method, while the surrounding counter-ions are modelled with a semiempirical approximation. Counter-ion distributions are derived from geometries generated by classical molecular dynamics simulations, with long-range electrostatics addressed through an implicit solvation model. By integrating the accuracy of quantum mechanics with the efficiency of molecular mechanics, this approach enables more precise and computationally practical predictions of the ESW for ionic liquid-based electrolytes. Our model was successfully validated ionic liquids based on the TFSI⁻ anion and the PYR13⁺, PYR14⁺ and EMIM⁺ cations.

3D-hydrogel matrix for *Synechocystis* sp. cultivation: mutual influence between microenvironment and microbial growth

Prof. Francesco Briatico-Vangosa, Italy

Poster Presentation

Abstract

Physical confinement in natural highly hydrated 3D microenvironments influences the dynamics of bacterial growth [1]. Microbial loaded hydrogels have potential application in biocatalysis, bioremediation, and production of synthetic communities. However, the understanding of how engineered microenvironments influence microbial growth and metabolic activities is still limited.

One of the main features affecting microbial growth is the mechanical properties of the soft matter [2]. Here we study how an engineered 3D microenvironment affects microbial growth by providing structural cues that influence proliferation and metabolism. Besides, we want to evaluate how microbial activity can alter material stability. To this, *Synechocystis* sp. PCC 6803 was encapsulated in calcium alginate hydrogels, and the system was analyzed from both biological and material science perspectives.

The hydrogel composition was based on internal gelation of alginate with Ca^{2+} , and its viscoelastic final properties were evaluated by frequency sweep in oscillatory dynamic mechanical measurement in linear viscoelastic regime. The crosslinking kinetic was followed by a time sweep test. We produced samples with a cell concentration of 107 cells per mL of hydrogel (Syn-Hy) and control hydrogels (C-Hy) without the addition of cells. The stability of the hydrogels, and bacterial growth and physiology (cytofluorimetry, microscopy, microelectrodes) were evaluated up to 27 days of culture at r.t. under controlled light conditions.

BG-11 was used as solvent for the hydrogel precursor solutions. However, the resulting hydrogels were not stable upon bacterial cells inclusion. Therefore, BG-11 composition was adjusted increasing Ca^{2+} concentration. The crosslinking times were minimally changed by the medium compositional change. The initial values of G' and G'' increased during the first day of immersion. For longer immersion times, Syn-Hy samples were macroscopically degraded, while C-Hy ones remained stable. Rheological properties steeply decreased for Syn-Hy, while C-Hy were slightly affected. From flow cytometry, *Synechocystis* growth rate in the hydrogel was comparable to that of the bacterial suspension in BG-11. Microscopy investigations showed the presence of heterogeneous microhabitats and the synthesis of extracellular polymeric substances within the hydrogel. Oxygen production confirms the photosynthetic activity of *Synechocystis*.

The obtained results indicate a reciprocal interaction between *Synechocystis* and the produced hydrogel, thus guiding the design of 3D matrices for microbial growth.

Cu-based dual-phase immiscible alloys

Ph.D. Ondrej Adam, Czech Republic

Canceled by the SO

Abstract

Cu-based immiscible alloys are a highly studied group of materials, whose research has been conducted primarily focusing on their electrical and magnetic properties. Nevertheless, they are currently being intensively studied also for their other properties, which are interesting both from a research and real application perspective. Much of the research into Cu-based immiscible alloys is currently focused on ultrafine-grained (UFG) alloys that possess excellent mechanical properties due to their dual-phase microstructure. In addition, unlike most UFG materials, immiscible alloys have very good resistance to grain coarsening, which allows them to retain their mechanical properties even after exposure to high temperatures.

Nevertheless, it is necessary to ensure the formation of a uniform UFG dual-phase microstructure. Due to the positive enthalpy of mixing of immiscible elements, phase separation often occurs already in the liquid phase. For the preparation of highly concentrated UFG immiscible alloys, it is appropriate to use production methods that do not involve a liquid phase. However, it is necessary to ensure the mixing of immiscible elements and thus create a supersaturated solid solution that can be subsequently decomposed into a dual-phase microstructure at elevated temperature. One of the suitable methods is high-energy ball milling. However, for the preparation of a bulk sample, the resulting powder must be sintered at elevated temperatures and thus the controlled creation of a UFG dual-phase microstructure is limited. High-pressure torsion (HPT) appears to be a suitable alternative. In this method, elemental powders are mechanically alloyed and consolidated at the same time. So the result should be a bulk sample with a microstructure composed of supersaturated solid solution.

This study focuses on preparing immiscible Cu-Fe and Cu-Ag alloys from the elemental powders using HPT. The Cu-Fe alloy represents one of the most studied types of immiscible alloy, which should exhibit great mechanical properties. The Cu-Ag alloy has the potential to be used as a substrate for Surface-enhanced Raman Spectroscopy, which also possesses a certain level of mechanical resistance. The study focused on the effect of the number of HPT turns on the resulting microstructure and hardness of the prepared samples. To achieve better mixing, mechanical alloying of elemental powders using high-energy ball milling before HPT was also tested. Subsequently, DSC analyses were performed on selected samples to study the decomposition of supersaturated solid solution. According to the results, the optimal annealing temperatures were selected to achieve a UFG dual-phase microstructure.

Paper 1114

Advanced investigations to understand the damage of a Face-Centered Cubic metallic alloy in presence of liquid lead and Pb-Bi eutectic and under mechanical loading

Dr. Ingrid Proriot Serre, France

Poster Presentation

Abstract

In presence of liquid metal, one of the major damages for the structural metallic materials could be due to corrosion by liquid metal and/or, under stress (mechanical stress or stress caused by temperature fluctuations), structural materials can be susceptible to liquid metal embrittlement (LME), i.e. partial or total loss of ductility in the presence of liquid metal and therefore an earlier fracture. These possible damages need to be investigated for the qualification of the structural metallic materials in contact with the coolant (liquid lead or the Lead-Bismuth Eutectic (LBE)) for the Lead Fast Reactors or Accelerator Driven Systems. Thus, because of the LME sensitivity of the Body-Centered Cubic alloys, the most ductile Face-Centered Cubic (FCC) alloys were preferred because of their low LME sensitivity below 450 °C and despite the corrosion observed, in particular the selective dissolution of Ni. But in recent years, cases of LME sensitivity have been observed for austenitic steels at temperatures above 450°C and for FCC Complex Concentrated Alloys (CCA) from 300 °C in the presence of liquid LBE and from 400 °C in liquid Pb. Intergranular cracks were observed and selective dissolution of Ni and Mn were noted in specific conditions. Lower strain rates and higher temperatures promote LME sensitivity. The objective of the work is the study the occurrence of damage in the presence of liquid lead, LBE, and bismuth for a FCC metallic alloy under mechanical loading and decouple purely corrosion-related aspects from those related to LME aspects by mechanical tensile testing, microscopic characterizations, and thermodynamic analysis. Tensile tests have been carried out in air and in liquid Pb, Bi, and LBE saturated with oxygen at temperatures between 300°C and 500°C, at different strain rates. After test, fracture surfaces and cross-sections of the fractured specimens have been observed using SEM (Scanning Electron Microscopy), EDX-SEM (Energy Dispersive X-ray), and SEM-EBSD (Electron Backscatter Diffraction), to analyse the effects of the liquid metal on the fracture mode, microstructure (phases and composition), and cracking. Additional TEM (Transmission Electron Microscopy) analyses have been performed to investigate the damage, especially phase transformations. Thermodynamic analyses using Thermo-Calc to understand the evolution of the material in the presence of liquid metal towards equilibrium are studied. Taking into account all these investigations, the corrosion, the corrosion induced by mechanical loading, and the liquid metal embrittlement occurrences are discussed.

Advances and challenges in direct additive manufacturing of Al₂O₃ and ZrO₂-based Eutectic Ceramic Oxide

Dr. Rosa Taurino, Italy

Poster Presentation

Abstract

Introduction

Al₂O₃-based directionally solidified eutectic ceramics have garnered significant interest over the past decades due to their exceptional high-temperature strength retention and creep resistance compared to metal alloys, as well as their superior oxidation resistance and microstructural stability relative to other ceramics. For these reasons, they have been identified as some of the most promising candidates for ultra-high-temperature structural applications. From a processing perspective, oxide eutectic composite ceramics have been produced through various solidification methods. However, these methods are often unable to achieve fine microstructures or fabricate large or complex-shaped components. To address these limitations, additive manufacturing (AM) presents a promising alternative for the production of monolithic and complex-shaped ceramic parts with fine and homogeneous microstructures.

The aim of this study is to evaluate the feasibility of using L-PBF technologies for the production of Al₂O₃-based eutectic ceramics.

In the initial phase of the study, the focus was on characterizing and optimizing the particle size distribution (PSD) of eutectic Al₂O₃-ZrO₂ based granules for use in various laser powder bed fusion (PBF) technologies. Initial characterization, performed using SEM imaging and laser granulometry, assessed the PSD, average particle size, and distribution width of the engineered batches. Subsequently, the optimized ceramic powders, with tailored size distributions, morphologies, and compositions, were selected for specific applications in L-PBF (fiber laser) and L-PBF (CO₂ laser) technologies. The addition of graphene to the studied compositions enabled an evaluation of its impact on laser beam absorption.

Enhancing Structural Stability and Energy Density in MgO-NaNO₃ Composite Phase Change Materials Through SiO₂ Nanoparticle Incorporation

Dr. Dimitrios Skondras Giousios, Poland

Poster Presentation

Abstract

Composite Phase Change Materials (CPCMs) offer a promising approach for high-temperature thermal energy storage (TES) applications, combining the high energy density of phase change materials (PCMs) with the structural stability of porous matrices. However, traditional CPCMs often face limitations in achieving high PCM content while maintaining mechanical integrity, particularly in oxide-based matrices like MgO. This study investigates the effects of SiO₂ nanoparticle (NP) doping on the structural and thermal properties of MgO-NaNO₃ CPCMs, comparing two distinct MgO types: Heavy MgO, characterized by larger particle size and lower surface area, and Light MgO, with smaller particle size and higher surface area.

We evaluated CPCMs with a 50% MgO–50% NaNO₃ baseline composition, along with formulations incorporating 5 and 10 wt.% SiO₂, as well as a high-PCM-content 70% NaNO₃ – 10% SiO₂ system. Our findings indicate that SiO₂ nanoparticles significantly enhance CPCM structural stability, irrespective of MgO type. Notably, CPCMs with only 5 wt.% SiO₂ were unable to sustain 70% PCM content, while those with 10 wt.% SiO₂ successfully stabilized this higher PCM concentration. This advancement increased energy storage density while maintaining thermal conductivity at the same level as the base 50-50 composition without SiO₂. The optimized 70% NaNO₃ – 10% SiO₂ CPCM exhibited only an 18% decrease in energy storage density compared to pure NaNO₃, a substantial improvement over conventional MgO-NaNO₃ CPCMs with lower PCM content.

A key observation was the differential effect of MgO type on SiO₂ synergy. Light MgO, due to its smaller particle size and higher surface area, exhibited better interaction with SiO₂ nanoparticles, further enhancing CPCM thermal performance when combined with SiO₂ compared to Heavy MgO. This suggests that finer matrix particles can optimize nanoparticle integration, improving composite integrity.

Overall, this study demonstrates that SiO₂ nanoparticles play a crucial role in enabling high-PCM-content CPCMs while preserving thermal conductivity and mechanical stability. By leveraging nano-enhanced stabilization mechanisms, these findings open new avenues for optimizing MgO-based CPCMs for high-temperature TES applications. Future work should focus on refining matrix-nanoparticle interactions and exploring alternative nanoparticle additives to further enhance CPCM performance.

Porosity evolution along simultaneous synthesis and sintering of zinc ortostannate

Dr. Eugeni Cañas, Spain

Poster Presentation

Abstract

Zinc ortostannate (Zn_2SnO_4) has received broad attention due to its excellent optical and electrical properties, as well as its stability. However, some research has shown the anomalous expansion that presents when synthesis and sintering are performed simultaneously. This research demonstrates that it could be used to obtain porous ceramics without the addition of any pore generator.

The starting point was a stoichiometric mixture of ZnO and SnO_2 . Its analysis in a hot stage microscope at $25\text{ }^\circ\text{C}\cdot\text{min}^{-1}$ showed that contraction begins around $1000\text{ }^\circ\text{C}$, but an expansion occurs between 1080 and $1200\text{ }^\circ\text{C}$, that presumably generates an increase in porosity. This fact was confirmed by firing dry-pressed specimens of the mixture (samples of $2\times 8\text{ cm}^2$ compacted at $250\text{ kg}\cdot\text{cm}^{-2}$) during 1 hour at different temperatures between $950\text{ }^\circ\text{C}$ and $1350\text{ }^\circ\text{C}$. The bulk density of fired specimens at $1050\text{ }^\circ\text{C}$ and $1150\text{ }^\circ\text{C}$ ($2,77$ and $3,14\text{ g}\cdot\text{cm}^{-3}$ respectively) was lower than the value corresponding to $950\text{ }^\circ\text{C}$ ($3,33\text{ g}\cdot\text{cm}^{-3}$). However, bulk density increased for specimens fired at higher temperatures ($3,92$ and $4,37\text{ g}\cdot\text{cm}^{-3}$ for the samples fired at $1250\text{ }^\circ\text{C}$ and $1350\text{ }^\circ\text{C}$ respectively).

Mercury intrusion porosimetry showed that total pore volume shows an inverse trend with respect to bulk density, peaking for the samples treated at $1050\text{ }^\circ\text{C}$. Concretely, samples fired at $1050\text{ }^\circ\text{C}$ had a pore volume of $0,20\text{ cm}^3\cdot\text{g}^{-1}$, a 42% higher than $0,14\text{ cm}^3\cdot\text{g}^{-1}$ obtained at $950\text{ }^\circ\text{C}$. However, the mean diameter increases with a nearly exponential trend with the sintering temperature, from $0,15\text{ }\mu\text{m}$ at $950\text{ }^\circ\text{C}$ to $1,22\text{ }\mu\text{m}$ at $1350\text{ }^\circ\text{C}$. These characteristics are compatible with a microfiltration membrane, with the advantage that no pore generator, as starch, was introduced in the composition. Consequently, the thermal cycle did not require a slow step for oxidise/decompose the additive, shortening the firing step and reducing the energy cost.

The abnormal behaviour under firing around $1050\text{ }^\circ\text{C}$ of the stoichiometric mixture of ZnO and SnO_2 around $1050\text{ }^\circ\text{C}$ generates a ceramic with high porosity and sub-micronic mean pore size that allows their use as microfiltration membranes with the advantage that no pore generator was needed.

Paper 476

Synthesis and characterization of polycationic Sn clathrates via ball milling

Dr. Nikolaos Moutzouris, Greece

Poster Presentation

Abstract

Clathrates are defined as inclusion compounds with the guests (atoms or molecules) completely and irreversibly enclosed in the cavities of the framework [1]. Based on the composition of the framework the clathrates classified as clathrate hydrates [2], the framework mainly consists of gas or liquid molecules, and intermetallic clathrates, where the host framework consists of four-bonded Si, Ge or Sn atoms. The intermetallic clathrates, depending on the charge of the framework, can be further classified as polyanionic and as polycationic clathrates. In the polycationic or inverse clathrates, the framework bears a positive charge and in their cavities halogen atoms (I, Br, Cl) are placed as guests. The most common synthesis of polycationic clathrates involves grinding and annealing of the reagents, or alternatively a combination of spark plasma sintering and high-energy ball milling [3].

In this work, we report the mechanochemical synthesis of reverse clathrates with the formula $\text{Sn}_{46-x}\text{M}_x\text{I}_8$, where $\text{M} = \text{Sb, In}$ and $0 < x < 8$. The synthetic route is a combination of planetary ball milling of the reagents and then high-temperature annealing in order to improve the purity and the crystallinity of the resulting products. The polycrystalline compounds are structurally characterized through Powder X-ray Diffraction and Rietveld refinement. The rattling modes of the guest atoms are also investigated through Raman spectroscopy. The thermoelectric properties of the compounds are also discussed in the context of potential device fabrication.

Acknowledgment: The research project is implemented in the framework of H.F.R.I call "Basic research Financing (Horizontal support of all Sciences)" under the National Recovery and Resilience Plan "Greece 2.0" funded by the European Union –NextGenerationEU (H.F.R.I. Project Number:14730).

Development and Optimization of Polymer-Metal Composites for Superior Thermal Management

Mrs. Norica Carmen Godja, Austria

Poster Presentation

Abstract

Efficient thermal management is critical for ensuring the success and longevity of spacecraft during extended space missions. Spacecraft encounter extreme challenges such as temperature fluctuations, radiation exposure, vacuum environments, and microgravity effects, all of which impact the performance of Thermal Interface Materials (TIMs).

This study explores nanocomposites, carbon-based pastes, metal sheets, and liquid metals, with the primary goal of identifying materials with high thermal conductivity that also meet the electrical and mechanical demands of space applications. The material design emphasizes the use of green polymers and additives, supporting the shift towards more sustainable practices in commercial space exploration.

While polymers generally have low thermal conductivity, the addition of highly conductive fillers such as ceramics, carbon materials, and metals can significantly enhance their overall performance.

By adjusting the concentration of high- and low-electrical conductivity fillers, the electrical properties are precisely tuned. Metallic nanocomposites use sinterable metallic microparticles as the matrix, with added fillers. The carbon-based TIM pastes category incorporates special fillers like graphite, graphene, CNTs, and metallic AgNWs or Cu/Ag core-shell nanowires.

The results of these developed materials—nanocomposites, polymer-based TIMs, metal sheets, and liquid metals—will be presented.

The influence of high-temperature high-pressure spark plasma sintering (HPHT/SPS) parameters on the initiation moment of the exothermic reaction in Ni-Al

Dr. Paweł Hyjek, Poland

Poster Presentation

Abstract

As part of the undertaken scientific activity, the sintering process of intermetallics from the Ni-Al system with a molar ratio of nickel and aluminum of 1:1, 2:1 and 3:1, respectively, was optimized. Sintering with simultaneous application of pressure and temperature was carried out using a globally unique HPHT/SPS hybrid device equipped with a Bridgman-type chamber. Using this device, it is possible to heat with high-frequency pulse current in order to achieve very high temperatures. Sintering of powder, placed in special containers, ensuring uniform pressure and temperature distribution, was carried out in the pressure range of 2 ÷ 7 GPa and temperatures of 873K-1473K. The applied sintering parameters made it possible to produce materials characterized by a high degree of compaction (88-100%). The influence of high pressure and temperature on the moment of occurrence of the exothermic reaction was demonstrated, different for individual alloys. High pressure causes this moment to be shifted to higher temperatures. Therefore, depending on the HPHT/SPS test parameters at which a given sinter was produced, a single, two or multi-phase microstructure is observed (XRD, EDS-SEM analysis). The conducted research and analyses allowed to determine the optimal sintering parameters: pressure and temperature for which a specific microstructure is obtained. It was additionally shown at what parameters of the powder mixture and sintering parameters the exothermic reaction is initiated. The produced materials are characterized by Young's modulus up to 210 GPa and hardness up to 715 HV1. Abrasive wear resistance tests conducted in the Ball-On-Disc system have shown that the materials are characterized by high resistance to this type of wear. Corrosion resistance tests of selected samples in 0.1M H₂SO₄ acid showed that their stationary potential values were stable for 24 hours of measurement. The samples did not show a tendency to selective or pitting corrosion. The corrosion potential values were very close to those obtained for pure Ni and increased slightly with time, indicating the high stability of the passive layers produced. As a result of the tests of strength properties conducted in a wide range of temperatures and strain rates, the brittle nature of most of the sinters produced was confirmed. In the compression test at room temperature, significant strength of up to 3 GPa was achieved (NiAl 2:1) and decent deformations of 10-25%. In the tensile test, at room temperature, the samples were quickly torn off. At higher temperatures, deformations of the order of 60% were achieved for individual samples.

In-Situ Precipitation of Secondary Phases for the Strengthening of AISI 316L Austenitic Steel

Mr. Jan Pokorný, Czech Republic

Poster Presentation

Abstract

The reinforcement of materials for demanding applications, such as high temperatures and extreme mechanical loads, can be achieved by incorporating fine oxide particles or other secondary phases into the matrix. This study explores the development of dispersion-strengthened austenitic steel AISI 316L, where secondary phase particles are formed directly during processing. Powder metallurgy techniques, specifically mechanical alloying (MA) and spark plasma sintering (SPS), are employed to fabricate ODS 316L steel with tailored properties. Reinforcement precursors, including yttrium hydride (YH₂), boric acid (H₃BO₃), and titanium (Ti), are introduced into the austenitic steel powders to enable the controlled formation of stable dispersoids during sintering. The ability of these elements to dissolve in a solid solution and subsequently precipitate as fine particles is systematically investigated. Spark plasma sintering is utilized for powder consolidation, offering precise control over temperature and densification while minimizing grain growth. The resulting materials are subjected to comprehensive microstructural and mechanical characterization, including scanning electron microscopy (SEM), transmission electron microscopy (TEM), and electron backscatter diffraction (EBSD). Additionally, mechanical testing, such as tensile and creep tests, evaluates the strengthening effects of the in-situ formed dispersoids.

This study aims to develop a reliable approach for producing ODS 316L steel with enhanced strength and thermal stability while maintaining good workability. The findings contribute to advancing ODS steel technology and provide insights for future applications in the energy, aerospace, and nuclear industries.

This research was funded by the Czech Science Foundation (project No. 22-04227L).

Microfluidic Synthesis of Targeted Lipid-Coated ZnO Nanoparticles for Advanced Cancer Immunotherapy

Mr. Alessandro Masoero, Italy

Poster Presentation

Abstract

Cancer immunotherapy has revolutionized oncology by improving long-term clinical responses and survival rates. However, it often fails due to immune evasion mechanisms, high costs and complex manufacturing processes. Cellular reprogramming offers new strategies to differentiate any cell type. Moreover, cells can be differentiated in situ bypassing the pluripotent state and enabling in vivo reprogramming. Small molecules (SMs) can boost the efficiency of traditional transcription factor-mediated reprogramming or even enable their substitution. Proper selective delivery of these SMs is crucial and nanotechnologies play a pivotal role in this context. In fact, SMs can be either encapsulated in liposome or absorbed on solid nanoparticles, enhancing both in vitro and in vivo efficacy while improving the selectivity of the delivery by exploiting targeting moieties such as monoclonal antibodies or peptides. Liposomes and lipid-coated nanoparticles can be both used as efficient tumor-targeted drug carrier. Our lipid-coated ZnO nanoparticles have the advantages of high drug adsorption capacity, enhanced stability, and biocompatibility when lipid-coated, bringing an advancement to the conventional drug-loaded liposomes. We employed a herringbone microfluidic chip to produce these NPs in a standardized, consistent, scalable, and high-throughput manner. Notably, this is a pioneering application of a microfluidic system for creating hybrid inorganic/organic L-ZnO NPs. To achieve specific tumor targeting, we incorporated ligands for EGFR receptors into the lipid coating. Characterization of these nonconstruct and their biocompatibility has been evaluated through different human and mouse in vitro models before assessing their internalization capabilities. The biocompatibility of both liposomes and L-ZnO NPs is significantly increased in in vitro experiments, in particular compared to pristine ZnO NPs. The use of a microfluidic chip ensures high reproducibility in the preparation process of these nanoparticles, resulting in consistent size, shape, and surface characteristics, and is successfully employed in the production of lipid coated inorganic nanoparticles. The incorporation of EGFR-targeting ligands into the lipid coating enables effective functionalization of the NPs which present enhanced specificity and efficacy of tumor targeting. Lipid-coated ZnO nanoparticles (L-ZnO NPs), synthesized via microfluidic chip, demonstrate superior biocompatibility, stability, and drug adsorption compared to bare ZnO nanoparticles. This method ensures reproducible and scalable production, suitable for clinical applications. Incorporation of EGFR-targeting ligands enhances tumor-specific drug delivery efficacy, showcasing potential for precise delivery in both therapeutic and cellular reprogramming contexts.

Paper 1402

Oxidation resistance of self healing carbon ceramic nanocomposites

Prof. Manuel Martinez Escandell, Spain

Poster Presentation

Abstract

Carbon materials are highly attractive for aerospace applications due to their exceptional properties, such as high thermal stability, low thermal expansion coefficient, excellent electrical conductivity, and low density. However, their use in this field is limited by their susceptibility to combustion reactions at temperatures above 500°C. Therefore, improving their oxidation resistance is crucial to ensure their viability in extreme aerospace environments.

To address this challenge, carbon materials reinforced with ceramic nanoparticles, such as silicon carbide (SiC), zirconium carbide (ZrC), and titanium carbide (TiC), as well as submicrometric particles of boron carbide (B₄C), Tantalum carbide (TaC) and hafnium carbide (HfC), have been developed. These composites enable the creation of self-sintering carbon materials with self-healing properties during oxidation.

During oxidation, the carbides oxidize to form a protective glassy layer that acts as a barrier against further oxidation of the carbon. This layer primarily consists of boron oxide (B₂O₃) and silicon oxide (SiO₂), forming a borosilicate glass. The introduction of metal carbides not only reduces the evaporation of boron oxide but also enhances the stability of the protective layer, leading to improved oxidation resistance. Additionally, these additives improve the wettability and dispersion of carbon, optimizing the properties of the composite material.

To study the behaviour of these materials, thermogravimetric analysis (TGA) was conducted in air up to 1600°C to observe the weight loss of the samples. Isothermal oxidation tests were also performed at different time intervals, exposing the samples to temperatures as high as 1500°C. These tests allowed for the evaluation of thermal stability and the effectiveness of the protective layer formed.

Samples have been characterised by X-Ray Diffraction (XRD) to identify the crystalline phases present in original, Stereomicroscopy and Scanning Electron Microscopy (SEM), to obtain a detailed view of the surface and the integrity dispersion of nanoparticles and sintering of the material. The protective layer generated during oxidation was characterized using techniques, including Scanning Electron Microscopy (SEM), to analyse the morphology and structure of the layer and XRD.

The incorporation of ceramic nanoparticles into carbon materials represents a promising strategy for enhancing their oxidation resistance in aerospace applications. The formation of a protective glassy layer, combined with the stabilization provided by metal carbides, not only increases the material's durability but also optimizes its performance under extreme conditions. These advancements open new possibilities for the use of carbon materials in the aerospace industry, where thermal resistance and stability are critical.

Numerical simulations of the elastic energy associated with a buried hexagonal network of dislocations and its application to semiconductor heterostructures

Prof. Salah Madani, Algeria

Poster Presentation

Abstract

With its nanoscale and discrete energy spectrum, the technology of self-assembled quantum dots (SAQDs) is becoming very alluring to provide a variety of advancements for electronics, including greater efficiency, lower power requirements, faster operating speeds, and many novel electronic proprieties [1,2].

Some prospective uses of semiconductor nanocrystals, including nanoscale memory devices and intersubband photo-detectors, have significant challenges in terms of how to arrange themselves in a very accurate way and how to manage their size distributions during the fabrication process [3].

One way to control the location of quantum dot nucleation and their size is the use of a functional substrate inducing a lateral self-organization by a buried dislocation network [4-6]. Let us note that more researches are still needed to determine the fundamental relationship between the dislocation network and SAQD nucleation.

In this work, the anisotropic elasticity theory based on the analyze of the elasticity of dislocations in subsurface layers [7-10], is used to determine the elastic field (displacements and stresses) and the stored elastic energy E_s , generated by an hexagonal network of buried dislocations located between a thin layer bonded onto a semi-infinite substrate. The effect of the thickness of the layer and the misfit mismatch are also shown. Finally numerical applications are presented for different heterosystems: CoSi₂/Si, GaAs/Si and CdTe/GaAs.

Energy barrier of twinning and transformation induced plasticity in titanium alloys - extension to the classical electronic based approach of TWIP/TRIP materials design with modulated yield strength

Ph.D. Piotr Kwasniak, Poland

Poster Presentation

Abstract

Twining and transformation induced plasticity (TWIP/TRIP) are novel deformation mechanisms of metastable β -Ti alloys characterized by extremely high work hardening and great ductility [1]. The main limitation of this materials group is relatively low yield strength governed by the energy barrier of $\{332\}\langle 113 \rangle$ twinning (TWIP) and stress induced $\beta \rightarrow \alpha''$ transition (TRIP). Recent investigation of TWIP/TRIP phenomena revealed that both lattice reconfigurations share the same shear-shuffle mechanism indicating their polymorphic nature [2]. Based on these findings we introduce the original, first principles-derived, extension to Bo–Md phase diagram focusing on the energy barrier (ET) of TWIP/TRIP transformation. To this end, a series of Ti-X (X = V, Nb, Ta, Cr, Mo, Mn, Fe and Re) alloys with different stoichiometry was analyzed to calculate the influence of particular solutes on ET. As a result, the solution strengthening of TWIP/TRIP has been parametrized for individual alloying elements with respect to atomic concentration, average electron-to-atom ratio e/a , Bo and Md values. Ultimately, determined hardening parameters were successfully used to estimate the Ti-X compositions of model alloys with TWIP/TRIP effects and to improve the yield strength of experimental ternary system. Presented study will be highly useful for designing new TWIP/TRIP alloys where apart from phase composition, the level of critical stress triggering the phase transformations can be also controlled.

Exploiting Cross-Responsiveness of Fluorescent Interpenetrated Zirconium–Organic Frameworks Integrated in Polymeric Membranes as a Multi-Analyte Gas Sensor Array

Ph.D. Juan Jesús Romero Guerrero, Spain

Poster Presentation

Abstract

In this work, a series of Zr metal-organic frameworks, whose hexanuclear clusters of Zr are connected with luminescent rodlike dicarboxylic acids, are used for the construction of a sensor array to selectively detect various analyte vapors. The chemical functionalization of the ligand (HOOC[PE-arylEP]COOH) (which alternates phenylene(P) and ethynylene(E) units) through the aryl core, is focused on obtaining six Porous Interpenetrated ZirconiumOrganic Frameworks (PIZOFs) with distinctive luminescent properties. Particularly, the synthesis of two new ligands (aryl = nitrobenzene; aryl = pyrazine) enabled the preparation of new PIZOFs (UPO-1 and UPO-2) with submicron sizes, thanks to the use of a microwaveassisted synthetic method. The fluorescence properties of these two new PIZOFs, along with four others already reported, are thoroughly evaluated and noticeable changes are observed in their optical properties based on variations in the aryl core of the ligands. Furthermore, the presence of various volatile analyte vapors particularly modified their characteristic emission, resulting in multiple optical responses that are combined to achieve selectivity in detecting these analytes. Specifically, the construction of a fluorescent sensor array is proposed, incorporating the six PIZOFs into polyvinylidene-fluoride (PVDF) films, capable of producing unique identification patterns for each analyte by leveraging the cross-responsiveness of these sensing materials.

Aging of High-Density Polyethylene - Characterisation and identification methods

Prof. Corinna Thomser, Germany

Poster Presentation

Abstract

Polyolefins represent one of the most used polymer types in packaging applications. The application in packaging sets specific requirements on the needed material properties. For rigid packaging, a central material is high density polyethylene (HDPE), which is used in bottles, canisters and large packaging such as IBCs. These products are usually produced in the blow moulding process. The used polymer needs to have fitting mechanical properties in the finished product to withstand the repeated mechanical stresses and be chemically stable to the packaged goods. With a more sustainable perspective on the use of plastic packaging one needs to investigate the longevity of HDPE products and HDPE. Answers to the question of how long a product can be used, need to be found, if a longer lifetime is a goal for more sustainability. An easy access to data and small experimental effort is desirable, ruling out long experiments on a product. Over the lifetime of a product, material properties change and can lead to a premature failure of a product. Polymers are affected by many environmental stressors. These vary by application and can include:

- temperature,
- UV exposure,
- medium in which they are used, or
- repeated mechanical stresses.

This is known as aging of polymers.

Real products can be used to analyse the effects of aging in a polymer with the drawback that the history of use is often not clear. To better differentiate between environmental aspects, simulated accelerated aging can be utilised, zeroing in on individual aging parameters and defining the impact of e.g. raised temperature during use. When comparing to real aged products or found polymer debris, an understanding of the effects of environmental impacts can help to assess the age and condition in which an unknown product has been used.

In this work methods to characterise types of aging in HDPE were assessed and ranked for usability, preciseness and finding fitting testing conditions. The samples are artificially aged with parameters such as raised temperature. The analysed methods will be split in to mechanical (e.g. tensile testing), optical (e.g. microscopy) and chemical characterisation (e.g. FTIR-identification) to detail the effects of environmental stresses on the material properties. A comparison is drawn between real products and lab-aged polymer samples. Material properties and aging mechanisms need to be assessed to be used as a base for material models to ease experimental effort and allow prediction of a products lifetime.

Electromagnetic Interference Shielding: Carbon-Based Materials and aluminosilicate Ceramic Fiber Composites

Mr. Javiel Fernández Marrero, Spain

Poster Presentation

Abstract

With the rapid advancement of technology, electromagnetic (EM) pollution has become a significant concern, as modern electronic devices and systems emit microwave radiation. This radiation can interfere with electronic circuits, leading to malfunctions and operational failures. To address this issue, the development of effective electromagnetic interference (EMI) shielding materials has become a critical area of research. Ideal shielding materials must meet several requirements, including chemical and corrosion resistance, lightweight properties, flexibility, tunable morphology, ease of processing, and cost-effectiveness. Carbon-based materials, such as graphene, carbon nanotubes, and reduced graphene oxide (rGO), have emerged as promising candidates for EMI shielding due to their exceptional electrical conductivity, lightweight nature, and ability to interact with electromagnetic waves. These materials can be incorporated into polymer matrices or used in hybrid composites to create efficient and versatile shielding solutions.¹ In this study, we propose a novel approach to developing EMI shielding materials by utilizing an aluminosilicate-based ceramic fiber as a template. This fiber was selected due to its inherent porosity, thermal stability, and compatibility with high-temperature processes. The fiber was incubated in an aqueous dispersion of graphene oxide (GO), allowing the GO to infiltrate its porous structure. The composite was then subjected to hydrothermal synthesis and thermal treatments to reduce the GO into reduced graphene oxide (rGO) within the fiber. This process imparted conductive properties to the composite material, making it suitable for EMI shielding applications. The resulting carbon-based material was characterized using electrochemical impedance spectroscopy to evaluate its conductive properties, and its morphology was analysed using scanning electron microscopy.

The proposed method offers several advantages. The aluminosilicate-based ceramic fiber is highly resistant to high temperatures, making it compatible with thermal synthesis processes. Additionally, the reduction of GO to rGO within the fiber is an eco-friendly procedure that uses only water as the reaction medium, eliminating the need for hazardous chemical reducing agents. This approach is scalable and aligns with sustainable manufacturing practices. The findings of this work demonstrate the potential of silicate-based ceramic fibers combined with rGO as a promising material for EMI shielding, offering a balance of performance, sustainability, and scalability for future applications in electronic protection.

OPTIMIZATION OF ALPHA AND GAMMA ALUMINA CATALYSTS VIA ADDITIVE MANUFACTURING

Mrs. Gemma Cruz Ortega, Spain

Poster Presentation

Abstract

Additive Manufacturing (AM) has emerged as a transformative technology for fabricating advanced ceramic catalysts, enabling precise control over structural features while reducing processing time and material waste. This study focuses on optimizing alpha (α) and gamma (γ) alumina (Al_2O_3) catalysts produced via Direct Ink Writing (DIW), evaluating their structural, thermal and catalytic properties. $\gamma\text{-Al}_2\text{O}_3$ is widely used in ethanol-to-ethylene dehydration due to its high surface area, thermal stability and porosity, whereas $\alpha\text{-Al}_2\text{O}_3$ offers superior mechanical strength, making it an ideal as a support material. This research examines the effects of the ceramic charge (CC) and sintering temperature on the microstructure and catalytic performance of DIW-printed Al_2O_3 scaffolds. The CC varied from 20 to 35 wt.% and sintering temperatures ranged from 400 to 600°C. Characterization of the scaffolds included phase composition, porosity, shrinkage and catalytic activity. The results demonstrate that these processing parameters critically influence key physicochemical properties. Shrinkage values ranged from 10 to 12%, directly impacting porosity and surface area. Notably, scaffolds with a CC of 32.5% sintered at 600°C exhibited an optimized microstructure, achieving an ethanol conversion efficiency of 99.7%, compared to 94.6% for samples sintered at lower temperatures. These findings underscore the importance of surface engineering via DIW-AM in developing high-performance catalysts, contributing to more sustainable and energy-efficient industrial processes.

Paper 297

Rigid polyurethane foams with a reduced petrochemical content

Pani. Patrycja Zakrzewska, Poland

Poster Presentation

Abstract

The prevailing emphasis on sustainability and the reuse of waste is precipitating a novel research direction. Rigid polyurethane foams (RPUFs) have recently seen a surge in utilization, primarily for the purpose of thermal insulation in buildings, but also in a variety of other applications. The popularity of PUR can be attributed primarily to its ability to adapt properties to meet specific application requirements [1, 2]. A potential opportunity to reduce the amount of petrochemicals in RPUF production is the use of bio-polyols derived from renewable feedstocks. The most commonly used feedstocks are natural oils and their derivatives (soybean oil, castor oil, palm oil, rapeseed oil and sunflower oil) [3, 4]. The issue with the raw materials cited is that they are food products. The utilization of these materials in the building industry has been demonstrated to engender an augmentation in demand, a phenomenon with the potential to culminate in elevated food prices or the exacerbation of the global hunger issue. Consequently, it is imperative to explore the potential of utilizing waste raw materials in the production of bio-polyols.

The research focuses on the characterization of fats recovered from municipal wastewater as a raw material for the production of bio-polyols. The subsequent phase involves the utilization of a ring-opening epoxidation process to synthesize bio-polyols from the fat fraction that has been recovered. The final stage of the research will entail the design of a rigid polyurethane foam system and the evaluation of the basic application properties. The RPUFs contain 5% and 10% bio-polyol from sewage sludge fats in exchange for polyol produced from petrochemicals. The effect of bio-polyol addition on foam morphology, apparent density, hardness and brittleness was characterized.

Preparation and characterization of eco-friendly composites utilizing waste leather and water-dispersed polyurethane

여자. Eun A Jeong, South Korea

Poster Presentation

Abstract

In 2019, the European Union (EU) set a goal of achieving carbon neutrality by 2050 through 'The European Green Deal'. To achieve this objective, the automotive industry has been actively promoting the utilization of recycled materials and the advancement of recycling technologies for leather derived from end-of-life vehicles (ELVs). While metals such as steel exhibit high recycling rates, natural leather and polyurethane (PU)-based artificial leather seats present significant challenges due to their bulkiness and limited recyclability, resulting in their predominant disposal through incineration or landfilling. This study aims to mitigate the environmental impact of the automotive industry by developing an eco-friendly recycled composite material for automotive interior applications through the recycling of waste leather recovered from discarded automotive seats. To minimize VOCs emissions, water-dispersible PU was employed as a binder instead of organic solvent-based PU, and the material was processed into a wet-laid nonwoven.

The adhesive layer and the grain layer were removed from the natural leather seat recovered from the scrapped car through a shaving machine, and the removed leather was subjected to the fibrosis of the leather through a sieve to manufacture waste leather fibers. The resulting waste leather fibers were blended with water-dispersible PU to fabricate composite nonwovens, and the effects of varying fiber content on the composite properties were systematically analyzed. The morphology of the nonwovens were observed using a scanning electron microscope (SEM) to analyze changes according to the variables. The mechanical properties were assessed using a universal testing machine (UTM) to determine the reinforcing role of waste leather fibers in the composite structure. Additionally, the thermal properties of the composites were analyzed using differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA).

Paper 515

Nanoscale examination of degradation in copper metallization layers using lab-based nanoTXM and DFXM

Mrs. Laura Neumann, Germany

Poster Presentation

Abstract

During application, high-power semiconductor devices undergo cyclic thermal loading caused by short circuit events. While the Cu metallization provides rapid cooling to the underlying semiconductor material, it is prone to thermo-mechanical fatigue caused by high thermal stresses due to the different thermal expansion coefficients. Determining the conditions for the onset of Cu metallization degradation, especially of void formation and crack growth, is therefore essential to further improve the reliability of high-power semiconductor devices in the future.

To understand the fatigue behavior Cu metallization layers were thermal cycled at heating rates of about 10^6 K/sec. At different degradation stages, the intragranular microstructure and strain evolution of singular Cu grains was observed, especially at high angle grain boundaries (HAGBs). Dark field X-ray microscopy (DFXM) measurements performed at the ID03 beamline at ESRF is used to study the crystal orientation across grains and their evolution during degradation, providing experimental evidence that mosaicity of Cu grains and residual elastic strain concentrations increase simultaneously in the vicinity of HAGBs. While this technique provides great access to the crystallographic information of the Cu structure, it is limited to a few grains and grain boundaries, lacking the big-picture approach to correlate the onset of crack and void formation with stress-strain distributions.

Lab-based transmission X-ray microscopy (TXM) with spatial resolutions of 50 nm allows precise examinations of microelectronic materials with significantly lower access barriers than synchrotron-based X-ray studies. The microscope can provide detailed nano X-ray tomographies (nanoXCT) and 2D radiographies of sufficiently thinned samples. However, this method can solely function in transmission geometry, thereby lacking the crystallographic information that would be needed for a conclusive approach to failure mechanisms.

Using lab-based nanoTXM and DFXM as complementary techniques achieves a comprehensive understanding of failure and deformation mechanism in the Cu metallization structures. Strain distributions in local grains can be correlated with small voids and cracks identified using nanoXCT, painting a comprehensive picture of intragranular microstructure refinement and condensation of structural defects near grain boundaries that perpetuate void formation and degradation in copper metallizations under fast-cycling thermal loads.

Laser Beam Welding of IN625: optimization of process parameters

Prof. Alessandra Varone, Italy

Poster Presentation

Abstract

Thanks to their good heat resistance, Ni-base superalloys are employed in the manufacturing of components for aeronautic, aerospace and energy fields. The repairing process of these components, when damaged, is of paramount importance due to the high costs related to their manufacturing. High-energy density techniques can be successfully employed to obtain reliable repaired parts, nevertheless a deep investigation on the effects of the welding parameters is crucial to optimize the process and improve the service life and reliability of the repaired parts.

In fact, welding process affect the microstructure of the Melted Zone (MZ) and Heat Affected Zone (HAZ) leading to several issues, such as a variation of mechanical properties and local chemical composition due to segregation of alloying elements; precipitation of secondary detrimental phases; solidification and liquation cracking. In this work, Laser Beam Welding (LBW) has been employed to investigate the welded seams on 2.5 mm thick plates of IN625 superalloy. Seams have been obtained varying the laser power ($P_m = 1700/2000/2300$ W), laser speed ($v = 15/20/25$ mm/s) and power modulation ($R = P_{min}/P_{max} = 0,6/0,8/1$).

Microstructural observations of the welded plates through Optical Microscopy (OM) and Scanning Electron Microscopy (SEM), and Vickers micro-hardness tests along the seams, have been carried out to investigate the influence of process parameters variation, namely the input energy density, on MZ and HAZ.

The optimal process parameters, leading to seams without macro-defects, such as cracks and pores, have been identified in $P = 2000$ W, $v = 25$ mm/s, $R = 0,6$.

This work was supported by PRIN 2022 project, ELAPSE: Laser Welding and Repair of Superalloys (project 20225YNH4M). ELAPSE is financed by European Union through PNRR funds.

Optimization of solution composition and parameters for electrophoretic deposition of SiO₂ coatings on NiTi alloy

Mrs. Barbara Rynkus, Poland

Poster Presentation

Abstract

Nickel-titanium (NiTi) alloy is widely used in medicine, especially in cardiology, due to its unique properties such as shape memory effect and superelasticity. However, its biocompatibility and corrosion resistance remain challenges, especially in biological environments. In order to improve these properties, surface modification was carried out by coating silicon dioxide (SiO₂) by EPD method (electrophoretic deposition) using polyethylenimine (PEI) as an electrolyte component.

In this study we analysed the effects of various concentrations of PEI in the electrolyte and deposition parameters, such as current voltage and process time, on the morphology and uniformity of the coatings. The EPD process was carried out in a suspension of SiO₂ nanoparticles in ethanol with PEI at various concentrations. The coatings were deposited at varying voltages and deposition times to determine the optimum conditions for forming a coating with a homogeneous structure and strong adhesion to the substrate. The obtained coatings were structurally and chemically characterised using scanning electron microscopy (SEM) and EDS spectroscopy. Electrochemical tests were also performed to assess corrosion resistance in simulated body fluids. In addition, a biological evaluation was carried out to determine the biocompatibility of the produced coatings. The results of the tests showed that the use of PEI at the appropriate concentration improves the homogeneity of the coating and increases its adhesion to the NiTi surface. The results indicate that electrophoretic deposition of SiO₂ coatings using PEI as an electrolyte additive is an effective method to improve the biomaterial properties of NiTi alloy.

Paper 919

Design and assessment of Si enriched innovative alloys resistant to liquid lead corrosion

Ph.D. Johanna Guibert, France

Poster Presentation

Abstract

The growing need for decarbonized and sovereign energy has renewed interest in nuclear energy, and particularly in advanced reactors designs. Among them, Lead-cooled Fast Reactors (LFRs) offer many advantages. However, their implementation requires the development of high-performance materials combining ductility, mechanical strength, creep and corrosion resistance in high-temperature liquid lead. These requirements can be contradictory. For instance, Ni-rich alloys exhibit excellent mechanical properties, but Ni has a high solubility in liquid lead. To address these challenges, research efforts have focused on protective coatings development and innovative material solutions. Among them, Alumina-Forming Austenitic Steels (AFA) have been proposed for their ability to form protective alumina layers in high-temperature oxidizing environments. Despite these progresses, alternative strategies are still underexplored.

Literature suggests that addition of silicon to stainless steels improve their resistance to liquid lead corrosion. Silicon promotes the formation of silica, a very stable oxide in liquid lead. From a long-term perspective, Silica Forming Austenitic steels (SiFa), which are not widely explored yet, represent a promising solution for structural elements in LFRs. This study aims to evaluate the potential of silicon-enriched austenitic steels for structural applications in LFRs. Two reference alloys, the Russian EP302M-sh and a high-Ni alloy, were selected as a base for comparison. Using these references, new compositions have been designed through thermodynamic calculations with Thermo-Calc. The design strategy is to stabilize a silica layer on the surface while maintaining a microstructure and mechanical properties close to those of the reference alloys.

Several alloys have been cast by cold crucible melting and their microstructures have been optimized (grain size, presence of secondary phases). The coherence between thermodynamic predictions and experimental results have been systematically verified to ensure the reliability of the alloy design. The mechanical behavior has been evaluated through hardness and compressions tests. In addition, oxidation tests revealed the presence of Si-rich oxides for some alloys.

Optimizing Electrospun Ceramic Fibers: A Direct Aqueous Approach for Cost-Effective Production

Dr. Jonas Gurauskis, Spain

Poster Presentation

Abstract

Optimizing the production of electrospun ceramic fibers is a relevant challenge in materials science, driven by the synergy between the intrinsic properties of ceramics and the unique advantages offered by electrospun fiber morphology. That is, high thermal stability, mechanical robustness, chemical resistance, high surface area, porosity and high potential for selective functionalization make electrospun ceramic fibers highly versatile and valuable at industrial level, for cutting-edge applications such as energy conversion, aerospace, heterogeneous catalysis, filtration and more.

Traditionally, a sol-gel approach has been employed for electrospinning ceramic fibers, offering precise control over chemical composition and structural homogeneity while allowing for the incorporation of dopants or additives to tailor material properties. However, it has several disadvantages that directly impacts its practicality and efficiency, that being expensive precursors and large volumes of organic solvents required, which can further escalate costs and raise environmental concerns.

Direct electrospinning of commercial ceramic powder aqueous suspensions represents a straightforward route, with fewer steps and less chemical handling compared with sol-gel electrospinning-based approach. This route is especially promising for industrial applications where simplicity, cost-effectiveness and scalability are priorities. For this, an example system of commercially available Al₂O₃ powder is presented, providing an in-depth discussion on the colloidal suspension details and resulting fiber characteristics and the intended applications.

Multifunctional oxide coatings with zeolites prepared by plasma electrolytic oxidation

Prof. Rastko Vasilic, Serbia

Poster Presentation

Abstract

The formation of mixed-oxide coatings by plasma electrolytic oxidation (PEO) proved itself as a valuable tool in many applications. PEO processing enables the incorporation of electrolyte components (including particles) into coatings, providing the pathway for tailoring the properties of such composite coatings. Generally, addition of particles to electrolyte used for PEO processing can act as a sealant making obtained oxide coatings more compact, thus increasing their wear and corrosion resistance. In contrast, highly porous PEO coatings feature an increase of the surface area available for photocatalytic, biomedical and luminescent applications.

Zeolites are porous crystalline materials, characterized by large surface area, exceptional adsorption properties and ion-exchange capacity. Although zeolites are mainly used as absorbers, an innovative immobilization of pure and Me-loaded (Me = Ce, Zn, Eu) zeolites on an inexpensive support using PEO processing proved to be beneficial when photocatalytic, adsorption, photoluminescent and corrosion protection properties are of interest.

Prepared mixed-oxide coatings with immobilized zeolites contain elements originating from the substrate and from the electrolyte. Aside from incorporation of Me-loaded zeolites from electrolyte, an attempt of co-deposited Me-species and corresponding zeolites from the same supporting electrolyte solution is presented. Both types of coatings are thoroughly characterized and tested in different applications. Coatings with incorporated Me-loaded zeolites show slightly better potential for application than those with co-deposited Me-species and zeolites, on the other hand they do require more complicated and time consuming processing procedure.

Effect of isothermal annealing on phase transformation and corrosion properties of UNS S32760 cast SDSS

Ph.D. Saira Sehar, Italy

Poster Presentation

Abstract

Because of their exceptional strength and corrosion resistance, with a PREN above 40, super duplex stainless steels (SDSS) are widely used to manufacture large valves and pipelines in off shore and desalination installations. In such applications, long-lasting and low maintenance cast metallic components are considered a viable option. However, in the temperature range where the precipitation of harmful phases is critical, cast components are particularly susceptible to slow cooling rates. This study investigates the mechanisms and kinetics of secondary phase formation in UNS S32760 super duplex stainless steel, subjected to isothermal ageing at temperatures ranging between 850 °C and 950 °C for 3 to 210 minutes. Among the possible secondary phases, the sigma (σ) and chi (χ) phases were identified as the main contributors to the instability of the duplex microstructure. Increasing the ageing time led to a higher percentage of secondary phase precipitation. It was observed that the kinetics and morphology of secondary phases are strongly influenced by variations in isothermal annealing temperatures. Since these aspects have a significant impact on corrosion properties, it was found that the finer the structure of intermetallic phases, the larger the sensitized surface area. Consequently, at the same volume fraction of secondary phases, a different degree of sensitization can be observed. This behavior was confirmed through DLEPR (Double Loop Electrochemical Potentiodynamic Reactivation) and CPT (Critical Pitting Temperature) corrosion tests. All isothermally aged samples were characterized using SEM-BSD combined with EDX analysis and quantitatively assessed using ImageJ software.

A case study of polymeric capsule failure in cold thermal energy storage applications

Dr. Maria Jesus Ariza Camacho, Spain

Poster Presentation

Abstract

Cold thermal energy storage (CTES) technologies are used in applications that need to keep the temperature below ambient temperature, even near or below 0 °C, such as refrigeration and freezing systems. These are especially important in cooling using solar energy, in order to maintain the thermal energy needs during cloudy conditions and the night. For that reason, they are considered a key point for the necessary transition to renewable energies in the near future [1]. One of the most studied CTES systems is based on encapsulated phase change materials (EPCMs) inside a tank through which the heat transfer fluid circulates. Capsules are usually made of a polymeric material, and must withstand the pressure of the fluid, and possible volume changes of the phase change material during the phase transition.

Within the European COOLSPACES4LIFE project we are developing a solar-powered air conditioning system, to be installed in the CIESOL building at the University of Almeria, which includes a new prototype of CTES system with EPCMs [2]. Commercial EPCMs with the appropriate properties for this installation have been purchased and they have been tested in a pilot tank. Some of these capsules have not withstood the operating conditions and have broken, causing the PCM to mix with the heat transfer fluid. This failure can seriously affect the operation of the whole facility if it occurs in the CIESOL installation.

In this work we studied the mechanical resistance of this commercial EPCM by subjecting it to the working conditions of the pilot tank, with thermal cycles between 25 and -10 °C, external pressures in the order of 1 bar and heat transfer fluid flow rates of about 4 L/min. Both, thermomechanical fatigue experiments and simulations using the computer-aided design software SolidWorks and its finite element analysis module (SolidWorks Simulation), were carried out to identify the causes of the failure and be able to propose solutions to improve the design and manufacture of new capsules. Cracks will be studied with advanced material characterisation techniques. Preliminary results in the pilot tank show all broken capsules developed a crack between 2 and 8 cm long, which always started in the same point and propagated in the same direction, which indicate that the failure will be due to a manufacturing defect detected in that area.

Paper 210

Effect of the residual stress induced by surface treatment processes on the mechanical behavior

Ph.D. Dongjun Lee, South Korea

Poster Presentation

Abstract

Residual stress is the stress that remains inside the material during the manufacturing process of the material and parts. Depending on the magnitude and direction of the stress, the mechanical properties of the material can be improved, and sometimes it can cause fracture. Processes that artificially apply compressive residual stress to surfaces to improve the mechanical properties of materials include those such as shot peening, laser peening, and ultrasonic peening. This surface treatment process establishes plastic deformation on the surface, improves the surface hardness, and induces compression residual stress, which delays the fatigue failure occurring on the surface. In addition, for shot peening, nano-grain grains are formed on the surface to improve yield strength and tensile strength. However, the magnitude of the residual stress decreases after plastic deformation or fatigue. In the case of fatigue crack growth, a low fatigue load is imposed, but existing residual stress changes around the tip of the crack due to the presence of plastic regions at the tip of the crack. In this study, various methods such as XRD and contour methods were used to measure the change in the residual stress distribution after tensile, fatigue, and fatigue crack propagation tests using materials with compression residual stress on the surface to which shot peening and laser shock peening were applied. In addition, the tensile and fatigue crack propagation behavior of materials with residual stress were studied after the shot peening and the laser shock peening processes.

Low temperature Peltier-based nanoindentation setup for in-situ measurements in SEM

Mr. Taulant Sinani, Germany

Poster Presentation

Abstract

The mechanical properties of materials at subzero temperatures are critical for various applications in aerospace, electronics, and polar engineering. However, conventional cryogenic nanoindentation systems face limitations in achieving precise thermal control and integration with in situ measurement setups. We present a novel Peltier-based nanoindentation system, designed for in situ testing within a scanning electron microscope (SEM), offering a compact, vibration-free, and energy-efficient alternative to the traditional liquid nitrogen cooling method at low temperatures, which often requires bulky liquid-based cooling systems and introduce mechanical instabilities through bubbling in the system.

Using a multistage Peltier cooler integrated into an in situ micro/nanomechanical testing platform (Alemnis AG), for the first time, the system achieves stable subzero temperatures down to -30 °C. Key innovations besides using the Peltier cooler include detachable sample and indenter holders, efficient thermal management via copper braids, a PTFE clamping mechanism, and an optimized heat sink design to maximize cooling efficiency while ensuring mechanical stability. A glycol-water circulating system is used to dissipate heat effectively while a graphite pad is applied on the interface between the heat sink and Peltier cooler, preventing overheating of the Peltier element and maintaining long-term stability. To ensure precise temperature monitoring, Type K thermocouples are strategically placed near the indenter tip and sample, providing real-time temperature readings and enabling fine control during experiments. The integration of precision heating elements behind the sample and indenter tip allows fine temperature control via a PID controller, minimizing thermal drift to fluctuations within ± 0.05 K. Unlike nitrogen cooling systems, this setup eliminates the need for specialized tubing inside the SEM, reducing system complexity and potential thermal instabilities. Additionally, avoiding liquid nitrogen lowers operational costs, as Peltier cooling does not require continuous refilling and offers more controlled and localized cooling compared to cryogenic fluids.

Initial characterization and thermal performance assessments demonstrate rapid cooling times (10–15 minutes) and effective stabilization (over hours) of temperature down to -30 °C for long-duration nanoindentation experiments. Next steps will include performing indentation tests on reference samples, like fused silica or single-crystalline copper. Future work aims to expand the system's applications by investigating water ice micro-mechanics, a key challenge in glaciology, planetary science and cryo-engineering, as well as other materials where traditional cryogenic systems that reach -150°C or lower are unnecessary but precise low-temperature control is already sufficient.

Thermophysical and surface properties of Al-Sn miscibility gap alloys (MGA) phase change materials for Thermal Energy Storage applications

Dr. Wojciech Polkowski, Poland

Poster Presentation

Abstract

As compared to paraffin wax and molten salts, metallic phase change materials (PCM) offer attractive properties for thermal energy storage (TES) by providing high volumetric latent heat, high thermal conductivity, recyclability and non-toxicity. In this regard, a special attention should be given to so called miscibility gap alloys (MGA). The MGA are defined as a mixture of two metals that are strongly immiscible. Thus, they are characterized by a microstructure of high melting point continuous matrix and lower melting point particles embedded inside. Typical metallic systems are Al-Sn or Fe-Cu. In this work, we present the results of investigation on thermophysical and surface properties of Al-Sn-based MGAs. Both model binary system (Al-Sn) and Al-based industrial alloys, are investigated. A set of key thermophysical properties (e.g. surface tension and density) was experimentally measured by sessile drop techniques and calculated by thermodynamic models. The samples and their final microstructures were analyzed by SEM/EDS and 3D-Computed Tomography. Furthermore, based on literature data and experimental observations, evaporation, oxidation and dissolution phenomena were described by using thermodynamic and fluidodynamic models.

Paper 1376

Fabrication of Raman-Nath and Bragg diffraction gratings on ophthalmic polymers by ultrashort laser pulses

Dr. Daniel Sola, Spain

Poster Presentation

Abstract

The inscription of diffractive elements in ophthalmic polymers to induce refractive index changes is of great interest in the fields of Optics and Ophthalmology to be applied for refractive correction. In this work, fabrication of linear periodic patterns in hydroxyethyl methacrylate by means of high-repetition rate femtosecond laser pulses is reported. In particular, both Raman-Nath and Bragg gratings have been inscribed underneath the surface to study to what extent the dimensions of the gratings are involved in the final refractive index change.

As the laser source, high-repetition-rate Ti:sapphire laser with a pulsewidth of 120 fs working at 80 MHz has been used. Compositional and structural modification was studied by means of micro-Raman spectroscopy. Finally, periodic patterns were characterized by diffractive techniques to ascertain the diffractive properties of the periodic patterns.

Polarization dependence on the emission of Nd doped bioactive W-TCP coatings on directionally solidified eutectic Calcium Zirconate-Calcium Stabilized Zirconia

Dr. Daniel Sola, Spain

Poster Presentation

Abstract

In this work we have developed and characterized coatings of Wollastonite-Tricalcium Phosphate, W-TCP, doped with Nd³⁺ ions on directionally solidified eutectic Calcium Zirconate-Calcium Stabilized Zirconia, CZO-CSZ, ceramics. The bioactive coatings were manufactured by the Laser Floating Zone, LFZ, technique. Before the solidification process, the bioactive coatings, doped with 1 wt% of Nd₂O₃, were previously placed by dip coating on the CZO-CSZ rod surface. Depending on the thickness of the coating and the applied laser power, an alloying or coating process was achieved. The optical characterization of these coatings revealed a strong dependence on the polarization direction in which the emission was collected so that both the excitation and emission spectra showed the existence of variations in the morphology depending on the polarization of the electric field. Micro-Raman characterization was also studied to assess the correlation of this anisotropic emission to the microstructural properties.

Paper 544

Analysis of STEM diffraction patterns with multiple ML algorithms

Mr. Sebastian Wissel, Germany

Poster Presentation

Abstract

Machine Learning (ML) assisted image analysis is applied in various fields of material science to gain knowledge about microstructures of different material classes. Since microstructures substantially influence the materials' properties, a deeper understanding of their interaction is necessary to optimize these properties. Even though a manual study of their interplay might be possible for single microstructural parameters, it gets almost impossible if multiple parameters are considered. These parameter restrictions are insignificantly for ML studies, which are also less computationally expensive. In this presentation, I show the prediction of grain orientations in energy material LiNiO₂ (LNO) with different ML algorithms and compare their performances. In our study, we used the classical image analysis ML model convolution neural network (CNN), its enhancement dense convolutional network (DenseNet) and a model of the transformer class, called SwinT transformer. As the first step, diffraction patterns (DP) of an LNO particle are gathered by scanning the particle with transmission electron microscopy. The grain orientations of the DP are determined by template matching and both, processed DP and corresponding grain orientation labels, are used to train the neural networks. All algorithms can then predict the Euler angles (correlate with grain orientation) of a single diffraction pattern and the predictions for a whole dataset can be visualized as an inverse pole figure (IPF). Automizing the analysis of huge amounts of DP, the trained models are computationally more efficient, than the extensive template matching previously used. In addition, there are differences in performance between the ML models.

Paper 1651

Shielding properties of a novel porous concrete towards Electromagnetic Interference

Dr. Dominika Zabiegaj, United Kingdom

Poster Presentation

Abstract

Electromagnetic interference (EMI) has become a pervasive issue in our increasingly connected world, affecting both natural ecosystems and human-made electronic systems. As technology continues to advance, the need for effective EMI shielding solutions has grown more urgent. This ongoing research project aims to explore an innovative approach to EMI shielding using specially designed concrete samples, combining cost-effectiveness with potential large-scale applicability.

An important aspect of this research is its potential environmental impact. By using a concrete mixture with fewer aggregates, the production process is expected to result in lower CO₂ emissions compared to traditional concrete manufacturing. This aligns with the growing need for sustainable construction materials that can also provide advanced functionalities like EMI shielding. The effectiveness of EMI shielding is typically measured in decibels (dB), with higher values indicating better shielding performance. Previous studies have shown that concrete composites can achieve shielding effectiveness ranging from 20 to 50 dB in the X-band frequency range, depending on their composition and thickness. Our experiment aims to evaluate how the unique porous structure of our concrete samples compares to these benchmarks and how to reduce the thickness of the concrete.

The results from this study could pave the way for the development of multifunctional building materials that not only provide structural support but also offer effective EMI shielding. Such materials could find applications in various sectors, including data centers, healthcare facilities, and critical infrastructure protection.

Green processes using 3D waste materials- water purification in Energy sector.

Dr. Dominika Zabiegaj, United Kingdom

Poster Presentation

Abstract

Vermiculite (VMT) is known to have excellent antibacterial and sorption properties (removal of anti-inflammatory drugs, dyes, heavy metals, bio-recalcitrant compounds, nitrogen, and phosphate compounds). Organically modified vermiculites are also well-known nanostructured adsorbents of organic compounds from water or gaseous phases, similar to organically modified smectites or bentonites. The Activated Carbon (AC) famous for extraordinary antiseptic properties and very high specific surface area, therefore, by merging the properties of AC and VMT in the foam form, we can achieve a new generation of materials that have high multielement sorption capacities and antibacterial properties, capturing contaminants and preventing the bacteria colony formation in water storages/systems for a long time. Additionally, having a very high specific area and specifically tailored opened structure, allows fast penetration and treatment of a contaminated water through the large and highly selective area derived from porous structure of a foam itself and additional porosity given by mixed AC and VMT. The presented work highlights the advancements in the sustainable materials that can be hired as filters/absorbents actively capturing i.e. Uranium and other heavy metals, other pollutants providing antiseptic capacities of the filters with a wide industrial application such as hydrogen production, long term space missions, CO₂ capturing and waste management.

The results from this study could pave the way for the development of multifunctional building materials that not only provide structural support but also offer effective EMI shielding. Such materials could find applications in various sectors, including data centers, healthcare facilities, and critical infrastructure protection.

Advancements In Sustainable Concrete for Global Challenges

Dr. Dominika Zabiegaj, United Kingdom

Poster Presentation

Abstract

Global warming is an important issue now a days and the major driver for this phenomenon is CO₂ emissions [1]. To tackle this issue both the thermal management system and CO₂ reduction are important tasks to develop. Moreover, due to the ageing nuclear power plants and the hazardous effect of radiation leads to the importance of having radiation shielding materials. It is important to develop novel composites that can withstand CO₂ emission under the thermal management system for radiation shielding material.

Concrete has been a widely accepted material for a variety of applications including thermal storage material, radiation shielding material, building structure materials etc. However, it has faced several challenges due to its density and weight, workability, cost, thermal insulation, maintenance and environmental impacts [2]. To tackle those issues, several researchers tried to develop novel concrete utilizing several the natural or industrial waste, fibres, minerals, nanoparticles so that it can help to reduce the CO₂ reduction to align with the net zero emission. However, there is still concern about the sustainability of those concrete and its effectiveness of the concrete, as there is still under review.

Incorporating porous structure to the concrete can be solution of the many issues towards its drawbacks. Porous structures help to reduce the weight of the structure having the larger surface area and high absorption capacity [3]. Moreover, it can be eco-friendly through utilizing the plants, soil, natural minerals which helps to reduce the CO₂ emissions to align with the net zero emissions [4].

To tackle all the concern, this research is focusing on two distinctive area. It will contribute a hollow review about the effectiveness of the novel concrete for radiation shielding material and its impact towards CO₂ reduction to maintain the net zero emissions. Moreover, this research also contributed towards developing a novel porous concrete composite utilizing the natural clay mineral to meet towards the sustainability and CO₂ reduction for radiation shielding applications.

Iron oxide-based catalytic structures as enablers of a thermochemical cycle based on solid sulphur for long-term storage of solar thermal energy

Dr. Christos Agrafiotis, Germany

Poster Presentation

Abstract

This work is part of a wider project aiming to demonstrate direct storage of solar energy into solid elemental sulphur. The concept, as originally proposed by General Atomics (Norman, J.H., US Patent 4,421,734, 1978), is a combination of three process steps that interconvert sulphuric acid to sulphur. In the first step, sulphuric acid (H_2SO_4) is first evaporated and then sequentially decomposed into sulphur dioxide and oxygen. This sulphuric acid splitting is the highest-temperature (650-1000°C) endothermic reaction step of the cycle. The heat needed can be supplied by Concentrating Solar Technologies (CST) since these temperatures are within the capabilities of state-of-the-art CST tower plants. In the second step, sulphur dioxide disproportionation, sulphur dioxide reacts with water to produce sulphuric acid and elemental sulphur. Hence, a significant proportion of the solar energy used to decompose the sulphuric acid is stored in sulphur for virtually unlimited time. In the third step, sulphur can be combusted on demand to release this stored solar energy as heat at temperatures in excess of 1200 °C, suitable for gas turbines and high-efficiency combined cycle power generation.

The present work comprises an integrated approach on catalytic sulphuric acid splitting. Typically, sulphuric acid is vaporized and driven first through a medium-temperature zone wherein it is thermally dissociated into steam and SO_3 ; the vapours mixture is then passed through a catalytic reactor at higher temperatures where the SO_3 splitting to SO_2 and oxygen is performed. Atomistic-scale simulations like Density Functional Theory (DFT) were employed to investigate the binding strength of SO_3 on various catalysts' surface, culminating to a plausible reaction mechanism. In parallel, a large number of iron oxide-based compositions - which are the state-of-the-art inexpensive splitting catalytic materials - single or mixed with other cations were investigated. They were shaped into spherical granules, catalytically tested and physico-chemically characterized before and after exposure to the reaction environment. Selected compositions were then shaped into larger-size honeycombs that underwent long-term (> 300 hours) catalytic testing in a suitably designed catalytic reactor test rig. Several of them demonstrated not only close-to-equilibrium conversion but also remarkable corrosion resistance under the reaction's "hostile" environment. The next goals are on the one hand to incorporate a large amount of iron-oxide-based inexpensive recycled materials into these catalytic structures and on the other hand to use the results for the design of a pilot-scale reactor for sulphuric acid catalytic splitting with renewable heat.

Direct Laser Writing of hybrid biocompatible 3D scaffolds for tissue engineering

Mr. Ioannis Syngelakis, Greece

Poster Presentation

Abstract

Developing an ability to fabricate high-resolution, 3D hybrid biocompatible structures at microscale is crucial to achieve novel scaffolds for tissue engineering. Generally, hydrogels have been widely employed as synthetic analogs of 3D extracellular matrices (ECMs), with their physical properties such as degradability and porosity playing a critical role in regulating the behavior of cells. In this study, we fabricated 3D scaffolds at microscale in order to use them as 3D ECMs mimicking the natural environment of cells. We present the design and development of a novel hydrogel-based photoresist tailored for fabricating 3D hybrid biocompatible scaffolds through multi-photon polymerization (MPP). The proposed photoresist consists of polyethylene (glycol) diacrylate (PEGDA) as a hydrogel incorporated with zinc-magnesium ions in varying concentrations. These ions play the role of photoinitiator absorbing the tightly focused laser beam resulting in MPP of PEGDA. This method is a versatile 3D-printing technique enabling us to design complex architected structures with high accuracy which is crucial to achieve the desirable properties of the ECMs (such as mechanical properties). Biodegradable metals such as zinc and magnesium, have been regarded as next-generation, biomedical implant materials to promote tissue repair and regeneration. These ions are naturally ambient in the human body playing a critical role in cell proliferation and differentiation. This photoinitiator-free approach (biodegradable metal ions instead of toxic chemical compounds) provide a new pathway for the development of 3D biocompatible scaffolds that are promising candidates for tissue engineering applications.

Recycling of Rigid Polyurethane Foam with Solid Filler: Flammability and Thermal Conductivity Analysis of Newly Synthesized Materials

Dr. Beata Zygmunt-Kowalska, Poland

Poster Presentation

Abstract

Rigid polyurethane foam (RPUF) is a widely used thermal insulation material, but its production depends on fossil raw materials, which is not sustainable. The transition to a circular economy is a growing trend in materials science. Studies in the literature consider the use of waste materials as fillers to reduce dependence on fossil resources in insulation products [1, 2]. The recycling of modified polyurethane materials with additives remains incompletely investigated.

The complex problem of the availability of raw materials for RPUF synthesis and their recycling is the subject of this study. Composites made with recycled raw materials obtained from waste polyurethane foam modified with fly ash (FA) are presented. Although numerous studies have examined the properties of FA-modified RPUF, its recycling remains unexplored [3, 4]. Ground foam was used as a filler to produce a new composite, and recovered polyol served as a base component. To evaluate the effect of recycled raw materials on the properties of RPUF, samples with 10–30% recycled polyol and 5–10 wt.% granulate were produced. The microstructure was analyzed using a scanning electron microscope (SEM), thermal conductivity was measured by the hot disk method, and flammability was tested using a cone calorimeter.

Microstructural analysis showed that increasing the recycled polyol content resulted in a slight increase in cell diameter and changes in cell wall thickness. The addition of granules reduces cell diameter by increasing the reaction mixture's viscosity, which hinders the nucleation process. Thermal conductivity measurements showed a slight increase with the addition of recycled material, confirming that insulating properties were maintained. In conclusion, incorporating recycled raw materials into RPUF reduces landfill waste and fossil raw material use, without significantly compromising material properties.

Direct Laser Interference Patterning with High-Power Multimode Fiber Laser

Dr. Bogdan Voisiat, Germany

Poster Presentation

Abstract

Direct Laser Interference Patterning (DLIP) has long been a preferred method for fabricating periodic micro- and nanostructures on large surface areas. Traditionally relying on single-mode lasers, DLIP has been limited by laser power, constraining its application for high-throughput industrial processing. This study introduces the integration of a high-power multimode fiber laser, capable of delivering power in the multi-kW range, with the specially designed Extended Laser Interference Patterning System (ELIPSYS®). This configuration successfully addresses the challenges of low spatial coherence and beam quality, enabling precise interference and unlocking the potential of multimode lasers for microfabrication.

The system demonstrated the ability to produce periodic line-like structures with spatial periods as small as 6.0 μm on stainless steel surfaces, providing versatility for various application needs. By optimizing laser parameters, such as pulse energy and pulse overlap, the process produced high-quality patterns with aspect ratios up to 0.8 while maintaining a high homogeneity across large areas.

Upscaling the high power of the multimode fiber laser enables unprecedented processing speeds, meeting industrial demands for scalable and high-throughput manufacturing. This work marks a significant advancement in DLIP technology, extending its applicability to large-scale, efficient surface microstructuring and opening new possibilities for advanced functional applications.

Paper 925

Optimization of parameters to obtain metallic cobalt from lithium-ion batteries with microwaves irradiation process

Mr. Lorenzo D'Ambrosi, Italy

Poster Presentation

Abstract

With the increasing volumes of spent lithium-ion batteries from electric vehicles and the concurrent increase in raw materials cost for cathode production, finding effective methods for recycling battery materials has become critically important. This study investigates a pyrometallurgical approach using microwave irradiation to achieve carbothermal reduction of LiCoO_2 . Infrared thermal camera was employed for temperature measurements, allowing to optimize the process parameters to obtain metallic cobalt. Specifically, the research included microwave experiments on mixed black mass samples of anode and cathode materials in different proportions, treated at varying power levels and exposure times under standard atmospheric pressure. The effect of the process parameters and therefore of the temperature on microstructure was studied with SEM-EDS and XRD analysis. The feasibility of wet magnetic separation method between cobalt and lithium compounds formed during the reaction was also evaluated. The results obtained from the final separation process indicated that individual compounds can be obtained at the end of the cycle; moreover, the optimization of time, temperature and microwave power during the tests allowed to obtain metallic cobalt.

Advancing Elastocaloric Cooling Solutions through 3D Printing of Superelastic NiTi shape memory alloy

Dr. Shirin Dehgahi, The Netherlands

Poster Presentation

Abstract

Elastocaloric cooling represents a promising and sustainable alternative to traditional refrigeration technologies, leveraging the reversible thermal changes in elastocaloric materials under applied mechanical stress. Shape memory alloys (SMAs), particularly NiTi alloys, exhibit exceptional elastocaloric properties driven by thermoelastic martensitic transformations. These transformations involve exothermic and endothermic phase changes between austenite and martensite phases during cyclic loading and unloading, enabling efficient heat exchange.

NiTi alloys, widely recognized for their remarkable shape memory effect (SME) and superelasticity (SE), are prime candidates for elastocaloric applications due to their excellent damping capacity, corrosion resistance, and biocompatibility. In this study, we explore the potential for advancing elastocaloric cooling systems through the additive manufacturing of NiTi using the laser powder bed fusion (LPBF) technique. LPBF enables the precise fabrication of complex geometries, which is critical for optimizing heat transfer and enhancing material performance. By manipulating the process parameters of LPBF and optimizing microstructural features, this work aims to pave the way for more efficient and scalable elastocaloric cooling solutions, contributing to the global push for sustainable refrigeration technologies.

Comprehensive microstructural characterization of the printed samples, including phase distribution, grain orientation, and defect analysis, was performed using advanced techniques such as X-ray diffraction (XRD), scanning electron microscopy (SEM), electron backscatter diffraction (EBSD), and X-ray computed tomography (CT). Subsequently, a complete thermo-mechanical analysis of the 3D-printed samples was conducted to identify key parameters for the development of elastocaloric performance. The wide range of possible sizes, shapes, and lattice structures achievable by LPBF opens new avenues for improving elastocaloric efficiency due to available deformations in tensile/compression and torsion modes. Direct adiabatic ΔT measurements mapped the elastocaloric properties and the heat transfer processes of the lattice structures. This analysis revealed critical insights into the relationship between microstructure and elastocaloric performance, highlighting the influence of LPBF processing parameters on the development of desirable textures.

Multiscale simulations and experimental analysis of polytypism and ultrafast growth rates in semiconductors using SiC nanowire synthesis as model.

Mr. Raúl De Armas Rodríguez, Spain

Poster Presentation

Abstract

NanoWire (NW) synthesis holds tremendous potential for a wide range of applications in energy, catalysis, composites, and electronic devices. One of the main methods for synthesising NWs is through Chemical-Vapour-Deposition (CVD) growth, an industrially scalable method that enables control over polytypism, aspect ratio, and integration on devices. One of the main methods for synthesising NWs is through Chemical-Vapour-Deposition (CVD) growth, an industrially scalable method that enables control over polytypism, aspect ratio, and integration on devices. Within the family of CVD methods, we use a variant termed Floating Catalyst Chemical Vapour Deposition (FCCVD), in which Liquid Metallic NanoParticles (LMNP) embedded in a gas stream function as catalyst, solvent, and growth medium. Gases precursors are incorporated into the LMNP, leading to supersaturation and subsequent nucleation via the Vapour-Liquid-Solid (VLS) mechanism. The growth conditions in FCCVD enable ultrafast growth of NWs, resulting in micrometre-long NWs within a minute residence time. Growth from the gas phase allows for direct assembly of NWs into macroscopic ensembles (e.g. yarns or fabrics).

NWs synthesised with FCCVD typically exhibit aspect ratios of between 12 and 2200. However, in the same NWs mixed polytypes, stacking faults can usually occur which degrades the electronic properties. Since the available information of the FCCVD method is scarce, it limits the synthesis to new materials and the use of other catalysts. The present study focuses on polytypism selection and growth rate, exploring several models and compared their results to experimental data reported in the literature. The input data was obtained with a wide variety of methods, from precise and costly methods such as ab-initio calculations to analytical models, as well as values reported in the literature. A high-throughput screening of different semiconductors was also carried out, using various materials and thermodynamics databases.

For SiC nanowires, which were successfully synthesised in the laboratory using Au catalyst, we have used ab-initio calculations for calculating critical parameters as the surface energy of different planes. We critically assessed the validity of different models and their sensitivity to the source of input data to calculate growth rate and polytypism selectivity. We have implemented a workflow to extend the approach to other semiconductor NWs. Finally, we also found a correlation between polytype selectivity and growth conditions in an FCCVD reactor that can be described from analytical equations to advance kinetic model and validated with experimental data.

Enhancement of UV Resistance and Water Repellency in Aramid Nonwoven Fabrics via TiO₂ and HDTMS Coating

씨. Hyun Yong Lee, South Korea

Poster Presentation

Abstract

Aramid nonwoven fabrics are widely utilized in industrial applications that require durability in extreme environments, such as aerospace and military sectors, due to their excellent mechanical properties, chemical resistance, and thermal stability. However, exposure to UV radiation with sufficient energy to degrade amide bonds and aromatic rings can lead to significant chemical degradation. Furthermore, prolonged moisture exposure can disrupt the hydrogen bonding network, resulting in a deterioration of mechanical properties. To overcome these issues, research has focused on improving UV resistance through chemical modifications, multilayer structures, and UV-blocking coatings, as well as enhancing water resistance through grafting, coating, and lamination techniques. Among these approaches, coating technology is particularly advantageous as it preserves the intrinsic structure of the fiber while adding functional properties.

In this study, a dipping method using a titanium(III) chloride (TiCl₃) solution was employed to coat the surface of aramid nonwoven fabrics with TiO₂, which provides a UV-scattering effect to improve UV resistance. To further enhance water repellency, hexadecyltrimethoxysilane (HDTMS), a hydrophobic agent with a long alkyl chain, was coated onto the TiO₂ layer via a sol-gel process. This dual-layer coating aimed to maintain the fabric's performance under humid and UV conditions. The surface microstructure of the coated nonwoven fabric was analyzed using scanning electron microscopy (SEM), and the composition of the coated particles was examined through Fourier-transform infrared spectroscopy (FT-IR) and energy-dispersive spectroscopy (EDS). The functional performance of the TiO₂/HDTMS-coated aramid nonwoven fabric was evaluated in terms of thermal and mechanical properties, UV absorption capability, and contact angle measurements. This research demonstrates a promising dual-functional coating strategy that enhances both UV resistance and water repellency in aramid nonwoven fabrics, contributing to their long-term durability and applicability in extreme environments.

Advancing Sustainable Filtration: Integration of 3D Printing and Graphene Oxide-Based Composites

Dr. Jose Brant De Campos, Brazil

Poster Presentation

Abstract

3D printing, or additive manufacturing, enables the construction of three-dimensional objects from digital models, such as CAD files. This technology stands out for its versatility, allowing the creation of complex and customized geometries difficult to achieve with traditional methods. It is widely applied in engineering, medicine, and industrial design [1]. Among the 3D printing methods, fused filament fabrication (FFF) uses thermoplastic filaments like PLA, a material valued for its practicality and low cost. Graphene, in turn, is notable for its exceptional properties, such as high mechanical strength, electrical conductivity, and the ability to form ultrathin films. In filter membrane production, its nanoparticulate structure provides high selectivity and efficiency. When oxidized, graphene oxide (GO) exhibits functional groups that introduce active chemical radicals, enhancing its interaction with elements such as heavy metals [2][3]. The integration of 3D printing and PLA-GO composites shows promise in developing advanced solutions for filtering organic and inorganic compounds. Structures made from PLA-GO filaments processed by FFF have demonstrated high efficiency in removing heavy metals like lead and cadmium, commonly found in industrial waste [3]. A commercial PLA filament with graphene from VOOLT3D was used. Characterization revealed GO peaks via Raman spectroscopy and the presence of nanometric structures, such as flakes and loose tubes on the surface, using scanning electron microscopy. Additionally, X-ray diffraction has been conducted to confirm the GO quality. The performance evaluation procedures includes filtration kinetics studies and adsorption isotherms. Optimizing manufacturing parameters, such as infill and layer thickness, and refining annealing conditions like temperature and time, this study lays the groundwork for the development of advanced filtration materials with enhanced heavy metal adsorption capabilities.

Influence of Synthesis Parameters on the Microstructure and Porosity of Hydroxyapatite

Dr. Jose Brant De Campos, Brazil

Poster Presentation

Abstract

Hydroxyapatite, due to its ability to easily replace cations and anions, is widely used in several areas, such as the pharmaceutical and especially in the area of biomaterials [1]. Also, hydroxyapatite has significant applications in the environmental area, mainly in water and soil treatment. When associated with porosity, it becomes ideal for catalytic processes [2]. For these purposes, it is essential to produce porous materials, since porosity increases the specific surface, favoring the contact area, improving absorption and facilitating the transport of substances. Given the wide applicability of hydroxyapatite, several synthesis methods are used. In this work, the precipitation method was used, widely adopted due to its simplicity [3]. This method basically consists of adding phosphate ions to a suspension containing calcium ions. For this, a variation in the dripping speed of phosphoric acid was performed. Slow addition rates allow gradual nucleation and growth of larger crystals, which can result in lower porosity, since the crystallites tend to compact more organized. On the other hand, a fast addition rate generates excess nuclei, leading to the formation of smaller, less organized particles and, consequently become more porous. This work aims to analyze the influence of the synthesis method on the porosity of hydroxyapatite, by controlling the parameters of the synthesis process. For this, the phosphoric acid was dripped at two different speeds, resulting in two types of hydroxyapatite. The characterizations performed on the hydroxyapatites were Transmission Electron Microscopy (TEM) for morphology and structures; Brunauer-Emmett-Teller (BET) measurements, to evaluate the influence on porosity; and X-ray Diffraction (XRD), to identify the phase formation. For Hydroxyapatite, the goal is to achieve a surface area similar to that studied by [4], in the BET, which is 144 m²/g.

Influence of Interfacial Characteristics on the Strengthening Mechanisms of B₄C-Reinforced Aluminum Matrix Composites

Lic. Juyeon Han, South Korea

Poster Presentation

Abstract

Aluminum matrix composites reinforced with B₄C have garnered significant interest as radiation-shielding materials due to the unique properties of B₄C, including its high melting point, exceptional hardness, and effective neutron absorption capabilities via nuclear reactions involving ¹⁰B. Consequently, Al/B₄C composites exhibit superior specific strength, hardness, and radiation-shielding efficiency. However, the inherent poor wettability between B₄C and aluminum results in weak interfacial bonding, thereby compromising the mechanical performance of these composites.

In this study, aluminum matrix composites incorporating 1.5, 3, and 5 vol.% B₄C were fabricated through hot rolling of mechanically milled composite powders, followed by heat treatment to induce partial decomposition of B₄C. This process facilitated the intercalation of B and C atoms into the aluminum lattice, leading to localized lattice distortion. The present work systematically investigates the influence of interfacial characteristics, modulated by varying heat treatment durations, on the strengthening mechanisms governing the mechanical behavior of B₄C/Al composites.

Tuning Wetting and Triboelectrical Properties for Water Energy Harvesting

Ph.D. Nicolo' Giuseppe Di Novo, Spain

Poster Presentation

Abstract

The evaporation, condensation, precipitation, runoff and wave motion of water during the water cycle provide a great source of energy that is still under-exploited. We present here preliminary results of novel triboelectric devices capable of converting the impact of water droplets and the evaporation and condensation processes into electrical energy, combining techniques such as femtolaser texturing, core-shell nanotube growth and surface functionalisation of rigid, flexible, transparent or porous substrates. In particular, for condensation, we have designed devices that exploit the spontaneous direction of condensation to transport ions induced by the presence of triboelectric nanostructures. For evaporation, porous nanostructured materials that exploit biphilicity to induce ionic currents. For droplet impact, we combined nanostructured surfaces that induce electrification by contact of opposite polarity.

Lignin-Derived Hard Carbon-MoS₂ Composite as a Potential Anode Material for High-Performance Energy Storage Devices

Dr. Amjid Rafique, Portugal

Poster Presentation

Abstract

Currently, Li-ion (LIBs) are considered one of the most advanced and dominant energy storage technologies. However, they are still struggling to satisfy the needs of higher and higher energy/power density for large-scale energy storage systems [1-2]. The limitations commonly result from active materials such as graphitic carbon anodes, which have a low theoretical specific capacity and a slow Li⁺ transfer number [3]. The rapid growth of energy storage technologies demands the development of advanced anode materials with high capacity, excellent cyclic stability, and broad operational voltage windows. In this study, we present a novel lignin-derived hard carbon-MoS₂ (molybdenum disulfide) composite as a potential anode material for energy storage devices. The composite leverages the abundant, renewable nature of lignin as a precursor for hard carbon and combines it with MoS₂ to achieve synergistic electrochemical performance. This hybrid material exhibits a wide operational voltage window of 0–4 V, making it compatible with next-generation high-voltage energy storage systems. Electrochemical testing reveals outstanding cyclic stability over 3000 charge/discharge cycles, with a capacity retention of over 90%, demonstrating its robustness under long-term operation. The enhanced performance can be attributed to the composite's unique structure, which combines the high conductivity and stability of hard carbon with the high theoretical capacity and layered structure of MoS₂. Additionally, the composite displays excellent rate capability, ensuring suitability for fast-charging applications. The lignin-derived hard carbon-MoS₂ composite represents a sustainable and high-performing anode material, offering a promising pathway toward scalable and environmentally friendly solutions for advanced energy storage devices. Further investigation into its structural optimization and integration into full-cell configurations is ongoing, paving the way for its practical application in lithium-ion and other battery technologies.

3D Printed Methyl cellulose/Gelatin-based Scaffolds for Cartilage regeneration

Ph.D. Duygu Ege, Turkey

Poster Presentation

Abstract

Articular cartilage is an avascular tissue with limited regenerative capacity. Older population often has degenerative diseases of articular cartilage which causes pain and difficulty with daily activity. Therefore, there is extensive biomaterials research for treatment of regenerative disease of the articular cartilage. Current treatment method is replacement surgery which has disadvantages, such as prolonged recovery times, need of revision surgery and relatively high cost. In this study, the mechanical properties of the natural cartilage is mimicked with 3D printing methylcellulose(MC)-gelatin-based scaffolds by varying gelatin concentration of MC/gelatin bioink. The scaffolds were printed with 20% infill density with a speed of 8 mm/sec at 42 degrees with dimensions of 10x10x2 mm. The printing pressure was varied between 8 to 30 psi depending on the viscosity of the prepared ink. The produced scaffolds were characterized by Fourier Transform Infrared (FTIR) spectroscopy, contact angle measurements, degradation studies and mechanical tests. FTIR results confirmed successful blending of MC and gelatin homogeneously within the 3D printed scaffolds which is essential for successful 3D printing. Printing accuracy of the scaffolds were determined by Image-J analysis which showed that the scaffolds had upto 92% accuracy with the input images. Contact angle values were found to be within the suitable range for human tissue which was ranging in between 40-70 degrees. Mechanical tests revealed that the produced scaffolds had a stiffness of about 10 kPa and compressive strength of approximately 90 kPa. The % strain values were about 45% which showed remarkable degree of ductility of the scaffolds. Swelling and degradation tests revealed that pH range of the scaffolds were within the physiological range (pH: 7.1-7.6) of human tissue. % weight loss of the scaffolds were found as 50% within 14 days period. Overall, the mechanical properties of the scaffolds require to be further developed by incorporation of an effective filler such as calcium phosphates or bioactive glasses. Due to their remarkable degree of ductility and shape fidelity, the produced scaffolds were found to be promising for future applications for articular cartilage regeneration. Furthermore, the results revealed that the potential application of the scaffolds may be extended for soft tissue engineering and drug delivery applications.

MECHANICAL BEHAVIOUR OF BIO-COMPATIBLE LATTICE STRUCTURES CANCELLOUS BONE REALISED BY FUSED FILAMENT OF Z-ABS MATERIAL UNDER COMPRESSIVE TEST

Prof. Outtas Toufik, Algeria

Poster Presentation

Abstract

Designing and manufacturing replacement cancellous bone structures by lattice structures and Additive Manufacturing (AM) techniques is an effective method to create lightweight orthopedic implants while ensuring that they are mechanically bio-compatible and their osseointegration ability with the host bone.

In this work, we suggest a new design based on three lattice structures from triply periodic minimal surfaces (TPMS) with a different volume porosity to replace cancellous bone based on predicting the mechanical stiffness. To predict the mechanical stiffness, the relationship between the effective modulus of elasticity and different porosity ratios of the lattice structures was determined by using three methods, finite element modeling (FEM) simulation, Gibson and Ashby method and a uniaxial compression test after manufacturing the lattice structures by using Fused Filament Fabrication (FFF) Technology. To demonstrate the efficiency of our approach, the comparison of both numerical and experimental results showed that the effect of structure difference and porosity ratio of lattice structures on the mechanical stiffness values effectively match the cancellous bone in terms of elastic modulus and porosity ratio.

Thermal drying for safe, high-quality and high-yield recycling of battery cells with liquid electrolyte

Mr. Lukas Loedige, Germany

Poster Presentation

Abstract

Sustainable lithium-ion and sodium-ion battery markets require efficient and effective recycling technologies for end-of-life batteries. Batteries represent a complex type of waste, composed of various materials that must be carefully separated and processed. In novel recycling processes, the individual materials are first liberated by shredding or disassembling the cells, resulting in the release of various gases and vapors. These volatiles include the constituents of the liquid electrolyte that fills the porous network of electrodes and separator, as well as gases produced by decomposition and side reactions during battery operation, some of which are toxic. Since these substances pose a serious risk to process safety and the environment, and also negatively affect the quality and recovery yield of critical and precious materials, a thermal drying step is implemented to remove them from the material flow to the required low residual levels.

The objective of this work is to identify and quantify volatiles from battery cells and to determine their release kinetics in the recycling process, depending on the material- and process-related properties such as the disassembly depth, macrostructure of the material (e.g. particle size and geometry) and the drying boundary conditions. For the experimental studies, the mass change (over time) of a battery cell during drying under controlled process conditions is recorded. The composition of the exhaust gas from the drying process is analyzed using FT-IR spectrometry.

Results on the release kinetics of volatiles, especially of electrolyte and electrolyte degradation products, under different process conditions are presented. In particular, the influence of the drying temperature on the formation of unwanted reaction products will be demonstrated. Additionally, the study assesses the effects of cell formation, cycling, and aging on the gas and vapor release and evaluates potential benefits of solvent extraction prior to thermal drying. The experimental results support the optimization of the drying process parameters and assist in the design of the recycling process, focusing on the targeted and strategic placement of thermal treatment within the process chain. This study will lead to more ecologic and economic industrial-scale recycling processes for ion-based batteries with liquid electrolyte which ultimately help to increase material circularity and provide high-quality secondary resources.

This work contributes to the research performed at Material Research Center for Energy Systems (MZE). The authors would like to acknowledge financial support of the Federal ministry of Education and Research (BMBF) via the SynBatt project "DiRecReg" (03XP0553C).

The effect of vanadium content on microstructure and magnetic properties of FeSi electrical steels

Mr. Ivan Petryshynets, Slovakia

Poster Presentation

Abstract

Grain-oriented (GO) FeSi steels are widely used as core materials in various types of transformers operating worldwide for the distribution, generation, and consumption of electrical energy. They are characterised by anisotropy of magnetic properties provided by requires a very strong Goss $\{110\}<001>$ texture. The primary magnetic properties of GO electrical steels are magnetic flux density and iron loss. The magnetic flux density is directly associated with the strength of the Goss texture, while iron loss consists of three main components: hysteresis loss, classical eddy current loss, and excess loss. A strong Goss texture is achieved through a technological route first proposed by Goss in 1934 [1], which has remained largely unchanged since then. To develop the Goss texture, inhibitors such as MnS, AlN, and a combination of MnS and AlN play a crucial role in controlling grain growth during primary and secondary recrystallization. In this study, new approaches to grain-oriented steel processing have been explored. The proposed method involves replacing conventional inhibitors, such as AlN and MnS particles, with particles precipitated from the solid solution by introducing vanadium. Typically, vanadium is used as an alloying element, primarily in heat-resistant and tool steels. However, in this work, we propose a novel approach for producing GO steels, utilizing VC nanoparticles as inhibitors in combination with a strain-induced grain boundary motion mechanism and continuous annealing under dynamic conditions during secondary recrystallization. Dynamic (fast-heating) annealing combined with VC particles was applied to grain-oriented steels to achieve abnormal grain growth with the development of Goss crystallographic orientation during secondary recrystallization. This abnormal grain growth resulted in the formation not only of a sufficiently sharp $\{110\}<001>$ Goss texture but also of the cube crystallographic texture $\{100\}<001>$, which is highly desirable for non-oriented electrical steel. Moreover, steels processed using the newly developed method exhibited magnetic properties similar to those of materials subjected to long-duration heat treatments. The coercive field of our steels reached approximately 11 A/m, indicating that the proposed heat treatment, in combination with VC nanoparticles, enables the production of steel with equivalent quality while significantly reducing heat treatment time compared to the conventional GO steel manufacturing process.

This work was carried out within the research project Funded by the EU NextGenerationEU through the Recovery and Resilience Plan for Slovakia under the project No. 09I03-03-V04-00314.

Development of Sustainable and Functional Materials from Textile Waste for the Circular Economy

Señora. Arantxa Ferrer Carrasco, Spain

Poster Presentation

Abstract

The textile industry is one of the main culprits of environmental pollution, generating around one million tons of textile waste per year in Spain, of which more than 90% corresponds to used clothing. This problem, aggravated by the rise of fast fashion and the fact that only between 10% and 12% of this waste is recycled, poses a critical challenge: reusing textile waste to mitigate its ecological impact. In view of these data, a new European directive on textile recycling will be issued by 2025.

In parallel, there is a growing need to develop sustainable and functional materials that contribute to a circular economy model, where waste is transformed into valuable resources.

This work focuses on the design of a composite material with a biodegradable polymeric matrix reinforced with recycled textile fibers. The objective is to develop an optimal material with conditions that allow its application in an industrial design product, with the aim of reintroducing it into the market. Thus, the aim is to promote the circular economy.

Over the course of a year and a half of research, multiple tests have been carried out to optimize the mechanical, structural and functional properties of this new material. In the initial stages, the focus was on the search for organic materials that would improve its characteristics. Subsequently, tests were carried out to test their strength, durability and impermeability. Thus, it was possible to select a small group of samples, since they obtained the best results in the different tests.

Currently, the study has been focusing on the incorporation of conductivity in the material. For this purpose, different options have been proposed and are being tested and analyzed. In addition, by incorporating graphene nanoplatelets in varying concentrations (0%-3%), it was possible to provide the material with conductive properties. Experimental tests showed that an optimum content of 2% in nanoplatelets allows electrical resistivity values of 1.2 k Ω -mm to be achieved, which is suitable for industrial applications. This opens up a whole range of new possibilities for using the material in a real application: a product to be introduced into the current market.

Mechanistic Insights into the Impact of Sulfide-Based Surface Treatments on Iron–Air Anodes

Mr. Adam Miles, Germany

Poster Presentation

Abstract

Over the past few years, interest in iron–air battery technology has been reignited as a promising solution to large-scale, cost-effective energy storage. By relying on abundant, low-cost, and environmentally friendly materials (here iron) and a theoretical high energy density, both industry and academia have been making significant efforts to enable the widespread adoption of this technology. However, practical application is severely hindered by electrode passivation as well as hydrogen evolution reaction (HER), which serves as a competing reaction of iron-oxide reduction, reducing electrochemical efficiency and cycle life. Various studies have reported successful mitigation of such effects via surface treatments of iron particles with sulfide-based compounds (namely Bi₂S₃), by promoting the formation of a conductive and stable FeS layer on the anode. Said layer improves iron utilization, suppresses passivation and leads to improved cell stability. While published work has extensively explored the improved electrochemical performance, the underlying mechanistic behavior remains poorly understood. The goal of this study is to present an in-depth characterization of sulfide-treated iron electrodes, to fully elucidate the exact effects of these treatments. This is achieved by utilizing various characterization techniques such as atom probe tomography (APT), X-ray photoelectron spectroscopy (XPS), and electrochemical impedance spectroscopy (EIS) and Transmission electron microscopy (TEM). A better understanding of the morphological and chemical changes induced by sulfide modifications, before and during cycling of the cells, shows that these treatments lead to enhanced charge transfer kinetics and increased cycle stability, shedding light on their role in improving iron–air battery performance. Our findings provide critical insights into the mechanistic origins of sulfide-induced enhancements, offering a pathway for optimizing electrode materials. By addressing key limitations, this work contributes to the advancement of iron–air technology for next-generation sustainable large-scale energy storage solutions.

Alternative sintering process of biomaterials for prostheses: microstructural control using electromagnetic field

Dr. Adolfo Fernández, Spain

Poster Presentation

Abstract

As the healthcare sector develops new technologies to prolong life, people tend to live longer, so the wear on specific organs becomes increasingly common. Hip fractures are often one of the causes of the deterioration in people's life quality when the population exceeds the average age of 80. Only in Spain, 48,000 surgeries were performed for hip fractures between 2017 and 2021.

The search for materials that replace bone tissue and that present high compatibility with the human body is a field that has been widely explored in recent years. This research aims to develop materials with better mechanical properties that prolong the useful life of prostheses, decrease the frequency of interventions, improve the people's quality of life, and use less energy consumption for their production.

The (Y, Ce) ATZ composite was selected for microwave sintering to study the effect of electric field sintering on the evolution of the microstructure as a function of temperature and time. Mechanical properties like conventional sintering temperature were obtained with 200 °C less and a dwell time of 15 min, as well as excellent behaviour against low-temperature degradation after 80 h at 120 °C and 1.7 bar. Developing stable biomaterials with enhanced mechanical properties is a priority to improve the quality of life and reduce the resources associated with surgical interventions and the production of parts.

• Keywords: Biomaterials; Prostheses; ATZ; Low-temperature sintering

Beeswax Content Effects on Mechanical Properties and Antioxidant Activity of Beekeeping Foundation Sheets

씨. Ki Tae An, South Korea

Poster Presentation

Abstract

To address the issue of waste generation from conventional disposable beekeeping foundation sheets, a reusable polypropylene (PP)-based beekeeping foundation was developed. However, when PP-based foundation sheets are exposed to outdoor environments for extended periods, ultraviolet (UV) radiation accelerates oxidative reactions, leading to physical and chemical degradation phenomena such as discoloration and deterioration of aroma. These issues can alter the structure of the foundation sheet and reduce bee-friendliness. To mitigate these problems, beeswax was used as an additive, providing both improved bee-friendliness and antioxidant effects. However, excessive addition of beeswax can deteriorate the overall physical properties of the foundation sheet; therefore, an appropriate formulation ratio that considers both mechanical properties and antioxidant performance must be established.

This study developed a PP composite material for beekeeping foundation sheets that balances mechanical properties and antioxidant performance. Homo polypropylene (homo PP) was compounded with beeswax, with beeswax content set as a variable to evaluate its antioxidant effects. In addition, to compensate for the reduction in mechanical properties caused by beeswax addition, inorganic fillers such as talc and wood flour, as well as organic compatibilizers, were added to enhance the performance of the composite material. These components were uniformly mixed through injection molding, then molded into foundation sheet shapes by injecting them into molds under high temperature and pressure.

To evaluate the changes in properties and antioxidant effects according to beeswax content, composites containing 2.5, 5, 7.5, and 10 phr of beeswax were manufactured. The thermal properties of the fabricated PP composites were analyzed using Differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA). Mechanical property changes were measured using a Universal testing machine (UTM). Surface analysis to confirm beeswax elution was performed using a Scanning electron microscope (SEM). In addition, to compare and evaluate the degree of photo-oxidation of the manufactured PP composites, Oxidative induction time (OIT) and Fourier transform infrared spectroscopy (FT-IR) were utilized.

PEEK composites with carbon nanoparticles for high performance applications

Mrs. Sofia Silva, Portugal

Poster Presentation

Abstract

The industry finds itself at a crossroads with various trends related to the green transition (electromobility, hydrogen fuel cells, etc.) and the digital transition (connectivity, autonomous driving, software, etc.). These trends necessitate the development of innovative materials and products to meet the increasing demand for high-performance applications like sensors, composites, wire and cabling. As functionality increases and weight reduction becomes critical, embedded systems are also emerging. The demand for new materials that combine high mechanical performance, and functionality is one of the key challenges in aeronautics and mobility, driving innovation in lightweight structures, fuel efficiency, and advanced manufacturing technologies.

High-performance thermoplastics, such as polyether ether ketone (PEEK), which combine exceptional properties like a high strength-to-weight ratio, chemical resistance, recyclability, a low coefficient of friction, electrical isolation, and thermal stability, can be used in demanding applications such as high-voltage electrical connectors and insulation components, providing reliable performance in harsh environments for mobility and space applications. When PEEK is reinforced with carbon-based fillers, its electrical conductivity can be tuned, making it suitable for applications that require efficient electrical pathways.

This research focuses on designing new materials for high-performance applications such as mobility and aeronautics. Filaments of PEEK, combined with multi-walled carbon nanotubes (MWCNT) and exfoliated graphite nanoplatelets (xGnP), have been developed through extrusion compounding and melt-spinning technologies. These filaments demonstrate improved electrical conductivity values (~ 2 S/cm) and can be employed as heating systems to achieve high temperatures through the Joule effect. These nanocomposites offer significant advantages in terms of sensitivity and durability, making them ideal for integration into composite structures, providing functionalities like embedded sensors, heating elements and structural parts for mobility and aeronautics. This work contributes to the advancement of technology by providing sustainable, efficient, and high-performance solutions that align with the industry's evolving needs. The findings have broad implications for the future of design and manufacturing, paving the way for more sustainable and technologically advanced systems.

Influence of ceramic additive in thermoplastic polymers for liners in Type IV hydrogen tanks

Mr. Axel Martínez-Gutiérrez, Spain

Poster Presentation

Abstract

Hydrogen tanks for mobility applications require a low weight to storage volume ratio. To achieve this, pressurized hydrogen storage vessels have evolved from fully metallic Type I vessels to the Type IV vessels. This lightweight design consists of an external load-bearing fibre epoxy composite structure wound onto a gas barrier liner that prevents hydrogen loss by permeation. The liner of Type IV vessels consists of a thermoplastic polymer, mainly HDPE or PA due to their low permeation rate and low material cost. This type of vessels faces challenges in terms of permeation requirements because hydrogen vessel regulations specify a maximum leakage rate per storage volume, while a further weight reduction is sought. The development of low permeability materials for these internal liners is of paramount importance.

Hydrogen diffusion can be influenced by the addition of impermeable fillers such as fibres or nanoparticles into the thermoplastic matrix. The rationale is to reduce the surface area to be permeated and create tortuous routes that increase the length of the diffusion path, reducing the material's hydrogen permeation.

The aim of the present study is to assess the effect of ceramic additives in PA6,6 for hydrogen storage applications, these compounds represent attractive materials for Type IV hydrogen containers in mobility applications. For this, ceramic platelets have been added to PA6,6 and small plates have been produced via injection moulding. The hydrogen permeation properties of the unreinforced and ceramic-filled PA6,6 have been evaluated using the differential pressure method, following the standard ISO 2782-1. This technique applies a constant pressure differential to evaluate hydrogen permeability, solubility and diffusion coefficients. The obtained results have been correlated with the resulting microstructure.

Effect of Stacking Fault Energy Regulation on the Microstructure and Mechanical Properties of Cu-Al-Zn-Sn Alloys

Mrs. Ga Eun Jo, South Korea

Poster Presentation

Abstract

Recent research has led to the development of new coloration methods for metallic materials. Among these, surface treatments have been widely used and optimized for different metals. However, a major drawback is that the colored layer is easily damaged by external influences and chemical reactions. To address this issue, we developed color alloys by selecting intermetallic compounds or solid solutions that naturally exhibit specific colors. In solid-solution alloys, these unique colors result from optical transition energies reflected within the visible light spectrum, which can be controlled through careful compositional design. Most transition energy-controlled color alloys are based on Cu alloys, but their weak mechanical properties make them difficult to apply in various fields. To improve this, we modified the microstructure of Cu-Al-Zn-Sn alloys through cold rolling, hot rolling, and annealing processes. We focused on defects formed in Cu-based alloys with low stacking fault energy during plastic deformation and heat treatment, intentionally inducing these defects to enhance mechanical properties. Additionally, by adjusting the Al content, we controlled the stacking fault energy to regulate defect density and analyzed how these changes affected mechanical performance. Our findings provide insights into the development of color alloys with both enhanced mechanical strength and tunable optical properties.

Additive Manufacturing of Gradient Polymer Nanocomposite Structures Using SLA 3D Printing

Dr. Ans Al Rashid, Qatar

Poster Presentation

Abstract

Additive manufacturing offers unique opportunities for fabricating complex structures with tailored material properties, and stereolithography (SLA) 3D printing has emerged as a promising technology for fabricating customized materials with tailored mechanical performance. This study presents an innovative approach for producing gradient structures using SLA 3D printing, employing photopolymer resins reinforced with nanoparticles. The method involves systematically varying the concentration and distribution of nanoparticle reinforcements within the resin matrix during printing, resulting in a controlled gradient of material properties across the 3D-printed structures. Our approach enables the design of mechanical gradients that mimic natural tissue interfaces, offering improved stress distribution, durability, and mechanical resilience. We investigate the influence of nanoparticle type, concentration, and gradient profile on mechanical properties such as stiffness and strength. Through a series of mechanical tests, including tensile and compressive testing, we demonstrate the significant enhancement in mechanical performance achieved by leveraging this gradient design. Additionally, the underlying mechanisms contributing to the improved properties are discussed. This work introduces a novel strategy to advance the field of SLA 3D printing, showcasing the potential for functional gradient materials in high-performance applications such as medical devices, structural components, and energy-absorbing materials.

Paper 218

Electrochemical study for the separation and recovery of gold and copper from waste printed circuit boards leach solutions

Mrs. Laura Grima-Carmena, Spain

Poster Presentation

Abstract

Hydrometallurgical processes have been extensively studied for the recovery of base and precious metals from electric waste. Waste Printed Circuit Boards (WPCBs) present a promising source of critical materials such as Cu and Au, but their complex composition makes the recovery of these metals from leachates challenging. This study aims to recover Cu and Au from leach liquors of real WPCBs extractions. Two different liquors are obtained from a sequential leaching process: The first mixture (M1) contains a high concentration of Cu (40 g/L) and other base metals (<7g/L). The second mixture (M2) contains Au (10 ppm) and Cu in a greater proportion (Cu:Au ratio of 1000:1) along with chlorides (1.5 M). Both the Cu and the chlorides hinder the selective extraction of the precious metal.

This study focuses on determining the optimal conditions for recovering selectively both metals by investigating the electrochemical behavior of mixtures M1 and M2 for Cu and Au recovery, respectively. Cyclic voltammetry (CV) and chronoamperometry (CA) techniques were employed to assess the recovery of these metals under varying conditions using a potentiostat-galvanostat (Metrohm, PGSTAT 302N). The experimental setup included a two-compartment cell with an Ag/AgCl reference electrode, a 1 cm² Ti substrate as the working electrode in the cathodic compartment, and a Pt wire as counter electrode in the anodic compartments.

The study for the Cu recovery in M1 was done in sulphate and chloride media, using different concentrations of CuCl₂, CuSO₄ and H₂SO₄. From the CV study, the operation potential for selective electrowinning was selected. A potentiostatic CA at the selected potential was performed with real M1 to recover Cu in a separate cell using a Ti plate (cathode) and a Pb plate (anode). The faradaic yield for Cu recovery and the deposit purity have been determined, proving a selective recovery of Cu.

The study of M2 was done in a separate cell, conducting CV and CA in different samples based on M2 composition, using HAuCl₄, CuCl₂, CuSO₄ and H₂SO₄. The study involved the CV of different gold, copper and chloride ratios, to determine the optimum conditions for the selective Au deposition. The maximum Cu:Au ratio, the chloride content and working potential were obtained. A potentiostatic chronoamperometry was held on real M2 to assess the selective gold deposition in such complex electrolyte.

Paper 425

The influence of spark plasma sintering parameters on the structure and properties of NiAl based materials

Ph.D. Marcin Chmielewski, Poland

Poster Presentation

Abstract

Sintering is a thermally activated process that depends on many technological factors, such as temperature, time, external pressure, atmosphere, etc. [1]. The progress of sintering, measured by an increase in the cross-sectional area of the intergrain neck and a decrease in the distance between the centres of two adjacent grains, leads to an increase in the density of the material. A great increase in interest in field assisted sintering techniques has been evident in recent years. The main advantage of the Spark Plasma Sintering technique is the direct resistive heating of graphite elements and electrically conductive powders [2]. Due to the high heating rates (up to 1000 °C/min) and short dwelling time at the sintering temperature, the limitation of undesirable material reactions and structural transformations can be obtained.

The goal of the presented work was to investigate the changes in the microscopic and macroscopic parameters related to the microstructure of the NiAl and NiAl-Al₂O₃ composites and its dependence on the sintering parameters (temperature and pressure). The materials were densified using Spark Plasma Sintering method. The applying of diversified sintering parameters allowed to obtain a materials with different relative density (from 70.0 to 97.5%). The analyses included SEM investigations by electron backscatter diffraction to evaluate the crystallographic orientation of NiAl grains and microcomputed tomography to visualize the grain evolution at different stages of sintering, especially the grain size, shape and boundary contact features. The application of the electric current resulting in high temperature and the additional external loading leads to the significant changes in the structure of sintered materials, such as the occurrence of lattice reorientation resulting in grain growth, increase in the grain neighbors, or the evolution of grain ellipticity, circularity, grain boundary length, and fraction.

Evolution of deformation micro-mechanism in thermally exposed Superalloy 625: Tracing strain hardening characteristic using a physics-based model

Ph.D. Sonika Chahar, India

Poster Presentation

Abstract

The Ni-based superalloy 625 possesses an outstanding set of creep resistance, high strength, corrosion resistance, and superior fatigue strength at elevated temperatures, making it suitable for high-temperature applications in the range of 650-750°C. Understanding the influence of lattice defects on secondary phase transformation during service and its impact on plastic deformation micromechanisms is crucial. This study establishes the microstructure-deformation micromechanisms correlation for Superalloy 625 alloy (Indian grade) during tensile deformation. It includes aging treatments of both solution-treated and solution-treated + cold-rolled alloys at 700°C for up to 1000 hours. Microstructural assessments are carried out on heat-treated alloys using scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDX), and high-resolution electron microscopy (HREM). Additionally, uniaxial tensile tests of the aged samples are conducted at room temperature, followed by fracture and microstructural analysis to observe dislocation activity and deformation features. A physics-based model is used to predict flow stress curves, accounting for the effects of grain structure, secondary phases, and evolving deformation micromechanisms.

The effect of the replacement of La by Sr in La_{1-x}Sr_xMnO₃ perovskite on the catalytic oxidation of light hydrocarbons

Dr. Catherine Drosou, Greece

Poster Presentation

Abstract

Perovskites, with general formula ABO₃, are highly promising materials in catalysis due to their excellent redox properties, high lattice oxygen ion mobility, and exceptional thermal stability. Their flexibility in replacing the A-site and/or B-site cations with other elements of the same or different valence (i.e., A_{1-x}A'_xB_{1-x}B'_xO_{3±δ}) allows them to create oxygen defects (vacancies) and modify the valence state of the transition metals in the B-site. This, in turn, alters (a) the mobility of O₂⁻ ions within the lattice and (b) their surface redox properties, thereby enhancing their catalytic performance.

In the present study, the catalytic activity of the perovskite La_{1-x}Sr_xMnO₃ (LS_xM), was comparatively examined for deep oxidation of light hydrocarbons, LHCs, namely CH₄, C₃H₈ and C₃H₆, under excess O₂ conditions. The effect of the gradual partial substitution of the A-site of La_{1-x}A'_xMnO₃ perovskite, (where A' = Sr and x = 0, 0.3, 0.5, and 0.7) on the activity and stability of the materials in deep LHCs oxidation. Various characterization techniques such as BET, XRD, and H₂-TPR were employed to assess their physicochemical properties, correlating them with their catalytic activity. Additionally, different pre-treatment protocols were applied, including (a) pre-reduction, (b) pre-oxidation, and (c) oxidative aging at high temperatures. It turns out that the primary factor affecting the performance of LS_xM was the degree of La substitution by strontium (Sr). The catalytic performance of the materials followed an inverted volcano pattern based on the variable x, with the most efficient catalyst being for x=0 while the least efficient for x=0.5. This observation strongly highlights the impact of x on the total surface area and the reducibility of the materials. Furthermore, complex hysteresis phenomena were recorded for the first time in the catalytic system during heating/cooling cycles, revealing new phenomena and findings that may be of interest to the catalysis under consideration.

A Case Study of Gas Turbine Failure: Unraveling the Impact of Soot Ingestion on NGV, Heat Shield, and Turbine Impeller Damage

Mr. Arief Sulistyono, Indonesia

Poster Presentation

Abstract

This study investigates the failure of an OPRA OP16-3A gas turbine engine that occurred at PT Pertamina EP's Xray-Jatibarang Platform in September 2021. The investigation focuses on identifying the root cause of the failure through detailed examination of the damaged components and laboratory analysis. The primary components of the OPRA OP16-3A gas turbine include the compressor, combustion chamber, and turbine. The failure affected several key components: the nozzle guide vanes (NGVs), turbine impeller, heat shield, and heat shield hanger ring. Damage was observed in the form of erosion, deposit formation, and material loss. The damaged components were analyzed using various techniques to determine material composition and assess the damage mechanisms. The NGVs, made of Alloy 754 (an oxide-dispersion-strengthened superalloy), exhibited erosion of the thermal barrier coating (TBC) and substrate material. The heat shield, composed of Udimet 500, showed evidence of deposit buildup and subsequent material loss. The turbine impeller, constructed from Alloy 718 and Udimet 720, displayed wear and damage, particularly in the clearance region. Based on the laboratory findings, the failure sequence was reconstructed. Soot particles ingested into the compressor were carried through the gas path, leading to erosion of the NGV's TBC. The eroded TBC particles, along with other debris, deposited on the heat shield. These deposits, combined with the high-temperature and high-pressure operating conditions, caused cracking and detachment of the heat shield material. The detached particles acted as abrasive agents, leading to wear and damage of the turbine impeller and heat shield. The root cause of the failure was determined to be the ingestion of soot particles into the compressor, which initiated the erosion process and triggered the subsequent damage to downstream components. The analysis concluded that the failure was not due to overheating but rather a sequence of events initiated by soot-induced erosion. The study highlights the detrimental effects of environmental contaminants on gas turbine performance and emphasizes the importance of effective filtration systems to prevent such failures. Further investigation into the specific mechanisms of soot erosion and the development of mitigation strategies are recommended.

INNOBIO Project – Predicting the behavior of casted bioceramics

Dr. M-Magdalena Lorente-Ayza, Spain

Poster Presentation

Abstract

Ceramic raw materials are used as biomaterials due to their inert behavior within the human body, their ability to be shaped into various forms and porosities, their high compressive strength, and their excellent wear resistance properties. These ceramics are used in components of the musculoskeletal system, hip and knee prostheses, bone grafts, dental and orthopedic implants, and heart valves. Despite the limitations imposed by their brittleness and low tensile strength, phosphate bioceramics, hydroxyapatites, alumina, zirconia, and zirconia-toughened alumina (ZTA) are widely used in the manufacture of biomaterials due to their high biocompatibility, tribological properties, and bone integration.

The advantages and disadvantages of biocompatible materials are closely linked to the manufacturing processes of the final products. Therefore, scientific advancement focuses not only on the development of new materials but also on the improvement and optimization of manufacturing techniques. One of the most commonly used shaping techniques is casting, due to its versatility and ability to reproduce complex shapes. This manufacturing process involves pouring a liquid material, such as molten metal or melted plastic, into a mold to create a solid piece with the desired shape.

Although research in the development of medical materials using casting techniques began years ago, as it is an economically accessible and sustainable technique, it remains of great interest due to the refinement of the technique and the derived methodologies. The INNOBIO project focuses on detailed research of casting techniques, integrating numerical simulation to predict the behavior of materials after shaping, which will reduce development times, minimize associated costs, and improve the quality and reliability of the final products. This will facilitate the understanding and prevention of possible defects in manufactured parts by means of virtual prototyping, saving time and resources during the manufacturing process.

The project "Investigación para la Innovación en Nuevas Aplicaciones de Materiales Biocompatibles – INNOBIO" is founded by Instituto Valenciano de Competitividad Empresarial (IVACE+i) and the European FEDER Funds.

Sustainable battery recycling using electrodialysis with X-ray fluorescence process control

Mr. Adam Isaksson, Sweden

Poster Presentation

Abstract

Recycling of lithium-ion batteries (LIBs) is important to secure the supply-chain of critical metals and to limit the demand for virgin raw materials. An important type of LIB contains lithium (Li), nickel (Ni), manganese (Mn) and cobalt (Co) as active material, referred to as NMC-type LIBs. Metals in spent NMC batteries are recycled by hydrometallurgical methods like leaching, solvent extraction and crystallization. Electrodialysis is being researched as a novel refining method in the recycling processes, requiring less chemicals and producing fewer by-products compared with conventional methods. A chelating agent such as ethylenediaminetetraacetic acid (EDTA) is added to the metal leachate, binding to nickel ions (Ni^{2+}) and forming a negatively charged chelate. This compound is then separated from the other positively charged metal ions by an electric field across a series of ion exchange membranes. Cobalt ions (Co^{2+}) and manganese ions (Mn^{2+}) are later separated in a similar way, forming the second and third most stable chelates with EDTA. A precise assay of the metal content is paramount for accurately dosing the chelating agent, as superstoichiometric additions give higher metal recovery at lower selectivity while substoichiometric additions give lower recovery but improve selectivity. Inductively coupled plasma optical emission spectroscopy (ICP-OES) is the standard laboratory technique for assaying leachates, having a low detection limit (ppb-ppm range) but requiring time-consuming sample dilution before analysis. In this study, X-ray fluorescence (XRF) was used to monitor metal content in electrodialysis feed and product streams. XRF is a quick assaying method with low operating cost obviating sample dissolution prior to analysis, making it suitable for on-line tracking of elements during operation despite its inability to measure Li and other light elements in solution. A synthetic sulfate leachate of NMC 111 black mass (0.01 M of Ni^{2+} , Mn^{2+} and Co^{2+} , respectively) was mixed with 10% molar excess of EDTA for Ni separation. Electrodialysis was performed at pH 2, achieving Ni separation factors of 20.2, 18.4 and 6.61 toward Li, Mn and Co respectively. Samples were retrieved during separation, later assayed using a Thermo Fisher iCAP 7000 ICP-OES and an Xore Boxray XRF analyzer. A linear correlation between assays from the two methods was observed, with a least-squares regression showing coefficients of determination (R^2) equaling 0.980, 0.999 and 0.999 for Ni, Mn and Co respectively. XRF is a promising technique for monitoring metal content in leachates and for production control, enabling upscaling of the electrodialysis process.

Materials Data Infrastructure and Ontology Development for Exemplary Reference Dataset

Mrs. Yusra Shakeel, Germany

Poster Presentation

Abstract

The development of new engineered materials relies on high-quality reference data and material standards. Especially mechanical properties at high temperatures, such as creep resistance, are crucial for potential structural applications of new alloys. Within NFDI-MatWerk, the exemplary reference dataset uses data from creep experiments on a single crystal Ni-based superalloy with benchmark material properties, along with a detailed experimental description and relevant information on material provenance and condition.

The FAIR (Findable, Accessible, Interoperable, and Reusable) principles are applied when distributing the reference datasets along with their metadata. FAIR Digital Objects (FDOs) are created to support machine readability and accessibility using Persistent Identifiers (PIDs). Our proposed workflow highlights two aspects: creation of FAIR DOs and ontology development. The experimental data generated is stored in repositories, such as Coscine or published on, for instance Zenodo. We develop a data schema to define a structured approach for collecting all the required information on a creep experiment. The entries are grouped according to their content and summarized under respective headlines, thereby forming a hierarchy of concepts. Based on this schema we create FDOs to make the reference dataset and its metadata interpretable for the external material scientists' community. Moreover, we develop a semantic description in the form of an ontology and a metadata schema to make the information explicit, and to enable interoperability between databases, automated analysis, and integration into simulation workflows. The reference dataset ontology (RDO) provides a formal description of concepts, which define reference data, e.g., standard, validation, curation, etc. and are based on the exemplary reference dataset. Thus, classifies the RDO as a top-level ontology with universal concepts. The experimental workflow and material characteristics, which are important for the interpretation of research data, must be described in an application-level ontology or mapped to other related ontologies, e.g., PMD (Platform Material Digital) Application Ontologies.

This approach ensures the FAIRness of the data and accelerates research in the field of Material Science and Engineering by providing high-quality reference datasets and material standards for the development of new alloys for high-temperature applications. The workflow, part of an overarching framework for management of reference data, has been successfully implemented for an example use case and will be supported by easy-to-use tools in the future.

Acknowledgments: This work is part of the consortium NFDI-MatWerk, funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under the National Research Data Infrastructure – NFDI 38/1 – project number 460247524.

Influence of Chemical Composition of FexZn1-xS on The Efficiency of Organic-Inorganic Hybrid Solar Cells

Dr. Thelma Serrano, Mexico

Poster Presentation

Abstract

This project aims in development and study of hybrid solar cells based on FexZn1-xS with P3HT to obtain a solar cell with greater conversion efficiency of energy.

Thin films of FexZn1-xS were obtained by chronoamperometry in a 3 electrodes cell, where the working electrode was ITO glass, Pt wire as a counter-electrode and Ag/AgCl as reference electrode.

The electrochemical bath was prepared with 10 mL of FeSO4 30 mM, 10 mL of ZnSO4·7H2O 30 mM and 20 mL of thiourea 30 mM and it was completed to 100 mL with water. pH was adjusted to 2.5 with H2SO4 and the reaction was carried out at room temperature for 600 s. The reaction was performed varying the potential (-1.2, -1.5 and -1.7 V) and the molar ratio of Fe:Zn (3:1, 2:1, 1:1).

The chronoamperogram shows the growth mechanism of the thin film on the ITO surface. Three different processes may be observed, the breaking of the double layer, the nucleation process and the growth process. The optical characterization by UV-vis shows absorption at 350-400 nm related to the presence of ZnS and a second absorption at 650 nm attributed to the Fe presence. The Fe content affects the optical properties of the materials, showing higher wavelengths as the Fe content increases. SEM images show a regular deposition with the absence of pores, in addition, when the content of Fe increases, the definition of the morphology and the particle size are better defined.

After the obtention of the ternary material, a solution of P3HT was deposited on top of the semiconductor by the spin coating methods at 4000 RPM. In addition, a solution of PEDOT:PSS 1.3% in water was deposited by spin coating in half of the cells in order to study the influence of a hole transport layer (HTL) on the efficiency of the cell. Finally, a counter electrode of Au was apply by sputtering, in order to close the circuit.

The result shows then increasing the amount of iron on the material produces a higher conductivity, what derivates in a better charge transportation in to the solar cell and a better efficiency, up to 1.5% for 0.25% of Fe. The precense of a HTL did not show an important influence on the efficiency of the solar cell, this indicates that the composition of the ternary, specially the addition of Fe to the crystalline structure determines the performance of the solar cell.

Mixed-matrix membranes modified with nano-SiO₂ for technical applications

Ph.D. Lukasz Zych, Poland

Poster Presentation

Abstract

The aim of the research was to obtain mix matrix membranes (MMM) which properties are modified by the addition of nanoparticles such as: TiO₂, SnO₂ or SiO₂. The MMM is a mesoporous composite material in which dispersed particles are embedded in a polymer matrix. The function of the matrix is to keep the particles dispersed, providing selective permeability due to interactions at the particle-polymer interface. The type of the filler influences the membrane properties such as; mechanical strength, selectivity towards particles/ions, increased permeability compared to polymeric membranes and higher thermal stability. The choice of the filler allows new properties to be imparted to the membrane resulting in an increase in service time, e.g. by reducing the deposition of inorganic as well as organic compounds (organic macromolecules produced by bacteria). The antifouling and immobilising properties of particles on the membrane surface represent a new research trend in MMMs, and allow to extend the range of membrane applications, which can be used both for gas separation and in wastewater treatment or water desalination processes. Our proposed approach is based on the use of nano-fillers in the form of SiO₂ or its forms modified with organic salts, altering the surface charge of the membrane and thus hindering adsorption of macromolecules as well as bacteria, or to bind the contaminant to the surface. Modifying the particles surface improve their compatibility with the matrix and facilitate their dispersion. A high degree of dispersion is a prerequisite for improving the mechanical properties of the membranes. In this study, SiO₂ nanoparticles chemically modified with organic salts such as polypyrrole were used. The characterisation of the powders consisted in determining particle size by DLS or TEM observation and assessing their wettability. The effectiveness of the particle modification was verified using the FTIR. The prepared particles were introduced into the PSU matrix. The effect of the particles on the polymer structure was investigated using FTIR and thermal analysis methods (DSC). Microstructural studies of the membranes consisted of SEM observations and determination of pore size distribution by the capillary flow porometry. An important step was the determination of the surface properties of the membranes, surface energy and electrical charge i.e. the surface zeta potential. The information on the surface state was contrasted with the adsorption of bacteria on the membrane surface. Results of the studies may help selection of membranes with properties suitable for medical, environmental and industrial applications.

Hybrid Reinforced Ferritic Alloy Fabricated by Mechanical Alloying and Spark Plasma Sintering: Preparation and Selected Properties

Mr. Bartosz Bucholc, Poland

Poster Presentation

Abstract

Oxide dispersion-strengthened (ODS) ferritic steels are advanced materials characterized by outstanding high-temperature strength, creep resistance, and corrosion resistance. Their primary method of production is powder metallurgy, which includes mechanical alloying (MA) followed by consolidation, most commonly through hot isostatic pressing (HIP) or hot extrusion (HE). ODS steels are typically reinforced with Y_2O_3 , which dissolves into the ferritic matrix during MA and facilitates the formation of ultrafine complex oxides containing Y and Ti, which provide remarkable functional properties and make them highly suitable e.g., for advanced nuclear energy applications. In this study, the reinforcement strategy was modified to a hybrid approach by incorporating both conventional Y_2O_3 and additional Al_2O_3 nanoparticles to enhance material performance. A production method was developed for Hybrid Reinforced Ferritic Alloys (HRFAs) with a fixed Y_2O_3 content and varying amounts of Al_2O_3 , using MA for powder preparation and an alternative consolidation method - spark plasma sintering (SPS). The aim was to explore whether this hybrid reinforcement approach could further boost the already exceptional characteristics. The fundamental properties of the alloys were investigated, focusing on microstructure and surface characteristics through techniques such as SEM, EDX/EDS, AES, and XPS. Additionally, their corrosion behavior in chloride-ion-containing environments was analyzed using open circuit potential (OCP), linear sweep voltammetry (LSV), and electrochemical impedance spectroscopy (EIS).

Paper 1448

Optimizing press-fit diodes reliability through manufacturing process modifications

Dr. Alberto Moure, Spain

Poster Presentation

Abstract

The reliability of press-fit diodes in power electronic applications is a challenge due to the multicomponent nature of these devices, because the high currents that leads to high temperatures during operation induce thermomechanical stresses at the interfaces. To assure long lifetimes and small failure rates, the design of the diode as a well as a robust manufacturing process is essential. In this work, we show how the changes in the manufacturing process to increase the robustness of the device determine the quality of the diodes. Heating processes were modelled and measured by thermography to determine the influence of the solder thickness and uniformity in the thermal behavior of the devices, so they can bear high currents to reach temperatures in the order of 250°C in the epoxy region, which is the hottest part of the diode. A further improvement of the behavior was obtained by the proper choice of an epoxy with a limited expansion. It eventually reduces the stress and strain effects at the interfaces, preventing the breakdown of the diodes even at continuous currents as high as 40 A.

Concentrated Solar Energy for the elaboration of VC-reinforced steel as a sustainable alternative to conventional arc melting

Prof. Pandora Psyllaki, Greece

Poster Presentation

Abstract

This work is part of an integrated research project targeted to investigate the feasibility of optimising a novel "solar surface treatment" process for the elaboration of carbide-based hardfacing layers with acceptable microstructure and satisfactory performance under harsh operating conditions. For this purpose, Concentrated Solar Energy (CSE) was applied for the fabrication of thick surface layers, composed of a dispersion of μm -sized vanadium carbide reinforcing particulates within the metallic matrix of St 37-2 common steel. All "solar" experiments were carried out in the solar furnaces of Plataforma Solar de Almería (Spain). Typical such campaigns involve (a) pre-deposition of a specific volume of the reinforcing particles onto steel substrates, (b) positioning of the materials system in a closed jar, onto a thermal insulating Al_2O_3 support, ensuring the continuous flow of Ar inert gas and (c) exposure of the materials system to CSE and dwell at surface temperature above the melting temperature of the substrate (1.540°C) for given time. Under these conditions, the solar radiation is concentrated solely on the area covered by the black pre-deposited powder and the heat is transferred to the underlying steel resulting in its melting during exposure, whereas the ceramic reinforcement remains unaffected due to its higher melting temperature ($>2.800^\circ\text{C}$). VC particulates are immersed into the melting pool and after solidification the requested composite layer is formed on the top of the steel substrate, having a thickness that depends on the dwell time at surface temperature higher than 1.540°C . Subsequently, the microstructure of the CSE-obtained surface layers was characterised by means of microscopy and X-ray diffraction, and their operation performance was evaluated during sliding wear tests and exposure to corrosive environments. The findings were compared with the corresponding ones concerning similar bulk composites fabricated via conventional arc melting that was applied for the elaboration of nm-sized vanadium carbide dispersions within a stainless steel matrix. The potential and limitations of both the CSE and the arc melting processes were evaluated using as criteria the performance of the respective composites, as well as the initial size of the reinforcing ceramic particles and the steel grade of the matrix. During the last two decades, Concentrated Solar Thermal Systems as the one proposed here were extensively studied and found successful implementation in the field of energy applications. The present attempt is focused to transfer relevant scientific findings to other potential applications like of materials engineering and "Green Metallurgy".

High-Temperature Concentrating Solar Technologies for direct surface processing of metallic parts

Prof. Pandora Psyllaki, Greece

Poster Presentation

Abstract

Surface modification, as a sub-field of Surface Engineering, targets on enhancing the performance and longevity of metallic parts that operate under severe environments that involve wear, abrasion, erosion and cavitation. Addressing these issues is crucial as industries strive towards sustainable solutions amidst global climate concerns. In particular, there is an increasing interest to develop new routes based on renewable energy sources that would be a reliable and efficient alternative to conventional surface modification processes of metals. The work presented here aims at the application of high-temperature Concentrating Solar Technologies for processing of metallic parts. Since 2014, a series of such "solar" campaigns implemented at Plataforma Solar de Almeria (Spain) by the authors' groups, which were targeted to the direct elaboration of wear-resistant composite surface layers, led to the proof-of-concept that, indeed, concentrated solar energy can be a promising renewable energy solution for the direct surface processing of metallic parts.

The project TWINSOLARSURF ("Twinning for solar energy-driven surface engineering of metallic parts"), a Horizon Europe-funded project that started in October 2024 and will last 3 years, capitalizes on these promising scientific results and aims to contribute to the development of a novel ecosystem in the frame of "Green Metallurgy" and in general of "Green Manufacturing". The consortium will work on an exploratory project on the research playground of surface processing of metallic materials for use in aggressive environments e.g. wear, abrasion, erosion and high temperature. In particular it will pursue the parallel development of ultra-hard as well as thermal barrier coatings (TBCs). The former will be elaborated on steel substrates via concentrated solar thermal energy; the latter will be targeted to protect metallic ducts carrying the heat transfer fluids in such solar thermal plants from excessive solar irradiation retarding their sensible heating beyond critical temperatures and mitigating the consequences of temperature overshooting. In parallel the partners will work together on a strategic plan for co-developing a space of excellence via a capacities' building programme, sharing knowledge, integrating expertise and skills and delving into new research avenues. The overall approach is fully linked to the European Green Deal strategy for green industrial technologies of the future, further penetration of renewable energies and building the skilled research personnel capable of addressing the global societal, political and environmental challenges of our future ecosystem.

Paper 1516

Influence of Hybrid Silica-Based Sol-Gel Coatings on the Fatigue and Corrosion Behaviour of 16Mo3 Steel

Mrs. Shirin Falakboland, Germany

Poster Presentation

Abstract

Surface morphology significantly influences the fatigue life of metallic materials. Therefore, improving surface performance is crucial for both economic and safety-related applications. Coatings can be beneficial in two ways: (i) mechanically suppressing slip bands and (ii) acting as a chemical barrier to mitigate corrosion. Sol-gel coatings have gained interest due to their tunable properties, which can be optimised by adjusting the synthesis parameters, such as synthesis steps, precursors, solvents, and catalysts. This has led to the development of silica-based hybrid coatings at Wroclaw University of Science and Technology, Poland, where the addition of organic moieties enhances flexibility while reducing porosity compared to pure inorganic coatings. These improvements can be beneficial for mechanical performance under cyclic loading and corrosion resistance. Our previous studies have shown that such coatings increase fatigue life in the very high cycle fatigue regime when tested using an ultrasonic fatigue system at a working frequency of 20 kHz. However, in this study, coated and uncoated specimens were tested in the high cycle fatigue regime under significantly higher stress levels. The tests were carried out at a stress amplitude of 295 MPa, a frequency of 5 Hz, room temperature, and zero mean stress using a servo-hydraulic fatigue testing system. The results indicated that the coating had no noticeable effect on fatigue life in the high cycle fatigue regime. Interestingly, analysis of the stress-strain hysteresis from the fatigue tests showed that, while both coated and uncoated specimens exhibited cyclic softening, this phenomenon began later in the coated specimens but developed more pronounced. To investigate the cause of this behaviour, the development of slip bands was studied in interrupted fatigue tests at specific load cycles using a scanning electron microscope. Additionally, the corrosion resistance of the coatings was evaluated by immersing both coated and uncoated specimens in a 3.5% NaCl solution for 72 hours prior to fatigue testing. The uncoated specimens exhibited early failure, whereas the coated specimens maintained the same fatigue life as those not exposed to immersion. To assess the impact of prior corrosion on fatigue behaviour, the fracture surfaces of failed specimens were closely analysed and investigated.

RHEOLOGICAL BEHAVIOR OF ZEOLITE PASTES REINFORCED WITH GRAPHENE FLAKES FOR 3D PRINTING OF MEMBRANES WITH POTENTIAL APPLICATION AS GAS SEPARATION

Prof. João Batista Rodrigues Neto, Brazil

Poster Presentation

Abstract

Zeolites are crystalline aluminosilicates characterized by an open-cavity structure consisting of micropores and channels, formed by three-dimensional tetrahedral units of SiO_4 and AlO_4 . This study aims to investigate the potential of these cavities for gas separation membranes. Membrane technology is widely used for the physical separation of CO , CO_2 , and H_2 mixtures during CH_4 reforming. Additionally, 3D printing has shown great promise in fabricating zeolite/graphene flake (GF) composite membranes with tailored configurations and hierarchical porosity. This is achieved through the successive layer deposition of optimized hydrogel inks containing varying solid contents (40–60 vol%) and additives such as surfactants, plasticizers, and binders to enhance rheological properties for effective 3D printing. Furthermore, the incorporation of graphene flakes (GF) with Faujasite-type (FAU) zeolite enhances packing density and consequently the viscosity of hydrogel inks, which can significantly improve both mechanical properties and surface area of the resulting membranes. In this study, a 3% (wt./vol.) alginate-based hydrogel was prepared in distilled water at 60 °C, after 0.5–1.0% (wt./vol) of GF solution were homogenized under magnetic stirring for 24 h. After that, commercial zeolites 13 X (ZEO-13X) powder was added to hydrogel with a suitable amount of bentonite (2.5–5 wt.%), as plasticizer, methylcellulose (0.5–1.5 wt.%), as thickener and PEG poly(ethylene glycol) (1–5 wt.%), as lubricant, to prepare inks. Hydrogel inks were homogenized under stirring at 250 rpm for 10 min, followed by rheological characterization, aiming to establish correlations with printability. A rotational rheometer (Haake Viscotester iQ) was used to determine the flow curves, and an oscillatory rheometer (Anton Paar MCR 92) was used to determine the yield strength and viscoelastic behavior. All inks exhibit pseudoplastic behavior, with a content of 1.0% (wt./vol.) of GF being identified as the most suitable for decreasing the viscosity of the ink for the manufacture of 3D membranes.

Paper 861

SYNTHESIS AND CHARACTERIZATION OF ALGINATE HYDROGELS CONTAINING 58S BIOACTIVE GLASS AND SILVER NANOPARTICLES

Prof. João Batista Rodrigues Neto, Brazil

Poster Presentation

Abstract

The 58S bioactive glass, composed of 60% SiO₂, 36% CaO, and 4% P₂O₅ (mol%), is widely recognized in tissue engineering for its bioactivity when interacting with biological systems. This study aimed to integrate sol-gel synthesized 58S bioactive glass particles into alginate hydrogels—a biocompatible material—to develop inks with optimal rheological properties for 3D printing. Additionally, we investigated the impact of incorporating varying concentrations of 58S (ranging from 15 to 35 vol%) on the rheological behavior of alginate hydrogel-based inks containing 1.5 to 5 wt.% of additives, including Halloysite clay (plasticizer), Dolapix CE 64 (deflocculant), and PVA (binder). The hydrogel inks were homogenized using a laboratory mixer (IKA RW 20) at 300 rpm for 20 min before rheological characterization to assess their printability. Flow curves were determined using a rotational rheometer (Haake Viscotester iQ), while an oscillatory rheometer (Anton Paar MCR 92) was employed to evaluate yield strength and viscoelastic behavior. All inks exhibited pseudoplastic behavior, with the 25 vol.% formulation identified as the most suitable for fabricating scaffolds for biomedical applications. These scaffolds retained their shape and were subsequently impregnated by immersion with silver nanoparticles synthesized via laser ablation.

Paper 1881

Temperature and Grain-Size Dependence of Deformation Behavior in Commercial-Purity Titanium

Prof. Chihrio Watanabe, Japan

Poster Presentation

Abstract

Thermo-mechanical treatments, including multi-directional forging and cold rolling, were employed to produce ultrafine-grained (UFGed) Grade 2 commercial-purity titanium sheets. A subset of these UFGed sheets underwent annealing under various conditions to prepare specimens with three distinct average grain sizes (0.07, 0.8 and 12 μm). These specimens were subjected to tensile tests both at room temperature (RT) and cryogenic temperature of 77 K. The deformation behaviors changed complicatedly depending on temperature and grain size. Regardless of grain size, all specimens exhibited significantly higher 0.2% proof stress, ultimate tensile stress and elongation to failure at 77 K compared to those at RT. Microstructural observations revealed that prismatic <a> slip was the primary deformation mechanism in all specimens, also with pyramidal <c + a> slip in the ones with grain sizes of 0.07 and 0.8 μm. Mechanical twinning in these specimens at RT was few. However, twinning, particularly {11-22}<11-2-3> compression twins, was considerably stimulated at 77 K. While twinning frequently occurred even at RT in the coarse-grained (12 μm) specimen, it was much more promoted at 77 K. It can be concluded, therefore, that uniform deformation caused by twinning-induced-plasticity effect largely contributed to the larger ductility at 77 K, improving the strength-ductility balance. These findings suggest that mechanical twinning, rather than slip activity, is the main factor influencing the temperature dependence of the mechanical properties in the CP-Ti specimens composed of different grain sizes.

Development of an Integrated UTM and PIXE System with Proton Beam Irradiation for Real-time Material Testing

Ph.D. Sang Chul Mun, South Korea

Poster Presentation

Abstract

The integration of real-time mechanical testing and non-destructive elemental analysis under radiation exposure is an important step forward in understanding material behavior in extreme environments. The present work focuses on the development of integrated universal testing machine (UTM) and particle-induced X-ray emission (PIXE) systems utilizing the MC50 cyclotron beamline. The aim is to provide a comprehensive insight into material performance by enabling simultaneous evaluation of mechanical properties and elemental analysis during proton beam irradiation. Currently, this setup includes a proton and neutron beam irradiation system, a beamline configuration, and a vacuum sample holder. Next steps include integrating UTM with real-time stress-strain monitoring capabilities and optimizing PIXE detector alignment for high-resolution elemental analysis. This integrated system will allow simultaneous observation of mechanical deformation and elemental redistribution under combined thermal and irradiation stresses, simulating high-radiation and high-temperature environments. Expected results include the ability to relate changes in mechanical properties to changes in elemental composition, which provides a new approach to material characterization. This bifunctional platform is expected to significantly improve the understanding of material behavior in nuclear, aerospace, and other high-intensity applications. By combining UTM and PIXE features, the system will establish a new standard for advanced material testing and provide critical data for the development of resilient materials tailored to extreme conditions.

Tribological testing and crystallographic analysis of high hardness, ultra-low friction Mo-S-C thin film coatings with self-assembling tribolayers

Mrs. Bethan Collins, United Kingdom

Poster Presentation

Abstract

Transition metal dichalcogenides (TMD) are a group of materials that are well-known for their low friction properties. The weak van der Waals forces between layers of covalently bonded atoms gives rise to easy shear and can therefore provide very low friction. These materials, however, have low hardness, meaning that in their pure form they display high wear rates. To improve their material properties, TMD coatings can be deposited with a doping element, which leads to the production of amorphous coatings with significantly increased hardness and density.

Although the as-deposited amorphous coatings do not initially feature the crystals responsible for the ultra-low friction properties of pure TMDs, the application of frictional forces has been found to lead to the creation of crystalline regions, or a 'tribolayer'. It has been shown via sliding wear tests that these coatings display an initial coefficient of friction (COF) of around 0.3, which rapidly reduces and can reach steady state values of as low as 0.025 at room temperature.

Molecular dynamic simulations were used to model the process of tribolayer formation to find the optimal carbon content that should provide the maximum hardness whilst still allowing for the creation of the tribolayer. This composition was then used to deposit the Mo-S-C coatings studied in this project. The coatings were deposited via magnetron sputtering, a physical vapour deposition (PVD) process, via high power impulse magnetron sputtering (HIPMS).

The coatings were tribologically tested using a linear reciprocating tribometer. A range of sliding conditions were used: applied load ranging from 5-20N, sliding frequency ranging from 1-20Hz and sample temperature ranging from 20-150°C. The tribological results showed COF ranging from 0.035 to 0.05.

The wear tracks were analysed using scanning electron microscopy with energy-dispersive X-ray spectroscopy (SEM-EDS), and Raman spectroscopy to search for crystalline regions within the wear tracks as evidence of tribolayer formation. Most of the wear track remained amorphous, however an area of crystalline MoS₂ was discovered. High resolution transmission electron microscopy was also employed to investigate the layer adhered onto the ball used in the wear tests, in which MoS₂ platelets were found although no compact tribolayer was present.

Influence of porosity on the electrical and thermal conductivity of sintered metal compacts

Dr. Fátima Ternero Fernández, Spain

Poster Presentation

Abstract

The influence of porosity on the electrical and thermal conductivities of sintered metal compacts is studied in this work. Contrary to what might be thought, the challenge of finding mathematically simple expressions with one or two empirical parameters (which can also be determined by measurement) is still relevant today, when other strategies of massive computing or AI prediction seem to occupy the whole scenario, overriding the traditional ways of acquiring knowledge. However, the advantages of the traditional way are clear, as they lead to a direct and clear understanding of the relationships between microstructure properties. In this paper, some of the expressions put forward by different researchers are confronted, validated and compared with data taken from the literature. The results confirm that this problem cannot yet be considered fully solved.

Paper 1546

Influence of pressure on the electrical resistivity of a metal powder mass under compression

Dr. Fátima Ternero Fernández, Spain

Poster Presentation

Abstract

In this work, a simple mathematical model is proposed to describe the variation of the electrical resistivity of a mass of metallic powder subjected to increasing compression. To date, this study has not yet received an answer that is fully satisfactory for a variety of powders and at the same time is mathematically simple. The current trend, more interested in other strategies of massive computation or AI prediction, does not seem to explore this traditional way of acquiring knowledge, which has, however, obvious advantages as it leads to a direct and clear understanding of the relationships between microstructure properties. In this work, a simple expression with few empirical parameters is proposed that allows fast and reliable predictions. The model is validated with experimental curves acquired in tests with commercial metal powders.

ISRU-approach on designing and fabricating successfully composite materials on the lunar soil

Prof. Donatella Giuranno, Italy

Poster Presentation

Abstract

By the Artemis program, NASA will land the first woman on the Moon, using innovative technologies to explore more of the lunar surface than ever before and the first long-term presence on the Moon will be established. One of its basic strategy is to enabling the in situ resources utilization approach (ISRU) by focusing on how to process Lunar soil (regolith-a complex mixture of oxides) by using already terrestrial developed advanced technologies for extracting pure elements (i.e. Si, Al, Mg, Fe, Ti, etc.), to produce breathing air, growing plants, and whatever sustain Moon habitants in such extreme conditions, e.g. building materials, screens against radiations, etc. Under a great ISRU-focus is also the "space junk" mainly consisting of light weight alloys based on Al, Si and Ti. A preliminary investigation on using lunar soil (regolith) properly combined/processed with metal particles of the abovementioned alloys for fabricating composites feasible as building/functional materials will be introduced in this paper. In particular, as an example, preliminary results obtained by interactions tests between Ti64NPs/DNA-1 regolith simulant will be shown and discussed, even by comparing the observed microstructure and reaction products at the interface with thermodynamic calculations on phase stabilities obtained by using FACTSage.

Processing Al-based MGA systems as phase change materials

Prof. Donatella Giuranno, Italy

Poster Presentation

Abstract

In energy storage applications, PCM (Phase Change Materials) stands in a sealed chamber near the heat source, exchanging thermal energy with the surrounding environment. In the Al-Sn system, aluminum (Al) serves as the housing material, while tin (Sn) is used as the phase change material. The theoretical phase change temperature of Sn is 232 °C, with a latent heat of 60.3 J/g, making this composite material suitable for medium-temperature thermal energy harvesting and storage applications. Due to the extremely low solubility of Al in Sn, the Al-matrix and the Sn-phase change material couple remain stable and do not react within the operating temperature ranges. Accordingly, composite microstructure should be long-term preserved even after several thermo-cycles. In this paper, preliminary study based on experimental observations, show the behaviour of selected Al-Sn alloys within heating and cooling processes, in view to find out the suitable process conditions for preserving microstructures and their performance under service conditions. Specifically, the behaviour and microstructure stability will be related to operating conditions and practical recommendations will be provided.

Healing effect of nanochitosan, collagen, keratin and hialuronic acid electrospun membranes in a pre-clinical study

Prof. Juliana Bernardi-Wenzel, Brazil

Poster Presentation

Abstract

The aim of this study was to produce electrospun membranes made of nanochitosan associated with collagen and keratin, with or without hyaluronic acid, and to evaluate their effectiveness in the healing process of cutaneous wounds in Wistar rats. Solutions of 4% (w/v) nanochitosan diluted in 90% acetic acid were prepared, plus 2% (w/v) collagen; 2% (w/v) collagen and 0.1% (m/m) hyaluronic acid; 2% (w/v) collagen and 12.5% (m/m) keratin; and 2% (w/v) collagen, 12.5% (m/m) keratin and 0.1% (m/m) hyaluronic acid. After homogenizing, the solutions were electrospinning with the following parameters: 12 cm distance between the needle and the collector, 20 kV and a flow of 2.0 mL/h to obtain the membranes. The membranes produced were characterized by scanning electron microscopy (SEM) and their antimicrobial activity was evaluated against the bacteria *Staphylococcus aureus* and *Pseudomonas aeruginosa*. The healing effect was evaluated in a pre-clinical study using Wistar rats, randomly assigned to five experimental groups, one for each type of electrospun membrane and a control with saline solution. The animals were given a surgical wound 2 cm in diameter in the dorsal region and the wounds were cleaned and covered with the electrospun membranes or just cleaned with saline solution (control). The healing of the wounds was monitored on days 3, 7, 14 and 21, when the area of the lesions was examined and the tissue collected for histological analysis. The results were submitted to analysis of variance (ANOVA) and the means were compared using the Tukey test ($p < 0.05$) to determine whether the treatments had a statistically significant reduction in the area of the wounds at each time point compared to the control. The electrospun membranes adhered well to the wound bed and did not require additional covering. The random arrangement of the fibers can be seen by SEM, with visible fragility in the structure of the nanofibers of the membranes containing keratin, which also showed the least adherence to the wound bed. The nanochitosan membranes with collagen were the most effective in the healing process, promoting faster wound contraction, differing statistically from the other treatments and the control group on the 7th and 14th day of evaluation, with greater induction of fibroplasia and epithelialization. It is therefore concluded that these membranes have potential for use as skin dressings, which will be evaluated in a clinical study.

SUBBIMATT - Sustainable, Biobased and Bio-inspired Materials for Smart Technical Textiles

Mr. Bruno Marco, Spain

Poster Presentation

Abstract

The SUBBIMATT project aims to develop a new generation of sustainable, biobased, and bioinspired smart technical textiles to address energy efficiency challenges in key applications such as adaptive building envelopes, automotive interiors, and advanced garments.

Objectives

SUBBIMATT follows a Safe and Sustainable by Design approach and focuses on:

- Developing circular textile intermediates from biobased materials.
- Engineering smart textile materials for motion actuators, energy harvesters, and tunable openness fabrics.
- Demonstrating real-world applications in construction, automotive, and wearable technologies.
- Creating innovative business models and integrating external developments to ensure market adoption.

Methodology

The project is structured into three key phases:

1. Preparation Phase: Development of novel debondable adhesives, biopolyurethane, and negative thermo-responsive materials to produce high-end coated fabrics, nanomembranes, and shape-memory filaments.
2. Enabling Phase: Integration of smart textile functionalities for mechanical actuation, energy harvesting, and tunable fabric openness.
3. Demonstration Phase: Implementation and validation of these materials in real-world use cases across the built environment, automotive, and fashion industries.

Expected Impact

SUBBIMATT is expected to generate significant industrial, environmental, and societal benefits:

- Boosting Industry Competitiveness: Strengthening the European textile sector through circular economy principles and innovative materials.
- Enhancing Sustainability Awareness: Promoting eco-friendly alternatives in buildings, mobility, and apparel.
- Improving Energy Efficiency: Showcasing smart materials that contribute to energy management in daily applications.
- Supporting EU Policies: Aligning with the EU Bioeconomy Strategy,

Modeling the Extrusion Process of PPS Solar Collectors

Mr. Dag Lindholm, Norway

Poster Presentation

Abstract

The European Union has stated clear objectives regarding reduced carbon emissions and increasing energy self-sufficiency as part of its broader environmental and energy policies. Among various technologies, the utilization of solar collectors that absorb and convert sunlight into usable thermal energy, is particularly relevant to achieving these strategic goals. Flat-plate solar collectors made of polyphenylene sulfide (PPS) offer the advantage of lower weight compared to traditional collectors based on metals like aluminum or copper. Reduction in weight makes installation easier and reduces transportation costs, while ensuring robust thermal performance and maintaining resistance to high temperatures and corrosion.

Inaventa Solar, a manufacturer based in Norway, produces flat-plate solar collectors using high-performance polymers, designed to provide heat for low and medium-temperature applications. Within the extrusion process, high-pressure molten PPS is forced through a die with numerous narrow channels to create thin-walled, high-performance solar absorbers. While the height and width of the water channels is adjustable and approximately 6 mm x 15 mm, the total width of the plate produced by the extruder is 1830 mm.

Accurate control of the die outlet temperatures, especially aiming for uniformity across the width direction to ensure consistent temperature in the PPS, are crucial for producing absorber plates suitable for use in solar collectors. A detailed CFD model was developed to enhance process understanding and to predict how process-related factors such as screw speed (line speed), barrel temperature, and cooling rate affect the extrusion performance and product quality. The model accounts for the heaters and the solid components of the extruder. It captures the complex flow of molten PPS from its entry to the die, through multiple narrow horizontal channels, to the die exit, where the absorber sheet is shaped. Recordings from thermocouples integrated into the extruder validated the model's predictions successfully.

A digital representation of the extruder, combined with integrated sensors and cameras, was developed to enhance control, increase productivity, and minimize waste. However, executing a detailed 3D model is computationally intensive and time-consuming, making it unsuitable for real-time predictions. To address this limitation, a reduced order model (ROM) was developed based on the CFD model, enabling real-time predictions and thus control of the extrusion process. This work presents the detailed CFD model and its surrogate, its verification against temperatures recorded during production, and examines the impact of variations in production speed, PPS inlet temperature, and extruder heater power settings.

Stimuli-responsive, drug-loaded nanoconstruct for multiple myeloma treatment: therapy and diagnosis

Mr. Nicolò Maria Percivalle, Italy

Poster Presentation

Abstract

Despite the progress made in the last few years, the development of effective tools against severe pathologies such as tumors is proving to be extremely challenging. While advancements in nanomedicine towards cancer treatment have exhibited that the use of nanocrystals (NCs) can be truly promising, potential drawbacks related to their utilization, such as the non-specific uptake of these materials in healthy organs and their potential immunogenicity, are still scarcely considered. This work aims to develop an innovative theranostic nanoconstruct based on lipid-coated, iron-doped zinc oxide nanocrystals (ZnO-Fe NCs), whose properties have revealed huge potential for in vitro and in vivo applications, focusing on the treatment of multiple myeloma, a tumor for which relapses and disease progressions are common among affected patients. The nanoconstruct therapeutic potential is due to its biocompatibility and the possibility to be remotely activated by ultrasound stimulation in order to ensure targeted drug release, while, for diagnostic purposes, it can be tested as contrast agent under ultrasound stimulation (i.e. echography).

To this aim, ZnO-Fe NCs were first synthesized and functionalized, before being coated with a shell composed of a mix of synthetic lipids, PEG and cholesterol. To further enhance the therapeutic capabilities of the nanotool, Carfilzomib (which is a commonly used drug for multiple myeloma treatment) was added into the lipidic shell. The obtained nanoconstruct was then deeply characterized, with particular focus on the diagnostic potential of the NCs as echographic contrast agent. Furthermore, to assess its therapeutic capabilities, it was administered to two different multiple myeloma cell lines to assess its intrinsic cytotoxicity (with and without the drug embedded into the shell) and when stimulated with ultrasounds, aiming at a sonodynamic treatment. Measurements performed through Electron Paramagnetic Resonance spectroscopy demonstrated indeed the generation of reactive oxygen species (ROS) derived from the ultrasonic stimulation of the nanoconstruct.

Preliminary in vitro results indicate that this innovative nanoconstruct can be an exceptionally interesting starting point for the treatment of multiple myeloma, since its therapeutic capabilities can be greatly enhanced by tailored adjustments, such as the functionalization of the lipidic shell for targeting purposes. Furthermore, echographic measurements demonstrated that the obtained nanoconstruct can be exploited not only as a therapeutic, but also as an extremely effective diagnostic tool.

Funding. This work is part of the project MITHoS (Multimodal Innovative Theranostic nanoSystem - Project n. 2020MHL8S9) founded by the Italian Ministry of University and Research (MUR) under the PRIN 2020 Funding scheme.

Influence of Mo on the mechanical and tribological properties of DCMS and HiPIMS deposited TiB₂+z thin films

Mr. Daniel Pölzlberger, Austria

Poster Presentation

Abstract

Transition metal borides (TMBs) represent a highly promising family of materials for functional coatings due to their abundance, cost-effectiveness, and exceptional mechanical properties. These include high melting temperatures, hardness of up to 60 GPa, excellent chemical and thermal conductivity, and outstanding resistance to wear. Theoretical predictions by density functional theory assessing the elastic constants revealed that the formation of ternary Ti-Mo-B₂±z might be a suitable approach to gain a less brittle character. In addition, Mo is also known to form self-lubricating phases such as MoO_x (Magnéli phases), which typically helps to reduce friction.

To study the effect of Mo on TiB₂±z three different target compositions were used for the non-reactive growth of ternary Ti₁-xMo_xB₂±z thin films: TiB₂/MoB 95/5 mol%, TiB₂/MoB 90/10 mol%, and TiB₂/MoB 80/20 mol%. The binary TiB₂+z system was deposited with a TiB₂/C 99/1 wt.% target. In addition, direct current magnetron sputtering (DCMS) and high-power impulse magnetron sputtering (HiPIMS) were employed to investigate the influence of different deposition techniques.

The structural and mechanical properties of the coatings were characterized by a wide variety of methods, such as scanning electron microscopy, X-ray diffraction analysis, and nanoindentation. The chemical composition was determined by inductively coupled plasma optical emission spectrometry and elastic recoil detection analysis. To verify the suggested enhancement on the brittle behavior of Ti₁-xMo_xB₂±z, fracture characteristics, such as KC and KIC, have been determined by cube corner indentation and in-situ micro-mechanical bending tests, respectively. Furthermore, tribological tests were conducted at room temperature and high temperatures of up to 600 °C to investigate the influence of Mo on the friction coefficient and wear mechanisms.

Paper 2113

Simulation of the homopolymerisation of bismaleimide monomers using tailored reactive Molecular Dynamics

Dr. Leonard Courapied, France

Poster Presentation

Abstract

Even if they were initially developed for the electronic industry, bismaleimide resins are widely used in high-performance composite applications, particularly when high temperature is the primary stress factor. Derived from the polyimide chemistry, bismaleimides resins are easier to process, more affordable, and emit fewer volatiles during their polymerization. Despite many decades of research aimed at evaluating their performance, the various chemical reactions involved in the formation of the polymeric network are not fully understood.

The reactions between bismaleimide monomers – including crosslinking via homopolymerization (1) and linear cyclo-polymerisation (2) - as well as their interactions with diallyl co-monomers through Alder-ene and Diels-Alder1 cyclization reactions, can be thermally or photochemically. However, due to a lack of solid-state analytical methods capable of distinguishing the specific carbon-carbon bonds formed in the cured resin, their respective contributions to the final polymer remain unstudied.

Molecular modeling, and more specifically reactive Molecular Dynamics can be a useful as a valuable tool for identifying the fundamental structure-property relationships in such systems. However, most reactive Molecular Dynamics approaches struggle to accurately describe the relevant reactions, especially concerted mechanisms such as Diels Alder reaction, where reactive groups cannot be easily differentiated using SMARTS notation with simple reaction formula $AB+CD=AC+BD$ proposed most of the time.

This work presents an alternative approach for describing the reactive behavior of a single -component bismaleimide resin, specifically 4,4'-bismaleimidodiphenylmethane (MDAB). The study explores two types of possible reactions, their impact on the polymeric network's topology, and estimates the fundamental properties of extreme simulated systems.

Two MDAB amorphous systems were considered: one consisting of 24600 atoms (600 molecules) and another with of 49200 atoms (1200 molecules). The reaction simulations and predictions of the network's thermomechanical properties were conducted using the Schrödinger Suite program with the OPLS4 force field.

A comparison of between linear MDAB systems with and without cyclic structures shows that the presence of cyclic structures has a minor impact on the mechanical properties when compared to the more significant changes induced by crosslinking. Overall, the simulations highlight emphasize the strong impact of crosslinking on enhancing the mechanical integrity of MDAB polymers, leading to a substantial increase in polymer moduli.

The Microstructure Evolution and Mechanical Response of Cold-Worked and Heat-Treated Heterostructured Materials

Mrs. Yu Han Lin, Taiwan

Poster Presentation

Abstract

Titanium alloys are widely used in aerospace due to their high strength and excellent corrosion resistance. One efficient way to improve the performance of titanium alloys is to increase the strength/specific strength further. Through traditional solid solution strengthening, precipitation strengthening, and fine-grained strengthening, material strength can be increased while sacrificing a certain degree of ductility. Heterostructured (HS) materials can alter their microstructure through heat treatment, forming heterogeneous regions composed of hard and soft zones. When HS materials undergo plastic deformation due to stress, geometrically necessary dislocations (GNDs) accumulate at the boundaries of heterogeneous regions, exhibiting a unique deformation mechanism that achieves both high strength and high ductility. Based on these reasons, this research will adjust the heat treatment parameters of titanium alloys, which introduced GNDs by cyclic loading, to obtain a heterogeneous microstructure composed of different proportions of fine α phase (hard region) and coarse β phase (soft region). And investigate the impact of GNDs density accumulated in various microstructures on their mechanical properties.

Understanding structure and wetting behavior of nickel-based coatings in contact with liquid tin droplet: atomistic simulations vs. experiment

Prof. Marcela Trybula, Poland

Poster Presentation

Abstract

The elimination of lead-based solders from electronics application (EU Directive 2002/95/EC) forced to search for new technological solutions, including alternative solder and coating technologies. Lead-free alloys (the alternative solders) react much faster with Cu substrates due to their high Sn content and increased soldering temperature, resulting in the uncontrolled growth of intermetallic compound (IMC) layers [1]. Ni-based coatings, obtained by electrodeposition and electroless techniques, are used to prevent Cu dissolution and limit excessive IMC growth, acting as diffusion barrier layers between Cu substrates and Sn solder[2,3]. The modification of chemical composition and structure of Ni-based coatings can further enhance coatings' thermal stability, wetting properties and limit the formation of undesired phases at coating/solder interface by slowing down the interfacial reaction rate.

Herein, we provide insight into the structure and wetting behavior of nickel-based coatings in contact with a liquid tin droplet by combining molecular dynamics simulations and sessile drop experiments. The impact of Ni-based coating structures ranging from amorphous to nanocrystalline, on the wetting mechanism of a liquid tin droplet was simulated. The structure, chemical, and phase composition changes of the interface zone formed between coatings and the solder were explored experimentally (using scanning and transmission electron microscopy techniques) and computationally [4,5]. 3D height profile maps were computed and compared with experimental results obtained using a non-contact confocal profilometer and atomic force microscopy techniques.

Plastic deformation in CrMnFeCoNi HEA: Linking 3D EBSD and Molecular Dynamics simulations

Dr. Michał Stróżyk, Poland

Poster Presentation

Abstract

High-entropy alloys (HEAs) are an emerging class of materials known for their outstanding mechanical strength, hardness, resistance to corrosion and irradiation, positioning them as promising candidates for use in extreme operating environments, such as aerospace, future fission (generation IV) and fusion power plants. In this work, the nanomechanical response of a Cantor CrMnFeCoNi HEA is examined through nanoindentation testing and characterized using three-dimensional Electron Backscatter Diffraction (3D EBSD) reconstruction. This advanced technique allows for high-resolution mapping of geometrically necessary dislocation (GND) density and grain reference orientation deviation (GROD) angles around the indent, offering valuable insights into localized deformation characteristics and strain gradients. Molecular dynamics (MD) simulations were used alongside experimental observations to capture atomistic-scale structural responses, showing qualitative agreement with mesoscale experimental results. The combination of 3D EBSD and MD simulations highlights the collaboration between cutting-edge experimental techniques and computational modelling, uncovering the intricate mechanisms of dislocation nucleation and evolution during nanoindentation. This study emphasizes the value of integrating multiscale approaches to enhance our understanding of deformation behaviour in HEAs.

Paper 2019

Electrochemical diagnostics for molten salt corrosion

Ph.D. Maria Elena Gennaro, Italy

Poster Presentation

Abstract

Recently, molten salts have been proposed for numerous applications: as coolants for advanced nuclear fission and fusion reactors, and as thermal vectors for thermal energy transfer. The characterization and understanding of the chemical behavior and mass transport of corrosion products and other solutes in the molten salt is critical for the design, licensing and operation of the various plants. Electrochemical techniques provide a powerful set of tools to investigate these phenomena. In addition, electrochemical techniques provide a direct approach to continuously monitor salt quality during operation, avoiding the need for sampling and subsequent analysis. The present study aims to investigate high temperature electrochemical techniques for the study and monitoring of corrosion in molten salt environments. A further objective is to assess the applicability in field cases of interest and to explore challenges in key areas of the energy transition (e.g. fusion, TES, CCUS). In order to carry out these analyses, an experimental cell for molten salts electrochemistry is proposed that can operate up to 800°C, in controlled environment, with the possibility of gas sweep, gas sampling and analysis. The cell can support a variety of materials and electrode configurations and potentiodynamic sweep, linear polarization resistance and other DC techniques have been applied.

pyiron - Developing and managing materials science workflows

Dr. Tilmann Hickel, Germany

Poster Presentation

Abstract

To support and accelerate the development of simulation workflows in computational materials science, the pyiron Integrated Development Environment (IDE) (<https://pyiron.org>) has been introduced with a focus on FAIR (findable, accessible, interoperable and reusable) workflows. The pyiron IDE covers the whole simulation life cycle in a single software platform and provides both developers of simulation workflows and their users with an intuitive and easy to use Jupyter notebook based interface that shields them from the underlying data and job management. Using a generic input and output format rather than code specific ones allows incompatible simulation codes to directly communicate, e.g., to exchange key quantities such as energies and forces of an atomistic configuration at every timestep of a molecular dynamics trajectory. Further, these simulation workflows can be applied for highthroughput screenings over the whole periodic table. This is enabled by the pyiron job management system, which allows an easy up-scaling from interactive Jupyter notebooks to HPC handling thousands of parallel simulations.

Within this presentation following a short introduction of the fundamental concepts behind the pyiron IDE, the focus will be on the user experience with this platform as the pyiron development is primarily driven by these applications to accelerate Materials Design. Some concepts that turned out to have a particular impact on the usability and gained traction with the pyiron users will be emphasised. This includes the generic interface for atomistic simulation codes, the interactive coupling of simulation codes during their execution, the up-scaling of simulation workflows for high-throughput screenings, and the extendability of pyiron which enables the integration of new simulation codes with minimal overhead. The presentation will end with an outlook on future innovative developments in order to further improve the attractiveness of pyiron for a broad range of users and simulation topics.

Paper 1388

Multi-species diffusion model for hydrogen within actual steel microstructure

Mr. Christian Posch-Peperkorn, Austria

Poster Presentation

Abstract

Properties and integrity of structural materials in service are strongly linked to their microstructure. The microstructure plays a key role in various embrittlement mechanisms, including hydrogen embrittlement (HE), which has drawn much attention in recent years due to a gradual transition to sustainable energy sources. The most common HE mechanisms include hydrogen enhanced decohesion (HEDE) and hydrogen enhanced localized plasticity (HELP), which can be strongly affected by diffusion behavior of H in the presence of other solutes. For instance, HEDE mechanism can be influenced by the reduction of hydrogen concentration at grain boundaries due to the presence of other interstitial elements. Similarly, the HELP mechanism can be affected by the redistribution of hydrogen near crack tips and the occupation of dislocation sites by competing interstitial species.

In this work we investigate the diffusion and trapping behavior of a steel that contains multiple alloying elements that can affect H trapping within the microstructure using a multi-physics finite element method (FEM) approach. Diffusion inside of the bulk of the grains is described by a thermodynamically based model considering the trapping of each species/trapping site pair as well as a stress state. Conversely, the diffusion via interfaces is modelled using a semi-atomistic approach that incorporates atomistic input on the interface properties from density functional theory (DFT) calculations.

Paper 98

Design and properties of novel innovative insulating materials for high-performance motors of electric vehicles

Prof. Takashi Yamashita, Japan

Poster Presentation

Abstract

The development of high-performance electric motors has become increasingly important owing to the paradigm shift in the energy system of mobilities from petroleum to electricity. Electric surge causes a partial discharge between the coil wires in the motors, which causes the breakdown of the insulation material on the coil. Therefore, the development of thermostable insulating materials with high electric discharge resistance is one of the key technologies for the practical application to next-generation electric devices.

We have recently developed a novel composite material, whose electric-discharge-resistant lifetime is 10 thousand times longer than conventional motor coil insulators using boehmite alumina (BA) as the filler.

A recently developed motor coils have complex geometries, which drastically improves the performance, and stability of motors, and allows downsizing of motors. However, performing insulating coating on the novel coil is difficult with the conventional varnish dipping method due to the surface tension of the solution. Electrophoretic deposition (EPD) is a technique that allows a coating without defect. Therefore, the development of polyimide (PI)/BA composite materials with EPD ability is important for high-performance electric vehicles and other electric devices.

We have developed several PI/BA hybrid EPD materials. One example of the hybrid electrodeposition materials of PI and BA was easily prepared by the reprecipitation method to give suspension whose particle size is 120 nm and the zeta potential was +38 mV. The suspension was very stable after long-time standing. The electrodeposition of the material was performed on a copper plate as a cathode by the imposed voltage from 10 V to 250 V. The thickness of the coating layer reached 63 micrometers after 10 min electrodeposition. The Coulomb efficiency, 10% weight loss temperature, and the BA content of the EPD coating were 28 mg/C, 512 °C, and 17%, respectively. The BA content of the EPD coating relatively corresponds to the original BA content in the EPD material. The breakdown voltage was more than 6.6 kV, which was obtained by measuring leakage current increasing the implying voltage by 500 V/s at AC 50 Hz.

The molecular design and properties of other PI/BA EPD materials are also discussed.

Chemical and Thermal Analysis of PLA Degradation and Stability Across Recycling Cycles for 3D Printing

Prof. Isabel Cristina Castellanos, Colombia

Poster Presentation

Abstract

PLA (polylactic acid) is a biodegradable and compostable polymer derived from renewable resources such as corn starch or sugarcane. Its use is particularly relevant in 3D printing due to its versatility and biocompatibility. Currently, pressure on its production is increasing due to the implementation of regulations and restrictions on single-use fossil-based plastics in various countries. However, our project advocates for promoting the reuse of PLA, given its wide potential, in order to avoid the mistakes made with single-use plastics, such as the "use and dispose" mentality. At present, extrusion is the main method employed for its recovery, though the number of reuse cycles remains highly limited.

This study evaluated the chemical changes in recycled PLA products using ATR-IR spectroscopy, as well as the thermal changes through thermogravimetric analysis. Our findings suggest that, beyond structural modifications of the polymer, controlling the loss, stability, and recovery of additives in the recycled material is crucial for improving product quality and optimizing its performance in future applications. Adequate management of these additives will significantly extend the reuse cycles of the material.

Use of cement paste containing foundry wastes as anodes for electrochemical chloride extraction in concrete

Mrs. Nuria Pereira Pinto, Spain

Poster Presentation

Abstract

One of the difficulties involved in the use of reinforced concrete is the corrosion of the embedded bars. The low density of iron oxides compared to the metal state causes internal stresses to be generated in the concrete structure, leading to cracks and potentially causing structural failures, of which many cases have been documented. Ideally, the strong alkalinity of the cement would allow the formation of a passive layer in the rebars, which could avoid the corrosion problem; however, the fact is that this situation is unlikely due to the presence, for example, of chlorides (very common in marine environments). This acidifies the conditions in which the reinforcement is found, accelerating the process of localized corrosion. In order to avoid the degradation of the metal reinforcements, there are two strategies: hindering the advance of chlorides or removing them from the concrete element.

This study focuses on the second point, using electrochemistry to extract chlorides from reinforced concrete elements that have been manufactured with added NaCl. To reduce the concentration of the aggressive ions, a conductive element, an anode, is placed on the surface of the structure to be treated and an electrical potential is subsequently applied. In this way, the chloride ions are forced towards the surface, away from the metal reinforcement, thus reducing the risk of localized corrosion.

In this study, the anodes were made from cement paste to which 6 mm long carbon fibres are added. The anodes also contain between 15-30% of the cement mass of residues obtained from the cast iron foundry industry.

Paper 186

Accelerated Oxidation of Stainless Steels in Heavy-Water Reactor Spent Fuel Pool Accidents

Mr. Taeyun Kwon, South Korea

Poster Presentation

Abstract

Spent nuclear fuel bundles from heavy-water reactors are stored on racks in spent fuel pools at reactor sites after discharge to allow for radioactive decay and cooling. These cylindrical fuel bundles, containing nuclear fuel rods, are arranged in stainless steel racks in a regularly spaced pattern to facilitate effective cooling, ensure radiation shielding, and maintain organized storage. To maximize storage capacity, high-density racks are commonly employed. In the event of coolant leakage, the spent fuel may overheat, causing the surrounding water to boil and create a high-temperature steam environment. Prolonged contact with overheated spent fuel further raises the temperature of the racks, increasing the risk of oxidation. Under these conditions, 304 stainless steel, the primary material used in the racks, is prone to rapid oxidation, potentially compromising its structural integrity. This study investigates the high-temperature oxidation behavior of 304 stainless steel in these accident scenarios.

To simulate the exposure of high-temperature stainless steel to a steam-containing atmosphere, an induction heating method was employed. The stainless steel specimens were heated inside a quartz tube while water vapor, generated by heating water on a hot plate, was continuously injected into the tube. Thermogravimetric analysis (TGA) was performed on STS304 specimens (8 × 20 × 3.5 mm) at temperatures ranging from 800 to 1100 °C for 2 hours. The oxidized specimens were characterized using scanning electron microscopy (SEM), energy-dispersive spectroscopy (EDS), and X-ray diffraction (XRD) to analyze their structure and composition.

The high-temperature oxidation of stainless steels in a steam-containing atmosphere was significantly more severe compared to exposure in a non-steam atmosphere. Furthermore, compared to literature data typically obtained in closed chambers containing steam, this study observed accelerated and more severe oxidation under the simulated accident conditions. SEM/EDS analysis revealed the formation of a bilayer oxide structure, with an Fe-rich outer layer and a Cr-rich inner layer. In water vapor environments, a higher proportion of iron oxide was observed, attributed to the decomposition of chromia into chromium hydroxide, which promotes the formation of iron oxide. This effect intensified at higher temperatures, leading to accelerated oxidation rates. These results demonstrate that high-temperature oxidation in water vapor, as expected during spent fuel pool coolant leakage accidents, significantly undermines the structural integrity of 304 stainless steel, highlighting its susceptibility in such scenarios.

A Combined Experimental and Simulation Approach to Understand Thermal Signatures, Bead Geometry, and Microstructural Changes in Laser-DED of Hastelloy-X

Mr. Malay Masanta, India

Poster Presentation

Abstract

This study investigates how the cooling rate and the melt pool life influence the bead geometry, microstructure, and microhardness of laser-directed energy deposited (DED) Hastelloy-X. The cooling rate as well as the melt pool life data were extracted from the thermal signatures captured by an IR pyrometer during the deposition process at different laser input processing conditions. Additionally, a thermal model was developed using finite element modeling software, incorporating temperature-dependent material properties, a Gaussian heat distribution, and accounting for convective and radiative heat losses, as well as the latent heat of vaporization of the material. The results predicted by this simulation closely matched the captured online thermal signatures of the molten pool. The simulation also provided insights into the remelting of the previously deposited layer during the deposition of the subsequent layer, a phenomenon that is challenging to capture with an IR pyrometer. The microstructure and phases of the deposited Hastelloy-X were examined using a scanning electron microscope and an X-ray diffractometer, respectively. The microstructural analysis revealed that the evolution was closely linked with the molten pool life and the cooling rate, which in turn depends upon the input laser attributes. With an increase in cooling rate and decrease in molten pool life, a modest reduction in grain size was observed. In addition, an increasing trend in microhardness values was detected on account of higher cooling rate. Furthermore, an increase in the melt pool lifetime resulted in an increased bead width, hence compromising the aspect ratio of the bead.

“Hybrid” multi-component alloys: chemical composition optimization to enhance an abrasive wear resistance

Dr. Yuliia Chabak, Slovakia

Poster Presentation

Abstract

The presentation is devoted to the “Three-body abrasion” wear behavior of “hybrid” multi-component alloys which are Fe-B-C alloys containing 5 wt.%W; 5 wt.%Mo; 5 wt.%V; 10 wt.%Cr and 2.5 wt.%Ti. The contents of carbon (0.3 wt.%, 0.7 wt.%, 1.1 wt.%) and boron (1.5 wt.%, 2.5 wt.%, 3.5 wt.%) were varied according to a full factorial design 32 method. The alloys were fabricated by sand-casting. In the as-cast state, the alloys performed near-eutectic (at 1.5 wt.% B) or hypereutectic (at 2.5-3.5 wt.% B) structure. The structural micro-constituents were (in different combinations): (a) (W,Mo,V)-rich borocarbide M₂(B,C)₅ as the coarse primary prismatic or the fibers of “Chinese-Script” eutectic, (b) Ti-rich carboboride M(C,B) of equiaxed shape, (c) Cr-rich carboboride M₇(C,B)₃ as the plates of “Rosette”-like eutectic, (d) Fe-rich borocementite M₃(C,B) as the plates of “Coarse-net” and Ledeburite eutectics. The metallic matrix was ferrite (at 0.3-1.1 wt.%C and 1.5 wt.%B) and “ferrite+pearlite” or martensite (at 0.7-1.1 wt.%C and 2.5-3.5 wt.%B). Bulk hardness varied from 29 HRC (0.3 wt.% C-1.5 wt.% B) to 53.5 HRC (1.1 wt.%C-3.5 wt.%B). The wear test results were mathematically processed and the regression equation of the wear rate as a function of carbon and boron contents was derived and analyzed. At any carbon content, the lowest wear rate was attributed to the alloy with 1.5 wt.% B. Adding 2.5 wt.% B led to an increase in wear rate because of the appearance of coarse primary borocarbides M₂(B,C)₅ which were prone to chipping under abrasion. At higher boron content (3.5 wt.%) wear rate decreased due to increasing the amount of the eutectic carboborides. The optimal chemical composition was found as 1.1 wt.%C-1.5 wt.% B with a near-eutectic structure having total 35 vol.% of carboborides (M₂(B,C)₅, M(C,B), M₃(C,B) and M₇(C,B)₃). The heat treatment (quenching and low-temperature tempering) resulted in a substantial increase in hardness and wear resistance. As the quenching temperature increased to 1150-1200 °C, hardness gradually increased to 66-67 HRC while the wear rate decreased by 3-6 times as compared to the as-cast state. The highest abrasive resistance was attributed to the alloys with 1.1 wt.% C which had a 2.36-3.20 times lower wear rate as compared with reference alloy (13 wt.% Cr cast iron, 66 HRC). The effects of carbon and boron on hardness and wear behaviour are analyzed using the regression models developed according to the factorial design procedure.

Defects in glass to metal bonds of electric terminals for hermetic seals

Mrs. Julia Puntigam, Austria

Poster Presentation

Abstract

Electric connectors are of fundamental importance for the long-term impermeability of hermetic seals. These connectors, made from glass and metal, function as electric terminals, guaranteeing power supply to the vessel's interior while ensuring a gas-tight enclosure. However, glass to metal bonding presents challenges because of dissimilar material characteristics, such as different melting temperatures, thermal expansion, and ductility. Time consuming, non-destructive tests (He-leak tests) in the manufacturing line expose a certain batch-dependent failure rate in a late stage of production. This study aims to investigate the root cause of the defects in the joint area of hermetic seals to optimize the production process and minimize waste. Separately, we inspected the quality of the incoming hermetic seal and its alteration during production. Micro-computed tomography tests reveal spherical cavities in the glass body and cracks along the glass-metal interface. During installation and subsequent assembly, significant temperature differences caused by the welding processes lead to thermal strain in the geometry close to the seal, causing crack initiation or growth in the glass body. Temperature measurements during the welding process quantify the acting thermal gradient. These data are used to validate a FEM model (Simufact Welding) which can subsequently aid in the welding procedure to minimize the load on the glass-metal interface. Based on the gained knowledge process optimizations preventing defects in the electrical terminals of hermetic seals ensure high quality and long-lasting products.

High-Throughput Screening of Precipitates in Al-Cu Alloys Using Compound Big Data for Aerospace Applications

Lic. Seoyeon Jeon, South Korea

Poster Presentation

Abstract

Aluminum alloys are widely used in aerospace applications due to their exceptional strength-to-weight ratio, corrosion resistance, and favorable thermal and electrical conductivity. Although high-strength aluminum alloys, including Al-Cu, Al-Si-Mg, and Al-Zn-Mg systems, have been extensively developed and applied in aerospace structures, their performance in space environments is often limited by precipitation-related challenges such as precipitation instability under prolonged thermal exposure. To overcome these limitations, there is a growing need for the discovery of entirely new precipitation-strengthening phases that can form in aluminum alloys while maintaining structural stability in space environments. Traditional alloy design approaches rely heavily on empirical trial-and-error methods, which are time-consuming and resource-intensive. To accelerate this process, we propose a novel high-throughput screening methodology utilizing materials big database to identify new precipitates that can form in aluminum matrices while effectively enhancing mechanical properties. By leveraging computational databases and predictive modeling, this approach enables the discovery of stable, high-performance precipitates, paving the way for the next generation of aerospace-grade aluminum alloys. Our analysis suggests that Al-Cu precipitates containing Lanthanum (La) or Strontium (Sr) may effectively enhance the strength of aluminum while also exhibiting high stability. To validate this further, we fabricated Al-Cu-La and Al-Cu-Sr alloys using casting and extrusion methods. Through differential scanning calorimeter (DSC) analysis, we explored the heat treatment profile for optimizing the formation of the desired precipitates. We will present the correlation between precipitate formation and mechanical properties under various heat treatment conditions.

Comparative Analysis of NiTi SMAs Powder Produced via Ultrasonic Atomization: Virgin Powder vs. Re-Powder from 3D Printed Parts

Prof. Mohammad Elahinia, United States

Poster Presentation

Abstract

The selection and management of feedstock have become increasingly critical to the economic efficacy of the entire process as additive manufacturing (AM) technologies have advanced at a rapid rate. The repurposing of discarded powders and scrap printed parts is of considerable industrial interest because of the recycle, particularly as the adoption of 3D printing continues to grow. In this study, the feasibility of recycling scrap NiTi shape memory alloy (SMA) parts that were produced through laser powder bed fusion (LPBF) has been examined in order to optimize material utilization and decrease expenses. The scrap parts were remelted using the ultrasonic atomization Re-Powder Amazemet machine, and fine, homogeneous powders with particle sizes below 75 μm were produced using an ultrasonic sonotrode operating at 20 kHz, which is appropriate for LPBF applications. Carbon and oxygen contamination were monitored and controlled at all stages of the process, from the initial feedstock to the melted ingot and final powder, to guarantee process integrity, in accordance with ASTM F3049 standard. The final powder exhibited properties that were analogous to the initial feed material, as evidenced by detailed analyses of the powder, including microstructural characterization, martensite-to-austenite transformation hysteresis, and chemical composition. These findings underscore the potential of ultrasonic atomization to facilitate the efficient recycling of waste, providing a promising solution to improve the economic and sustainable viability of AM processes.

Inkjet printing of PVDF-TrFE thin films: influence of solvent and annealing conditions on piezoelectric properties

Mrs. Giulia Mecca, Italy

Poster Presentation

Abstract

Among organic piezoelectric materials, poly(vinylidene fluoride-co-trifluoroethylene) (PVDF-TrFE) is a highly versatile polymer that, beside high piezoelectric and ferroelectric properties, also presents high biocompatibility, chemical resistance and thermal stability [1]. Moreover, its ability to be deposited in the form of thin films via advanced manufacturing techniques like Inkjet Printing (IJP) makes it even more suitable for the next generation of flexible sensors and energy harvesters [2]. Indeed, IJP is based on the controlled deposition of droplets of an ink containing the material of interest and this approach is characterized by intrinsic properties of customizability, scalability, and cost-effectiveness.

The use of IJP, however, implies the use of fluid inks, where PVDF-TrFE is dissolved in suitable solvents. On this note, it is important to analyze and understand how solvents, necessary for the printing process, affect ink's printability and piezoelectric properties. In fact, PVDF-TrFE gains its piezoelectric properties thanks to a specific crystalline phase, called β -phase, whose formation can be favored or suppressed by some organic solvents and by annealing the layer after the printing process [3].

The present work aims at studying and comparing, for the first time, how different solvents affect the printability, the β -phase content and the polarizability of PVDF-TrFE thin layers obtained via IJP. Additionally, this work aims at determining if the annealing process can be avoided, by selecting a proper solvent, without loss of performance, further reducing time and costs of productions. To these aims, test samples are produced by inkjet printing silver electrodes and thin PVDF-TrFE-based active layers on Kapton as substrate. The active layers are printed using four different inks, containing the same amount of PVDF-TrFE dissolved in four different solvents and solvents' combinations: Dimethyl Sulfoxide and Methyl Ethyl Ketone (DMSO/MEK with 70/30%wt.), Dimethyl Sulfoxide (DMSO), Cyclopentanone (CP), and N,N-Dimethylformamide (NN-DMF). Following the printing process, samples are analyzed exploiting a special combination of Raman analysis and Piezoelectric Force Microscopy (PFM), first to assess the β -phase content present in each sample and then to assess its polarizability.

APPLICATION OF 3D PRINTING TECHNOLOGY TO CERAMIC WASTE RECYCLING

Mr. Jose Carlos Rebollo-Alburquerque, Spain

Poster Presentation

Abstract

In a context of industrial transformation, additive manufacturing or 3D printing has established itself as a key technology within Industry 4.0, with particular interest in areas such as civil engineering and the biomedical sector. However, the availability of raw materials remains a challenge. In this regard, the use of waste as a source of materials represents a sustainable and highly relevant alternative. Unlike polymer-based 3D printing, which is well studied, the printing of ceramic and metallic materials, especially those derived from waste, still presents significant challenges and research opportunities. This study focuses on the fabrication of ceramic parts through 3D printing, using industrial waste. Additionally, organic waste will be employed as plasticizers to improve material consolidation and extrusion. The research will address the formulation of suitable mixtures for 3D printing, considering the necessary rheology and plasticity for optimal part manufacturing. Key process variables will be analyzed, such as extrusion speed, material deposition thickness, and the influence of different binder and ceramic waste combinations. Subsequently, the printed parts will be sintered and characterized to evaluate their physical properties, such as porosity and density. This investigation aims to contribute to the development of new solutions in additive manufacturing, promoting the valorization of industrial waste and sustainability in the production of ceramic materials.

Development and enhancement of a physics-based mean-field creep model for martensitic 9-12% Cr steels with application to Grade 91

Mrs. Laura Witzmann, Austria

Poster Presentation

Abstract

"Creep deformation poses a significant challenge to the durability of components in high-temperature applications, with martensitic 9% Cr steels, such as Grade 91 (9Cr-1Mo), serving as a widely used standard material in industry due to its excellent high-temperature strength, manufacturability, and creep resistance. At our institute, a physics-based mean-field creep model was developed based on data for pipe material P91 at 650°C under a constant stress of 70 MPa. This model was subsequently extended to other martensitic 9-12% Cr steels, including pipe material P92 (9Cr-2W-Mo), rotor material FB2 (9Cr-1Mo-1Co), and another novel Cr steel, resulting in further optimization, enhancement, and validation of its predictive capabilities. These advancements are now being specifically adapted for P91, including a refined description of diffusion mechanisms and an improved model for Zener pinning, which increases the accuracy of simulated subgrain coarsening. Precipitate data stem from re-evaluated thermo-kinetic simulations in software MatCalc. Additionally, the model is being extended to simulate creep behaviour at temperatures below 650°C, as these are more relevant for practical applications compared to higher temperatures. The enhanced model enables accurate predictions of creep curves, microstructural evolution, and time-to-rupture behaviour, demonstrating excellent agreement with experimental data. This framework not only advances the understanding of creep mechanisms in P91 and related steels but also serves as a powerful tool for optimizing high-temperature materials and supporting material design in both research and industrial applications. Implementation of the model into the developed creep behaviour software CreeSo is planned.

Laser Surface Texturing of Titanium-Based Implant Alloys

Prof. Tamara Holjevac Grgurić, Croatia

Poster Presentation

Abstract

Titanium alloys are widely used as implant materials, due to their excellent biocompatibility, and good mechanical and corrosion properties. Titanium implants primarily serve as mechanical support, and are bio-inert, lacking antibacterial properties. Bacterial infections are a major cause of implant failure and surgical revisions. Therefore, the focus of research is on infection prevention, which has made infection prevention a key focus of research. The challenge lies in modifying the implant surface to enhance antibacterial properties without affecting the bulk material.

The aim of this study is to examine the impact of laser surface alloying of Ti6Al4V alloy with copper on the microstructure, phase transformations, hardness, mechanical, corrosion, and antibacterial properties of the material. Thermodynamic modeling was performed using Thermo-Calc software based on CALPHAD method, and phase stability in equilibrium conditions was determined. Surface microstructure and distribution of Ti2Cu phase were analyzed by Optical Microscopy and Scanning Electron Microscopy (SEM), equipped with an energy dispersive X-ray spectroscopy (EDS) detector. Identification of phases was carried out by X-ray Diffraction analysis (XRD), while phase transformations were detected by Differential Scanning Calorimetry (DSC). A correlation between laser beam optimization and hardness, corrosion, and antibacterial effectiveness was established.

Paper 961

A semi-industrial prototype bearing ceramic materials for Carbon Capture and Storage

Dr. Mónica Viciano, Spain

Poster Presentation

Abstract

In order to meet the European Union's CO₂ targets, CO₂ capture and storage (CCS) as well as CO₂ capture and utilization (CCU) techniques are being implemented for the industry. Moreover, to overcome the new challenges in the industry decarbonization, the study of mineralization and thermal catalytic hydrogenation processes are required unless these technologies are mature today. These mature technologies need the development of pilot plants for the specific industrial processes.

Herein, we will describe the results obtained within the construction of a prototype for CO₂ capture from industrial streams. This prototype is based on different sorbent materials including a modified ceramic material revalorized from industrial wastes. These novel materials are characterized, formulated and tested in the semi-industrial pilot plant, to study their capacity of carbon capture and storage. Moreover, the reactivation or regeneration of the spent materials are studied and evaluated.

Texture Evolution in Transforming and Twinning Materials: A Comparison of Neutron Diffraction and MTEX-Based Simulations

Ph.D. Jan Čapek, Czech Republic

Poster Presentation

Abstract

The evolution of crystallographic texture during deformation plays a crucial role in defining the mechanical properties of materials, particularly those undergoing phase transformations or twinning. This study compares neutron diffraction experiments with MTEX simulations to analyze texture development under mechanical loading. By correlating experimental and simulated texture evolution, we assess the accuracy of modeling approaches in capturing grain reorientation, variant selection, and twinning behavior. The results provide insights into the microstructural mechanisms governing deformation in complex materials and highlight the predictive capabilities of computational methods.

A comparative study of the effect of the active phase (Rh, Ru, Ir and Ni) and catalyst support on CO₂ methanation reaction

Prof. Ioannis Yentekakis, Greece

Poster Presentation

Abstract

The rapid increase in atmospheric CO₂ levels, due to our continued dependence on fossil fuels (coal, oil and natural gas) for energy production, which intensifies the greenhouse effect and accelerates climate change, imposes the urgent need to review our energy strategies. The global community is now moving in a coordinated manner towards the so-called "energy transition" and the reduction of CO₂ emissions. The capture and reuse of emitted CO₂, in the sense of recycling it by converting it into fuels (e.g. methane, methanol), is currently receiving significant research and technological interest. In this work, we study the catalytic performance on CO₂ methanation reaction of the noble metals ruthenium (Ru), rhodium (Rh) and iridium (Ir) compared to that of nickel (Ni). These active metals are supported on various metal oxide supports, namely γ -Al₂O₃ (AL), Al₂O₃-CeO₂-ZrO₂ (ACZ), and CeO₂-ZrO₂ (CZ), which exhibit different values of labile lattice oxygen (oxygen storage capacity, OSC), a factor critical for enhancing redox reactions. Our goal is to comparatively evaluate the effectiveness of the various active metal phases in the reaction, but also how the properties of the various supports used affect the catalytic behavior through metal-support interactions. Our findings revealed a clear ranking in the catalytic performance of the active phases, as Ru > Rh > ~ Ni > Ir, regardless of the supports on which they were dispersed. Furthermore, we observed a significant, but not monotonic, effect of the oxygen storage capacity of the support on the CO₂ methanation performance. Interestingly, supports that possess an intermediate oxygen storage capacity, such as ACZ, demonstrated optimal enhancement of the active phase for CO₂ methanation. These insights emphasize the importance of catalyst support properties in the design of efficient methanation catalysts. By carefully tailoring the OSC of the support, metal-support interactions can be optimized and, consequently, the catalytic performance.

Europium-based 3D structures fabricated via Multiphoton Lithography for increase of Photoluminescence in optical frequencies

Mr. Savvas Papamakarios, Greece

Poster Presentation

Abstract

Recent advances in material science's field have revealed high potential in development of novel applications using high photoluminescent materials. One of this very interesting materials is Europium (Eu), which has shown interesting properties in the optical frequencies. Motivated by the high photoluminescence that Eu shows, here we present a fabrication method using Multiphoton Lithography (MPL) focusing on ultra-fast LEDs and nano lasers using all-dielectric devices.

MPL is a 3D fabrication process relying on direct laser writing using ultrafast laser sources and suitable photosensitive materials which offers a few tens of nm resolution for rapid 2D and 3D printing with a layer-by-layer approach. For the purposes of our research, Europium(III) acetate hydrate is processed in Europium methacrylate (EuMAA) diluting it in methacrylic acid to achieve Ligand exchange. Then, EuMAA is incorporated in our in-house hybrid material, SZ2080, well known for its chemical, mechanical and optical properties. This Zr-based material enables the fabrication of 3D structures with high resolution using MPL, and due to the chemical stability, it can host different luminescent ions. Different concentrations of EuMAA were tested to achieve the maximum increase of photoluminescence with the lowest fabrication defects.

The final hybrid materials are processed using MPL, to create 3D structures, with two different excitation sources. One using a fiber green laser (515 nm) and the other using a fiber IR laser (780 nm).

The processed samples undergo through calcination process at different temperatures in order to remove the organic part and activate Eu to exhibit high photoluminescence in 3D structures with micro and nanoscale size. The samples then, are characterized using Micro- photoluminescence spectroscopy with different excitation wavelengths.

Using specific 2D and 3D geometries, known as metamaterials, photoluminescence can rise even more and potentially be used in photonic devices, such as in the development of all-dielectric LEDs, lasers, and single photon emitters.

Paper 1431

The influence of copper on the distribution and trapping of hydrogen in steels

Mr. Philipp Hammer, Austria

Poster Presentation

Abstract

Copper (Cu) plays a dual role in steel production: it is a tramp element that poses challenges during processing due to its difficulty in removal, yet it is also intentionally added to certain steel grades, particularly in shipbuilding and offshore industries, to enhance corrosion resistance and hardening through Cu precipitation. The shift towards electric arc furnace (EAF) steelmaking and increased recycling rates are expected to raise the levels of tramp elements in future steel products. Cu precipitates, which transition through various phases and interface types with the iron matrix, not only contribute to hardening but also show potential in mitigating hydrogen embrittlement, although isolating their specific effects remains challenging.

In this study, we investigate the role of Cu segregation and Cu precipitates, in particular the influence of their morphology (bcc, 9R, fcc) on the hydrogen trapping strength of Cu interfaces with bcc iron (Fe) at the atomistic level with the aid of density functional theory (DFT) calculations. Furthermore, we subsequently use the calculated hydrogen trapping energies as an input to a thermodynamic hydrogen trapping model based on the Oriani equation in order to investigate the hydrogen distribution in a model steel microstructure. A model investigation of hydrogen uptake at Cu precipitates as a function of their shape and volume fraction provides a conclusion about their role in hydrogen embrittlement.

Development of Doxorubicin Selective Electrochemical Sensors based on Surfactant-Modified ZnO-Nanoparticles

Mrs. Katarina Aleksić, Serbia

Poster Presentation

Abstract

Electrochemical sensors (ECS) are powerful tools for detecting water pollutants due to their high sensitivity, selectivity, rapid response, and portability. Their performance can be significantly enhanced by modifying bare electrodes with functional materials, such as noble metals, metal oxides, polymers, and carbon-based compounds.

In this study, ZnO-based materials were synthesized and applied as electrode modifiers for the electrochemical detection of doxorubicin (DOX), an anticancer drug that poses environmental and health risks due to its toxicity and accumulation in water systems. ZnO particles, were synthesized in the presence of two different surfactants - cetyltrimethylammonium bromide (CTAB, $C_{19}H_{42}BrN$, Alfa Aesar, Ward Hill, MA, USA) as a cationic, and triblock copolymer Pluronic® F127 ($EO_{106}PO_{70}EO_{106}$, Sigma-Aldrich) as a nonionic surfactant, using a microwave processing of a $Zn(OH)_2$ precipitate. The synthesized materials were characterized using XRD, Raman, FESEM, UV-Vis DRS, and PL spectroscopy to comprehend their crystal structure, morphology and optical properties, and finally to correlate their physicochemical properties with electrochemical activity for detection of DOX as a pollutant in water.

Cyclic voltammetry (CV) was employed to quantify DOX using three types of screen-printed electrodes: Au, Pt, and C. The working ink for screen-printed electrodes modifying was prepared by mixing 10 mg of ZnO materials with 1.5 mg carbon black, 40 μ L of 5% Nafion solution, 225 μ L ethanol, and 225 μ L water. CV was performed in 25 mL of phosphate buffer (0.1 M, pH = 7.0) with the addition of doxorubicin infusion solution (Ebewe Pharma, 50 mg DOX / 25 mL) in a portion of 10 μ L to completely 160 μ L. All measurements were done in a potential window of -0.4 – 0.6 V at a scan rate of 50 mV/s. SiZY-Coat: Silicon-Zirconium-Yttrium coatings for graphitic materials

Mr. Filip Kateusz, Poland

Poster Presentation

Abstract

Major disadvantage of carbon-matrix composites is their susceptibility to oxidation, which can occur at temperatures above 400°C in atmospheric air. Therefore, for applications in oxidising environments, it is standard practice to deposit oxidation-resistant SiC coating or to convert carbon matrix into a carbide material following the reactive melt infiltration (RMI) approach with pure Si. Despite its well-established position, described technology is not without its drawbacks. These include a decrease in the protective values of the SiC-coating over time or a significant increase in the density of the composite by converting carbon into SiC.

In this paper we present the ambition of the "SiZY-Coat" project, which is to explore the feasibility of synthesising a new type of multiphase protective coating that conditions oxidation resistance at high temperatures while maintaining an attractive low density of the starting material. The coating is obtained by RMI of porous graphitic material surfaces with eutectic Si-10Zr alloy in the presence of Y₂O₃ nanopowders. This approach provides an opportunity to study numerous high temperature phenomena occurring during the process, such as the influence of surface roughness on wetting kinetics or the adopted process parameters on the oxidation resistance of the coatings. The preliminary results presented facilitate the wider application of RMI methods for the production of advanced oxidation resistant coatings for carbon based materials.

BATCycle: green chemistry for recycling Li-ion NMC-111 Cathode material.

Mrs. Marta Revello, Germany

Poster Presentation

Abstract

Lithium-ion batteries (LIBs) are one of the most common batteries used in Electric Vehicles (EVs) due to high energy and power density and longer-life span. Alongside EVs increased production, the demand for LIBs has risen as well. For metal recovery from LIBs, end-of-life is the most used feedstock in the recycling industry, nonetheless rejected scrap from production of cathodes is also a high source of material. Production waste rates of LIBs are reported to be approximately 5% to 30%, which may vary with manufacturers.

Among LIB chemistries, Nickel Manganese Cobalt (NMC) cathodes are preferred for applications that require continuous cycling. Considering their high concentrations of critical materials, such as Cobalt and Lithium, NMC recycling is crucial. [3] Electrochemical recycling of LIBs, due to its selective metal recovery, is a growing interested in recycling companies. However, because of NMC complex chemical composition the recovery rate of high purity metals from electrochemical processes is limited. [4]

This study proposes a green chemistry approach for recycling of NMC-111 production waste. A pretreatment has already been design. A treatment to selectively recover all critical materials that compose the active material are then tested and studied. Using only methanesulfonic acid as electrolyte, and NaOH for precipitation, to recover metal oxide compounds from the active material in multiple stages of the process at room temperature. The study also presents the use of a drum electrode setup as the working electrode, which increases the dissolution kinetics of the material in the electrochemical cell.

Paper 353

Investigation of the impact of reducing the albedo of the coloured wall tiles of an Italian building heritage of the Second Twentieth Century for sustainable restoration purposes

Dr. Davide Casotti, Italy

Poster Presentation

Abstract

Restoring Italy's mid-20th century architectural heritage involves addressing the increasing demand for summer cooling, which has outpaced winter heating needs since the early 2000s. A promising solution is the renovation with solar reflective (SR) materials that can lower air temperatures and reduce reliance on air conditioning. However, it is essential that the renovation process respects the architectural and stylistic characteristics that define these structures by preserving their appearance and chemical-physical properties.

Inkjet-printed colored ceramic wall tiles are excellent materials for this purpose, as they can achieve solar reflectance (SR) properties by using appropriate engobe formulations and special infrared (IR)-reflective inks, often referred to as cool materials. Furthermore, tile production allows for the incorporation of secondary raw materials (SRMs) thereby reducing the environmental impact of the tiles and contributing to sustainable urban regeneration.

This study aimed to develop cool colored wall tiles that could potentially be applied to renovate an Italian building representative of the mid-20th century, specifically Bologna's former Library Pelagalli. Particularly, we investigated several engobe formulations with the highest possible SR value while ensuring that it contains at least 30 wt. % of SRMs. A selected formulation was then used to prepare inkjet-colored cool wall tiles featuring industrial IR-reflective inks. The thermal, physical and optical properties of such tiles were then used to perform a microclimate and fluid dynamics analysis during a day characterized by a heat wave (hypothetical ex-post). The same analysis was also performed with the properties of the conventional tiles currently placed in the building (ex-ante).

The preparation of the SR engobe was studied by examining several SRMs. We investigated the thermal (emissivity, specific heat, thermal conductivity), aesthetic (colour, gloss), physical (density), and optical properties (absorption, solar reflectance) of the tiles after firing at 1205 °C in a 50-minute cold-to-cold industrial firing cycle. It was discovered that an engobe formulation containing 33 wt.% of SRM allows the production of coloured cool tiles, which have solar reflectance (SR) values that are 7% to 90% higher than those of the original coloured tiles currently from the Bologna's building.

The change in albedo can affect the thermal conditions of the representative building. To analyse this effect, the properties of the developed cool-coloured tiles were input into ENVI-met software for a microclimate and fluid dynamics analysis. The results indicate that using these tiles can contribute to the sustainable urban regeneration of buildings from the second half of the twentieth century.

Half-Heusler thermoelectrics based on $\text{TiFe}_{0.5}\text{Ni}_{0.5}\text{Sb}$ compounds synthesized via mechanical alloying

Dr. Panagiotis Mangelis, Cyprus

Poster Presentation

Abstract

Thermoelectric materials with high power factor PF like half-Heusler need optimization in the scattering processes within the material by decoupling the transport phonons and electrons to achieve a better thermoelectric performance. Adjusting dopant concentrations to optimize the carrier concentration and density of states effective mass is one know way to achieve better performance. The other suitable option is to modulate the microstructure and point defects of the material via methods like annealing, thus improving the thermoelectric performance due to the weak electron-acoustic phonon interaction by selective defect reduction. One suitable candidate for investigation is $\text{TiFe}_{0.5}\text{Ni}_{0.5}\text{Sb}$ -based half-Heusler compounds that have an adjustable band structure and intrinsic low thermal conductivity.

This work focuses on the synthesis and characterization of $\text{TiFe}_{0.5}\text{Co}_{0.15}\text{Ni}_{0.35}\text{Sb}$ compounds synthesized via mechanical alloying using a ball milling process. The material characterization included XRD, SEM and EDS analysis and it was done using samples made by hot-press sintering.

Paper 796

Stress relaxation and analysis of activation volumes in 9% Cr-steel: insights into dislocation glide

Dr. Florian Riedlsperger, Austria

Poster Presentation

Abstract

This work investigates the stress relaxation behavior of martensitic 9% Cr steel P91, a material of key interest in high-temperature applications. We focus on determining the activation volume, a critical parameter for calculating the glide velocity of mobile dislocations. To achieve this, data from repeated stress relaxation tests were analyzed, obtained from experiments in a deformation dilatometer at 650°C under a compressive stress of 200 MPa. The established logarithmic relaxation law was compared to a new analytical solution, derived by combining the Orowan equation with Hooke's law. This new approach, which accounts for the material's microstructural condition, provides a potential improvement over traditional methods. In the new method, the activation volume is found to depend on the dislocation density. This characteristic was determined using transmission electron microscopy (TEM) for different relaxation conditions. Additionally, synchrotron data from the same samples were complementarily evaluated using a modified Williamson-Hall approach. The findings contribute to the calibration of the dislocation glide velocity and are essential for improving the predictive accuracy of mean-field creep models in the primary creep regime. The close relationship between relaxation and creep behavior is also discussed, offering insights that could enhance the performance and longevity of high-temperature materials.

Positron Annihilation Spectroscopy: Unlocking Atomic Insights for Next-Gen Energy Materials

Dr. Eric Hirschmann, Germany

Poster Presentation

Abstract

We introduce the Positron Research Infrastructure (pELBE) at the ELBE linear accelerator, hosted at HZDR, as part of the ReMade@ARI (REcyclable MAterials DEvelopment at Analytical Research Infrastructures) project under the Horizon Europe program. [1]

Positrons, as the anti-particles of electrons, provide a highly sensitive, non-destructive probe for detecting defects at low concentrations in a wide range of materials, including metals, semiconductors, polymers, and porous materials.

pELBE offers a wide range of advanced positron annihilation spectroscopy techniques for the precise characterization of point and extended defects, their agglomerations, and nano-, micro- and mesoporous systems, both with interconnected and isolated pore structures.

This method is used to understand key properties of advanced materials at the atomic level, such as: identifying defect structures in carbon-capture materials like MOFs to enhance their efficiency, optimizing free volume in bio-based polymer membranes, investigation of fatigue in polymeric materials, or determining pore size distribution in nanofiltration membranes designed for sustainable resource recovery and circular economy applications.

The established role of positron annihilation spectroscopy in materials research makes it a powerful tool for material innovation.

Paper 481

Characterization of Oxidized Alginate-Gelatin Nanocomposite Hydrogels Incorporating MXene Nanosheets for 3D Bioprinting

Mrs. Lisa Schöbel, Germany

Poster Presentation

Abstract

Hydrogels are highly promising materials for tissue engineering applications due to their high water content and ability to fabricate individualized three-dimensional (3D) scaffolds. To further enhance their functionality, hydrogels can be combined with conductive materials, creating electrically conductive hydrogels (ECHs) that can mimic the electrical microenvironment of bone tissue. Such properties can promote osteoblast attachment, proliferation, and differentiation, ultimately driving bone tissue regeneration.

In this study, an oxidized alginate-gelatin (ADA-GEL) hydrogel was modified with MXene, an electrically conductive and osteogenic two-dimensional (2D) nanomaterial, to produce degradable and 3D printable nanocomposite hydrogels. We comprehensively investigated the influence of MXene concentration on the hydrogels' morphology, mechanical and electrical properties, 3D printability as well as swelling and degradation behavior. Additionally, cell-material interactions were evaluated in both 2D and 3D cell culture models using MG-63 osteoblast-like cells.

The results demonstrated that the hydrogel properties could be tailored by adjusting the MXene concentration, allowing the creation of a library of ADA-GEL-MXene nanocomposite hydrogels. Scanning electron microscopy and micro-CT imaging were performed to detect the MXene particles embedded in the hydrogel matrix. While the mechanical properties remained consistent across different hydrogel formulations, the electrical conductivity increased with higher MXene loading. Furthermore, all formulations supported 3D printing of grid-like scaffolds up to 10 layers. Moreover, the incorporation of MXene nanosheets improved the osteogenic differentiation compared to the pristine hydrogel, as evidenced by alkaline phosphatase staining. However, a critical MXene concentration threshold was identified above which cell behavior was compromised.

In conclusion, optimizing the MXene concentration is crucial to balancing mechanical strength, electrical conductivity, and biocompatibility. Nevertheless, the developed ADA-GEL-MXene hydrogels show great potential for 3D bioprinting and bone tissue engineering, with the additional possibility of applying electrical stimulation in future studies to enhance bone regeneration.

New Thermal Barrier Coatings with Polymer Derived Ceramic Bond Coats for TiAl alloys

Mrs. Gabriela Ryczek, Poland

Poster Presentation

Abstract

Current state-of-the-art materials for blades in jet turbine engines are monocrystalline nickel-based superalloys. For application in the hot section, they are coated with thermal barrier coatings (TBCs) made of an outer layer of zirconium oxide stabilised with yttrium oxide (YSZ) with a thickness of 100-300 μm . An inner layer (bond coat) based on a diffusion aluminide layer or a metallic interlayer of MCrAlY (M=metal) with a thickness of approx. 80 μm is applied below the TBC and additionally protects the turbine blade from oxidation. TiAl alloys represent a very interesting alternative for the lower temperature section of the jet engine with a much lower density than Ni (3.7-3.9 vs. 8.0-8.7 g/cm³) and are already used in the cold section of some jet engine turbines. Application of a TBC could allow the use of TiAl turbine blades at higher temperatures. However, when combining TBCs and TiAl alloys, a compatibility problem with the bonding layer (MCrAlY) arises due to the formation of brittle phases at the interface.

To address this the application of TBCs on the Ti48Al2Cr2Nb (4822) alloy with a bond coat based on polymer-derived ceramic coatings from the SiAlOC system are being explored for higher temperature applications. SiAlOC coatings were already shown to improve the corrosion resistance of 4822 [1]. TBCs of YSZ were obtained at several different temperatures using an EB-PVD process. SEM and EDS microstructural studies along with advanced structural studies using Raman confocal imaging showed that using a hollow cathode (HC) plasma in the EB-PVD process formed columnar ceramic coatings successfully at temperatures up to 200°C lower than typical, while still meeting the requirements for TBC applications. The TiAl specimens with a SiAlOC bond coat and EB-PVD TBC were oxidized in lab air for up to 800 h. Metallographic cross-sections were prepared to study the impact of oxidation and the overall adhesion of the coatings.

Characterization of antifouling efficiency, mechanical and chemical properties of polydimethylsiloxan Fouling Release coatings

Mrs. Erica Tubaro, Italy

Poster Presentation

Abstract

The increasing demand for sustainable marine coatings has driven research toward non-toxic solutions for protecting bronze propellers from biofouling and corrosion. Conventional biocidal antifouling systems, while effective in reducing microbial adhesion, are subject to stringent environmental regulations due to their ecological impact. As a result, silicone-based fouling-release coatings have emerged as a promising alternative. However, these systems often suffer from suboptimal mechanical properties and adhesion issues, leading to detachment over time. Additionally, their long-term antifouling performance requires further optimization to match that of traditional antifouling coatings.

This study evaluates the performance of environmentally friendly fouling-release coatings, with a particular focus on the role of polydimethylsiloxane (PDMS)-modified topcoats in enhancing biofouling release while maintaining adequate mechanical properties. The research explores key formulation parameters of the silicone topcoat, including the influence of catalysts, silicone oils, and functional additives. A comprehensive characterization approach is adopted, involving scratch testing, profilometry, protein adhesion and toxicity assessments, crosslinking density evaluation, and in situ monitoring of biofouling growth on immersed coated panels. Additionally, Fourier-transform infrared spectroscopy (FTIR) and scanning electron microscopy (SEM) are employed to analyze the structural and chemical characteristics of the coatings. The findings provide valuable insights into the development of high-performance fouling-release coatings with improved durability and antifouling efficiency.

High-temperature interactions of amorphous alloys TiCuZrPd with a Kovar substrate

Prof. Anna Sypien, Poland

Poster Presentation

Abstract

Modern industrial applications require joining of heterogeneous materials without increasing weight, particularly in the sectors of transportation, aerospace, and automotive industry where enhanced mechanical and thermal properties are essential. In particular, the rapidly developing space sector imposes specific requirements and exhibits significant interest in joining dissimilar materials, especially in applications where monolithic structural components are replaced by chemically and structurally complex materials. The most promising method for achieving durable joints is high-temperature brazing, which enables bonding without melting the base metal, thereby preserving its initial structure and properties, provided that a properly selected brazing filler and optimized temperature-time parameters are used in the joining process.

Consequently, the research on the welding of dissimilar materials was conducted, focusing on the analysis of physicochemical phenomena occurring at the solder/substrate interface. High-temperature joining of FeNiCo alloy was investigated using amorphous TiCuZrPd solder with varying palladium and tin content. The commercial Kovar alloy (4J29) was used as the substrate. Wettability tests showed that for the solder alloys indicated as Pd-10 and Pd-14, the wetting angle was about 47°, while for Pd-20 and Sn-2, it was around 87°. Despite the limited wettability, durable and homogeneous joints were obtained without defects such as separation, cracking, or discontinuities in the intermetallic layer. At the substrate-solder interface, a reaction zone was formed, consisting of two intermetallic layers: Fe₂Ti (IMC1) and Ti₂Cu/CuTi (IMC2), resulting from the diffusion of elements between the filler metal and the substrate. The least favorable properties were observed for joints with Pd-14 solder. DSC analysis revealed that the solder material retains its glassy properties under rapid heating during the high-temperature joining process, passing through a supercooled liquid phase with high deformability typical of metallic glasses, enabling precise adaptation to the joint geometry. TMA analysis indicated a linear volume change of the system during heating, up to the point of the increased plastic deformation under the stress. Structural cross-sectional studies confirmed the formation of a reaction IMC zone on both edges of the solder-substrate interface. The results demonstrated that brazing of the system Kovar/Pd-X/Kovar is feasible at 880°C without the need for interlayer or fluxes. The results demonstrated that brazing of the system Kovar/Pd-X/Kovar is feasible at temperature 880°C.

PREPARATION AND CHARACTERIZATION OF ROTOMOLDED FOAMED POLYETHYLENE BLENDS WITH IGNIMBRITE DUST

Mr. Francisco Ramón Romero Artilles, Spain

Poster Presentation

Abstract

ABSTRACT

Ignimbrite powder (Ig), a byproduct of stone extraction, was used as reinforcement with an azodicarbonamide-based chemical foaming agent (CBA) to produce polyethylene (PE) parts via rotational molding. The outer layer of the sample was a polyethylene composite with 0-10 wt% mineral, while the inner layer was foamed polyethylene (using 3 wt% CBA) blended with 0-30 wt% ignimbrite. Mechanical characterization showed an increase in maximum stress and elastic modulus in both bending and tensile tests with mineral addition. The composite with 10 wt% ignimbrite in the outer layer and 30 wt% in the foamed inner layer exhibited the greatest difference. Impact tests showed no major differences from neat polyethylene, though impact resistance slightly increased with 10 wt% ignimbrite in the outer and 20 wt% in the layer. Thermogravimetric tests indicated no differences between the blends used, thus keeping the thermal stability of PE even when adding mineral powder and foaming agent. Based on this work, a balance between mechanical, thermal and aesthetics properties of the rotomolded parts can be achieved by selecting the composite with neat PE in one layer.

Thermochemical Synthesis of a Sodium Silicate Activator from Refractory Casting Bag Residues for Sustainable Geopolymer Production

Mr. Pedro Delgado-plana, Spain

Poster Presentation

Abstract

The development of sustainable alternatives to conventional alkali activators in geopolymer production is strategic given that their use represents the main environmental impact associated with geopolymer manufacture. This study presents a novel approach for synthesizing a sodium silicate activator from a scarcely utilized residue derived from the degradation of refractory casting bags employed in the ferroalloy industry. It is generated as a by-product in electric arc furnace operations during the production of ferroalloys such as silicomanganese, and remains largely unexploited, thus representing both an environmental challenge and an opportunity for valorization within a circular economy framework.

The primary objective of this research is to utilize this refractory casting bag residue (RCBR) in the thermochemical synthesis of sodium silicate by mixing it with sodium hydroxide (NaOH) and subjecting the mixture to a thermal treatment at 300 °C. The activator is designed to achieve a molar ratio of 1:1 (SiO₂:Na₂O), and subsequent processing via planetary mill, obtaining a fine, homogeneous powder. This solid activator is then employed in the production of one-part geopolymers, aiming to replace commercial activators. Comprehensive characterization of the synthesized activator was conducted using Fourier-transform infrared spectroscopy (FTIR) and X-ray diffraction (XRD). The technological properties of the resulting geopolymers were also evaluated through common standardized tests.

Preliminary findings indicate that the sodium silicate activator produced from RCBR exhibits a reduced content of inert phases (in comparison with alternative activators from other residual sources) and facilitates the manufacture of geopolymers with mechanical strengths comparable to those achieved using commercial activators. These results suggest that RCBR can serve as a viable raw material for the production of sustainable activators, thereby reducing environmental impacts and promoting waste valorization. This study not only offers a promising alternative to commercial activators but also contributes to sustainable waste management practices in high-temperature industrial processes aligning with current policies in circular economy.

Exploring the Influence of Stimuli on 4D Printed Components: A taxonomy of Stimulus, Smart Materials and Transformation Effects

Mrs. Jiayue Qin, United Kingdom

Poster Presentation

Abstract

Exploring the Influence of Stimuli on 4D Printed Components: A taxonomy of Stimulus, Smart Materials and Transformation Effects

Jiayue Qin

Prof. Eujin Pei

Brunel University of London

Abstract

4D printing is a significant advancement in additive manufacturing, enabling dynamic, self-actuating structures through stimuli-responsive materials. While widely explored in engineering and biomedical fields, its application in fashion and footwear remains underdeveloped due to the challenges of integrating material science with design aesthetics and functionality. The key gaps include the absence of accessible design frameworks for non-technical designers and a comprehensive taxonomy linking stimuli, smart materials, and transformation effects. These limitations hinder informed decision-making in material selection, transformation predictability, and adaptive functionality in design. This study addresses these challenges by investigating the influence of thermal, humidity, light, pH, electric, magnetic, and mechanical stress on 4D-printed components, developing a structured design application guide to facilitate creative industry adoption.

This study follows a qualitative research approach within the Design Research Methodology, progressing from literature review to experimental studies and expert interviews. The literature review establishes an initial classification of stimuli, revealing that thermal and humidity stimuli induce gradual, reversible transformations, light and pH stimuli allow localized or selective changes, and mechanical, magnetic, and electric stimuli enable rapid, on-demand actuation. Furthermore, this research introduces a new classification framework integrating stimuli, smart materials, and their transformation effects. This taxonomy forms the basis of the proposed design application guide, structured using the Technology Acceptance Model, which categorizes stimuli and materials based on perceived ease of implementation and usefulness in creative design, ensuring accessibility for non-technical designers. To refine and validate the guide, experimental studies will investigate how different sources and combinations of stimuli, along with printing techniques, influence material responses. Additionally, semi-structured interviews with experts in 4D printing and fashion design will assess the guide's practicality, feasibility, and clarity. Experts will apply the guideline in design and provide feedback to enhance its usability.

This study contributes to the broader adoption of 4D printing in the fashion industry by offering (1) a categorized taxonomy of stimuli-responsive materials, (2) practical design methodologies tailored for creative applications, and (3) a conceptual framework promoting interdisciplinary collaboration. The proposed guide provides structured insights into material selection, deformation simulation, and printing workflows, enabling

Optimizing MOF morphology for enzyme immobilization: Insights from Nanoscale Characterization

Prof. Joerg Jinschek, Denmark

Poster Presentation

Abstract

Imagine enzymes, nature's catalysts, can operate efficiently under the extreme conditions (i.e., high pressure, temperature, salt concentration) and revolutionize biocatalysis applications. Enzymes are highly efficient catalysts, playing a vital role in biocatalysis, biosensors, and biomedical applications. However, their use is often limited by lack of stability, loss of activity under harsh conditions, and limited reusability. These limitations demand the development of advanced support materials that can improve enzyme stability, preserve long-term catalytic efficiency, and enable easy recovery and reuse. In this regard, metal-organic frameworks (MOFs) have emerged as highly tuneable hierarchical materials known for their chemical and thermal stability. Their synthesis process allows precise control over structural properties, including composition, size, morphology, and crystallinity, making them well-suited for enzyme immobilization and encapsulation. With their high porosity and structural adaptability, MOFs provide a protective yet accessible environment for enzymes, enhancing their stability and catalytic performance for various applications.

The aim of this study is to improve enzyme stability and catalytic efficiency by precisely controlling MOF properties and immobilization strategies. By systematically investigating enzyme immobilization via adsorption and covalent bonding strategies as well as varying enzyme concentrations, we aim to understand how these parameters affect the structural integrity and catalytic properties of enzyme-MOF nanocomposites. Advanced (electron) microscopic and spectroscopic techniques were employed to confirm the successful attachment of enzymes onto the MOF surfaces and to elucidate the interactions at the enzyme-MOF on the nano scale. Immobilization efficiency and enzymatic properties were measured.

Our results demonstrate that controlling the MOF chemistry as well as morphology and choosing the right immobilization strategy significantly improves enzyme stability and minimizing leaching, while optimal enzyme concentration ensures a balance between catalytic efficiency and structural integrity. High-resolution scanning/transmission electron microscopy reveals uniform distribution of enzymes inside the MOF at the nanoscale level.

By addressing the critical challenges in enzyme immobilization on MOFs, this study lays the foundation for the rational development of MOF-based biocatalytic systems and paves the way for more sustainable and efficient biocatalysis applications.

Crystallinity and mechanical properties in glass-ceramic glazes by Raman Spectroscopy

Mr. Jesus Gabriel Madrid Negrin, Spain

Poster Presentation

Abstract

The amount of crystalline phases in glass-ceramic glazes is a key factor in achieving their mechanical and technical properties, apart from the aesthetic modifications they entail (opacity, or gloss, among others). Considering the possibility of correlation of the amount of crystals in the glaze with the rest of the properties, in this work we have designed glaze formulations to adjust the amount of crystalline phases generated in the glaze during the sintering cycle.

The glazes have been evaluated by Raman spectroscopy paying attention to the differences in intensity of the crystalline phase spectra according to their quantity. From a calibration line and the use of chemometrics, the present quantity of crystallizations was predicted. The study has been compared with results obtained by XRD of the same samples, reaching similar results for both methodologies. In addition, the mechanical properties of the glazes have been compared with the results of crystallinity, finding a direct relationship between them.

The possibility of knowing the amount of crystalline phases by means of a simple Raman spectroscopy study and predicting the mechanical properties of the sample has been confirmed.

Paper 386

Synthesis of eugenol derived biobased polymers as Green alternative to plastics

Señora. Maria Diaz Galbarriatu, Spain

Poster Presentation

Abstract

The chemical industry has traditionally relied on crude oil and gas as feedstocks. However, this heavy reliance on fossil resources is increasingly at risk due to anticipated shortages and price volatility. Moreover, global warming driven by CO₂ emissions and growing environmental concerns have prompted Industry and Academia to explore and develop new, sustainable, and safer chemical processes. In recent decades, Green Chemistry has emerged as a promising approach for synthesizing polymers addressing the drawbacks of traditional fossil resource dependence of conventional synthetic methods. Thus, Green Chemistry aims to create materials that are "benign by design", focusing on the importance of sustainable feedstocks and minimizing their harm to ecosystems. Therefore, the development of biobased polymers has increased significantly, because of their low toxicity and price, renewability, sustainability, and biodegradability. For that, aromatic green raw materials are studied. Eugenol, extracted from clove oil or cinnamon extract, or even through the depolymerization of lignin, offers different functionalities in its structure that allow easy modifications and make it a versatile precursor for polymeric materials. In addition, the synthesis of polymers should go in accordance with the concepts of circular economy, prioritizing recyclability from the beginning to provide a sustainable solution for plastic waste and for preserving monomeric units across multiple recycling cycles.

Nowadays, polymer industry uses polyols and polyisocyanates to synthesize polyurethanes (PUs), since they are incredibly versatile due to their diverse structures and properties. However, polyurethanes have been ranked among the 50 most hazardous polymers due to the respiratory sensitizing and carcinogenic properties of diisocyanates, as well as the toxicity of phosgene used in their production. Hence, non-isocyanate polyurethanes (NIPUs) represent a promising alternative to traditional polyurethanes, with significant environmental and health benefits. In fact, a carbamate monomer easily obtained from eugenol has been employed as starting material to the synthesis of a series of NIPUs via transurethanization reaction carried out in the absence of solvent. The focus of this work is the characterization of those new biobased NIPUs in order to understand structure–property relationships, fundamental for processing and real-world applications. The resulting polymers were structurally characterized by Nuclear Magnetic Resonance (NMR) and Fourier Transform Infrared spectroscopy (FT-IR), while their thermal properties were determined through Thermal Gravimetric Analysis (TGA) and Differential Scanning Calorimetry (DSC). Lastly, Gel Permeation Chromatography (GPC) was used to determine molecular weight and polydispersity. Furthermore, NIPUs research and innovation continue to drive this field towards a more sustainable future.

Evaluation of properties of PA 12 used in the Multi Jet Fusion printing process after reprocessing in an extruder.

Dra. Joyce Azevedo, Brazil

Poster Presentation

Abstract

The multi jet fusion (MJF) printing process is a variation of the powder fusion process, which uses a polymeric matrix applied in the form of a jet and fusing and detailing agents that are fused by the action of infrared radiation. Among the polymeric materials used in the MJF process, PA 12 (polyamide) dominates almost the entire market due to its easy and flexible processing. During printing, only a minority of powders are sintered during the cycle, approximately 10%, the remaining powder must be reused in other cycles or can be recycled. In this sense, this work evaluated the properties of PA 12, originating from the MJF printing process, when subjected to reprocessing in a twin screw extruder and thus predict its behavior in mechanical recycling. For this purpose, this polymer was reprocessed 5 (five times). At each extrusion cycle, the polymer fluidity index was measured, characterized by thermogravimetry (TG) and Fourier transform spectroscopy (FTIR). The samples subjected to extrusion showed an increase of approximately 300% in the fluidity index value. This result follows a tendency of increasing as the number of reprocessing cycles increases, which can be associated with the polymer degradation process in the presence of humidity and temperature. The spectra obtained by FTIR indicated a reduction in the intensity of the peaks of some chemical groups present in the polymer with the number of reprocessing cycles, which implies a lower concentration that the species absorbs. The TG results indicated that the thermal stability of the polymer was maintained with the reprocessing cycles, however the amount of final residue is greater, which indicates a greater amount of degraded material. The behavior observed from the characterizations performed indicates fragility of the material to the mechanical recycling process.

Superelastic Behavior Improvements of Ti-Nb-Mo Alloys via Heat Treatment

Mrs. Wei Chen Xu, Taiwan

Poster Presentation

Abstract

There is a rising demand for nickel-free vascular stents due to concerns over the release of nickel ions from conventional NiTi stents, which may cause allergic reactions and potential long-term health risks. Ti-Nb-Mo alloys have emerged as a promising alternative, offering excellent biocompatibility along with superelasticity and shape memory properties. However, optimizing their mechanical performance, particularly their superelasticity, remains challenging. Hence, this study aims to investigate the effect of heat treatment on the microstructure and mechanical properties of Ti-Nb-Mo alloys, focusing on enhancing their superelastic behavior. The alloys were fabricated using a vacuum arc melting furnace and subjected to various heat treatment conditions to regulate their phase composition and grain structure. Scanning electron microscopy (SEM) and X-ray diffraction (XRD) were employed to analyze the microstructural evolution, while tensile tests were conducted to evaluate the mechanical response. This research provides insights into the correlation between heat treatment parameters, microstructural evolution, and the resulting superelastic properties of Ti-Nb-Mo alloys. The findings are expected to contribute to the development of nickel-free vascular stents with improved mechanical performance and biocompatibility..

Graphene-based electrospun nanofibers in the removal of U(VI) from aqueous media

Mr. Andreas Hadjianastasi, Cyprus

Poster Presentation

Abstract

Water is one of the most valuable natural resources on earth. Nowadays, rapid growth of industrialization and human activities lead to water contamination by toxic metals such as radioactive metal ions, which pose significant environmental and public health challenges. Adsorption is a widely used treatment method that can be used in removing such hazardous elements [1]. Electrospinning is a versatile technique employed in the fabrication of nano- and microfibers, exhibiting high surface area to volume ratio and tunable properties, particularly well-suited for water treatment applications [2]. In this study, methacrylic random copolymers containing tertiary amino groups were synthesized by conventional free radical polymerization and characterized in respect to their chemical composition and molar mass. These polymers were combined with polyethylene oxide (PEO) to produce blended fibers by means of electrospinning. PEO is well-known for its highly electrospinnability, biocompatibility and good mechanical properties [3]. By altering the electrospinning conditions including the applied voltage, the needle-to-collector distance, the polymer solution concentration, etc., the optimum electrospinning conditions were determined. Moreover, these materials were further functionalized with carbon-based nanomaterials such as graphene oxide (GO) to enhance their adsorption capabilities [4]. The resulting fibers were characterized in respect to their morphology and they were evaluated for their efficiency in the removal of radioactive elements such as uranium ions (U(VI)).

Numerical simulation of pressurized microtubular reversible solid oxide cells for hydrogen production

Mr. Jesús Castillo, Panama

Poster Presentation

Abstract

Solid oxide cells (SOCs) are devices capable of separating hydrogen molecules from water vapor for storage and later use. Additionally, they can operate in reverse mode as fuel cells, converting the chemical energy of a fuel into electrical energy. In particular, microtubular solid oxide cell configurations have garnered significant interest in the scientific community due to their high efficiency under high-temperature operating conditions and the ability to withstand rapid thermal cycling during high-temperature operation, distributing heat more homogeneously across the structure and enhancing structural robustness. Additionally, in microtubular geometry, reducing the diameter increases power density per unit volume, as it provides a larger active area for the electrochemical reaction.

This study focuses on the performance of high-temperature microtubular solid oxide cell in fuel cell and electrolyzer modes between 600 and 800 °C, analyzing the effects of electrode gas pressurization (ranging from 1 to 10 bar) on polarization, the chemical reaction, temperature distribution, and thermal gradients under reversible operation conditions for hydrogen production and energy generation. A multiphysics model will be implemented using the computational tool Ansys for simulation and results analysis. This is an ongoing work which provide simulation results that are compared and validated with experimental data. The simulated models will contribute to a better understanding of the impact of gas pressurization on micro tubular solid oxide cell performance and serve as a design tool for high-temperature microtubular solid oxide cell systems.

The Platform MaterialDigital Workflow Store - Sharing Scientific Workflows within the MSE community

Mr. Buldin Artem, Germany

Poster Presentation

Abstract

The MaterialDigital Platform (PMD) project, launched in 2019, aims to advance digitalization in material science and engineering in Germany. The project focuses on creating a robust infrastructure for managing and sharing material-related data. The PMD Workflow Store is a key component of this initiative. It serves as a repository where scientists and engineers can access, collaborate on, and upload workflows for material simulation and analysis. The platform features centralized access and sharing, automated validation, a searchable index, and a commitment to continuous enhancement based on user feedback.

Here, we introduce the PMD Workflow Store and demonstrate how it streamlines collaboration and knowledge sharing within the scientific community. We show that this platform simplifies access to diverse workflows, ensuring high standards of quality and consistency. The Workflow Store accelerates research and development by providing a single entrypoint to discover and share workflows and workflow modules from and with the MSE community.

We highlight the transformative impact of the PMD Workflow Store on the material science community. This platform not only meets current needs but also aims to incorporate tools for future advancements. As digital workflows become indispensable in material science, the PMD Workflow Store aims to become a vital resource for researchers and engineers.

Enhancing FAIR Data Management in Materials Science and Engineering (MSE): Integrating FAIR Digital Objects into the MSE Knowledge Graph

Mr. Ebrahim Norouzi, Germany

Poster Presentation

Abstract

The Materials Science and Engineering Knowledge Graph (MSE-KG) [1] serves as a central knowledge base for integrating and structuring research data within the NFDI-MatWerk [2]. It provides a semantic backbone that connects datasets, research outputs, institutions, and infrastructures, ensuring interoperability and enhanced data discovery. The MSE-KG facilitates a unified and structured approach to manage heterogeneous data. Despite its structured approach, challenges remain in ensuring that research objects remain machine-actionable, persistent, and interoperable across different domains. To address these challenges, the integration of FAIR Digital Objects (FDOs) has been proposed as a solution for enhancing machine-actionability and interoperability of digital research assets in the MSE domain.

In the context of NFDI-MatWerk, with the integration of FDOs into the MSE-KG we aim to enhance the findability, accessibility, interoperability, and reusability of research data. This work investigates the representation of FDOs within the knowledge graph, addressing key questions such as the availability of FDOs, their association with datasets, provenance records, and licensing terms. By linking datasets, publications, and software to their respective FDOs, the MSE-KG provides structured access to research objects and ensures their long-term usability. The study further explores how FDOs are referenced within the knowledge graph, their accessibility via persistent links, and the implications of integrating semantic descriptions for enhanced machine-actionability.

Influence of UV polymerization conditions on the physicochemical properties of temporary dentures fabricated by the Digital Light Processing additive manufacturing

Ph.D. Wojciech Kajzer, Poland

Poster Presentation

Abstract

Dynamic technological developments have not only allowed existing manufacturing processes to be improved but have also contributed to the emergence of entirely new manufacturing methods. One of these is 3D printing, which enables the creation of three-dimensional objects layer by layer based on a digital model. This technology was mainly used for rapid and cost-effective prototyping. Currently manufacturing technologies vary in layer application, curing methods, and materials used. The wide range of possibilities has contributed to their application in medicine, among other fields. One area in which 3D printing has potential is dental prosthetics, where DLP (Digital Light Processing) is being used. This method involves the selective curing of successive layers of liquid resin using light. The greatest advantage of DLP over time-consuming traditional manufacturing methods is a significant reduction in production time for temporary dentures. In addition, the use of 3D printing makes it possible to produce more accurate and customized dentures, which is crucial in terms of treatment efficiency and improving the patient's quality of life. Although the DLP method and the resins used in it have proven themselves in dental prosthodontics, their application in this area is relatively new and continuous research is needed to improve knowledge of their capabilities and limitations.

Therefore, the aim of this study was to evaluate the influence of the curing time and conditions of resin processed by DLP technology on the physicochemical properties of temporary dental prostheses. For these medical devices, an analysis of the influence of the time and type of gas atmosphere used during post-processing curing in UV ovens on their physicochemical properties was carried out. Polymerization was used in a UV oven in air for 10, 20 and 30 minutes, in a UV oven with a nitrogen protective atmosphere for 10 minutes. The control group consisted of 3D-printed samples not subjected to the curing process. The morphology, topography, surface roughness and wettability, hardness, compressive strength and abrasion resistance were studied. The samples were tested both before and after the accelerated ageing process, which was carried out using a thermocycler. The samples were subjected to 5000 cycles of transition from 5 °C to 55 °C, which corresponds to 6 months of in vivo use of temporary dentures.

The results indicated that specimens cured in nitrogen atmosphere for 10 minutes had higher post-ageing durability compared to all alternative curing options used without a protective atmosphere regardless of their duration.

On a physics-based model of HBS pores overpressurization and its effects on high burn-up fuel fragmentation

Mrs. Elisa Cappellari, Italy

Poster Presentation

Abstract

In nuclear reactor accidents with high heating rates and/or temperatures of oxide fuel, overpressurization of gas-filled bubbles and pores can lead to fuel material rupture into fine fragments and gas release into the rod free volume. A fracture-mechanics-based model, developed and validated by the author, predicts fission gas release from micro-cracks propagating from overpressurized grain-boundary bubbles in UO_2 . This work extends the model to High Burn-up Structures (HBS), focusing on fuel fragmentation driven by overpressurized HBS pores. The extension required further investigation into stress intensification due to spherical pores and detailed knowledge of gas content, cavity size, shape, and number density. Additionally, the dependence of HBS material properties on temperature, burn-up, and low-angle grain-boundary (LAGB) accumulation were considered, based on experimental observations of UO_2 radial microstructural evolution. The extended model is integrated into SCIANTIX, an open-source computer code, developed at Politecnico di Milano, aimed at simulating fission gas behaviour in nuclear fuels at the meso-scale level. Once validated against experimental data, the model will provide a tool for predicting high burn-up fuel fragmentation (HBFF), allowing the extension of average burn-up limits of nuclear fuel and enhancing the efficiency and economic viability of nuclear power.

Paper 1327

Characterization of the H₂-rich fuel combustion process - model and experimental approach

Prof. Marcin Drąjewicz, Poland

Poster Presentation

Abstract

Materials used in the aerospace industry must exhibit high resistance to extreme temperatures and aggressive combustion environments. In addition to assessing the impact of flame and high temperature on such materials, it is also crucial to gain a detailed understanding of the combustion process itself, its mechanisms, and the factors that govern its progression. Therefore, the aim of this study was to conduct computational simulations of combustion processes and perform experimental investigations of methane and methane-hydrogen mixture combustion under various conditions. A comparative analysis of the obtained results against numerical models was then carried out to assess their accuracy and identify key parameters influencing combustion processes. The experiments were conducted using a specialized research furnace, designed and manufactured by Proximo Aero, located in the Hydrogen Laboratory of Rzeszów University of Technology.

Selective Lithium Extraction from Geothermal Brines using Advanced Adsorbent Materials

Ph.D. Francesco Pini, Italy

Poster Presentation

Abstract

In a world increasingly relying on batteries for energy storage, lithium sourcing has already gone from being a mere matter of technology to a matter of geopolitical relevance. Electric vehicles, smartphones and energy harvesting are just some of the uses of lithium that are gaining more and more importance in our everyday lives in the era of renewable energy.

Since lithium mines and salts are found in just a few regions of the planet (Australia, Andean range, China, US), it is crucial to explore alternative routes of lithium extraction to achieve a more affordable supply. Geothermal fluids are high-temperature aqueous solutions found in geothermal reservoirs, often exploited for energy production. These solutions have a high content of dissolved minerals and may contain lithium salts in non-negligible concentration.

Extracting lithium salts from geothermal brines can represent a solid alternative to mining. Thus, the optimization of materials which can be integrated in processes of selective extraction of lithium from brines is of major importance. Lithium titanate (LTO) and lithium manganese oxide (LMO) are regarded as very promising materials for the task, due to their ability to desorb and adsorb lithium ions multiple times without degrading, by the mutual substitution of Li^+ and H^+ ions in their structure in function of pH.

In this study, some materials and processes for selective lithium removal from a solution are presented: doping LTO and LMO with other transition metals can increase their lithium adsorption capacity and augment their stability in terms of dissolution of the bulk material. Doped LTO and LMO materials show remarkable lithium adsorption/desorption yields, as more than 20mg of lithium can be adsorbed and desorbed from each gram of material for each cycle. In addition to doped LTO and LMO, other materials, including zeolites and novel composite structures, are being investigated. Kinetics and extraction conditions have also been studied to optimize the process, keeping an eye on a reaction scale-up.

The selectivity of extraction of Li^+ ions against competing ones (Mg^{2+} , Na^+ , K^+ , etc.) has been quantified. Pre-treatment strategies are being explored to further enhance the selectivity of lithium extraction. Real geothermal brines from reservoirs on Italian soil have been sampled, characterized and used in laboratory to test the materials.

This study lays the groundwork for the development of a scalable process for lithium recovery from geothermal brines, potentially contributing to a more sustainable and secure lithium supply chain.

Scalable Fabrication of Flexible Perovskite Solar Modules via Roll-to-Roll Two-Step Deposition and Tailored Photonic Annealing

Dr. Dong Seok Ham, South Korea

Poster Presentation

Abstract

Perovskite solar cells (PSCs) offer high efficiency and mechanical flexibility, making them strong candidates for next-generation flexible photovoltaics. However, the scalable fabrication of high-quality perovskite layers via roll-to-roll (R2R) processing remains a challenge due to difficulties in controlling crystal growth and drying rates. In this study, we demonstrate a scalable R2R-compatible two-step deposition method—sequentially coating PbI_2 and formamidinium iodide (FAI)—combined with intense pulsed light (IPL) annealing to overcome the limitations of conventional thermal annealing. The rapid, localized energy delivery of IPL enables efficient perovskite crystallization without damaging flexible substrates or requiring prolonged heating. To further enhance the PbI_2 -to-perovskite conversion, cesium formate (CsForm) and cesium iodide (CsI) were incorporated into the PbI_2 precursor solution. This modified composition improved film morphology and facilitated low-hysteresis device operation. Additionally, we developed an IPL-based dual-annealing approach optimized for the R2R process, which significantly reduced device hysteresis and improved overall film quality. Using this method, we successfully fabricated large-area ($10 \times 10 \text{ cm}^2$) flexible PSC modules achieving a power conversion efficiency (PCE) of 11.25%, the highest reported to date using a fully R2R process. Our results highlight the potential of IPL-assisted R2R two-step processing as a scalable and efficient route toward commercial production of flexible PSCs.

Optimization of thermal pretreatment parameters to enhance black mass recovery in lithium-ion battery recycling

Mr. Mikel Merchán, Spain

Poster Presentation

Abstract

The progressive electrification of transportation is driving a significant increase in the production of lithium-ion batteries in recent years. These batteries contain elements classified as critical, such as lithium, cobalt, nickel, and graphite. Despite ongoing research to minimize their presence in new batteries, these elements remain essential in modern battery technology.

To mitigate the environmental impact of the extraction of these elements from minerals, it is crucial to increase the recycling rate of batteries that reach the end of their life cycle. To promote this recycling, the European Union has established a series of targets in the new Battery Regulation that came into force in 2023, setting recovery targets of 95% for cobalt and nickel by 2030.

Once the possibility of extending their life in stationary storage devices is discarded, post-consumer batteries can be subjected to a dismantling process followed by shredding and a series of separation processes that result in the production of a black mass. This black mass then undergoes a refining stage where the metals are recovered and can be used as precursors in the manufacture of electrodes for new battery cells.

Reducing impurities in the black mass is key to achieving better performance in the refining process, and the application of a thermal process to the shredded material has been shown to be effective on that purpose, thereby increasing the quality of the black mass. This work presents the results of a study conducted to investigate the influence of different parameters of this thermal process on both the recovery yield of the black mass and its quality.

Aerogels and Xerogels from Biogenic Phenols and Furfural

Dr. Thomas Anklam, Germany

Poster Presentation

Abstract

Both climate change and the depletion of fossil feedstocks drive the demand for high performance materials based on renewable natural resources. Due to their remarkable thermally insulating and light-weight properties that can be traced back to their unique microstructure, aerogels and xerogels based on phenolics, such as resorcinol-formaldehyde (RF), have received increasing attention.[1] Furthermore, high char yields resulting from carbonization of RF gels render them attractive precursors for porous carbons, which- in turn- are interesting for electrochemical applications. However, RF is made from fossil precursors, and thus biogenic alternatives to these phenolic aerogels are highly sought-after.

In that context, we report on three phenolic aerogels and xerogels made from bio-based monomers, namely cardanol-furfural, thymol-furfural, and eugenol-furfural.[2] We have investigated the conditions of gelation, solvent exchange, and drying, and characterized properties such as chemical structure, density, surface area, pore size and -volume, microstructure, thermal stability and wetting behavior. Furthermore, we report on the carbonization of these bio-based aerogels and xerogels. Especially carbon xerogels based on eugenol-furfural show promising pore characteristics and significantly higher char yield when compared to carbons based on cellulose aerogels. These gels can, thus, be considered attractive candidates for larger scale production and further studies in electrochemical applications.

Lignocellulosic solid-state electrolyte for energy storage devices

Mrs. Bárbara Aguiar Carmo, Portugal

Poster Presentation

Abstract

Energy storage devices are essential in modern technology, but their use faces challenges related to sustainability, durability, and safety. Traditional liquid electrolytes present risks such as leakage and flammability, which affect the performance and reliability of batteries and supercapacitors. To develop safer and more sustainable solutions, it is important to replace these electrolytes with durable and environmentally friendly alternatives. Solid electrolytes made from abundant, biodegradable materials offer a promising way to improve electrochemical performance while reducing environmental impact.

In this study, we investigate the use of cellulose and lignin – two abundant, biodegradable and renewable biopolymers – as the basis for solid-state electrolytes. The electrolyte layer is prepared by dissolving lignin and cellulose in water at low temperatures, making the process both economical and sustainable. A neutralization process is then used for the addition of cellulose microfibrils, improving the mechanical properties and ionic transport within the material. Additionally, we conduct a detailed examination of the membrane preparation parameters, focusing on the influence of using different crosslinking agents to optimize the electrolyte's structural integrity and performance.

The resulting solid electrolyte achieved an ionic conductivity of 0.2 mS/cm at room temperature and demonstrated electrochemical stability up to 0.8 V, ensuring reliable performance. We also examined how temperature affect the structure and conductivity of the material, leading to an increase in the ionic conductivity of the electrolyte to 1.16 mS/cm at 80°C. These bio-based materials provide environmental benefits along with flexibility, chemical stability, and adjustable ionic conductivity, making them strong candidates for next-generation energy storage systems. By refining their composition and processing methods, we aim to create a solid electrolyte that is both sustainable and efficient, helping to develop safer and greener energy storage solutions.

To assess the performance of these bio-based solid electrolytes, we conducted a series of tests, including ionic conductivity measurements, electrochemical stability analysis, thermal stability and mechanical characterization. Additionally, we tested different electrode materials to determine the most compatible option for optimal electrochemical performance. By studying the interaction between the electrode and electrolyte, as well as overall cell stability, we aim to determine the best combination for effective energy storage. This study highlights the potential of bio-based solid electrolytes and provides a foundation for further research to improve their performance and applications in sustainable energy storage.

Paper 511

Electrifying foil characterization – Mechanical characterization of electrode materials for simulation purposes

Mr. Matthias Pferschy, Austria

Poster Presentation

Abstract

With the ever-increasing share of electric vehicles (EVs) in the global automotive market, the entire industry is gradually transitioning towards a more sustainable future. However, numerous reports of serious fires involving electric cars highlight the growing importance of ensuring the safety of Li ion batteries (LIBs). Additionally, the lifespan of these LIBs in the cars is a widely discussed topic, not only in the used car market but also among manufactures aiming to increase cell longevity. To address these challenges effectively, a detailed understanding of the behaviour of LIBs under critical thermo-mechanical loading conditions is essential.

The goal of our project is to provide a comprehensive modelling tool for the simulation of the thermo mechanical response of LIBs. Nevertheless, the most advanced modelling tool is only as good as its input parameters making reliable and repeatable measurements for the mechanical characterization of electrode materials essential. Even for conventional LIBs, this mechanical characterization is still a long way from being fully developed, which is mainly due to the sensitivity of the used foils materials.

Existing standards as well as various testing methods from the literature for foil testing were compared and evaluated for their suitability. In addition, further refinements were made to suit the requirements of the existing machinery and sample materials. Initially, the electrode material was analysed for possible anisotropy in the foil plane to determine the necessary number of tests. In a next step, new processes were developed for the damage-free alignment and gripping of the samples in a testing machine for quasi-static tensile tests. Additionally, different methods for precise and gentle elongation measurement were researched for the tensile tests, since thin foils have a more varied fracture behaviour than their respective bulk materials due to their higher brittleness. Finally, various options for the accurate measurement of Young's modulus were compared.

Paper 962

Corrosion behavior and mechanical properties of ER70S-6 Wire Arc Additively Manufactured Steel

Mrs. Dimitra Ioannidou, Greece

Poster Presentation

Abstract

One of the most widely utilized Additive Manufacturing processes for construction steel is Wire Arc Additive Manufacturing (WAAM), exploiting its agile deposition rates and large-scale printing, as it is performed in ambient environments. WAAM manufactured steel is also suitable for the construction industry due to higher tolerance indicated for mechanical properties. The Cold Metal Transfer (CMT) printing technique was employed in the current study, which results in better distribution of the drops transfer rate, because of the reverse movement of the electrode and the zero current supporting the transfer process. In the present research work, the corrosion behavior and mechanical properties of WAAMed ER70S-6 wire steel are investigated via potentiodynamic polarization and tensile tests. Cooling methods of the printed samples used for these experiments include Natural Cooling (NC) and compressed Air Cooling (AC) with and without water admixture. Potentiodynamic Polarization tests were performed using a 3.5 wt.% NaCl solution at three different values of pH, namely 4, 7 and 9, and the corresponding results were plotted on Tafel diagrams. Post-corrosion observations were made employing Light Optical Microscopy (LOM), Scanning Electron Microscopy (SEM) and Energy-Dispersive X-ray Spectroscopy (EDS). The mechanical properties were assessed via stress - strain diagrams and the results were correlated to the different cooling methods implemented.

Overview of agricultural waste-based SCMs from Kenya for climate care and a circular economy

Mr. Thomas Pfeiffer, Germany

Poster Presentation

Abstract

More climate sparing cement production has been target of industry and researchers since the building industry is coping with a growing demand (1) (2) (3). This is produced by the climate- and energy-intensive burning of clinker at roughly 1450 °C, whereas the majority of emissions are released due to the decomposition of limestone (CaCO_3) to reactive CaO (4) (5) (6). In order to abate this, furnaces' bottom ash is utilized as supplementary cementitious materials (SCM) if the composition is adapted as the UGR showed in Granada (7). However, the reaction of which depend on the right mineral oxide content (CaO , SiO_2 , Al_2O_3) and proportioning.

Any such ash producing process has a positive carbon footprint, meaning that significant CO_2 equivalents are emitted into the atmosphere. This general research question aims at finding suitable ash from biomass waste, which could theoretically generate the necessity of testing hundreds of biomasses. In a later step, however, operating an artificial intelligence system will sort the data and prioritize those that are worth deepening. Kenya has significant amounts of biomass waste, whereby healthy growing biomass will be excluded from ash production. The Bundesanstalt für Materialforschung und -prüfung (BAM), the Meru University of Science and Technology (MUST) and SRH Universities are researching the potential for climate relief through circularity and provide the data relevant for this publication. Funded by the Volkswagen foundation that consortium is studying the Kenyan case as a pilot relevant for many parts of the African continent. About forty percent of that East African country's population elaborates 21% of the national economy (11) and hereby deals with significant waste materials from biomass such as shells, peels and pruning. Not only Biomass waste like maize, cassava, bamboo or sugarcane bagasse is interesting, but also invasive plants such as mesquite.

As a first step, this research will set up a model, a database to record which biomass waste is produced where and what the water content amounts to. In the 2nd step samples are taken systematically and ashed above 650 °C for varied times, so determining the ash content from the biomass waste. The 3rd step is measuring mineral content with a focus on CaO , SiO_2 , Al_2O_3 through X-ray fluorescence (XRF) analysis. These three steps presented here will be followed by determining the pozzolanic properties along with compressive strength, spread flow and other relevant indicators.

Paper 187

High-Temperature Oxidation Behavior of Zirconium Alloys in Simulated Spent Fuel Pool Accident Conditions

Mr. Woohyun Lim, South Korea

Poster Presentation

Abstract

Spent nuclear fuel is typically stored in wet storage pools, where decay heat is dissipated, and radiation is safely contained using a coolant. Although accidents in these storage pools are rare, events like natural disasters causing coolant leaks cannot be completely ruled out. In such situations, spent fuel rods can overheat due to the inability to remove decay heat. As the coolant evaporates, the rods are exposed to a steam-rich environment, which significantly accelerates the oxidation of zirconium alloy cladding and may lead to catastrophic failures. This study focuses on understanding the high-temperature oxidation behavior of zirconium alloys under such accident-like conditions.

To mimic the self-heating effect observed in real-world accidents, an induction heater was employed. Weight changes were monitored in real-time and normalized to weight change per unit area for direct comparison with literature data. The results clearly showed that oxidation rates in a steam atmosphere were much higher than in air, emphasizing the aggressive nature of steam in promoting cladding degradation. Additionally, tests conducted in such an open environment, where self-heated high-temperature zirconium alloy was exposed to a continuous steam flow, revealed faster oxidation rates and greater weight gains compared to the previous results reported in the literature, which were often performed in closed chambers with static steam.

The oxidized samples were further examined to understand their surface morphology and chemical composition using scanning electron microscopy (SEM) and energy-dispersive spectroscopy (EDS). Phase composition was analyzed through X-ray diffraction (XRD), while cross-sectional studies highlighted variations in oxide thickness and composition at different depths. These findings shed light on the mechanisms that cause cladding failures during accident scenarios, offering valuable insights to enhance the safety and dependability of spent nuclear fuel storage systems.

Paper 426

Compressive strength as a screening tool for quality control of tubular honeycomb ceramic filters

Mr. Manuel Antonio García Galán, Spain

Poster Presentation

Abstract

Honeycomb tubular ceramic filters are the most common ceramic filter design, whose standard quality control in the industry is based on assessing whether or not a relevant filtration parameter, typically permeability, of one or more randomly selected filters meets the desired specification. Ceramic filters are however particularly prone to fracture, yet it is not common to measure their strength as an integral part of quality control, or to do so inadequately. Because a lower-than-expected strength is an indication of processing problems, strength-based screening can be an ideal complementary tool for the quality control of ceramic filters. The aim of this work is to assess the mechanical integrity and reliability of commercial honeycomb tubular ceramic filters at their typical processing stages using simple compression testing and Weibull analysis, and to show the usefulness of this methodology as a complementary screening tool for quality control.

Paper 530

Tailoring the Microstructure of 3D printed pieces by incorporating Cellulose Nanofibers into the PLA-based formulations containing Inorganic Phases

Prof. Zoilo Gonzalez, Spain

Poster Presentation

Abstract

In recent years, manufacturing technology has undergone a remarkable transformation due to the invention and expansion of additive manufacturing (AM). Among its most promising applications, AM enables the development of complex, efficient and stable structures using ceramic, polymeric, metallic, or composite feedstocks. Within the broad spectrum of 3D printing techniques, fused filament fabrication (FFF) has garnered significant interest for its suitability in printing composite materials while ensuring good applicability.

In this work, FFF was employed to fabricate specifically designed structures using a PLA matrix in which functional phases were added (e.g., TiO₂, CuO, hydroxyapatite) to create advance 3D printed pieces. The proposed patterns were digitally designed to maximize surface area exposure to the surrounding medium, enhancing their functional performance. But also, cellulose nanofibers, obtained through a biorefinery process (that allow to valorize local agri-food wastes), were incorporated into the PLA/inorganic formulations to further enhance the microstructural surface area. Following fabrication, the physicochemical, structural, and functional properties of the composite membranes were characterized.

High-temperature deformation behaviour of nickel-based superalloys

Prof. Vasile Danut Cojocaru, Romania

Poster Presentation

Abstract

In this study, the high-temperature deformation behaviour of INCOLOY alloy 925 was investigated through deformability and microstructure evolution in the (1050 - 1200) °C temperature range. The microstructure evolution of INCOLOY alloy 925 was investigated by X-ray diffraction (XRD) and Scanning Electron Microscopy - Electron Backscatter Diffraction (SEM-EBSD) techniques. The deformability of INCOLOY alloy 925 was investigated by the up-setting method, using a gravity-drop hammer, with the following deformation energy/impact energy (E): 545.2 J, 1,021.5 J, 1,480.6 J, and 1,905.3 J. Data referring to deformation resistance (σ) and mechanical work (A) as a function of deformation temperature (T) and deformation energy/impact energy (E) was obtained and analysed. It was shown that increasing the deformation temperature leads to an increase in the obtained deformation degree (degree of reduction in height). By analysing the rate of increase in the deformation degree as a function of the applied impact energy, it was shown that the rate of increase in the deformation degree rises with the increase in the applied impact energy. Also, it was observed that the evolution of the deformation resistance (σ) as a function of temperature (T) shows a decreasing tendency while increasing the deformation temperature, for all impact energies, and that, the evolution of the mechanical work (A) as a function of temperature (T) shows a decreasing tendency while increasing the deformation temperature, for all impact energies.

Keywords: nickel-based superalloys; INCOLOY alloy 925; plasticity.

Thermodynamic Approach for Metal Recovery from Black Powder of Used Secondary Batteries through Pyrometallurgical Process

Dr. Young-Min Kim, South Korea

Poster Presentation

Abstract

The increasing use of secondary batteries has resulted in a significant accumulation of waste batteries, raising environmental concerns and the need for efficient recycling methods. Black powder, a by-product of waste battery recycling, contains valuable metals such as cobalt, nickel, and lithium. Recovering these metals through a pyrometallurgical process offers a promising solution for sustainable resource management. In this study, a thermodynamic approach was applied to optimize metal recovery from black powder using a pyrometallurgical process. To enhance the phase separation between reduced metals and slag, the viscosity variation of slag was analyzed by modifying its composition. Additionally, equilibrium phase changes at different temperatures were investigated to determine optimal operating conditions. These thermodynamic calculations were conducted using the FactSage software. The results provide insight into improving the efficiency of metal recovery by controlling slag properties and reaction conditions.

Solid-State Ionic Characterization of Oxygen and Metals in Lead Nuclear Coolant for the Development of Corrosion Resistance Materials

Ph.D. Giacomo Gregori, Italy

Poster Presentation

Abstract

The effect on climate of fossil fuel energy generation is stimulating the interest in the Lead-cooled Fast Reactors (LFRs) as carbon-free energy source. newcleo ltd. is developing an LFR through its LFR-AS-30/200 programme. LFR technology is hindered by the Liquid Metal Corrosion (LMC) on steels: lead dissolves the alloying elements (Fe, Cr, and Ni) reducing the structural integrity and altering the coolant chemistry. Advanced steels include alloying metals (AMs) providing LMC resistance by the formation of passivating oxide layers when exposed in lead. The rational design of these starts from the thermodynamics of the AM-O-Pb systems, based on the accurate assessments of the oxygen and AMs thermochemical properties in lead, such as the solubility, the activity coefficient, and the oxide solubility products. Solid-State Ionic devices based on zirconia electrolyte – i.e. the Electrochemical Oxygen Sensors (EOSs) and Oxygen Pumps (EOPs) – are reliable for thermodynamic investigation in liquid lead-alloys. In this work we describe the development of our EOS/EOP technology and its application both on the small and pre-industrial scale. On the small-scale, combining the potentiometry with the EOS and the coulometry with the EOP, we assessed the oxygen activity coefficient and the solubility limit in the thermal range of 620-825 K, obtaining results aligned with literature. For the INNUMAT European project, we will also characterize together with ENEA the Fe-O-Fe₃O₄-Pb and the Cr-O-Cr₂O₃-Pb systems by measuring the metal elemental solubilities and the solubility product constants for the related oxides. The thermochemical data being acquired will play a key-role in the modelling of the LMC phenomena and the selection of structural materials for our LFR programme. On the pre-industrial level, we are scaling up the EOS/EOP devices to support the Oxygen Control System (OCS) on the SOLEAD facility storage tank. Specifically, we are testing the kinetics for the dissolution and linear diffusion of oxygen across a fixed section of the tank, between an injection point (gas bubbling or EOP) and a monitoring point (EOS). The results should provide an empirical model of oxygen diffusion in lead to a target surface of a material to be passivated. Moreover, we are testing the efficiency of the electrolytic oxygen removal by EOP at different oxygen contents. These studies investigate the dynamic response of a big-scale lead pool to a possible failure of the OCS, and the effects on the materials corrosion resistance when the normal operating conditions for the coolant chemistry are lost.

Functionalization of Phthalocyanines for their use as crosslinkers in 3D-printable photopolymer systems

Dr. Giulia Rossella Delpiano, Italy

Poster Presentation

Abstract

Phthalocyanines (Pcs) are a widely investigated class of macrocyclic compounds with remarkable optical, electronic, and thermal properties. These characteristics have led to their widespread application in fields such as organic photovoltaics, sensors, catalysis, and photodynamic therapy. However, their inherently low solubility and processability limit their direct application in polymeric systems. To overcome these challenges, the functionalization of phthalocyanines has been explored as a strategy to improve their compatibility with photopolymerizable formulations while maintaining their intrinsic properties.

In this study, we report the functionalization of metal-centered phthalocyanines via esterification to introduce reactive sites suitable for crosslinking reactions. The functionalized phthalocyanines (f-Pcs) were synthesized and characterized through spectroscopic techniques such as UV-Vis, FTIR, and NMR to confirm successful functionalization. The obtained f-Pcs were then incorporated into photocurable resin formulations to act as crosslinking agents, facilitating their covalent integration into polymer networks. The goal was to transfer the unique electronic and optical properties of Pcs into photopolymer matrices without compromising their stability and dispersion. The formulated resins containing f-Pcs were subjected to photopolymerization using digital light processing (DLP) 3D printing, a cutting-edge additive manufacturing technique that enables high-resolution fabrication of complex structures with precise control over geometry and material composition. DLP offers several advantages over conventional photopolymerization methods, including faster curing times, improved resolution, and reduced material waste. These benefits make DLP particularly suitable for integrating functional additives like f-Pcs into photopolymerizable systems. By leveraging the capabilities of DLP 3D printing, this study aims to develop novel polymeric materials with enhanced optical and electronic properties, expanding the application potential of phthalocyanine-based materials. This work provides a new approach to incorporating phthalocyanines into additive manufacturing processes, paving the way for their use in advanced coatings, optoelectronics, and smart material development. Future research will focus on optimizing printing parameters and material formulations to maximize the performance and scalability of these systems.

Fluid Flow and Heat Transfer Control in Spray Forming: Toward Improved Steel and AM Powder Production

Dr. Ali Mostafazade, Denmark

Poster Presentation

Abstract

Spray forming is an advanced manufacturing technique that integrates metal atomization and deposition to produce high-quality steel and metal powders. Despite its potential advantages, such as refined microstructures and reduced segregation, its adoption in steel production remains limited compared to traditional continuous casting methods, primarily due to economic considerations and process difficulties. However, spray forming offers a unique capability to produce metal powders suitable for additive manufacturing (AM) applications. Achieving desired material properties in both bulk steel and powders necessitates precise control over the spray forming process. Critical parameters include fluid flow dynamics, heat transfer characteristics, primary and secondary atomization, and solidification patterns, all of which significantly influence the final microstructure and properties of the products. For instance, to ensure a uniform microstructure in the deposited ingot, it is essential to maintain a consistent top surface temperature during spraying, which requires full control over the different process parameters. In this study, we employ a comprehensive multi-scale and multi-physics numerical simulation approach using advanced CFD techniques to model the entire spray forming process. The simulations begin with the molten metal's transfer from the furnace to the tundish, followed by its flow through the tundish to the nozzles. At the nozzle exit, high-pressure nitrogen gas atomizes the molten metal into fine droplets. These droplets either deposit onto a substrate to form ingots or are collected as powders for AM applications. By analyzing and optimizing fluid flow and heat transfer throughout these stages, we aim to enhance control over the process, thereby improving the material properties of both the produced steel and powders. Our objective is to develop a well-designed and controlled spray forming process that minimizes impurities and inclusions, resulting in high-quality steel and powders tailored for AM applications. This research contributes to advancing spray forming technology, highlighting its potential as a viable method for producing superior materials for various industrial applications.

xrd_simulator: Towards a PyTorch-based framework for FEM simulation of crystalline materials and diffraction experiments

Dr. Marc Raventós, Spain

Poster Presentation

Abstract

X-ray powder diffraction, particularly synchrotron-based techniques, is a powerful tool for characterizing crystalline materials. However, conventional diffraction analysis often relies on collapsing diffraction signals into one-dimensional profiles for fitting, which eliminates critical information related to crystallographic texture and local strain fields. This limitation hinders the extraction of spatially resolved microstructural details essential for advanced materials characterization [1].

To address this challenge, the open-source Python package `xrd_simulator` enables the simulation of monochromatic X-ray diffraction experiments directly from finite element method (FEM)-based meshes [2]. By incorporating crystal deformation and polarization effects, `xrd_simulator` facilitates realistic diffraction simulations of deformed microstructures obtained from prior FEM calculations. Figure 1 presents a schematic representation of the primary reference systems used in an `xrd_simulator` experiment.

This work focuses on an ongoing effort to accelerate diffraction simulations by reimplementing `xrd_simulator` in PyTorch with GPU acceleration. This transition significantly enhances computational efficiency, enabling simulations of FEM meshes containing up to one million tetrahedral elements within seconds, compared to the tens of hours required by CPU-based methods. Figure 2 illustrates the results of an `xrd_simulator` experiment and a potential application of the tool in testing 3D reconstruction techniques such as XRD-CT [3].

Beyond simulation, the framework is intended to be extended into a direct analysis tool by leveraging the PyTorch forward model for inverse problem-solving. By minimizing the difference between experimental and simulated diffraction patterns, this approach aims to refine microstructural parameters such as crystal orientations and phase distributions within the sample, providing a pathway toward automated, high-throughput diffraction data analysis [4].

The versatile role of tannic acid as green crosslinker and bioactive compound in the development of Gellan Gum-based hydrogels for in situ cartilage repair

Prof. Elvira De Giglio, Italy

Poster Presentation

Abstract

The articular cartilage regeneration is a central focus of scientific research due to its limited capacity for self-repair following trauma or disease. This limitation arises from the absence of blood vessels, nerve structures, and a low cell population. Despite the promising prospects, a persistent challenge in this area is the lack of sufficient functional integration between engineered and natural tissues [1]. In this study, an innovative hydrogel based on a blend of two Gellan gums (GG) with different acyl content, cross-linked with Tannic acid (TA) and magnesium ions has been proposed as biomaterial for cartilage tissue engineering. Considering the poor mechanical properties of GG, the use of TA as new green cross-linker represents a promising strategy since, in addition to its crosslinking action, it displays also bioactive properties, due to its anti-inflammatory and ROS scavenging capacities [2,3]. Chemical-physical characterization by FTIR-ATR, XPS, SS-NMR, DSC, SEM, weight loss, water-uptake and rheological tests was carried out to ascertain the interactions involved in the hydrogels cross-linked structure. Cytocompatibility, chondrogenic and anti-inflammatory evaluation were tested on Human mesenchymal stromal cells (hMSC), demonstrating that GG/TA hydrogels support the immunomodulatory role and confirming the ability of TA to ameliorate LPS-induced inflammation. Along with its anti-inflammatory properties, TA exhibited also strong antibacterial activity, which is crucial for materials used in cartilage regeneration. The obtained cross-linked hydrogels showed mechanical and rheological performances that made them ideal systems for damaged cartilage repair. In summary, this research highlights the possibility of exploiting the multiple advantages deriving from the use of this natural polyphenol in the development of a natural hydrogel for application in cartilage tissue engineering.

The formation of solid-state zinc thermal diffusion coatings on steel surfaces and their wear performance

Mr. Jorge santos, Portugal

Poster Presentation

Abstract

This study investigates the formation of solid-state zinc thermal diffusion coatings on high-strength steel surfaces and evaluates their wear performance. Traditionally, hard chromium electroplating coatings are applied to improve bicycle steel gears' wear and corrosion resistance, raising environmental and health problems. The gears are typically made from steel and are applied after carburising or through hardening to endure high and cyclic stresses in service. Bicycle gears are components of rear hubs that connect the rim to the spokes, maintaining the wheel's integrity and containing bearings and springs that enable the wheels to rotate around the axle. Solid-state zinc thermal diffusion coatings offer an alternative, as they do not carry the environmental risks and the hydrogen embrittlement associated with hard chromium electroplating. In this study, quenched and tempered 40 CrMnNiMo 8-6-4 steel rings were embedded in zinc powder within a sealed alumina container. This assembly was then placed in a furnace for diffusion heat treatment with varying temperatures. Optical and scanning electron microscopy, energy-dispersive X-ray spectroscopy and X-ray diffraction were used to analyse zinc thermal diffusion coatings. Vickers microhardness profiles were also determined on uncoated and coated steel rings. Pin-on-disk wear tests were conducted on the solid-state zinc thermal diffusion-coated steel rings, using a DIN 100Cr6 steel ball as the counter body to study wear performance. Zinc diffused into the steel surface during the solid-state diffusion heat treatment, forming the Γ and δ phases with increasing zinc content. This study's temperatures and holding times for the zinc thermal diffusion treatments did not significantly change the hardness profiles for the quenched and tempered 40 CrMnNiMo 8-6-4 steel substrates. This investigation contributes to a better understanding of solid-state zinc diffusion coating formation on steel substrates as a viable alternative to hard chromium electroplating for bicycle rear hub gears.

Biodegradable polymer coatings release active ingredients in implantology

Ph.D. Janusz Szewczenko, Poland

Poster Presentation

Abstract

Currently, the primary purpose of using implants is to provide conditions for proper tissue regeneration. Regardless of the application, implants are intended to stabilize tissues. However, the effect of implantation may be inflammation and postoperative complications. They may be caused by a natural reaction to a foreign body or the release of their degradation products. Unfortunately, postoperative wound infections caused by microorganisms contaminating the wound during or after surgery remain a problem. The main direction of research aimed at reducing inflammation and postoperative complications is to modify the material selection from which the implant is made and the modification of its surface, specifically metal implants. A very interesting direction for modifying the surface of implants is to apply coatings of biodegradable polymers to them. These polymers will play a protective role by limiting the adverse effects of the tissue environment and body fluids and, thus, the process of their degradation. In addition, they can be a matrix for active substances with anti-inflammatory or regenerative properties that can be released locally to the tissue. Depending on the time of tissue regeneration, it is possible to support these processes by adequately selecting the type of polymer and active substances. The basis for selecting the type of polymer is its degradation time, which depends on its chemical composition and structure, as well as the environmental conditions of the body. Designing and applying mono- and multi-layer coatings consisting of various polymers with different active substances is possible. Using implants with coatings with controlled kinetics of the release of active substances may be an alternative to the commonly used systemic pharmacotherapy. Direct, local delivery of active substances to the tissue regeneration area should have a beneficial effect on the process of regeneration.

The applied biodegradable single or multilayer coatings should be characterized by an even distribution of active substances. These conditions are necessary for controlling the kinetics of their release. The ultrasonic spray method enables the application of such external coatings.

The paper presents research results on a multilayer PLGA coating composed of inner layers containing hydroxyapatite, intermediate layers of pure PLGA, and outer layers containing dexamethasone. Studies of the substrate-coating system's physicochemical properties were carried out for samples in their initial state and after long-term exposure to PBS solution. The obtained results indicate good protective properties of the coating and controlled release of active substances.

Effect of steam and gamma-irradiation sterilization treatments on sustainable thermoplastic elastomers

Mr. Stefano Gozzini, Italy

Poster Presentation

Abstract

This work is part of a research activity aimed at redesigning from a sustainability perspective a reusable protective mask for cleanroom applications, currently produced with conventional non-sustainable polymeric materials. This study examines the mask frame, produced by injection moulding in a thermoplastic elastomer (TPE), and the possibility of using sustainable TPEs to replace the one currently used is investigated. To this aim, considering the requirement of reusability of the mask, and that the mask must be subjected to adequate sterilization treatments after each use in the cleanroom, the attention was directed to the study of the effects of industrial sterilization processes on the properties of the candidate TPEs. Six industrially relevant TPEs with a reduced environmental impact, differing for the chemical nature, were examined in the form of specimens cut out from injection moulded 2 mm thick plates specially prepared. The ordinary TPE currently employed to produce the frame was also analysed. Both steam and gamma irradiation sterilization treatments were considered as these are the two types of sterilization methods to which the mask is exposed when in service. The TPE samples underwent steam sterilization in the laboratory, by means of an autoclave, following a standard sterilization cycle (121°C-30 minutes) repeated for up to 55 times. Gamma-irradiation treatments were carried out externally, by a company that provides gamma sterilization services for industrial goods, and different increasing radiation doses (up to 125 kGy) were used. The effects of the various sterilization treatments were assessed by structural (Wide Angle X-ray Scattering, WAXS) and calorimetric (Differential Scanning Calorimetry, DSC) analyses, as well as by mechanical tests. Concerning these latter experiments, both uniaxial tensile tests in quasi-static conditions and instrumented impact tests were carried out. The impact tests were performed with a pendulum in tensile-impact configuration on double-edge notched specimens. For the various TPEs examined, the effects promoted by the sterilization processes on the mechanical performances are discussed based on the outcomes from the structural and thermal characterization, in the attempt to identify the best sustainable TPE candidate for the obtainment of the protective mask frame.

Component-test for determination of welding residual stresses and their effect on stress relief cracking in thick-walled welds

Dr. Michael Rhode, Germany

Poster Presentation

Abstract

Controlling the residual stress level during welding of creep-resistant Cr-Mo-V steels is crucial to avoid so called stress relief cracking (SRC) during post weld heat treatment (PWHT) of large-scale components. In the present study, a laboratory scale test specimen (slotted sample with 400 mm width, 400 mm length and 25 mm thickness) was used to simulate thick-walled component welds made of 13CrMoV9-10. The aim was to identify the level and distribution of residual stresses to evaluate the suitability of the specimen for laboratory based SRC testing. High restraint was ensured by the specimen geometry with a narrow welding gap in the center. This gap was filled by multi-layer submerged arc welding. Two specimens were welded with identical parameters and compared in the as-welded state and after PWHT (705 °C for 10 h). Neutron diffraction was used to determine the residual stresses in the weld metal, the heat-affected zone (HAZ) and the base material at different depths longitudinal, transverse, and normal to the welding direction. The experiments were performed on the former instrument E3 of the research reactor BER II of Helmholtz-Zentrum Berlin (HZB), Germany. Complementarily, laboratory X-ray diffraction was applied to characterize the surface residual stresses. In the welded condition, especially in the weld metal and the adjacent HAZ, the longitudinal residual stresses reached values of up to 1,000 MPa to 1,200 MPa due to the increasing strength and hardness of the CrMoV-material during welding. The conducted welding experiments revealed that way higher residual stresses in the welded joint have to be anticipated before the PWHT is performed than it was expected in advance. This demonstrated the necessity of suitable component-like welding tests as they must ensure realistic mechanical stiffness (hindered shrinkage of welding joint by slotted self-restraint sample) and heat dissipation conditions (definition of minimum welding joint thickness vs. welding process-specific heat input).

MATERIAL AND DESIGN SOLUTIONS RELATED TO BODY PROTECTION AND MEANS OF DIRECT COERCION WITH HIGH COMMERCIALIZATION POTENTIAL

Prof. Marcin Struszczyk, Poland

Poster Presentation

Abstract

The presentation discusses the experience of the Institute of Security Technologies "MORATEX" in the development of ballistic personal shields, in particular ballistic helmets, ballistic vests and shields used in the area of demining, incl. humanitarian demining based on the composite technologies. Material solutions protecting humans against a number of ballistic phenomena and scenarios related to situations with the use of melee weapons will be presented.

The aim of the research was to develop a number of material system solutions and utility forms conducive to increasing the comfort of use and aesthetics of the product using the principles of design thinking.

Solutions with high commercialization potential will be presented in the field of: hybrid ballistic helmets, composite ballistic inserts based on atmospheric plasma or low-temperature plasma modification technologies, body shields used in demining processes or during operational activities of sapper services.

Ballistic and other functional requirements specified in the research will also be presented, conducive to increasing the level of user protection while at least maintaining the ergonomics of the developed personal protections.

Other technological solutions related to coercive technologies selected as part of the implemented processes of mapping technologies with the greatest commercialization potential, including the use of multi-criteria analysis, will also be presented.

The presented design and material solutions were indicated as part of the analysis of the commercialization potential and technology mapping as part of task No. 1 "Development Incubator", as part of the project entitled "Science4Business - Science for Business".

Black mass recovery from lithium-ion battery recycling: interplay of efficiency and chemical composition

Ph.D. Barbara Abreu, Portugal

Poster Presentation

Abstract

The unprecedented demand for lithium-ion batteries, which inevitably reach the end of their lifecycle, is driving the growth of the battery recycling industry. Recycling these batteries is crucial not only for environmental sustainability but also for their significant economic potential: lithium-ion batteries contain critical raw materials, such as lithium, cobalt, nickel, and manganese, in concentrations often higher than those found in natural resources.

Recycling typically begins with shredding, followed by sieving to recover the “black mass,” a fine powder rich in valuable metals, depending on the specific battery chemistry. One of the main challenges in reintroducing black mass into the battery production cycle is achieving high purity with minimal contaminants, which is essential for its further refinement into high-purity individual components via hydrometallurgical processes. As in many industrial separation processes, there is often a trade-off between recovery efficiency and product quality. Thus, careful optimization is necessary to balance material recovery with purity, ensuring both economic viability and environmental sustainability. This study systematically examined sieved fractions of black mass, focusing on optimizing sieve mesh sizes to enhance the recovery of active material. The results demonstrate that selecting appropriate sieve mesh sizes significantly improves active material recovery while reducing contaminant levels. A detailed chemical analysis of the refined black mass confirms its improved purity, reinforcing the effectiveness of this optimization approach.

This work was developed within the scope of the project “NGS – New Generation Storage” [C644936001-00000045], financed by PRR – Plano de Recuperação e Resiliência under the Next Generation EU from the European Union.

Utilization of Wind Turbine Waste in Cementitious Materials: Circularity and Sustainability

Señor. Javier Martínez De Iturrate Vicente, Spain

Poster Presentation

Abstract

The increasing decommissioning of wind turbines has created a challenge in waste management. This study proposes an innovative cementitious composition that partially replaces Portland cement with wind turbine waste (RAG), oxy-combustion ashes (OXI), and polymeric waste (PS), contributing to the circular economy in construction. The mechanical properties and feasibility of these materials for structural and non-structural applications were evaluated.

The waste materials were characterized using XRD. Mixes were prepared with 10% and 20% cement weight replacement using RAG, OXI, and PS. Compression and flexural strength tests were conducted at 7 and 28 days according to UNE-EN 196-1. Additionally, carbon footprint and water consumption were analyzed.

The results indicate that mixes with up to 15% OXI and RAG substitution exhibit mechanical strengths equivalent to or superior to conventional cement. Water absorption was reduced by up to 36% in mixes with porcelain adhesive cement. The "MIX" composition (6.67% OXI + 6.67% RAG + 6.67% PS) provides an optimal balance between strength and circularity, significantly reducing the carbon footprint.

It is concluded that incorporating these waste materials into cementitious compositions is both technically and environmentally viable, effectively reducing industrial waste and aligning with the principles of the circular economy.

Representing MSE Research Metadata Using the NFDI MatWerk Ontology: Patterns and Use cases

Dr. Hossein Beygi Nasrabadi, Germany

Poster Presentation

Abstract

NFDI-MatWerk (National Research Data Infrastructure for Materials Science and Engineering) is a German initiative focused on developing a digital infrastructure that integrates decentralized data, metadata, workflows, and a materials ontology to improve interoperability and reproducibility in materials science and engineering (MSE) research data processing. The NFDI MatWerk Ontology (MWO) is a unified framework developed by the Task Area Ontologies for Materials Science (TA-OMS) within the NFDI-MatWerk initiative. Its primary goal of MWO is to standardize the representation of materials data, ensuring consistency and interoperability across diverse datasets and research activities. By creating structured vocabularies and frameworks, MWO facilitates efficient data discovery, integration, and reuse, thereby enhancing researchers' ability to find, share, and utilize materials data effectively. The newest version of MWO (V3.0.0) has been mapped to the Basic Formal Ontology (BFO) and NFDIcore ontologies and integrated well with Platform MaterialDigital Core Ontology (PMDco v3.0.0). This talk showcases example ontology design patterns (ODPs) developed using MWO and their application in representing practical MSE-based use cases, highlighting their capacity to enable scalable, reusable, and semantically robust knowledge frameworks. ODPs are reusable and modular components that encapsulate best practices for solving common challenges in ontology development, thus help domain experts and developers to create consistent, efficient, and extensible ontologies. The example structural, content-based, and presentation ODPs were designed to define foundational arrangements of entities, address domain-specific knowledge, and optimize user interaction with ontologies. To illustrate the practical utility of ODPs, we presented several use cases within the MSE domain, such as representing metadata for materials, instruments, large-scale facilities, researchers, organizations, educational events, resources, datasets, data portals, and material research software. Through these cases, we emphasize how ODPs facilitate development by offering standardized templates for tasks such as hierarchy modeling, semantic relationship management, and data source integration, while also supporting ontology-driven solutions that are technically sound and adaptable to changing domain requirements.

Microstructural characterization of GTA and EB welded Inconel 718®, subjected to prolonged high-temperature aging conditions.

Mrs. Despoina Theochari, Greece

Poster Presentation

Abstract

Inconel 718 is a precipitation-hardened nickel-based superalloy consisting of nickel, chromium and niobium which enables it to maintain structural integrity under severe thermal and mechanical stress, even at elevated temperatures.

In the present study, Inconel 718 specimens were welded using two different techniques: Electron Beam Welding (EBW) and Gas Tungsten Arc Welding (GTAW). They were then subjected to Post Weld Heat Treatments (PWHT), according to AMS 5662 SAE Standards. After the PWHT, all samples were exposed to the following heat treatments: aging at 700 and 800°C for 24 up to 500 hours in order to investigate their microstructural characteristics and correlate them to the attained mechanical properties. Scanning Electron Microscopy and X-Ray Diffraction were employed for the microstructure characterization, and revealed the precipitation of gamma prime & gamma double prime phases and a significant amount of carbides. Specimens subjected to aging for 500 hours contained delta phase dendritic grains along with smaller volume fractions of gamma prime & gamma double prime phases. Additionally, uniaxial tensile and Vickers microhardness tests were conducted. An increase in mechanical strength of all specimens that were heat-treated was revealed. Finally, the welded zones exhibited excellent mechanical properties after aging for over 24 hours at 700 and 800°C. That makes them suitable for components such as turbine blades, jet engine parts, and pressure vessels.

Using Small-Angle Scattering to Investigate the Structure of Mesoporous Silica and the Spatial Arrangement of Ionic Liquid Films at the Pore Surface

Dr. Julian Fischer, Germany

Poster Presentation

Abstract

The use of mesoporous materials, e.g., ordered mesoporous silica (OMS), for molecular heterogeneous catalysis is of great interest for industrial applications [1]. By embedding an organometallic catalyst inside the mesopores, high surface areas and high catalyst loadings can be realized. The use of an ionic liquid (IL), which contains the catalyst and adsorbs in a thin film on the surface of the OMS (Supported Ionic Liquid Phase, SILP), thus represents a pragmatic approach to significantly increase the selectivity of reactions [3]. To clarify the role of confinement, scattering methods such as small-angle X-ray scattering (SAXS) and small-angle neutron scattering (SANS) are powerful techniques to investigate the structure of nanoscale objects and complement the results of other analytical methods.

Based on SAXS data recorded of pristine OMS materials, we developed a universal multiscale model to analyze the structure at different, independent structural levels, describing the pore-to-pore distance, pore diameter, microporous corona thickness and the micropore length scale. By extending the model with the scattering contribution of the IL, we show that as the filling degree of the pore volume increases, the IL first fills the corona of the micropores and then forms a shell, whose thickness is believed to play an important role in the performance of the confined catalyst. Utilizing scheduled complementary SANS measurements to adjust the scattering contrast via the pressure-dependent filling of the OMS materials with deuterated methane will not only provide more information about the accessibility of micro- and mesopores, but also about the ILs spatial arrangement in the OMS material [4], i.e., whether it penetrates both micro- and mesopores, whether it uniformly wets all pore surfaces or whether the IL even blocks parts of the pores.

Identification of the dissipative micro-mechanisms during mixed-mode fracture of pressureless silver sintered joints in power packages

Prof. J.P.M. (Johan) Hoefnagels, The Netherlands

Poster Presentation

Abstract

Lead-based solders remain in use for high-power semiconductor devices due to a lack of alternatives. Pressureless silver sinter is the most promising replacement, offering a high melting point, excellent electrical and thermal conductivity, low elastic modulus, and low processing temperature. This study investigates the microscopic failure mechanisms affecting interface fracture toughness in two pressureless sintered silver interconnects under mixed-mode delamination. One material contains nanoparticles (NP) between 100–800nm, while the other consists of microflakes (μF) between 1–10 μm . Both were sintered between silver-electroplated copper plates at 250°C and 280°C, forming ~45 μm porous silver layers.

The mixed-mode fracture behaviour was measured with a custom miniature mixed-mode bending setup achieving steady-state delamination at a controlled mode-mixity between mode-I and -II loading, with in situ optical microscopy and digital image correlation to monitor the crack-tip strain field evolution [1,2]. Each test was complemented with post-mortem Scanning Electron Microscopy (SEM) fractography analysis.

The two interconnect materials show pronounced differences in failure behaviour, either interface delamination or bulk fracture, and mixed-mode interface fracture toughness. The NP-interconnects exhibit an expected (nearly linear) increase in interface fracture toughness with increasing mode angle. However, the μF -interconnect exhibits a never-reported mini-mum in the fracture toughness at ~15° mode angle, constituting a 3-fold decrease compared to mode-I delamination. Careful investigation of the cracked samples, by combining side-view SEM imaging, optical profilometry of the fracture surface, and x-ray CT scanning, revealed the intricate details of this unexpected behaviour, showing, e.g., that the fracture morphology switches from bulk to interface fracture between a mode angle of 0° and 30°. This study offers valuable insights into the complex interplay between the microstructures of the interconnect, its failure micro-mechanisms, and the resulting mixed-mode interface fracture toughness [3].

Advanced materials characterization tools: The development of Harmonised documents (CHADA) for Liquid Nitrogen Adsorption and SAXS results on hierarchical porous carbons.

Dr. Fotios Katsaros, Greece

Poster Presentation

Abstract

Energy storage devices such as batteries and supercapacitors are key side-components of tomorrow's European power grid fed with a largely increased share of inherently intermittent renewable energies. Currently, nanotechnology offers several tools towards the decarbonization. Despite the already established commercial use of electrolyzers, huge efforts are required to minimise their critical content (e.g. noble metal), increase the efficiency and improve their cost-effectiveness. Therefore, a global method for widening, deepening, and accelerating the finding of sustainable technologies is needed. Addressing these challenges, KNOWSKITE-X project aims at a science-driven method to develop fine-tunable active materials relevant to energy conversion and storage. Nowadays, hierarchical porous carbon-based have attracted much attention as materials for supercapacitors. The hierarchical pores can exhibit the advantages of each pore size with a synergistic effect during the electrochemical charge–discharge process. On the other hand, the development of relevant characterization methodologies and tools for assessing key properties are critical. Due to the variety of materials and their properties, common terminologies, metadata and documentation are needed. Thus, protocols for sample handling, running characterisation and tests were developed and turned into harmonised documentation (CHADA). In this work, the CHADA scheme for liquid nitrogen adsorption (LN2) and Small Angle X-rays Scattering (SAXS) techniques were built considering: (1) Sample; (2) Method; (3) Raw data and (4) Data processing parameters, enabling the construction of the metadata structure for the specific material's characterization technique. Thus, the LN2 and SXAS characterization metadata of the developed hierarchical porous carbon were prepared and uploaded to project's data platform.

Funding

This work is part of the project entitled 'Knowledge-driven fine-tuning of perovskite-based electrode materials for reversible Chemicals-to-Power devices (KNOWSKITE-X)' funded by the European Union, and granted by the European Health and Digital Executive Agency (HaDEA) [Grant Number 101091534] as part of the "Horizon Europe" framework program (HORIZON-CL4-2022-RESILIENCE-01-19).

A dual light and magnetic responsive mesoporous silica nanosystem for cancer therapy

Dr. Blanca González, Spain

Poster Presentation

Abstract

Superparamagnetic iron oxide nanoparticles (SPIONs) have the capability to generate an intrinsic magnetic field in the presence of an external magnetic field (MF) and this magnetic response persists only as long as the external MF is applied. In addition, these nanosystems can be magnetically guided and focused to the desired location, which is an advantage for clinical purposes. In terms of biomedical applications this property allows for real time non-invasive follow-up treatments. Furthermore, SPIONs have excellent biocompatibility, chemical stability, low production cost, ease of surface functionalization, easy elimination via metabolization and renal excretion. Therefore, SPIONs have been widely studied for multiple biomedical applications such as magnetic resonance imaging (MRI), hyperthermia therapy, targeted drug delivery and recently bone tissue engineering. Furthermore, there has been remarkable breakthrough in the current research on osteogenesis mediated by iron oxide nanoparticles.

On the other hand, photodynamic therapy (PDT) has emerged as a promising alternative, using photosensitizers that, upon light activation, generate reactive oxygen species to induce cell death in targeted tissues. We have recently designed a novel third-generation rhodium-based nanophotosensitizer (RhNPs-MSNs-Tf) incorporating Rh nanoparticles (RhNPs) into the structure of mesoporous silica nanoparticles (MSNs) functionalized with transferrin (Tf) for active targeting of tumor cells. The use of MSNs improves the vehiculization of the near infrared responsive RhNPs in physiological media. After physicochemical characterization, the RhNPs-MSNs-Tf system demonstrated significant singlet oxygen generation upon near-infrared (NIR) irradiation, confirming its ability to induce PDT. Its photodynamic efficacy and cytotoxicity was also proved using an in vitro model, a mass spectrometry-based untargeted metabolomics and the in vivo chicken chorioallantoic membrane model.

In this study, we have first obtained SPIONs via a thermal decomposition method and transferred them to aqueous media via ligand interchange with dimercaptosuccinic acid. Then, the external surface of the rhodium-based nanophotosensitizer (RhNPs-MSNs-Tf) has been decorated with the SPIONs via covalent attachment to the transferrin protein. Hence, both photodynamic and magnetic guidance properties are integrated into a single nanocomposite to obtain a more efficient cancer therapy.

Characterization of osteoarthritis bone changes with nano-CT observation

Dr. Monika Ostapiuk, Poland

Poster Presentation

Abstract

The musculoskeletal system is made up of bones, muscles, joints, tendons, ligaments, fascia, and neuromuscular junctions. It is responsible for maintaining stable posture and movement of the body. Musculoskeletal disorders (MSDs) are defined as diseases of locomotor system or injuries to bones, cartilage, joints, tendons, ligaments, muscles, and nerves. In total, they include more than 150 disease entities. The most common MSD include: pain and functional failure of joints as a result of previous injuries, chronic overload, and degenerative joint disease (osteoarthritis – OA). The treatment of MSD, regardless of the cause, should be interdisciplinary. To be effective therapy, it is necessary to evaluate the tissues forming and surrounding the upper and lower limb joints: muscle, cartilage and bone tissue. One of the methods that allows for the assessment of tissue condition is computed tomography (CT), and interdisciplinarity may consist of conducting detailed research with engineering units using the most modern solutions, such as nano-CT systems. However, there is a limit to the size of tissue samples that must be taken from the already removed long bone epiphysis during surgery (total knee arthroplasty – TKA; total hip arthroplasty – THA; reverse shoulder arthroplasty - RSA). In the current modern approach to treatment, a thorough and meticulous analysis of the tissues involved in the disease process is indicated. In our work, due to the increase in the number of patients suffering from degenerative joint disease, we focus mainly on the methodical evaluation of bone and cartilage tissue. The aim of this study was to determine whether nano-CT analysis of samples (taken from the epiphyses of the proximal tibia obtained during TKA) is an appropriate tool to assess changes in the structure of the subchondral bone plate and bone trabeculae as a result of the development of OA. Research has the consent of the relevant Ethics Committee to conduct the study (KB-0024/150/11/2024). Observations using Zeiss Xradia 510 Versa nano-CT allowed assessment of the degree of mineralization of the subchondral bone plate and changes in the arrangement and density of trabeculae bone in this zone. Furthermore, changes in the cancellous bone was also observed. The results will be the basis for the development of personalized implants using additive technology and medical instruments.

Development of a PIXE Analysis System Using the MC50 Cyclotron Beamline

Ph.D. Seyoung Oh, South Korea

Poster Presentation

Abstract

Particle Induced X-ray Emission (PIXE) is a non-destructive analytical technique widely used for the precise identification of elemental compositions in materials. This project aims to develop a PIXE system utilizing the MC50 cyclotron beamline, designed to enhance analytical precision and versatility across a broad range of applications. The current infrastructure includes proton and neutron beam irradiation systems, a well-configured beamline, and a vacuum sample holder. A key focus of the development process is the precise control of proton beam energy to optimize elemental excitation and improve analysis accuracy. By tuning the proton energy, the system will provide enhanced detection capabilities for various elements while ensuring minimal interference from background signals. The integration of advanced detector alignment and beamline optimization is expected to enable efficient and reproducible elemental mapping. Once completed, the PIXE system will offer a robust platform for material analysis in areas such as environmental studies, cultural heritage preservation, and advanced material research. This project aims to establish a high-performance PIXE analysis system, advancing the potential of non-destructive elemental characterization for both academic and industrial applications.

Densification, microstructure and properties of ZrB₂ particle reinforced copper matrix composite by spark plasma sintering

Prof. Iwona Sulima, Poland

Poster Presentation

Abstract

Copper matrix composites are materials whose use requires excellent mechanical properties as well as high electrical or thermal conductivity. Mechanical properties can be effectively improved by adding a ceramic reinforcing phase to the copper matrix. Crucial aspect in the design of copper matrix composites is to produce a material with good mechanical properties and good conductivity. Spark Plasma Sintering (SPS) is an advanced manufacturing technology that enables the production of very dense composite materials. This study focuses on the effect of sintering temperature (850°C, 900°C, and 950°C) and pressure (20 MPa and 35 MPa) and amount of reinforcing phase on the microstructure and properties of copper matrix composites. The composites with various zirconium diboride contents (5-20 wt%) were synthesised by ball milling and successfully consolidated using Spark Plasma Sintering (SPS). The relationship between the change of ZrB₂ content and physical, mechanical, electrical, corrosion and tribological properties was studied. Scanning electron microscopy (SEM) and electron backscatter diffraction (EBSD) were used to analyse microstructure evolution in copper matrix composites.

The density of the sintered composites was measured by Archimedes' principle. Vickers microhardness and compression tests at room temperature were carried out to investigate the mechanical properties. The electrical conductivity of the samples was determined using a the four-point method. Ball-on-disc method was carried out to study the wear behavior of based composites. The corrosion behaviour was examined in an environment of H₂SO₄ using electrochemical techniques. Experimental data showed that the properties of Cu-ZrB₂ composites depended significantly on the SPS sintering conditions. The optimal sintering temperature was 950°C with a pressure of 35 MPa. Composites exhibited a high degree of consolidation. The relative density of the sintered composites is in the range of 95-97%. The results showed that the higher content of ZrB₂ in the copper matrix is responsible for the improvement in Young's modulus, hardness and wear resistance with the reduction of the conductivity and corrosion resistance of sintered composites.

Dendrite Growth on Aluminum Anodes in Non-Aqueous Aluminum Batteries: Influence of Alloying and Electrolyte Chemistry

Ph.D. Ghadir Razaz, Sweden

Poster Presentation

Abstract

99.99% Al (1xxx) is currently used as the negative electrode for aluminum-base battery. However, this high-purity 99.99% Al hinders the development of Al-based batteries in practice due to its high cost and complex manufacturing process. Therefore, 99.99% Al needs to be substituted with a suitable Al alloy. Additionally, the passivating oxide film covering the Al surface is another issue in Al-based batteries, as it impacts the plating/stripping process on Al in the battery. In general, the knowledge regarding Al negative electrodes in this context is insufficient and requires further detailed study. In this study, three aluminum electrodes from different alloy series—1xxx, 2xxx, and 5xxx, each with different surface and oxide film properties—were fabricated. Plating/stripping tests were conducted on symmetric cells of each alloy. The results demonstrate that the 5xxx aluminum alloy exhibited the best plating/stripping performance compared to the other alloys. Specifically, 5xxx alloys displayed the lowest voltage hysteresis throughout cycling, while 2xxx alloys showed the highest voltage hysteresis. Full cell studies of Al/graphitic cells revealed that cells assembled with 99.99% Al and 5xxx exhibited nearly identical performance throughout recorded cycling numbers. In contrast, cells assembled with 2xxx alloys exhibited a 38% lower efficiency in cycling performance compared to those constructed with 99.99% Al and the 5xxx alloy. These findings highlight the critical role of Al oxide and surface properties in influencing the behavior of Al-based batteries. The results are further discussed in terms of oxide film properties, surface microstructures, and the interphase layer formed on the Al surface. Furthermore, this work sheds light on the oxide film issue, which is recognized as a challenge in Al-based batteries.

DEVELOPMENT OF WEAR-RESISTANT SURFACES BY DEPOSITION OF SOL-GEL COATINGS DOPED WITH Co_Ni NANOPARTICLES

Dr. Maria Fe Menéndez Suárez, Spain

Poster Presentation

Abstract

Surface wear degradation is one of the main causes, together with fatigue and corrosion, that frequently obliged the replacement of equipment parts, increasing maintenance labors and the associated economic cost.

Surface wear degradation is usually partly solved by the application of anti-wear coatings with low coefficient of friction directly on the component parts and techniques based on vacuum processes (CVD and PVD) allow the growth of conformal and dense layers. Indeed, different kinds of coatings based on nitrides (TiN, CrN), carbides (TiC, CrC, W₂C, WC/C), oxides (mainly Al₂O₃), molybdenum disulfide (MoS₂) and diamond-like carbon (DLC) have been widely investigated showing great properties of resistance and adhesion. In the last two decades ceramic coatings (e.g. SiO₂, ZrO₂ or Al₂O₃), with interesting mechanical and corrosion resistant properties, have also been developed using sol-gel technology. Indeed, the sol-gel is a promising alternative to the deposition by vacuum techniques since the deposition parameters, including composition, are easily modified what allow to develop low-cost coatings (1).

The nanotechnology advances have enabled the development of innovative sol-gel formulations with improved tribological properties. Results have been reported in which a Al₂O₃_sol-gel matrix doped with MoS₂ nanoparticles (15-25 vol%) has led to the development of a coating with a very low friction coefficient ($\mu = 0.02$) and minimal wear rate. It has also been shown that small amounts of SiC nanoparticles (5 vol%) improve the anti-wear properties of alumina. Just as anti-wear sol-gel layers developed with Al₂O₃, Ni doped TiO₂ films have been successfully obtained (2).

This work reports the experimental results obtained after the surface modification of galvanized steel DX51D+Z with different coatings of SiO₂_sol-gel/Ni₂O₃_nanoparticles or SiO₂_sol-gel/Co₂O₃_nanoparticles. In all tests the unmodified steel tribological response has been improved, achieving a reduction of 35% in the friction coefficient and a wear rate decrease of 20%. Finally, the current research will be expanded, with the aim of going on with the investigation of the anti-wear effect of other doping agents.

Very high cycle fatigue behavior and failure mechanism of Fe-24Mn-10Al-1C lightweight steels

Mr. Haokun Zhu, China

Poster Presentation

Abstract

Numerous studies have demonstrated the viability of lightweight Fe-Mn-Al-C steels for exhibiting an improved balance of high strength and high ductility in industry applications. However, there are few reports on the very high cycle fatigue (VHCF) performance and fracture mechanism of lightweight steels, which undoubtedly greatly limits its further application. Currently, we have achieved a good mechanical properties (tensile strength 750MPa, elongation 42%) in the investigated duplex lightweight steels. In addition, the investigated steels also exhibited a good fatigue strength (310 MPa) and high ratio of fatigue strength to ultimate tensile strength (σ_f / σ_{UTS} , 0.42). According to our previous research, the investigated steels are composed of austenite. During the quasi-static tensile test, movement of dislocations are dominated planar slip in austenite. However, the cyclic loading may change the dislocation configuration and dislocation structures, which may influence the VHCF performance of the investigated steels. Therefore, in order to further clarify the relationship between microstructure and fatigue performance in Fe-Mn-Al-C lightweight steels, the dislocation structures evolution has been characterized by TEM. In addition, the fracture surfaces will be analyzed by SEM. The three stages of fatigue failure (crack initiation, stable crack propagation and sample failure) could be identified. Through analysis the results of Electron Backscatter Diffraction (EBSD), the effect of ferrite and austenite on VHCF performance and fracture mechanism could be also discussed. Based on above results, we systematically discussed VHCF behavior and fracture mechanism of the investigated steels.

Ab initio simulations of small nanoparticles mechanical properties

Mrs. Sandrine Brochard, France

Poster Presentation

Abstract

Because of their small size and high surface-to-volume ratio, nanoparticles often show specific properties making them interesting systems for many applications in various fields such as biomedicine, biochemistry, catalysis, electronics, etc. They are also largely used as reinforcement components in many materials because their mechanical properties are often better than their bulk counterparts. Indeed, nanoparticles can be synthesized with few or even no internal defects. These latter are potential sources of dislocations or cracks, thus limiting the strength and toughness of bulk materials. In contrast in nanoparticles, dislocations have to be formed at surfaces or homogeneously, which implies much higher stress levels. Nanoparticles are thus often much stronger than the corresponding bulk materials.

It is now well established experimentally and by means of numerical simulations that the strength of materials tends to increase when the size of the considered system decreases, up to characteristic dimensions of about ten nanometers. What remains unsolved is if that increase persists at the lower scales, when the dimensions are further reduced down to a few nanometers.

In that context, we performed ab initio molecular dynamics simulations to investigate the mechanical properties of nanoparticles with sizes of 1 to 2 nanometers. The use of first-principles calculations offers the required accuracy for such a study and complements advantageously experimental studies, giving direct access to the deformation mechanisms. The nanoparticles were compressed along several directions, various shapes were studied and materials with different crystallographic structures were considered: silicon, silicon carbide, aluminum and tungsten. The obtained results show that the strength depends on the nanoparticles shape in all cases, whereas its variation with size depends on the material. The famous "smaller is stronger" rule seems to break down for some systems, though the theoretical bulk strength can be reached or even exceeded depending on the nanoparticles shapes and the compression orientations. Amorphization occurs in most of the nanoparticles, but different and original plasticity mechanisms are also observed in some cases.

Assessing the anticorrosion efficiency of functionalized hybrid sol-gel coatings for environmentally-friendly passivation of galvanized steel

Dr. Lucía Florentino, Spain

Poster Presentation

Abstract

The use of hexavalent chromium-based conversion coatings for corrosion protection of galvanized steel and other metals has been widespread due to their exceptional corrosion resistance and self-healing properties. However, the toxic and carcinogenic nature of hexavalent chromium has led to its restriction in many countries. In response to these concerns, silane technology has emerged as a promising alternative. Among the silane-based solutions, sol-gel coatings have shown particular promise in enhancing corrosion resistance when applied to metallic surfaces.

The sol-gel process involves creating an oxide network through hydrolysis and condensation reactions of various precursors in a liquid medium. These coatings can be synthesized using either inorganic or organic precursors, each offering unique characteristics. To harness the benefits of both precursor types, researchers have developed hybrid coatings that incorporate organic components into the inorganic matrix. This innovative approach yields coatings with distinctive properties in terms of morphology, size, and multifunctionality, resulting from the synergistic interaction between organic and inorganic components. These hybrid coatings effectively combine the durability and chemical resistance of inorganic materials with the flexibility and functionality of organic compounds. As a result, they demonstrate enhanced performance in various applications, including corrosion protection, wear resistance, and surface modification.

This research focused on the synthesis of hybrid sol-gel coatings under varied experimental conditions. The process involved the hydrolysis of 3-(Glycidioxypropyl) methyl diethoxy silane (GPTMS) and tetraethyl orthosilicate (TEOS). To improve coating thickness and mitigate stresses during curing, polyvinylpyrrolidone (PVP) and polyethylene glycol (PEG-6000) were incorporated into the formulation. Furthermore, various corrosion inhibitors were added to the sol-gel matrix in different concentrations in order to enhance the anti-corrosion properties and extend the coating's durability. These inhibitors included ZnO and ZrO nanoparticles, as well as lanthanum and zirconyl nitrate. The application of the sol-gel film to galvanized steel plates was accomplished using the dip coating technique. To assess the corrosion resistance of the coated samples, salt spray tests were conducted.

The corrosion resistance of galvanized steel was substantially improved, with the onset of white rust delayed by over 264 hours. This marked enhancement in protective performance demonstrates the efficacy of the developed coating system in significantly extending the durability of the galvanized steel substrate under corrosive conditions.

Smart Coatings Through Sol Gel Microencapsulated Additives

Dr. Lucía Florentino, Spain

Poster Presentation

Abstract

The microencapsulation of active substances for inclusion in smart surface coatings is currently pro-posed as a novel technique to protect their integrity and functionality, so that their activity does not take place until the capsule shell is opened upon receipt of a stimulus. Metallic corrosion continues to be a current problem in the industry as it is a degradation process that occurs naturally and inevi-tably. Among the methods available to prevent this phenomenon, the application of coatings is the most convenient alternative. However, their use entails other problems such as cracking or degrada-tion, so they must be repaired, since any crack or defect would cause corrosive substances to reach the metal surface. Nowadays, it is necessary to find new solutions to solve corrosion problems locat-ed in inaccessible sites, such as off-shore facilities, to reduce maintenance costs. For this reason, the use of self-healing coatings, based on the use of additives, is considered in recent times as the most innovative option. Direct doping with these additives has been widely studied but has some disad-vantages, such as easy leaching from the matrix or reaction with some of its components and conse-quent loss of efficiency. Isocyanates are the most promising self-healing reagents as they do not require a catalyst, however, their encapsulation is hampered by their high reactivity. In this work, isolation of these compounds was carried out efficiently by microencapsulation. Most examples in the literature are based on the introduction of these capsules in epoxy resins but few and very recent are the examples where they are introduced in sol gel matrix for self-healing coating of a galvanized steel. Here we describe the encapsulation technique of interesting additives by sol gel technology, synthesizing “microcontainers” of these compounds to achieve a more prolonged effect and isolate the inhibitor from the coating matrix. In addition, these microcapsules are dispersed in a new sol gel coating formulation specially designed for galvanized steel to increase its corrosion resistance and provide it with self-repairing capabilities.

On the other hand, microencapsulation of liquid lubricants contained in a rigid silica shell is also studied in this work, together with their integration in a coating matrix. In this manner, another type of smart coating was designed, in order to act as a self-lubricating material when these cap-sules are deposited by dispersion in certain coatings. Its application on the design of energy-efficient machinery offers a solution to reduce energy consumption.

LOW- VELOCITY IMPACT PERFORMANCE OF 3D PRINTED CONTINUOUS FIBRE REINFORCED BIOINSPIRED COMPOSITES STRUCTURES

Prof. Miguel Ángel Caminero Torija, Spain

Poster Presentation

Abstract

This study proposes the development and mechanical characterization of bioinspired composite material structures based on Bouligand-type helicoidal architectures, processed using Fused Filament Fabrication (FFF) additive manufacturing technology. These structures can be found, for example, in the exoskeletons of various crustaceans and insects. It has been observed that such structures enhance the mechanical properties of the material, particularly its toughness and impact resistance. FFF-based additive manufacturing is a highly promising technology for polymeric materials and presents an alternative to conventional techniques due to its ability to create functional structures with complex geometries.

In this work, thermoplastic matrix composite structures reinforced with continuous carbon fibre were manufactured. The primary goal was to characterize the mechanical behaviour, specifically the toughness and low-velocity impact resistance, of bioinspired helicoidal composite structures reinforced with continuous fibre, depending on the reinforcement arrangement through the thickness. Additionally, the effect of a post-processing technique, hot compression, was analysed to reduce the porosity inherent to the manufacturing process. Mechanical characterization was performed using standardized ASTM D3039 tensile tests and ASTM D790 three-point bending tests. Furthermore, interlaminar shear strength (ILSS) tests were conducted in accordance with ASTM D2344 standards to analyse the effects of porosity, matrix-fibre interaction, and layer-to-layer interaction on the interlaminar behaviour for each configuration. Finally, Charpy impact resistance tests were performed according to ASTM D6110 for the different helicoidal configurations. The fracture surfaces were then analysed using scanning electron microscopy (SEM) and optical microscopy.

A sustainable approach to design electrode in structural battery composite applications

Dr. Shohel Siddique, United Kingdom

Poster Presentation

Abstract

A simple, cost-effective, scalable and increasingly efficient structural battery composite (SBC) is under development in our group now. To follow through this innovation aspects, a sustainable anode material for SBC is developed and demonstrated. A low-cost, abundant and most importantly the raw material sourced from a spent brewery waste (draff) that is used to synthesise activated carbon at relatively low temperature (≤ 500 °C) under pyrolytic environment and without using any harsh and toxic chemicals. These draff derived engineered activated carbons (DEACs) are characterised by different physical characterisation techniques such as XRD and Raman spectra which revealed the mixed amorphous and graphitic crystalline nature of the DEACs whereas FE-SEM and BET analysis results highlighted the high porous nature of DEACs. The DEACs anode further showed a promising rate capability and an excellent reversible specific capacity of 43-236 mAh g⁻¹ at 0.2 A g⁻¹ current density after 100 cycles. The sample synthesised at 500 °C using 1:4 pyrolysed C: KOH showed the highest quality and demonstrates superior electrochemical performance as anode material in a sodium ion battery coin cell with 87% capacity retention over 100 cycles and >99% coulombic efficiency. Hence, this work will promote the development of sustainable SBC utilising the low cost, green and high-performance electrode produced from the waste stream.

Effect of Post-Processing Parameters on the Surface Properties of Ti6Al4V Scaffolds Manufactured by SLM

Ph.D. Ada Orłowska, Poland

Poster Presentation

Abstract

Additive manufacturing technologies based on selective sintering of metal powders can be used to produce implants with appropriate mechanical properties and favorable conditions for osseointegration by providing space for bone tissue penetration into the implant. While powder-based additive manufacturing allows for precise control of the implant's pore structure, modifying the surface properties—especially in the central regions—remains challenging. These properties are crucial for the final functionality of the implants.

The aim of this study is to evaluate the effect of post-processing parameters, namely annealing and etching, on the surface properties of scaffolds made from Ti6Al4V using selective laser melting (SLM, 3D EOS M100). The designed porous structure, based on a diamond-shaped lattice with a pore size of approximately 600 μm , featured an open architecture with spherical pores. The manufactured samples were initially cleaned with compressed air and then subjected to ultrasonic cleaning. After cleaning, the samples were weighed, and their true porosity was determined using helium pycnometry (Micromeritics® 1305).

The samples were vacuum annealed for 2 hours at 800°C, 900°C, and 1000°C, followed by vacuum cooling. Subsequently, they underwent single-step etching for 9 minutes and sequential etching (3 $\times$ 3 min) in 50 ml of HF/HNO₃ solutions at different concentrations (1%/10%, 2%/5%). After each immersion step, the scaffolds were ultrasonically cleaned. The surface topography of the modified samples was analyzed using scanning electron microscopy (SEM, Tescan Vega) and optical profilometry (3D Surface Metrology Microscope, Leica DCM8), performed globally and on selected small areas. Surface wettability was assessed by measuring the static contact angle (CA) of a 5 μl water droplet using an optical tensiometer with a topography system (Theta 3D). Additionally, to determine the effect of thermal treatment on the material structure, metallographic sections were prepared and etched with 8% HF to reveal the microstructure. Metallographic analysis was conducted using a Leica DMI8 A microscope.

The conducted research demonstrated the influence of annealing temperature on the metallographic structure and grain size. However, the grain elongation along the OZ axis, characteristic of additive manufacturing technologies, was preserved. Annealing did not affect the observed surface topography. Sequential etching minimized the mass loss of the scaffolds, which is crucial for maintaining their potential mechanical strength. The applied modifications positively influenced the surface wettability of the tested scaffolds.

Additively Manufactured short carbon fibre reinforced Polymer and Aluminium alloy Multi-Material joints using Friction Stir Welding (FSW) for light and thermal management applications in the transport sector.

Dr. Marta Alvarez - Leal, Spain

Poster Presentation

Abstract

The EU aims to be climate-neutral by 2050 – an economy with net-zero greenhouse gas emissions. In this sense, lightening the weight of components used in the transport sector has become a strategic point for reducing CO₂ emissions. In this context, the gradual replacement of actual 100% aluminium components with hybrid aluminium-polymer solutions can become a strategic line for the transport sector. These innovative approaches aim to reduce weight while ensuring properties such as heat dissipation; a capability that polymers alone often lack. Friction Stir Welding (FSW) emerges as a crucial advanced technology for joining aluminium and polyamide (PA6) reinforced with short carbon fibres, both additively manufactured.

Friction Stir Welding offers several advantages, including the ability to create strong, defect-free joints at relatively low temperatures, minimizing thermal distortion and preserving the mechanical properties of the materials involved, but definitely, the most important advantage of FSW is that the material does not melt. As industries seek to improve efficiency and sustainability, the development of these hybrid materials reflects a promising trend towards innovative engineering solutions that leverage the unique properties of each constituent material, ultimately leading to enhanced product performance and longevity.

This study employed a heavy-duty robot equipped with a Friction Stir Welding (FSW) head to create joints between multi-materials fabricated through additive manufacturing. The polymer matrix, polyamide 6 reinforced with short carbon fibres, was produced using Material Extrusion (MEX), while the aluminium alloy AlSi10Mg was manufactured via Laser Powder Bed Fusion (L-PBF). To ensure the integrity of the polymer and prevent degradation due to elevated temperatures, optimal processing parameters were meticulously determined. Furthermore, to enhance the mechanical strength of the joints, various interlocking strategies were developed and strategically implemented by the research team. Comprehensive visual inspections of the joints were conducted alongside mechanical testing to assess the viability and effectiveness of this innovative approach. The results aim to contribute significantly to advancements in multi-material welding technologies within the context of additive manufacturing.

In this international research study facilitated by the European Multitem project under the Horizon Europe program, the successful integration of polymeric materials with aluminium alloys was achieved through the FSW technique. Innovative interlocking strategies between the two materials enhanced the mechanical strength of the joints. This solution applies to two actual industry use cases in the transportation sector, including one for an aerospace component belonging to the multinational THALES.

Pulsed laser interference heating of FeSiB ribbons - Structure and properties characterization

Dr. Agnieszka Radziszewska, Poland

Poster Presentation

Abstract

Pulsed laser interference heating (PLIH) is a technique that allows regular distribution of micro- and nanostructures on the surface of various materials. It is characterized by high efficiency, precision, and resolution, which leads to improvement of material properties, such as magnetic, biomedical, mechanical, optical, or tribological properties. PLIH allows for precise impact of energy on a precisely defined area of the material surface, which makes this technique very promising for use in fields such as electronics, energy, biomedicine, or nanotechnology. Under the influence of pulsed laser heating, a fine-crystalline structure of the material can be obtained because of the occurrence of rapid cooling and a high crystallization rate. This works in favor of modifying the structure of thin surface layers of the material, minimizing thermal deformations, and enabling precise control of the thickness of the processed layers. PLIH is based on the phenomenon of interference of two or more coherent laser beams, which leads to the formation of periodically distributed micro-areas on the surface of materials. Many industries are looking for new materials with improved properties, including magnetic materials, such as FeSiB alloys with the addition of, e.g. Cu and Nb. The aim of the research is to improve the magnetic properties of these materials while maintaining their mechanical properties by heating thin surface layers of FeSiB alloys. The use of the PLIH technique, including laser surface annealing, has the following functions: to accelerate the process of creating a nanocrystalline structure, increase crack resistance, reduce production costs, and significantly improve process efficiency. This work presents the structure and changes in the properties of the material subjected to laser interference surface heating.

Composite materials obtained by reactive infiltration: The Si-Ti-C system

Prof. Javier Narciso, Spain

Poster Presentation

Abstract

Within the aeronautical industry, one of the most advanced materials used is the SiC/Ti composite material, where the reinforcement is SiC fibers obtained by CVD, among other parts, which have been used in the manufacture of turbine blades. Therefore, the Si-Ti-C system is of vital importance in this industry [1].

In this work, another view of the Si-Ti-C system is shown, but in this case for the manufacture of SiC/TiSi₂ composite materials by reactive infiltration [2-4]. These materials have the advantage over SiC/SiC obtained by reactive infiltration in that at high temperatures, as occurs with the SiC/MoSi₂ system, there is a ductile-brittle transition that makes them viable competitors as a complement to SiC/SiC in jet engines, where they have achieved an improvement in energy efficiency of 5%.

In this research, both the infiltration process of different Si-Ti alloys and the optimization process are presented. The infiltration kinetics and the thermomechanical properties of all the materials obtained have been analyzed. The mechanical properties have been analyzed both at room temperature and at 900° C. These materials show an increase in bending strength of 25% compared to their counterpart obtained by Si infiltration at room temperature, and have shown greater creep resistance.

Modelling and Experimental Verification of the Freezing Process in Ice Templating

Mrs. Justyna Więcek-Chmielarz, Poland

Poster Presentation

Abstract

Introduction

Novel material solutions in cardiac surgery are highly anticipated, due to the multitude of complications and the need for fast and efficient regeneration. Advances in materials engineering and its link to tissue engineering may offer promising tools for creating a new type of prosthesis for the heart. The work has a basic character and focuses on the development of a new concept of myocardial regeneration in the form of porous materials

Goal

The work involved the scientific development of correlative microscopy technique to control the process of porous material creation based on ice templates. The porous scaffold was developed with the intended application in heart regeneration.

Methods

The porous structures were fabricated using an ice templating technique. The material prepared in this way has a controlled architecture depending on the freezing direction. To introduce a controlled temperature gradient during freezing, copper inserts with various inclination angles were used. Copper was chosen due to its high thermal conductivity, allowing for effective heat transfer and controlled ice crystal growth. In accordance with the angle between the surface of the insert and the bottom of the vessel, the conductive material influenced the degree of the material porosity. In this study, an alginate solution was used. The freezing process was carried out at three distinct temperatures: -20°C, -80°C, and -196°C (liquid nitrogen), to investigate the effects of different cryogenic conditions on the formation of porous structures. This approach aimed to create a tailored porosity gradient, which was a critical parameter for optimizing toward future tissue integration. The fabrication process was preceded by finite element modelling of the temperature distribution. In the work, porosity was controlled using complementary microscopy techniques, including digital microscopy, acoustic microscopy, scanning transmission electron microscopy and confocal laser scanning microscopy.

Results and discussion

The analysis of the relationship between temperature conditions and the resulting pore's shape and size, enabled to understand how ice templating can be tailored for tissue engineering applications. The simulations provided insights into how different inclination angles affected the temperature gradient, enabling better control over the material properties in subsequent fabrication steps. By adjusting the insert angles, it was possible to induce variations in the local cooling rate, leading to differences in pore size, distribution, orientation and overall microstructure.

Study of the tribological behavior of SnO₂ coatings under low atmospheric ethanol contamination

Prof. M. C. Marco de Lucas, France

Poster Presentation

Abstract

Friction and wear at the interface between solids have a major impact on the service life of all kinds of mechanical systems. The development of high-performance dry lubricants to deal with this problem must take into account the surrounding atmosphere, including the presence of contaminants. Different physico-chemical mechanisms involving the materials in contact and their internal and external (ambient) contaminants can compete and give rise to the formation of lubricating interfaces through mechanically activated chemical reactions involving particles generated at the contact [1-2]. Traces of contaminants (in the ppm or ppb range) are enough to initiate the creation and maintenance of this lubricating and anti-wear interface [3,4].

The aim of the present work is to investigate the influence of very low concentration of volatile compounds, at ppm level, on the tribological behavior of surface coatings. To this end, tin oxide, known for its sensitivity to the adsorption of ethanol molecules, was chosen as the material to study. Indeed, SnO₂ is used as a sensitive material for ethanol gas sensors.

PVD-deposited SnO₂ thin films on silicon substrates were subjected to friction in three different atmospheres: laboratory air, dry N₂ and dry N₂ contaminated with 1000 ppm ethanol vapor. Contact conditions: sliding speed 8 mm/s, average contact pressure 330 MPa, room temperature, 100Cr6 sliding counterpart and 500 reciprocating friction cycles. The results showed a strong impact of the gaseous environment on the coefficient of friction, as well as on damage and wear. This effect, expected for N₂ compared with laboratory air, was also observed in the case of N₂ contamination with traces of ethanol, with a reduction in average friction by a factor of 2.5 to 3, and much lower friction damage.

The study of friction tracks on SnO₂ films and steel counterparts using surface analysis techniques is essential to advance our understanding of the tribochemical mechanisms involved. Here, SEM observation of friction scars and elemental EDX analysis have been complemented by XPS, SIMS and micro-Raman spectroscopy. Surface analysis shows that material composition at the interfaces varies, particularly in terms of the proportion of iron oxides. The formation of a mixed Fe-Sn-O compound has also been investigated.

Role of Chemical and Physical Conditions on Nitrogen Insertion During High-Temperature Oxidation of titanium in Air

Prof. M. C. Marco de Lucas, France

Poster Presentation

Abstract

Metals and alloys are used in many technological applications requiring extreme temperature conditions. Their resistance to high-temperature oxidation becomes a major challenge, enabling them to be used for longer or shorter periods of time, depending on the type of application. In the aeronautics sector, an additional selection criterion for reducing operating costs is material density. Titanium combines low density with good specific strength and wear resistance, as well as good corrosion and oxidation resistance up to 550°C. Many ways were explored to increased High Temperature resistance of alloys, specially titanium ones.

Then, we will present various studies focusing on the role of physical conditions which govern formation of the oxide layer and also in the case of oxidation of titanium in air the insertion of nitrogen into metal substrates. And so, various reactive surface treatments using a laser source and classical oxidation in a furnace are displayed for at high temperature oxidation in air in the case of different metallic bases (iron, titanium and aluminum).

We will discuss the role of the coalescence rate on nanoparticle formation in the case of a laser plasma plume for laser ablation (Ti, Al and Fe) [9,10], but also the role of the solidification temperature of the different phases during cooling of the liquid bath formed by laser marking treatment of titanium [6,7, 10]. In the case of high-temperature oxidation in air of titanium alloys, we will also discuss presence of additional elements, or the surface state on the role of additional elements in the formation of the nitride layer at the metal-oxide interface [2].

In these studies, the choice of analytical techniques to determine the location of nitrogen and quantify its insertion was of great importance. Specific and complementary analyses were carried out under synchrotron radiation (ID22-ESRF and SWING-Soleil), or by techniques using ion beams (Saclay) such as Rutherford backscattering spectrometry (RBS) or Nuclear Reaction Analysis (NRA). Other characterization techniques such as electron microscopy, electron microprobe (EDX, WDS), X-ray diffraction and Raman spectroscopy have also been used to complete the studies.

The challenge of understanding the conditions of formation of such nitride phases results in the different properties for those kind of oxynitride layers, in terms of adhesion, protection against oxidation and also accommodation of various mechanical stresses such as friction or wear.

Evaluation of the remaining service life of district heating preinsulated pipes: In-depth study of a method based on the thermogravimetric analysis of the insulating polymeric foam

Dr. Marco Rolfi, Italy

Poster Presentation

Abstract

To plan activities aimed at the maintenance and improvement of district heating systems, in a logic of energy efficiency and investment containment, great importance is attributed to the evaluation of the residual service life of the preinsulated bonded pipes in use. A preinsulated pipe is a multi-material system consisting of a steel pipe, in direct contact with the circulating hot water, a rigid polyurethane (PU) foam as thermal insulation, and an outer polyethylene casing. Specific technical-scientific literature suggests that the ageing process of a preinsulated pipe is controlled by the decay of the physical characteristics of the PU foam. In consideration of this, a laboratory testing method based on the thermal analysis of the PU foam has been recently proposed as a promising approach for the estimation of the residual service life of a preinsulated pipe. This method is based on the study of the degradation processes of a PU foam sample collected from a preinsulated pipe, from tests at the thermogravimetric analyser. It allows determining a parameter characteristic of the actual degradation state of the PU foam under investigation, thus enabling an evaluation of the pipe ageing conditions. In this work, this thermogravimetric analysis-based approach is critically reviewed with the final aim of outlining a solid testing protocol that could be used as a reference testing scheme in routine preinsulated pipes condition assessment operations. For this purpose, both the aspects related to the execution of the tests (testing conditions) and those related to data processing are carefully investigated. PU foam samples, collected from preinsulated pipes in service for different periods of time, and taken from areas subject to different levels of thermal load (when in service), are examined. Furthermore, for some pipes, the information obtained from the application of this method is discussed based on the outcomes from other pipe characterization techniques.

Paper 157

Mechanical in-situ investigation of Ni/PU hybrid foams for energy absorption and protection applications using X-ray computed tomography

Mr. Jonas Fell, Germany

Poster Presentation

Abstract

Metallic foams are porous materials that exhibit unique properties, making them valuable for a wide range of applications. Their high strength-to-weight ratio and excellent thermal conductivity make them ideal for use in lightweight construction and as heat exchangers. Additionally, their exceptional energy absorption capabilities make them well suited for crash protection in automotive and aerospace industries, enhancing safety during impacts. Metallic foams are also incorporated into protective equipment to absorb shocks and mitigate damage.

In this study, Ni/PU hybrid foams produced via electrodeposition and optimized for energy absorption are investigated. These foams are designed for use as mobile protective barriers in explosive ordnance disposal services and as façade elements for critical infrastructure, such as embassies. To enable the attachment of large foam elements to a façade, inserts must be embedded into the foam. Consequently, inserts are incorporated into the PU foam and subsequently coated via electrodeposition to ensure a secure bond with the foam. This critical interface, along with the foam's compression behavior, is analyzed using X-ray computed tomography (CT).

X-ray CT is a powerful, non-destructive technique for three-dimensional (3D) imaging of materials. It enables in-situ analysis of microstructures and their evolution during mechanical testing, providing detailed insights in 3D. The study presents mechanical in-situ investigations using a load cell to perform compression tests. Additionally, the load cell is adapted to conduct pull-out tests to evaluate the connection strength between the inserts and the foam. These experiments are performed on foams with varying pore sizes, allowing for a comprehensive understanding of the influence of pore size on mechanical behavior and insert bonding.

Paper 930

Effect of Laser Treatment on the High-Temperature Oxidation of Titanium Alloys Through Surface Nitrogen Enhancement

Ph.D. Donata Kuczyńska-Zemła, Poland

Poster Presentation

Abstract

High-temperature corrosion of Ti-based alloys remains a challenge in applications operated above 600 °C. Recent experimental studies have shown that atmospheric nitrogen significantly influences the oxidation of Ti and its alloys in an air atmosphere [1-3], with a synergistic interaction between nitrogen and alloying elements [1,2]. The interaction of nitrogen with alloying elements contributes to the formation of a compact oxide scale and reduces the mass gain during high-temperature tests. Therefore, this work's main aim is to intentionally introduce nitrogen into the surface region of the near- α Ti alloy using laser surface treatment (LST) and to evaluate its resistance to high-temperature oxidation. LSTs were performed using the Brilliant laser (nanosecond, 1064 nm) on the multi-component Ti-alloy Timetal 834 (Ti-Al-Sn-Zr-Nb-Mo-Si-C). Treatments were performed in the air atmosphere with varying laser settings to modify the nitrogen content in the surface layer, producing samples with distinct surface colors, including yellow, purple, and blue. Oxidation tests at 650 °C for 100 hours in an air atmosphere revealed a significant improvement in the high-temperature oxidation resistance of LST-treated samples. To explain the observed phenomenon, the modified Ti834 samples (both unoxidized and oxidized) were analyzed in terms of morphology, roughness, chemical composition, and phase composition. Particular emphasis was placed on examining the microstructure and chemical composition of cross-sections after laser treatment.

A systematic comparison of surface conditions after LST and their oxidation resistance enabled the identification of key factors responsible for enhancing high-temperature oxidation resistance. LST modification, through microstructure refinement and presence of the nitrogen in the surface region, causes changes in the oxidation behavior of Ti834 alloy.

These findings are especially significant as they can facilitate the development of surface treatments tailored for applications in the aerospace, automotive, and gas turbine industries.

Laser micro-textured aluminium metallic surfaces for self-cleaning and stickers anti-vandalism urban furniture applications.

Ph.D. Ana L. Martínez Díez, Spain

Poster Presentation

Abstract

The development of new materials with improved properties and new functionalities is a permanent challenge for the industry to obtain differentiating products or products with high added value. In the case of urban furniture, such as bike parking, bins, bus shelters..., the most common innovation trends focus on aesthetic design improvements. Important aspects such as self-cleaning and stickers anti-vandalism are generally not taken into account what rapidly interfere on the furniture appearance and force to do costly maintenance works. Most studies and actual solutions for urban furniture protections are mainly focused on the application of functionalized coatings with anti-adhesive and hydrophobic properties. However, these coatings life time is relatively short and oblige to periodic maintenance works with the consecutive associated costs.

Laser patterning is a promising method to achieve a direct surface modification on metals, due to the potentially high fabrication speeds, low waste and a single-step processing (1-3). Moreover, as the micro-textured surface is carried out in the metal substrate itself, the surface properties reached last for a long time.

This work reports the surface modification of Aluminium AA60-61, using several micro-textured patterns, to develop superhydrophobic and anti-adhesive properties by means of a solid-state pulsed Nd-YAG nanosecond laser with the 1064nm wavelength (Rofin). Directly after fabrication, the samples show a hydrophilic behavior but gradually become superhydrophobic over time with the maximum contact angle of 158,6° being achieved after 60 days, exhibiting a self-cleaning property. This wettability modification has been explained by a surface oxidation of the aluminium.

Furthermore, the micro-textured pattern has been successfully developed to ensure an anti-adhesive property, facilitating an easy and perfect removal of the stickers. Overall, this work demonstrates a cost effective, direct write, environmentally friendly and fast processing method to modify wettability of aluminium metals for anti-vandalism applications.

Electrochemical Charging of MAX Phases and MXenes as Candidates for Hydrogen Storage Materials

Mrs. Rebeca Miyar, Germany

Poster Presentation

Abstract

Hydrogen storage is a critical challenge in the transition to renewable energy systems, where hydrogen serves as a clean, efficient energy carrier. However, current storage methods face significant limitations in scalability, safety, and efficiency, highlighting the need for innovative solutions. MAX phases and their two-dimensional derivatives, MXenes, have emerged as promising materials due to their unique layered structures, which provide favorable hydrogen trapping sites; including interstitial spaces within carbide and M-A layers, interlayer regions between MXene sheets, and surface terminations. These materials exhibit the potential to store and release hydrogen under mild conditions while maintaining structural integrity, positioning them as strong candidates for practical hydrogen storage applications. Although theoretical studies have demonstrated the potential of MAX phases and MXenes for hydrogen storage, experimental efforts thus far have been limited, with only a few studies exploring gas-phase hydrogen charging. Electrochemical hydrogen charging presents an attractive alternative, enabling solid-state storage at room temperature and ambient pressure. Despite this potential, no studies have yet investigated electrochemical hydrogen charging of these materials, the mechanisms of hydrogen diffusion, or the effects of hydrogenation on their structural and functional properties. Herein, we address this gap by presenting the first demonstration of electrochemically charged MAX phases and MXenes, presenting associated challenges and evaluating their hydrogen storage capabilities. To characterize hydrogen trapping behavior, diffusion mechanisms, and microstructural effects, we employed a suite of advanced techniques, including hydrogen charging, thermal desorption spectroscopy (TDS), Kelvin probe (KP) measurements, in-situ X-ray diffraction (XRD), and scanning electron microscopy (SEM). By gaining deeper insight into hydrogen permeation and trapping mechanisms, this work lays the foundation for the development of sustainable and efficient hydrogen storage technologies for future energy systems.

Lanthanide and bi-lanthanide loaded zeolites for wastewater treatment

Prof. Ljiljana Damjanović-Vasilić, Serbia

Poster Presentation

Abstract

The pharmaceutically active substances, widely used in human medicine, veterinary medicine, and aquaculture, represent an important group of emerging pollutants. They often enter the aquatic ecosystems through various sources such as municipal wastewater, inappropriate disposition of expired medicines, human and animal excretions, livestock farming. Numerous pharmaceutically active substances can be found in various water sources at concentrations ranging from ng/L to µg/L, because traditional methods for water treatment are insufficiently effective for their removal. During the past decade fluoroquinolone (FQ) antibiotics, norfloxacin (NOR) and ciprofloxacin (CIP), have been often detected in the environment. Long-term exposure to these compounds can cause harmful effects on aquatic organisms and human beings. Therefore, development of materials efficient for their removal, using simple and inexpensive methods, is an important research area.

Zeolites are microporous hydrated crystalline aluminosilicates of alkali or alkali earth elements (e.g. sodium, calcium). Because of well-defined structures made of pores and channels, large surface area, and high thermal stability, these materials are frequently used in adsorption, separation, and catalysis. Zeolites exhibit three-dimensional open framework structure composed of TO₄ (T = Si, Al) tetrahedra which are connected via corner oxygen atoms. The negatively charged framework is neutralized by charge-balancing cations, that are located in pores and channels and can be easily replaced by other cations via simple ion exchange procedure. Additionally, the amount of cation dopants is controlled by the aluminum content and zeolite structure.

In this work, two structurally different zeolites (FAU, BEA) have been loaded with lanthanide cations Eu, Ce and Tb, using cost effective and simple ion-exchanged procedure from diluted aqueous solution of lanthanide nitrate salts. The physicochemical characterization of prepared materials Eu-Y and Eu-β, as well as CeTb-Y and CeTb-β zeolites was done by X-ray powder diffraction analysis, FTIR spectroscopy, scanning electron microscopy with energy dispersive spectroscopy, ultraviolet–visible diffuse reflectance spectroscopy, X-ray photoelectron spectroscopy, fluorescence spectroscopy, and low temperature N₂ adsorption-desorption. Photoluminescence, adsorption and photodegradation with exposure to simulated solar light of NOR and CIP served as a tool to estimate potential application of prepared multifunctional materials. The photocatalytic degradation of NOR and CIP after 180 minutes of irradiation was ~30 % for both Eu-Y and CeTb-Y zeolites. The results showed the highest removal efficiency after 180 minutes of irradiation for Eu-β (~75 %) and CeTb-β (~65 %) zeolites, that resulted from two processes: adsorption and photocatalytic degradation.

Paper 2026

Integrated SERS-based microdroplet platform for antibiotics detection in water

Mrs. Bruna Alves, Portugal

Poster Presentation

Abstract

The detection of antibiotics in marine environments is a growing concern, as their presence can lead to environmental imbalances and contribute to antibiotic resistance [1]. In our study, we explore the use of surface-enhanced Raman scattering (SERS) as a promising analytical tool for detecting these contaminants owing to its high selectivity, being one of the most sensitive techniques currently available. Additionally, SERS has other advantages that hold particular significance in sensor development, including reduced time requirements and the potential for in-situ measurements, which are important for real-time water monitoring [2].

The analytical applicability of SERS is intricately linked to the fabrication of highly efficient SERS substrates. In this work, a series of hybrid composites were developed by integrating covalent organic frameworks (COFs) with gold nanoparticles (GNPs). COFs are crystalline, high-surface-area materials that can act as chemoreceptors for the antibiotics. When attached to a plasmonic surface such as GNPs, these highly porous hybrid composites facilitate the concentration of molecules near the plasmonic surface, generating a unique SERS fingerprint spectrum that enables the antibiotic detection [3]. We integrate the highly sensitive SERS detection enabled by the composites in a microdroplet-sensing platform, which facilitates an automated, reproducible and ultra-fast multiplexed detection in nanoliter volumes [4]. First, we evaluated the encapsulation and stability of the hybrid composite inside the microdroplets, which were fabricated using a T-junction microfluidic device paired with a mixer to enhance the interaction between the composite and the antibiotics using an in-house developed detection microfluidic device. The antibiotic detection was carried out using a portable Raman system with a 785 nm laser line. The initial results indicate that this approach shows great potential for developing an autonomous, in-situ sensor with high sensitivity for monitoring antibiotics in water systems.

Detection using computer vision and analysis of the mechanical effect of fiber orientation degree in composite materials.

Prof. Juan Antonio Almazán-Lázaro, Spain

Poster Presentation

Abstract

A precise understanding of mechanical properties of materials enables a more efficient use, reducing resource consumption during manufacturing and optimizing the final weight of components. In long-fiber-reinforced composites, predicting and correcting fiber alignment deviations during production is especially beneficial in Industry 4.0. This study presents advances in fiber orientation monitoring in thermoplastic and thermosetting composites. A methodology is described to analyze fiber orientation distribution over large material areas. Computer vision and image processing algorithms help control fiber alignment throughout manufacturing. Before production, improper fiber orientations can be detected and adjusted. After manufacturing, the method helps estimate the final mechanical properties of the laminate based on fiber distribution. Results show high detection accuracy across various composite materials, allowing for reliable mechanical property predictions. This approach can also be applied to more complex composites using advanced vision techniques.

Olive oil waste as basis for polyurethane coatings

Dr. Antonio Peñas Sanjuan, Spain

Poster Presentation

Abstract

Despite the recent burgeoning interest for biobased materials, plant oils have been studied for more than 20 years as building blocks in a wide range of synthetic routes. Demanding policies from EU government and increasingly requests from overall society is forcing to an overtaking to fossil-based products, marked by a detrimental large footprint.

Vegetable oils are mainly constituted by a mixture of triglycerides, which are three long fatty acids with some double bonds intercalated in the aliphatic chains, which varies depending on the source. These double bonds are considered reactive sites as well as other routes are based on breaking of the chains and consequently extraction of derived esters.

Polyurethane (PU) is a crucial polymer in our daily life. Discovered in the 80s, it has become one of the most versatile groups of polymers used. One of the main reasons is the variety of properties which depends on the sort of synthesized PU that goes from rigid foam, flexible foam, coating, elastomers, adhesives and sealants. Some industries are already facing the challenge to substitute some of the components. One of the biggest dares is to meet the requirements and accomplish those properties compared to fossil-based PU.

As far as we know, only a sort of PU foam has been recently partially obtained from olive oil. In this work, non-competition with food principle is kept and only a material considered as a waste derived from milling industry has been used. Thus, the first objective aims at the valorisation of a waste product such as earth residue generated during the refining process in the milling. In a unitary transformation process, this waste material can represent an amount larger than 1000 tons per day. An analysis of fatty acid composition and physicochemical properties was carried out with different solvents. In a second step of this approach, the extracted sample was converted into the ester in order to homogenously react with diethanolamine and obtain the necessary amount of hydroxyl groups which is the ground of the customized amide-polyol. Later, the polyol synthesized is used for a straightforward PU coating formulation with an NCO ratio ranging between 1.5 and 2.5.

NMR, FTIR and DSC characterization of the polyols has been performed to confirm the chemical synthesis. Specific tests of the coatings such as adhesive, anti-corrosion and hydrophobicity index have been analysed to find out its properties.

Recycling and Calcination Behavior of Leaching Sludge from Secondary Batteries

Mrs. Seungyun Han, South Korea

Poster Presentation

Abstract

As the electric vehicle and electronics industries continue to grow rapidly worldwide, the demand for secondary batteries has also increased significantly. This surge has led to a rising concern regarding the efficient recycling of waste secondary batteries, which is emerging as a critical environmental and economic issue. Among various waste by-products, Fe-Al leach residual sludge is typically managed through landfilling or chemical treatment. However, these conventional disposal methods pose serious long-term environmental risks, such as soil and water contamination, while also incurring high treatment costs. Therefore, developing alternative approaches to effectively recycle and upcycle this sludge is essential.

Leach sludge primarily consists of approximately 95% aluminum hydroxide ($\text{Al}_2(\text{OH})_3$) and contains small amounts of valuable metals, including Ni, Co, and Fe. Additionally, aluminum oxide (Al_2O_3) is widely used across industries such as electronics, petroleum, chemicals, refractories, and ceramics, with demand continuing to rise. However, securing a stable supply of raw materials has become an increasing concern due to potential export restrictions imposed by bauxite-producing countries. This highlights the urgent need to explore alternative sources for aluminum oxide production and sustainable material recovery solutions.

To address these issues, this study aims to analyze the calcination behavior of Fe-Al leaching residual sludge from the secondary battery impurity removal process and investigate its potential for upcycling into high-value-added materials. By converting this waste into a valuable resource, we reduce the environmental impact associated with secondary battery waste disposal and promote a circular economy, and we expect that our findings will contribute to advancing green recycling technologies, increasing resource efficiency, and promoting sustainability in the battery industry.

Enhancing Purity of Cu-Based Alloys Recovered from WEEE through Oxidative Refining

Mrs. Seungyun Han, South Korea

Poster Presentation

Abstract

With the increasing use of electronic devices worldwide, the efficient recycling of waste electrical and electronic equipment (WEEE) has become essential in addressing the growing challenge of electronic waste and its environmental consequences. In 2019 alone, 53.6 million metric tons of e-waste were generated, highlighting the urgent demand for more effective recycling methods. However, only 17% of this waste is currently recycled, leading to the continuous loss of valuable materials such as copper, gold, and silver. One of the primary obstacles in WEEE recycling is the difficulty of efficiently separating and purifying these valuable metals, a crucial step in minimizing environmental impact and conserving resources.

This study explores the oxidative refining process as a technique for purifying metals recovered from waste printed circuit boards (PCBs), a major component of WEEE. The research focuses on the FeO-CaO-SiO₂ slag system and its effectiveness in removing impurities while enhancing the purity of recovered copper alloys. The FeO-CaO-SiO₂ slag system was chosen due to its low melting point and viscosity, properties that are vital for efficient slag formation and effective metal-slag phase separation during the refining process. The findings indicate that optimizing the FeO, CaO, and SiO₂ composition within the slag can significantly improve impurity removal and enhance the purity of the recovered metals.

Paper 1284

Harmonization of materials testing for LFR: R&D proposal on guidelines for corrosion tests in molten Pb/LBE

Ph.D. Serena Bassini, Italy

Poster Presentation

Abstract

The scattering on experimental data is an important issue for the design of nuclear systems working with innovative coolants. Indeed, the difficulty to predict the corrosion and mechanical behaviour because of the non-alignment of experimental data is reflected in the delay in the qualification path of materials in the specific environment. About that, in the frame of the past European collaborative project GEMMA, Round-Robin tests on static corrosion tests in Pb and LBE (candidate coolants for LFR systems) were performed by various European laboratories to check the alignment of the methodology and the results. The round-robin tests were performed by the partners in Pb and/or LBE using the same experimental conditions (same type of material, HLM temperature, comparable oxygen concentration, comparable surface finishing) but using their own experimental device for corrosion tests. At the end of the corrosion tests, a large scatter of data in terms of entity of corrosion was observed among the results of the various partners participating to the tests.

Currently, there are no commonly agreed standards related to the execution of corrosion tests in liquid metals such as liquid Pb alloys. Preliminary guidelines for corrosion tests and post-test analysis of specimens have been implemented a decade ago in the MATTER project and round-robin tests have been performed by laboratories in LBE. However, despite using the same device for corrosion tests and test specimens were centrally produced, the results of the tests varied significantly. For this reason, aiming at speeding up the qualification of materials, it is mandatory to identify potential reasons of the data scattering and to prepare and develop adequate guidelines/protocols and standards for the execution of the corrosion tests and the post-test analysis on the exposed specimens. The present abstract describes an R&D project proposal focused on the alignment of the methodology and results in the corrosion practice in molten Pb/LBE. The proposal was developed in the frame of the activities of CEN Workshop 064 Phase 4 "Design and Construction Codes for Gen II to IV nuclear facilities" promoted by AFCEN. The project is organized in three main phases and tasks: 1) preliminary definition of guidelines for corrosion tests and post-test analysis of specimens; 2) execution of round-robin tests by the European laboratories to validate the guidelines and to take possible actions to mitigate the scattering; and 3) final version of the guidelines and submission of standard practices to standardization bodies.

Paper 634

Development of a Machine Learning Model for Estimating Microstructural Phase Fractions in Compacted Graphite Iron (CGI)

Mrs. Sandra Gajoch, Poland

Poster Presentation

Abstract

This paper focuses on improving the process of prediction of the percentage composition of microstructural phases in vermicular cast iron using machine learning techniques. Vermicular cast iron is widely used in industry due to its high resistance to varying operating conditions, however, its mechanical properties depend on precise control of the microstructure. A key problem with traditional analysis methods is their time-consuming and subjective assessments, which limits their repeatability and efficiency in industrial applications. Therefore, the paper proposes an approach based on machine learning techniques, which allows for the automation of the microstructural analysis process.

The study used images obtained by scanning electron microscopy (SEM), which enabled accurate classification of ferritic, pearlitic and graphite phases. For segmentation and phase analysis, K-means clustering algorithms and the Gaussian Mixture Model (GMM) were used, which allow clustering of areas with similar properties without the need for manual labelling. However, the analysis showed that in some cases these algorithms had difficulty correctly distinguishing between phases whose color and intensity of pixels are very similar.

To increase the efficiency of classification, an iterative approach was implemented, consisting of selective detection and segmentation of specific microstructural phases. The results indicate that this approach allows for a significant improvement in the precision of the analysis compared to classical methods. Ultimately, the use of neural networks such as Mask R-CNN enabled more accurate recognition of phase boundaries and a more precise estimation of their percentage composition.

Ultimately, the presented approach allows for a significant reduction in the time needed to analyze microstructures, while increasing the precision and reproducibility of the results. Further work could focus on the use of even more advanced deep learning methods that will enable further optimisation and full automation of microstructural analysis of vermicular cast iron.

Research carried out as part of the project POIR.04.01.04-00-027/18-00.

Metal-organic frameworks for Li-S batteries

Prof. Miroslav Almasi, Slovakia

Poster Presentation

Abstract

Energy is currently one of the most important human needs and is also necessary for the development of technology and human civilization. Currently, rechargeable lithium-ion batteries (Li-ion) with energy densities of 200-400 Wh/kg, 500-1300 Wh/L, which have dominated the market since the 1990s, are the most commercially used. Although continuous Li-ion battery research is progressing, and batteries are achieving energy densities approaching their theoretical values, they are no longer sufficient for current energy consumption demands.

The electrochemical reduction of sulfur in lithium-sulfur (Li-S) batteries is not based on an intercalation/deintercalation process like Li-ion batteries but on a conversion reaction mechanism where intermediates are formed during the charging/discharging. The operating potential of the Li-S battery is 2.1 V versus Li/Li⁺, representing a theoretical energy density of 2500 Wh/kg and 2800 Wh/L. Li-S batteries are the most widely investigated due to their high storage capacity and are considered as the next-generation energy-storage technology.

However, challenges such as low sulfur conductivity ($\sim 5 \times 10^{-30}$ S/cm), significant volume expansion ($\sim 80\%$) during cycling, and the polysulfide "shuttle effect" lead to electrode degradation and rapid capacity fading. Metal-organic frameworks (MOFs) have been investigated as sulfur hosts in Li-S battery cathodes to address these limitations. Porous materials with high surface area and stability have been shown to effectively confine polysulfides and limit their unwanted migration, improving battery performance.

MOF-based materials, including MIL-101(Fe)-NH₂, MOF-76(Gd), and STAM-1, have demonstrated the ability to enhance cathode conductivity and facilitate electrolyte and sulfur infiltration. MIL-101(Fe)-NH₂, with a surface area of ~ 3500 m²/g, achieved an initial discharge capacity of 705 mAh/g at 0.5C and retained 476 mAh/g after 200 cycles, with a low capacity fading rate of 0.162% per cycle. Similarly, carbonized MOF-76(Gd) exhibited an initial capacity of 658 mAh/g and maintained 93% of its capacity after 200 cycles. STAM-1, a Cu(II)-based MOF, provided a discharge capacity of 452 mAh/g at 0.5C, retaining 430 mAh/g after 100 cycles with a Coulombic efficiency of 97%.

In addition to stabilizing the cathode structure and mitigating volume fluctuations, these MOFs accelerated the conversion of sulfur species, enhancing overall battery efficiency. The results confirm that well-engineered metal-organic frameworks can significantly improve the performance, cycle life, and energy storage capabilities of Li-S batteries, paving the way for more efficient and durable next-generation energy storage systems.

Paper 1842 1 White light emission in tailored nanostructured thin films produced by pulsed laser deposition

Dr. Jose Gonzalo, Spain

Highlight (Oral Presentation 20')

Abstract

Energy consumed for lighting accounts for 15-20% of world electricity consumption and is responsible of a 5% of total CO₂ emissions. This is why conventional incandescent and fluorescent light sources are being replaced by the more efficient and sustainable solid-state white-light emitting diodes (W-LEDs). Current commercial W-LED technology for lighting is based on InGaN blue LEDs combined with crystalline YAG:Ce³⁺ phosphors embedded in an epoxy resin coating. However, they show a deficient red emission and thermal constraints that limits their performance. Thus, exploring non-traditional doping elements is essential for the development of more efficient and reliable phosphors with improved color rendering. Specifically, in the current trend of reducing device dimensions it is very important to design thin film nanostructures with new concepts to increase efficiency and improve sustainability.

Pulsed laser deposition (PLD) has demonstrated to be an optimum technique to synthesize artificial nanostructures with a predesigned configuration thanks its ability to sequentially deposit layers of materials in a single step.[1] In this work, we exploit this characteristic of PLD to obtain near-white light emission nanostructured materials by precisely controlling the dopant distribution and nanostructure configuration along the growth direction. In particular, we will show two successful examples of this approach: i) The inclusion of Ag nanoparticles in europium oxide (EuOx) thin films, which leads to a broad PL white emission band that is related to the simultaneous presence of Eu²⁺ and Eu³⁺ ions in the nanostructure, and the coupling of Eu ions with Ag NPs; and ii) The synthesis of Bi and V-codoped MgAl₂O₄ nanostructured thin films consisting of undoped, Bi-doped or V-doped MgAl₂O₄ spinel layers, in which the optimum Bi/V concentration ratio and the adequate distribution of the different types of layers lead to near white light emission by the combination of the characteristic PL response of Bi³⁺ ions and that of V⁵⁺ ions present in [VO₄]³⁻ groups.

Selective laser processing of particle accelerator beam-screen inner surfaces for electron cloud mitigation

Dr. Marcel Himmerlich, Switzerland

Oral Presentation (20')

Abstract

Laser-induced surface roughening facilitates the reduction of secondary electron emission (SEE) from materials [1], which is crucial for mitigating electron cloud (EC) formation in particle accelerators operating with positively charged species, such as the Large Hadron Collider (LHC). The laser-induced material transformation also enables other functionalities such as surface blackening or wetting behaviour variation with a wide parameter tuning range. This study focuses on the development of a selective laser surface treatment of the copper inner surface of beam-screen (BS) pipes, which have a length of up to 15 meters, a cross section of about 50 mm, and are installed in LHC superconducting (SC) magnets. The main technical challenges for the laser processing are the reduction of treatment time, the control of ablation depth, and the minimisation of particulate dust creation. Based on the found correlations between processing parameters using ultrashort-pulsed lasers and the resulting materials properties [2], and considering all technical constraints given by SC magnets with BS of several meters of length and small apertures, a tailored laser processing strategy was developed [3]. It includes the creation of a rough copper surface with nanoparticle-covered trenches of 15-20 µm depth, and an initial secondary electron yield maximum of 1.4-1.5. This treatment is selectively applied to the most relevant regions inside the BS. The resulting material properties are characterized including the surface topography and resistance as well as the SEE at both room temperature and cryogenic conditions. The efficiency to mitigate EC formation and thus improve beam quality is demonstrated via EC simulations and electron-induced conditioning experiments. This study also explores under which treatment conditions the risk of particulate detachment from the surface, which could lead to critical beam interaction, can be minimized. Furthermore, the presentation will describe the technology needed for fibre-based laser light distribution [4] as well as the optimisation of the robot-based laser spot scanning, the required synchronisation between laser scanning in the tube and cable/fibre transportation system, and the strategy for the extraction of ablated particulates.

Paper 2027 4 Fabrication and Nanosecond Laser Processing of TiN Nanoislands for Robust Plasmonic Applications

Mrs. Stavros Panos, Greece

Highlight (Oral Presentation 20')

Abstract

The rapid development of clean energy technologies requires innovative research methodologies that enable scalable, high-throughput fabrication of functional nanostructures. Nanosphere lithography (NSL) has emerged as a promising, cost-effective technique for nanostructures fabrication, offering a rapid and scalable approach compatible with wafer-scale manufacturing. This study improves NSL-based fabrication by adding nanosecond laser annealing as a fast post-processing step to improve the structural and functional integrity of titanium nitride (TiN) nanoislands, a type of refractory conductive nitride, along with ZrN, HfN, NbN, and TaN that have a lot of potential for uses in plasmonics and energy harvesting. To accelerate the production of defect-free, highly conductive TiN nanoislands, process parameters were systematically optimized, including UV ozone treatment to refine the interstitial voids in the nanosphere mask and reactive magnetron sputtering conditions tailored to enhance deposition precision. The introduction of nanosecond laser heating as a rapid, non-contact annealing technique ensures superior structural stability while preserving the optical and electronic properties of the fabricated nanoislands. The resulting nanostructures demonstrate exceptional resilience to thermal and optical stress, positioning them as ideal candidates for applications in plasmonic-enhanced solar energy harvesting, high-efficiency photodetectors, and advanced catalysis.

Consolidation by Spark Plasma Sintering of β -Eucryptite/ Al_2O_3 composites obtained by colloidal route

Dr. Adolfo Fernández, Spain

Oral Presentation (20')

Abstract

Thermal expansion of materials has been regarded as a challenge for many precision applications due to the internal stress caused by high thermal gradients. In this context, ultrastable materials are essential for numerous industrial applications [1]. β -Eucryptite, which belongs to the hexagonal LAS family, has garnered significant interest for the development of low-CTE ceramic composites. The primary issue with this material lies in obtaining dense ceramic bodies without forming a vitreous phase, as this can lead to relatively poor mechanical properties. One potential solution to this problem is to employ unconventional sintering methods, such as Spark Plasma Sintering (SPS) [2], combined with the addition of secondary phases [3, 4].

In this study, the influence of incorporating alumina nanoparticles on the mechanical and thermal properties of β -Eucryptite–alumina composites, prepared via a colloidal route and sintered using SPS, has been investigated. The composites were characterized in terms of microstructure, hardness, toughness, Young's modulus, and mechanical strength. The presence of alumina nanoparticles helps control the grain growth of β -Eucryptite and enhances the mechanical properties: hardness is increased by at least 25%, fracture toughness by 30%, and mechanical strength by more than 40% in the composites compared to monolithic β -Eucryptite. Additionally, the composites exhibit a very low thermal expansion coefficient, making them promising materials for various industrial applications.

Paper 1345 1 High-temperature stability of Al-based structured electrodes

Dr. Marietta Seifert, Germany

Highlight (Oral Presentation 20')

Abstract

Sensors working at high temperatures are required in industry to monitor and optimize high-temperature processes. Wireless devices, such as surface acoustic wave (SAW) sensors, allow measurements at locations which are difficult to access by wired systems. To realize a high-temperature stable SAW sensor, a high-temperature stable piezoelectric substrate as well as a high-temperature stable metallization are required. The two Al-based metallizations TiAl and RuAl are investigated as an alternative to the expensive high-temperature stable Pt-based solutions reported in literature. The high-temperature long-term stability of extended thin films as well as of structured electrode systems were analyzed for both alloys. Ti-Al multilayer films were deposited by e-beam evaporation from pure material with a total thickness of 200 nm. The RuAl films were deposited by co-sputtering from elemental targets with additional thin Al layers on top, in the center and at the bottom with a total film thickness of 130 nm. The films were deposited on $\text{Ca}_3\text{TaGa}_3\text{Si}_2\text{O}_{14}$ (CTGS), which is a high-temperature stable piezoelectric substrate, as well as on thermally oxidized Si as a reference. The samples were annealed in high vacuum or in air for a duration up to 192 h and at temperatures up to 800 °C. Scanning electron microscopy (SEM) and especially transmission and scanning transmission electron microscopy (TEM and STEM) in combination with energy dispersive X-ray spectroscopy (EDX) were performed to analyze the morphology and possible degradation of the thin films. First experiments revealed a chemical reaction between the CTGS and the Al-based alloys, proving the necessity of the addition of suited barrier layers between the metallization and the substrate. In addition, an oxidation protection layer on top of the samples was required. For these additional layers, SiO_2 , AlNO or a combination of both was used. In case of the TiAl samples, the experiments demonstrated a long-term high-temperature stability in air up to at least 500 °C and for 192 h and a short-term stability at 600 °C. In contrast to this, due to the noble character of Ru, the RuAl samples showed hardly any degradation at 600 °C. A long-term stability was achieved at 700 °C and the samples were almost completely oxidized after annealing at 800 °C for 192 h. For both material systems, a strongly improved high-temperature stability will be achieved in high vacuum or by a suited encapsulation of the sensors.

This research was funded by German BMWI (03ET1589 A) and DFG (470028346).

Paper 811 2 Electrochemical synthesis of reactive Al/CuO nanocomposites at ambient temperature without surfactants

Mrs. Anastasia Batenkova, Switzerland

Oral Presentation (20')

Abstract

Reactive metal-oxide nanocomposites (or nanothermites) have gained significant attention in fields like propulsion, sterilization, energy storage, and advanced joining technologies. Among them, Al/CuO nanothermites stand out for their potential in applications such as soldering, welding, micro-actuators, and microelectromechanical systems (MEMS). The thermite reaction between aluminium metal (fuel) and copper(II)-oxide (oxidizer) is highly exothermic ($\Delta H_f^0 = -1'193 \text{ kJ/cm}^3$) and can thus provide enough heat to produce a molten Cu phase for e.g. reactive soldering. This study presents a two-step electrochemical synthesis route for fabricating Al/CuO nanocomposites with a very high density of pristine (i.e. unreacted and uncontaminated) Al/CuO interfaces, as required to obtain a self-propagating high-temperature synthesis (SHS) reaction upon ignition. In a first step, a nanoporous CuO framework is produced by electrophoretic deposition (EPD) of CuO nanoparticles (NPs) dispersed in ethanol. The resulting nanoporous CuO scaffold is then electrochemically infiltrated with Al using an ionic liquid as electrolyte (carried out in a protective Ar atmosphere to prevent oxidation of Al). Specific additive-free surface treatments, such as ozonation and thermal oxidation, were developed (as guided by XPS) to tune the chemical surface state of the CuO NPs to obtain stable highly-concentrated CuO NP dispersions and reproducible EPD processes without the use of any organic additives, like surfactants. An empirical correlation between the chemical surface state of aged and surface-treated CuO NPs (determined by XPS) and the ζ -potential of the dispersed NPs in ethanol (determined by the electroacoustic method) could thus be established. The nanoporous CuO thin-films with tunable thickness and porosity were characterized by a combined analytical approach using XPS, positron annihilation lifetime spectroscopy (PALS), BET (Kr adsorption), and HR-SEM with FIB. Successful electrochemical infiltration of Al into the nanoporous CuO scaffold could be demonstrated. The proposed 2-step electrochemical synthesis route is scalable, cost-effective, and environmentally friendly and, moreover, can be performed at ambient temperature, thus preventing premature reactions between Al and CuO.

Paper 1496 3 Atomic-scale metastable structure formation in nickel-aluminum alloys synthesized far from equilibrium
Mr. Zhehao Chen, Finland
Highlight (Oral Presentation 20')

Abstract

The present study reports on the structure formation in epitaxial nickel-aluminum (Ni-Al) films (Al content up to ~25 at.%) grown on MgO(001) substrates by magnetron sputtering. Nanoscale structure and chemistry probes, along with theoretical calculations consistently demonstrate that the alloy films consist of face-centered cubic (FCC) solid solution (denoted as γ phase) and/or ordered $L1_2$ Ni₃Al phase (denoted as γ' phase) domains. The Al contents in the range ~10-25 at.% the γ and γ' -phase domains are homogeneously intermixed at the atomic-scale, forming a coherent matched lattice with one overall lattice parameter. The lattice parameter expands as the Al content increases, with γ -phase domains being progressively replaced by their γ' -phase counterparts. Isothermal annealing of films containing ~14 at.% Al, coupled with structural and nano-mechanical characterization, reveal that the nanostructure retains its integrity for temperatures up to 673 K, while the film hardness increases from ~5 (as deposited films) to ~6 GPa. Further increase of the annealing temperature to 873 K and 1073 K cause the coherent to dissolve leading to discrete γ and γ' phases and reduction of hardness to values of ~4 GPa. These observations confirm the metastable nature of the as-deposited nanoscale structure of the thin-film Ni-Al alloy system providing new insights for meta-stable intermetallic thin film synthesis.

Paper 1994 4

Tailoring the plasmonic response of Ag/NiO heterostructures by solid state dewetting for spintronic applications

Mrs. Carmen del Pino-Batlles, Spain

Oral Presentation (20')

Abstract

Antiferromagnetic materials (AFM) have recently attracted attention for their potential use as active elements in spintronic applications. A key challenge is the manipulation of AFM domains in the absence of external magnetic fields, with light irradiation being one possible way. In this line, the activation and manipulation of spin waves in AFM by plasmonic nanomaterials through light is a challenge. This approach in the field of spinplasmonics has been scarcely investigated and its potential is impressive.

In this work, a hybrid system based on Ag nanoparticles (NPs) on an AFM NiO film is fabricated from bilayer deposition by dual ion beam sputtering plus subsequent solid-state dewetting of Ag by post-annealing processes. The epitaxial growth of the system has been controlled by different types of substrates (MgO, SrTiO₃ and Al₂O₃), obtaining commensurate and incommensurate growth of layers in different crystallographic directions depending on the substrate and its crystallographic orientation. In addition, the morphological characteristics of Ag NPs are controlled as a function of the different substrates and thermal post-treatments. A study of the chemical state of the Ag NPs and the stability of the system as a function of thermal post-treatments and over time is also carried out. All these features allow the control of the plasmonic characteristics of heterostructures for future application.

Paper 2050 5 Study of the evolution of AgxAuy plasmonic nanoparticles on NiO antiferromagnetic layers for spintronics applications

Mr. Cayetano Hernández-Gómez, Spain

Oral Presentation (20')

Abstract

Spintronics is presented as a novel route for a whole new era of data processing devices which will exploit the great properties of spin-waves or magnons, such as non-linear dynamics, low energy consumption and ultra-fast responses. In this line, hybrid systems based on plasmonic nanoparticles (NPs) on antiferromagnetic (AF) layers show high potential to stimulate spin-waves by light through que plasmon-magnon interactions. However, developing these hybrid systems requires a detailed comprehension of physical -chemical interactions between AF and plasmonic NPs.

In this work, we study the evolution of AgxAuy NPs on NiO AF layers after the solid-state dewetting (SSD) of plasmonic nanostructures. AgxAuy and NiO bilayers were grown by dual ion-beam sputtering at high-vacuum environment and subsequently a post-annealing at 500 °C was carried out to generate the nanostructuring of metallic layer. The evolution of plasmonic NPs and their interaction with the AF layer was evaluated varying annealing time and the atmosphere during the SSD process. The nanostructuring of the AgxAuy film has been studied in terms of Scanning electron microscopy (SEM), UV-visible absorbance and Raman spectroscopies, as well as by X-ray photoelectron spectroscopy (XPS). When the annealing process is performed in a 10-2 Pa oxygen partial pressure, AgxAuy nanoparticles are formed, while a semi-dewetted AgxAuy nanostructure film is observed when the annealing is performed in high vacuum conditions (10-5 Pa). The AgxAuy composition, around 60% Au and 40% Ag atomic concentration, have been determined by EDX and XPS. The chemical state of the different elements present in the hybrid AM-plasmonic system during the nanostructuring process was followed by XPS in situ when the annealing is performed in high vacuum and ex situ when it is performed in oxygen atmosphere, finding changes in the XPS spectra depending on the dewetting state of plasmonic NPs.

Paper 1030 1 **Oxygen-induced decomposition of the BCC HfNbTaTiZr high-entropy alloy**

Dr. Régis Poulain, France

Highlight (Oral Presentation 20')

Abstract

The HfNbTaTiZr alloy is one of the most thoroughly investigated body-centered cubic (BCC) high-entropy alloys, due to its ductility and malleability at room temperature. However, experimental studies on the phase stability of this alloy have produced conflicting results. While some studies report a single-phase solid solution above 900 °C, others mention the presence of secondary phases or short-range clustering up to 1450 °C.

The aim of this work is to investigate the factors affecting the stability of an initially single-phase BCC HfNbTaTiZr alloy by heat treatments at 900 °C up to 1000 hours in different atmospheres. The BCC solid solution remains stable at this temperature but O contamination originating from the aging atmosphere leads to the co-precipitation of an O-enriched hexagonal close-packed (HCP) Hf-Zr-rich phase and a second Nb-Ta-rich BCC phase. Diffusion of O in the atmosphere from the surface to the core of the sample is faster along grain boundaries than through the grain interior. This results in an inhomogeneous distribution of precipitates, formed at grain boundaries by a monotectoid reaction. Similar phases were observed in a HfNbTaTiZr enriched with 3 at.% O, thus confirming the role of O in phase stability.

During this presentation, the influence of O on the BCC phase stability will be demonstrated and the crystallographic aspects of the oxygen-contaminated microstructure will be discussed and compared to the BCC-HCP microstructure found in other type of alloys. These aspects will include the orientation relationship between the different phases, the location of the precipitation, and the growth orientation of the precipitates.

Paper 588 **2** **Phase stability and mechanical behaviour of oxygen-doped refractory high-entropy alloys.**
Ph.D. Mariano Casas-Luna, Czech Republic
Oral Presentation (20')

Abstract

In recent years, there has been a growing interest in exploring the central regions of multi-element phase diagrams, leading to the development of a new class of alloys known as complex concentrated alloys (CCAs). Among these, high-entropy alloys (HEAs) are characterized by a high configurational entropy that can stabilize a single-phase microstructure. These alloys exhibit a wide range of attractive physical properties, making them promising candidates for advanced applications even at high-temperature conditions.

One approach to further enhancing HEA properties is the introduction of interstitial elements, such as oxygen, which can significantly influence phase stability and mechanical behaviour. Although the impact of interstitial oxygen has been observed in specific traditional alloy systems, such as TiZrNb, its role in HEAs remains largely unexplored. This study focuses on four refractory HEAs composed of quinary systems based on the AlTiNb system, incorporating Cr, Fe, Mo, and/or Zr, specifically designed to achieve low-density single-phase alloys. The alloy compositions were carefully tailored by CALPHAD method to ensure a single-phase body-centred cubic structure. To investigate the effects of oxygen doping, interstitial oxygen was introduced at concentrations of 0.5 and 1.0 atomic percent. The study systematically examines its influence on phase stability and mechanical properties, particularly microhardness and compressive strength. The experimental results shed light on the role of oxygen in enhancing phase stability, as demonstrated by microstructural observations and X-ray diffraction analyses. Additionally, interstitial oxygen improved the hardness and mechanical performance of most of the studied alloys, which has significant implications for the development of next-generation CCAs with controlled oxygen content.

Paper 1609 3 **Hydrogen-assisted spinodal decomposition in a TiNbZrHfTa complex concentrated alloy**
Mr. Chengguang Wu, Germany
Oral Presentation (20')

Abstract

Understanding hydrogen-metal interactions is critical for developing refractory complex concentrated alloys (CCAs), applicable to the hydrogen economy. In this study, we revealed a hydrogen-assisted spinodal decomposition phenomenon at the nanoscale in an equiatomic TiNbZrHfTa CCA upon its exposure to H₂ at 500 °C. Such a decomposition pathway was characterized by a periodic compositional modulation with an up-hill diffusion behavior of the principal metallic elements, particularly Zr, over an extended treatment period (from 0.5 h to 2 h) in an H₂ atmosphere, probed by three-dimensional atom probe tomography. Consequently, the decomposed alloy consisted of a needle-shaped phase enriched in Zr and Ti and a phase enriched in Nb and Ta. Crystallographically, the spinodal features aligned preferentially along $\langle 001 \rangle$ directions of the matrix phase to minimize elastic strain energy. To better understand the role of hydrogen in spinodal decomposition, a statistical thermodynamic model was further developed by incorporating hydrogen to predict the phase stability of the TiNbZrHfTa-H system. This analysis suggested that hydrogen destabilizes the single solid-solution phase by expanding the spinodal region. Such nanoscale spinodal decomposition enhanced the hardness and anti-abrasive properties of the investigated alloy. Thus, this study not only provides fundamental insights into the effect of hydrogen on phase stability, but also demonstrates a novel alloy design strategy by introducing hydrogen as an interstitial alloying element to tailor the microstructure.

Paper 937 4 **Influence of Carbon Content on the Microstructure and Mechanical Properties of High-Entropy (Mo Nb Ti V W)C Carbides**
Mrs. Fanni Hakanen, Finland
Oral Presentation (20')

Abstract

High-entropy carbides (HEC) have attracted much interest because they combine several, at least five, elements in a unique way, giving these ceramics excellent mechanical properties and heat resistance. In this study, we investigate how varying carbon content affects the microstructure and mechanical properties of (Mo Nb Ti V W)C high-entropy ceramics. (Mo Nb Ti V W)C system was prepared by carbothermal reduction route using metal oxides and carbon as starting materials. Powder compositions were tailored based on thermodynamic predictions. The synthesized powders were then subjected to spark plasma sintering at high temperatures. The microstructural analysis focused on the changes induced by the carbon content, such as grain structure, distribution of elements, and secondary phase formation. Mechanical properties were investigated by nanoindentation to obtain information on hardness and elastic modulus. The results revealing the causalities between design, processing and properties of HECs are presented in this study, focussing on the influence of carbon content. Understanding the role of carbon content in these ceramics is essential to tailor their properties for advanced structural applications.

Paper 1863 5 **Influence of Si on structure, mechanical properties, and thermal stability of reactively and non-reactively sputtered high-entropy (Hf,Ta,Ti,V,Zr) carbides**
Mr. Muhammad Awais Altaf, Austria
Oral Presentation (20')

Abstract High-entropy metal-sublattice carbide thin films, (Hf,Ta,Ti,V,Zr)C, with and without Si addition, are synthesized via reactive and non-reactive magnetron sputtering. Structural analysis confirms a stable single-phase face-centered cubic (fcc) structure across all coatings, even at Si contents up to 21 at% and after annealing at 900 °C and 1400 °C. Unlike for binary nitrides, the increasing Si content promotes grain-growth rather than refinement, as evidenced by detailed X-ray diffraction and transmission electron microscopy studies. Mechanical testing shows hardness and elastic modulus values of 31–36 GPa and 397–427 GPa, respectively, with no strong dependence on Si content. Si addition increases deposition rate and grain size while preserving a dense, fine-fibrous growth-morphology. Dynamic simultaneous thermal analysis up to 1400 °C reveals minor carbon loss in Si-free reactively and non-reactively prepared samples above 850 °C and 1000 °C, respectively. Despite this, all coatings retain their single-phase fcc structure and the Si-free (Hf_{0.19}Ta_{0.24}Ti_{0.25}V_{0.21}Zr_{0.11})C film only softened from 33.12±3.2 GPa to 29.08±2.57 GPa upon annealing at 900 °C. These findings highlight the exceptional thermal stability and mechanical resilience of high-entropy carbide thin films, positioning them as promising candidates for high-temperature applications.

Paper 1243 8 **Spinodal Decomposition in FeMnNiCoCu High-Entropy Alloys: A Combined Theoretical and Experimental Study**
Mr. Niklas Marschall, Germany
Oral Presentation (20')

Abstract Spinodal decomposition in complex multi-component alloys is less explored and not yet fully understood. While chemical thermodynamics provides robust predictions of a spinodal character, the inclusion of elastic energy contributions can shift the boundaries of phase stability. In this study, we explore the interplay between chemical and elastic contributions in the spinodal decomposition of FeMnNiCoCu High-Entropy Alloys (HEAs) with a focus on Fe₂₀Mn₁₀Ni₂₀Co₃₀Cu₂₀. Notably, this alloy lies outside the chemical spinodal for 873 K but within the elastic spinodal, which showcases the potential significance of elastic contributions. To test our predictions, we performed annealing experiments at 873 K over durations ranging from 0 to 240 h. X-ray diffraction (XRD) measurements are employed to track phase evolution. Selected samples are further analysed using transmission electron microscopy (TEM) to provide insights into the resulting microstructural changes. The results of the thermodynamic and kinetic models suggest that elastic energy may play a decisive role in phase decomposition processes. The experimental data will also serve to critically assess the validity of the elastic spinodal and their potential overestimation. This combined theoretical and experimental approach provides a deeper understanding of the mechanisms driving phase evolution in multi-component alloys.

Paper 2116 1 **High-entropy MAX phase with high strength and large plasticity mediated by local chemical fluctuations**

Prof. Yuan Wu, China

Highlight (Oral Presentation 20')

Abstract

MAX phases are an emerging kind of material with a unique combination of metallic and ceramic properties, and they have great potential to be utilized as high-temperature components. However, their lack of plastic deformation capability and low strength (particularly at high temperatures) result in unsatisfactory mechanical properties, which restricts their potential applications. In this study, we introduced local chemical fluctuations (LCFs) into atomic packing layers of MAX phases by applying the high-entropy concept learned from the metal community. We substituted Ti in the model Ti₂AlC MAX phase with Zr, Nb, and Ta and successfully developed a high-entropy MAX phase (TiZr_{0.6}NbTa)₂AlC while preserving its lattice structure. The enhanced LCFs in this new MAX phase created strong lattice strains, increasing the resistance to dislocation slip and then leading to a high compressive yield strength of over 500 MPa even at 1473 K. Also, the LCFs stimulated cross-slips and stacking faults during deformation, effectively alleviating strain localization, promoting uniform deformation, and eventually enhancing plasticity at room temperature and the elevated temperature. Our work not only sheds light on understanding the deformation mechanisms of MAX phases in general, but also offers a valuable route for improving their mechanical properties, making them competitive as the next-generation lightweight high-temperature materials.

Micromechanical characterization of multimetal carbides

Prof. Gaurav Mohanty, Finland

Oral Presentation (20')

Abstract

High entropy carbides (HEC) are multi-metal carbides containing at least four metal atoms at near-equiatomic concentrations. They exhibit unconventional mechanical and physical properties due to the disorder in terms of metal cation packing, but the inherent brittleness of these carbides limits their applicability. Recent micromechanical studies have revealed that certain grain orientation promotes the activation of slip in these multimetal carbides with enhanced yield and failure strength compared to their monocarbides¹. Up till now, the high entropy carbide compositions presented in literature have been rich in critical raw materials (CRM), such as hafnium, tantalum, zirconium.

In this study, we explore the feasibility of fabricating certain sustainable multimetal carbide compositions which are free from at least one CRM and analyze their micromechanical behavior. Based on the entropy forming ability, certain compositions were synthesised – HfNbTaTiZrC and MoNbTaVWC. X-ray diffraction and electron microscopy techniques confirm the crystal structure and formation of single-phase multi-metal carbides with chemical homogeneity. The hardness and elastic modulus dependance on the grain orientation were studied with high throughput nanoindentation mapping studies. The elastic modulus and hardness of the multimetal carbide phases were found superior to HfC and TaC monocarbides. Moreover, the experimental interpretations of the operative deformation mechanisms based on the strain rate sensitivity and activation parameters for deformation will also be detailed.

The phase transition of multi-component (TiZrVNb)C ceramics: The phase decomposition induced by carbon content

Dr. Qingyi Kong, China

Oral Presentation (20')

Abstract

The phase decomposition can enhance the mechanical properties of carbide ceramics effectively, which can overcome the difficulty of enhancement of mechanical properties for single-phase multi-component carbide ceramics. In this work, a series of non-stoichiometric (TiZrVNb)_{Cx} ceramics were prepared by spark plasma sintering (SPS) at different temperatures. The effects of carbon content on phase compositions, microstructure evolution, and mechanical properties were investigated in detail. The phase decomposition took place with the reduction of carbon content. Two different solid solutions of (Ti, V)-rich and Zr-rich phases formed originating from the decomposition of equimolar single-phase solid solution, namely the Zr-poor phase and Zr-rich phase, respectively. The distribution of Nb element is relatively uniform. The semi-coherent interfaces between the Zr-poor phase and the Zr-rich phase can harden and strengthen effectively under the synergistic effect of grain refinement. The ceramics with phase decomposition structures have apparent advantages compared to single-phase high-entropy carbides. This work provides an important train of thought for the microstructure tailoring and properties optimization of multi-component carbide ceramics.

Paper 1855 5 **From binary to high-entropy : tailoring microstructure and mechanical properties of diboride-carbide composites through reactive sintering**
Dr. Sijia Huo, China
Oral Presentation (20')

Abstract

Ultrahigh-temperature ceramics, such as diborides (MB_2s) and carbides (MCs) of transition metals (Ti , Zr , Hf , Nb , Ta), possess outstanding physical and chemical properties, including high hardness, modulus, thermal conductivity, and excellent resistance to thermal shock and ablation. These materials are therefore well-suited for extreme environmental applications. Notably, certain MCs can react with MB_2s at specific temperatures, leading to the formation of multi-component solid solutions. Compared to the self-diffusion mass transfer in single-phase MB_2s , the reaction-driven interdiffusion between MB_2s and MCs enhances mass transfer and facilitates densification. This in-situ reaction and solid solution coupling process not only improves densification but also suppresses excessive grain growth and may introduce additional solid solution phases. The formation of these multi-phase solid solutions, along with the microstructure refinement induced by reactive sintering, typically results in improved mechanical properties. Since diborides and carbides exhibit similar exchange reactions and solid solution behaviors, a binary system (boride + carbide) can serve as a starting point for designing more complex multi-component systems. When diborides and carbides of different metal atoms are employed for reactive sintering, the resulting materials tend to form high-entropy ceramics (HECs), which exhibit intricate phase formation, microstructure evolution, and tunable mechanical properties dependent on phase fractions. This work offers new insights into the design of diboride-carbide dual-phase composites from a binary to high-entropy systems.

Paper 801 **2** **Hydrogels based on natural polymers for the magneto-mechanical stimulation of cells**
Mrs. Arianna Bartolomei, Spain
Oral Presentation (20')

Abstract

The development of 3D cell scaffolds utilizing magnetic-responsive materials represents a significant advancement in addressing persistent challenges in Tissue Engineering [1, 2]. This approach enables the creation of structured materials that can be simultaneously manipulated by external magnetic fields, providing non-invasive control over both the mechanical properties and biological behavior of the scaffolds.

In this study, we introduce a novel class of magnetoactive, biocompatible hydrogels synthesized by incorporating biopolymers (such as polysaccharides and proteins), magnetic microparticles, and living cells into a colloidal suspension. These hydrogels function as an effective artificial extracellular matrix that supports and promotes cellular growth, proliferation, and differentiation. To achieve controlled patterning of the scaffold's microstructure, a triaxial magnetic field [3] is applied during gelation, organizing the magnetic particles into microstructures within the hydrogel matrix. Non-stationary magnetic fields are then used to remotely activate and manipulate these microstructures over time, offering dynamic control over the cellular microenvironment.

To analyze the hydrogels' response to magnetic stimulation, we integrate advanced techniques such as videomicroscopy and confocal rheometry with the triaxial magnetic field generator. These methods allow for real-time, in-depth observation of the hydrogel's behavior under magneto-mechanical forces. The results demonstrate that magneto-mechanical stimulation induces significant changes in the internal microstructure of the hydrogels, leading to localized deformations. These deformations are shown to influence key cellular processes, including migration, proliferation, and differentiation. Additionally, ongoing investigations are focused on understanding how these mechanical deformations affect cellular biochemical and morphological changes.

This innovative approach offers important insights into the interaction between cells and magnetoactive materials, providing a pathway for optimizing their use in biomedical applications. This work enhances our understanding of how mechanical and magnetic stimuli can influence cellular behavior, paving the way for the next generation of Tissue Engineering solutions. Furthermore, the precision and control enabled by the triaxial magnetic field technique establish it as a valuable tool for microrheological characterization, facilitating the analysis of hydrogel mechanical properties at the microscale in ways previously not achievable.

Next-Gen Radioprotection: Thermo-Sensitive Hydrogels for Localized Amifostine Release

Mr. Dario Castellana, Spain

Oral Presentation (20')

Abstract

Amifostine is the only FDA-approved pharmacological agent for the treatment of radiation-induced damage in head and neck tumoral malignancies; however, its clinical application is constrained by the absence of an efficient delivery system. Most conventional systemic administration routes have demonstrated suboptimal concentration in the interested site and rapid clearance of Amifostine. With the increasing incidence of cancer leading to a rise in radiation-based therapies, our objective is to mitigate its adverse effects by employing an adjuvant platform designed to improve the state of art of anti-tumoral clinical strategies.

We have developed a multimodal platform to support a localized and controlled release of the radioprotective agent within the X-ray-irradiated region, aiming to modulate the non-therapeutic effects triggered by the treatment. The thermo-responsive polymer pNIPAM was conjugated with hyaluronic acid to form an injectable, thermo-sensitive hydrogel preloaded with nanoparticles that encapsulate and regulate the kinetic release of Amifostine. FTIR and H-NMR analyses confirmed the synthesis of HA/pNIPMA polymer, temperature sweep characterization performed via rheological analyses confirmed

sol-gel transition at body temperature. Hydrogel's application is intended for local injection, thus exerting its therapeutic benefits specifically at the site of radiation exposure.

The healing approach is based on the in-situ delivery of the radioprotective agent in a therapeutic concentration. Amifostine is encapsulated within PLGA nanoparticles, which were synthesized via a double emulsion technique, achieving an encapsulation efficiency of 86% and a complete release of the cargo over 24 hours.

In order to mimic the tumoral micro-environment and the diseased tissue, we have generated a spheroidal 3D model based on oral mucosa tumor cell line (Cal27), human dermal fibroblasts (HDF) and human microvascular endothelial cells (HMEC). The spheroids are cultured in ultra-low attachment plates and then embedded in collagen to resemble the extracellular matrix. Amifostine's ROS scavenging properties and clinical efficacy in 3D model have been characterized after irradiation using an X-ray irradiator simulating the radiation dose, 2Gy to 20Gy in single or multiple dose regimes, to which cancer patients are subjected during radiotherapy sessions.

In conclusion, our work focuses on enhancing the current application of Amifostine as a radioprotective agent during radiotherapy sessions. The platform we are developing is designed to optimize a safe release while promoting localized therapeutic effects, minimizing the drug's off-target tissue accumulation.

Solvothermal production of a piezoelectric layer on titanium implant materials

Mrs. Josephine Roth, Germany

Oral Presentation (20')

Abstract

Demographic changes and advancing technologies have led to an increase in surgical procedures and the growing use of implants, particularly in dental and orthopedic applications, where titanium is predominantly used. Despite the numerous advantages of titanium, postoperative complications such as implant loosening and inflammation remain prevalent. To address these issues, surface modifications are required to enhance properties like osteointegration and the suppression of inflammatory reactions. Biomimetic development concepts, e.g. the interaction of tissue with piezoelectric surfaces, are very promising to be adopted. [1] This study focuses on developing a piezoelectric coating of barium titanate (BaTiO_3) on fabricated titanium implants.

Barium titanate, with its comparatively high piezoelectric charge constant of 200 pC/N, exhibits a pronounced ability to generate (bio-) electrical signals under mechanical stimuli, promoting metabolic activity, facilitating structural remodeling and growth. [2] In the study, the synthesis of barium titanate involves anodic oxidation of titanium to form a titanium oxide layer, followed by a two-step solvothermal process to convert the oxide into.

Intensive research have focused on the first step on transformation. The thickness, morphology and density should be adjusted so that ductile, adhering and tetragonal BaTiO_3 is produced, which is necessary to realize the piezoelectric reactions. For this purpose, anodic oxidation is investigated by varying the electrolytes, the voltage (20 – 100 V) and the oxidation time (5 minutes – 3 hours). Electrolytes used include sulfuric acid, sodium sulfate, a phosphate buffer and ammonium tetrafluoroborate. Resulting titanium oxide layers were analyzed via scanning electron microscopy (SEM) and X-ray diffraction (XRD) to assess their structure and phase composition.

Results indicate a positive correlation between oxidation duration and voltage (up to 80 V) and the thickness of the titanium oxide layer. The majority of electrolytes produced stable oxide layers with flower-like oxide structures emerging from the base layer. Only ammonium tetrafluoroborate generated tubular and spherical crystalline structures. Regardless of the morphology, anatase titanium oxide layers were formed in almost all experiments, except for one experiment using sodium sulfate, which produced rutile titanium oxide.

Future experiments will assess the ability of these titanium oxide layers to facilitate a optimized formation of barium titanate with the piezoelectric properties of the coating.

Paper 1650 1 Microstructure development in case-carburized bearing steels for wind turbines

Prof. Maria Jesus Santofimia, The Netherlands

Keynote (Oral Presentation 40')

Abstract

Large-sized main shaft steel bearings are crucial components in wind turbines. Malfunction of these critical parts can lead to complete gearbox failure and prolonged downtime. To withstand the high loads, shaft bearings need high fatigue strength, toughness, and wear resistance. These combinations of properties can be achieved through case-carburization, which is a heat treatment process that enriches the surface of steel with carbon, creating a hard, wear-resistant outer layer while maintaining a tough core. After case-carburization, the processing of these steels is followed by annealing, hardening and tempering, leading to a complex microstructural evolution that eventually determines the performance of these gigantic components. This work examines the microstructural evolution of case-carburized steels during annealing, hardening and tempering, for two different annealing routes: bainitic and pearlitic. Investigations combine microstructural characterization by optical and electron microscopy, electron backscatter diffraction and X-ray diffraction with thermodynamic and kinetics simulations. It will be shown that the evolution of the microstructures is not only affected by the carbon gradient after case-carburization, but also, and very strongly, by the inherent segregation bands of substitutional elements present from solidification. Bainitic annealing produces alloy-rich regions with twice the fraction of martensite-austenite islands compared to alloy-lean areas, leading to a bimodal grain distribution and carbide-dense bands after hardening. In contrast, pearlitic annealing results in three distinct regions: a pearlitic case, a sharp transition zone, and a martensitic-ferritic core, with hardening producing a uniform distribution of retained austenite. After tempering, these microstructural variations lead to significant hardness differences even in areas with constant carbon concentration. This study highlights the importance of understanding microstructural development during shaft bearing processing to design microstructures for maximum performance.

Paper 623 2 A New Carburizing Steel Grade for Aeronautical Transmission: Design and Modelling

Mr. Romain Bordas, France

Oral Presentation (20')

Abstract

To achieve carbon neutrality by 2050, the air transport sector is implementing new technical solutions related to synthetic fuel, but also to aircraft engine technology. The evolution of aircraft engines tends to considerably reduce polluting emissions and fuel consumption. To meet these needs, new technologies have recently emerged such as the power gear box and ceramic ball bearings. These new technologies highlight several metallurgical challenges and request the development of new grades or processes. The purpose of this presentation is to review current metallurgical solutions and to present the latest developments in case-hardening grades aiming at increasing surface hardness levels, while maintaining the right balance between mechanical strength and toughness, focusing on a new carburizing grade developed by Aubert et Duval, the C65NiL®.

In recent years, to meet the demand for improved performance compared with M50NiL, new grades have appeared, such as FERRIUMC64® developed by Questek, or ARCTIC 15® developed by SKF whose metallurgical design and performance will be described. We will highlight the design criteria and the technical difficulties to increase the level of surface hardness. Details on a new carburizing grade, C65NiL®, developed by Aubert et Duval will be given. This grade has an original metallurgical design that enables to achieve a hardness level of more than 825 HV (about 65 HRC) after thermochemical and heat treatments with a toughness level comparable to M50NiL.

the interest of artificial intelligence, in particular machine learning, to predict a hardness profile after carburizing and quality heat treatment with C65NiL, will be shown. We will see how these new digital design tools can accelerate metallurgical design, speed up the thermochemical processes or analytical balancing, while highlighting the limitations.

Paper 1600 3 **The Influence of Mo and Cu on Microstructure and Mechanical Properties of Air-hardening Ductile Forging Steels**
Mr. Oguz Gulbay, Germany
Oral Presentation (20')

Abstract

Air-hardening ductile forging steels are gaining industrial interest due to their potential to reduce the global warming impact of steel forgings. To investigate their robustness against recycling-induced impurities, the effect of Cu and Mo needs to be investigated. For this matter, three alloy variants were produced: reference steel without Mo or Cu, Mo-alloyed steel, and Mo+Cu-alloyed steel. The microstructural evaluation is supported by X-ray diffraction and experimental continuous cooling-transformation (CCT) diagrams. Mechanical properties are characterized by tensile and hardness testing. The results show that the reference and Mo-alloyed steels consist of bainite and martensite. While reference steel primarily exhibits bainite with 6.2% retained austenite (RA), the bainite fraction decreases in Mo-alloyed steel along with RA to 5%. On the other hand, in Mo+Cu-alloyed steel, the critical cooling rate to form martensite further decreases, resulting in a fully martensitic microstructure with 2.8% RA after air cooling. While Mo alloying enhances strength compared to the reference steel but leads to the lowest ductility, Mo+Cu alloying results in the highest strength without significant ductility loss. The further assessment of mechanical properties will be completed with instrumented Charpy impact tests and fractographic analysis for deeper understanding.

Influence of Nitride-forming Elements Al, B, and Ti on the Kinetics of Austenite Grain Growth in Microalloyed Steel

Mr. Markus Führer, Austria

Oral Presentation (20')

Abstract

The alloying of aluminum, boron, and titanium significantly influences the microstructure and the mechanical properties of microalloyed steel. Al is used as a deoxidizer in the steel production process, and aluminum nitride (AlN) plays a crucial role in grain size control due to its strong pinning effect [1]. Boron, as segregated at grain boundaries rather than precipitated as boron nitride (BN), acts as an economically very interesting hardenability promoter [2]. Titanium further protects boron from forming BN and facilitates the nucleation of acicular ferrite, enhancing the steel toughness [3]. These elements exhibit a complex interplay, competing for nitrogen, with titanium showing the highest affinity, followed by boron and aluminum [4]. This competition affects the formation and distribution of nitrides, which in turn impacts the microstructural steel characteristics.

The influence of precipitates such as AlN, BN, and TiN on grain growth kinetics in austenite is governed by Zener drag [5], which impedes the movement of grain boundaries. Among these, AlN exhibits the most significant effect in retarding grain growth [1], while fine TiN particles also notably contribute [3]. Moreover, the presence of Ti and B modulates the availability of nitrogen for Al. Thus, especially for B-alloying, it has been reported to significantly increase the austenite grain size [2].

This study investigates the grain growth behavior in high-purity vacuum induction melted alloys with varying fractions of Al, B, and Ti. The resulting microstructures are characterized metallographically by employing light optical microscopy (LOM), scanning electron microscopy (SEM), and electron-backscatter diffraction (EBSD).

By using the present experimental results, we simulate the grain size evolution using a mean-field approach, as implemented in the software package MatCalc [6] and the Calphad-type open-licensed MatCalc database mc_fe_v2.060.tdb.

Paper 1671 5 **Habit plane induced anisotropy of lath martensite micro-plasticity in dual-phase steel**
Dr. Tijmen Vermeij, Switzerland
Oral Presentation (20')

Abstract

Among the Dual-Phase (DP) steel microstructure constituents, lath martensite is generally considered to be the hard and brittle phase that determines strength and restricts ductility. However, recent studies have shown that lath martensite islands can deform in a considerable ductile manner in DP steels. These observations have been related to recent studies on fully lath martensitic steels, in which strong plasticity preferentially occurred over the habit plane through various competing micromechanical deformation mechanisms. However, it has been unclear to what degree these insights can be extended towards DP steel microstructures. Therefore, this paper presents a study in which the lath martensite plastic anisotropy in DP steel is correlated to the habit plane orientation. To this end, a series of advanced micromechanical measurement and identification methods are employed, ranging in scale and complexity, to unravel the individual mechanisms and to assess the statistics of the influence of the habit plane orientation. On well-defined "1D" and "2D" specimens, microstructure-correlated strain mapping and identification of micro-plasticity shows that the habit plane determines how plasticity percolates through the lath morphology in cases of a favorably oriented habit plane. Through a "3D" bulk experiment, a more comprehensive and statistical study on a large number of coarse martensite islands, embedded in a ferrite matrix, reveals that strong plasticity occurs most frequently over the habit plane, even when it has relatively unfavorable orientations.

Selective oxidation in ternary Fe-Al-Mn model alloys

Mrs. Ludivine Robert, France

Oral Presentation (20')

Abstract

In industrial steelmaking process, steel strips undergo several heat treatments during which total surface oxidation or selective oxidation of alloying elements may occur. Under protective atmosphere, Fe-Al-Mn alloys reveal a transition in oxidation mode of the less noble elements, from external to internal with increasing water partial pressure. The formation of external iron particles is often mentioned along with internal oxidation. An experimental study aims to address the oxidation mechanisms based on diffusion and the correlation with the formation of iron particles depending on experimental conditions.

The experimental device consists in a furnace, equipped with three infra-red lamps insuring a rapid heating phase. The particularity of this apparatus resides in the direct connection with an X-rays Photoelectron Spectroscopy equipment, allowing precise in-situ surface characterizations, exempt from air contamination [1].

The study of the oxidation behaviour of a ternary ferritic Fe-Al-Mn model alloy is conducted at 840 °C, in dry conditions ($p_{H_2O} = 1\text{ Pa}$) and humid conditions ($p_{H_2O} = 610\text{ Pa}$). The samples are held for 0; 25; 76 and 150 s at 840 °C. During heat treatment, the native iron oxides are reduced but alloying elements are oxidized. The nature and morphology of surface oxides is analysed by X-rays Photoelectron Spectroscopy and Field Emission Gun Auger microscope. Cross-sections extracted with a Focused Ion Beam are characterized by Energy Dispersive Spectroscopy and electron diffraction in a Transmission Electron Microscope. The surface coverage and the oxidation depth are investigated by Field Emission Gun Scanning Electron Microscope.

In dry conditions, a continuous layer of Al_2O_3 is formed on the surface, the oxidation mode is purely external. In wet atmosphere, external MnO particles are observed while internally, MnO nodules, $MnAl_2O_4$ and a continuous layer of Al_2O_3 at the oxidation front can be found. A variation in internal oxidation depth and nature is observed with increasing holding time, enabling a kinetic approach of the diffusion mechanisms.

7

Iron oxidation simulation on IF-Ti steel: kinetics and diffusion mechanisms

Ph.D. Mathilde Romé, France

Oral Presentation (20')

Abstract

Advanced High Strength Steels (AHSS) are high-alloyed steels presenting enhanced mechanical properties. Their growing use in the automotive industry makes their galvanizing process a key operation that enables their systematic use in exposed parts. Galvanizing operations involve a thermal annealing followed by a coating step to protect the steel sheets against corrosion. The annealing takes place in a reducing atmosphere (typically N₂-5 vol.%H₂). However, this atmosphere reducing towards iron is oxidizing for most alloying elements such as Si, Mn, Al, and Cr because of water traces in the atmosphere. The high amounts of these elements in AHSS promote selective oxidation during annealing, leading to coating defects.

A solution is the pre-oxidation technique, also called total oxidation, to avoid these defects. It implies the controlled formation of an iron oxide scale in an oxidizing atmosphere, followed by a reduction step where the previously formed minor elements oxides get covered under the newly reduced iron oxide layer. This way, a metallic surface can be obtained for the hot-dip galvanizing [1,2].

Because the gas-metal reactions happening during pre-oxidation are complex, this paper focuses on the pre-oxidation of an IF-Ti (low-alloyed steel, Interstitial Free Titanium) to first elucidate the basic behavior of an industrial “almost pure” iron material. Thus, an overview of the oxidation of an IF-Ti steel in various oxidizing atmospheres at 600 °C is presented. The annealing tests are performed in a resistance-heated furnace in which the gases are injected at 300 °C, assuming to allow a direct thermodynamical equilibrium with the sample. The targeted oxidizing powers are set by the oxygen-to-gas ratio as in industrial DFF (Direct Fired Furnace using gas burners).

Thickness measurements of oxidation layers will allow to draw iron oxidation kinetical laws. The measurements are performed by Secondary Ion Mass Spectrometry for extremely thin oxidation layers (thinner than 50 nm). SEM images of samples' cross-sections allow the measurement of thicker layers and morphological observations of the oxidized layers, the substrate underneath and the interface between them. Iron oxide phases are identified by Raman spectroscopy and X-ray diffraction. An interpretation of these results will be proposed to determine the diffusion mechanisms occurring during thermal oxidation in a low-alloyed steel substrate.

Paper 228 1 **Thymol-Zinc Combinations for the Prevention of Biofilm Formation on 3D Printed Polysaccharide-based Scaffolds**

Prof. Carmen Alvarez-Lorenzo, Spain

Keynote (Oral Presentation 40')

Abstract

The rise of bacterial infections linked to biofilm formation on biological and material surfaces is a major concern. Developing medical devices that combine antibiofilm and antimicrobial activity with wound healing properties offers a promising strategy for preventing soft tissue and musculoskeletal infections. However, non-antibiotic alternatives are preferred due to antimicrobial resistance, and using non-drug, Generally Recognized As Safe (GRAS) substances can simplify regulatory approval, classifying the device as a medical product rather than a medicine. Additionally, there is increasing interest in using biodegradable polymers for sustainable scaffolds to minimize environmental impact.

This study aimed to develop 3D-printed medical devices based on xanthan gum (XG) and guar gum (GG) to reduce biofilm formation, produce antimicrobial effects, and support wound healing. For the design, we considered that hydroxypropyl- β -cyclodextrin (HP β CD) could enhance the scaffolds' ability to host antimicrobial essential oils like thymol, while XG could hold divalent metal ions like Zn²⁺ to provide complementary mechanisms for biofilm prevention. The approach included: i) obtaining and characterizing HP β CD-thymol complexes, ii) loading HP β CD-thymol and free thymol into an optimized ink, iii) incorporating Zn²⁺ into the 3D-printed scaffolds, and evaluating antimicrobial activity through microcalorimetric techniques and biofilm cell viability tests. The antimicrobial properties of the scaffolds against *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Staphylococcus epidermidis* were evaluated both by CFU counting and by real-time monitoring of metabolic heat using isothermal microcalorimetry. Calorimetric techniques, although still incipiently applied in the field of the regenerative medicine, may provide more precise, direct and robust information on the performance of the scaffolds minimizing risks of bias associated to subsequent handling and steps of traditional microbiological techniques. The biocompatibility of the scaffolds was assessed using hemolysis and cell viability tests, while angiogenic and tissue integration properties were evaluated in an in ovo CAM model [1].

Surface Design of Faceted Oxide Particles: Boosting Antimicrobial Properties

Ph.D. Cristina Pavan, Italy

Oral Presentation (20')

Abstract

The rise of antibiotic-resistant bacteria poses a significant threat to healthcare, environmental health, and sustainability. Developing selective antimicrobial materials that effectively combat infections while remaining safe for mammalian cells is a critical priority. Metal oxide nanoparticles (MOs), including copper oxides (CuO and Cu₂O) and titanium oxide (TiO₂), are promising candidates for their non-specific multiple mechanisms of antimicrobial action against a broad spectrum of bacterial species, including some important multidrug-resistant bacteria.

This study aims to synthesize MOs with highly controlled morphologies and structures to optimize their surface chemical characteristics and boost antimicrobial effects. MOs surface characteristics and size were deeply characterized in both dry and wet environments with a suite of physico-chemical techniques. Moreover, the mechanisms of MOs antimicrobial activity, including the capacity to generate reactive oxygen species (ROS) and ion release in biomimicking fluids were explored. The antimicrobial activity of the most promising MOs was assessed towards Gram-positive (*Staphylococcus aureus*) and Gram-negative (*Escherichia coli*) bacteria and their cytocompatibility was assessed towards model cellular membranes (red blood cells).

Cu₂O and TiO₂ nanoparticles with well-defined crystallographic facets were successfully synthesized, achieving precise morphological control. In situ formation of core-shell Cu₂O/CuO heterostructures via mild heating of cubic Cu₂O nanoparticles enhanced Cu₂O stability. Notably, Cu₂O exhibited a stronger bactericidal effect than CuO due to its oxidation state and electron transfer ability, copper ion release, and ROS generation due to the Fenton reaction. Furthermore, hemolytic assays confirmed the cytocompatibility of the material with mammalian cells, underscoring its potential for antimicrobial applications. Further studies will elucidate faceted-mediated TiO₂ antimicrobial mechanisms and probe doping with nitrogen and carbon compounds to enhance bactericidal activity. These findings provide new insights into the role of metal oxide surfaces in antimicrobial efficacy and present a promising strategy for developing next-generation antimicrobial agents.

Functional starch/porphyrin-based materials for wound healing

Dr. Ana Cerqueira, Portugal

Pre-recorded video presentation. Oral Presentation (20')

Abstract

Effective wound care is crucial for preventing infections and promoting skin regeneration. However, both conventional and modern wound dressings often have limitations, such as inadequate exudate absorption, poor moisture balance, and difficulty in removal, which can delay healing and increase the risk of secondary infections. These challenges highlight the urgent need for innovative materials to enhance wound management. Polysaccharides, due to their biocompatibility, have been emerged as promising candidates for developing advanced wound dressings. On the other hand, porphyrin derivatives, known for their photosensitizing properties and ability to eliminate pathogenic microorganisms, offer a novel approach to antimicrobial wound care. In this study, functional starch-based films doped with a porphyrin–triphenylphosphonium derivative were developed using the solvent casting method. Comprehensive characterization of the films was performed, including mechanical, physicochemical, and biological evaluations, to assess their suitability for wound healing applications. The incorporation of porphyrins conferred a yellowish color while maintaining transparency, and increasing water uptake, stretchability, and photosensitizing activity. By integrating antimicrobial photodynamic therapy into a polysaccharide-based platform, these innovative dressings have the potential to reduce infection risks and contribute to the advancement of more effective and sustainable wound care solutions.

Dendritic zeolites as drug delivery systems to face antimicrobial resistance

Ph.D. Beatrice Fodor, Spain

Oral Presentation (20')

Abstract

Antimicrobial resistance (AMR), occurring when bacteria become unresponsive to traditional treatments, is recognized as a significant global health emergency. This situation makes it imperative to seek new therapies.¹

Zeolites are crystalline microporous aluminosilicates that could serve as promising drug delivery systems for antimicrobial drugs due to their properties such as regular porosity, ion exchange capacity, and high surface area. However, the microporous nature of conventional zeolites with pores of less than 1 nm, limits their encapsulation capacity.² Recently, a dendritic ZSM-5 zeolite (MFI structure), featuring radially oriented and branched nanounits and highly interconnected pore channels that create trimodal porosity (micro, meso, and macro-pores), was reported by some of us.³ This material displays remarkable adsorption and catalytic properties showing the potential to overcome the limitations of conventional zeolites due to its improved accessibility. Dendritic zeolites have not yet been explored as drug delivery systems. Aluminum, a primary component of zeolites, has been associated with potential neurotoxicity, embryotoxicity, and carcinogenic effects.⁴ By substituting aluminum with safer heteroatoms, such as gallium, in the zeolitic framework, we can reduce toxicity and introduce new functionalities, given that gallium has proven antibacterial ability, among others.⁵

Herein we propose a combined therapy based on a dendritic gallium containing zeolite (Ga-MFI) loaded with a broad-spectrum antibiotic (i.e. amikacin) within its porosity. The dendritic zeolites were prepared using a modified procedure based on a previous work.³ Following their synthesis, the dendritic nanoarchitecture was confirmed, along with its small nanometric size (209 ± 39 nm). The biocompatibility of the nanomaterial was assessed in HL60 cells exhibiting cell viability higher than 99% even at high concentrations (1 mg/mL). Then, amikacin was encapsulated within the meso/macro-pores by an incipient wetness impregnation method, reaching important loadings of 28 ± 6 wt.%.

Paper 1141 6 Engineering exosome-functionalized electrospun fibres: a new strategy for modulating cellular responses in soft tissue

Ph.D. Ewa Stodolak-Zych, Poland

Oral Presentation (20')

Abstract

The surface of polymer nanofibers is typically highly hydrophobic, as described by the Wenzel and Cassie-Baxter models. This hydrophobicity reduces protein adsorption and cell adhesion. However, appropriate surface modifications can enable the incorporation of bioactive compounds, such as exosomes. Its small membrane vesicles of endocytic origin secreted by most animal and plant cells with sizes ranging from 50 nm to 150 nm. This structure are capable of inducing tissue regeneration by delivering growth factors, proteins, microRNAs, messenger RNAs, noncoding RNAs, and lipids. Altering the surface morphology of nanofibers to modulate their biological activity represents a novel strategy for regulating immune and cellular responses in vivo. In this context, nanofibers serve as carriers for exosomes, a subclass of extracellular vesicles that play a crucial role in intercellular communication. Once released, exosomes deliver bioactive molecules that regenerate tissues, guarantee homeostasis and accelerate soft tissue regeneration. In this study, we used plant exosomes from marigold (*Calendula officinalis* L.), which were introduced onto electrofibres made from a biocompatible polymer – polylactide (PLA). The surface of the fibres was chemically modified by ammoniolysis - to increase its chemical activity. Deposition of exosomes on the surface was carried out by electrospray. The fibre membranes were then examined from microstructural (SEM), structural (FTIR-DRIFT), and physicochemical perspectives. The biocompatibility of non-woven membranes with exosomes and membranes with added exosomes was tested by determining the viability and cytotoxicity of RAW 274.3 macrophage cells after 3 and 7 days of their contact matrix surface. Membrane modification with exosomes has been shown to significantly affect the secretion of anti-inflammatory interleukins and stimulate collagen secretion. Membrane modification with exosomes has been shown to significantly influence the secretion of anti-inflammatory interleukins and stimulate collagen secretion. Functionalization with an Amino Acid and Silver of Titanium Surfaces for Balancing Cytocompatibility and Infection Control

Prof. Silvia Spriano, Italy

Highlight (Oral Presentation 20')

Abstract

Orthopedic and dental implants must fulfil two primary functions: to ensure effective osseointegration, even in the case of poor host bone quality and to reduce the risk of infections. The first function is almost met by current surface treatments of titanium and titanium alloys, which are widely used for bone implants. Concerning the second function, existing implant surfaces remain significantly inadequate.

A bacteriostatic and antibiofilm action would be sufficient for bone implants, as the primary goal is to prevent the need for implant removal due to biofilm formation. A second surgery is highly invasive and carries a significant risk of further infections and localized bone resorption. Conversely, a strong antibacterial effect could compromise the cytocompatibility of the implant. The combined action of local bacteriostatic surfaces coupled with the systemic assumption of antibiotics in the first days after implantation, could be a good strategy to avoid the risk of biofilm formation on bone implants guaranteeing a fast osseointegration process.

In the case of titanium and its alloys surface functionalization with silver ions or nanoparticles has been extensively studied to impart antibacterial properties to bone implants. However, this strategy presents challenges in balancing surface cytocompatibility with antibacterial efficacy, mainly if nanoparticles are formed. Additionally, recent reports indicate the emergence of bacterial strains resistant to silver. We investigated the antibacterial properties and cytotoxicity of Ti6Al4V functionalized with silver using a cysteine-silver solution. To optimize the surface for functionalization, the alloy underwent a previously established chemical treatment. Characterization was carried out through Field-Emission Scanning Electron Microscopy (FESEM), zeta potential titration curves, release testing, and X-ray Photoelectron Spectroscopy (XPS) analysis. Antibacterial assessments included inhibition halo tests with *S. epidermidis* and biofilm formation assays with *S. aureus*. Additionally, direct cell cultures with human mesenchymal stem cells (hMSCs) and a co-culture model of bacteria and hMSCs were conducted. The findings revealed that silver ions (Ag^+) were predominant on the functionalized surface (58%), while a significant proportion of Ag-S chemical bonds (22%) was also detected, with minimal presence of metallic silver nanoparticles. hMSCs exhibited proper adhesion and alignment, and the functionalized surface demonstrated the ability to maintain cell viability in a co-culture of bacteria and fMSCs. These results confirm the effectiveness of cysteine as a linker for silver functionalization on Ti6Al4V, achieving a balance between cytocompatibility and bacteriostatic properties. The role of cysteine in preventing the development of resistance by bacteria will also be discussed.

3D-printed PEEK with Antimicrobial and Bioactive Coatings Using Vacuum Arc Plasma Deposition

Mr. Jay Phruekthayanon, Germany

Oral Presentation (20')

Abstract

The integration of additive manufacturing (AM) in biomedical engineering has revolutionized the fabrication of medical implants, particularly using polyetheretherketone (PEEK), a high-performance polymer with excellent mechanical strength, biocompatibility, and radiolucency. However, the clinical application of PEEK implants remains challenged by the need for enhanced antimicrobial properties and improved osseointegration. This study presents a novel hybrid manufacturing approach that combines Fused Filament Fabrication (FFF) 3D printing with in-situ vacuum arc plasma deposition to generate antimicrobial and bioactive thin-film coatings on PEEK implants. This hybrid method paves the way for new personalized, infection-resistant, and osseointegrative implants, particularly in orthopedic and spinal applications where infection control and simultaneous tissue integration are of critical importance. The study investigates the application of this manufacturing method to produce different metal and metal oxide coatings on 3D-printed PEEK in a single-step fabrication. The tested coatings include silver (Ag), copper (Cu), and zinc (Zn), for their antimicrobial potential, and titanium dioxide (TiO₂) due to its osseointegrative potential. Surface characterization using a laser scanning microscope (LSM) reveals that thin film coating generated by this method maintains the surface structure of its substrate and only minimally alters its surface roughness. The surface wettability is highly increased by TiO₂ coating. Cross-cut tests confirm strong adhesion of the thin film coatings to the PEEK substrate. Results from bacterial adhesion assays show that zinc, among the tested coatings, exhibits the highest antimicrobial efficacy against *Staphylococcus aureus*, with a significant reduction in bacterial counts at a minimum coating thickness of 20 nm. Additionally, TiO₂ coating confirmed its role in enhancing the osteoblast adhesion and proliferation, thus being a suitable candidate for improving PEEK bioactivity. Further, a TiO₂/Zn composite coating demonstrates a strong combination of antimicrobial protection and osteogenic support, suggesting its potential for reducing post-surgical infections while promoting bone integration. Future research will focus on optimizing Zn release kinetics to balance antimicrobial activity and biocompatibility, thus preparing the clinical applicability of these kinds of novel 3D-printed PEEK implants for infection prevention.

Metal Ion-Enhanced Titanium Abutments for Optimized Soft Tissue Attachment

Mr. Luis Abenia, Spain

Oral Presentation (20')

Abstract

Peri-implantitis, a condition characterized by gingival inflammation and bone loss, affects over 50% of patients and represents a significant challenge in oral health. Titanium (Ti) and its alloys, widely used in dental implants, exhibit excellent mechanical properties and biocompatibility. However, their biological inertness results in weak adhesion between human gingival fibroblasts (HGFs) and implant abutments, compromising the gingival seal and facilitating bacterial infiltration. To enhance biological performance, this study explores the functionalization of anodized Ti surfaces with metal ions (Mg^{2+} , Mn^{2+} , Zn^{2+} , Zr^{4+} , Sr^{2+} , and Cu^{2+}) to improve HGF adhesion and modulate bacterial colonization.

Ti6Al4V discs were anodized and subsequently treated with metal chloride solutions, followed by heat treatment and washing. Surface characterization was performed using SEM/EDX, contact angle measurements, and ICP analysis to determine ion presence and release. In vitro HGF assays evaluated cell adhesion, migration, proliferation, and collagen secretion, while immunoassays assessed gene expression of immune markers. Proteomic analyses identified adsorbed proteins, and antimicrobial tests were conducted using *Streptococcus gordonii*.

Results indicated that all ions, except Cu^{2+} , enhanced HGF adhesion. Mn^{2+} , Zr^{4+} , and Sr^{2+} significantly increased cell projection and proliferation, while Zr^{4+} and Sr^{2+} promoted collagen secretion. Ion-treated surfaces exhibited immunomodulatory effects and altered protein adsorption profiles. However, bacterial colonization remained unchanged.

In conclusion, the functionalization of Ti surfaces with Sr^{2+} , Zr^{4+} and Mn^{2+} demonstrates promising potential to improve gingival integration of dental abutments. While bacterial adhesion was not significantly reduced, the enhanced cellular response suggests these modifications may contribute to better clinical outcomes by reinforcing the peri-implant soft tissue seal.

- Paper 2111 4** **An innovative heparinization strategy for blood-contacting biomaterials: Alternating current electrophoretic deposition for enhanced hemocompatibility and antibacterial properties**
Dr. Hatice Ferda Özgüzar, Belgium
Oral Presentation (20')

Abstract

Titanium alloys (aTi) are widely used in orthopedic and dental implants due to their excellent mechanical strength, corrosion resistance, and biocompatibility. Recently, their application has expanded to blood-contacting devices (BCDs) such as stents, heart valves, and grafts, but aTi-based BCDs often face challenges in interacting with biological tissues, leading to the risk of thrombosis and infection. To address these limitations, we present an innovative surface modification technique using alternating current electrophoretic deposition (AC-EPD) to coat bare aTi substrates with heparin (HEP). This method provides a rapid, cost-effective, single-step process that overcomes the shortcomings of existing approaches. aTi heparinized substrates (aTi-HEP) exhibit a significant improvement in hemocompatibility, achieving an 80% reduction in protein adhesion, an effect that persists for seven days. In addition, aTi-HEP effectively prevents platelet adhesion and reduces the rate of hemolysis by 50%, highlighting the improved blood compatibility. In addition, aTi-HEP improves fibroblast cell viability by 30%, indicating superior biocompatibility. Improved antibacterial performance was also observed, with reductions in *S. epidermidis*, *S. aureus*, and *E. coli* colonization of 36%, 43%, and 25%, respectively. In conclusion, the AC-EPD heparinization method provides a simplified, efficient, and cost-effective strategy for aTi substrate modification, paving the way for safer and more effective BCDs. This approach has significant potential to improve patient outcomes by minimizing complications associated with thrombosis and infection.

Paper 1379 **5** **Surface modification of bioactive glasses through plasma technology to impart antiadhesive properties**
Prof. Marta Miola, Italy
Oral Presentation (20')

Abstract

Bioactive glasses are widely investigated and used in the field of bone tissue regeneration. However, their surface, if not appropriately modified, can be quickly colonized by bacterial strains, with subsequent formation of biofilm, detachment and development of infections in the surrounding tissues.

This work focuses on the surface modification of two glass compositions (SBA2 and S53P4) via non-thermal atmospheric pressure plasma treatments to impart antimicrobial properties, avoiding the use of antibiotics or antimicrobial agents. This technique allows to provide tailored surface characteristics by adjusting parameters such as process gas and reactor conditions. The glasses were produced using the melt and quenching technique, the melt was cast into a mold to obtain a bar, subsequently cut into slices which were polished to level out the surface. Samples were activated using He/O₂ or He/N₂ plasma and subsequently coated with polymer coatings (e.g. siloxanes) to impart antiadhesive properties. Plasma-treated glasses were characterized in terms of morphology and composition using Field Emission Scanning Electron Microscopy (FE-SEM) with energy dispersive spectroscopy (EDS) and Fourier Transform InfraRed (FTIR) spectroscopy, surface properties by optical laser confocal microscopy, Water Contact Angle (WCA) and zeta potential measurements. Moreover, in vitro bioactivity tests in simulated body fluid and bacterial assays were carried out to evaluate the surface ability to reduce bacteria adhesion.

The obtained results evidence that the plasma-treated samples show a modified topography, roughness and wettability, and different functional groups, useful for inhibiting bacterial adhesion. The bioactivity of the glasses is maintained even after depositions or plasma treatments and finally, a significant reduction of multidrug-resistant *Staphylococcus aureus* is observed on the surfaces of the two treated glasses. Therefore, the non-thermal atmospheric pressure plasma treatment represents a promising technique for developing bone regeneration devices able to promote osseointegration and decrease infection development.

Paper 1904 6 Development of a novel antibiotic-doped calcium-phosphate cement for bone infection treatment

Mr. Eneko Elezgaray, France

Oral Presentation (20')

Abstract

This study aims to develop a degradable and biocompatible calcium phosphate cement (CPC) loaded with gentamicin and vancomycin for the local treatment of a broad spectrum of strains causing osteomyelitis. The two antibiotics were incorporated, either individually or in combination, into the solid phase of the Graftys® Quickset (GQS) injectable cement. The impact of their incorporation on the physicochemical properties of the cement was examined, the antibiotics release was evaluated, and the biocompatibility was validated in vitro. The antibacterial properties were characterized for different bacterial strains including Gram + and – bacteria, *S. aureus*, *S. epidermidis*, *Pseudomonas aeruginosa* and antibiotic-resistant strains, such as MRSA or MRSE, either in planktonic or biofilm state. The incorporation of antibiotics did not result in any significant alterations of the intrinsic properties of the GQS cement. Apart from an extended setting time, which remained in an acceptable range for the clinician, mechanical strength, porosity, injectability are not altered. These results are confirmed by an XRD study which confirms that there is no direct interaction between the antibiotics and the cement during hardening. The loaded cement enabled the rapid release of very high concentrations of antibiotics locally around 10 to 100 times the minimum inhibitory concentrations for the organism in presence, without exerting any cytotoxic effects on human osteoblasts but with a strong and wide antibacterial effect on various bacteria grown as planktonic or as a biofilm. Altogether, these data indicate that this new version of the GQS cement loaded with gentamicin and vancomycin represents a very attractive local treatment of osteomyelitis.

Paper 1726 2 Unraveling the Plastic Deformation Mechanism in Oxide Glasses via Atomistic Simulation and Coarse-Grained Analysis

Dr. Jiahui Zhang, Finland

Oral Presentation (20')

Abstract

Amorphous materials, valued for their optical transparency, insulation, and oxidation resistance, are indispensable in applications ranging from architectural glass to electronic displays. However, their limited mechanical performance, particularly the absence of a robust plastic deformation mechanism, restricts their widespread utility. Recent experimental studies have revealed that amorphous alumina (α - Al_2O_3) thin films exhibit remarkable plasticity at room temperature, challenging traditional perceptions of amorphous materials' mechanical behavior.

This study investigates the plastic deformation mechanisms of α - Al_2O_3 using molecular dynamics simulations and complementary characterization methods targeting medium-range order (MRO). Our findings demonstrate that viscous flow governs the deformation behavior of α - Al_2O_3 under mechanical stress, distinguishing it from other amorphous oxides. The unique structural characteristics of α - Al_2O_3 , attributed to its harsh preparation condition, likely underpin its enhanced plasticity.

To expand the scope of our understanding, we developed a coarse-grained analytical model that bridges atomic and mesoscopic scales, enabling a quantitative evaluation of medium-range structural features. This model reveals the critical role of MRO in dictating the plastic deformation capacity of amorphous oxides, including amorphous alumina and silica. Our approach provides a versatile framework for assessing and predicting the mechanical performance of amorphous materials, paving the way for designing amorphous systems with improved mechanical properties.

This work offers a deeper insight into the deformation mechanisms of amorphous oxides and broadens the potential for their application in mechanically demanding environments.

Paper 1854 4 Numerical Investigation on the Laser Absorptivity in Laser Additive Manufacturing of Copper using Beam Shaping

Ph.D. Baoshun Zhou, Denmark

Oral Presentation (20')

Abstract

Copper has been widely used in various engineering applications due to its excellent thermal and electrical conductivity properties. The laser powder bed fusion process (PBF-L) involves multiple physical phenomena, e.g. phase change, evaporation, melting, solidification, microstructural evolution, etc.

This work simulates the PBF-L process of copper under infrared laser irradiation at the deposition scale using the finite volume (FVM) solver OpenFOAM, including various physical effects such as buoyancy, surface tension, evaporation, and the Marangoni effects. The simulation results have been verified by a decent agreement with experimental measurements in terms of melt pool profile at different combinations of laser, ranging from conduction to transition and keyhole modes.

For copper PBF-L, there has been disagreement in the literature regarding the correct absorption rate of laser power, especially in simulation-related work.

Here, we investigate the influence of laser power, scanning speed on the absorptivity, and provide a reference for the contour of global absorptivity V.S. process settings.

Beam shaping generally has an influence on the melt pool shape and the printing quality, and here we apply two types of laser beam shapes, one with Gaussian and one with Ring-shaped profiles as input heat sources, to investigate their effects. This work is performed for simulating the melt pool at dense substrates at single track, single layer, shedding light on the fundamental impacts of the process settings on melting and global absorptivity.

Influence of material strength on microshear bands formation through crystal plasticity simulations

Dr. Vitesh Shah, Austria

Oral Presentation (20')

Abstract

Capturing highly localized deformation features in a deformed microstructure is critical for further recrystallization simulations. Quite often recrystallized nuclei originate from such localized deformation zones. The highly localized deformation in such zones can lead to formation of texture components different from regular deformation/rolling texture components on a very local scale. From the basis of crystal plasticity simulations (DAMASK) of different aluminium alloys, we show that propensity of such localized deformation is a function of material strength and deformation temperature. Higher material strength and lower deformation temperatures lead to more localized deformation resulting in micro-shear bands. This holds relevance for hot-rolling, where the rolling temperature can control the localized deformation in material and thus, eventually affecting the recrystallized microstructure. The full-field crystal plasticity simulation data will be used to understand the mechanisms behind the phenomena. Also, it will be investigated as to which texture components form in these localized deformation zones and if they have potential to be recrystallized nuclei.

The Role of Plastic Deformation in Martensitic Transformation of Low Carbon Steel

Mr. Hesham Salama, Germany

Oral Presentation (20')

Abstract

The complex interplay between the rapid martensitic transformation and the plastic relaxation during martensitic transformation in low-carbon steel is investigated using a combined phase-field and phenomenological crystal plasticity approach. The large transformation-induced deformations and local lattice rotations are rigorously described within the finite strain framework. The study reveals that plastic relaxation plays a crucial role in accommodating the transformation-induced deformations of martensite in the parent austenite phase. By systematically varying the plastic slip rate, imposed cooling rate, and carbon content, the simulations provide insights into the interdependence between these factors, contributing to a better understanding of the martensitic transformation process and the resulting microstructures. The phenomenological crystal plasticity model effectively relates the plastic relaxation rate to the rate of martensitic transformation with a significant time scale difference between the two processes. The findings contribute to a deeper understanding of the interplay between the rapid martensitic transformation and the requirement for plastic deformation.

Investigation of Carbide Effects on the Mechanical Properties of AISI 420 Steel by Crystal Plasticity Simulation

Mr. Kegu Lu, The Netherlands

Oral Presentation (20')

Abstract

Understanding the role of precipitates in determining the mechanical properties of metallic materials is essential for optimizing their design and performance. This study investigates AISI 420 stainless steel, which consists of ferrites with carbide precipitates in its annealed state. A virtual laboratory framework is developed using a multiphase crystal plasticity (CP) model to systematically explore the effects of carbide—including their volume fraction, distribution at grain boundaries, average size, and quantity—on the steel's mechanical response across scales. The methodology involves constructing representative volume elements (RVEs) from microstructural characterization of the as-received material, calibrating material parameters within the CP model, and validating the model against experimental texture and mechanical properties. A series of RVEs were generated by systematically altering carbide characteristics to evaluate their influence on stress-strain behavior, anisotropy, and micromechanical interactions between the ferritic matrix and carbides. This research underscores the effectiveness of a virtual laboratory in bridging microstructural attributes with macroscopic mechanical behaviors and demonstrating its feasibility for studying microstructural influences. The insights gained are not only relevant to AISI 420 steel but can also be extended to other steels containing hard, elastically distinct precipitates, offering a broader perspective on microstructure-property relationships.

Paper 1629 2 Modeling complex diffusion phenomena in compositionally-graded single-crystal Ni-based superalloys

Dr. Ahmadreza Riyahi khorasgani, Germany

Oral Presentation (20')

Abstract

The present work consists of modeling various complex diffusion-related phenomena in single-crystal Ni-based superalloys including CMSX-10 and CMSX-4, under isothermal annealing and composition gradient. The simulated diffusion events include multi-component diffusion of elements and vacancies, phase transformations, dissolution of precipitates and Kirkendall pores nucleation, growth and their morphological instability.

The applied methodology combines novel quantitative phase-field models coupled with thermodynamic and diffusion parameters based on the CALPHAD approach.

For all simulated efforts, the achieved results are compared with experimental data such as measured interdiffusion profiles, SEM analysis of microstructure and synchrotron X-ray tomography of the Kirkendall pores.

Advancements in DFT methods for the investigation of complex transition metal oxides

Dr. Elena Arroyo-de dompablo, Spain

Oral Presentation (20')

Abstract

Methods based on Density Functional Theory (DFT) play a central role in designing advanced functional oxides, allowing the identification of promising materials through property prediction, and the understanding of the underlying structure-composition-property relationship. In the last decades, the DFT+U method has enabled the investigation of transition metal oxides with strongly interacting d-electrons. However, progress in the modelling of correlated TM oxides demands the enhancement and assessment of improved exchange-correlation functionals. This is particularly defying for complex oxides combining different TM ions. [1,2] This communication discusses the performance of the strongly constrained and appropriately normed (SCAN) meta-GGA functional and its SCAN+U derivative to model the basic physical properties of Fe⁴⁺-based perovskite oxides.

Going into property prediction, DFT serves to identify oxides with catalytic activity for the dissociation of water into hydrogen (HER process) and oxygen (OER process), as well as the combination of oxygen and hydrogen to produce water (HOR and ORR processes). Electronic descriptors, such as the oxygen 2p-band center or the intermediate absorption energies, show strong correlations with properties that directly influence the catalytic activity, such as the area-specific resistance (ASR) for ORR, and the OER overpotential in Alkaline Electrolyzers (AEL). [3,4] While previous studies have mainly focused on simple perovskite ABO₃ oxides, this communication explores complex Fe⁴⁺-based perovskites. Complementary experimental investigation on SrFe_{1-x}MoxO_{3-δ} perovskites [5] allows for discussing the reliability of electronic descriptors for property prediction.

First principles investigations of metastable group IV transition metal diboride solid solutions

Mr. Christian Gutschka, Austria

Oral Presentation (20')

Abstract

A prominent class of refractory ceramics, transition metal diborides, has recently attracted scientific attention – both in their bulk and thin film form – due to their high-temperature stability and extreme mechanical properties. The thin film community has primarily focused on metastable solid solutions, where alloying with silicon leads to massively enhanced oxidative properties combined with only minor drawbacks in hardness. However, theoretical investigations of TM-Si-B₂ based systems have been limited until now.

Therefore, this study employs ab initio methods to shed light on the physical fundamentals of metastable solid solutions of TiB₂, ZrB₂, and HfB₂ with silicon. Utilizing Density Functional Theory (DFT), the structural and mechanical properties were investigated and compared well with experimental thin films. Methods such as Crystal Orbital Hamilton Populations (COHPs) allowed to couple chemical stability and elemental bonding properties, whereas Radial Distribution Functions (RDFs) and simulated XRD patterns unraveled a direct connection between experimentally explored Si solubility limits and AlB₂ type structure loss. Moreover, a novel ab initio-based statistical technique was explored to investigate maximal solubilities in the metastable solid solution state. Furthermore, a structural instability of ternary diborides concerning transition metal vacancies was found, in contrast to low variations of the chemical stability at high silicon contents.

Unraveling Atomistic Mechanisms of Pressure-Induced Phase Transitions in Silicon and Germanium

Dr. Fabrizio Rovaris, Italy

Oral Presentation (20')

Abstract

Silicon and Germanium are some of the most studied materials for their importance in the microelectronic industry, but they have been studied so far mainly in their most stable phase: the diamond cubic. However, they also exhibit several metastable allotropes, some of which are very promising for their superior optoelectronic properties. These allotropes can be experimentally synthesized starting from the dc by inducing solid-solid phase transitions driven by pressure, like the BC8/R8 phases and the hexagonal diamond [1].

In this work, we advance the understanding of the atomistic mechanisms underlying pressure-induced Phase Transitions in Si and Ge by combining state-of-the-art techniques for the atomistic simulations of kinetic processes in solid-solid phase transitions. In particular, we exploited massively parallel Molecular Dynamics simulations [2] based on Machine Learning potentials, like the GAP potential for Si [3] and an ad-hoc developed Neural Network potential for Ge [4]. We complemented such simulations with the solid-state Nudged Elastic Band [5] calculations. Particular focus is devoted to the search for transition processes showing the local nucleation and growth of a phase inside a hosting matrix. We explicitly show the improved estimation of the transition rates considering the local nucleation process compared to the more simplified full-cell transition models [6]. Examples will be provided for several phase transitions in both silicon and germanium. Finally, we exploited a high-throughput search method for exploring possible transition paths based on the solid-state Dimer method [7] and the adaptive Kinetic Monte Carlo scheme in order to automatize the search process for physically relevant phase transitions.

Uncertainty in the era of machine learning for atomistic modelling

Dr. Kevin Rossi, The Netherlands

Oral Presentation (20')

Abstract

Machine Learning Potentials (MLPs) have revolutionized the simulation of complex material systems by offering high efficiency and accuracy. However, their reliability can be compromised when simulations explore configurations not well-represented in the training data. [1]

In this presentation, I will then focus on how to assess the accuracy and precision of MLPs. First I will define the concept of robust and non-robust extrapolation, and of transferability, in the context of machine learning potential validation and exploitation. I will then discuss extrapolation metrics that enable to quantify the reliability of a MLP prediction. [2] Next, I will elaborate on how to estimate the uncertainty in MLPs predictions, and how to rigorously propagate the latter when estimating a physical observable from molecular dynamics sampling. [3].

I will conclude my talk with a reflection on: i) how uncertainty estimate and propagation is central to other machine learning for science application as well, ii) what our community can do to foster the development of workflows and models, which rigorously account for sources of error and uncertainties [4]

Paper 1234 2 **Unveiling the Origin of the Yield Stress Anomaly in L12 Intermetallics via Multiscale Atomistic Approaches**
Mr. Xiang Xu, Germany
Oral Presentation (20')

Abstract We investigated the yield stress anomaly (YSA) in L12 intermetallics using a multiscale atomistic approach, bridging electronic-scale calculations with large-scale molecular dynamics simulations through machine-learning-based interatomic potentials. An ab initio database of temperature-dependent Gibbs energy for relevant planar defects in L12 Ni₃Al was developed, covering the full temperature range of the YSA. Machine-learning interatomic potentials, trained and benchmarked against DFT results, achieve accuracy comparable to ab initio calculations. Key dislocation mechanisms, such as cross-slip and dislocation jumps, were successfully observed and analyzed. These MD results enabled the development of a phenomenological model that captures the YSA characteristics, providing deeper insights into the high-temperature performance of Ni- and Co-based superalloys.

Paper 1144 5 **Microstructural control of aluminum alloys under high pressure**
Dr. Sha Liu, China
Oral Presentation (20')

Abstract Pressure is one of the canonical thermodynamic variables which control the equilibrium conditions of a physical system. Precipitation strengthening in Al alloys is hindered by the limited solid-solubility, while it can be enhanced under pressure. In this work, the Al-Mg phase diagrams at 0 and 4 GPa of hydrostatic compression were constructed by first-principles calculations. The enthalpy and internal energy of configurations was obtained by density functional theory. Cluster expansions were fitted to account for the relationship between internal energy and atomic occupation while the PV term was only sensitive to alloy concentration. Monte Carlo simulations were performed to obtain the Gibbs free energy of solid phases while that of liquid were obtained from CALPHAD. The entire phase diagrams under 0 GPa and 4 GPa were constructed, and the increment in solid solubility due to the hydrostatic pressure was ascertained. Finally, a solid solution heat treatment was performed under hydrostatic pressure, followed by precipitation experiments to ascertain the precipitate structure and volume fraction. The influence of enhanced solid-solubility under high pressure was also verified with Al-Si alloy and Mg-Li alloy.

Machine Learning-Based Predictive Model Integrating Experimental Data and Multiphysics Simulations for Product Quality Assessment in Metallic Laser Powder Bed Fusion: Deformation, Surface Roughness, and Part Density

Ph.D. Hao-Ping Yeh, Denmark

Highlight (Oral Presentation 20')

Abstract

Product quality is a key metric for evaluating the performance of LPBF machines. Among various indicators, deformation, surface roughness, and part density are closely interconnected. Higher deformation often leads to surface irregularities, affecting overall part quality. Similarly, lower density caused by porosity or incomplete fusion results in a rougher surface due to balling effects and uneven solidification. In contrast, high-density parts exhibit smoother surfaces, as uniform melting and solidification reduce surface defects. Part density also plays a crucial role in deformation. Lower density weakens structural integrity, making the part more susceptible to warping and distortion. Conversely, high-density parts provide better mechanical stability, reducing residual stress and minimizing deformation. This interdependence highlights the need for optimized process parameters to achieve the desired balance between deformation, surface quality, and density in LPBF manufacturing.

This work focuses on rapid quality prediction using a machine learning model. Since direct measurement of the aforementioned quantities is challenging, a validated finite element-based part-scale thermo-mechanical model serves as a data generator. This model simulates 3D displacement and stress maps under varying laser process parameters, including laser power, scan speed, hatch spacing, powder thickness, and beam shape profile. Meanwhile, data for other quality criteria, such as surface roughness and part density, is obtained through in-house experiments, measurements, and an FVM-based thermo-fluid dynamic model, ensuring a comprehensive dataset for training the machine learning model. The proposed approach consists of two parallel predictive models: The first model, a sequence-to-sequence learning framework, takes 3D geometry and laser settings as inputs to predict residual stress and displacement profiles. The second neural network model uses laser process parameters to first predict surface roughness (S_a , S_q , and S_z) and texture (Str). These surface characteristics are then used as inputs to predict part density, given their strong correlation. Finally, the model optimizes the process parameters to minimize defects and enhance overall quality. This framework enables efficient, data-driven process optimization, significantly reducing the need for extensive simulations and experiments.

Paper 991 1 **Data-driven study of the enthalpy of mixing in liquid alloys**

Dr. Guillaume Deffrennes, France

Keynote (Oral Presentation 40')

Abstract

The enthalpy of mixing in the liquid phase is a key input in Calphad and machine learning [1] models for predicting the melting temperature range of alloys. As a result, it is an important property for the design of a variety of alloys, such as brazing alloys, cast alloys, or phase change materials for thermal energy storage. In multicomponent liquids, the main contribution to the enthalpy of mixing comes from the pairwise interactions, yet, this property has only been measured in at most a third of the binary systems. Therefore, predicting the enthalpy of mixing in binary liquids remains highly important, and to this day, Miedema's semi-empirical model [2] has been regarded as the most reliable for this task.

This presentation will focus on using machine learning to predict the enthalpy of mixing in binary liquids formed by 70 elements. To achieve this, we collected enthalpy of mixing data from the literature in more than 400 binary systems. By using active learning and clustering models, we identified the need for new data for liquids with a refractory metal, which we obtained in 29 binary systems using ab initio molecular dynamics simulations. This led to improvements to our machine learning model [3], which was already performing better than Miedema's model. We will also discuss the temperature dependence of the enthalpy of mixing, and the reliability of its extrapolation from the binary systems in multicomponent liquids. Through this presentation, we will outline directions for further research on this property, which is essential for predicting phase equilibria.

Modeling of precipitation processes in multicomponent alloys

Mr. Sylvain Ducottet, France

Oral Presentation (20')

Abstract

The time evolution of a precipitate population under non-isothermal conditions in a multicomponent alloy is presented. The tracking of this population is carried out using a particle size distribution model, and calibrated with experimental measurements performed by Atom Probe Tomography reported in the literature.

The model incorporates the thermodynamic properties of the alloy extracted from a database. Local equilibrium at the interface is considered, including the curvature effect. The analytical solution of the unsteady diffusion problem for a non-diagonal diffusion matrix, previously validated by a numerical solution for an isolated precipitate, is employed to determine the growth kinetics.

A new iterative algorithm is proposed to fix the interfacial operating point. This point is defined by (i) the equilibrium tie-line between phases and (ii) the solute diffusion flux balance on each side of the interface. An approximation related to the diffusion flux for species of large diffusion coefficients is applied to overcome the difficulties associated to uniform solute profile. It enables an efficient computation of the solution.

The model is applied to the growth of gamma prime phase precipitates in a gamma phase matrix for the Inconel 738 superalloy. This application highlights the impact of common simplifications found in the literature, such as assuming a diagonal diffusion matrix or a steady-state diffusion regime. The potential applications of the model will also be discussed, including the tracking of solid-state precipitation kinetics in direct coupling with an additive manufacturing process. The presented model is integrated into the PhysalurgY software library developed at CEMEF.

Role of Intermetallic Phases in Fe-based Shape-Memory Alloys

Dr. Mario J. Kriegel, Germany

Oral Presentation (20')

Abstract

Shape-memory alloys (SMAs) based on the Fe–Mn–Al–Ni system provide promising advantages over conventional NiTi-based alloys in terms of materials costs and cold workability. The shape-memory effect in these alloys proceeds quite unusually between a bcc-type parent phase (Stukturbericht designation A2) and a martensitic fcc-type phase (A1). Thereby, coherent nano-sized precipitates (B2) inside the parent matrix are necessary to suppress dislocation-driven plasticity, which would interfere with the martensitic transformation and thus deteriorate the superelastic properties. The B2 precipitates are based on the intermetallic phase AlNi and their size, volume fraction and the chemical composition strongly influence the transformation temperature, superelastic strain, critical stress to induce the martensitic transformation and stress hysteresis. To understand energetic contributions of the intermetallic B2 precipitates to the parent phase in order to initiate the martensitic transformation, thermodynamic calculations were performed using a quaternary Al–Fe–Mn–Ni CalPhaD (Calculation of Phase Diagrams) database. With the aid of extrapolated T_0 temperatures for the B2 precipitates and energetic considerations (EAM potentials) of the differences between B2 and $L1_0$, both adopted from literature data, the thermodynamic stability of the B2 phase was approximated.

Calorimetric studies are essential for SMAs to describe thermodynamic properties over a wide temperature range, because e.g., the T_0 temperatures fall below ambient temperatures in these systems. Therefore, specific heat capacity functions of various intermetallic phases in the binary system Al–Ni and the ternary system Fe–Ni–Ti were measured using the classical three-step method in heat-flux and power-compensated differential-scanning calorimeters. Moreover, enthalpy increment measurements were performed using a Calvet-type calorimeter in transposed drop calorimetry mode. In order to verify the applicability of thermodynamic calculations for a target-oriented alloy design of Fe-based SMAs, several samples with varying fractions of B2 particles and different stabilities against the martensitic transformation were prepared, annealed, subsequently tested using nanoindentation, and analyzed using electron-backscatter diffraction (EBSD). In order to describe the deformation behavior and to assess the reversibility of the martensitic transformation upon loading and unloading, the work-recovery ratio was determined from indentation curves. Since the martensitic transformation behavior is strongly dependent on the crystal orientation, the nanoindentation and EBSD measurements were performed on numerous differently oriented grains. It is shown that the volume fraction and the stability of the intermetallic B2 precipitates against the transformation towards an $L1_0$ -like state severely influence the overall stability of the parent state in Fe–Mn–Al–Ni SMAs and consequently, the reversibility of the martensitic transformation.

Paper 61 **4** **Creep resistance of metal-ceramic composites based on austenitic stainless steel and recycled magnesia particles**
Mr. Moritz Mueller, Germany
Oral Presentation (20')

Abstract

In this study, creep properties of potential materials for carbon-free electrodes used in the fused-salt electrolysis of primary aluminium are investigated. The examined metal-ceramic composites feature an austenitic stainless-steel matrix (60 vol.%) reinforced with coarse-grained recycled magnesia particles (40 vol.%) sourced from spent MgO-C refractory lining bricks. These composites were produced using the field-assisted sintering technique (FAST), as this processing route results in a low porosity. A pre-oxidation of the composites at 900 °C was found to promote the formation of a protective MgO-FeO solid solution surface layer, enhancing corrosion resistance against both molten aluminium and molten cryolite [1,2].

Creep experiments under compressive loading conditions were conducted at 900 °C to compare composites reinforced with recycled magnesia to reference composites reinforced with fresh-fused magnesia. Results indicate that the recycled nature of the particles does not impair creep resistance. On the contrary, composites containing recycled magnesia particles demonstrated superior creep strength due to their smaller, more uniform particle size distribution within a given size fraction. This is the result of mechanical crushing steps during the recycling process. The influence of a pre-oxidation on the creep resistance was examined. Furthermore, variations in the volume fractions of steel and magnesia were evaluated for their impact on creep strength. Microstructural deformation mechanisms were characterized using back-scattered electron imaging and electron backscatter diffraction measurements in a scanning electron microscope.

In summary, this study compares the creep properties of coarse-grained steel-ceramic composites reinforced with either fresh-fused or recycled magnesia particles and examines how the narrower and more homogeneous particle size distribution of the recycled reinforcements enhances creep resistance.

- Paper 1692** 5 **Influence of the fabrication process on the oxidation behavior of a eutectic high-entropy alloy**
Mrs. Rita Carbajales, Spain
Oral Presentation (20')

Abstract

High entropy alloys are considered a promising option for high-temperature applications due to the possibility to achieve excellent oxidation resistance. However, processing conditions play a crucial role in determining the final microstructure and, consequently, the material's properties. This study examines the impact of various fabrication methods on the microstructure, mechanical properties, and high-temperature oxidation behavior of a non-equiatom AlCrCoFeNi_{2.1} eutectic high-entropy alloy (EHEA). The alloy was fabricated using traditional arc-melting and a powder metallurgy (PM) technique, spark plasma sintering (SPS), using gas-atomized powders as starting materials. While the fabrication method had a minimal effect on the primary phases present, it significantly impacted the microstructure morphology. Additionally, differences in mechanical properties were observed. All samples primarily consisted of a body-centered cubic (BCC) phase and a face-centered cubic (FCC) phase. However, the arc-melted alloy exhibited a typical lamellar structure, whereas the SPS-ed alloy displayed also globular structures in certain regions. The powder metallurgical method of SPS significantly refined the grain size. Powder metallurgy routes enabled the microstructure of the samples to be tailored to improve mechanical properties and oxidation resistance. During oxidation tests, samples fabricated by SPS exhibited more homogeneous oxide layers.

- Paper 957** 6 **Influence of the oxygen partial pressure on the oxidation mechanism of rutile-type oxide-forming refractory high entropy alloys**
Mr. Fabian Lanoy, Germany
Oral Presentation (20')

Abstract

The lack of intrinsically protective oxides inhibits most refractory-based alloys from being used as high temperature structural materials. The catastrophic oxidation of most refractory metals, resulting in the formation of volatile or voluminous oxides, begins as low as 500 °C. Recent investigations found potential refractory compositionally complex, or high entropy alloys (HEAs), offer improved oxidation resistance at temperatures as high as 1500 °C. Additionally, high entropy alloys have been shown to be capable of exhibiting greater strengths than conventional alloys.

The Cr-Ta-Ti-Al-Mo HEA system is potentially oxidation resistant through the formation of a thin and continuous CrTaO₄ at the interface between the substrate and a mixed outer oxide scale. CrTaO₄ has been shown to play a role in the oxidation resistance of other high temperature oxidation resistant alloys, including some Ni-based superalloys. High temperature oxidation experiments of Cr-Ta-Ti-Al-Mo were performed at 1000°C in Ar-O₂ atmospheres with varying oxygen partial pressures to clarify the dominant defect structure(s) and formation mechanism(s) of CrTaO₄. As rutile-type oxides are known to be very susceptible to doping, small additions of elements with varying oxide valences were added to investigate a potential doping effect. Higher valence doping of Cr-Ta-Ti-Al-Mo was successful in showing reduced oxygen diffusion through the oxide and thus better oxidation performance.

Dynamic recrystallization during hot deformation of an oxide-dispersion-strengthened ferritic steel

Dr. Michael Mayer, Austria

Oral Presentation (20')

Abstract

Future technologies for green energy production strongly rely on high-temperature alloys in order to maximize their efficiency. Among many candidate alloy systems, oxide dispersion strengthening (ODS) has shown its potential regarding creep resistance many times, but production via powder metallurgy is still challenging. Moreover, the alloy contains only a low amount of critical raw materials. To support the establishment of this alloy class, the dynamic recrystallization behavior of a novel ODS alloy during hot-rolling was simulated by using Gleeble compression testing. The hereby achieved microstructure was investigated by scanning electron microscopy and correlated with a finite-element model to obtain the local deformation and deformation rate. These coupled methods led to a set of material data that was further used for the modeling of the recrystallization behavior of this novel ferritic ODS alloy.

Paper 682 1 Effects of laser parameter on the recrystallization temperature of additively manufactured IN718

Ph.D. Joong Eun Jung, South Korea

Highlight (Oral Presentation 20')

Abstract

Recently, research on additive manufacturing (AM) technology has been actively pursued in high-value-added industries due to its potential to overcome the design limitations of conventional manufacturing methods, enabling a significant reduction in manufacturing time and a remarkable enhancement in performance. Manufacturing high-temperature gas turbine components represents one of the most effective fields for harnessing the advantages of AM technology, with active research primarily focusing on Ni-based, Co-based, and Ti-alloys. However, challenges arise in addressing property degradation such as crack formation, ductility reduction, and anisotropy before/after heat treatment, which must be overcome to expand their applications. In this study, IN718 specimens were fabricated using laser-based powder bed fusion (L-PBF) by varying laser power, laser scan speed, layer thickness, and hatch distance. The changes in recrystallization temperature according to each laser parameter were investigated after applying various solution heat treatment temperatures. Furthermore, the residual stresses and microstructure analysis of as-built specimens were performed to understand the driving force for recrystallization according to the laser parameters. The specimens were manufactured within a volumetric energy density (VED) range of 61.7 J/mm³ to 260 J/mm³ by varying laser power (370W, 380W, 390W), laser scan speed (600mm/s, 800mm/s, 1000mm/s), layer thickness (25μm, 37μm, 50μm), and hatch distance (0.1mm, 0.11mm, 0.12mm). Solution heat treatment was carried out at 1,065°C, 1,080°C, and 1,095°C with a 90-minute interval while aging heat treatment was performed using AMS standard conditions. The volume fraction of recrystallized grain was determined using the Grain Orientation Spread (GOS) value obtained from Electron Backscatter Diffraction (EBSD), and areas with GOS values below 1 degree were considered as recrystallized grains. Additionally, the occurrence of recrystallization was identified when the volume fraction of recrystallized grains after heat treatment exceeded 50% of the observed area. Within the experimental range, the recrystallization temperature of L-PBF IN718 decreased with increasing laser power, scan speed, and layer thickness. As a result, the variation in recrystallization temperature showed minimal correlation with VED and mainly depends on the cooling rate of the melt pool, which is influenced by the volume of the melt pool and the heat dissipation of the melt pool.

Paper 527 **2** **Additive manufacturing of a high-temperature coating for aero-engine applications**
Mrs. Ingrid Bergheim, Norway
Highlight (Oral Presentation 20')

Abstract

Traditionally, the production of metallic overlay and bond coatings for high temperature applications such as nickel-based superalloy blades in aero-engines is achieved by thermal spraying processes. In this study, we investigate the potential to produce such coatings by additive manufacturing processes that will allow the repair of such components on- or near-wing. In particular, the well-known overlay coating Ni-25Cr-6Al-0.4Y (at.%) was deposited by a laser-based directed energy deposition (DED) process directly on a nickel-based superalloy substrate. The primary aim is to investigate the microstructure in the as-built condition after the deposition. As such coatings are not traditionally produced by additive manufacturing processes, a multi-scale analysis was deployed to investigate the as-built microstructure. Electron backscatter diffraction (EBSD) revealed columnar grains consisting of columnar dendrites along the building direction. Scanning electron microscopy (SEM) and electron probe microanalysis (EPMA) revealed the presence of micro-segregation of Y and Al between the dendritic and interdendritic regions. Besides, no cracks were observed between the deposited coating and the superalloy substrate. Finally, atom probe tomography (APT) provided compositional information at near-atomic scale for various phases formed during the DED processing. The Y-rich regions observed by EPMA were further confirmed by APT, while other phases were also measured which revealed significant compositional differences at the nano-scale. These observations will be presented in detail and potential future steps for processing coatings by additive manufacturing techniques will be discussed.

Paper 1187 3

Control of impurity elements in molten Ni-based superalloy

Prof. Youngjo Kang, South Korea

Oral Presentation (20')

Abstract

Nickel-based superalloys are special alloys that enhance heat resistance through the addition of various alloying elements. In particular, aluminum plays an important role in the formation of Ni₃Al and securing high-temperature strength. However, the presence of impurities such as O, N, S, and H in superalloys can lead to the formation of brittle phases by reacting with the alloying elements added for the desired properties, which critically affects the mechanical properties of the superalloy. Therefore, controlling these impurities is crucial. When produced solely through Vacuum Induction Melting without additional refining processes such as Electro Slag Remelting or Vacuum Arc Remelting, the use of slag is limited due to the vacuum conditions, making effective removal largely dependent on vacuum control.

In this study, various experiments were conducted to establish fundamental data for controlling the formation of three non-metallic inclusions (O, S, H) in molten nickel-based superalloys. First, for sulfur, desulfurization experiments were carried out to investigate the desulfurization capacity based on the types of desulfurizers and their addition methods. Inclusions were analyzed to elucidate the desulfurization mechanism and derive optimal desulfurization conditions based on the predicted changes in sulfur concentration during ceramic filtering.

For oxygen, equilibrium deoxidation experiments were conducted using the equilibrium reaction between Al and Al₂O₃, varying the aluminum content in nickel. The equilibrium solubility of oxygen in Ni-Al alloys with compositions ranging from 0.0005 wt% to 15 wt% was measured, and equilibrium constants and interaction coefficients were derived using interaction coefficient models such as WIPF (Wagner's Interaction Parameter Formalism) and Redlich-Kister type polynomial. Evaluations of deoxidation equilibrium were conducted for each model.

For hydrogen, equilibrium experiments of H₂ gas were conducted at three temperature ranges (1773 K, 1823 K, 1873 K) using Sievert's law to derive the equilibrium constant for the reaction of hydrogen dissolving in pure nickel as a function of temperature. At 1873 K, the equilibrium hydrogen solubility of Ni-Al alloys with hydrogen concentrations ranging from 1 to 6 wt% was measured, deriving the equilibrium constant for the hydrogen dissolution reaction in Ni-Al alloys. The interaction coefficient between aluminum and hydrogen was also derived through changes in the activity coefficient of hydrogen with increasing aluminum concentration.

A new model for particle pinning in 2d polycrystals

Dr. Madeleine Bignon, France

Oral Presentation (20')

Abstract

Grain growth control is a critical factor in optimising the microstructure and properties of polycrystalline materials. This study presents a novel analytical model for predicting the effects of second-phase particle pinning on grain growth in a two-dimensional polycrystalline system. Unlike classical models on Smith Zener pinning, that focus mainly on limiting grain size, our approach also accounts for grain size heterogeneity, improving our understanding of microstructure stabilisation. Our findings reveal that particle pinning not only restricts grain expansion but also prevents the complete disappearance of smaller grains, resulting in bimodal grain size distributions. The model quantifies the interaction between grain boundaries and particles at equilibrium, predicting both the sizes and the fraction of large and small grains in the final pinned microstructure. Furthermore, the model highlights the significant influence of initial grain size on the final stabilized grain size, challenging conventional assumptions that limiting grain size is governed solely by particle size and volume fraction. Validation against full-field level-set simulations demonstrates very good agreement, confirming the model's predictive accuracy. The possible extension of this 2D model to 3D microstructures is explored. The ability of this approach to provide a simple yet robust framework for designing materials with tailored grain size distributions and improved performance is discussed.

Influence of cobalt content on the grain growth and recrystallization kinetics of VDM Alloy 780

Mr. Fernando Pascual Goce, France

Oral Presentation (20')

Abstract

VDM Alloy 780 is a newly developed Ni-Based superalloy aiming service temperatures up to 750°C. This alloy is a derivative of Alloy 718, where cobalt content is raised at the expense of iron and the Al/Ti ratio is modified to increase its microstructural stability at higher temperatures while maintaining its mechanical properties in this temperature range.

Raising cobalt is expected to reduce the stacking fault energy (SFE). Low values of SFE may affect the movement of dislocations during deformation by modifying mechanisms like dislocation dissociation, cross-slip, dislocation climb and deformation twinning. This is expected to directly affect the dynamic and post-dynamic recrystallization kinetics of the alloy. Also, alloying elements in solid solution may also influence the grain boundary mobility, affecting the grain growth behavior of the alloy.

The presented work aims to study the dynamic (DRX) and post-dynamic (PDRX) recrystallization, and grain growth (GG) kinetics in supersolvus domain varying the cobalt content in VDM Alloy 780. Cobalt contents from 0 to 25 %wt. have been investigated, where cobalt is replaced by nickel in the weight balance.

To analyze the microstructure evolution as a function of heating time, annealing tests have been carried out at 1050°C with different holding times followed by water quenching. The mean equivalent grain size of a statistically significant population of grains has been calculated and compared. Initial experimental observations exhibit that GG seems to be impacted by the changes in chemical composition, being slower for higher cobalt contents.

To analyze the recrystallization kinetics, cylindrical samples have been compressed up to various strain levels and using different strain rates at 1050°C. Immediate water quenching after deformation was performed to study DRX. Alternatively, samples were left after deformation at the test temperature for different holding times to study PDRX. According to the first experimental results, DRX kinetics seem to be relatively slower for materials with higher cobalt contents. However, their PDRX behavior is observed to be relatively fast.

Here we will discuss the effects of Co content on the microstructure mechanisms during recrystallization process in VDM Alloy 780.

Paper 783 **6** **Precipitation and microstructure features affecting the mechanical properties of a newly developed Ni-Based Superalloy**
Dr. Masood Hafez Haghighat, Germany
Oral Presentation (20')

Abstract

Ni based superalloys are prominent candidate for aerospace applications to be employed under demanding conditions. Emerging new technologies to improve engine efficiency and reduce environments footprints require alloys to withstand severe conditions and higher temperatures. VDM Alloy 780 offers a diversity of properties namely microstructure uniformity, high oxidation resistance and good mechanical properties up to 700°C as well as weldability and good hot workability making it a suitable candidate for aerospace applications.

Depending on the application, grain size following forging process should be controlled to meet the required mechanical properties and in-service requirements. Grain size and precipitation of gamma' and eta/delta precipitations during and following hot deformation is the direct consequence of the thermally activated microstructure mechanisms like recrystallization, grain growth and precipitation kinetics. These could be tuned through multi-stage heat treatment including solution treatment and aging processes.

In this work, the influence of forging temperature and the subsequent heat treatment process on the microstructure and tensile properties are studied. Two different forging temperatures, namely 950°C and 1050°C, are used to study the microstructure development in subsolvus and supersolvus domains, respectively, giving rise to full recrystallization and grain coarsening in supersolvus domain. The subsolvus hot deformation, however, adds to the complexity of dislocations multiplication and dynamic recrystallization in the presence of gamma' particles. The following heat treatment assists completing the recrystallization process and obtaining uniform distribution of gamma' precipitates, at which delta phases appear not to be present at high amount. This defines the mechanical properties particularly the tensile strength and elongation at rupture. It appears that the following heat treatment could eliminate the effects of the deformation temperature on the tensile properties through the microstructure modifications. Tuning the grain size and the amount of gamma' precipitations with a unique processing route could improve the mechanical properties of the VDM Alloy 780 making it appropriate for high performance applications.

Paper 165 1 **Effect of rhenium on rotating bending fatigue properties of single crystal superalloys**

Prof. Jian Zhang, China

Highlight (Oral Presentation 20')

Abstract

Aero-engine blades undergo fatigue damage due to cyclic stress-strain deformation during service. Rhenium (Re) is an important strengthening element for superalloys. However, there is limited information in the literature regarding the influence of Re on the rotating bending fatigue behavior of single crystal (SX) superalloys, and the associated damage mechanism remains unclear. In this study, a SX superalloy without Re (referred to as the 0Re alloy) and a SX superalloy with 2 wt.% Re (referred to as the 2Re alloy) were used for comparison. The rotating bending fatigue behaviors of both alloys were evaluated at 800 °C and 900 °C. Detailed microstructure characterization was performed using scanning electron microscopy (SEM) and transmission electron microscopy (TEM).

It was found that most of the fatigue crack initiation sites were pores near the surface at 800 °C, and the rotating bending fatigue strength of the 2Re alloy increased from 380 MPa to 410 MPa compared to the 0Re alloy. In the 0Re alloy, γ' precipitates sheared by stacking faults were observed, while dislocations moved through the γ channel by bowing and cross-slip in the 2Re alloy. The addition of Re increased the misfit in the superalloy and hindered dislocation movement in the γ matrix, leading to improved rotating bending fatigue performance of the alloy. As the fatigue testing temperature increased, the fatigue crack initiation sites gradually shifted from pores to the surface, indicating that oxidation damage became dominant during fatigue. It can be seen that oxidation cracks of both alloys were lower at 800 °C. However, oxidation cracks on the surface of the 2Re alloy significantly increased compared to those in the 0Re alloy at 900 °C, due to the detrimental effect of Re on the oxidation resistance of superalloys, which led to a decrease in rotating bending fatigue strength.

- Paper 391** **3** **Effect of withdrawal rate and wall thickness on the microstructure of LEKv – 94 single crystal nickel-based superalloy**
Mr. André Baldissera, Germany
Oral Presentation (20')

Abstract

LEKv – 94 is a variant of the single crystal (SX) nickel-based superalloy LEK-94, which has different concentration of refractory elements Re, W and Ta to the original. Due this modification, its SX castability is previously checked through Bridgman technique. Furthermore, process parameters that affect the solidification rate and temperature gradient, as withdrawal rate and wall thickness are changed and their influence on the microstructure and microsegregation of elements are observed. Thin-walled and cylindrical samples are casted under withdrawal speed (V) of 1 to 10 mm.min⁻¹ and single crystals were obtained between 1 and 5 mm.min⁻¹. Crystallographic orientation [001] was obtained for all SX, and the maximal crystal deviation related to it was 15°. The primary dendrite arm spacing (PDAS) has remained under 450 µm for both SX geometries. Tertiary dendrite arms were observed between 3 and 7 mm.min⁻¹ and the lowest primary dendrite arm spacing (PDAS) was found for 5 mm.min⁻¹. The thin-walled areas (0.4 mm and 2.0 mm) showed a reduction of PDAS values compared to cylindric geometry Ø 15 mm. In all combinations, microsegregation analysis showed that elements Co, Re, and W segregate to the dendrite core with Al, Ni, Cr, Mo, Ta, and Ti partitioning to the interdendritic regions.

- Paper 872** **4** **Revealing the influence of temperature, stress and strain rate on deformation mechanisms of the Ni-based superalloy Udimet 720Li**
Mr. Julian Völkl, Germany
Oral Presentation (20')

Abstract

Udimet 720 is a Ni-based superalloy, which was developed more than 40 years ago. Its derivative alloy Udimet 720Li exhibits slight differences in the carbon, boron and chromium content. Although this alloy has already been investigated, there is no systematic parameter study regarding the creep properties and the related deformation mechanisms at various temperatures and stresses or strain rates, respectively. As it is known e.g. that the deformation mechanisms can vary from APB-coupled dislocations to stacking fault shearing and microtwinning at different temperature-stress or temperature-strain rates combinations, respectively, this study was performed. Those different mechanisms have a major influence on the performance of superalloys, which can be used for alloy development and creating new material models. Before investigating the creep behavior, the fully heat-treated condition of Udimet 720Li was analyzed via scanning and transmission electron microscopy to present the status quo condition. For the purpose of analyzing the creep performance, tensile tests and tensile creep tests at temperatures between 650 °C and 750 °C with resulting deformation rates between 10⁻³ s⁻¹ and 10⁻⁷ s⁻¹ were performed and analyzed via transmission electron microscopy. The occurring dominant deformation mechanisms regarding the different test parameters will be compared and categorized in trends. The importance of the deformation mechanisms for alloy development and material models will be discussed.

Paper 1973 5 Hot tensile behavior of cold worked XH43 superalloy at 650 °C - Role of η phase.

Mr. Sagar Patil, India

Oral Presentation (20')

Abstract

XH43, a wrought Ni-Fe-based superalloy, is widely used in aerospace applications due to its excellent mechanical properties and high-temperature corrosion resistance. The strength of this alloy is primarily derived from the precipitation of γ' (Ni_3Ti) and γ'' (Ni_3Nb) phases through a conventional dual aging process. The evolution of these strengthening phases is significantly influenced by prior thermomechanical processing, particularly cold working. In this study, the effects of cold rolling followed by two-step and three-step aging on the microstructural and textural evolution of XH43 superalloy were investigated using scanning electron microscopy (SEM), transmission electron microscopy (TEM) and electron backscattered diffraction (EBSD) techniques. Microstructural characterization reveals that three stages of aging promote the precipitation of needle-like $[\text{Ni}_3(\text{Ti}, \text{Nb})]$ precipitates. Cold rolling increased the volume fraction of γ' and γ'' precipitates, enhancing the strengthening effect. However, at higher degrees of cold rolling, the formation of hexagonal η (Ni_3Ti) precipitates was observed. Hot tensile testing at 650 °C revealed that the η phase played a crucial role in improving hot ductility across all cold rolling conditions. These findings provide insights into optimizing the thermomechanical processing of XH43 superalloy to tailor its microstructure and mechanical performance for high-temperature applications.

Paper 973 6 Live presentation of CreeSo - Creep Software

Dr. Gerold Zuderstorfer, Austria

Oral Presentation (20')

Abstract

"CreeSo" is short for "Creep Software". This application is currently developed at the Institute for Engineering Materials – Metals and Alloys at the JKU Linz, Austria. The institute works on different models for the simulation of creep and other material properties utilizing descriptions of the microstructure for the materials in question. The resulting systems of differential equations cannot be solved analytically and numerical methods have to be applied. CreeSo provides a GUI (Graphical User Interface) for the creation of the model and the simulations. It enhances the speed of the simulation by a factor of approximately 10 compared to MatLab. CreeSo also contains a variety of tools for e.g. creation of time-to-rupture (TTR) diagrams, comparison to creep curves, parameter finding, and data export. Although it still is a prototype, CreeSo is built as a desktop and online version so that researchers outside our institute can also access our models and carry out simulations. A subset of the functionality can even be tried out publicly under <https://imk.jku.at/creeSo>.

Paper 1852 1 Programmable meta-material composites for regulating force, energy dissipation & recovery

Prof. Mahdi Bodaghi, United Kingdom

Keynote (Oral Presentation 40')

Abstract

The development of programmable meta-material composites offers new frontiers in smart manufacturing, where materials can be engineered to regulate force and stiffness, dissipate energy, and recover mechanical properties after deformation. This talk presents our latest advancements in meta-material composites, leveraging principles of non-linear instability, visco-pseudo-elasticity, shape recovery, sustainability, and additive manufacturing.

By developing programmable lattice architectures and reinforcing them with bio-based additives, these meta-composites exhibit programmable stiffness profiles (positive, negative, or zero), shape recovery, and hysteretic energy dissipation. They can regulate force and stiffness, while efficiently absorbing and releasing mechanical energy on demand. This makes them highly applicable components for automotive/rail/aerial vehicle, protective sports gear, and medical devices, where impact mitigation, energy dissipation and recovery play a crucial role.

This presentation will discuss novel computational and experimental approaches for developing these structures, including finite element modelling, composite development, and thermo-mechanical testing. The research explores how the interplay between material properties and geometric design can significantly enhance response tuneability, impact resilience, lightweighting, comfort, and durability, promoting sustainability by reducing material waste before and after fabrication. By integrating nonlinear mechanics with sustainable material innovations, this study lays the foundation for next-generation high-performance, responsive, and energy-dissipating structures.

4D Printing of a Transformable Exoskeleton Protector using Shape Memory Polymer

Prof. Keun Park, South Korea

Highlight (Oral Presentation 20')

Abstract

In this study, a 4D printing technology was developed to fabricate a transformable exoskeleton protector using a shape memory polymer. The proposed approach aimed to meet specific requirements: high elongation, thermo-responsive deformation capability, and shape-recovery characteristics. To achieve thermo-responsive deformation, a polyurethane (TPU)-based shape memory polymer with a glass transition temperature of 55°C was employed. The exoskeleton protector was designed using a re-entrant honeycomb structure with dimensions of 70 × 40 × 2 mm, capable of elongating up to 70%. The exoskeleton protector was additively manufactured using an extrusion-type 3D printer. Tensile elongation and shape-recovery behaviours were evaluated under varying temperature conditions, with the protector heated in a 60°C water bath prior to elongation. Comparative tensile tests with other porous structures, including square and circular hole arrays, revealed that the re-entrant structure achieved the highest elongation (up to 70%) compared to other structures (approximately 20%), confirming its suitability as a transformable exoskeleton protector. This high elongation provides sufficient length to wrap around half of an adult's wrist, making it an effective protective structure. Furthermore, the deformed protector exhibited excellent shape recovery, with a recovery ratio of 98%. Once recovered, the protector returned to its original compact dimensions of 70 × 40 × 2 mm. This slim profile, combined with its shape transformation capability, makes it highly portable and convenient for use as a practical exoskeleton protector.

Next generation of stimuli responsive materials for 4D macro- and microprinting

Mr. Finn Kröger, Germany

Highlight (Oral Presentation 20')

Abstract

Emerging in the 1980s 3D printing has undergone a prosperous development, enriching multiple fields in academia and industry, increasing its societal impact as high-tech 3D fabrication method continuously. Beside extension of the available technological toolset, one key breakthrough was the conceptualization of 4D printing in 2013. 4D printing describes the implementation of time as fourth dimension to standard 3D printing allowing the generation of smart 4D structures. Such 4D objects can change their shape or material properties in controlled fashion upon exposure to a suitable stimulus such as light, temperature or pH, etc, contrasting traditional 3D printing that produces static structures. Due to its inherently dynamic and functional characteristics 4D printing has established as ideal fabrication approach for smart and dynamic applications in advanced fields such as soft robotics, smart optics and life science among others.[1] Basis for the success of 4D printing in the last decade was the large progress made in smart ink design enriching the 4D material library. However, the current set of materials for 4D printing is still limited in several aspects: The versatility and extent of response respectively actuation, the adjustability of material properties postprinting, as well as aspects such as biocompatibility highly relevant for application in life sciences.

Our main focus is to tackle these challenges by designing and developing new smart materials for light-based 4D printing at the macro- and microscale. For this purpose, we employ our knowledge as organic and polymer chemists to introduce new functionalities and smart characteristics by chemical engineering of materials at the molecular level. Exemplary we investigated new polymeric architectures equipped with functional units such as bottlebrush polymers, or linear prepolymers according to their printability and extended their range and quality of actuation. By implementation of dynamic covalent chemistry into our printed structure at the macro- and microscale we were able to show highly dynamic features by reversible mechanical property adjustment via simple postprinting protocols.[2],[3] Furthermore, we succeeded in the design of bioinks based on proteins such as collagen achieving new printable 4D biomaterials for the next generation of smart devices in life sciences.[4]

Paper 1349 4 Bioinspired approach to autonomous deployment of 4D-printed structures for space applications

Prof. Antoine Le Duigou, France

Oral Presentation (20')

Abstract

The pursuit of advanced space exploration requires innovative solutions that reconcile minimal stowage volume with rapid and reliable deployment. Traditional deployable structures often rely on intricate mechanical systems involving multiple moving parts, which are not only prone to mechanical failure but also often present high energy expenditure, making them ill-suited for missions where energy conservation is paramount. In this work, we propose potential solutions that harness adaptive materials produced via 4D printing—a process integrating time-dependent functionality into 3D-printed structures—to achieve autonomous and rapid deployment upon external stimuli, such as temperature variations.

Our design leverages shape-memory polymers (SMPs), known to be able to store and release elastic energy in response to thermal stimuli [van Manen, 2017]. Advances in additive manufacturing have enabled precise control over material composition and internal architecture, allowing the anisotropic properties of the resulting structure to be tailored in order to achieve the desired deployment kinetics [Jourdan, 2023]. Upon exposure to a temperature change, the structure transitions from a compact, stowed configuration to a fully deployed state. This mechanism eliminates the need for additional actuators or energy-consuming systems, thereby reducing the complexity and potential weak points inherent in conventional designs. This work aims to present concepts leading to structures that can reliably and rapidly deploy, with potential for applications where both speed and energy efficiency are critical.

The inspiration for our study is drawn from natural organisms that have achieved efficient passive deployment strategies with millions of years of evolution. For instance, the rapid opening of seed pods [Hofuis, 2016] and the unfolding of insect wings [Phan, 2024] serve as models for energy-efficient, self-actuating systems. These biological mechanisms typically exploit stored elastic energy and material anisotropy to achieve swift morphological changes without active control, and provide solutions that can be abstracted and implemented in passive deployable architectures for space applications that benefit from nature's optimization.

This work builds upon progress in both adaptive materials [Le Duigou, 2025] and bioinspired design [Poppinga, 2010], demonstrating that 4D printing can produce structures that are not only compact during launch but also capable of rapid, autonomous deployment. By combining insights from materials science and biological systems, this study is intended as a step towards the development of deployable structures that meet the stringent requirements of modern space exploration.

Paper 1260 5 **Effect of printed material stiffness on the curvature of 4D textiles: experimental and computational analysis**
Dr. Chiara Pasini, Italy
Oral Presentation (20')

Abstract

4D textiles are a unique class of 4D printed materials, i.e. 3D printed materials capable of shapeshifting after printing. They are created by printing 2D structures onto elastically pre-tensioned fabrics, enabling them to transform from flat systems into 3D objects. This transition occurs either through a rapid self-shaping process when the tension on the fabric is released, or through a delayed, remote actuation triggered by a thermal stimulus. The resulting objects typically assume curved shapes, whose curvature is dictated by the mechanical equilibrium between the textile's recovery stress and the stiffness of the printed structure.

This study investigates how the final curvature is influenced by the stiffness of printed elements and the pre-stretch of the textile. An FDM printer was used to prepare the specimens by printing on Lycra fabric both simple and complex geometries (a longitudinal bar on a monoaxially stretched textile, and single or multiple star-shaped patterns on biaxially stretched textiles). A systematic variation of the realization parameters allowed to produce various states of curvature, from a flat state where curvature is hindered, through more regular curvatures, to multi-stable buckling conditions. While Lycra was selected for its compliance (Young's modulus, $E \sim 1$ MPa) and high stretchability, the flexural stiffness of printed elements was modulated by varying their thickness and using materials with different Young's moduli: i) PLA ($E \sim 10^3$ MPa); ii) TPE ($E \sim 10$ MPa); iii) PLA later heated above its T_g to reduce the modulus to a value similar to that of the textile, while also investigating shapeshifting via thermal actuation. The curvature and local strain evolution during shape transformation was analyzed using a stereoscopic digital image correlation (DIC) system, to explore the relationship between strain fields and the 4D textiles' structural and kinematic behavior. This helped provide key data for developing and validating analytical models to predict the final shape of both simple and complex structures.

A finite element model was created, calibrating it on the specific properties of the various constituents, and attempting to describe the whole 4D textile history, from textile stretching, through the printing phase, to the shape transformation upon stress release. The model was shown to be capable of accurately reproducing the behavior of 4D textiles, especially regarding the shape and the displacement of the curved elements and the occurrence of multi-stability, although some discrepancies also emerged, which could be addressed by implementing the model with better defined parameters.

Transforming Jewelry Design: Shape Memory Polymers and the Advances of three- and four-dimensional Printing

Dr. Dilip Chalissery, Germany

Highlight (Oral Presentation 20')

Abstract

Shape memory polymers (SMPs) belong to the class of smart materials¹. Thermoresponsive SMPs can retain a temporary shape after thermomechanical treatment, also known as programming, until they are heated above their switching temperature, whereupon they largely recover the original shape. Among the various SMPs, thermoplastic polyurethanes (TPUs) have proven to be promising material candidates for the development of new applications due to their modifiable mechanical and thermal properties. Researchers have used additive manufacturing (AM) to process TPUs because it fulfills the criteria of design freedom and cost efficiency for prototyping in equal measure, so that the hurdles for small series production are low. This makes the technology attractive in new application contexts, e.g. in the jewelry industry. In the field of jewelry design with smart materials, first steps were taken by the development of shape memory alloy-based rings that open to reveal embedded gemstones² and SMP flower rings that can move dynamically and are produced by digital light processing³. Basically, AM of objects with good structural resolution is essential to manufacture jewelry from SMP. In this context, fused filament fabrication (FFF) is a promising platform to print filigree structures, e.g. from polyester urethane⁴. For this contribution, a polyester urethane characterized by shape memory properties was synthesized and compounded with dye particles to improve its optical appearance. The obtained filament was used to produce demonstrators for jewelry in the form of earrings and bracelets using the FFF process. The pieces of jewelry were modified by programming so that they were temporarily stabilized in a new shape and could later be switched back to their original shape. In a further approach, a polyether urethane was developed and employed to carry out four-dimensional printing via FFF, a method which allows manufacturing thermoresponsive objects without the need of programming⁵. This time, the investigation of shrinkage effects was the primary focus against the background of the transformation of the jewelry into another shape. In any case, the additively manufactured jewelry was evaluated from a functionality point of view and against the background of sustainability aspects.

A new generation of bio-renewable vitrimer based on vanillin

Ph.D. Camilla Noè, Italy

Highlight (Oral Presentation 20')

Abstract

The development of sustainable polymers has become a key focus in materials science, with a strong emphasis on creating recyclable, self-healing, and high-performance alternatives to conventional plastics. Vanillin, a bio-derived aromatic compound, has emerged as a promising building block for polymeric materials due to its renewable nature, structural rigidity, and functional versatility. Among the various dynamic covalent networks, the category of vitrimer stands out. In fact, vitrimers possess the unique ability to undergo network rearrangement through associative bond exchange reactions while maintaining overall crosslink density. This characteristic allows vitrimers to combine the durability of thermosets with the re-processability of thermoplastics, distinguishing them from traditional polymer classes. With its aldehyde functionality, vanillin serves as an excellent precursor for imine formation, reacting with amine compounds to create a stable yet adaptable polymer network. This imine reversible bond allows the material to exhibit self-healing capabilities and recyclability without compromising mechanical strength. Therefore, vanillin-based vitrimers utilizing imine chemistry present a compelling alternative for a wide range of applications.

This work carefully investigated a vanillin-based imine vitrimer with various techniques. After successfully confirming the vanillin-based building block formation with Fourier Transform Infrared Spectroscopy (FTIR) and Nuclear Magnetic Resonance (NMR); the kinetic of the reaction was investigated by real-time rheology test. Subsequently, Differential Scanning Calorimetry (DSC), Dynamic mechanical thermal analysis (DMTA) and thermogravimetric analysis (TGA) were performed to determine the glass transition temperature (T_g) and thermal stability of the new crosslinked network, providing insights into the material's thermal behaviour. Rheological analyses were conducted to evaluate the viscoelastic properties and the dynamic exchangeability of imine bonds, confirming the vitrimer nature of the material. Furthermore, the mechanical strength, flexibility, and toughness of the polymer were investigated by tensile test.

Finally, self-healing and chemical recyclability tests, such as scratch recovery and different reprocessing cycles, demonstrate the material's durability and sustainable potential. In conclusion, vanillin-based vitrimers utilizing imine chemistry represent an innovative and eco-friendly approach to developing a new class of sustainable polymer materials. Further optimization of these materials can unlock new possibilities for next-generation sustainable applications in various industries.

Shape memory behavior of wetting-programmable lamellar surface

Mrs. Gissela Constante, Germany

Oral Presentation (20')

Abstract

Developing wetting-programable shape-changing topographical surfaces is essential for creating new materials and technologies that enable droplet manipulation and the creation of actuators. Smart materials, such as shape memory polymers, are used to fabricate surfaces capable of switching their mechanical properties to modify their wetting behavior. In this research, high-aspect-ratio lamellar surfaces composed of shape memory polymers exhibited significant deformation under water droplet dynamics. The lamellar surface topography was fabricated using melt-electrowriting (MEW) of polyurethane microfibers. Two different types of stimuli – temperature and light exposure – were applied to modify the mechanical properties, thereby influencing the deformation and recovery of the original surface. Wetting studies demonstrated that the deformation of the high-aspect-ratio lamellar surface can be tuned not only manually but also by the presence of a liquid droplet. This behavior is controlled by temperature variations induced through direct heating/cooling or light exposure when the lamellae were stained with black ink. The forces exerted on the system were analyzed for the deformation of both fixed and non-fixed (cantilever-like) lamellae. The interaction between the liquid and the thermo-responsive topography introduces a novel wetting behavior. This feature opens new possibilities for applying such topographies in the design of smart elements for microfluidic devices, such as smart valves.

Melt-electrowritten smart light-responsive lamellar structure with carbon nanoparticles incorporated into polymer matrix

Mr. Ilia Sadilov, Germany

Oral Presentation (20')

Abstract

Nowadays, the interest in smart materials is increasing. These materials can change their properties under different external stimuli such as temperature, light and others. These materials can be used in wetting applications such as microfluidic devices, oil/water separation and others. Wettability can be changed in two common ways: changing their topography or chemical modification of the surface. The topography of smart materials can be controlled by external stimuli. For example, melt-electrowritten lamellar structure of polyether-urethane with poly(1,10-decylene adipate) (PEU-PDA) wrinkles at 70°C [1]. Although the heating is not localized and cannot heat a local part of the sample. On the other hand, light has the advantage due to localization and can be converted into heat energy, which is better absorbed by dark surfaces. A solution to this problem was presented for a lamellar structure with coated blank ink that was locally heated by laser exposure [2].

Here, we present a novel approach to fabricate lamellar structure with a dark surface by using PEU-PDA with incorporated 0.2 wt.% graphene nanoplates (GN) or multi-walled carbon nanotubes (MWCNT). The incorporated particles increase the melting point of the soft segments up to 10°C. When exposed to an infrared (IR, 808 nm) laser, the coated lamellae wrinkle due to thermal expansion, confirming the local heating of the irradiated area. The temperatures of covered lamellae reach 50°C and 70°C for GN and MWCNT composites respectively. The main drawback of wrinkling is the lack of a certain direction, in this case capillary forces can determine the bending direction of the lamellae. Water droplets placed between two lamellae cannot bend the lamellae at room temperature due to the high elastic modulus of the lamellae. When exposed to the laser, the coated area of the lamellae bends in the presence of droplets due to the decreased elastic modulus of the lamellae. In addition, the direction of the bending can be changed by adding an additional droplet in a neighboring position. This approach allowed us to obtain a lamellar structure with programmed topography due to capillary forces and local heating. These adjustments may help us to create a new type of microfluidic devices or soft robotics.

Paper 66 3 **Joining, Coating and Characterization of SiC/SiC and SiC-based cladding materials for safe Nuclear Energy Applications**

Ph.D. Aurora Pizzinat, Italy

Oral Presentation (20')

Abstract

Silicon carbide (SiC) fiber-reinforced silicon carbide matrix composites (SiC/SiC composites) represent a cutting-edge solution for improving safety in nuclear fuel cladding technology as well as for use in advanced fusion and fission reactors. Despite their promise, challenges remain in optimizing the materials and processes for joining and coating these composites. Recent research efforts have renewed the interest in SiC preceramic polymers to address these issues. This approach involves the use of polycarbosilane polymers enhanced with SiC nanoparticles and fibers. The process includes a series of thermal treatments: curing the material in vacuum at 200°C to establish initial structural integrity, followed by pyrolysis in an inert atmosphere at 1450°C to convert the polymer into a robust ceramic form. These steps are critical for achieving strong and durable joints.

Paper 1259 4 **Mechanical properties of neutron irradiated 316L stainless steel additively manufactured by laser powder bed fusion: effect of post-manufacturing heat treatments**

Dr. Milan Konstantinovic, Belgium

Oral Presentation (20')

Abstract

Rapid advancements in additive manufacturing (AM) technologies are driven by the opportunity for industries to revolutionize the global part manufacturing and supply chain landscape. They are now opening up opportunities for nuclear industry to build complex components while reducing cost, time, energy consumption and carbon footprint [1]. In that context, austenitic stainless steels are one of the main targets to be used for reactor core and primary coolant system components, since they offer a good combination of strength, ductility, and toughness, together with low sensitivity to oxidation-corrosion and superior irradiation resistance.

In this work we performed an investigation of 316L material produced by AM, Laser Powder Bed Fusion (L-PBF) process, with four heat treatment conditions: stress relief, low and high temperature solution annealing and hot isostatic pressing (HIP) [2]. Neutron irradiation experiments were performed in the material testing reactor BR2 of SCK CEN at 300 °C and with a dose up to about 4 dpa. Pre- and post-irradiation experiments were performed, including Charpy impact and tensile tests as well as the microstructural investigations based on scanning electron microscopy and transmission electron microscopy.

Despite variation between initial conditions in terms of microstructure and yield stress, neutron irradiation causes hardening in all investigated alloys, with a converging yield stress for all alloys at about 4 dpa. In all Charpy tests of 316L L-PBF samples, the increase of neutron dose caused a gradual decrease of absorbed energy: at the highest dose of about 4 dpa, the relative decrease of absorbed energy is the largest for the solution annealed at 1150 °C (SA1150) and HIP batches. An increase of irradiation induced hardening is fully correlated to the decrease of absorbed impact energy. This study does not indicate a positive impact of the HIP treatment regarding in-pile mechanical properties, since impact of the porosity difference is observed. Microstructural investigations focusing on the fracture surface properties and atomic scale defect characterization were performed allowing mutual comparison of different additive manufacturing batches and the reference material to their mechanical properties.

Paper 705 **5** **Impact of vanadium addition on the mechanical properties and irradiation resistance of FeCrAl-Y2O3-Ti ODS alloys for components of Generation IV nuclear reactors**

Dr. Tomasz Stasiak, Poland

Oral Presentation (20')

Abstract

Generation IV nuclear reactors will operate at higher temperatures and under higher irradiation doses than existing Generation III and III+ reactors. Therefore, there is an urgent need to develop irradiation-resistant materials with good high-temperature properties. FeCrAl oxide dispersion strengthened (ODS) alloys possess good strength at high temperatures. The good irradiation resistance of ODS alloys is related to the nanometric oxide precipitates homogeneously distributed in the matrix that act as sinks for irradiation-induced defects, mitigating irradiation damage. Moreover, FeCrAl ODS alloys present good corrosion and oxidation resistance due to the formation of a thin protective alumina layer on the surface. Alloying elements can be added to FeCrAl ODS alloys to further improve their properties.

The aim of this study is to evaluate the impact of vanadium on the mechanical properties and irradiation resistance of FeCrAl-Y2O3-Ti-V alloys prepared by mechanical alloying and spark plasma sintering. Moreover, susceptibility to 475°C embrittlement was investigated. The properties mentioned above are crucial for the application of ODS alloys in Generation IV nuclear reactors. The microstructural investigations were performed by SEM-EDS, EBSD, and TEM. Mechanical properties were evaluated by hardness measurements, nanoindentation, and tensile test at temperatures up to 800°C. The irradiation resistance was analyzed by Fe²⁺ ion implantation up to 5 dpa at 300°C. The conducted tensile tests show high mechanical strength, i.e., the yield strength is 893±23 MPa at room temperature and 490±8 MPa at 600°C. The elongation generally increases from approximately 12% at room temperature to more than 20% at higher temperatures. The addition of vanadium increases the strength at all tested temperatures, mostly due to promoting the formation of nanometric oxides. The FeCrAl ODS alloy with vanadium seems to be resistant to 475°C embrittlement since the alloy reveals similar ductility and strength in tensile tests before and after annealing at 475°C for 1000 h. The studied FeCrAl ODS alloys also reveal good irradiation resistance, showing only an increase of hardness by 10%. The results show promising properties of FeCrAl ODS alloys and the positive impact of vanadium on mechanical properties.

Paper 1573 1 Bio-Waste Derived Activated Carbon for Sustainable Energy Storage Applications

Mr. Tesfay Berhe Gebreegziabher, United Kingdom

Pre-recorded video presentation. Oral Presentation (20')

Abstract

Due to escalating climate changes and energy crises, the need for alternative renewable energy sources is crucial. H₂ has emerged as a green energy carrier however, its shipment and storage are the major obstacles to its large-scale adoption. The existing hydrogen storage systems, such as geological formations, pressure tanks, and liquid hydrogen, suffer from limited capacity, low energy efficiency, high costs, and safety concerns. To address these challenges, reliable, safe, and efficient alternative materials with high gravimetric capacity are vital. Hydrogen storage in porous carbons is considered a promising technology due to the rapid rate of hydrogen adsorption-desorption, natural abundance of raw materials, and good regeneration capacity, particularly in automotive applications. Despite encouraging findings, no material currently meets the U.S. Department of Energy (DOE) target of 6.5 wt% hydrogen storage at ambient conditions. Hence, this study investigates bio-waste-derived activated carbon as a sustainable hydrogen storage material with integrated thermal management properties. Spent coffee grounds were carbonized at 350 °C, 400 °C, and 450 °C, followed by KOH activation at 800 °C under the flow of argon gas. The synthesized activated carbons were characterized using SEM, TGA, and BET surface area analysis, and their hydrogen uptake capacity was evaluated using a gravimetric sorption analyzer.

The results revealed that the activated carbons exhibited high thermal stability (retaining >80% mass at 600 °C), well-developed porosity (SEM images), and high BET surface area (up to 2728 m²/g for Arabica and 1983 m²/g for Robusta), contributing to enhanced hydrogen adsorption capacity. The hydrogen uptake at room temperature and 35 bar pressure was 0.997 mmol/g for Robusta spent coffee activated carbon. Given their high thermal resistance and adsorption efficiency, these materials hold potential for waste heat recovery, adsorption-based cooling, and hydrogen-powered thermal energy systems. This study highlights the dual role of bio-waste-derived activated carbon in hydrogen storage and thermal energy management, contributing to the development of sustainable and net-zero energy solutions.

Keywords: Hydrogen adsorption, activated carbon, spent coffee grounds, renewable energy, thermal energy management.

Paper 1090 2 Innovative and sustainable materials for high temperature Thermal Energy Storage (TES) systems
Dr. Ioanna Giannopoulou, Cyprus
Oral Presentation (20')

Abstract

Renewable energy, such as solar, wind, ocean and geothermal energy, plays a crucial role in mitigating climate change and the global warming effect. It is clean and available almost everywhere to meet the growing energy demand in a sustainable way, eliminating the greenhouse gas emissions caused by the exploitation of fossil fuel reserves. Among the different renewable energy sources, the sun is the most abundant. However, the intermittency and weather-dependency of solar energy make challenging its industrial application.

Thermal Energy Storage (TES) technologies tackle this challenge, acting as a link between solar power generation and optimal load distribution. TES systems can be classified as sensible, latent, and thermochemical heat storage systems, with the sensible TES systems being the only ones that have currently commercial industrial applications. However, the commercial sensible heat storage systems struggle to supply high heat temperatures, due to limitations of the used materials' thermal and mechanical stability. For example, the Ordinary Portland Cement-based materials and especially concrete, which are widely used in sensible solid-state TES systems, undergo thermal degradation at temperatures higher than 450 °C. However, the decarbonization of certain manufacturing processes in energy intensive industries, such as glass, metal, and cement, make essential the development of novel, for low-cost materials that can withstand higher temperatures, offering higher storage capacity to sensible TES systems. This work aims to investigate the use of geopolymers based on Construction and Demolition Waste (CDW) as an alternative to the Ordinary Portland Cement-based materials for TES systems that will operate at temperatures higher than 700 °C. Geopolymers are sustainable materials with very good mechanical and thermal properties and an inherent fire resistance. The development of CDW-based geopolymers was theoretically investigated in both alkaline systems, of sodium and potassium and their applicability in TES systems was experimentally evaluated. Specifically, their thermal stability at temperatures up to 800 °C was studied and basic thermal and mechanical properties, such as specific heat, thermal diffusivity and compressive strength at these temperatures, were evaluated. The experimental results of this research revealed that the developed CDW-based geopolymers are very promising materials to be applied in sensible TES systems working at high temperatures.

Enhancing thermochemical heat storage performance with additively manufactured aluminum alloys: A study on porous matrix design and heat transfer

Mrs. Harshita Gupta, The Netherlands

Oral Presentation (20')

Abstract

This study focuses on incorporating aluminum alloys to enhance heat transfer due to their high thermal conductivity in addition to corrosion resistance, thereby improving thermochemical heat storage (TES) performance. Achieving high-performance TES systems requires the development of materials and processes that withstand thermal cycling and enable efficient heat transfer. TES operates by drying out hydrated salts to store energy and rehydrating them to release it. However, the inherent low thermal conductivity of these salts limits heat transfer and reduces the overall efficiency of TES systems. In this study, we address the following knowledge gap- by exploring how introducing a porous designed matrix can overcome this limitation by improving heat transfer. Specifically, we investigate the role of both the porous structure and its surface chemistry in enhancing salt-based TES performance. To this goal: (1) we will use laser powder bed fusion (LPBF) to fabricate aluminum porous matrices, leveraging its design flexibility to create tailored structures. However, 3D printing aluminum alloys via LPBF presents challenges, such as hot-cracking susceptibility due to their wide solidification range. To address this, LPBF process parameters—such as laser power, scanning speed, and hatch spacing—will be optimized. Additionally, careful metal powder handling was employed to minimize oxidation, enabling the production of defect-free materials. (2) The porous matrix will be designed to maximize surface area, allowing for the use of the maximum amount of salt, and ensuring efficient heat exchange. To evaluate performance, the thermo-mechanical properties of both the porous matrix structures and the salt-infused matrix will be investigated. Thermal conductivity will be measured using the thermal plane source method, while mechanical performance will be assessed through compression testing of the porous matrix. Overall, this study demonstrates the feasibility of additively manufactured aluminum 6xxx-series porous matrix for advanced thermal management. It emphasizes the design flexibility offered by LPBF and highlights the importance of parameter optimization in overcoming processing challenges. This work opens a pathway toward high-performance TES and heat exchanger solutions.

Paper 326 **4** **Additive Manufacturing of An Sn-Based Alloy on Silicon Wafer by Laser Powder Bed Fusion for Advanced Cooling of Electronic Circuits**
Dr. Amin Hodaei, The Netherlands
Oral Presentation (20')

Abstract

The constant growth of interest in miniaturization of power sources for electronic circuitries necessitates utilizing high-performance cooling to fulfil their thermal management requirements. Unlike conventional cooling methods that rely on heat sinks mounted on conventional thermal interface materials (TIM), which create thermal resistance and reduce heat extraction efficiency at their interfaces, we are, hereby, proposing an additive manufacturing approach using Laser Powder Bed Fusion (LPBF) to realize wafer-scale printing of an Sn-based interlayer material on which a heat sink can be fabricated. The alloy's low melting point (~ 250 °C) mitigates thermal stresses during solidification and cooling that occur in the LPBF process. The thermal conductivity of this Sn-based alloy, estimated at 39.4 ± 6.7 W/mK, surpasses those of common thermal interface materials (1-10 W/mK), making it a competitive option for heat management applications. Microstructural analysis of the printed layers on Si wafer confirms the alloy's uniformity and compatibility with silicon, proposing its effectiveness as a thermal interface material for cooling applications. By optimizing the volumetric energy density exerted during the LPBF print process, we could realize structures that are fully dense and free of cracks. The successful formation of the Sn-based alloy on Si wafer by LPBF is a stepstone for the realization of wafer-scale full additive manufacturing of heat sinks onto it.

Paper 1180 5 Development of GrCop42/Copper-Inconel 718 multi material structure through laser powder bed fusion for heat transfer applications
Ph.D. Ehsan Marzban Shirkharkolaei, The Netherlands
Highlight (Oral Presentation 20')

Abstract

The development of multi material structures using laser powder bed fusion (LPBF) technology by combining desired thermo-mechanical properties, offers significant potential for enhancing heat transfer applications, particularly in aerospace. This study focuses on the fabrication of pure Copper-Inconel 718 (Cu-IN718) and Copper alloy-In718 (GrCop42-IN718) multi-materials, by leveraging the high-temperature strength and thermal stability of IN718 with the great thermal conductivity of Cu and GrCop42. The integration of high-strength IN718 with high-thermal conductive Cu/GrCop42, aims to improve heat exchanging capabilities, specifically for advanced engineering applications. However, additive manufacturing of high-strength multi material interfaces remains challenging due to significant differences in their thermo-physical properties and weak bonding and defects in interface.

In this study, the effects of process parameters and the consequence of materials in layers or each layer on the interface properties of the LPBF'd Cu-IN718 and GrCop42-IN718 were analyzed, and the process parameters were optimized to reach the good metallurgical bonding interface between Cu/GrCop42 and IN718. Through this research the interface microstructure characteristics, element distribution, phases in interface, thermal conductivity, and microhardness of these multi materials were investigated. The melting behavior, mixing of IN718 and Cu/GrCop42 elements and in-situ phases in interface, and formation mechanism of multi materials in different consequence of materials were discussed. The formation of interface characteristics is primarily driven by Marangoni convection, which enhances the mixing of IN718 and Cu/GrCop42 elements, facilitates the development of a stable transition layer at the interface, and enables a seamless transition between the two metal interfaces. Compared to IN718, the Cu-IN718 and GrCop42-IN718 multi material structures exhibited significantly enhanced thermal conductivity. These advancements open up and paves the way for the additive manufacturing of multi materials in next-generation aerospace structures.

Paper 928 6 **Novel material development for Ammonia based Thermochemical Heat valorization from Data Centers**
Mr. Alvaro Martínez, The Netherlands
Oral Presentation (20')

Abstract

With the energy consumption of data centers continuously rising and no signs of slowing down, the need to recover and utilize their low-grade waste heat becomes imperative for sustainable growth. However, the efficient valorization of this thermal energy remains a challenge due to its low temperature. In this work, framed inside the IPCEI-CIS-MISD project, we focus on the development of novel materials for ammonia-based thermochemical heat storage systems, designed to capture and upgrade waste heat from data centers for more efficient energy utilization. In order to achieve this, we through the development of hybrid heat storage and upgrade system employing multi-material 3D printing, effective thermochemical materials (TCM) and novel reactor design so that we leverage the absorption-desorption of ammonia on novel TCMs to valorize low temperature heat. The Temperature Swing Absorption (TSA) unit enables the upgrading the heat thanks to the large exothermicity of the ammonia absorption. With an efficient and sustainable use of energy in mind, a prototype of a thermochemical heat transformer will be built considering the three scopes mentioned. First, adequate TCM selection and synthesis is carried out to understand the relationship between physico-chemical properties and absorption dynamics. Then, the utilization of hierarchical supports will be explored to enhance heat and mass transfer in the system. To achieve this, temperature programmed desorption of ammonia, nitrogen-physisorption, X-ray Diffraction and X-ray Fluorescence techniques will be used to stablish chemistry-architecture-performance relationships. Overall, this study aims to demonstrate the feasibility of composites as TCMs for low-grade waste heat recovery from data-centers.

Paper 2196 7 **Non-vanadium aqueous redox flow batteries**
Prof. Yongchai Kwon, South Korea
Oral Presentation (20')

Abstract

Aqueous Redox flow batteries (ARFBs) are a promising technology for large scale energy storage system. For improving the performance and stability of the ARFBs, the determination of proper active materials is most crucial. The active materials are dissolved into supporting electrolytes, and such developed two electrolytes like anolyte and catholyte are stored in tank, determining cell voltage and maximum solubility. In turn, capacity and power density of ARFBs are decided. Vanadium has been played as the role so far. However, due to its low reserves and rapid cost fluctuation, many attempts have been made to replace it to other materials. As the alternative, iron (Fe) based complexes coordinated with different ligands are considered due to the benefits of wide redox potential window, high solubility to supporting electrolyte, low crossover rate, and relatively cheap price. In this presentation, their electrochemical properties and kinetic parameters are evaluated quantitatively to determine their optimal condition. In turn, cycle tests of ARFBs using them are implemented to measure their performance and stability. As a result, it is proved that ARFB using Fe complexes as redox active materials is viable enough to compete with vanadium RFB and lithium battery in some prospects.

Paper 1616 8 Hybrid foamed concrete as a porous material for thermal energy management applications.

Dr. Dominika Zabiegaj, United Kingdom

Oral Presentation (20')

Abstract

Environmental pollution and energy crisis are one of the biggest problems the world is facing due to industrialisation, rapid population and living standards growth. Just in the UK, heat represents almost half of the use of energy, as around 80% of domestic heat is supplied by natural gas. Under current trends towards environmental pollution, waste and the Ordinary Portland Cement's production (in >5 billion tons annually, as concrete, due to its inherent strength and durability properties, is the second most used substance on Earth after water, thus responsible for more than 7% of the CO₂ global emissions), are one of the most significant in impacting (negatively) the global climate and human wellbeing.

To reduce the building thermal energy consumption (reducing the space heating and cooling energy) and increase energy saving for civil buildings while in service. Thus, the work presented here is focused on the design and fabrication of the novel hybrid freestanding concrete (Fig.1.) based on the foam scaffolding, to be applied as a light thermal insulation material [], with unique tailored structural properties. The study included the systematic research on the single interface (bubble) by Profile Analysis Tensiometer (PAT), the stability measurements of the 3D foam dopped with Portland Cement, followed by an appropriately design gel casting protocol [], in order to achieve a low-costs, high-porosity, fire- resistance material.

Paper 1024 1 Thermal Characterization of combined Al-Based and Sn-Based Alloys as Composite Phase Change Materials for Thermal Energy Management

Ph.D. Silvia Marola, Italy

Oral Presentation (20')

Abstract

The combination of aluminum-based (Al-based) and tin-based (Sn-based) alloys can be considered to produce composite phase change materials (c-PCMs) for thermal energy management and thermal energy storage characterized by peculiar combinations of high sensible and latent heat capacity at intermediate temperature together with high thermal conductivity.

This study utilizes simple models and Thermo-Calc simulations to predict and analyze the thermal properties of these alloys, including thermal conductivity, phase transition temperatures, specific heat capacity, and latent heat of fusion of the c-PCM phase. These properties are further investigated through experimental techniques such as laser flash analysis (LFA), differential scanning calorimetry (DSC), providing a comprehensive understanding of their thermal behavior.

The thermal cycling nature of thermal management material further requests to check the characterization length change of the material under repeated thermal cycles, which in the study was performed by dilatometric tests. The thermally cycled alloys offered the possibility to obtain preliminary insights on the microstructural stability of the investigated composite PCMs.

The relationship between chemical composition, microstructure, and thermal response of the alloys upon thermal cycling are analyzed, providing insights into material selection for efficient and thermally stable thermal storage/management systems.

These findings contribute to the development of advanced metallic PCMs for renewable energy and waste heat recovery applications.

Paper 1778 2 **Metallic-Phase Change Materials casting: comparison of experimental results with theoretical consideration.**

Mrs. Humaira Arshad, Italy

Oral Presentation (20')

Abstract

Metallic Phase Change materials could offer an alternative to salt-based PCM, when higher thermal conductivity is required. Among metallic PCM, Al-Sn based alloys have received considerable interest and several methods of production were proposed, mostly based on powder processes, to obtain the desired microstructure. In the present work, several Al-Sn metallic Phase Change Materials, with different composition, were produced by induction melting and cooled by different means. The obtained cast products and their microstructures were analyzed by image analyses. Results were correlated to material properties and casting/pouring conditions, try to establish a comparison with theoretical consideration.

Paper 1222 3 **Suitability of plasma sprayed AlSi10Mg+Sn coatings for Thermal Energy Management**
Mr. Matteo Molteni, Italy
Oral Presentation (20')

Abstract

Phase Change Materials (PCMs) are smart materials, which can store/release thermal energy at constant temperature via latent heat of transformation. Solid-liquid transformation is the most exploited one. In this view, the design of a suitable container for the managing the volume of the liquid PCM is fundamental. In this view, the adoption of immiscible systems, made up by at least two elements which do not interact at both solid and liquid phase, demonstrates to be an added value for these purposes. Al-Sn is one of the most relevant examples. The former acts as high thermally stable matrix, whereas the second one works as active PCM. In order to function properly, the active PCM should be efficiently dispersed in the matrix, which can effectively promote confinement. A high solidification rate has to be imposed to the material when liquid for the achievement of such a microstructure. In this view, plasma spray coating technique is tested for establishing its suitability as production process for PCM purposes. AlSi10Mg and Sn powders were employed for this work. An Al-Si-based alloy is selected since Si do not perturb the immiscible nature of the Al-Sn binary system. Microstructural analyses, both in as-produced and heat-treated conditions, were performed on the samples in order to establish if they are able to meet or not PCM requirements for a prolonged service as thermal management coatings. Also surface roughness analysis was performed in this sense to monitor the appearance of the coating. Their cyclic thermal performances, at least for preliminary stage, are tested as well with repeated DSC. Dilatometric tests are employed for understanding the thermo-mechanical behaviour of the resulting coatings. Plasma spray technique reveals to be a practical solution for the realization of PCM temperature management coatings.

Exploring the potentialities of TPMS-based composite Phase Change Materials

Mr. Matteo Molteni, Italy

Oral Presentation (20')

Abstract

Organic Phase Change Materials (PCMs) represent a powerful tool for thermal energy storage or thermal management purposes. Indeed, exploiting their high latent heat of fusion per unit mass and heat capacity at constant pressure, they can store/release high amount of thermal energy at constant temperature, i.e., the one of the phase transition. However, their intrinsic low thermal conductivity, severely limits their performances. For this reason, organic PCMs are usually embedded in high thermally conductive matrices, usually metallic, either ordered or disordered. In the meanwhile, additive manufacturing technologies enables the production of complex topologies, among which Triply Periodic Minimal Surfaces (TPMS). This latter definition identifies a family of structures with superior surface-to-volume ratio, ideal for exchange processes. Hence, composite PCMs (C-PCMs) are obtained from the combination of the two.

Effective thermal conductivity studies, even involving different material combinations, not only limited to organic PCMs, are numerically performed on different configurations, in order to highlight the advantages offered by TPMS over conventional lattices with the means of adimensional indexes.

C-PCMs thermal behaviour is also examined in terms of geometrical features under transient regime and a univocal methodology for establishing the triggering of the onset convection in this kind of composite is set via developing a permeability-dependent modelling.

Last but not least, the authors exploit the possibility of filling the C-PCM with different materials, having different transition temperatures and thermophysical properties. Indeed, another peculiar feature of the TPMS is to split the surrounding domain into two non-interconnected and non-interacting regions. This allows the possibility of having a multi-step temperature management, which can find application beside working system with a specific working temperature range, matching the two different PCM transition temperature.

The study successfully demonstrates at least from numerical point of view the feasibility of having such a system.

Paper 1655 4

Exploring the microstructural and electrochemical behavior of the CuMnNiSn alloy for thermomagnetic applications

Mr. Matheus Bellot Alvarenga, Brazil

Oral Presentation (20')

Abstract

The major part of the energy globally produced is lost during energy conversion, and most of it is released as heat, this waste heat can be classified into three grades: high temperature (above 650 °C), medium temperature (230–650 °C), and low temperature (below 230 °C) [1]. High and medium-grade waste heat can be readily utilized, but for low-grade waste heat, there is no effective way to recover it [1]. In this sense, developing thermomagnetic devices that use ferromagnetic materials with Curie temperatures close to room temperature may allow the recovery of low-grade waste heat [2]. In this study, the thermal, electrochemical, and microstructural behavior of the CuMnNiSn alloy was evaluated to verify its potential application in thermomagnetic devices. Material's phase composition was studied using X-ray diffraction (XRD), scanning electron microscopy (SEM), and energy dispersive X-ray spectroscopy (EDS), the electrochemical behavior in refrigeration fluids was studied by potentiodynamic polarization, and the thermal behavior was studied by differential scanning calorimetry (DSC). The microstructural characterization by XRD, SEM, and EDS indicates that the as-cast alloy presented two phases with equimolar composition, but with different space groups (Fm-3m and F-43m). The linear polarization analyses were initially evaluated using distilled water as a corrosion medium, which did not strongly affect the material's surface, with a corrosion current density of $\sim 1.6 \mu\text{A cm}^{-2}$ and a corrosion potential of $\sim -81.3 \text{ mV}$. A thermal treatment was carried out to improve the homogeneity of the alloy and verify its microstructural and electrochemical response, but the heat-treated alloy still presented two phases, with a similar corrosion behavior ($\sim 1.5 \mu\text{A cm}^{-2}$ and $\sim -68.5 \text{ mV}$). Nonetheless, preliminary results indicated that the Curie temperature of the CuMnNiSn alloy reduces from 100 °C to 60 °C after heat treatment, which is an attractive characteristic for the recovery of low-grade waste heat energy.

Paper 1407 5 Optimization of Heat Transfer Between Phase Change Materials and Thermal Loads Using Thermal Conductivity Enhancers
Mr. Benjamin Fenk, Switzerland
Oral Presentation (20')

Abstract

For future human space missions, ensuring crew health is paramount. Research has shown that calcium signaling, a fundamental cellular process, can be influenced by microgravity, making it crucial to investigate. Current experiments employ the fluorescent protein CaMPARI2, which irreversibly photoconverts under elevated Ca^{2+} and ultraviolet light, and require precise thermal control due to heat flux from LEDs exceeding 2.5 W/cm^2 . Because these temperatures must be kept stable without external power, phase change materials (PCMs) are used to stabilize temperature. However, PCMs have low thermal conductivity, limiting effective heat dissipation. This study addresses that challenge by investigating discrete thermal conductivity enhancers, added as separate structural elements, to improve heat transfer without reducing PCM volume.

A variety of configurations were evaluated, including aluminium foams of varying porosities, carbon foam, fibrous metal networks, and traditional fin or pin structures. These configurations were selected to optimize thermal conductivity while maximizing the proportion of PCM within the buffer, thereby preserving the overall thermal storage capacity of the system. The investigation began with preliminary experiments using a water-filled, simple setup to screen and eliminate materials that did not meet the necessary performance criteria. This phase allowed the identification of promising candidates based on their ability to rapidly conduct heat away from a simulated load. Building on these results, the second phase involved integrating the selected enhancers into a prototype container filled with PCM. This setup more closely mimicked realistic operating conditions by incorporating a controlled thermal source and subjecting the system to regulated heating and cooling cycles. Finally, a third set of experiments was performed using a real thermal buffer assembly within a functional system, providing further insight into the operational performance and integration challenges of each enhancer type.

Results indicate that specific aluminium foams, fins, and pins significantly improve heat dissipation compared to a baseline PCM system and other structures. However, while aluminium fins offer excellent thermal transfer, they are relatively heavy, which reduces the available PCM volume and overall energy storage capacity. Additionally, achieving a reliable thermal interface between the enhancer and the container proved challenging with foams. In contrast, conical aluminium pins emerged as the optimal solution, providing comparable thermal performance while being lighter and easier to integrate, thereby preserving PCM capacity and ensuring effective thermal management.

All mission-specific requirements, including minimal mass, limited volume, and precise temperature control, were successfully met, confirming the viability of this approach for future human spaceflight applications.

Paper 1125 1 Interrelation between Microstructure and Thermal Conductivity of Metal-Graphene Material Systems

Mr. Hyunjong Lee, The Netherlands

Highlight (Oral Presentation 20')

Abstract

In this study, the relationship between microstructure and thermal conductivity of metal-graphene material systems, such as pure copper-graphene, $\text{AlSi}_{10}\text{Mg}$ -graphene and Ti6Al4V -graphene, is examined. In these material systems, the distribution of graphene within the metal matrix influences the thermal conductivity to a large extent, introducing considerable thermal anisotropy [1]. Furthermore, the interface thermal conductance (ITC) between the metal and graphene forms a critical factor that may impact the total heat transport across. To date, thorough studies on the relationship between these factors have not yet been conducted. Hence, in this paper, we investigate the influence of the material microstructure on the thermal conductivity of metal-graphene composites comprised of metals with thermal conductivities ranging from 6.7 W/mK for Ti6Al4V to 366 W/mK for pure copper.

The addition of graphene to metals has been proposed as an efficient way to improve the thermal conductivity, as graphene exhibits a high in-plane thermal conductivity of 3,000–5,000 W/mK [2]. However, the low through-plane thermal conductivity of 5–10 W/mK of graphene, combined with its incompatibility issues with metals, makes it difficult to develop composites with superior thermal conductivity. For instance, the ITC of pure copper-graphene has been reported to be 23 MW/m²K, whereas that in polymer-graphene material systems has been demonstrated as 50–165 MW/m²K [3]. Accordingly, only rather limited thermal conductivity improvements in some metal-graphene systems have been reported [4].

In this work, we measured the thermal conductivities of pure copper-graphene, $\text{AlSi}_{10}\text{Mg}$ -graphene, Ti6Al4V -graphene as a function of the graphene wt.%. These findings were confronted with the microstructures characterized using scanning electron microscopy and transmission electron microscopy. Moreover, the wt.% dependency of the thermal conductivity is compared with theoretical thermal models, such as effective medium approximation. The thermal model was also adopted to describe the effect of ITC on the overall thermal conductivity. Some composites form interfacial bonding layers, such as Al_4C_3 and TiC which alter the conductivity. It was observed that the thermal conductivity increases by up to 150 % in Ti6Al4V , as a result of these interface reactions. The corresponding influence of microstructural features on the resulting thermal conductivity will be discussed in the final presentation.

Elastocaloric effect in polycrystalline NiMnTi alloys produced through suction casting and melt-spinning processes

Dr. Francesca Villa, Italy

Oral Presentation (20')

Abstract

The use of caloric materials for solid-state cooling applications presents a promising and sustainable alternative to traditional vapor compression-based refrigeration methods. In particular, elastocaloric technologies offer advantages such as compactness and simplicity of operation, reduced environmental impact and high efficiency. Among elastocaloric materials, superelastic shape memory alloys (SMAs) stand out, owing to the reversible stress-induced martensitic transformation which involves a high latent heat. NiMnTi-based alloys, in particular, show remarkable elastocaloric performance due to the large unit cell volume change during the Austenite-to-Martensite transition. In this study, two polycrystalline NiMnTi alloys were produced using two different processing routes, i.e. melt spinning and suction casting, starting from the arc melted precursor material. The effects of processing parameters and heat treatments on the thermoelastic martensitic transformation and on the alloy microstructure were investigated through calorimetric and microstructural analyses. Moreover, isothermal compression tests were performed to evaluate the superelastic behavior and the cycling stability of the produced alloys. In addition, the elastocaloric performance was evaluated in terms of adiabatic ΔT directly measured by thermocouples during quasi-adiabatic mechanical testing. The NiMnTi samples produced via suction casting demonstrated the highest elastocaloric performance, with an adiabatic ΔT reaching up to 15 °C. Lower performance was exhibited by melt spun ribbons, in which an inverse behavior was detected in tensile strain recovery measurements under applied loads. The current study contributes to expanding the fundamental knowledge on NiMnTi alloy produced by means of a cost-effective and traditional casting process in order to lay the foundations for further development of advanced processing routes, including melt-spinning and suction casting.

Paper 752 3 **Magneto-mechanical coupling in NiMnGaCu multicaloric alloys: functional experimental investigation under magnetic field**
Dr. Elena Villa, Italy
Oral Presentation (20')

Abstract

The Ferromagnetic Shape Memory Alloys (FeSMA) attracted increasing interest like multicaloric materials for solid state refrigeration. The most important field coupling is correspondent to magnetic and mechanical induction of thermoelastic martensitic transformation (TMT). In the present work we show for the first time an experimental investigation on NiMnCu polycrystalline alloy, in ad hoc developed experimental set up for stress strain curve in isothermal conditions under magnetic field. In this way we measured the elastocaloric and magnetocaloric effect at the same time. The entropy changes ΔS and the functional caloric parameters ΔT_{ad} vs magnetic field until 0.5 T are evaluated. The application of magnetic field seems to act like a supplementary mechanical longitudinal stress and the precise contribute of magnetic field is considered. These preliminary results are fundamental to complete understanding and modeling of coupled multicaloric phenomenon.

Paper 964 **4** **Kirkendall Effect guided Void Formation in PVD Manufactured Cu-Au Thin Films for low Thermal Conductivity Coatings**
Mr. Oliver Wipf, Switzerland
Oral Presentation (20')

Abstract

First observed in 1947, the Kirkendall-effect describes the mechanism of vacancy diffusion at the interface of two dissimilar materials where diffusion of some atomic species are strongly favored over the others. Thus, if these fluxes are not equal and in opposite direction, which is true for binary metallic interfaces, there must be a net flux of atoms which is matched by a flux of vacancies in the opposite direction. An important result of this effect is the accumulation of pores, also known as Kirkendall pores, near the interface of the two different materials. These pores are a result of the unbalanced atomic fluxes through the interface when the system is heated to a temperature where atomic diffusion becomes pronounced. In many manufacturing and joining applications, the formation of Kirkendall voids is undesirable as it poses a threat to device performance, through degradation of electrical and mechanical properties. However, in 2004 the Kirkendall effect was first used to explicitly create hollow nanoparticles with a single pore formed by the diffusion of Co and O, S or Se. The research direction of actively creating Kirkendall voids has been growing ever since. Currently, most Kirkendall voiding research is focusing on spherically or radially symmetric systems, but void formation has not yet been studied extensively in physical vapour deposition (PVD) manufactured thin film systems. In this work, we seek to further leverage the Kirkendall effect to design porous microstructures for a better understanding of the Kirkendall voiding mechanism in thin films. This will be done by leveraging the findings of Kirkendall-void formation in simple systems such as coated nickel wires and applying it to thin films. The films will be manufactured by a PVD process to then be annealed in a rapid thermal annealing (RTA) oven under vacuum. The manufactured thin films show high porosity, where the location and size of the pores can be controlled by the sputtering process. The porosity reduces the thermal conductivity of the films making them viable options for low thermal conductivity

Thermal Optimization for Sustainable Data Center Cooling Using Thermochemical Heat Systems

Mr. Chung Yu Yeh, The Netherlands

Oral Presentation (20')

Abstract

In this research, the integration of Thermochemical Materials System (TCMs) technology into data center (DC) cooling systems is evaluated as a method to improve energy efficiency by reducing electricity and water consumption, with a key focus on its impact on power usage effectiveness (PUE) and water usage effectiveness (WUE), critical metrics in data center energy efficiency. The rise of AI and machine learning has increased demand for high-power computing, leading to greater heat generation in data centers' cooling processes. While cooling temperature reach 40°C to 60°C, waste heat recovery presents a key opportunity. By capturing and repurposing waste heat, TCMs technology serves a dual purpose for heating applications, such as supporting nearby heat demands, while simultaneously enhancing cooling efficiency by reducing the load on conventional chillers. A benchmark model of data center cooling loop is developed to simulate key energy performance metrics, including electricity consumption for compressors and water usage in cooling towers. Conventional cooling systems, such as cooling towers, economizers, and mechanical chillers, are analyzed as a baseline for comparison. The integration of TCMs allows for transforming the rejected heat from DC cooling process, providing heating and cooling benefits. The results demonstrate that the proposed TCMs integration is adaptable to varying cooling water temperature requirements and significantly reduces overall electricity consumption and water usage. This integration enhances cooling performance, supports the nearby heating demands, and lowers environmental impact. This study highlights the technical feasibility and benefits of TCMs as a sustainable cooling solution, emphasizing material selection's impact on waste heat recovery efficiency. Future research should assess their techno-economic feasibility for cost-effectiveness and broader adoption in data center operations.

Paper 365 1 **Bio-Based NIPU Nanoemulsion Sponges for Sustained Drug Delivery in Topical Wound Delivery**

Mrs. Evangelia Balla, Greece

Oral Presentation (20')

Abstract

The growing demand for greener and more sustainable polymeric materials has significantly driven the interest of scientific research in recent decades. In this context, non-isocyanate polyurethanes (NIPUs) have emerged as a promising alternative to conventional polyurethanes (PUs), which rely on toxic isocyanates and petroleum-derived precursors. NIPUs are synthesized via non-isocyanate pathways, most commonly through the reaction of cyclic carbonates with amines, forming urethane linkages without the use of hazardous monomers. This approach not only reduces toxicity but also aligns with the principles of green chemistry by utilizing bio-based raw materials, offering reduced environmental impact, lower carbon footprints, and enhanced safety in production and application.

In the present study, polymer sponges based on novel bio-based non-isocyanate polyurethanes (NIPUs) deriving from bio-based di-acids (adipic, succinic, azelaic, and malonic), 1,6-hexamethylenediamine, and glycerol carbonate via a polyaddition reaction which were developed for the topical wound administration of chloramphenicol (CHL), a broad-spectrum antibiotic. The NIPUs were synthesized via a polyaddition reaction using bio-based di-acids (adipic, succinic, azelaic, and malonic), 1,6-hexamethylenediamine, and glycerol carbonate. The sponges were designed to provide a biocompatible and environmentally friendly platform for sustained drug release in wound treatment. Infrared spectroscopy (FTIR) confirmed the formation of urethane linkages, while scanning electron microscopy (SEM) verified the porous morphology suitable for drug loading and controlled release. Swelling behavior studies demonstrated the sponges' ability to retain moisture, promoting an optimal wound-healing environment. Enzymatic hydrolysis tests revealed a degradation profile compatible with biomedical applications, ensuring a balance between stability and bioresorption. The developed NIPU-based sponges present a promising alternative for sustainable and efficient drug delivery in topical wound care.

Engineering bacterial nanocellulose membranes for skin applications

Dr. João P. F. Carvalho, Portugal

Oral Presentation (20')

Abstract

The growing concerns with sustainability and safety are driving the design of biomedical devices and other therapeutic systems towards innovative biobased solutions. For example, the use of natural polymers as an alternative to conventional synthetic counterparts is gaining increasing interest, due to the inherent biocompatibility and biodegradable nature of the former. Bacterial nanocellulose (BNC) is a highly pure nanocellulose produced by some aerobic bacteria (e.g., bacteria from the *Komagataeibacter* genus) in the form of hydrogel-like membranes with an intricate porous 3D nanostructure and very high water content (>98%). The capacity of BNC membranes to be easily impregnated with aqueous solutions, together with its notable mechanical properties and biocompatibility, allows the use of BNC for the delivery of different drugs and bioactive compounds, in the form of patches, membranes, skin care/cosmetic products and other systems for biomedical applications. In this communication we will dive into recent works of our research group on the use BNC for the topical/transdermal delivery of anti-inflammatory (i.e., diclofenac¹) and antiviral drugs (viz. acyclovir²), but also of bioactive plant extracts³, hyaluronic acid⁴ and dexpanthenol⁵, highlighting the thorough characterization of the BNC-based materials, including their biocompatibility and drug-delivery performance.

Paper 810 3 **Bacterial nanocellulose membranes containing flavonoid-based metal complexes with potential for wound healing**
Mrs. Adriana Gomes, Portugal
Oral Presentation (20')

Abstract

Wounds, especially deep, chronic and infected wounds, often infected by multidrug-resistant bacteria, represent an increasing burden worldwide. An ideal wound dressing material should be biocompatible, malleable and non-adherent, capable of absorbing exudates while hydrating the wound site, and possess biological functionalities that support the wound healing process, such as antioxidant and antibacterial activities [1]. Bacterial nanocellulose (BNC), a singular nanocellulose substrate produced by non-pathogenic bacteria, is increasingly used as a wound dressing due to its nanofibrillar three-dimensional structure, which provides ideal conditions for wound healing, in combination with its biocompatibility, good gas permeability and ability to incorporate bioactive compounds [2]. An example of bioactive compounds that can be incorporated into BNC membranes are flavonoid-based metal complexes, which can exhibit 3D structures, mechanisms of action that cannot be achieved with organic molecules alone, and even enhanced biological activities due to the synergistic combination between the ligands and the metal ion [3,4].

In this context, the aim of this work was to develop innovative wound dressings composed of BNC membranes loaded with flavonoid-based metal complexes. For this purpose, two novel coordination compounds, namely zinc(II) complexes incorporating quercetin or morin and the N-donor ligand 1,10-phenanthroline, were synthesized in the presence of the BNC membranes. The resulting materials were characterized by X-ray diffraction, infrared spectroscopy, thermogravimetric analysis and SEM/EDS analysis, and evaluated regarding their mechanical properties as well as their antioxidant and antibacterial activities. The incorporation of the flavonoid-based metal complexes improved the healing ability of BNC by impart it with biological properties that boost the wound healing process.

First-Principles Insights into the Enhanced Catalytic Activity of Mg-Doped Prussian Blue for Hydrogen Peroxide Decomposition

Dr. Pritam Das, South Korea

Oral Presentation (20')**Abstract**

Reactive oxygen species (ROS) play a dual role in biological systems, acting as essential signaling molecules under physiological conditions while causing oxidative stress when overproduced. While controlled ROS levels are crucial for cellular communication, immune defense, and tissue repair, excessive ROS can disrupt homeostasis, damage biomolecules, and contribute to chronic diseases such as cardiovascular disorders, neurodegenerative conditions, and cancer. As a result, regulating ROS levels has become a key focus in the development of therapeutic strategies.

Nanozymes, a class of nanomaterials with enzyme-like catalytic properties, have emerged as promising candidates for mitigating oxidative stress. By mimicking natural antioxidant enzymes like superoxide dismutase (SOD), catalase, and peroxidase, nanozymes efficiently neutralize ROS, converting reactive species such as superoxide radicals (O_2^-) and hydrogen peroxide (H_2O_2) into less harmful molecules. Among various nanozymes, including those based on gold, manganese, cerium, and iron (Fe)-based materials stand out due to their intrinsic SOD-mimetic properties. However, challenges such as structural instability, potential cytotoxicity, and limited biocompatibility at therapeutic doses hinder their clinical translation. Recent studies have begun exploring the environment-specific catalytic behavior and long-term toxicity of Fe-based nanozymes, particularly Prussian Blue.

In this study, we investigate the dissociation of H_2O_2 on Prussian Blue and its modified structures using first-principles simulations. To determine the dissociation pathways of H_2O_2 , we consider all possible interfaces of Prussian Blue. Our analysis explores key electronic properties, including work function, d-band center, and H–H bond stretching, to elucidate their roles in H_2O_2 activation. Bader charge analysis further reveals electron redistribution between the support material and adsorbed H_2O_2 . Additionally, employing the Computational Hydrogen Electrode (CHE) method, we incorporate solvent effects to enhance the accuracy of our findings.

Furthermore, we examine the impact of magnesium (Mg) doping in Prussian Blue, which leads to the formation of Prussian White. Depending on Mg concentration, the charge state of Fe and doping sites of Mg are altered, significantly influencing catalytic activity. Notably, Mg incorporation reduces the H_2O_2 dissociation energy barrier by 38%, demonstrating its potential to enhance catalytic efficiency. Our collaborative work with experimental researchers aims to optimize Prussian Blue nanozyme structures for improved ROS regulation and biomedical applications.

Oral Presentation (20')

Abstract

Nitric oxide (NO) is a radical gas produced by the human body to maintain homeostasis serving as a biological mediator and chemical transmitter. It is necessary in vascular muscle relaxation, neurotransmission, and response to infection. Due to its physiological role, its light, diffusible nature, NO is also delivered exogenously through NO-donors for applications in wound healing, oncology and neurology¹.

Its therapeutic potential depends on precise control and calibration of NO release.

However, current mechanisms are spontaneous and influenced by factors such as scaffold type, concentration, and environment. Monitoring NO kinetics, localization, and dosage remains challenging without advanced techniques².

Gas sensors offer high sensitivity, but are unsuitable for liquid biological environments. Widely used methods like the Griess assay lack real-time monitoring and exhibit high variability. Techniques such as electrochemical sensors, chemiluminescence and high-performance liquid chromatography are effective but prone to interference, costly and impractical for frequent biological assays³.

A promising colorimetric approach involves the oxidative reaction between NO and oxyhemoglobin, shifting absorption bands to serve as a quantitative NO indicator. This method is sensitive, straightforward, and cost-effective. However, it is limited to spectrophotometric measurements of hemoglobin solutions, restricting sample volume, monitoring duration, and parallel assays. Compared to the Griess Assay, the hemoglobin assay has a similar limit of detection (~1 µM) but higher repeatability.

To address these limitations, we developed a high-throughput protocol automating 24-hour monitoring and enabling parallel analysis of 96 samples. This system supports diverse formats and was designed for NO release detection from solid hydrogel matrices. Reducing the sample volume improves the LOD by enhancing sensitivity through better concentration dynamics and signal detection. This innovation provides thorough NO release monitoring, advancing smart-releasing materials for therapeutic applications.

Dissolvable pullulan microneedles for transdermal lidocaine delivery

Mr. João M. S. P. Leite, Portugal

Oral Presentation (20')

Abstract

Local anesthetics, such as lidocaine, play a crucial role in various medical procedures, ensuring pain reduction and minimal discomfort for patients. However, administration of these local anesthetics often brings some discomfort or pain in the case of hypodermal injections and may be hindered by a slow skin diffusion when using creams and ointments. In the past years, microneedles (MNs) gained relevance as innovative drug administration systems that can overcome the barrier of the stratum corneum and administer a drug in a swift and minimally invasive way.¹ Herein, dissolvable lidocaine-loaded pullulan microneedles (PL-Lid MNs) were produced through micromolding and characterized to evaluate their potential for the non-invasive administration of anesthetics. The produced MNs displayed sufficient mechanical strength, enduring up to 1.5 N per needle without breakage. The ability to overcome the stratum corneum was confirmed by insertion in a parafilm skin model, reaching a depth up to 381 μm , and further validated by insertion in excised human abdominal skin where the MNs successfully reached the dermis. The dissolution of these MNs was evaluated in an agarose hydrogel model and showed complete dissolution of the MN tips after 10 min. The dissolution profile of lidocaine in PBS showed a release of 79% after 10 mins. The safety of the developed MNs was evaluated against three skin cell lines (HaCaT, 3T3, and RAW 264.7) by the resazurin assay, with all showcasing cell viabilities over 80% upon contact with the MNs. Additionally, the effect of the released lidocaine was studied on a sensory neuron cell line using fluorescence microscopy, showing that the lidocaine released from PL-Lid MNs had a similar effect in dorsal root ganglion (DRG) neurons as an in situ delivery of a lidocaine solution (14 mM). Moreover, we were able to elucidate how fast the released lidocaine provoked a response in neuronal cells through real-time fluorescence imaging by confocal microscopy. In sum, our results demonstrate the Pullulan MNs are an efficient system for the administration of lidocaine, with a low on-set time (<10 mins) owing to its swift dissolution and consequent drug release, contrasting the conventional methods for local anesthetic administration.

Development of a hydrogel composed of alginate and lysozyme amyloid nanofibrils for the administration of a novel chemotherapeutic chrysin-based metallodrug

Prof. Carmen Freire, Portugal

Oral Presentation (20')

Abstract

Flavonoid-based metallodrugs have emerged as promising chemotherapeutic drugs [1]. In particular, chrysin has been shown to induce apoptosis and inhibit cancer cell growth and proliferation through cytotoxic effects [2,3]. In this work, we successfully synthesized and structurally characterized a Cu(II)-chrysin-based metallodrug with potent cytotoxicity against human melanoma (A375) and human hepatocarcinoma (HepG2) cell lines. The compound exhibited IC₅₀ values of $1.29 \pm 0.04 \mu\text{M}$ for A375 and $1.93 \pm 0.08 \mu\text{M}$ for HepG2 cell lines. Furthermore, cell cycle studies revealed an increased percentage of cells in the G2/M phase, suggesting cell cycle arrest in both cancer cell lines. This promising chemotherapeutic candidate was then incorporated into a nanocomposite hydrogel, composed of alginate and lysozyme nanofibrils, that was fully characterized in terms of its optical, electric, thermal and mechanical properties. In vitro release studies were also performed under homeostatic and non-homeostatic conditions. Finally, the antioxidant activity and the cytotoxicity of the loaded hydrogel were accessed in A375 and HepG2 cells to evaluate its antitumoral potential.

Hybrid Polymeric Biomaterials for Tissue Engineering: Electrospun Fiber-Reinforced Hydrogels

Prof. Hyun Jong Lee, South Korea

Oral Presentation (20')

Abstract

Electrospun fibers and hydrogels have distinct but complementary roles in tissue engineering, offering a combination of mechanical support, topographical guidance, and a biomimetic 3D microenvironment. Electrospun fibers enhance mechanical stability and provide anisotropic structural cues, while hydrogels emulate the extracellular matrix, fostering cell proliferation and differentiation. By integrating these materials, hybrid scaffolds can achieve advanced functionalities tailored to diverse tissue engineering applications.

This study presents the development of composite scaffolds that leverage the synergy of electrospun fibers and hydrogels. Two approaches were explored: first, fragmented and surface-modified polycaprolactone (PCL) electrospun fibers were incorporated into hyaluronic acid (HA) hydrogels to improve cell adhesion, proliferation, and extracellular matrix production. The hybrid scaffold demonstrated enhanced mechanical properties and cytocompatibility, supporting fibroblast function in soft tissue engineering applications. Second, aligned PCL fibers embedded within gelatin methacryloyl (GelMA) hydrogels were designed to promote muscle cell differentiation. The aligned fiber structure significantly improved scaffold strength and facilitated cell alignment, resulting in enhanced muscle tissue formation.

Additionally, magnetic particles were integrated into electrospun fibers to enable precise alignment within hydrogels using external magnetic fields. This innovation introduces a new dimension of structural control, enabling the formation of anisotropic scaffolds that replicate the native organization of complex tissues. The magnetic alignment of fibers within the hydrogel matrix enhances both the mechanical properties and the directional guidance of cellular behaviors, paving the way for novel approaches to tissue regeneration.

The findings highlight the versatility of electrospun fiber-reinforced hydrogels and their potential to address challenges in soft and musculoskeletal tissue engineering by offering tunable mechanical properties, topographical guidance, and spatial organization. These hybrid biomaterials represent a promising platform for the development of next-generation scaffolds tailored to the needs of regenerative medicine.

Paper 832 3 Additive Manufacturing and Optimization of Magnetoactive Polymer Composites Based on Cobalt Iron Oxide

Dr. Ans Al Rashid, Qatar

Oral Presentation (20')

Abstract

The advancement of Additive Manufacturing (AM) techniques has facilitated the fabrication of multifunctional smart materials, pushing the boundaries of 3D printing into the realm of 4D printing. 4D printing structures can undergo controlled, time-dependent transformations in response to external stimuli. Stereolithography (SLA), an additive manufacturing technique, utilizes photopolymerisation to enable the fabrication of structures with high resolution and remarkable efficiency, making it a suitable platform for the fabrication of responsive materials. This study focuses on the synthesis of novel magnetoactive polymer composites (MAPCs) tailored for 3D printing via SLA and their potential use in biomedical applications. Magnetoactive polymer composites (MAPCs) are a class of smart materials consisting of two major constituents, a non-magnetic matrix and magnetic fillers. These composites exhibit tunable mechanical properties, including elasticity, damping, form, and shape, when subjected to an external magnetic field enabling remote actuation and deformation without direct physical contact. The MAPCs synthesised in this study are composed of cobalt iron oxide (CoFe_2O_4) nanoparticles at varying concentrations within a biocompatible photopolymer resin, enhancing the magnetic responsiveness of the polymer. Cobalt iron oxide, a ferrimagnetic material with high coercivity and notable magnetostrictive properties, is particularly well-suited for applications requiring remote actuation and magnetic control. Following synthesis, the composites were optimised to ensure their suitability for SLA-based 3D printing by adjusting and refining processing parameters to achieve optimal printability and structural integrity. After 3D printing and optimisation, mechanical testing was conducted to identify the ideal combination that resulted in the best mechanical performance. The synthesised MAPCs were further characterised to assess their chemical, thermal properties. This study works on advances in the development of stimuli-responsive biomaterials with potential applications in remote actuation and implantable devices. The ability to fabricate these dynamic structures through SLA represents a significant step toward the development of advanced, multifunctional biomaterials with transformative potential in medicine and engineering.

Paper 1900 6 **Tubular polyester-based electrospun constructs with anti-adhesive and anti-inflammatory potential to repair ruptured deep flexor tendons**
Prof. Arn Mignon, Belgium
Oral Presentation (20')

Abstract

Tendons connecting muscle to bone, provide strength and stability, withstand tension and release stored energy. Current treatment methods of hand tendon traumas have shortcomings, including insufficient mechanical strength, possible adhesion reactions with surrounding tissue and inflammation issues.

The current research aims to counter both mechanical and biological problems. To achieve this, a reinforced, tubular polyester-based construct has been electrospun, composed of: an inner electrospun polyester layer containing an anti-inflammatory component (Naproxen), a middle reinforcement layer with braided monofilament and an outer electrospun polyester layer containing an anti-adhesion component (hyaluronic acid, HA). As polymer material, an acrylate-endcapped urethane-based poly(ϵ -caprolactone) precursor (AUP) has been used and benchmarked against commercially available poly(ϵ -caprolactone) (PCL).

After proving the success of the synthesis ($^1\text{H-NMR}$), the materials with the bioactive compounds were electrospun on tubular collectors. PCL clearly led to thicker fibers ($8.77 \pm 1.88 \mu\text{m}$) than the AUP/PCL blend ($4.30 \pm 0.41 \mu\text{m}$). The constructs remained stable for > 9 weeks, the period lesioned tendons need to pass to advanced healing [1].

In vitro assays showed that incorporation of bio-active components was successful and not-cytotoxic for human fibroblasts. These tests also indicated that HA induced a burst release in PCL constructs, while a prolonged release was observed in the stronger and denser network of AUP/PCL. Introduction of the intermediate braided monofilament layer, between the electrospun layers led to strengths of $8.56 \pm 1.92 \text{ MPa}$ as shown by ex vivo sheep tendon tensile tests [2]. The final constructs have also been used in an in vivo study on 40 rabbits [3]. A comparison was made between tubular, medicated electrospun polymers with/without reinforcement, a tubular braid as such and a modified Kessler suture as a control. Histologically, an excellent repair was observed at the tendon site with significantly different adhesion pattern depending on the applied technique.

These multilayered electrospun constructs represent a very promising mechanical and biological solution to repair deep flexor tendons. In on-going follow-up research, the potential of poly(L-lactic acid)-PCL triblock-copolymers is being explored to control biodegradability and improve the mechanical strength without the need of a braided intermediate layer.

Paper 459 **1** **Synergistic effects of arginine and tannic acid on chitosan matrices: A green approach for hemostatic sponge development**

Ph.D. Rizos Evangelos Bikiaris, Greece

Oral Presentation (20')

Abstract

This study presents the development of a novel multifunctional hydrogel biocomposite sponge designed to address the complexities of wound healing, including rapid hemostasis, infection prevention, and tissue regeneration. Recognizing the limitations of conventional wound dressings that lack multifunctionality, this study introduces a 3D chitosan/tannic acid (CS/TA) hydrogel. After testing three chitosan/tannic acid (CS/TA) ratios, CS/TA-1 (1:0.16), CS/TA-2 (1:0.25), and CS/TA-3 (1:0.34), the most effective formulation, CS/TA-2, was enhanced with sodium alginate (SA) and arginine (Arg) for optimal performance. Arginine, with its unique guanidinium functional group, acted as a green crosslinker, enhancing the sponge's mechanical strength, hemostatic efficiency, and biocompatibility while promoting cellular interactions. Its inclusion significantly amplified antioxidant activity (>90%), mitigating oxidative stress and contributing to enhanced therapeutic outcomes. Ionic crosslinking and freeze-drying created a porous, absorbent sponge with high water retention and compression resilience. SEM confirmed the sponge's interconnected porosity, enabling cell infiltration and nutrient exchange. Blood Clotting Index (BCI) assessments demonstrated the hemostatic effectiveness of CS/TA/SA/Arg-3, with 25% BCI at 5 minutes and 20% at 15 minutes, along with excellent hemocompatibility, achieving a 2.08% hemolysis rate. These results suggest the hydrogel sponge's potential for effective wound management in emergencies and clinical applications.

Paper 622 2 Numerical analysis for a PEGDA microfluidic-device featuring a Y-shape for hydrogel microspheres synthesis

Lic. Anayancy Itzel Villatoro Guillén, Mexico

Oral Presentation (20')

Abstract

The microfluidics devices offer remarkable flexibility, integration capability, improved precision and efficient raw materials use. Implementation of different channel sizes and geometries is key to generate monodisperse droplets. The microfluidics operation relies on the viscous forces interplay, capillary forces, nozzle diameter, surface tension between the dispersed and continuous phases. Polyethylene glycol diacrylate (PEGDA) is a polymeric material used in tissue engineering and biomedical applications due to its biocompatibility and ability to form three-dimensional networks through photopolymerization. In this study a numerical analysis was performed in order to find the ideal conditions for the PEGDA hydrogel microspheres formation by using different flow rates featuring a Y-microfluidic device by considering a prepolymer PEGDA hydrogel solution as the dispersed phase and mineral oil as the continuous one. As a result, the numerical analysis shows that the small-size microspheres diameter (200 to 600 μm) is inversely proportional to the flow rate increase for the continuous phase while the dispersed-phase flow rate is kept constant. On the other hand, by decreasing the continuous flow rate, it does not generate the microsphere due to it agglomerates the dispersed phase. In contrast, the increment on the continuous flow rate allow to form ovals due to the drift that present the dispersed phase. The application milestone is focused on drug delivery such as in cancer treatments in order to improve the efficiency and reduce the side effects such as cytotoxic ones. By having the smaller the particle, the most efficient it can be.

Predicting Printability of Bio-inks by Capillary Rheology

Mr. Farhad Sanaei, The Netherlands

Oral Presentation (20')

Abstract

Background and purpose:

Extrusion-based 3D bioprinting offers a promising avenue for the fabrication of near-physiological tissue models but faces technical challenge in reliability and reproducibility. Hydrogel printability is commonly assessed by rotational rheology (RR), which does not capture the flow profile of extrusion process, resulting in poor reliability and predictability of the assessment, while visual assessment of filament morphological features is commonly performed after the bioprinting. The lack of reliable methodologies for hydrogel extrusion affects material design, bio-ink development, cell viability, and print quality, limiting the translatability of RR results to real-life extrusion of these materials. We hypothesize that faithful assessment of printability requires understanding the phenomena affecting bio-inks in the reservoir and the nozzle during the extrusion process. To this end, we employ principles of capillary rheology (CR), which characterizes material deformation and flow through capillaries, for quantitative assessment of bio-ink printability.

Methods:

We developed a CR system which enables real-time quantification of in situ bio-ink properties in a printing-like setup. For these experiments, we selected model bio-inks based on Pluronic F-127 and gelatin methacrylate (GelMA).

Results and conclusions:

Our results show a considerable discrepancy in key printability-related properties such as viscosity and shear-thinning with CR compared to RR. Besides shear-thinning behavior, CR reveals nuanced flow dynamics throughout the extrusion process, which reflect material-dependent changes in extrusion uniformity. Effects of material properties such as viscoelasticity, compressibility, and temperature sensitivity are reflected on CR data. Moreover, the integrated temperature sensors in CR show a dramatic temperature gradient throughout the bio-ink from the syringe to the capillary end, which significantly affects bio-ink behavior. These discrepancies suggest that RR cannot faithfully predict the material flow behavior under capillary extrusion, leading to inaccurate assessment when translating to extrusion process. All in all, CR provides accurate and more information on extrudability of hydrogels and pinpoints extrusion-dependent phenomena in each stage of printing course which cannot be captured with RR. Our ongoing work aim to correlate CR and visual data for quantitative printability assessment by analyzing extrusion instabilities and uniformity to find the best pattern to optimize the bioprinting process.

Dielectric Properties of Chitosan-Based Bionanocomposites

Mrs. Dayana Guzmán Sierra, Portugal

Oral Presentation (20')

Abstract

Chitosan, a versatile biopolymer derived from chitin, has garnered significant attention due to its exceptional properties, including biocompatibility, biodegradability, and antimicrobial activity [1]. This study investigates the impact of chemical modifications and the incorporation of organic and inorganic fillers on the dielectric properties of chitosan-based bionanocomposites. Understanding these properties is crucial for developing advanced materials for applications in energy storage devices, sensors, and biomedical engineering [2,3].

Using Electrical Impedance Spectroscopy (EIS) and Fourier Transform Infrared Spectroscopy (FTIR), we systematically examined the relationship between the chemical structure of chitosan and its electrical behavior. The results revealed that neutralization process and the introduction of chitin nanofibers and barium titanate nanoparticles significantly influenced the capacitive component of the dielectric response mainly in the capacitive behavior. However, the resistive component of the chitosan films exhibited minimal changes upon these modifications. These findings provide valuable insights into the factors that rule the dielectric properties of chitosan-based materials, helping in the development of novel bionanocomposites with tailored electrical characteristics for diverse applications.

Synthesis of P3HB/Chitosan Blends with Enhanced Properties for Biomedical Applications

Mrs. Esther Mula, Spain

Oral Presentation (20')

Abstract

Poly(3-hydroxybutyrate) (P3HB) is a biopolymer from the polyhydroxyalkanoate family, naturally synthesized by bacteria as a storage form of carbon and energy.¹ Despite the limitations posed by its high crystallinity and production costs,² holds substantial potential due to its appealing properties. Among them, exhibits piezoelectric behaviour, rendering it promising for biomedical uses by providing mechanical or electrical stimuli via piezoelectric effects.³

To address some production constraints, the ring-opening polymerization (ROP) of rac- β -butyrolactone (BBL) using metal catalysts has facilitated the synthesis of tailored P3HB.⁴ Aluminum-based catalysts, in particular, offer advantages due to aluminum's abundance and cost-effectiveness,⁵ and they have demonstrated strong ROP activity.^{6,7}

On the other hand, chitosan (CS), a natural biopolymer, has gained considerable attention in tissue engineering and regeneration over recent years due to its advantages, including biocompatibility and antimicrobial properties.⁸ Additionally, it has demonstrated piezoelectric properties, due to its non-centrosymmetric crystalline structure.⁹ However, its limited mechanical strength has hindered its application.

This study aims to combine the strengths of both P3HB and chitosan to create a material with improved mechanical properties for biomedical applications. To address this, we employ an aluminum complex with phenoxyimine ligands to produce atactic P3HB with varying molecular weights via the catalytic ROP of (BBL). These biopolymers, along with chitosan, were used as additives in blends with high-molecular-weight bacterial P3HB to enhance the material's functionality. The blends were processed via both solvent casting and electrospinning techniques, and a morphological, thermal, and piezoelectric analyses were conducted, allowing a comparative study of their structure and properties providing insights into their suitability for applications. Furthermore, a comparative biological study with fibroblast cells assessed the biocompatibility of each blend type, highlighting the influence of processing methods on cellular interaction.

Synthesis and characterization of electrospun fibers based on piezoelectric bioplastics

Ph.D. Valentina Sessini, Spain

Oral Presentation (20')

Abstract

Nowadays the production of electricity from renewable and wasted resources is an important challenge. A green way to produce electrical energy can be the recovering and conversion of wasted mechanical energy such as vibration, kinetic energy, or deformation energy, in electricity. This process is called mechanical energy harvesting. Piezoelectric materials could be applied to build piezoelectric energy harvesters (PEHs) as promising independent renewable power sources for low-power electronic devices such as wireless sensors, portable devices, stretchable electronics, and medical implants (biosensor) [1-2]. In this context, green piezoelectric bioplastics such as poly-L-lactic acid (PLLA), polyhydroxybutyrate (PHB) and their copolymers could represent an interesting alternative that have benefits regarding carbon footprint, thus decreasing the environmental impact of PEHs devices. However, the practical application of bioplastics is limited because its piezoelectric constant is much lower than those of ceramic piezoelectric materials, PVDF and its copolymers [3]. Thus, to find new strategies and pathway for the large-scale production and processing of green bioplastics with improved piezoelectric properties is a challenge.

This communication will focus on the design of new bioplastics with improved piezoelectric properties for energy harvesting applications offering innovative potential industrial solutions. Different strategies to develop and boost piezoelectric properties of different biobased systems will be showed such as the catalytic synthesis of PLLA and its copolymers with controlled structure and biobased additives for bacterial PHB. Emphasis will be placed on the polymeric architecture as well as on the processing method to activate the piezoelectric properties. In fact, optically active polymers can be polarized by mechanical drawing avoiding the application of high electrical fields. The morphology, thermal, electric, and piezoelectric properties of the different bioplastics will be also presented in this communication.

The authors would like to thank the Ministerio de Ciencia e Innovación (Spain) and the European Community "NextGenerationEU"/PRTR (TED2021-130871B-C22, RYC2021-033921-I).

Paper 219 2 **Electrolytic leaching of critical materials from Waste Printed Circuit Boards: a sustainable method**

Mrs. Laura Grima-Carmena, Spain

Oral Presentation (20')

Abstract

Waste Printed circuit boards (WPCBs) are becoming a global concern as they are an increasing source of toxic waste as well as a source of valuable materials. Pyrometallurgy is the most commonly used recycling method, but it consumes large amounts of energy and it has a low selectivity. Besides, the heterogeneity of their composition hampers an effective recovery, requiring a combination of technologies to recover its valuable materials. This work presents an environmentally friendly alternative. The process consists in a sequential leaching of base and precious metals using electrolysis in mild acid conditions at room temperature. The main advantages of the proposed method are low current density, inexpensive reagents, and short operation times.

First, WPCBs from a local company were selected and dismantled, crushed and separated using magnetic and pneumatic processes. The non-magnetic fraction (<2mm) was used in the leaching tests. The in-house leaching system includes a two-compartment cell, a glass column where the leaching takes place, two tanks and a pump. NaCl and H₂SO₄ were used as electrolytes in both compartments. The chloride concentration of both electrolytes was 1.5 M and the initial acid concentration was 0.05 M. The cell was operated in galvanostatic mode using a current density of 400 A·m⁻².

The process was divided in 3 sequential steps. The first step aims to leach the base metals with no extraction of precious metals, the second step focus on the extraction of precious metals and the third step was included to check the end of the leaching process. A concentration process was performed by reusing the electrolytes and introducing different batches of WPCBs, to increase the metal concentration in each solution and improve their potential recovery from these solutions. After the process, the remaining WPCBs were analyzed to verify the metal content of each batch. The concentration of Cu, Au, Ag and Pd was monitored during the leaching tests, with an accumulated extraction yield of 98%, 95%, 90% and 68%, respectively.

Ink formulation from spent NiMH batteries

Dr. María Fernanda Gazulla Barreda, Spain

Oral Presentation (20')

Abstract

The list of critical raw materials for the European Union is continuously expanding, with an increasing number directly affecting the ceramic industry. Notable among these critical raw materials are Co, Ni, Li, B, Sr, Ce, and Pr, which are widely used in the ceramic sector. These materials are considered critical due to their economic importance and the risk of supply disruption. All of them are mined in countries outside Europe, and the refining processes are mainly carried out in China, which is the major supplier of many of these raw materials.

Therefore, securing alternative sources of raw materials is essential, which necessitates the exploration of end-of-life products containing critical raw materials and the development of recovery processes that are both environmentally friendly and economically viable. A NiMH battery cell is made of a cathode, whose active material, in the charged state, is nickel oxyhydroxide (NiOOH), and an anode, mainly composed of hydrogen in the form of a metal hydride. The metal alloy is responsible for hydrogen storage and those normally used are the rare-earth (Misch metal) alloys based on lanthanum nickel (LaNi₅), known as the AB₅ class of alloys, in which La is sometimes partially substituted by Co, Ce, Nd, or Pr.

In this study, a separation process for the components of a NiMH battery was developed, using mechanical processes and considering the magnetic properties of the different materials. As a result, the active materials from both the cathode and anode were separated, and their potential use as secondary raw materials for the formulation of functional inkjet inks—capable of generating heat transfer systems—was explored. The results are at the laboratory scale, and further work is underway to advance to the pilot plant level before industrial-scale implementation.

Synthesis of LNMC cathode from recovered precursors from secondary source materials

Ph.D. Gorka Barquero-Carmona, Spain

Highlight (Oral Presentation 20')

Abstract

In recent years, the global lithium-ion battery market has grown by around 13% and is estimated to reach \$87.5 billion by 2027 due to the demand for portable electronic devices and electric vehicles, which is enhanced by the goals set by the European Union to achieve carbon neutrality by 2050.

LNMC cathodes, which are crucial for their high energy density, thermal stability, and long cycle life, depend on scarce raw materials like lithium, nickel, manganese, and cobalt.

For this reason, the recovery and recycling of critical metals from secondary sources, such as spent lithium-ion batteries, could be a promising solution, as it would reduce environmental impact and the dependence on primary sources.

This work focuses on the synthesis of LNMC cathodes using recovered precursors from secondary sources, lithium-ion batteries specifically.

Each precursor is obtained through specific recovery processes based on pyrometallurgical and hydrometallurgical methods. The recovery begins with a solid material known as black mass, which is obtained through crushing processes of spent lithium-ion batteries. This material is subjected to a carbothermic reduction followed by hydrolysis, allowing the selective extraction of lithium as a carbonate. Meanwhile, the insoluble solid residue is subjected to a hydrometallurgical route involving leaching. The resulting leachate is treated with oxalic acid, a precipitating agent, to recover a Ni-Mn-Co mixed oxalate. These steps ensure efficient separation and recovery of high-purity precursors for cathode synthesis.

The LNMC cathode synthesis procedure is based on a first step of solid reactive milling where the precursors are mixed for two hours in a planetary mill in stoichiometric quantities for a specific LNMC cathode. The mixture is then subjected to a heat treatment in order to decompose the precursors and make them more susceptible to the reaction. Finally, the temperature is raised to sinter the mixture. The sintering step was carried out in an oxygen atmosphere to maintain oxidative conditions.

The obtained black powder, which is characterized by analytical techniques such as XRD, SEM and ICP-OES, is identified as NMC cathode with a specific stoichiometry.

Paper 482 **5** **Selective recovery of rare earth elements from electric vehicle motor NdFeB type magnets**
Dr. Lorena Alcaraz, Spain
Oral Presentation (20')

Abstract

Electric mobility is a fundamental solution to reduce the environmental impact of mobility, as it contributes to reduce greenhouse gas emissions and improve air quality in cities. However, this transition to electric vehicles is intimately linked to the increase of critical raw material use. An example is the exploitation of rare earths, essential elements in the manufacture of motors and batteries that allow these cars to operate efficiently. Every electric car contains around 2 kg of NdFeB type magnets, about 30% of which is neodymium, a valuable and scarce resource that must be recovered and reused. This growing demand has increased the need to ensure a responsible and sustainable supply of these elements, which are not only crucial to the performance of electric motors, but also presents geopolitical and environmental challenges.

This work develops a rare earth recovery process, that starts from sintered NdFeB magnets obtained after the dismantling of electric car motors. The precursor material is a provided powder obtained through a hydrogen decrepitation process (HPMS: Hydrogen Processing of Magnetic Scrap). Subsequently, this powder was treated by chlorination roasting process, followed by liquid-liquid extraction stages using selective extraction agents in order to eliminate the iron and obtain a solution rich in rare earths. A successive stage of selective separation by liquid-liquid extraction technique allows the obtention of separate rare earth compounds that undergo a calcination process to obtain the REE oxides, which have further potential applications.

The final products have been characterized by techniques such as Inductively Coupled Plasma – Optical Emission Spectroscopy (ICP-OES), X-Ray Diffraction (XRD), Infrared Spectroscopy, and Scanning Electron Microscopy (SEM). The analyzed materials are identified as Neodymium and Holmium oxalates and oxides.

Reduced graphene oxide supported on polyurethane foams for metal recovery from e-waste

Mrs. Maria Giuseppina Genduso, Italy

Highlight (Oral Presentation 20')

Abstract

The growth of global population and digitalization is rising the global demand of materials. In the last decade, critical raw materials (CRMs) have received much attention, due to their importance in strategic sectors such as the transition to climate change, aerospace, and safety. Waste from electric and electronic equipment (WEEE) represents an enormous resource due to their wide metal composition. However, nowadays, the majority of waste materials is wrongly discarded or misplaced, producing a huge loss of valuable metals.

WEEE can be treated in different ways to recover the contained critical raw materials, spanning from pyrometallurgical treatments to hydrometallurgical ones. The adsorption step, used into hydrometallurgical plants after various leaching steps, is a versatile technique because of its high recovery efficiency, short extraction time, high enrichment factor, simplicity, and low cost. The adsorption process makes also use of a wide variety of sorbents with different characteristics, such as silica- and carbon-based, green, and polymeric materials.

Graphene based materials have shown a great potential in this field of application, also owing to their high specific surface area. In this work, we exploit the adsorption behaviour of a 3D object composed by reduced graphene oxide (rGO) supported on commercial polyurethane (PU) flexible foams of 20 PPI. PU foams have been dip coated with a rGO aqueous dispersion, obtained after a mild reduction of commercial GO with L-ascorbic acid, performed under magnetic stirring at room temperature and pressure. The excess of dispersion on the foam has been removed by the use of compressed air; then, the coating has been consolidated in the oven at a temperature of 40 °C for 1 hour. The foams have been used to remove and recover different metals that can be found in e-waste.

Lanthanum, copper, and silver were selected as representative of e-waste critical (and strategic) raw materials. Adsorption was carried out on simulated mono- and multi- ionic solutions at different initial concentrations, from 1 mg/L to 1 g/L. The volume of the contacted solution was 100 mL. The experiments were performed under magnetic stirring at room temperature and pressure. The solution was analysed via ICP-OES before and after the adsorption experiment, to determine its composition.

Preliminary results revealed a higher affinity of the rGO-coated foams for silver ions, being able to reach a capture efficiency of 59 wt.%. Moreover, SEM analysis performed at high magnifications revealed the presence of silver clusters on the surface of rGO.

Eco-friendly electrospun lignin membranes for sustainable precious metal recovery from e-waste

Ph.D. Virginia Venezia, Italy

Oral Presentation (20')

Abstract

Advances in technology have led to a significant increase in the consumption of electrical and electronic equipment, resulting in the generation of large quantities of waste electrical and electronic equipment (WEEE). This waste contains hazardous substances such as lead, mercury and flame retardants, which release harmful dioxins during incineration, posing serious environmental and health problems [1]. WEEE is a rich source of base metals (Cu, Fe, Ni and Zn) and precious metals (Ag, Au, Pt and Pd). For example, one tonne of electronic waste can yield up to 0.2 tonnes of copper, while discarded mobile phones are particularly rich in gold. Consequently, WEEE serves as an important reservoir of precious metals, making their sustainable recovery critical to meeting global metal demand and advancing the circular economy [1].

This study explores an environmentally sustainable strategy for the recovery of precious metals from WEEE, focusing on the valorisation of biowaste using biomolecules such as humic acids (HA) and lignin (L) as functional components of biocompatible polymeric matrices (e.g. polyvinylpyrrolidone, PVP). These biomolecules were incorporated into electrospun fibers. The resulting materials were subjected to an extensive physicochemical characterization and tested as biosorbents for the selective extraction of precious metals (e.g. Au, Pd) under optimal pH conditions with varying concentrations of metal ions in solutions mimicking real leachates. SEM microscopy confirmed the formation of uniform, defect-free fibers, while swelling tests demonstrated the exceptional water absorption capacity of the mats without structural degradation. Preliminary adsorption experiments showed very good adsorption performance for Au³⁺ ions at pH 3, with negligible interaction with Cu²⁺ ions. The selectivity of the sorbents was evaluated in multi-metal solutions, confirming that effective adsorption requires simultaneous adsorption and reduction processes, which can be due to the high concentration of carboxylic and phenolic groups in the chemical structure of biowaste [2]. Biowaste-based sorbents represent a promising, environmentally friendly solution for the recovery of metals from WEEE, in line with the principles of the circular economy. It also offers an environmentally sustainable and cost-effective alternative to conventional electrochemical reduction techniques.

This work was supported by MITE (ora MASE - Ministero dell'Ambiente e della Sicurezza Energetica) Progetto di ricerca PESoMeNo – "Processi rigenerativi ecoSOstenibili per il recupero e la valorizzazione di Metalli Nobili da RAEE".

Enhanced Metal Recovery from spent Lithium-Ion Batteries Using ChCl:PTSA Deep Eutectic Solvents: A Study on Conventional and Microwave-Assisted Leaching Process

Dr. Elif Güloğlu, Turkey

Pre-recorded video presentation. Highlight (Oral Presentation 20')

Abstract

With the increasing demand for lithium-ion batteries, the quantity of end-of-life batteries is also rising. Due to the valuable metals they contain and the environmental hazards they pose, the recovery of lithium-ion batteries at the end of their lifespan has become essential. Moreover, maintaining high metal extraction efficiency while minimizing environmental impact is critically important in recovery processes. At this point, deep eutectic solvents (DES) emerge as a promising alternative due to their several advantages, including their organic composition, reusability, biodegradability, the ability to achieve high metal extraction efficiency through synergistic effects, and minimal water consumption.

In this study, the recovery of metals contained in the cathode active powder of end-of-life NMC type batteries was investigated using solvometallurgical method. Choline chloride (ChCl) and p-toluenesulfonic acid (PTSA) were synthesised in 1:1 molar ratio and used as DES. In conventional leaching experiments, temperature, time, reductant addition, solid/liquid ratio were optimised for maximum metal recovery. Similarly, the effect of operating conditions on leaching efficiency was investigated for microwave assisted leaching process. As a result of conventional leaching experiments, Li, Mn, Co and Ni metals were completely leached into ChCl:PTSA solution at 100°C, 2 hours and 1/50 solid/liquid ratio conditions. When 5 wt% fructose was added to DES, approximately 100% yield was obtained under the same conditions at 60°C. Additionally, a series of experiments were conducted to determine the effect of microwave assistance on the leaching efficiency, and the results were compared with those obtained using the conventional leaching method. According to the results, at a solid/liquid ratio of 1/20 and 100°C for just 10 minutes, all metals were dissolved nearly 100% efficiency.

Paper 1598 3 Sustainable Recovery of Rare Earth Elements from Nd-Fe-B Swarf via Hydrogen Plasma Reduction

Mrs. Naritai Chimed, Germany

Oral Presentation (20')

Abstract

Rare earth permanent magnets (REPMs) are critical components in electric vehicles, wind turbines, and consumer electronics due to their excellent magnetic properties. REPMs on the basis of Nd-Fe-B typically contain 29–31 wt.% rare earth elements (REEs), primarily neodymium (Nd), praseodymium (Pr), dysprosium (Dy), and terbium (Tb). Approximately 80% of global Nd consumption is dedicated to REPM production, and Nd-Fe-B demand is expected to exceed 260,000 tons per year by 2035, driven largely by electrification and the transition to renewable energy sources.

However, REE mining and refining present serious environmental and geopolitical challenges. Extraction generates toxic waste, including acid-leaching agents, heavy metals, and radioactive byproducts like thorium and uranium, which contaminate the environment and pose health risks to urban areas. Geopolitically, supply chains are vulnerable to disruptions and import dependency due to the concentrated production and processing in specific regions. As a result, recycling of REPMs is becoming increasingly important as an economically and environmentally sustainable alternative to primary production.

This study focuses on the recovery of REEs from Nd-Fe-B grinding swarf, a significant yet underutilized waste generated during REPM production. It is estimated that 6–73 wt.% of the REPM material is lost as swarf, making it a major untapped source for critical materials. Nd-Fe-B magnet swarf can contain up to 37 wt.% REEs, such as Nd and Dy. Current hydrometallurgical and pyrometallurgical methods for recycling swarf face substantial limitations. Hydrometallurgical processes, although effective in extracting REEs, require large volumes of leaching media and can produce hazardous waste, making their sustainability questionable. In contrast, pyrometallurgical approaches demand high energy input, precise temperature control, and often result in slag formation, which limits the overall efficiency. These limitations underscore the necessity for a more effective and sustainable recycling strategy.

In this study we demonstrate a novel approach using hydrogen plasma reduction (HPR) as an energy-efficient and environmentally sustainable method to recover and separate the various REEs from the swarf without generating hazardous by-products with high recovery rates. We investigate key process parameters of the HPR method to evaluate its feasibility for REE recovery. Advanced characterization techniques are employed to provide insight into phase transformations, reduction kinetics, microstructure and the purity of the recovered phases. We will discuss whether HPR can serve as a viable recycling and extraction pathway for REPM swarf, offering a sustainable and environmentally responsible solution to reduce reliance on primary REE production in the future.

Paper 1607 4

Electrochemical leaching of CIGS PV panels for recovery of CRMs

Mr. Himanshu Khadse, Germany

Oral Presentation (20')

Abstract

Copper-Indium-Gallium-di-Selenide or CIGS panels are one of the promising alternatives in the market for thin-film solar technologies. CIGS panels are lightweight, durable and use less semiconductor materials as compared to Si-based PV modules [1, 2]. According to EU CRM materials report 2023, indium gallium and copper which are raw materials for CIGS panels are rated as critical materials subject to their high supply risk and moderate economic importance [3]. The development of robust recycling methodologies for copper indium gallium selenide (CIGS) photovoltaic panels and associated production waste presents a viable pathway towards securing the supply of critical raw materials (CRMs). While a range of recycling processes have been explored, many current approaches demonstrate limitations. Specifically, challenges remain in achieving both efficient material separation and high material purity within a single process. Furthermore, certain methodologies necessitate operation under highly toxic conditions, resulting in the generation of secondary waste streams which require further management. Within this research electrochemical leaching for separation and recovery of materials from CIGS solar panels is studied. The scope of study is to determine efficiency of semiconductor coating separation from glass in H₃C-SO₂-OH (Methanesulphonic Acid). Using ICP-OES/MS and XPS techniques the dissolution and de-coating efficiencies are calculated. The investigation includes the observing effective separation of the glass and coating material at different acid concentrations in novel drum electrode[4]. Within the study, sustainability analysis of the processes from ecological, safety and social aspects are briefly discussed.

Hydrogen Processing of Recycled NdFeB Powders via HPMS and Production of New Magnets

Ph.D. Alba Berja Torres, Spain

Oral Presentation (20')

Abstract

Neodymium Iron Boron ($\text{Nd}_2\text{Fe}_{14}\text{B}$) magnets are essential components in modern technology, including electronics, renewable energy systems, electric vehicles, and household appliances. The increasing demand for rare earths, coupled with supply chain vulnerabilities and environmental concerns, underlines the urgency of developing efficient and sustainable recycling strategies to reduce dependence on primary raw materials and support a circular economy. This recycling approach supports the objectives of the Critical Raw Materials (CRM) Act, aiming to recycle at least 25% of the EU's annual raw material consumption by 2030 while promoting circular economy practices and strengthening supply chain sustainability. This approach utilizes a closed-loop recycling process for NdFeB magnets, employing Hydrogen-Processing of Magnet Scrap (HPMS), a technique patented by researchers at the University of Birmingham. Through this method, dense NdFeB magnets from end-of-life devices are efficiently converted into hydrogenated powder, which is then refined via jet-milling to reduce particle size. Subsequently, the recycled powder is degassed to eliminate hydrogen, restoring its original composition, microstructure, and magnetic properties, ultimately enabling the production of new magnets. This work explores optimal annealing conditions for dehydrogenation in vacuum varying temperatures up to 900°C, heating rates and dwell times for the final production of bonded magnets by injection moulding and also optimal parameters for the fabrication of sintered magnets by spark plasma sintering. The degassed final powder suitable for bonded magnet production exhibits competitive properties compared to virgin material, achieving a coercive field of 434 kA/m. SPS sintered magnets present a remanence magnetization of 1.26 T and a coercive field of approximately 1200 kA/m, comparable to magnets found in the market (N40).

Electrochemical recovery of metals and silicon from c-Si photovoltaic module

Mr. Alan Dsouza, Germany

Highlight (Oral Presentation 20')

Abstract

The popularity of photovoltaic energy has soared in recent decades due to its affordability, ease of installation, and minimal environmental footprint [1]. As the number of photovoltaic panels installed continues to rise, so will the amount of waste generated, considering that these panels have a lifespan of approximately 25 years [2]. c-Si PV panels contains glass (75 wt%), Al (10 wt%), polymers (8 wt%), Cu (0.8 wt%), and other metals (such as Pb, Sn, Zn and Ag) (> 1 wt%), and also Si (5 wt%)[3], which is a critical material for the European union [4].

Si wafers were recovered from the end-of life Photovoltaic module by delamination of glass and back sheet in a solvent bath followed by the thermal decomposition of EVA by means of pyrolysis. Subsequently, it was treated electrochemically to separate metals such as Al, Cu, Sn, Pb and Ag in 1mol/L H₃C-SO₂-OH with 1mol/L HCl (1:1 v/v). The electrochemical treatment was conducted using an indigenously built drum electrode with platinised titanium inlet mesh. Si, Cu and Sn were recovered in 99%, 98% and 82% purity respectively. The three-step c-Si PV panel recycling process ensures recovery of the PV glass, the back sheet, Si, Cu, Sn and EVA as pyrolytic oil. According to a close-loop recycling approach, the recovered silicon and metals are used in an additive manufacturing process to prepare flexible PV-module.

Paper 247 1 Sustainable ceramics: Circular economy implementation and prospects

Mr. Wendilia Jean Toussaint Garango, Germany

Oral Presentation (20')

Abstract

The ceramics industry is at a turning point shifting from a traditional linear economic model towards a sustainable circular economic approach. The ceramics manufacturing process has been energy-intensive. Ceramics recycling is hindered due to technical, regulatory, and financial barriers. This practice has contributed to 19 million tons of carbon dioxide (CO₂) yearly emissions within the European Union with the ceramic brick industry contributing 2.7% of global CO₂ emissions. Though studies have investigated energy efficiency and emission reduction in the ceramics industry, there is little focus on integrating circular economy principles through its value chain. This work aims to identify prominent advancements in three major areas: raw material optimization, product durability and resource recovery. This work employs a qualitative approach by synthesizing insights from peer-reviewed studies and real-world examples from 2000 to 2025 to identify emerging trends, obstacles, and opportunities in implementing sustainable practices. It emphasizes novel materials, manufacturing processes, digital technology, and energy-efficient solutions regarding industry developments, opportunities, and challenges. A contribution of this paper lies in its relevance to Sustainable Development Goals 11 (Sustainable cities and communities), 12 (Responsible production and consumption), and 13 (Combat climate change and its impacts), specifically by reducing carbon emissions and conserving natural resources. Results show an increase in the diffusion of practices like material recovery and energy-efficient technologies; while factors like barriers to high implementation costs and complex regulatory systems are presented. A supportive policy framework should be emphasized to maintain technological innovation and cross-industry collaboration as a recommendation to overcome these barriers and drive a circular economy principle within the ceramics industry.

Sustainable Geopolymer Catalytic Supports from Construction and Demolition Waste and Metakaolin Activated with Alternative Siliceous Waste-Derived Activators

Mr. Pedro Delgado-plana, Spain

Oral Presentation (20')

Abstract

This research proposes the synthesis of innovative geopolymer-based catalytic supports derived from a precursor blend of construction and demolition waste (CDW) and metakaolin (MK) activated with alternative solid activators synthesized from siliceous waste. The objective of this research is to obtain advanced catalytic supports for environmental remediation application, such as CO₂ capture and pollutant degradation, which also contribute to the circular economy by reusing waste materials.

In this study the precursor consists of a mix of CDW and MK in equal proportions, combining the abundant availability of CDW with the high reactivity of MK. The activation process employs a novel solid activator produced by mixing a silica-rich waste, such as waste glass or spent diatomaceous earth, with sodium hydroxide in a defined proportion. This mixture is subjected to thermal treatment at 300 °C to synthesize sodium silicate, which functions as the activator in the geopolymerization process. Following activation, the resulting alkali-activated materials are dried, ground, and subsequently treated with a slightly acid solution of ammonium chloride. A final calcination step at 550 °C is performed to develop the microstructure necessary for catalytic functionality, with an emphasis on creating a high BET surface area and a pore size distribution predominantly within the 2–50 nm range.

Preliminary assessments show that the alternative activator and an optimal liquid to solid ratio promote the formation of a geopolymer matrix with a tailored porous architecture, essential for catalytic efficiency. The materials synthesized using this method exhibit a good catalytic performance. Furthermore, the low-temperature processing route for the alternative activator results in potential energy savings and a reduced environmental impact, aligning with sustainable production and circular economy principles.

The results of this research pose CDW and MK as valid precursors in the manufacture of geopolymer-based catalytic supports and contribute to the development of sustainable construction materials and innovative remediation technologies, offering a practical route for mitigating environmental pollution

Paper 374 3 Building with Rammed Earth: Characterization and Optimization of Earth Mixes from a Monticello d'Alba Case Study

Dr. Federico Iorio Esposito, Italy

Oral Presentation (20')

Abstract

This study explores the potential of rammed earth (RE) as a sustainable construction material by evaluating the mechanical and compositional properties of an earth-based mixture designed for structural applications.

The investigation focuses on "Casa del Thè," a pavilion built using a tailored RE mixture (Tmix), combining quarry waste-soil (Tb) and vineyard soil (Tv). Comprehensive geotechnical (Atterberg Limits, Specific Gravity, Granulometry) and chemical and materials characterizations (ATR-FTIR, TGA, XRD, XRF) characterized the constituents. Optimal water content for compaction was determined using Standard Proctor tests, for both Tb and Tmix, followed by UCS tests to compare their mechanical behaviors. To evaluate the compressive strength (UCS) of the mixture, cylindrical samples were made at the construction site. The mixture was then recreated in the laboratory using the same ratios to ensure better control over the preparation methodology.

A granulometric optimization was achieved computationally by blending Tb with other soils to approximate an ideal grain size distribution for RE, resulting in an optimized mixture with an average UCS of 0.99 MPa.

Results indicated that while the initial Tmix yielded a UCS of 1.67 MPa, the optimized mixture demonstrated a slight UCS reduction, highlighting a trade-off between granulometric refinement and compressive strength.

Comparative analysis of on-site and lab-prepared samples revealed that Tb and Tmix achieved UCS values of 1.44 MPa and 1.24 MPa, respectively, underscoring the influence of preparation methods on material performance. Overall, the findings suggest that with targeted adjustments in soil composition and compaction, rammed earth can be effectively adapted for broader, sustainable structural applications.

Paper 920 4 **Recent advances in microencapsulated phase change materials for energy-efficient buildings**
Mrs. Andrea Isabel Bardales-Cortés, Honduras
Oral Presentation (20')

Abstract

Phase Change Materials (PCMs) has been recognized for their ability to release as well as store the substantial heat in response to variation in ambient temperature which provides an innovative solution for enhancing thermal regulation in building design. Although the recent literature is more focused on the incorporation of the microencapsulated phase change materials (MPCMs) into various building materials. This review will thoroughly categorize the recent advances in the MPCMs based on their material composition and phase change characteristics, offering a brief overview of their diverse applications in building thermal regulation. Initially, different types of MPCMs will be discussed which is followed by synthesis techniques and their simulation using multiple softwares like EnergyPlus, TRNSYS, and ANSYS Fluent etc. The pros and cons of different PCMs will also be overviewed and compared to each other. Moreover, it compiles the study on the MPCMs into building materials like roofs, walls, paints, floors, cement, bricks, and windows. This review will also address the gaps in between the existing research work. In summary, this work highlights the recent advancements and offers valuable insights into MPCM applications across various building components, providing as a key resource for scientists, engineers, and professionals in academia and industries.

Paper 319 5 **Assessment of earthen soil binder for 3DP**
Prof. Muammer Koc, Qatar
Oral Presentation (20')

Abstract

The use of earthen soil-based materials for 3D printing (3DP) has emerged as a promising avenue in the pursuit of sustainable construction practices. This study presents a comprehensive review of existing literature on the application of earthen soil in 3DP, focusing on its challenges, potential, and opportunities within the framework of a circular economy. Earthen soil, being abundant and locally available in most regions, offers immense potential as a low-cost, eco-friendly material for additive manufacturing in construction. The review examines different aspects of earthen soil for 3DP, including material formulation, rheological properties, structural performance, and the influence of natural additives such as fibers and nanoclay. Key challenges such as shrinkage, cracking, and limited strength are discussed, alongside innovations in material modification and process optimization to overcome these limitations. Additionally, the study highlights the potential for integrating earthen soil-based materials into sustainable construction practices, reducing resource extraction and minimizing waste generation. This work aims to provide insights into the opportunities for leveraging earthen soil in advancing 3D printing technologies for construction, emphasizing its role in creating low-carbon, resource-efficient, and locally adaptive solutions.

Development of Hemp insulation Biopanel with Tannin-Based Adhesives: A Sustainable Solution for Green Construction

Mr. Juan Carlos Guerrero Ramos, Spain

Oral Presentation (20')

Abstract

The European SNUG project has among its objectives developing innovative solutions for manufacturing sustainable materials, with a particular focus on the construction and habitat industries. A key breakthrough of the project is the creation of hemp-based biopanel using tannin-based adhesives, designed to replace traditional materials derived from non-renewable and highly polluting sources. The tannins-based adhesive is developed by CHIMAR, production protocols and material characterization are handled by AIDIMME and KEAS scale up to a industrial level the bio-panels.

Tannins, natural phenolic compounds found in various plant species, have been explored as a potential alternative to the ingredients of synthetic adhesive formulations, that are traditionally used in construction materials. The tannin-based resins developed by CHIMAR are formaldehyde-free and exhibit excellent bonding capabilities with various biomasses, including hemp, making them ideal for particleboard production. These resins provide a biodegradable, non-toxic solution that aligns with the principles of sustainability.

Hemp, a renewable natural resource with exceptional mechanical properties, serves as an ideal material for manufacturing insulating panels. The use of hemp shives as a substitute for wood in bio-panels enhances both the mechanical properties and sustainability of the resulting boards.

The bio-based tannin adhesives not only enhance the mechanical performance of hemp panels but also ensure a high level of sustainability, offering a greener adhesive solution for a wide range of industrial applications.

AIDIMME has researched tannin-based adhesives and hemp shives formulations, determining the best resin-to-fiber ratios for panel production. Their findings suggest 10–12% resin concentration for optimal performance.

AIDIMME have also assessed fire reaction, mechanical, durability and sustainability properties. Additionally, a Life Cycle Analysis is underway to compare the environmental impact of these bio-panels to conventional synthetic materials.

KEAS leverages the lower bulk density of hemp shives, a byproduct of the textile industry, to create boards with better insulation. This approach supports industrial symbiosis and involves KEAS adjusting the industrial production lines to incorporate hemp as a wood substitute.

Preliminary findings show that hemp bio-panels with tannin-based adhesives not only provide a sustainable alternative but also match or surpass conventional materials like wood panels and petrochemical composites. These advantages make hemp bio-panels a viable choice for eco-friendly buildings, supporting circular economy principles. This

Paper 2013 1 **The scaling and use of solid sorbents for decarbonisation of industrial CO₂ emitters**
Prof. Edward Lester, United Kingdom
Oral Presentation (20')

Abstract

The road to decarbonisation is perhaps facing a turbulent future, particularly in the short term. Despite the absence of a unified approach to reducing carbon, Europe continues to be a leader in this transition, and has moved from 80% reduction targets in greenhouse gas emissions by 2050 to a Net Zero target. Many other countries have similar targets. Metal organic frameworks (MOFs) represent a next generation route to sequestering CO₂ from flue gas, with the greatest chance of reducing the energy penalty to the operator. Currently, amine-based technologies are being deployed, though the environmental concerns and high regeneration energy usage show the overall inefficiency of these materials.

There are many researchers around the world making MOFs in batch and flow. At present, scale of production tends to be quite low i.e. grams to 10's or 100's of grams, which has not helped in the 'take up' of the new and exciting material. Through the use of novel continuous mixing reactors, we have been able to take grams per hour to kg's per hour to tons per hour production rates. The paper will explain this road to scale up from our initial paper on continuous flow synthesis in 20121. Each MOF requires a different approach to synthesis, but many can be manufactured hydrothermally.

Promethean Particles has a 1000tn/year production plant in Nottingham and is planning significantly larger production in the next few years.

Beyond the manufacture of MOFs, there is still work to be done around MOF performance, particularly at higher TRL levels. Those seeking to use MOFs for CO₂ sequestering generally investigate selectivity, uptake kinetics and capacity i.e. the ability of the MOF in question to selectively remove CO₂, the rate of gas uptake into the MOF structure and the overall CO₂ wt% uptake, respectively. These are all important characteristics but the practical application of MOFs in industrial systems will require much more work. This paper will also detail some of these areas e.g. Life-Cycle Assessment (LCA) is a tool allowing for a complete cradle-to-cradle overview of a product's life-cycle, using real-world data to inform computer models of the processes involved in manufacturing, using, disposing and recycling materials. We carried out LCA on a particular MOF, to identify the areas of high environmental impact, and to evaluate changes that could reduce these. This paper will present LCA data as well as an appraisal of potential for recycling approaches.

Paper 520 3 **High-cell-density strategies to maximise bacterial production of biopolymers from real by-products**
Dr. Federico Cerrone, Ireland
Oral Presentation (20')

Abstract

Polyhydroxyalkanoates (PHAs) are biological polyesters synthesised by bacteria and viewed as a replacement for petrochemical plastic in many different applications. However, they suffer from suboptimal thermal and mechanical properties. An improvement in their material properties (for example: flexibility, crystallinity and toughness) is obtained when the microbial biosynthesis of PHA can produce a variety of carbon lengths in the PHA sidechains. This can be tailored depending on both the fed carbon source and the choice of microorganism. An economically viable and circular approach where the chemical structure of these biopolymers is tailored by using a variety of chemically related precursors to PHA and where these precursors are coming from real world by-products can expand the potential applications of these polymers and improve their material properties. A mathematical modelling approach targeting high-cell density (HCD) cultivation is paramount if one wants to increase yields and volumetric productivities of the bioprocess. Using real world by-products (dairy side-stream feedstocks, grass treatment by-products and waste-originated fatty acids) we cultivated a range of bacterial PHA producers using a bioreactor-based approach aiming at a HCD cultivation. Pulse-feed cultivations of *Burkholderia sacchari* IPT101 using a dairy-side stream as the sole carbon source produced a bacterial biomass of 120 g/L (as cell dry weight, CDW) with 25% of polyhydroxybutyrate (PHB). Individual fed-batch cultivations of *Pseudomonas putida* CA3, *Pseudomonas chlororaphis* IMD555 and *Burkholderia sacchari* IPT101 using a by-product of grass treatment as the main carbon source and fatty acids by-products as PHA inducers produced microbial biomass up to 90, 37 and 44.5 g/L of CDW, respectively containing 33%, 65% and 10% of PHA, respectively (Cerrone et al. 2014, Cerrone et al 2015). Fed-batch cultivation of *Pseudomonas umsongensis* GO16 using a mixture of fatty acids (by-products from a specialty chemical-producing company) as a unique carbon source produced a blend of short chain length (scl) and medium chain length (mcl)-PHA up to 25 g/L of CDW with 55% of PHA (Cerrone et al. 2023). This last bacterial strain is the only known strain capable of producing blends of scl-PHA and mcl-PHA, manufacturing therefore natural biocomposites.

Development of mycelium-based composite materials through valorization of agro-industrial wastes

Mr. Muhammad Bilal Saeed, Italy

Oral Presentation (20')

Abstract

Global environmental awareness and strict legislation are currently driving research towards the implementation of sustainable and environmentally friendly processes, aiming also to minimize dependence on non-renewable resources in line with the principles of the circular economy. Mycelium-based materials have emerged as natural and sustainable alternatives to conventional synthetic plastics. Valorization of agro-industrial residues as alternative nutrient sources for mycelia/fungi growth meets multiple sustainability objectives, minimizing both the environmental pollution from waste disposal and the final production cost of materials.

Walnut shells, a zero-value agro-industrial lignocellulosic by-product generated in thousands of tons from walnut processing industries worldwide, could be a sustainable feedstock to produce mycelium-based composites. The present study focuses on the valorization of walnut shells through the cultivation of different basidiomycete fungi (mushroom-producing fungi) for the development of 3D mycelium-based materials. Our results provide insights into the morphological, physicochemical and mechanical properties of 3D mycelium-based composite materials relevant to various engineering applications. These materials exhibit good mechanical strength, hydrophobic properties and thermal stability, offering a promising, sustainable light-weight alternative to conventional plastics, with low energy consumption. Additionally, the mycelium-based composites showed enhanced oil removal from different emulsions with a wide range of oil content. Our findings will help in the development of eco-friendly and durable mycelium-based composites alternatives to conventional synthetic plastics and composites that are non-biodegradable, high in emissions and costly.

Direct chemical conversion of *Pleurotus ostreatus* whole mycelium into biodegradable films

Ph.D. Ala Eddine Fares Merisani, Italy

Oral Presentation (20')

Abstract

The indiscriminate use of petroleum-based plastics for single-use food packaging has caused serious environmental issues due to their non-biodegradable nature. Consequently, there has been growing interest in developing new bio-based and biodegradable materials, especially for the specific application. Fungal biomass represents an abundant and inexpensive source of biopolymers with excellent potential for sustainable materials. However, tailoring fungal biomass into materials with specific properties requires precise control over the manufacturing process. This research project adopted a green chemistry approach to develop new sustainable biobased materials, adhering to the principles of zero waste and circular economy. Raw mycelium biomass (*Pleurotus ostreatus*) was directly converted into eco-friendly materials using low-energy, non-toxic, and cost-effective, water-based alkaline treatments. To adapt these materials for food packaging, processing conditions, such as solution incubation time, and glycerol plasticizer content were systematically varied. The morphological and physicochemical properties of the resulting materials were investigated, as well as their mechanical properties and water vapor permeability. Crucially, the research also assessed the migration of material components into food simulants and the biodegradability of the developed films, essential for safe and environmentally sustainable food packaging. This work provides a comprehensive analysis of the relationship between the alkaline treatment duration and plasticizer content on the mechanical performance of mycelium-derived films. The resulting films exhibited promising mechanical properties, surpassing those of previously developed mycelium-derived films, making them suitable for food packaging applications. These findings offer a valuable new approach to developing mycelium-based materials through green chemical methods and represent a significant step towards a sustainable future in food packaging.

Vegetable oils as source of building blocks for high added value materials

Dr. Giovanni Perotto, Italy

Oral Presentation (20')

Abstract

The valorization of biomass into high added value applications require the development of enabling technologies that can transform these biomass into materials with desirable performances. Here, I will show how byproducts of vegetable oil can be transformed into interesting building blocks for the synthesis of new materials. Coatings for sustainable leather, plasticizers for bioplastics and foams are only few examples of materials that can be made out of these building blocks.

The valorization method is based on trans esterification of the triglycerides and epoxidation of the insaturations in the fatty acid, to create a library of building blocks with different functionalities.

The applications that I will present, show how biobased materials, when engineered together, can be a credible alternative for high performance materials. Foams can be created using only oils and vegetable biomass. Oil-based coating can provide excellent water resistance to leather and cotton, without changing the breathability, flexibility and the microstructure of the substrate. Biobased plasticizers can facilitate the processing of bioplastics. These high performing materials synthesized from waste and byproducts are an example of circular economy in material enabled by green chemistry.

COPPER AND ZINC REMOVAL BY BIOCHAR-BASED MATERIALS

Dr. Marianna Guagliano, Italy

Oral Presentation (20')

Abstract

The use of zinc oxide (ZnO) and copper (Cu) salts in livestock farming, particularly in monogastric animals, has contributed over the past thirty years to environmental issues such as eutrophication. Despite zinc and copper are essential elements in the animal's diet, these feed additives are mainly excreted in the animal's feces, resulting in their accumulation in the ecosystem. Various approaches can be employed to prevent high accumulation levels of Zn and Cu, among which adsorption is one of the simplest and most environment-friendly methods for pollutant capture. In this scenario, biochar is the residual carbonaceous by-product generated by the thermochemical conversion - gasification and pyrolysis processes - that is emerging as a circular and sustainable sorbent material, due to its physico-chemical properties. Biochar is known to contribute to the mitigation of climate change, specifically in the CO₂ capture as recalcitrant carbon stable for hundreds of years.

In this study, biochar obtained by chestnut waste has been studied as potential sorbent for copper and zinc in simulated conditions. Six different biochars, generated by both pyrolysis and gasification at BEElab (Università di Modena e Reggio Emilia, Italy), were tested for metals capture at different initial metals concentrations (3.3 mM – 100 mM). A maximum metal's capture of 99% and 53% was found for copper and zinc, respectively. The biochar obtained by gasification process emerged as the most effective sorbent for the metals' removal, probably due to its textural, morphological and physico-chemical characteristics; namely, in terms of surface area and porosity.

Moreover, biochar was immobilized in 3-D structured materials in cooperation with Opigeo S.r.l (Grisignano di Zocco, Vicenza) to move towards industrial application, and to overcome the limits connected with the use of biochar in powder form. Preliminary batch tests with simulated copper solution showed a metal capture efficiency in the range of 14 -44% when an initial copper solution 100 mM was applied.

Advancing the Future of High-Performance Materials: Bio-Based Epoxy Resins for Sustainable Innovations

Prof. Alice Mija, France

Oral Presentation (20')

Abstract

Extensively employed in aerospace, automotive, construction, and renewable energy, traditional epoxy resins are burdened by a reliance on bisphenol A (BPA)—a hazardous petrochemical—along with non-recyclability and minimal bio-based content. Recent innovations have sought to resolve these issues by developing cutting-edge materials combining environmental sustainability with exceptional thermomechanical properties. Our recent work focused on the development of >140 formulations of bio-based epoxy resins (1–4) with a bio-renewable content from 86% to 99% while exceeding the performance benchmarks of conventional materials. The resins boast impressive thermomechanical characteristics: storage moduli ~2.1 and 3.7 GPa, Young's moduli from 0.6 to 1.5 GPa, and glass transition ranging from 110 to 220 °C. Additionally, they exhibit thermal stability > 300 °C and minimal water absorption (0–0.5%). Free from BPA, compliant with green chemistry principles and REACH regulations, these resins align with stringent safety and sustainability standards. When reinforced with carbon or vegetable fibers, these bio-based resins enable the creation of composite materials with remarkable properties (5,6). The composites show storage moduli ~ 43 GPa and compressive strengths ~ 400 MPa. Their interlaminar shear strength, ~ 63 MPa, shows strong fiber-matrix adhesion, confirmed by SEM. These materials support the principles of circular economy through their Recyclable, Repairable, and Reshapable properties. Sectors as aerospace, renewable energy, and automotive manufacturing stand to benefit from these innovations, which reduce reliance on fossil fuels, cut greenhouse gas emissions, and offer sustainable end-of-life solutions.

Ionic liquids for biopolymer dissolution and regenerated fiber spinning

Prof. Wenwen Fang, Germany

Oral Presentation (20')

Abstract

Biopolymers derived from renewable resources are gaining attention for their sustainability and potential to replace synthetic materials in various applications. However, the natural forms in which these biopolymers exist—often in highly organized, crystalline, or fibrous structures—present significant challenges in processing. For example, cellulose in plant cell wall forms a highly packed, crystalline structure, making it challenging to be dissolved or extracted using conventional solvents.

In recent years, ionic liquids (ILs), particularly super base-based ILs, have emerged as promising solvents for the dissolution and processing of biopolymers. The ILs can disrupt the hydrogen bonding in biopolymers and facilitate the dissolution. In this work, we present our recent developments in using super base-based ionic liquids for the dissolution of cellulose and proteins extracted from biomass and waste streams, with a particular focus on fiber spinning and the production of sustainable textiles. The biopolymer dopes, prepared by dissolving cellulose and proteins in these ionic liquids, provide a pathway for high-performance fiber production with customizable properties. One application is the incorporation of functional particles during the dope preparation step to produce fibers with tailored functionalities, such as UV sensing, which can be integrated into smart textiles.

Additionally, we explore the production of hybrid fibers by blending cellulose with keratin, extracted from waste wool textiles. Keratin, by itself, lacks sufficient mechanical strength to form fibers. However, by dissolving keratin alongside cellulose, we achieve a spinnable hybrid dope. The resulting hybrid fibers exhibit high mechanical strength derived from cellulose and improved hydrophobicity from the keratin, highlighting the potential of biopolymer-based textiles in high-performance applications. This approach also contributes to reducing the reliance on synthetic polymers and promoting a circular economy by utilizing waste-derived resources.

Despite the advantages of super base-based ionic liquids, challenges remain in their application, including their susceptibility to hydrothermal hydrolysis during recycling and sensitivity to moisture during dissolution process. To address these issues, we have explored various cations and anions to improve the stability and recyclability of the ionic liquids.

This work presents a promising approach to overcoming the challenges in biopolymer processing and highlights the potential of ionic liquids in the development of sustainable, functional textile fibers, contributing to a circular economy.

Biobased Antioxidants: A sustainable solution to thermomechanical degradation of recycled polypropylene

Mr. Jeevan Joseph, Sweden

Oral Presentation (20')

Abstract

The increase in environmental concern and the regulatory restrictions on synthetic additives in plastics have steered the need for sustainable alternatives. Many conventional antioxidants effectively protect plastics from thermo-oxidative degradation but raise concerns due to their potential toxicity, migration into food contact materials, and poor biodegradability. To address these challenges, this study explores the possibility of using benign bio-based materials as antioxidants in recycled polypropylene. Natural compounds such as clove oil, quercetin, tocopherol, and their combination (quercetin and tocopherol) were evaluated to determine their potential ability to replace the synthetic antioxidants. Their interaction with secondary antioxidants is also studied. The objective is to assess their ability to enhance thermal stability, ultraviolet degradation, oxidative resistance, and mechanical properties of recycled PP under oxidative and weathering conditions.

The results demonstrate that all tested antioxidants improved the thermal and oxidative stability of recycled PP compared to the unstabilized recycled PP. Thermogravimetric analysis (TGA) revealed enhanced thermal resistance, with oxygen induction time (OIT) and oxidative onset temperature (OOT) data confirming significant antioxidant activity, particularly for the quercetin and tocopherol combination, which exhibited a synergistic effect. The OIT values increased to 80 minutes under an oxygen atmosphere at 200°C. OOT values for quercetin and quercetin-tocopherol combination showed higher values, 258°C and 268°C, respectively. UV aging tests highlighted the ability of the antioxidants to mitigate degradation induced by UV light and moisture, with quercetin and its combination with tocopherol providing the most pronounced long-term stabilization. Mechanical testing of aged and unaged samples indicated that biobased combinations effectively maintained tensile and impact properties. Clove oil, although showing moderate stabilization effects, presents a promising bio-based option due to its ease of incorporation into the polymer matrix.

Among all formulations, the quercetin-tocopherol combination displayed superior overall performance, achieving an optimal balance between thermal stability, oxidative resistance, and retention of mechanical properties after aging. The findings contribute to advancing environmentally friendly solutions in polymer stabilization, reducing reliance on conventional synthetic additives.

Synthesis of lignin-based resin using epoxidized cross-linkers from bio-sources.

Dr. Gloria Romero Vega, Italy

Oral Presentation (20')

Abstract

Epoxy resins are an important class of thermosetting polymers, representing 70% of the total polymeric resin market. One of the main fossil-based aromatic monomers used for their synthesis is bis(4-hydroxyphenylene)-2, 2-propane, also known as bisphenol A (BPA). Still, this compound is toxic to human health and the environment.

For replacing BPA, a promising natural solution is lignin due to its aromatic structure, making it an attractive natural replacement for aromatic monomers. Lignin is the most abundant aromatic biopolymer present in nature and is a highly available byproduct from pulp and paper industries.

Extracted lignin has a variety of chemical structures that depend on the extraction method and the plant source, strongly impacting the mechanical properties, solubility, thermal stability, and reactivity. There are some methods, such as lignin fractionation or chemical modifications (i.e., epoxidation), which help to increase lignin reactivity and obtain a less dispersed structure with more homogeneous and reproducible properties but reduce the potential of lignin in sustainable bio-based materials because of the use of organic solvents and the increase of the processing steps. Furthermore, fractionated lignin is not commercially available on an industrial scale. More sustainable approaches are based on reactive melt processing of technical lignin without any purification steps before or after the chemical modification. Moreover, most lignin-based resins use non-renewable cross-linkers, increasing the negative impacts on the environment.

In the literature, some studies used bio-based cross-linkers in lignin-based resins, but the lignin must be modified to increase the epoxy content.

This work proposes a new strategy to produce fully bio-based epoxy resins that improve the sustainability of the final product by valorizing unmodified technical lignin and exploiting its natural advantages in combination with non-toxic bio-based epoxidized cross-linkers.

Influence of processing methods on the crack resistance for a polypropylene/recyclate blend and the virgin material

Mrs. Carina Maurer, Austria

Oral Presentation (20')

Abstract

In recent years, there has been a growing trend toward processing more recyclates and producing blends of virgin materials with recyclates for new products. Recyclates' properties depend on the feedstock, the treatment, and subsequent processing. Each additional processing step not only raises costs but also increases the thermal and/or mechanical stress on the materials. In industrial practices, pure materials are usually blended with recyclates in a single extrusion process to avoid the need for additional compounding. However, improving the mixing quality, which is particularly important when working with recycled materials, is usually achieved by pre-compounding the material before extrusion. As a result, understanding the effects of both processing methods is highly relevant.

This study investigates how different processing methods, such as direct extrusion and compounding, affect the short-term properties and crack resistance of virgin polypropylene (PP), recycled PP, and a blend consisting of 90% virgin PP and 10% recycled material. To assess the impact of various processing histories, all three materials were either extruded once, extruded twice, or compounded, resulting in nine different thermal and mechanical histories.

For the subsequent determination of the mechanical parameters (tensile test, Charpy impact test) and crack resistance using CRB tests, compression-molded sheets were produced. In addition, the MFR values were also measured to receive an overview of the rheological properties of the materials. This allows the influence of the higher thermal and shear stress caused by the twin screw and the second extrusion process to be measured. It was found that the manufacturing methods had no significant influence on Young's modulus, yield stress, or impact strength of the blends. In contrast, the notched impact strength and crack resistance were notably affected, which could have a significant impact on product performance.

Ecotechnology applied to the manufacturing of ecological material by biomineralization processes with the *Sporosarcina pasteurii* bacteria

Dr. Angela Ruiz Plaza, Spain

Oral Presentation (20')

Abstract

The integration of microorganisms into the manufacturing of biomaterials represents an innovative advance in sustainable construction. This study explores the potential of regenerative biotechnology applied to architecture, with a particular focus on the use of the *Sporosarcina pasteurii* bacteria to solidify granulated materials and produce resistant structures through 3D printing. This technique not only reduces environmental impact by minimizing energy consumption, but also aligns with the principles of the circular economy by transforming organic waste into valuable resources.

The cement industry is responsible for approximately 8% of global carbon dioxide (CO₂) emissions, being one of the main sources of greenhouse gases. This problem has driven the development of innovative and sustainable solutions in the construction field. In this context, the use of the *Sporosarcina pasteurii* bacteria represents a promising alternative. This bacteria has the ability to induce biomineralization by precipitating calcium carbonate, a process that allows granular materials to be solidified in a sustainable way, without the need for traditional chemical binders and with a considerable decrease in energy use.

This project combines biotechnology and 3D printing to manufacture biocemented tiles. The methodology is structured in several phases: (1) cultivation and optimization of the growth of *Sporosarcina pasteurii* under controlled conditions; (2) design and manufacture of plastic matrices by 3D printing, using CAD software to obtain precise structures; (3) preparation and inoculation of the matrices with bacteria to promote the biomineralization process; and (4) characterization of the tiles obtained using physical-chemical analysis techniques and mechanical tests to evaluate resistance and durability.

From an economic perspective, the production of these biomaterials presents reduced costs compared to conventional materials, particularly on a large scale. Their application in extreme environments, such as the desert or even Mars, could facilitate autonomous construction through 3D printing with in situ materials.

From M.A.R.T.E. (Microbiology and Regenerative and Techno-Ecological Architecture) research group we lead this emerging field, exploring new possibilities for the integration of biotechnology and sustainable architecture. The implementation of these advances in the construction industry could mark the beginning of a new era in materials manufacturing, promoting innovative and environmentally responsible solutions.

Preliminary results show that this technology not only reduces the environmental impact of construction materials, but also allows the incorporation of pigmenting bacteria to provide aesthetic value. This innovation has the potential to transform the industry, reducing the use of non-renewable resources and promoting more sustainable construction practices.

Paper 2055 1 **Damage nature in metallic material during very high cycle fatigue**

Prof. Guocai Chai, Sweden

Keynote (Oral Presentation 40')

Abstract

The primary cause for material damage under cyclic loading has been considered to be intimately related to plastic deformation irreversibility. Intrusion and extrusion of persistent slip bands (PSB) formed at the surface cause fatigue crack initiation (stage I) and then crack propagation follows (long crack propagation, stage II). For fatigue in a very high cycle regime ($> 10^7$ cycles), surface damage becomes negligibly small due to low stress amplitude. Crack initiation may shift from surface to subsurface with increasing fatigue life or decreasing applied stress. Fatigue crack initiation starts at subsurface defects such as inclusions, pores, and microstructure inhomogeneities by stress localization or concentration. Based on the recent results, this work will provide a review or discussion on fatigue damage and crack initiation in polycrystalline metallic materials without any defect as mentioned. They include the following four processes: formation of stress/strain localization; formation of dislocation sub-cells and grain fragmentation; fully grain fragmentation; fatigue crack initiation. During cyclic loading, the soft grains with larger Schmid factors can undergo higher plastic strain amplitude in the crystal plane. This results in strain localization and formation of dislocation sub-cells and grain fragmentation in the grains. Very high cycle fatigue will also result in exhaustion of local plasticity and consequently lead to crack initiation in the matrix. They start mainly at grain boundaries or triple junction points. Once a critical size (crack origin or FGA) has formed or the crack length has reached a threshold value (or stress intensity factor threshold), the stage II crack propagation will occur. This work can increase our understanding on the material nature for fatigue damage and crack initiation during very high cycle fatigue.

Paper 916 2 **Fatigue strength enhancement of welded steel through residual stress tailoring by electrodeposition of a Cu/Ni multilayer thin film**
Mr. Niclas Spalek, Germany
Oral Presentation (20')

Abstract

The integrity and longevity of industrial structures heavily depend on the performance of their connections. This is especially relevant for welded joints in civil engineering, where, despite their widespread use and importance, they present significant implications related to permanence. The geometry of welds and the inherent metallurgical changes occurring within the heat-affected zone predispose these areas to premature failure under cyclic loading, leading to a reduced lifespan compared to the surrounding base material. Moderating the effects of fatigue results in increase of material usage, which raises weight, handling difficulties and sustainability concerns. Methods of post-weld treatments increase the usable lifetime of welded structures by changing its geometry or the residual stress states in the surface to postpone crack initiation and propagation. Here, a novel post-weld treatment is investigated, which enables the tailoring of the residual stress states in the surface proximity by deposition of a Cu/Ni nano-structured multilayer onto the weld and its surroundings. Energy dispersive X-ray diffraction experiments across the depth on a variety of electrodeposition process conditions are conducted, thereby gaining insights into the change of residual stresses in the heat affected zone and base material. Across all process parameter sets, the superficial residual stresses are transformed to be compressive in nature, resulting from strain equilibration between the tensile residual stresses in the 10µm thin film and the steel substrate. Subsequent fatigue testing is conducted to correlate the tailored residual stress data to the lifetime enhancement of the welded specimen. The results indicate, that a dramatic increase in cycle numbers with a decrease in the slope of the S/N curve is achieved, yielding to a multifold increase in the usable lifetime of welded components. For the design process of welded structures, FAT classes above 200 are proposed, far exceeding the fatigue strength of the base material.

Paper 960 **4** **Microcrack initiation of a second-generation nickel-based single crystal superalloy during thermal fatigue**
Mr. KUO YIN, China
Oral Presentation (20')

Abstract

Ni-based single crystal superalloys consisting of γ/γ' microstructure are widely used in the turbine blades of aero-engines due to their extraordinary high-temperature mechanical properties. Compressive and tensile stresses induced by the thermal cycle are inevitable and may lead to crack formation during the service of the turbine blade. However, how these cracks nucleated is still unclear. In this work, the nucleation process was simulated and investigated by performing a thermal fatigue test (ranging from room temperature to 1100 °C) on a second-generation Ni-based single crystal superalloy. The results show that the γ/γ' microstructure in both dendritic and interdendritic regions almost remains unchanged during thermal fatigue. In contrast, the micropores were mainly observed in the interdendritic region. Their volume fraction and equivalent diameter increase with the increase of thermal fatigue cycles, while the sphericity shows an opposite trend and transforms from the spherical shape to the irregular morphology. Meanwhile, the kernel average misorientation (KAM) map analysis indicates a stress concentration around the micropores. A high density of dislocations was observed at the γ/γ' interface, and some of them even sheared into the γ' precipitates to form low-angle grain boundaries around the micropores. These low-angle grain boundaries were subsequently transformed into high-angle grain boundaries due to crystal rotation along with the local intense plastic deformation during thermal fatigue. Thus leading to the local recrystallization near the micropores. The area of the recrystallized region increases as thermal fatigue proceeds, contributing to the microcracks nucleation at the grain boundaries near the interdendritic micropores. The local recrystallization and microcracks nucleation were closely related to the equivalent diameter and shape of micropores. The quantitative analysis indicates that the recrystallization-associated micropores were larger than 20 μm in equivalent diameter and less than 0.4 in sphericity, while the microcrack-associated micropores exhibited a larger equivalent diameter and lower sphericity. This study will be helpful in understanding the microcracks initiation of Ni-based single crystal superalloys during thermal fatigue and improvement of process control of turbine blade production.

Paper 1027 5 **Low Cycle Fatigue of High Manganese Steel with Variable Microstructure Processed by Laser Powder Bed Fusion**
Mr. Alfred Muchangi, Czech Republic
Oral Presentation (20')

Abstract In this study, the low cycle fatigue behaviour of a high manganese steel X30Mn22 was investigated in several microstructural variants featuring different predominant crystallographic orientations. Metastable austenitic solidification structure of studied material underwent strain-induced martensitic transformation which is crystallographic orientation-dependent. Therefore, the studied types of structures, {011}- and {111}-textured, and without predominant texture, showed different cyclic behaviour characterized by various magnitude of cyclic hardening. Notable variations in fatigue lifetime were found also with respect to the type of microstructure. To explain underlying deformation mechanisms a detailed SEM characterization was carried out on initial microstructures, surface relief after cyclic loading, and internal deformation structures. Localization of cyclic plastic deformation resulted in martensitic transformation via γ (FCC) $\rightarrow \epsilon$ (HCP) $\rightarrow \alpha'$ (BCC) sequence, which was identified in all microstructural variants. These processes created a distinct surface relief which induced fatigue crack initiation and promoted fatigue crack propagation.

Paper 733 6 **Surface inspection to detect early fatigue crack initiation in low cycle fatigue regime of high carbon steel using a scattered light sensor**
Mr. Phanuphak Seensattayawong, Germany
Oral Presentation (20')

Abstract Fatigue damage is the major factor in the failure of components. During the fatigue loading, the local plastic strain deformation is formed as persistent slip bands (PSBs) and emerges on the surface as persistent slip markings (PSMs). The PSM can develop roughness and be observed on the surface as extrusions and intrusions. The intrusions are possible sites of crack initiation. Thus, surface roughness development is a reasonable way to inspect fatigue damage. Many techniques were utilized to inspect and monitor the cracks and fatigue damage to protect the components and predict the remaining lifetime. Most of these techniques consume a lot of measuring time. In this study, a scattered light sensor from Optosurf will be performed to measure and determine the roughness evolution during cyclic loading of a high-strength steel 115CrV3. As a result, the profile measurement, areal measurement, and the derived Aq values are suitable to illustrate severe surface changes before failure. Moreover, the Aq values using a scattered light sensor are comparable with the results using a confocal microscope (Nanofocus).

Effect of Surface treatment on Residual Stress distribution and mechanical properties of Butt-Welded S45C Joints

Mrs. Cho Yunji, South Korea

Oral Presentation (20')

Abstract

Residual stress generated during the welding of automotive components significantly affects their fatigue life and fatigue crack growth. Welding defects and residual stress can lead to crack initiation in the welded joint, ultimately resulting in failure. To address this issue, this study aims to control residual stress in welded joints and evaluate its impact on mechanical performance.

In this research, laser peening was selected as a surface treatment method to introduce compressive residual stress and improve the fatigue life of butt-welded S45C medium-carbon steel. The residual stress distribution before and after surface treatment was measured and analyzed using the Contour method and X-ray diffraction (XRD) method.

To evaluate the effect of compressive residual stress on mechanical performance, tensile and fatigue tests were conducted before and after the surface treatment. Additionally, the microstructural changes induced by the surface treatment were analyzed to understand their influence on material properties. The results provide insights into the effectiveness of laser peening in enhancing the fatigue resistance of welded joints.

Paper 1034 1 **Premature Failure of a Coated Gas Turbine Compressor Rotor at SP Subang: A Synergistic Effect of Corrosion, Erosion, and Coating Degradation**

Dr. Sri Hastuty, Indonesia

Oral Presentation (20')

Abstract

This study investigates the premature failure of a coated gas turbine compressor (GTC) rotor at SP Subang, Indonesia, focusing on the mechanisms contributing to deposit formation, coating degradation, and subsequent rotor damage. The compressor in question utilizes a three-stage rotor-stator configuration. A key observation is the significantly shorter operational lifespan of the coated rotor (292 days) compared to its uncoated predecessor (606 days), suggesting that the coating, intended to enhance durability, may have inadvertently contributed to the accelerated failure. Analysis of deposits collected from the rotor blade leading edges revealed the presence of iron carbonate (FeCO_3) and iron hydroxide ($\text{FeO}(\text{OH})$), indicating a corrosion process driven by the presence of water and CO_2 . Laboratory analysis of the inlet gas stream confirmed exceptionally high levels of both water (167 lb/mm scf) and CO_2 (23.16–33.30 % mol), significantly exceeding the NORSOK P-001 standard of 13.3 L/mm scf (~29.3 lb/mm scf) for water content. These elevated levels promote the formation of carbonate ions, which are highly corrosive to steel components. Furthermore, the presence of silica (sand) particles in the deposits and the observation of flow-induced scratches on the stator stage suggest erosive wear as a contributing factor. The combined action of corrosion and erosion likely exacerbated the damage to the Sermalon coating, which was found to be damaged, particularly at the rotor blade tips where the deposits were concentrated. Analysis of the soaking solutions used for turbine cleaning (Petroce and Army) revealed the presence of corrosive elements, potentially hydrochloric acid (HCl), which could have further compromised the coating integrity. The presence of iron, carbon, and oxygen in the residual particles from both the soaking solution and the suction scrubber water reinforces the formation of FeCO_3 . The study underscores the critical influence of gas composition, particularly high water and CO_2 content, on GTC rotor lifespan. It highlights the complex interplay between corrosion, erosion, and coating degradation in accelerating component failure. The findings emphasize the need for improved material selection, more effective coating strategies, and optimized cleaning procedures to mitigate these detrimental effects in gas turbine compressors operating in challenging environments like SP Subang. Further investigation into the specific mechanisms of coating failure and the synergistic effects of corrosion and erosion is recommended.

Paper 1059 2 **Effect of dynamically reconstructed microstructure on the precipitation of secondary phases and their impact on corrosion properties in a cast UNS 32760 super duplex stainless steel**
Ph.D. Mirko Pigato, Italy
Oral Presentation (20')

Abstract

This study investigates the impact of hot plastic deformation on the precipitation of secondary phases during cooling in cast UNS S32760 super duplex stainless steel (SDSS). Due to their dual-phase microstructure and chemical composition, SDSS optimally balance mechanical strength and corrosion resistance. However, thermomechanical treatments can induce the formation of intermetallic phases such as sigma (σ), chi (χ), and chromium nitrides, which may negatively affect the alloy's overall performance. To explore these effects, experimental tests were conducted to assess how the degree of deformation and strain rate influence dynamic softening mechanisms and secondary phase precipitation during cooling. The deformation was simulated using open-die forging at 1100 °C, followed by two different cooling conditions: a slow cooling rate (0.25 °C/s) and water quenching. This setup enabled the examination of ferrite decomposition under two distinct scenarios: precipitation of thermodynamically stable secondary phases at equilibrium, and the formation of nitrides due to nitrogen supersaturation of ferrite during rapid cooling. A thorough microstructural characterization, combined with phase quantification and corrosion testing, was carried out to assess the impact of these phases on mechanical integrity and corrosion resistance. The results show that hot plastic deformation significantly promotes sensitization, with a clear relationship between deformation parameters and the extent of secondary phase precipitation. Moreover, variations in strain conditions influence the dynamic reconstruction mechanisms, leading to significant changes in the kinetics of both stable and metastable intermetallic phase precipitation. This study offers new insights into the complex interactions between hot deformation, dynamic softening, and secondary phase precipitation kinetics, enhancing our understanding of their role in corrosion performance. The findings can be applied to optimize thermomechanical processing strategies, reduce the formation of detrimental phases, and improve the durability of SDSS in aggressive environments.

THE MULTISCALE NATURE OF MATERIALS DEGRADATION: USE OF ION SELECTIVE SENSORS FOR HIGH RESOLUTION IMAGING AND CHEMICAL CHARACTERIZATION

Prof. Ricardo M. Souto, Spain

Oral Presentation (20')

Abstract

The performance of metallic components is often limited by the loss of their properties due to environmentally induced degradation. Advanced research in corrosion science mainly aims for a better understanding of the surface chemical processes involved in the microscale, thus promoting the efficient and durable application of metallic materials to new societal expectations. To better control corrosion and its effects, researchers must integrate emerging advances in many areas of science and technology to understand mechanistic effects and relate them to underlying structures, compositions, and dynamics. It has long been known that corrosion processes start at micrometre or nanometre scales, although until recently no suitable techniques were available to study reactions at such scales. Additionally, surface chemical heterogeneity is frequently observed for many metallic materials, particularly when dealing with alloys or joined (galvanically coupled) metals, but this can also occur with individual metallic materials that were once mistakenly considered stable and uniform in their passive state, examples of which are stainless steels and prosthetic-quality titanium. The issue of surface inhomogeneity is even more relevant when corrosion protection methods involve the chemical modification of surfaces. Progress in corrosion research will therefore depend on the availability of experimental techniques capable of probing materials with high spatial and chemical resolution in operation. In this context, the use of scanning electrochemical microscopy (SECM) in corrosion science has been shown to be a powerful technique. However, the application of SECM to the study of corrosion reactions has been significantly slower than that for other electrochemical applications, partly because in its early stages SECM was mainly an amperometric and potentiostatic technique. Although attractive advantages were recognised in regard to performing local quantitative electrochemical experiments, the possibility of using all the electrochemical techniques on both the probe and the substrate, and the possibility of coupling in situ electrochemical measurements with other techniques, their application to corrosion systems was limited by the requirement of a redox process at the tip for imaging (feedback mode). In fact, the addition of a redox mediator to the solution for its faradaic conversion at the tip would inevitably generate a Nernst potential at the metal surface under investigation, which may significantly alter the spontaneous mixed potential state of the corrosive system, and thus produce changes in the mechanism of the process under investigation. Advances have resulted from the application of potentiometric operating modes, involving ion-selective microelectrodes as tips, as described in this contribution.

Advances in Cermets for harsh environments: Unlocking Wear and Corrosion Resistance Through Microstructure and Binder Optimization

Prof. Keke Chang, China

Oral Presentation (20')

Abstract

The performance of cermets (ceramic-metal composites) in harsh environments depends significantly on their microstructure, binder phase, and the interplay between material properties under varying conditions. This presentation explores our recent advances in the design of high-performance cermets, particularly focusing on the optimization of wear resistance and corrosion behavior. Key innovations include the development of TiC-based and WC-based cermets incorporating multi-principal element alloy binders (e.g., CoCrNi, CoFeAl) and rare-earth dopants, which enhance the toughness, wear resistance, and corrosion resistance of these materials. The research employs advanced experimental techniques, including high-temperature tribological testing and electrochemical corrosion studies, to characterize the degradation behavior of these materials under harsh conditions. Coupled with these experimental investigations, data-driven modeling and simulation approaches, including thermodynamic phase stability analysis and microstructural modeling, offer deeper insights into the mechanisms controlling wear and corrosion. The formation of oxide tribolayers, along with the role of binder composition and phase stability, is identified as key to mitigating degradation, especially in high-temperature and corrosive environments. Furthermore, a deeper understanding of the complex tribocorrosion mechanisms will be discussed, shedding light on how these insights can guide the future development of cermets for demanding industrial applications such as mining, drilling, and high-temperature machinery. The findings offer a robust framework for enhancing the durability of materials in extreme service conditions, which could pave the way for new high-performance composites.

Paper 1332 5 Slurry and cavitation erosion behavior of HVOF sprayed Metallic and Cermet Coatings

Dr. ANDERSON Marendra Pukasiewicz, Brazil

Oral Presentation (20')

Abstract

HVOF thermal spraying is a deposition process that aims to increase the service life of engineering products in various types of media, such as corrosion, abrasion, and erosion. The intended study seeks to understand the effect of the residual stresses on the cavitation and slurry wear resistance of different metallic (316L and Hastelloy C276) and composite coatings, (WC17Co, Cr3C2 25NiCr). This study aims to observe how different coating materials are affected by the stresses generated during and after deposition, which is a result of the impact of the particles and their cooling and thermal contraction process. The coatings were characterized by metallographic techniques optical and electronic microscopy, and microhardness. After surface preparation (grinding and polishing), cavitation and slurry tests were performed. It was observed that the WC and Cr3C2 coatings are more clearly influenced by stresses generated during the deposition, where a minor peening effect and formation of a tensile residual stress reduce the cavitation resistance. Two different Cr3C2 25NiCr powders were performed; agglomerate and sintered showed more sensitivity for these deposition parameters. In contrast, the metallic coatings, 316L and C276, are more affected by different deposition aspects which affect the oxidation and porosity process. 316L and C276 coatings presented lower cavitation resistance for the samples with higher oxide phase content, probably reducing the adhesion between splats. The slurry resistance of the coatings are not so sensible to the processes parameters and stresses, and are only affected by metallurgical aspects, like presence, quantity and type of the hard phase. WC17Co show better slurry resistance than other coatings.

Paper 940 6 Effect of Grain Size on Corrosion Behaviour of Rolled Pure Magnesium

Ph.D. Abhigna Kodam, India

Oral Presentation (20')

Abstract

Grain refinement is one of the most widely used processing techniques for enhancing the strength and ductility of metals and alloys. This grain size variation impacts the electrochemical characteristics of the system. Systematic research on the impact of grain size on corrosion is lacking in the existing literature. Prior studies address the impact of grain size of pure Magnesium on corrosion behaviour without separating the effect of texture and localized stresses. The impact of grain size on corrosion has been investigated using pure magnesium that has been rolled and annealed while maintaining a consistent texture. A wide range of grain sizes was considered while keeping localized stresses and texture consistent. The corrosion rate was calculated and the corrosion behaviour was studied using potentiodynamic polarisation testing, electrochemical impedance spectroscopy, and corroded surface characterization to get a broader insight into the corrosion mechanisms. It has been noted that as grain size increases, the corrosion rate increases. This study contributes to the systematic and thorough understanding of the impact of grain size on the corrosion behaviour of pure Mg.

Paper 1415 1 **Design and implementation of an in-situ electrochemical setup for fatigue testing under the influence of hydrogen charging**

Dr. Anna Sophie Jelinek, Austria

Highlight (Oral Presentation 20')

Abstract

In view of the increasing use of hydrogen in the energy industry, a comprehensive understanding of hydrogen embrittlement is essential to ensure the safety of materials under real operating conditions. The complex interplay between cyclic loading and hydrogen-induced degradation requires advanced experimental methodologies for reliable assessment.

For this purpose, an electrochemical in-situ hydrogen charging cell was integrated into a fatigue test rig to systematically investigate the influence of hydrogen on fatigue performance of metallic materials. The setup consists of a two-electrode configuration with a platinum counter electrode in a double-walled laboratory glass cell, enabling precise temperature control of the electrolyte. The soft martensitic steel 1.4313 (X3CrNiMo13-4) was selected as a model material to validate the experimental approach. Fatigue tests were carried out at a stress ratio of $R=0.1$ and a frequency of 10 Hz with varying hydrogen charging durations in a 22% NaCl solution containing 1 g/l Thiourea at 50°C. Experiments were conducted using both pre-charged samples and in-situ hydrogen charging to distinguish between general fatigue effects and those driven by hydrogen diffusion. Samples that were pre-charged failed immediately during the first cycle, indicating a purely hydrogen-induced failure. In contrast, in-situ charging reduced the number of cycles to failure compared to tests conducted in air. Hence, the fracture surfaces still exhibited significant regions of fatigue crack growth, indicating the interplay between fatigue and hydrogen-induced failure. Beyond evaluating the number of cycles to failure, the study focused on analysing fracture surfaces through scanning electron microscopy. Beside the typical fatigue characteristics (e.g. striations), the fracture surfaces showed typical features of hydrogen embrittlement, including intergranular brittle fracture with gaping grain boundaries, ductile deformed hairlines on the grain surfaces and transcrystalline 'feathered' sections, as well as quasi-cleavage fracture. These findings confirm the reliability of the developed setup, which is therefore suitable for further investigations into hydrogen-related degradation of various metals and alloys. To further elucidate the role of hydrogen in fatigue crack initiation, correlative studies employ high-resolution SEM and atom probe tomography to analyse the fracture initiation sites at the atomic scale.

Fatigue Corrosion Performance of Cast- and Chip-Based Produced AA6060 under Varied Heat Treatments

Mr. Alexandros Prospathopoulos, Greece

Oral Presentation (20')

Abstract

Over the last few decades considerable efforts have been made to cope with the energy waste in material production methods. This is aimed at the increasing sustainability level to be aligned with modern environmental, social, and economic requirements. A promising approach to overthrow this problem is the utilization of solid-state recycling route in converting aluminum machining chips directly into semi products to save time, reducing the CO2 footprint and cost-consuming experimental try-outs. This model may make the process an intriguing alternative solution due to its clear environmental benefits in the production of complex profiles.

In the present work, chips of aluminum alloy (AA6060) were subjected to compaction and then hot extrusion conducted at 500°C through porthole die, followed by various heat treatment profiles to study the resultant material fatigue corrosion behavior. The same tests were also conducted on Cast based hot extruded specimens for comparison reasons.

This alloy was submitted to fatigue corrosion tests under the conditions of $R = 0$, $f=25\text{Hz}$ and simulated sea water 3.5% NaCl corrosion solution.

Optical and scanning electron microscopy (SEM) were used to conduct detailed fractographic analysis of the micro-morphological fatigue failure features.

Comparisons were also directly made connected to materials deriving from various production routes to highlight the role of the homogenization heat treatment on the fatigue corrosion resistance. The influence of corrosion on the fatigue crack propagation was also investigated.

The findings revealed that the corrosion fatigue life of chip-based specimens was comparable to that of the cast-based specimens (conventionally produced) and that the ensuing heat treatment (homogenization) enhanced the performance of the chip-based materials and corrosion resistance.

The study concluded that (heat treatment determination control) contamination control is essential to prevent galvanic corrosion during solid-state recycling of machining chips. This work suggested that solid-state hot extruded recycling of aluminum machining chips can improve fatigue and corrosion behavior in aluminum alloys.

Effect of Pitting Corrosion on Fatigue Behaviour of a Cast, Anodized Aluminium-Silicon alloy

Mrs. Arianna Pavesi, Italy

Oral Presentation (20')

Abstract

Aluminium-Silicon (AlSi) alloys are excellent materials for the metal casting of complex-shaped automotive components, thanks to their optimal castability and strength-to-weight ratio.

During the service life, automotive components can be exposed to corrosive environments. For this reason, cast AlSi alloys are typically anodized to grow a protective, micrometric Aluminium oxide layer on their surface with an associated improvement of the corrosion resistance. However, the presence of chlorides (e.g., on-road de-icing salts and coastal air) can trigger pitting corrosion in anodized AlSi components, despite the presence of the anodic layer.

Since corrosion pits are known to play a crucial role in fatigue performance, it becomes fundamental to study the effect of pitting corrosion on the mechanical performance of cast, anodized AlSi alloys.

At this regard, the work aims at correlating the increasing exposure time to a chloride-rich environment (i.e., neutral salt spray chamber) to the fatigue life of a cast, anodized AlSi₆Mg₂-T6 (where x=7%wt and y=0.5%wt) alloy. Three batches of cast, anodized AlSi specimens are produced and placed in a neutral salt spray (NSS) chamber for 0, 480 and 1000h. The evolution of corrosion pits is monitored by means of X-ray microtomography. Then, tensile and high-cycle fatigue tests, metallography and fracture surface analyses are performed to understand the effect of pitting corrosion on the fatigue behaviour. It is demonstrated that corrosion pits nucleate within the first 480h of exposure to NSS and, as the time increases to 1000h, they increase in dimensions. Consequently, as the dimension of corrosion pits increases, the fatigue life of the cast, anodized AlSi alloy decreases. Moreover, surface fracture analysis reveals that after 1000h of NSS exposure corrosion pits become the predominant and sole nucleation site for the fatigue crack, despite the presence of casting defects (i.e., shrinkage pores and entrapped oxides) and defects in the anodic layer.

In conclusion, this work not only unveils the mechanism of corrosion pit formation in cast, anodized AlSi alloys, but also demonstrates the detrimental effect of corrosion pitting on the fatigue performance of these materials.

Paper 103 4 **Fatigue properties of nitrogen-strengthened high Cr-Ni austenitic stainless steels at 77 K**
Prof. Osamu Umezawa, Japan
Oral Presentation (20')

Abstract

The low fatigue resistance of nitrogen-strengthened austenitic steels in the high-cycle fatigue range at cryogenic temperatures is related to the subsurface crack generation. This failure mode was favored by the coarse microstructure. The high-cycle fatigue properties of 24Cr-15Ni-4Mn-0.3N and 22Cr-12Ni-4Mn-0.3N-(Nb,V), in mass%, austenitic stainless steels were examined at 77 K. Nb and V show the advantages of high strength and excellent weldability owing to grain refinement by their precipitates. The present study is concerned with obtaining a systematic understanding of the microstructure of the fatigue strength and examining its subsurface crack generation. The solution-treated and cold-groove-rolled steel bars were annealed at temperatures that controlled the partially recrystallized (PR), fine recrystallized (FR), solution-treated (ST), and grain-grown (GG) microstructures. Their average grain diameters were in the range of a few μm to hundreds μm . Uniaxial load-controlled fatigue tests were performed at 77 K with a stress ratio of $R=0.01$, using liquid nitrogen immersion. The high-cycle fatigue strength of the heat-treated materials was not directly proportional to their tensile strength, and the ratio of the fatigue strength at 10^7 cycles to the tensile strength decreased approximately from 0.8 to 0.3 in the order of PR, FR, ST, and GG. Subsurface crack initiation was detected in the lower peak stress and/or in the longer life range for all materials. In particular, ST and GG exhibited a sharp drop in fatigue strength over 10^6 cycles owing to subsurface crack initiation. Grain refinement in the microstructure predominantly resulted in a higher fatigue resistance to this mode of failure. Movable dislocations on various types of slip systems may provide less strain incompatibility at grain boundaries owing to a rather homogeneous deformation; however, improving the fatigue strength between the PR and FR was not remarkable because of the maintenance of the planar slip mode. In contrast, coarsened grains provide larger subsurface crack sizes to initiate crack propagation, resulting in a lower fatigue strength.

Paper 1672 5 Investigation of High-Temperature Fatigue and Microstructural Influences on Crack Propagation in Nickel-Based Superalloy IN718

Mr. Lars Bähren, Germany

Oral Presentation (20')

Abstract

Nickel-based superalloys such as IN718 are essential for high-temperature applications in aerospace, power generation, and oil and gas industries. These alloys are characterized by their excellent mechanical properties and corrosion resistance, primarily optimized by precipitation hardening using secondary phases such as γ' and γ'' precipitates.

The fatigue life of IN718 at elevated temperatures is significantly influenced by environmental effects and mechanisms such as dynamic embrittlement (DE) and stress assisted grain boundary oxidation (SAGBO). Experiments with varying dwell times under peak load conditions have shown that longer dwell times weaken grain boundaries and lead to a transition to time-dependent crack growth. Interrupted tests and microstructural analysis after specific load cycles provided insights into crack propagation behavior and the damage mechanisms.

The influence of grain boundary properties and precipitates on crack propagation has been investigated to better understand transgranular and intergranular cracking behavior. The role of special grain boundaries (CSL boundaries) and the positioning of precipitates in influencing crack deflection were of particular interest. A combination of imaging techniques such as light optical microscopy (LOM) and scanning electron microscopy (SEM), together with 2D and 3D electron backscatter diffraction (EBSD) were used to correlate crack path evolution with microstructural features.

This study aims to provide insights into the complex interplay between time of mechanical loading, microstructure, and fatigue mechanisms. The ultimate goal is to achieve a deeper understanding of crack behavior in IN718 under high-temperature fatigue loading, which can be used to design future optimization strategies for advanced applications.

Investigating the correlation between wear and fatigue properties of cryogenically treated high-alloyed tool steels using cyclic indentation testing

Mr. Farid Tadross, Germany

Oral Presentation (20')

Abstract

The service life of tools made from high-alloyed tool steels is determined by their wear and fatigue properties, which are influenced by the microstructure formed during thermal treatments. Conventional heat treatments, including quenching and tempering, aim to achieve a balance between strength and toughness for various applications. However, in high carbon steels, this process often results in significant amounts of retained austenite, compromising dimensional stability. To address this, cryogenic treatments at temperatures between -80 °C and -196 °C can be applied to reduce the retained austenite content. In addition, when combined with subsequent tempering, these treatments refine the carbide and martensite structure, improving both hardness and toughness.

As tools are often subjected to cyclic loading during their service life, it is essential to consider the cyclic deformation behaviour in addition to the commonly investigated properties such as hardness and toughness. However, the analysis of cyclic deformation behaviour requires extensive experimental effort, making the optimisation of cryogenic treatment parameters time consuming. As described by Kramer et al. [1], the PhyBaLCHT method, which is based on instrumented cyclic indentation testing (CIT), allows an efficient assessment of the cyclic deformation behaviour and thus offers great potential for characterising the effects of cryogenic treatments. Accordingly, previous studies [2] have shown a strong correlation between the mechanical properties obtained in CIT and the wear resistance of cryogenically treated blanking tools made of Vanadis 4E.

Consequently, the aim of this study is to develop an evaluation procedure for cryogenic treatments based on CIT. This requires a thorough understanding of the relationship between cryogenic treatment parameters, the measures obtained in CIT, and the corresponding wear and fatigue behaviour. Therefore, Vanadis 4E specimens were subjected to various cryogenic treatments and compared with conventionally heat treated specimens. Subsequently, more than 40 different heat treatment conditions were analysed using CIT. Based on these results, sufficiently different conditions were selected for broad analyses of the fatigue behaviour, the microstructure and the wear performance in blanking tests. In accordance with [2], the results confirmed a strong correlation between the fatigue strength and the wear resistance with the mechanical properties determined in CIT. Moreover, these correlations could be attributed to microstructural phenomena, in particular the differences in carbide and martensite structure. In conclusion the work presented confirms the applicability of CIT for the characterisation of cryogenically treated tools.

Paper 721 2 **Experimental quantification of the uncertainty in the mechanical properties of short fiber reinforced thermoplastics**

Mrs. Vanessa Hauschel, Germany

Oral Presentation (20')

Abstract

The injection molding process is one of the most important processing techniques for short fiber reinforced thermoplastics. This is mainly due to the fact that parts with complex geometries can be produced in large quantities at reasonable cost. However, the injection molding process influences the mechanical properties of the final part in a non-deterministic due to natural occurring uncertainties [1]. This makes reliable predictions using common simulations methods rather difficult. As the fibers dominate the mechanical behavior the influence of the injection molding process on typical fiber characteristics such as the fiber content, the aspect ratio and fiber orientation are the main cause for the occurring scatter. Additionally, the scatter in bulk material properties contributes to the resulting variability in part properties. This aspect is of particular importance for mechanically recycled polymers as the additional recycling step causes further fiber breakage [2].

Overall, it is not obvious if the scatter occurs due to slight variations of the fiber orientation or changes in fiber length during the process. Furthermore, it is also not clear to which extent the polymer matrix contributes to the scatter of the mechanical properties and whether it can be attributed to the elastic or viscous behavior of the polymer.

In order to investigate the mentioned effects experimentally, several test specimens are prepared by varying the process settings in the injection molding process. Tensile tests and dynamic mechanical analyses are conducted to analyze the scatter of the mechanical properties. Additionally, μ CT scans are carried out to verify how the injection molding process affected the fiber orientation and fiber length. To be able to quantify the material-induced uncertainties, two different batches of a post-consumer recycled material are investigated and compared to a virgin material.

Results have shown that the fiber length directly affects the fiber orientation. However, it was shown that the change of process settings in the injection molding process leads to a change in fiber length and fiber orientation as desired and the occurring scatter was successfully quantified.

HYBRID BALLISTIC HELMET MADE IN A ONE-STEP PRESSING PROCESS

MSc Góreczna-Skrzyńska Emilia, Poland

Oral Presentation (20')

Abstract

Ballistic head protection based on the composite technologies (hybrid or single-blade composite) should protect the user's head against bullets and fragments differing in the energy of the penetration. Ballistic resistance of above-mentioned protections depends on impact angle, type and velocity of the bullets and on the material system used for the processing of the helmet as well as its shape.

Developing technology of ballistic head protection is aimed at finding new high-strength materials, mainly based on ultra-high molecular weight polyethylene (UHMWPE) fibres, reducing the mass of the final product while increasing its ballistic protection. The idea of the study was based on the thesis that the stable connection of the two types of the fibrous materials differing in the structure, topography as well as in type of the polymer (para-aramid and polyethylene) will increase the ballistic resistance as well as allows to reduce the mass of the final products. Ballistic helmets were evaluated using ballistic impact attenuation test as well by estimation of the Head Injury Criterion (HIC).

The development of ballistic head protection technology is synergistic with the development of new composite high-strength materials, based mainly on UHMWPE fibers, reducing the mass of the product while increasing its ballistic protection. The idea of the presented research was based on the thesis that a stable combination of two types of fibrous materials differing in structure, topography, as well as the type of polymer (elaborated composition of para-aramid and polyethylene fibres) will increase ballistic resistance and also reduce the weight of the final products.

The aim of the research was to develop a hybrid ballistic helmet with reducing of the risk of head injuries. The newly developed head protections' solution for special tasks was based on the extensive virtual model elaborated in software designed for modelling physical phenomena.

The designed helmet meets the parameters included in the PN-V-87001:2011, NIJ Standard 0106.01 and PN-EN 397+A1:2013-04 Standards, while reducing the probability of head injuries by designing the helmet structure in such a way that the HIC parameter, which is a measure of the probability of head injury resulting from an impact, reaches the level of ≤ 800 , assuming that the areal density of the helmet will be $\leq 8.8 \text{ kg/m}^2$.

The project "Hybrid combat helmet reducing the risk of head injuries" was implemented under the Smart Growth Operational Programme 2014-2020, contract number: POIR.01.01.01-00-1293/20-00 and supported by European Regional Development Fund.

Advanced Finite Element Modeling of Reinforced PPS Extrusion for Solar Thermal Collectors: Integrating Crystallization Kinetics and Thermo-Mechanical Behaviour

Dr. Gulshan Noorumar, Norway

Oral Presentation (20')

Abstract

Energy efficiency and sustainability are critical considerations in modern manufacturing, driven by the need to reduce environmental impacts, lower costs and to apply to stringent quality standards. In manufacturing processes one can minimize energy consumption by reducing production defects and integrating advanced technologies - such as IoT and AI - for real-time energy management. Prediction of defects and their prevention are essential for reducing scrap rates in production, as they ensure higher resource efficiency, lower costs, and improved product quality. Simulations play a pivotal role in enhancing sustainability by enabling better decision-making and process design with reduced need for physical tests.

Inaventa Solar, located in Norway, specializes in the development and production of solar thermal collectors, which captures and absorbs solar radiation to convert it into usable energy. Their manufacturing process is a unique extrusion method that produces structured sheets of Polyphenylene sulphide (PPS) reinforced by 10% glass fibres. However, adding fibres leads to strongly anisotropic material properties, which poses challenges for numerical simulations of the process.

In this paper, we present a novel modelling methodology to represent glass fibres in PPS sheets with a Finite Element Model (FEM) capturing the material anisotropy. Further, we have modelled the PPS extrusion process using our in-house software (SiSim) to predict the thermo-mechanical behaviour of the material [1]. After exiting an extrusion die, the sheets are first cooled in a calibrator, where the thickness is controlled by an external pressure. Further downstream, the sheets enter an annealing oven, where a sufficient degree of crystallization is achieved through a heating cycle. The process simulations capture the crystallization phase of the PPS along with the thermal-induced stresses in the model while passing through the calibrator and the annealing oven. The modelling has been conducted in three steps starting with:

1. Developing a material model for FE simulations to represent reinforced PPS,
2. Defining the model behaviour in a unit-scale model to investigate the effects of geometry and temperature differences in the die,
3. Applying these learning outcomes to a global model of the PPS based thermal sheets.

The resulting global model is validated against physical data collected during the extrusion process and the crystallization model is validated against Differential Scanning Calorimetry test data. Finally, a surrogate model for the FE model is integrated with sensors to provide live predictions of defects in the manufacturing line.

Potential of pultrusion for the production of C/C composites

Mr. Husam Ahmad, Germany

Oral Presentation (20')

Abstract

Carbon fiber reinforced carbons (C/C) are lightweight and high-temperature materials with a density of less than 2 g/cm³ and operating temperatures exceeding 2000 °C. The carbon matrix can be produced either by gas-phase infiltration of a fiber preform (Chemical Vapor Infiltration, CVI) or by impregnating the fibers with suitable resins followed by pyrolysis (Polymer Infiltration and Pyrolysis, PIP). In the PIP process, the fibers are impregnated with a low-cost phenolic resin and formed into carbon fiber reinforced plastic (CFRP) composites using various shaping techniques, e.g. hand lay-up, winding, resin transfer molding, and hot pressing. During the subsequent pyrolysis process at temperatures up to 2500 °C, the plastic matrix transforms into glassy carbon. This results in mass loss and volume shrinkage, leading to a cracked C/C composite. To achieve dense C/C materials, multiple re-impregnation and pyrolysis cycles are usually required. According to the state of the art, the available technologies result in high production costs and geometrical constraints. Therefore, there have always been attempts to reduce the costs of C/C composites by using low-cost raw materials, modifying the matrix composition, or altering the CFRP forming process. In the current contribution, a new approach for the production of C/C composites by utilizing pultrusion as one of the most cost-effective manufacturing processes for fiber-reinforced plastics is introduced. Compared to the state of the art, this process can produce profiles of various cross-sections in large lengths with fiber volume fractions of up to 70%. Additionally, matrix additives can be integrated into the process to influence the properties of the final C/C composite. The main focus of the work will be on the influence of different process parameters such as pultrusion speed, fiber architecture, and the usage of additives such as graphite. The composites are mainly characterized by light and electron scanning microscopy, density and porosity measurements, and three-point bending tests. The parameter-dependent properties of the pultruded C/C composites are presented and discussed.

Roll to Roll Manufacturing of Multifunctional High-Nanotube-Content Nanocomposite Fabrics

Dr. Yadienka Martinez-Rubi, Canada

Oral Presentation (20')

Abstract

Carbon nanotubes (CNTs) have long been considered promising for development of advanced composite materials, due to their outstanding properties along with low density. Particularly, composite materials with high nanotube content are often necessary in order to achieve mechanical, thermal or electrical conductivity requirements. Various applications of free-standing polymer nanocomposites have shown promise at the laboratory scale; however, scalable integration and fabrication methods are needed in order to meet the technology readiness level for commercialization. We have developed a solution method for the production of such nanocomposites in the form of nonwoven fabrics using a thermoplastic polyurethane (TPU) adhesive. Appropriate selection of the solvents and optimization of a TPU solvent/non-solvent volume ratio enhanced interactions between CNTs and polymer chains in solution, improved CNTs disentanglement, and significantly reduced the filtration time for a fast recovery of composite sheet of controlled composition. The method provides for controlled adsorption of TPU on the nanotubes surface for tailoring of the nanocomposite properties (e.g. conductivity, strength, toughness and adhesion). The resulting prepreg-like fabrics can be handled and employed analogously to other fabric and prepreg materials. CNT/TPU fabrics have been layered, laminated or infused to produce thick nanocomposites, or integrated with conventional composites, for a series of multifunctional composites demonstrations (e.g., electromagnetic shielding, heating, flame resistance, thermoelectric). We partnered with the Canadian company Integran Technologies through the Innovative Solutions Canada (ISC) Program to translate this batch filtration method to a roll-to-roll fabrication process. This new fabrication process not only supports larger-scale, continuous fabric production, crucial for industrial application, but also facilitates direct deposition onto other substrates and the production of other high-nanomaterial content nanocomposites.

Paper 1353 1 **Incorporation and Optimisation of Post-Consumer Recycled (PCR) Polyethylene for Advanced Rotomoulding Applications**
Mr. Jake Kelly-Walley, United Kingdom
Highlight (Oral Presentation 20')

Abstract

Post consumer recycled materials (PCR), from domestic packaging waste, were assessed in order to understand the relationship between processing and properties in the rotational moulding (RM) process. Domestic PCR material was considered because RM recycled materials can be less abundant and stable in supply. The PCR materials from packaging streams allow the use of consistent feedstocks from sophisticated recycling systems. Despite this, it was established, since the material was not intended for use in RM, many factors such as, PCR polymer properties, zero-shear viscosity and thermal stability restrict the use of recycled materials in this polymer processing technique.

This work provides an overview of studies adopting strategies from the wider polymer processing literature on how to incorporate PCR, but applied to the RM process. In particular this work addresses the collection of baseline data which analysed processing behaviour and quantified mechanical properties for recycled high-density polyethylene (rHDPE) and linear-low-density-polyethylene (LLPDE) blends. Increases in porosity were recorded with an increase in rHDPE, due to an increase in zero-shear viscosity. Blends containing 30% PCR content recorded a greater than 50% reduction in impact performance. Such reduction in properties limits the number of useful applications. As a result, approaches to reduce viscosity, improve impact performance and restabilization were made.

Investigation regarding mechanochemical processing focused on reduce the viscosity of the rHDPE materials. In this work, increases in elongation at break of up to 230% were observed, however mechanochemical processing did not significantly change zero shear viscosity under such conditions. In addition, powder size and shape negatively affected the rotational moulding process.

Addition of copolymers and impact modifiers was reviewed via twin-screw extrusion. This study assessed addition of ethylene propylene diene monomer rubber (EDPM), styrene block copolymers (SBC), polyolefin elastomers and ethyl vinyl acetate (EVA). Improvements in impact strength over 100% were observed.

Another avenue for assessment regarding mechanical properties and performance is that related to 'restabilisation' as defined in the literature. The influence has been explored on rotational virgin materials, identifying changes in densification during processing. Increases of 33% peak impact strength were observed when using recycled material blends, however an extended processing time was required. Addition of antioxidants delayed the increase in density in line with previous virgin studies.

Overall, this is a summary of work aimed to improve the quantity of recycled content, and material performance for rotational moulding, an area of literature which remains broadly unexplored.

Paper 1279 2 Discrete Element Method Approach for Powder Flow Modelling in Rotational Moulding

Mr. Mathijs Goris, Belgium

Oral Presentation (20')

Abstract

Robomoulding is an innovative rotational moulding technique that offers lower power consumption, automation, and the ability to produce more complex products compared to traditional methods. It also comes with greater flexibility in motion and temperature control. In order to end up with well-shaped products with a uniform thickness, typically, trial-and-error approaches are used to set up and fine-tune the process settings, but this is inefficient and time-consuming. To reduce set-up time and improve process understanding, this research focuses on modeling the powder flow. A high-fidelity model based on the discrete element method (DEM) is developed to capture the complex behavior of powdered materials during moulding. Hereto, irregular particle shapes are introduced, as in previous research it was shown that small spheres do not allow for interlocking and as such are not capable of representing accurately the dynamic angle of repose (DAOR) of the powder. A design of experiments is conducted to generate a response surface model (RSM) that links powder particle settings with the DOAR. The high-density polyethylene (HDPE) powder is characterized using the DOAR in a GranuDrum™. The optimal set of model parameters is determined by combining the RSM together with measurements from the physical setup. These parameters are validated in the GranuDrum™ framework and further empirically validated in a full-process simulation to predict powder distribution. The simulation results show strong agreement with the powder distribution in the physical product, demonstrating the model's effectiveness in improving process insight and reducing reliance on trial-and-error methods.

Paper 1437 4

Engineering Lignin/Recycled Polymer Composites as Precursors for Sustainable Carbon Fibers

Mr. Rui Araújo Ribeiro, Portugal

Oral Presentation (20')

Abstract

The global pursuit for environmentally friendly and cost-effective precursor materials for carbon fiber production has led to the exploration of lignin-derived products [1]. Lignin, an abundant plant component and a major byproduct of the paper industry, presents a sustainable alternative for several advanced applications. The aromatic nature of lignin makes it a potential source for graphite-based materials such as carbon fibres [2]. Most carbon fiber production methods require solution polymerization and fiber forming through wet spinning, with a heavy environmental burden. Melt spinning is an alternative technique for the production of cost-effective fibres that does not require the use of solvents, is environmentally friendly and an industry-ready process [3]. In the present work, lignin was melt mixed with polymers to create composite fibres. Three polymers were selected, namely glycol-modified polyethylene terephthalate (PET-G), a blend of polycarbonate with acrylonitrile-butadiene-styrene (PC/ABS), and polybutylene terephthalate (PBT), and softwood Kraft lignin obtained by the LignoForceTM process was used. The composites were produced with lignin contents of 50 and 60 wt.%. A prototype modular small-scale fully intermeshing co-rotating twin-screw extruder coupled to a prototype die for fiber spinning, performed melt mixing and fiber spinning in a single step. Composite fibers were thermally stabilized by heating in air at rate of approximately 0.5°C/min. The as-produced and thermally stabilized fibers were characterized by thermal analysis (thermogravimetry and differential scanning calorimetry), infrared and Raman spectroscopies, and mechanical testing. It was observed that, approximately above 250 °C, the chemical and physical characteristics of the lignin-rich composite fibres undergo changes, with an apparent increase of the aromatic content. Mechanical properties such as the storage modulus increased after thermal stabilization. In conclusion, the proposed strategy is interesting to produce high lignin content fibres with potential for thermal treatment and formation of carbon fibres. Further studies will focus on the carbonization process.

Enhancing Sustainability in Polymers: Gum Rosin as a Key Component for Green Solutions

Mr. Henrique Costa, Portugal

Oral Presentation (20')

Abstract

The growing demand for eco-friendly solutions in the automotive and footwear sectors is driving innovation in material development through bio-based and sustainable raw materials. These industries, with significant environmental footprints, seek to integrate greener alternatives without compromising technical performance and quality. This work highlights advancements achieved by incorporating gum rosin resin derivatives into polymeric matrices, showcasing their potential as multifunctional natural raw materials for synthetic and biodegradable polymeric solutions.

The RN21 project intends to valorise natural resin extracted from pine trees and their derivatives as versatile bio-based raw materials, and pretends to enhance the resin sector's value chain, expanding its applications to packaging, textiles, automotive, and footwear industries. Experimental workflows include formulation, compounding, sample production, and performance evaluation, with a focus on maintaining or improving key technical properties.

In the automotive sector, gum rosin resin derivatives have been applied to interior components produced via injection moulding. Selected for their thermal stability and compatibility with conventional polymer processing techniques such as extrusion, these derivatives enable the development of bio-based polymeric matrixes with enhanced mechanical properties and processability. Research within a Portuguese consortium achieved incorporation levels of up to 30%, resulting in materials with bio-based content of up to 40%. These innovations align with industry sustainability goals while maintaining or exceeding the performance of conventional materials.

The footwear sector has similarly adopted gum rosin resin derivatives in the development of polymeric compositions for soles. By incorporating up to 20% of these derivatives into bio-based polymeric matrices via extrusion compounding, materials with a bio-based content of up to 55% were developed. These compositions exhibit mechanical robustness and processability, meeting the demands of industrial-scale production and the growing need for sustainable footwear solutions.

Results demonstrate the significant impact of gum rosin derivatives on the environmental footprint and functionality of polymer-based materials. By leveraging abundant and renewable resources, this work provides a pathway to sustainable innovation in materials science, addressing the pressing need for eco-friendly alternatives in high-impact industrial applications.

This work acknowledges the RN21 project, funded by the Environmental Fund through Component 12 – Promotion of Sustainable Bioeconomy (Investment TC-C12-i01 – Sustainable Bioeconomy No. 02/C12-i01/2022), of European funds allocated to Portugal by the Recovery and Resilience Plan (PRR), within the scope of the European Union (EU) Recovery and Resilience Mechanism, framed within the Next Generation EU, for the period 2021–2026.

Revalorization of Ion Exchange Resins in elastomeric matrix

Mrs. Andrea Estefania Valencia Cadena, Spain

Oral Presentation (20')

Abstract

Ion exchange resins (IER) are widely used in several industrial fields, mainly in water purification systems. Recently, these resins are used as active media to store chemical elements to be used to dry-electropolish metals and composite materials. This process is an innovative technology capable of polishing complex geometries, maintaining tolerance by doing an homogenous post-processing average roughness reduction. This process uses sulfonated polymeric IER particles, capable of absorbing and retaining the electrolytic active liquid media under service-like working conditions. These particles lead to produce a layer-by-layer roughness reduction, from peaks to valley creating oxides during the oxidation/redaction process which is absorbed and attached to the active media decreasing the life-time under service-like working conditions. Several Key-factors control the IEP life-time, being the most important one: size, the electrical parameters, etc. of the object to be polished, and the number of specimens processed in the machine. However, the main problem of this technology is that the active media may be resubstituted every 100 hours to maintain the quality of the process. Currently, active polymeric media is incinerated generating CO₂ increasing greenhouse gases. Within the aforementioned information, there is a need to revalorize and/or find a reutilization route of all the IER used to achieve a zero waste in 2026.

In this work, a protocol to revalorize the IER used in the dry-electropolishing process are used as a reinforcement particle to develop a new composite polymeric material was developed trying to improve the mechanical strength for the composite developed material. Two different binders (Polylactic acid (PLA) and Thermoplastic polyurethane (TPU)) with four polymeric IER charges were investigated (0 "used as reference", 10, 20, and 30 wt. %). After that prior to conduct the specimens through an injection process, the homogeneity of the different investigated mixtures was investigated by using thermogravimetrically and calorimetric analysis. Finally, the different mixtures were mechanically tested through tensile tests to be able to correlate the polymeric charges and the binder nature with their macroscopic properties (young's modulus, maximum tensile strength, plasticity index, and ductility). Finally, the microstructure of the composite as well as the post-mortem specimens will be microscopically investigated by using Focused Ion Beam and Scanning Electron Microscope.

Paper 19 1 Designing Rubber for Mars Missions

Dr. Rafal Anyszka, Poland

Highlight (Oral Presentation 20')

Abstract

Mars missions involve progressively sophisticated equipment, which must operate in the harsh Martian environment. New designs of landers, rovers, and now helicopters push the performance levels beyond current boundaries. This includes the materials used for the construction of the new equipment.

Rubber is one of the most unique materials used in technology because of its viscoelastic properties. This means that rubber exhibits viscous and elastic behavior simultaneously. Because of this, it is currently an irreplaceable material in the construction of tires, vibration dampers, or seals.

With the constantly growing performance of Mars equipment, material requirements increase as well. This will be especially important when considering manned Mars missions. Astronauts will have to wear properly sealed Mars suits and crewed rovers will have to drive at much higher speeds than the current rovers, generating more vibrations. To meet these expectations, an application of rubber elements seems inevitable. This project aims to develop rubber compounds designed to withstand the Mars environment while simultaneously preserving their viscoelastic properties in the highest possible temperature range. To meet these requirements, blends of Butadiene Rubber (BR) with Vinyl-Methyl Silicone Rubber (VMQ) are used as the polymer matrices because of their very low glass transition temperature assuring flexibility in a broad range of temperatures. BR provides better mechanical properties and wear resistance than VMQ, which in turn exhibits better flexibility at low temperatures and UV resistance. It is expected that BR/VMQ blends exhibit a synergistic improvement of properties in comparison to both rubbers alone. The blends are filled with various types of carbon black improving their mechanical properties and homogeneity. Also, different curing systems are used in the blend design, as well as oil replacement with non-volatile BR oligomers.

This paper presents the most important advancements in Mars rubber development achieved during the RED 4 MARS project [1].

Shaping the future of space exploitation with advanced materials and processes

Dr. Ugo Lafont, The Netherlands

Oral Presentation (20')

Abstract

Maturation of technologies based on advanced materials and their related process is a key aspect in the development of space mission. Driven by the necessity to improve performance, decrease system complexity and keeping high level of reliability or simply to reduce mass and cost, materials with enhanced (multi)functionalities by design and manufacturing process simplification are needed. However, nowadays it must be done implementing a sustainable approach whereas it targets ground based or out-of-earth/in space manufacturing processes.

In this paper, we will present a general assessment of new technology development based on advanced materials including polymeric materials (thermoplastic, thermoset, vitrimer), self-healing materials, composites and metals. Their added value will be associated with their related processing technologies and new design concept. In this respect, the recent advance on the use of 3D/4D printing concepts suitable for space application will be exposed and discussed with an emphasis on the role of meso-structuration and biomimetism. In the last part, the role of materials including several sources of feed stock (e.g. polymers, regolith) in the implementation and development of out-of-earth / In-space manufacturing capabilities will be put in perspective against the current state-of-the-art and available technology.

Paper 1828 3 Effect of the use of new aviation fuels on polymeric materials for use in aircraft

Ph.D. Ana Romero Gutiérrez, Spain

Oral Presentation (20')

Abstract

The growing problem of environmental pollution and the current dependence on fossil fuels are generating interest in finding sustainable alternatives for the transport sector. Decarbonization has become the roadmap of regulations proposed by governments and institutions to reduce the carbon footprint, which has driven the development of sustainable aviation fuels (SAF). The physicochemical properties of SAF are like those specified in regulations for traditional fossil kerosene, but their fully paraffinic nature may affect the compatibility of these fuels with aviation materials with which they are in contact. This work analyses the effect on two thermoplastic polymers, nylon and high-density polyethylene (HDPE), which are used in fuel transfer systems and pipes, of two conventional kerosene fuels (Jet A-1 and JP-8) and a mixture of Jet A-1 and 30% (v/v) of SAF. For the development of the study, immersions were carried out at 71 °C for 28 days, as established by ASTM D4054. The properties evaluated to determine the compatibility between these polymeric materials and the fuels with which they are in contact are the stress at the elastic limit and the deformation at the breaking point. Additionally, other physical-mechanical properties such as hardness and dimensional and mass variation were measured to obtain a more complete evaluation of the behavior of the materials in service. Results showed that the influence of the three fuels on both materials was similar, which could mean that the 30% SAF blend would be equally compatible with those materials as with fossil kerosene fuels. These results confirm that, in addition to the known environmental advantages of SAF, the blend of kerosene fuels tested would not compromise the integrity of the materials used in fuel distribution systems.

Pt nanonetwork coatings for spacecraft charging mitigation in photovoltaic solar arrays

Dr. Juan Ramón Sánchez-Valencia, Spain

Oral Presentation (20')

Abstract

Spacecraft charging is a well-known charge accumulation process induced by the interaction of the space environment (plasma, solar radiation, and high-energy particles) with the surfaces of space vehicles. This phenomenon is the root cause of catastrophic electrostatic discharge (ESD) arcing on the non-conductive surface of spacecraft, as is the case of photovoltaic cover glasses. Therefore, it is a critical issue that compromises the integrity and limits the lifetime of space solar arrays. Within the framework of the ESA contract Ref. 40001139513/22/NL/CRS, the present research addresses this problem by developing a new type of transparent conductive nanocoatings consisting of percolated platinum-based nanonetworks developed by plasma processing techniques.

The fabrication approach combines the remote plasma-assisted deposition (RPAVD) of a hybrid platinum plasma-polymer nanocomposite with the room-temperature plasma etching of the resulting layer.[1]-[3] Both processes are consecutively carried in the same plasma reactor in a single fabrication run. This method exclusively involves vacuum deposition and plasma manufacturing techniques widely applied in different industrial sectors, including the development of optical coatings for photovoltaic applications. Thus, it can be scaled for either the large-area (up to a few m²) processing of windows and cover glasses or the mass-scale manufacturing of microelectronic/optoelectronic devices.

Recent studies addressed the development of solar cell photoelectrodes consisting of nanoporous TiO₂ optical coatings[2] and Pt nanostructured electrodes[3] developed by combined RPAVD and soft plasma etching at mild temperatures (~120°C). The current communication extends this approach to the room temperature fabrication of highly transparent and conductive nanoporous coatings (solar transmittance > 85 %) consisting of laterally interconnected Pt-nanonetworks. Process optimization provides a good balance between optical transmittance and sheet resistance. For a suitable spacecraft charging assessment, sheet resistance measurements were conducted in vacuum at different temperatures and complemented with advanced secondary emission yield and VUV photoemission measurements. This characterization was used to model, using SPENVIS' EQUIPOT and SPIS-6 simulation tools, the surface charge and potential developed in different orbits onto photovoltaics arrays coated with the Pt-nanonetworks. These analyses confirm the good performance of the developed transparent conductors for spacecraft charging mitigation applications in photovoltaic solar arrays.

Space experiments on High-Temperature Molten Oxides, Metals and Alloys Using an Electrostatic Levitation Furnace on the International Space Station

Dr. Chihiro Koyama, Japan

Oral Presentation (20')

Abstract

Assessing the thermophysical properties and solidification behaviors of melts at temperatures exceeding 2000°C, presents significant challenges due to reactions between the molten samples and their containers as well as heterogeneous nucleation. To overcome these issues, containerless techniques such as electromagnetic, aerodynamic, and electrostatic levitation have been developed. In electrostatic levitation, the Coulomb force between a charged sample and surrounding electrodes is utilized to precisely manipulate the sample's position. Our team have developed the Electrostatic Levitation Furnace (ELF), incorporating key technologies necessary for stable sample positioning and accurate scientific observation. In 2016, ELF was installed on the International Space Station (ISS). Using the microgravity environment, samples which cannot be electrostatically levitated mainly due to their poor charges could be precisely position controlled, melted, and their thermophysical properties such as density, surface tension, and viscosity were obtained. To date, 17 missions—excluding private commercial experiments—have been conducted. Of these, 13 missions related to molten oxides, metals and alloys were selected by JAXA and 4 by NASA. Nine missions have successfully completed space experiments, three are currently ongoing, and eight are in preparation on the ground. Among these experiments, the thermophysical property measurements of molten oxides, metals and alloys, which are strongly related to materials science, will be presented, and the obtained data will be discussed.

Paper 1582 1 Titanium Production Through Carbon Free Methods - The UAT Process

Ph.D. Alex George, United States

Oral Presentation (20')

Abstract

Reducing the reliance on carbothermic reduction of metal ores is a key challenge facing the metallurgical industry in the modern age. Carbothermic reduction processes emit greenhouse gases and often other harmful chemicals. To help overcome this issue, UAT has developed and patented a scalable metallothermic reduction route for the production of titanium. The process presented here consists of two major steps: 1) metallothermic reduction of a Ti bearing ore to form a metal phase and a slag phase and 2) electrorefining of the extracted metal to form a high purity titanium "wool" product. The UAT method produces no direct greenhouse gases, outperforms existing processes in energy requirements, and functions using a wide variety of ore types. Furthermore, alloys such as Ti-64 and TiAl can be produced directly without the implementation of an alloying stage. The resulting wool can be ground into powder, directly pressed and sintered without the aid of a binder, or used as a feedstock for other melting processes. In this presentation, we will review the thermodynamic basis of the extraction step, as well as some details of the electrorefining step, discuss the various types of ores that can be used, and review a variety of alloy compositions that can be directly synthesized with UAT's two-step process.

Paper 2193 2 Sustainable Aviation Fuels from CO₂ and H₂: Additive Manufacturing-Enabled Catalyst Systems
Dr. Jonas Gurauskis, Spain
Oral Presentation (20')

Abstract

The transportation sector, like many others, faces the critical challenge of reducing fossil fuel consumption and minimizing carbon dioxide (CO₂) emissions—a concern that is particularly acute in aviation, which accounts for approximately 2–3% of global CO₂ output. In response, innovative methodologies are required for the production of renewable synthetic fuels from CO₂ and green hydrogen (H₂).

This study introduces a Power-to-X technology designed to convert CO₂ and H₂ into sustainable fuels and high-value chemicals—such as synthetic kerosene for aviation—alongside other valuable products, all under comparatively mild reaction conditions. The process commences with the electrochemical reduction of CO₂ to carbon monoxide (CO), followed by the dehydration of primary alcohols and subsequent chemocatalytic reactions that synthesize long-chain hydrocarbons via biomimetic strategies.

The presentation will detail the process design with particular emphasis on integrating additive manufacturing techniques to fabricate catalytic systems exhibiting hierarchical porosity distribution. These advanced structures facilitate enhanced mass transport and improved overall process efficiency. By obviating the need for multiple upgrading steps and enabling operation under milder conditions through a hybrid catalyst integration system, the proposed concept markedly enhances the energy efficiency of fuel production, yielding higher outputs compared to conventional methods.

This advancement holds a potential for decarbonizing the aviation industry by providing a sustainable alternative to fossil-derived jet fuels, thereby reducing the sector's carbon footprint.

Sustainable Synthesis of High-Performance Lithium Nickel Manganese Oxide Cathodes: A Study of Mn-Based Precursors and Calcination Effects

Dr. Ioannis Michos, Greece

Oral Presentation (20')

Abstract

Lithium-ion Batteries (LIB) have been in the center of research interest in recent years due to the growing demand for efficient energy storage across diverse applications. From small consumer electronics such as smartphones to large-scale implementations in electric vehicles (EVs), buses and e-bikes, LIBs play a crucial role in modern energy solutions. Additionally, their integration into grid-level storage systems, particularly in conjunction with photovoltaic (PV) and wind energy, is expanding rapidly. One of the most critical components of LIBs, both in terms of cost and efficiency, is the cathode. Among the various cathode materials studied, lithium cobalt oxides (LCO), derived materials such as nickel-rich layered oxides ($\text{LiNi}_x\text{Co}_y\text{Mn}_{1-x-y}\text{O}_2$) and lithium-rich layered oxides, and high-capacity organic cathodes have been extensively explored. In particular, lithium manganese oxides (LMO) and lithium nickel manganese oxides (LNMO) have attracted significant attention due to their high working voltage ($\sim 4.7\text{V}$), favorable theoretical capacity ($\sim 147 \text{ mAh g}^{-1}$), and cost-effectiveness. This study focuses on the development of high-performance LNMO cathode materials with a targeted stoichiometric composition of $\text{Li}_1\text{Ni}_{0.5}\text{Mn}_{1.5}\text{O}_4$ (LNMO). Two different Mn-based precursors were investigated: (i) calix-flashed calcined and quench-cooled Mn_xO_y micron-sized powder and (ii) MnO_2 synthesized in NTNU via the HAlMan process. The HAlMan process is a novel method that enables the production of MnO_2 during the process from readily available, low-cost raw materials, reducing dependency on conventional mining and refining methods. By utilizing this approach production costs can be optimized while aligning with green chemistry principles, contributing to the development of environmentally friendly cathode materials for next-generation lithium-ion batteries. Both precursor materials were subjected to calcination at 800°C to achieve the desired spinel structure, ensuring optimal electrochemical performance. A comparative analysis was conducted to assess the impact of precursor selection on the structural, morphological, and electrochemical properties of the synthesized LNMO. Additionally, the influence of varying calcination conditions was explored. X-ray diffraction (XRD) confirmed the formation of a well-ordered spinel phase, while scanning electron microscopy (SEM) provided insight into structural and morphological information depending on the precursor selection. Electrochemical characterisation, including galvanostatic charge-discharge cycling and electrochemical impedance spectroscopy (EIS), provided valuable insights into capacity retention, rate performance, and ionic conductivity. The findings highlight the advantages of using calix-flashed calcined Mn_xO_y and HAlMan-processed MnO_2 as a sustainable and cost-effective alternative Mn source for LNMO synthesis over commercially available Mn_xO_y sources, reinforcing their potential for next-generation lithium-ion batteries.

Development of new equations for unsaturated infiltration.

Prof. Javier Narciso, Spain

Highlight (Oral Presentation 20')

Abstract

Infiltration processes are widely used in the manufacture of composite materials, but today it is still a challenge to find equations that accurately describe the process. The equation that governs them (Navier-Stokes equation) has not yet been solved. Therefore, there are different approaches that describe the process more or less faithfully. First of all, we must define whether the process is reactive or not. In the case of reactive infiltration, it is the chemistry that governs the process, as has just been clearly demonstrated [1], a fact of great relevance since in transport there are two fundamental parts that are manufactured using this technique.

If there is no chemical reaction, there are two main approaches to describe the process, if we ignore the simplest one, which is Darcy's law [2], such as Richard's law and the modification of Darcy's law for unsaturated liquids where we can use the Brooks and Corey approximation [3] or others [4].

In this work, a new approximation is shown based on the description of fluid dynamics in non-cylindrical pores of liquids that do not wet the solid and the effect of saturation. Another very different case is when the liquid wets, and under certain conditions the flow of fluids can occur through what has been called creeping liquids.

The equations developed have been used to describe the infiltration process of liquid Al alloys, in porous media mainly of porous SiC preforms, and to a lesser extent of Al₂O₃, TiC, graphite [4-6]

Paper 50 **6** **High-Entropy Zirconates as future Thermal Barrier Coatings: Resistance to Corrosion by Volcanic Ashes and Sands**
Mr. Jonas Johannes Pflug, Germany
Oral Presentation (20')

Abstract

Optimization of processes and the maximization of the usage of resources is crucial for an environmentally lower impact of technology. In this context, thermal barrier coatings (TBCs) are used in airplane turbines, to protect the metallic substrates from high temperature and harsh atmospheres. This allows operating the system at temperatures higher than the melting point of the substrate. With increasing operating temperature, the fossil fuel is combusted more completely, and the efficiency according to Carnot is maximized. The state-of-the-art TBC material yttria-stabilized zirconia is supposed to be advanced. Rare-earth high-entropy zirconates are promising new TBC materials. Therefore, their thermophysical properties need to be investigated and assessed. Additionally, TBCs also need to act as environmental barrier coating (EBC), withstanding inorganic dusts, sands or volcanic ashes that are ingested into the turbine while operation. These debris particles are mainly composed of calcia, (magnesia), alumina and silica, thus commonly called C(M)AS. The melting of these particles can lead to the infiltration of the T/EBC, and due to chemical interaction, the coating can be damaged irreversibly. The interaction of those new materials with (C(M)AS) need to be examined in order to estimate the resistance and extend of corrosion.

Our investigation of the high-entropy rare-earth zirconates ($\text{Nd}_{0.2}\text{Sm}_{0.2}\text{Gd}_{0.2}\text{Dy}_{0.2}\text{Er}_{0.2}$) $_{2}\text{Zr}_2\text{O}_7$ and ($\text{Y}_{0.2}\text{Nd}_{0.2}\text{Sm}_{0.2}\text{Gd}_{0.2}\text{Dy}_{0.2}$) $_{2}\text{Zr}_2\text{O}_7$ with the (C(M)AS) model compositions $\text{C}_{24}\text{A}_{17}\text{S}_{59}$ and $\text{C}_{33}\text{M}_9\text{A}_{13}\text{S}_{45}$ (values in mol%) show the formation of the apatite $\text{RE}_{14}(\text{SiO}_4)_9\text{O}_3$ and zirconia as main reaction products. The $\text{C}_{33}\text{M}_9\text{A}_{13}\text{S}_{45}$ interaction shows a faster consumption of the zirconates that are detectable via X-ray diffractometry (XRD) only after 5 min of reaction time. Zirconates are still detected after 1 h of $\text{C}_{24}\text{A}_{17}\text{S}_{59}$ interaction. For reaction with $\text{C}_{24}\text{A}_{17}\text{S}_{59}$ longer than 50 h, additionally the formation of zircon is observed, which is the result of a higher content of silicon in comparison to $\text{C}_{33}\text{M}_9\text{A}_{13}\text{S}_{45}$. Thus, in the $\text{C}_{33}\text{M}_9\text{A}_{13}\text{S}_{45}$ corrosion, all silicon is consumed for the formation of the apatite phase. Next to XRD analysis, energy dispersive electron microscopy (EDX) is used to determine the newly formed phases. With this method the non-crystalline anorthite phase $\text{CaAl}_2\text{Si}_2\text{O}_8$ is identified, which is the residue of non-reacted $\text{C}_{24}\text{A}_{17}\text{S}_{59}$ that is forming a glass upon cooling.

Infiltration experiments gain deeper insight into the solid-melt interaction and diffusion of cations during the reaction progress.

This work is funded by the German Federal Ministry of Education and Research with the project BMBF NanoMatFutur MEO-TBCs [grant number: 03XP0301A].

Paper 1298 1 Self-healable polymer electrolyte for lithium batteries, targeting light-mediated and 3D-printable processes

Prof. Federico Bella, Italy

Keynote (Oral Presentation 40')

Abstract

In the pursuit of enhancing the longevity and safety of lithium batteries, our research introduces a novel self-healing poly(urea-urethane) gel electrolyte. This dynamic covalent network, synthesized through the reaction of tris[2-(isopropylamino)ethyl]amine with hexamethylene diisocyanate followed by the addition of polyethylene glycol, exhibits remarkable self-healing properties activated at low temperatures. Notably, the gel electrolyte demonstrates higher ionic conductivity compared to conventional liquid electrolytes embedded in porous separators.

Electrochemical evaluations reveal that lithium symmetrical cells utilizing this gel electrolyte achieve homogeneous lithium plating and stripping, maintaining stability over extended cycles. Furthermore, even after significant mechanical damage, the electrolyte's self-healing capability ensures the recovery of electrochemical performance, sustaining over 100 charge/discharge cycles at a C/5 rate post-repair [1,2].

This innovative approach not only addresses mechanical vulnerabilities inherent in battery systems, but also aligns with sustainable practices by extending battery lifespan and reducing waste. Our findings suggest that integrating self-healing mechanisms into battery electrolytes holds substantial promise for the development of safer, more durable energy storage solutions.

Moreover, this Li⁺-conducting self-healing gel electrolyte extends its potential beyond conventional battery applications. Its high ionic conductivity and mechanical resilience make it an ideal candidate for Li-mediated electrochemical ammonia synthesis, a promising route for sustainable nitrogen fixation [3]. By stabilizing the Li-metal interface and preventing dendrite growth, this electrolyte enables efficient and prolonged operation under harsh reaction conditions. This breakthrough paves the way for next-generation ammonia production systems, leveraging lithium's reactivity while ensuring process stability and scalability.

Melt-spun Cu-Al based ribbons as current collectors for Anode-Free cells in ASSBs

Mrs. Luisa Policastro, Italy

Oral Presentation (20')

Abstract

All-Solid-State Batteries (ASSBs) were conceived to meet the need for a higher energy density and safety. Li-metal can be exploited in this type of cells, using a solid electrolyte, that reduces dendritic growth. Despite this, Li-metal is flammable, must be stored in a moisture-free atmosphere, and its production is environmental impacting. In this context, anode-free system emerged to avoid these problems: a current collector (CC), usually made of copper, is used as a support to plate Li-metal coming from the cathode. The optimization of the CC composition and the CC/electrolyte interface is essential to achieve high performances. [1]

The purpose of this study is the synthesis and characterization of new alloys to obtain greater lightness, lithiophilicity and lower production costs than traditional Cu-based CCs. In the Cu-Al system, a high percentage of Al leads to brittle alloys, due to the formation of intermetallic compounds. So, the specific goal of this work is to improve mechanical properties, thanks to the stabilization of the β phase. Aiming to inhibit the eutectoid decomposition and the formation of biphasic mixtures, some ternary alloys have been synthesized, by adding Ni and Mn, which enable to extend the field of existence of β phase, improving mechanical properties.[2] Various alloys, with different compositions, were synthesized from parent elements in an induction furnace, and then subjected to an annealing treatment. Moreover, the rapid solidification from the liquid phase was performed by melt-spinning, obtaining metal ribbons with desired size, to be directly used in anode-free cells. Prepared samples were characterized by SEM-EDX and XRD. Melt-spinning has given better results than annealing. The formation of the β phase, with a martensitic structure, has been obtained in the 83-13-4%wt Cu-Al-Ni ribbon; in the case of Cu-Al (85-15 and 90-10 wt%) and Cu-Al-Mn (80-15-5 wt%) ribbons, XRD and SEM-EDX revealed a decrease in the intermetallic phase and an increase in the β phase. Future targets are the synthesis and characterization of lithiophilic Cu-Al-Mg ribbons, the creation of a surface coating to improve the Li-plating on the anode side and the demonstration of anodeless cells using a sulfide-based electrolyte and the developed CC.

Paper 678 **3** **Investigation of Processing and Microstructure on Electrode Materials for Fe-Air Battery Performance**

Mr. Prabhakar Kumar, India

Oral Presentation (20')

Abstract

Iron-air batteries are gaining attention as sustainable and cost-effective energy storage solutions, particularly for grid-scale applications, due to their high theoretical energy density, abundance of raw materials, and environmental recyclability. This study examines the electrochemical performance of three iron-based electrode materials—Fe bulk sheets, Fe₂O₃ powder pellets, and Direct Reduced Iron (DRI) pellets—for Fe-air battery applications.

Fe bulk sheets were fabricated by cold rolling iron sheets to varying thicknesses under different deformation levels. Increased deformation enhanced electrochemical performance by refining the grain structure and increasing surface area, which facilitated improved reaction kinetics.

Fe₂O₃ pellets were produced by compressing Fe₂O₃ powder with pore-forming agents and binders, followed by sintering to enhance mechanical stability. While these pellets exhibited moderate electrochemical performance, their effectiveness was limited by lower electrical conductivity and sluggish reaction kinetics.

In contrast, DRI pellets, prepared by compressing DRI powder with pore-forming agents, conductive additives, and binders, demonstrated superior electrochemical performance. Their high porosity, increased exposed surface area, and optimized microstructure enabled efficient ion transport and redox reactions. As a result, DRI pellets exhibited higher discharge capacity, lower charge transfer resistance, and improved cycling stability compared to Fe bulk sheets and Fe₂O₃ pellets.

This study highlights the importance of material microstructure and porosity in determining electrochemical performance. Among the investigated materials, DRI pellets with various additives emerge as the most promising electrode candidate for Fe-air batteries, offering a scalable and efficient energy storage solution.

Paper 1936 **5** **Improvement in Performance of Energy Storage Technologies through Online Acoustic Emission Sensor-Based Battery Mixing**
Mrs. Yeonjee Choi, South Korea
Highlight (Oral Presentation 20')

Abstract

The progress in battery technology is propelled not only by enhancements in materials and energy density but also by the optimization of manufacturing processes. A key element of battery production is the mixing process, as the uniformity of the mixture greatly affects both the stability of the final product and its overall performance. This study presents a real-time analysis technology designed to assess the homogeneity of battery slurry mixing. It proposes strategies to enhance the consistency of slurry viscosity and boost the efficiency of the mixing process.

The ongoing research and development of inline monitoring technologies and analysis have led to significant advancements in the methods used for analyzing battery mixing processes. The previous method as ex-situ approaches have been continuously refined. Leverage real-time analytics to improve electrode uniformity and minimize material waste and energy consumption to increase production efficiency and further optimize battery performance. A real-time optimization method that incorporates artificial intelligence (AI) and machine learning (ML) to reduce manufacturing defects, ultimately enhancing the quality and reliability of energy storage devices.

In this study, we propose a method to analyze the homogeneous mixing of cathode slurry in real time to evaluate the performance of energy storage devices. For real-time process evaluation, we utilize acoustic emission sensors and ultrasonic sensors, complemented by domain-specific signal processing algorithms to accurately detect the homogeneity of mixture and optimize endpoint of mixing. Data collection involved experiments using an IoT sensor developed at Korea University attached to a NETZSCH PMD mixer, along with a differential-pressure viscometer from NETZSCH for auxiliary viscosity measurements. This methodology enables the early identification of quality degradation factors in battery manufacturing early and respond quickly.

The technology developed in this study is anticipated to facilitate the realization of eco-friendly processes and advance sustainable battery manufacturing technologies. Such technological advancements are crucial for reducing production costs and minimizing environmental impact. This ultimately contributing to a transition to a sustainable energy system through next-generation energy storage manufacturing innovation.

Paper 460 3 **Containment of metallic phase change materials for latent heat thermal energy storage solutions**

Mr. Paolo Lai Zhong Lo Biundo, Norway

Oral Presentation (20')

Abstract

The transition to renewable energy sources like solar and wind is essential for a sustainable future, but their intermittency presents a significant challenge to energy grid stability. An energy storage solution is needed to store surplus energy and release it upon demand. Latent heat thermal energy storage (LHTES) is a promising technology for addressing this challenge. With the EU funded THERMOBAT and SUNSON projects we are exploring new phase change materials (PCMs). As LHTES systems evolve, the development of heat-to-electricity converters capable of operating at temperatures above 1000°C has highlighted the need for PCMs that can perform reliably under such demanding conditions. Ferrosilicon, a cost-effective and well-established material, shows significant potential due to its high volumetric latent heat, enabling energy storage capacities surpassing 1 MWh/m³. In this study, ferrosilicon is alloyed with boron to leverage boron's exceptionally high latent heat and further enhance energy storage performance. This study addresses the critical challenge of containing such Fe-Si-B alloys at temperatures between 1100°C and 1400°C, utilizing sealed graphite containers. The containment system must counteract the alloy's high reactivity and vapor pressure while preventing material loss and ensuring an inert atmosphere. A series of graphite-based crucibles, with different ceramic additions and with BN coating, were subjected to 100 thermal cycles and subsequently analyzed using computed tomography (CT scan) and scanning electron microscopy (SEM). Results indicate that bare graphite, despite forming SiC at the alloy interface, effectively contains the alloy over the 100 cycles with minimal degradation to both the PCM and the crucible. The BN coating provides an additional layer of protection, mitigating reactions at the interface, reducing the contact angle. These findings highlight the viability of sealed graphite containers as a cost-effective and robust solution for containing metallic PCMs in high-temperature LHTES systems.

Paper 248 4 Development and characterization of solid-liquid metal alloys phase change materials for high temperature thermal energy storage

Dr. Laura Teodorescu, France

Oral Presentation (20')

Abstract

The present work provides a study on the properties of metallic PCMs for integration into a TESS (thermal energy storage system) unit for heat storage at high temperatures. Al-Cu-Si alloys were selected in the temperature range 550°C - 850°C, and CALPHAD calculations were performed using FactSage 8.2 software (SGTE and FTLite databases). After optimal selection, the fabricated alloys were examined using a range of techniques to obtain the thermal properties and a full thermo-mechanical characterization. Thermal analysis was carried out using a STA 449 F3 JUPITER (Netzsch) with each sample placed in an alumina crucible (85 µL). To avoid oxidation, the samples were heated with N₂ flow at 80mL/min. The samples density was measured using the Archimedes Principle and confirmed with a He gas pycnometer (Accupyc 1340 Micromeritics). The coefficient of linear thermal expansion (CLTE) was measured using a thermomechanical analysis equipment (TMA-SETSIS EVO SETARAM) which provides information on the solid-to-solid phase transitions. The CLTE measurements of the developed materials will help for later implementation of the metallic PCMs into any container for stress consideration at solid state.

The selected PCMs were thermally cycled 20, 40, and 100 times through the solid-liquid phase under air. DSC and LFA were used to assess changes in the thermal properties of the PCMs, such as melting point, latent heat, specific heat, thermal diffusivity, and thermal conductivity. Changes in the PCMs' thermal characteristics, including their melting point, latent heat, specific heat, thermal diffusivity, and thermal conductivity, were evaluated using DSC and LFA. The selected PCMs achieved the TES system's maximal energy storage density of 500 kWh/m³ for a temperature difference of 300°C. Finally, the materials examined in this study shown remarkable stability and energy storage densities, making them viable options for large-scale application. Afterwards, the PCMs will be inserted into a 3.5m height storage unit made of refractory bricks as mechanical support to prevent any leakage.

Polymeric waste shells for developing new microencapsulated phase change materials (MPCM)

Mr. David Vera-Rivera, Spain

Oral Presentation (20')

Abstract

Polymers are one of the most produced materials in the last decades, due to its relatively good mechanical properties with low density and its extremely low cost of fabrication and processing. The polymers production comes principally from the refining of petroleum, that is the main fossil fuel. The main consequence of the high plastic production is that, in municipal solid wastes (MSW) and refuse derived fuels (RDF), the plastic fraction is in constant increase, being for polystyrene (PS) the 15 % of this fraction. This fraction is directly responsible for the presence of microplastics, which affects adversely the ecosystems. These wastes in natural environment cause different diseases including irritation and, in the worst cases, can lead to cancer.

On the other hand, energy consumption in buildings is in an increasing trend, being heating, ventilation and air conditioning (HVAC) systems one the main end-use sectors. HVAC contributes with approximately 7 % of global electricity, causing near of the 3 % of carbon dioxide (CO₂) annual emissions in the world. Thermal energy storage (TES) is a potential technology for more sustainable buildings, playing key role in saving energy. Phase change materials (PCM) are a kind of materials widely used in TES, which uses latent heat from phase changes to store or release energy. The possible phase transitions are solid-solid, liquid-gas, solid-liquid and their reverse paths, due their reversible nature. The most common system are solid-liquid transitions. Melting is an endothermic process and solidification is exothermic. Taking into account the above premises, melting is for heat storage, absorbing energy and solidification releases the energy in heat form. Microencapsulation of PCM is an extended technology for its preservation, resulting in microencapsulated phase change materials (MPCM). The microencapsulation brings to the PCM thermal, chemical and mechanical resistances for future uses as in building, inside cementitious materials. MPCM are constituted by a core/shell system where the core is PCM and the shell material depends on the future usage. The most produced MPCM are using polymeric materials as shell, like PS. To undergo a more sustainable process, production of polymeric shell microcapsules using plastic wastes is a possible way to study.

Paper 1505 6

A re-investigation of the phase diagram of the disodium hydrogen phosphate/water system and its consequences for latent heat storage applications

Dr. Rebecca Ravotti, Switzerland

Oral Presentation (20')

Abstract

Latent heat storage (LHS) using Phase Change Materials (PCMs) has attracted the interest of researchers and policymakers as a promising technology to increase the share of renewables in contexts where space is either restricted, or a cost-limiting factor. The selection of suitable materials characterized by a reliable behaviour over long-term thermal cycling is the first essential criterion to the development of a LHS. Salt hydrates are a promising class of PCMs given their promising thermophysical properties such as high energy capacities, high densities and low cost. Disodium hydrogen phosphate dodecahydrate (DSPD) is particularly interesting due to its melting point over the range 30-32 °C – a temperature range for which there are fewer choices of PCMs. Despite its attractive properties, data on the melting point and phase change enthalpy of DSPD appear inconsistent in the literature, and concerns over its usage as PCM have also been highlighted because of reports of polymorphic behaviour.

In this study, a systematic investigation of the phase diagram of DSPD was performed using a wide variety of techniques, including differential scanning calorimetry (DSC), thermogravimetric analysis (TGA), single crystal and powder X-ray diffractometry coupled with DSC (PXRD-DSC), hot-stage microscopy (HSM) and X-ray computed tomography (XCT). Different compositions of disodium hydrogen phosphate in water were produced and studied to clarify whether the phase diagram derived from previous studies is correct. In addition, single crystals of DSPD were successfully obtained.

The results showed evidence of polymorphism in DSPD, but this was not found to influence the overall phase diagram or long-term behaviour and stability. More notably, a strong tendency to dehydrate was observed, leading to a general instability and tendency to produce a mixture of the dodecahydrate and heptahydrate forms, rather than pure DSPD. This had been mistakenly labeled as a polymorphic phase transition in the phase diagram. A new methodology was developed using XCT, which enabled the in-situ observation of the solvent-mediated dehydration process, while a new approach to DSC data analysis allowed quantification of the ratio of disodium hydrogen phosphate dodecahydrate and disodium hydrogen phosphate heptahydrate present in samples at different compositions.

This work challenges the currently accepted phase diagram of the disodium hydrogen phosphate/water system. The use of different techniques to understand the behaviour and stability of salt hydrates paves the way for more reliable latent heat storage solutions.

Paper 1484 1 **Uncertainty quantification of composite failure**

Mr. Dominik Motlib, United Kingdom

Highlight (Oral Presentation 20')

Abstract

The failure of composite materials is a complex phenomenon, but one which must be understood by engineers during the design process in order to generate an optimised design solution. A major challenge when designing large scale composite structures, notably those utilised in the aerospace sector, is the uncertainty associated with mechanical simulation models (finite element models, for example) which are used to drive the design process. Model solutions are typically generated using low fidelity representations due to the scale of the assemblies. Such practices yield expedient results however key quantities of interest, particularly at failure “hot spots”, may be subject to relatively large levels of uncertainty. This paper considers the challenge of interpreting uncertainty within low fidelity finite element models of composite materials. A goal orientated error estimator is implemented in a finite element model of a reference carbon fibre reinforced plastic component. This allows for a quantifiable error field in the stress field to be developed. These stress value distributions are then used to compute a range of composite failure potentials, with confidence bounds of the failure metrics quantified and the most likely failure mode suggested. The combination of the discretisation error estimated from the goal orientated error estimator alongside the error in the composite failure metrics are then compared with empirical data from fibre reinforced composite tests, demonstrating the failure of the falls within the range computed by the error estimator scheme. This work is conducted with the intention of expanding this methodology onto large composite aerospace structures, allowing for the design engineer to iterate during the design concept phase at low computational expense.

Paper 2016 2 **Fatigue performance of steels for next generation electric heavy-duty vehicles leaf springs**
Prof. Mattias Calmunger, Sweden
Oral Presentation (20')

Abstract

The automotive suspension system is the link between the structure of the vehicle and its wheels. Thus, its crucial for the absorption of road induced vibrations and for improving vehicle maneuverability and user comfort. For heavy-duty vehicles, the leaf springs are an important part of the suspension system, responsible for supporting the vehicle weight and absorbing the vertical vibrations and impacts due to the road conditions. Thus, the springs are exposed to dynamic forces and need to withstand many cycles without failure during their service life. It should also be noticed that failure of a main leaf spring may significantly affect the steering behavior of the vehicle and must be regarded as a critical safety component. To fulfill the safety requirements and the increasing demand for lightweight structures it is typically required to have an optimized design and accurate manufacturing processes, especially from the point of view of fatigue.

This study aims to investigate the possibility to enhance the durability of leaf springs for electric heavy-duty vehicles by introducing advanced high-strength steels and optimizing surface treatments. The study will investigate the impact of surface treatments such as shot-peening on different high-strength steels and their fatigue life. The findings are expected to be applicable to various automotive components, promoting broader adoption of advanced materials and manufacturing techniques in the industry.

The results showed that the fatigue life can be enhanced by selecting the appropriate high-strength steel and by optimizing the surface treatments. Fatigue performance of the different advanced high-strength steels as well as residual stress evolution of different surface treatments will be discussed.

Paper 1501 3 **Uncertainty quantification and validation for centre hole-drilling residual stress measurement: A combined finite element and experimental framework for enhanced reliability in advanced materials**

Dr. Aadarsh Mishra, United Kingdom

Oral Presentation (20')

Abstract

A. Mishra¹, R. Evans¹, G. Karrar¹, R. Lye¹, J. P. Rouse¹, C. J. Bennett¹

¹Mechanical and Aerospace Systems (MAS) Research Group, University of Nottingham, Nottingham, NG8 1BB, UK

Residual stress assessment is critical for ensuring structural integrity in aerospace, automotive, and energy applications. The hole-drilling method, standardized in ASTM E837 [1], is widely used in industry but its accuracy is limited by uncertainties in calibration coefficients linked to geometric parameters, material properties, and drilling conditions. While ASTM E837 provides a foundational framework, it does not address error propagation from material properties or tooling variability, which this study quantifies. Our work employs finite element analysis in ABAQUS to investigate these uncertainties, focusing on isotropic materials such as steel. A 3D model simulates incremental drilling using the model change function, removing material in discrete steps. A parameterized python script automates variations in hole diameter, material properties (such as Young's modulus and Poisson's ratio), and drilling increments, enabling strain computation based on these parameters.

This computational strategy bridges experimental and numerical approaches, offering a scalable platform for isotropic/anisotropic materials and complex geometries. Automated parametric scripting enhances calibration reliability, addressing manual system limitations. By isolating hole size, step increments, and material isotropy effects, the methodology in our study provides actionable guidelines to reduce measurement bias. These findings improve the confidence in residual stress evaluation for safety-critical applications like welded aerospace components, where precise stress quantification reduces premature failure risks.

Paper 436 4 **Influence of microstructural features on Charpy impact toughness properties of low alloy steels.**
Mr. Billel Sadoune, France
Oral Presentation (20')

Abstract Keywords: Fracture mechanics, ductile-brittle transition, Low alloy steels, Microstructure.

Summary :

One of the primary challenges in the nuclear industry is ensuring the safety and security of the installations. Critical structures such as large forged components in low-alloy steel require an in-depth understanding of their mechanical properties to guarantee long-term reliability and performance under normal, incidental, or accidental operational conditions.

The exceptional scale of these components, obtained through ingot forging, inherently leads to localized chemical heterogeneities and variations in thermal history. Consequently, these variations result in a wide range of microstructures, inducing a substantial variability of mechanical properties within a single component. Despite extensive research, a satisfactory predictive tool for fracture properties remains elusive.

This research systematically investigates the key microstructural features influencing fracture properties of low alloy steel, with a focus on explaining and quantifying the statistical aspects of brittle cleavage failure in the ductile-brittle transition.

Our methodology employed mechanical tests on four precisely controlled microstructures. Starting from a reference tempered bainitic microstructure, we methodically varied three metallurgical parameters suspected influent on fracture properties: precipitate size (controlled by tempering conditions), prior austenite grain size (controlled by austenitizing temperature), local chemical composition (controlled by sampling area). Advanced scanning electron microscopy (SEM) and fractographic analyses provided comprehensive insights into mechanical property variations.

The result of this research will be instrumental in developing an advanced numerical model using a micromechanical approach [1] to simulate brittle failure at the microscopic scale.

Paper 513 **5** **Characterization of microstructure in bent Al-Mg-Si-Cu alloys and their correlation to crack development at high and low quench rate**
Mr. Florian Zrim, Austria
Highlight (Oral Presentation 20')

Abstract

Al-Mg-Si-Cu alloys are widely utilized in automotive applications due to their excellent formability and mechanical properties. However, during bending processes, material failure can occur in the form of cracks, the development of which is strongly influenced by the microstructural features and the quench rate. This study investigates the microstructural characteristics and grain boundary precipitates that contribute to crack development. To explore these phenomena, laboratory samples were produced and subjected to high and low quench rates after solution heat treatment, with subsequent bending until failure and ex situ analysis in the scanning electron microscope (SEM). This enabled a systematic evaluation of the correlation between microstructure, bending angle, and quench rate.

Using advanced electron backscatter diffraction (EBSD) combined with conventional SEM, a geometrical transformation method was applied to precisely correlate EBSD data with SEM secondary electron (SE) and backscattered electron (BSE) images. This integrated approach facilitated a detailed microstructural analysis and allowed a clear allocation of features, such as precipitates, in relation to grains or grain boundaries. Additionally, it provided a robust means to distinguish between transgranular and intergranular fracture, an aspect of studying crack development that is often challenging with conventional BSE imaging due to insufficient grain contrast, especially in highly strained materials.

In the bend tests, the high quench rate material successfully achieved the full bending angle before failure, whereas the low quench rate material failed at a significantly lower bending angle. Experimental observations revealed intergranular fracture as the dominant failure mechanism in the low quench rate material, indicating weakened grain boundaries. Further analysis using energy dispersive X-ray spectroscopy (EDX) identified the presence of needle-shaped Q-phase grain boundary precipitates in the low quench rate material, which appeared to play a critical role in crack development. These precipitates exhibited mechanical degradation, forming pores under strain during bending. This pore formation, coupled with mechanical stress, explains the grain boundary weakening leading to intergranular crack propagation. In contrast, the high quench rate material exhibited no Q-phase precipitates at the grain boundaries, correlating to improved resistance to crack formation during bending and thus explaining the difference in bend angle.

This study highlights how microstructural features might be correlated with mechanical performance in aluminium alloys. By employing the geometrical transformation technique for EBSD-SEM data alignment, critical insights into the interplay between grain boundary precipitates and crack development were obtained.

Exploring three dimensional orientation and residual stresses in railway steels

Dr. Louis Lesage, France

Oral Presentation (20')

Abstract

Railway wheel steels, comprising a fine lamellar pearlitic microstructure interspersed with pro-eutectoid ferrite, experience combined thermal and mechanical loads that may induce material failure due to increased local residual stress.

In this study, we use an advanced synchrotron technique, dark-field X-ray microscopy, in which the X-ray diffracted beam is magnified by an objective lens, forming a 2D projection of a grain. By using a line beam, this technique enables the 3D mapping of lattice variations, including both crystallographic orientation and lattice strain. This non-destructive method allows for the characterisation of grains embedded in bulk with a resolution down to 100 nm and is applied here to pro-eutectoid ferrite grains.

In addition to an as-manufactured sample, we studied samples that underwent low-cycle fatigue tests followed by isothermal heat treatments at 300–600°C. The as-manufactured sample shows an orientation variation up to 0.5° and compressive elastic strain up to 1.8×10^{-3} but no direct correlation between the measured compressive strain and lattice orientation. The low-cycle fatigue tested samples exhibit an increase in orientation spread up to 3–4°. These grain-level observations were correlated with bulk X-ray diffraction results, which revealed a non-monotonic evolution of residual stress levels with annealing temperature, as well as with macroscopic mechanical tests.

Such an analysis of the evolution and distribution of residual stress, as proposed here, is essential to inform finite element models that can predict the mechanical behaviour of these materials.

Dynamic Strain Aging in CP-Titanium: Insights from Tensile and Cyclic Loading Tests

Mrs. Nafiseh Ghavidel, Germany

Oral Presentation (20')

Abstract

Dynamic strain aging (DSA) is a critical phenomenon influencing the mechanical behavior of materials, driven by the interaction between dislocations and diffusing solute atoms. This study investigates the occurrence of DSA in commercially pure titanium (CP-titanium) under quasi-static tensile and cyclic tension-compression loading. Tensile and low-cycle fatigue (LCF) tests were carried out in a wide temperature range from 25 – 600 °C at strain rates of $10^{-5} - 10^{-1}$ /s. A systematic comparison is conducted to identify and analyze the temperature, strain rate/frequency, and incubation strain conditions where DSA manifests in these loading modes. Microstructural and mechanical properties, such as microhardness, are also evaluated to elucidate the impact of DSA under each loading regime.

During tensile deformation, DSA manifests through several distinct features, including a plateau in the strength-temperature relationship, serrated yielding in stress-strain curves, and negative strain rate sensitivity (SRS). In the case of cyclic deformation, DSA can be observed as a plateau or peak in the cyclic peak stress-temperature relationship and a negative temperature dependence of the plastic strain amplitude or hardening trend. These findings provide new insights into the mechanisms of DSA in CP-titanium and lay the foundation for optimizing CP-titanium for applications where tensile and cyclic loading are critical.

Paper 429 1 **Aging-Induced Embrittlement in Short-Fiber Reinforced Thermoplastics: A Micromechanical Approach Using Numerical Homogenization**

Mr. Mahmoud Ashour, Germany

Oral Presentation (20')

Abstract

Aging studies are critical for ensuring that engineering plastic components can endure physico-chemical degradation under operating conditions. The degradation kinetics can be assessed by exposing parts to aging environments and testing them afterwards. However, this empirical approach is time-consuming and costly. An advantageous approach would be to simulate those aging tests. The aim of this research program is to develop a simulation method for virtualizing the aging tests of injection-molded thermoplastic parts, specifically addressing aging of the mechanical behavior at the component level. To achieve this in the framework of finite element (FE)-based mechanical simulations, it is crucial to establish failure criteria based on local aging descriptors. This work is focused on the hydrolytic degradation of polyamide 6.6, reinforced with 30 wt.% short glass fibers. Hydrolytic aging of 4 mm thickness PA66-GF30 part results in non-limited diffusion hydrolysis leading to a uniform reduction in molecular weight of the polymer matrix, causing progressive embrittlement, which manifests as a reduction in strain at break during uniaxial tensile tests. To achieve accurate simulations, the research aims to develop a failure criterion based on local aging descriptors. Using micro-mechanical analysis of a 3D representative volume element (RVE), the study links local degradation effects (such as molecular weight reduction) with the overall mechanical response of the composite. This approach allows finite element (FE) simulations to predict aged component failure. The study also discusses the construction of the RVE, which accounts for fiber microstructure, and the identification of the elastoplastic constitutive law for the PA66 matrix. The focus is on proposing a physics-based failure criterion that correlates with damage initiation under various levels of hydrolytic degradation.

Paper 1160 2 **Advancements and Challenges in Automated Non-Destructive Testing: AI- Driven Techniques, Emerging Trends and Future Directions**
Dr. Kangkana Baishya, United Kingdom
Oral Presentation (20')

Abstract

Non-Destructive Testing (NDT) is essential for ensuring the structural integrity and reliability of critical components in industries such as aerospace, automotive, electronics, and energy. The growing need for precision, repeatability, and efficiency has driven the adoption of automated NDT techniques, which leverage advanced imaging, sensors, and AI-driven analysis to improve defect detection and characterization. This paper provides a comprehensive review of key automated NDT methods, including Automated X-ray Inspection (AXI), Automated Ultrasonic Testing (AUT), Automated Optical Inspection (AOI), Acoustic Emission Testing (AET), Eddy Current Testing (ECT), and Infrared Thermography (IRT). While these methods offer significant advantages in terms of speed, accuracy, and scalability, challenges remain in standardization, reliability assessment, and the mitigation of false positives and negatives.

A critical evaluation of these techniques is presented, highlighting their strengths, limitations, and areas where AI and machine learning can further enhance defect detection and classification. The paper also examines the integration of real-time monitoring, digital twin technology, and hybrid NDT approaches as emerging trends that could address current gaps in reliability and uncertainty quantification. Additionally, industry adoption challenges, regulatory compliance, and the need for improved Probability of Detection (POD) metrics are discussed. The findings emphasize that while automation has revolutionized NDT, further advancements in AI-driven analytics, sensor fusion, and adaptive algorithms are necessary to achieve higher accuracy and broader applicability across industries.

Paper 1539 4

Micromechanical study of the influence of ion irradiation on the mechanical properties of anodized Al6061-T6 alloy

Dr. Sergio Sao Joao, France

Oral Presentation (20')

Abstract

In the nuclear industry, materials are subjected to extreme environments, including high radiation flux, elevated temperatures, and corrosive conditions. Ensuring the durability and mechanical integrity of protective coatings is essential for the long-term performance of critical components. Anodized alumina coatings are widely used for their corrosion resistance and mechanical properties, but their behavior under irradiation remains insufficiently understood. Ion irradiation can induce structural modifications, affect mechanical strength, and alter residual stress distribution. Understanding these effects is crucial for optimizing materials intended for nuclear applications. This study investigates the micromechanical response of an alumina-based anodized layer subjected to silicon ion irradiation, providing insights into its potential durability in radiation-intensive environments.

A hard anodized layer with an average thickness of $49.1 \pm 1.9 \mu\text{m}$ was developed on an Al6061-T6 alloy through anodization in oxalic acid, followed by sealing in boiling water. SEM and TEM analyses revealed a U-shaped columnar structure in the longitudinal cross-section, while the top surface exhibited a flaky and/or gel-like morphology. X-ray diffraction and TEM confirmed the anodized layer was amorphous.

Silicon ion irradiation, performed at energies from 3.5 MeV to 0.5 MeV, resulted in a damage dose estimated between 6 and 7 dpa up to $\sim 2 \mu\text{m}$ depth. This irradiation also led to Si implantation within the anodized layer at $\sim 0.6 \text{ at.}\%$. Post-irradiation microscopic examination revealed curled or rolled surface features on the exposed top layer, while the irradiated zone exhibited a smoother texture. Despite irradiation, the affected region remained amorphous.

To assess irradiation effects on mechanical properties, in situ micropillar compression and splitting tests were conducted using SEM. These tests enabled direct comparison of plasticity and fracture toughness between non-irradiated and irradiated layers. Micropillar compression experiments demonstrated irradiation-induced hardening of $\sim 30\%$, with a plastic flow stress of $\sim 3 \text{ GPa}$. Fracture toughness (K_{IC}) measurements from micropillar splitting indicated this property remained unchanged after irradiation, with $K_{\text{IC}} \approx 2.2 \text{ MPa}\sqrt{\text{m}}$.

By testing over a dozen micropillars with different geometric shape factors, unrelaxed compressive residual stresses of $\sim 1 \text{ GPa}$ were measured in the irradiated layer. Finally, in situ observation of deformation and cracking mechanisms provides insights into the mechanical properties in relation to the previously characterized microstructure, contributing to a broader discussion on the impact of ion irradiation on anodized layers.

Paper 1336 5 Study on microscale strain localization and slip activity in ferrite-carbides steel: An integrated study of SEM-DIC and crystal plasticity modeling
Mr. Yadong Zhou, The Netherlands
Oral Presentation (20')

Abstract

This work investigates microscale strain localization and slip activity in ferritic AISI 420 stainless steel using an integrated approach of scanning electron microscopy-based digital image correlation (SEM-DIC), electron backscatter diffraction (EBSD) and crystal plasticity (CP) modeling. The microstructure, consisting of ferritic grains with finely dispersed carbides, exhibits early strain localization that intensifies under increasing global strain, ultimately forming interconnected shear bands. Statistical analyses indicate that localized deformation does not arise from any single microstructural parameter—such as grain size, grain boundary misorientation, maximum Schmid factor, or carbides' effect—but rather from an interplay of constraints. Specifically, poor geometrical alignment of slip transfer at misaligned grain boundaries, constrained slip paths between ferrite grain boundaries and carbides, and limited accommodation in smaller grains collectively promote strain localization. The CP model, enhanced by a realistic representative volume element (RVE) that incorporates nanoscale carbides, reveals local stress heterogeneities and clarifies slip transfer/blocking behavior. To enhance the identification of active slip systems, a new accumulated shear methodology integrates loading history, overcoming the transient limitations of velocity-gradient-based methods. Collectively, these findings underscore the role of microstructural incompatibilities in driving strain localization and point to strategies—such as optimizing grain boundary alignment, refining annealing processes to minimize the formation of small grains, and promoting a more dispersed distribution of carbides—to improve formability in ferritic steels.

Paper 1342 3

Precipitation evolution in FeNbVC microalloyed steels during welding

Dr. Hugo Lannay, France

Oral Presentation (20')

Abstract

This study explores the precipitation of (Nb,V)C carbides in microalloyed steels during welding and stress relief heat treatment (SRHT) of nuclear power plant secondary circuit pipes. A focus is made on how the heat history influences the mechanical properties of the material through particle size distribution evolution. This research investigates the effect of thermal cycles and alloying elements (Nb and V) on the nucleation and growth of precipitates within the Heat-Affected Zone (HAZ). Four model steel alloys (without Nb and V, with Nb, with V, with both) are studied and a thermomechanical simulator is used to reproduce welding cycles and SRHT. The chemistry and the distribution of precipitates are characterised using electron microscopy. Hardness and Charpy impact tests are performed to assess the link between precipitation and mechanical properties. Simultaneously, a KWN model [1] is developed to simulate the evolution of the precipitation distribution at each point of the HAZ, during welding and SRHT, incorporating classic nucleation and growth theories (CNGTs). This study provides valuable insights that emphasise the link between thermal cycles, precipitation and mechanical properties. In particular, far from the weld, precipitates do not evolve; in the opposite, near the weld, they are completely dissolved. However, in the sub-critical HAZ (just below Ac1), precipitates can grow up and be one of the causes of the ductility drop observed at these distances.

Paper 591 **6** **Experimental and numerical study of the interaction of a Zinc based alloy with Stainless Steel 430**

Mrs. Judy Rosso, France

Oral Presentation (20')

Abstract

The ATRUIM reactor design, a loop-type Sodium-cooled Fast Reactor (SFR), stems for the necessity of enhanced safety for the next generation of nuclear reactors. One of the key feature of this concept, introduced to meet the required safety standards, is the design of a compact and passive Decay Heat Removal System (DHRS). This component is tasked with storing the excess heat from the nuclear core during an emergency shut down, operating without external intervention and electricity for multiple days. To ensure the system's compactness, the design choice fell onto a modular storage, where the metallic Phase Change Material (PCM) selected to store the excess thermal heat, Zamak (Zn-4% Al), is encapsulated in multiple SS430 boxes.

In working condition, the encapsulated Zamak will first interact mechanically with the walls of the box, then it will undergo phase change (i.e. melting), that will lead to thermochemical reactions. This study requires the characterization of the intrinsic properties of the individual materials and their interaction behaviour as it may modify the thermal response of the system. Thermal properties are acquired by Differential Scanning Calorimetry (DSC, Netzsch Jupiter F3). For the thermochemical interactions between Zamak and SS430, an experimental setup is developed to study their wetting behaviour. Small samples of Zamak set on SS430 plates are placed inside a tubular furnace (Nabertherm RHTH 120/600/17). The temperature inside the furnace is brought over melting temperature at 450°C in a N₂ atmosphere. A different behaviour is observed when the surface of Zamak is left untreated compared to when it is cleaned with 37% HCl; the untreated Zamak does not adhere to the SS430, a phenomenon that is observed when the surface oxide is chemically removed. We simultaneously develop a numerical model (STAR-CCM+, Siemens) representative of the melting behavior experimentally observed. The experimental and numerical data are utilized to accurately represent the materials and the effects of their interactions.

To further explore the thermal behavior of the modular storage system, an experimental setup for the elementary unit box (15x15x25 cm) is developed. The box is filled with an ingot of Zamak and heated on one side. A reciprocal CFD numerical model is defined to include the heat transfer mechanisms and the phase change behavior. Experimentally, IR thermography is used to measure the temperature distribution on the external surface. The dynamic of this temperature field coupled with numerical simulations will be used to identify the thermal evolution of the system.

Paper 1621 1 Functional phosphate glasses for daily applications

Dr. Julian J. Reinosa, Spain

Highlight (Oral Presentation 20')

Abstract

Phosphate glasses are obtained at lower melting temperatures than silica-based glasses, so their use can have a sustainable advantage in terms of energy consumption. However, their applications are limited due to their hygroscopic properties and high leaching capacity. In this work, controlled leaching phosphate-based glass materials are developed for functional applications that increase sustainability. For this purpose, different formulations and thermal treatments were applied to the designed compositions, so that we were able to adjust the leaching capacity of the glasses to the requirements of the applications. All this thanks to the modification of the short-range order in the microstructure of the glass and this control has allowed different applications: On the one hand, some phosphate compositions exhibit preservative properties and are suitable for use in contact with food. They are currently used as a bacterial reset due to their rapid dissolution in the presence of moisture. However, in this work, 50% less phosphate than is commonly used in the food industry has been used to achieve antimicrobial properties over time, and not only in the form of a reset. On the other hand, the doping of such glasses allows them to modulate their radiation absorption properties in different wavelength ranges of the spectrum which, together with the control of the leaching capacity, has allowed them to be used as sustainable inorganic sunscreens in sun creams. The sunscreen currently used is TiO₂ in different particle sizes, leading to the deterioration of the seabed when deposited. Therefore, the application of Fe/Ce doped phosphate glasses is a sustainable solution to the use of TiO₂ in the cosmetics sector.

Paper 1179 2 **A bespoke atmospheric pressure plasma process for the fabrication of three-dimensional glutathione-silver nanoparticle-polylactic acid composites for skin regenerative applications**
Ms. Anindita Bhar, Taiwan
Oral Presentation (20')

Abstract

Glutathione (GSH) is an antioxidant which performs anti-inflammatory effects via protecting cells from reactive oxygen species and reactive nitrogen species, making it an ideal candidate to be immobilized on polylactic acid (PLA) for skin regenerative applications including wound dressings. Although PLA shows favourable properties for a wound dressing including being biodegradable, biocompatible and sustainable with good breathability and softness, its poor antibacterial ability and chemically-inert nature leads to the absence of cell recognition sites and increases the difficulty of immobilizing functional groups or materials, such as GSH or silver nanoparticles, resulting in the limitation of its further applications for biomaterials. To tackle these issues with an improved modification efficiency, a bespoke process composed of plasma-induced polymerization, reduction and grafting was developed to fabricate a three-dimensional glutathione-silver nanoparticle-polylactic acid composite. An atmospheric pressure plasma nozzle system utilising an acrylic acid-based hybrid precursor was developed and employed to activate the PLA surface, prepare and deposit silver nanoparticles, then graft GSH to contrive a three-dimensional PLA composite possessing antibacterial and anti-inflammatory properties with improved process efficiency. A comprehensive analysis of the wettability, hydrophilicity stability, surface morphology and depth profiles, elemental composition and biocompatibility of the plasma-fabricated PLA composite was performed. An enduringly stable PLA surface along with the presence of carboxylic acid functional groups, silver nanoparticles and GSH antioxidant was observed, suggesting the potential application of this bespoke process on tailoring functional wound dressings.

Paper 935 3 **Controllable Delamination in Multi-Material Multilayer Plastic Packages Using the Addition of oxide particles at the Interface**
Mr. Syahwira Taqwa Triadi, United Kingdom
Oral Presentation (20')

Abstract

Controlling interfacial behaviour is crucial for optimising the performance of multilayer materials, enabling functionalities such as self-healing, self-peeling, and smart bonding. Reversible mechanical interlocking offers a promising strategy for controlling interfacial bonding in these systems.

In this study, oxide particles with optimised structures were applied to polymer surfaces to enhance interfacial bonding. Single lap shear tests were conducted to evaluate shear strength at the interfaces of low surface energy polymers. The results indicate that specific oxide particles with desired geometries significantly improve interfacial shear force. While previous studies have demonstrated an enhanced shear and peeling force by adding oxide particles, a comprehensive understanding of the underlying mechanisms still remains limited. To address this gap, this study further employs modified theories to calculate the interactions between polymers and oxide particles, providing deep insights into interfacial locking mechanisms. The findings can have direct implications for the recyclability of current Multi-Material Multilayer Plastic Packages (MMPPs) applications. During use, different polymer layers can be locked tightly by particles, while after use, the locking can be reversed, facilitating easy delamination of the layers. This approach presents a viable pathway toward sustainable packaging solutions by enhancing both mechanical performance and end-of-life separability.

Paper 942 **4** **Rosin-Derived Materials for Active Packaging: A Sustainable Solution for Meat Preservation**

Ph.D. Barbara Abreu, Portugal

Oral Presentation (20')

Abstract

The growing demand for sustainable food packaging solutions has increased interest in bio-based materials and encapsulation technologies. Within the RN21 project, this study explores the use of rosin resin and its derivatives to synthesize limonene-loaded particles and polymeric films with enhanced gas barrier properties. These advancements aim to extend shelf life, improve food safety, and support the transition to circular and sustainable economies.

Rosin, derived from pine trees, presents a renewable alternative to conventional resins. In this work, rosin derivatives were used to develop a sustainable delivery system encapsulating limonene, a natural antimicrobial and antioxidant compound. Flash nanoprecipitation yielded spherical nanoparticles (~150 nm) with a 30% theoretical loading content and 40% production yields. These particles were incorporated into biopolymeric matrices using melt blending, forming functional films for active packaging. The films underwent controlled release studies simulating real-world meat packaging conditions.

Another strategy involved incorporating rosin resin derivatives into biopolymers. A biopolymer was compounded with a rosin-derived resin via twin-screw extrusion, producing composite pellets that were then processed into films through blown film extrusion. The inclusion of gum rosin resin significantly enhanced the barrier properties against water vapor and oxygen, yielding a denser, less permeable matrix. Functional coatings further improved these properties, reducing WVTR and OTR more than 70% when compared to the original substrate.

This work demonstrates the potential of rosin-derived materials as eco-friendly alternatives for active packaging. By integrating renewable resources and advanced encapsulation techniques, these solutions address industry demands for high-performance packaging while contributing to global sustainability goals. Extending shelf life and reducing food waste provides both economic and environmental benefits. The authors acknowledge the RN21 project, funded by the Environmental Fund through Component 12 – Promotion of Sustainable Bioeconomy (Investment TC-C12-i01 – Sustainable Bioeconomy No. 02/C12-i01.01/2022), of European funds allocated to Portugal by the Recovery and Resilience Plan (PRR), within the European Union (EU) Recovery and Resilience Mechanism, framed within Next Generation EU, for 2021–2026.

Paper 1400 6 **Encapsulation of Clove Essential Oil into Sepiolite for Active Food Packaging Applications**
Dr. Cástor Salgado, Spain
Oral Presentation (20')

Abstract

The incorporation of clays as carriers of active substances in polymeric materials is gaining increasing attention. Essential oils (EOs) can provide valuable properties to plastic materials, although their high volatility poses challenges for large-scale industrial applications. This work presents a green, scalable, and versatile method for encapsulating clove essential oil (CO) into food-grade sepiolite clay, which was organo-modified by acid-activation using the food additive E-297 to ensure safety for food packaging applications. The resulting multicomponent nano-materials (MCNMs) enhanced the thermal stability of CO, enabling its incorporation into a low-density polyethylene (LDPE) matrix.

The MCNMs released 10 wt% of CO after 14 days under ambient conditions. Films with different clay loadings (0.5 wt%, 1 wt%, and 2 wt%) were produced by extrusion-blowing, showing optical and thermal properties comparable to pure LDPE. The antimicrobial activity of the films was evaluated against *E. coli*, *Salmonella enterica*, and *Listeria innocua*. Remarkably, the MCNM-films retained 70% of the encapsulated CO after three years of aging at room conditions while still releasing aroma. The films passed the overall migration tests for simulants A and D1, complying with European regulations for food-contact materials.

Additionally, the method was successfully applied to encapsulate other essential oils such as cinnamon, mentha arvensis, oregano, citronella, strawberry, thyme, and rosemary. These findings demonstrate the high potential of MCNMs and composite films for applications in active food packaging and agriculture.

Paper 1494 7

Water sorption, conversion rate and fracture toughness of liquid rubber modified dental composites

Pani. Monika Sowa, Poland

Oral Presentation (20')

Abstract

Dental composites based on dimethacrylate resins have good aesthetics and mechanical properties, but their brittleness and susceptibility to fracture require modification to improve damage resistance and reduce water sorption and material degradation. The purpose of this study was to assess the effect of liquid rubber addition on the physicochemical properties of dental composites, particularly water sorption, conversion degree, and fracture toughness. Various types of composites, conventional and flowable, were analyzed, both with and without 5% liquid rubber content (a total of 4 combinations). The composite matrix consisted of a mixture of BisGMA (20 wt.%), BisEMA (30 wt.%), UDMA (30 wt.%), and TEGDMA (20 wt.%). As a modifier, liquid rubber Hypro 2000X168LC VTB was introduced at 5 wt.% relative to the matrix. Both the flowable and conventional materials were microhybrid composites, differing in their component proportions. The filler content in the flowable composite was 50% vol., while in the conventional composite it was 80% vol.

The results showed that the liquid rubber-modified samples exhibited lower water sorption compared to their unmodified counterparts. Average water sorption for the conventional composite decreased by 27.4%, while for the flowable composite, it decreased by 11.8%. The addition of liquid rubber contributed to an increase in the degree of conversion which was confirmed by FTIR studies. A higher degree of conversion indicates a lower amount of residual monomers, which can limit material degradation and improve its longevity in the oral environment. Additionally, a more cross-linked polymer structure can result in increased fracture resistance and reduced susceptibility to wear, which is crucial for the long-term functionality and aesthetics of dental restorations. Fracture toughness analysis revealed positive effects of liquid rubber addition. The fracture toughness coefficient increased by approximately 12% for the conventional composite and by approximately 20% for the flowable composite. It can be assumed that liquid rubber acts as a factor reducing crack propagation within the material structure, enhancing its energy absorption capacity, and improving resistance to mechanical loads. The findings suggest that the addition of liquid rubber can positively influence dental composites by reducing water sorption, increasing the degree of conversion, and enhancing the fracture toughness. More studies are needed, including long-term stability assessment as well as fatigue behavior under simulated oral conditions.

Paper 747 1 **The influence of thermal interference fit value on the stress and strain distribution in the area of divided tools used in the dynamic hot hammer forging process**

Ph.D. Lukasz Lisiecki, Poland

Oral Presentation (20')

Abstract

One of the methods for generating cost savings in the die forging process of heavy products on a hammer is the use of split dies. The selection of appropriate models for predicting die wear allows for the identification of areas with the most intense wear, which can be incorporated as a replaceable die insert. The nature of the hammer forging process requires the use of uniform tools, as any additional elements used to connect the insert with the die fail to function effectively during dynamic forging. Therefore, the only feasible way to incorporate a replaceable insert is by joining it using thermal interference fit. This phenomenon not only enables the connection of tool components but also introduces additional modifications to the stress and strain state before and during the forging process which has a significant impact on the tool load level and its durability. This study presents research on the modification of stress and strain states in the tool area through the application of varying thermal interference fit values between the main part of the forging die and the replaceable insert. To achieve this, a research methodology was proposed, utilizing the analysis of strain field changes on the tool surface using a Digital Image Correlation system (DIC). The analysis covered both the tool during the interference fitting process and the simultaneous temperature gradient equalization, as well as during the forging process under laboratory conditions with full control of process parameters (such as tool movement speed, pressing force, and instantaneous tool positions). The research results were compared with numerical simulations (FEM) of the test. Additionally, an industrial forging process was analyzed, with particular attention to tool wear mechanisms and the distribution of stress and strain in tools joined using thermal interference fit.

Application of the stochastic model of thermomechanical processing to simulation of the evolution of heterogeneous microstructures and evaluation of the uncertainty of the product properties

Dr. Danuta Szeliga, Poland

Oral Presentation (20')

Abstract

Two aspects of the thermomechanical processing of steels are considered in the paper. The first is problem of the heterogeneity of the modern steels' microstructure, which has been intensively studied during last few decades. It was shown that complex phase steels with heterogeneous microstructure show excellent mechanical properties. The second aspect is connected with uncertainty of the properties of products. Many researchers have pointed out recently that the knowledge of the possible spread of parameters, such as a grain size, is needed for a reliable design of the production processes. In the industrial conditions the variations of final product properties are caused by uncertainties in the boundary conditions during the manufacturing and by the stochastic character of some metallurgical phenomena. We assumed that the stochastic model of multi-step hot deformation and controlled cooling after deformation can deal with both these aspects. In the stochastic hot deformation model a random character of the recrystallization was introduced. The model was extended by including phase transformations during cooling after hot forming. Nucleation of the new phase was considered as random process. In consequence, prediction of the heterogeneity of the microstructure in the room temperature became possible. Reliability of the model depends, to a large extend, on the proper identification of the coefficients in this model. Identification of the hot forming model was based on the inverse analysis for the hot compression tests. Identification of the stochastic model of phase transformation was based on the continuous cooling dilatometric tests. The complete model calculates histograms of the grain size during thermomechanical processing, as well as histograms of microstructural parameters of the final products after cooling. Relations between microstructure and mechanical properties allow to evaluate the uncertainty of the latter. In the present work the model was applied to simulations of industrial processes of rolling and controlled cooling of eutectic steel rails and bainitic steel rods. Histograms of the microstructural parameters were calculated for various cooling strategies. Advanced features of the microstructure, which decide about products properties, such as interlamellar spacing in the pearlite or thickness of ferrite plates in the bainite, were calculated. The variations of final product properties, which include hardness of rails and strength of rods, were evaluated.

Paper 2061 3

Evidence for a new work hardening stage at colossal strains

Dr. Oliver Renk, Austria

Oral Presentation (20')

Abstract

Traditional work hardening stages have been investigated for decades and the underlying mechanisms are widely accepted. Because of dynamic recovery mechanisms, work hardening quickly diminishes and ceases already at relatively small equivalent strains ($\epsilon_{VM} > 10$). At this stage, commonly referred to as the steady state or saturation regime, a dynamic equilibrium between grain refinement and dynamic recovery (i.e., by mechanically driven grain boundary migration) is established. A vast number of studies using severe plastic deformation techniques support the existence of this saturation regime. Meanwhile, few reports question such steady state, but suggest another strain hardening regime might be entered for strains > 1000 . Nevertheless, so far, neither an in-depth analysis nor a general theory for such ultra-SPD strain hardening has been established.

In the present work we subject pure metals to HPT at room temperature up to exceptionally high strains ($\epsilon_{VM} > 10000$). The results confirm the existence of a saturation stage, but provide solid evidence for the reinitiation of strain hardening at colossal strains ($\epsilon_{VM} > 1000$). This behavior can be observed independent of the crystal structure. Detailed microstructural investigations confirm that the new work hardening stage manifests in noticeable additional grain refinement and hardness increase. Although at this stage the strain hardening rate is weak, a distinct hardness gain (~30% compared to the classic steady stage condition) can be measured. Texture, and the existence of subgrains still support dislocation-based plasticity. Unexpectedly, the specimens subjected to such colossal strains possess – despite their reduced grain size – an improved thermal stability, which according to atom probe tomography, cannot be related to a continuous impurity take up during HPT deformation. Other mechanisms, thus need to explain the reinitiation of work hardening as well as the intriguing thermal stability, which will be the center of discussion.

Paper 1959 4

Microstructural aspects of plastic deformed martensite decomposition in the Ti-6Al-4V alloy

Dr. Maciej Motyka, Poland

Oral Presentation (20')

Abstract

The formation and decomposition of martensite in titanium alloys is usually associated with their heat treatment to achieve high mechanical properties. The presence of α' and α'' martensitic phases in these alloys also determines the effects of thermomechanical processing or additive manufacturing. Analysis of the results of previous studies indicates that the decomposition mechanism of plastically deformed α' martensite differs from that of undeformed, occurring during conventional tempering. This paper presents the results of TEM and SEM microscopic investigations of Ti-6Al-4V alloy plastically deformed in the quenched state and tempered statically – i.e. conventionally – and dynamically – by a high-temperature plastic deformation process. The change in grain morphology during the martensite decomposition process has been assessed, including the change in grain orientation (EBSD), as well as the reorganisation of structure defects.

Paper 6 **1** **Microstructural and Mechanical Properties Study of Friction Stir Welded 316L Stainless Steel**

Prof. Michael Regev, Israel

Oral Presentation (20')

Abstract

Bead on plate Friction Stir Welding (FSW) was used in the current study to simulate butt welding of 316L stainless steel, which requires a WC welding tool and high welding parameters. Once the optimal welding parameters had been determined, the cross section of the plate was metallographically inspected to ensure that the weld had penetrated through the entire thickness and that the FSW'ed material had no defects or WC particles originating from the welding tool. Optical and Scanning Electron Microscopy (SEM) metallographic characterization, along with microhardness tests, were performed on each of the different zones of the welded joint, namely, the parent material, the heat affected zone (HAZ), the thermomechanically affected zone (TMAZ), and the stir zone. Both the parent material and the FSW'ed material were subjected to tensile tests and fractography studies. As for the parent material, there were minor differences between specimens whose longitudinal axis was parallel to the rolling direction of the plates and specimens whose longitudinal axis was normal to the rolling direction. FSW'ed specimens showed higher microhardness and yield strength, but fracture always occurred within the stir zone. An Electron Back Scatter Diffraction (EBSD) and Transmission Electron Microscopy (TEM) study were performed to investigate the microstructural changes during welding. The occurrence of microstructural changes during welding as well as their influence on the mechanical properties will be referred and discussed.

Paper 16 **2** **Recrystallization mechanisms activated during multi-pass forging of austenitic stainless steels**
Mr. Hugo Latuner, France
Oral Presentation (20')

Abstract

Multi-pass forging is widely used to produce large components in austenitic stainless steels for Generation III and III+ nuclear reactors. A better understanding of the multi-pass forging process is essential for optimizing the final microstructure and mechanical properties of the materials. This study aims to investigate and model the microstructural evolution during multi-pass thermomechanical processing, with particular emphasis on the mechanisms of dynamic and post-dynamic recrystallisation. To achieve this, uniaxial hot compression tests were performed as an experimental simulation of multi-pass hot forging, exploring different thermomechanical conditions and focusing on small strain increments. The resulting microstructures were characterised using SEM-EBSD. The EBSD data were then used to develop a mean-field model integrating dynamic and post-dynamic recrystallisation phenomena. In addition, the effects of successive deformations on the microstructure were analysed to better understand the role of elastic stored energy in recrystallisation mechanisms and its effect on the final grain size distribution.

Paper 20 **3** **Textural evolutions in aluminum alloys building by multi-layer friction surfacing (MLFS) deposition**
Prof. Farzad Khodabakhshi, Belgium
Oral Presentation (20')

Abstract

The texture of aluminum alloys in additive manufacturing (AM) using multi-layer friction surfacing (MLFS) was analyzed through electron backscatter diffraction (EBSD) characterization. This study focused on three different aluminum alloys: AA5083, AA6061, and AA7075. After conducting MLFS deposition in the solid state and optimizing the corresponding processing parameters, various sections of the consolidated aluminum alloy structures were characterized using EBSD to reveal their microstructural details and dominant orientations. The textural assessments indicated a significant contribution of shear-based components induced by the friction stirring process, particularly in the direction normal to the building orientation (BD). Comparing the three alloys, it was found that as the fraction of secondary phase precipitates increased from AA5083 to AA7075, the predominant shear-based texture was notably influenced by the role of micro- and nano-scale precipitates. Microscopic observations suggest that these precipitates can affect the dynamics of recrystallization (DRX) through particulate-stimulated nucleation (PSN) and Zener-pinning mechanisms. Consequently, the preferred orientation shifts from the ideal shear texture to a greater prevalence of other texture components.

Paper 2070 4 Effects of Severe Plastic Deformation under the particular conditions of the KoBo Extrusion Process of Various Metallic Materials

Prof. Romana Sliwa, Poland

Oral Presentation (20')

Abstract

The KOBO extrusion process is an unconventional method of extrusion based on the phenomenon of superplasticity as an effect of a special state caused by the oscillatory motion of the die. It allows to perform the process at low temperature with severe plastic deformation (SPD) under cyclic change of deformation path conditions and to significantly reduce the force of the press. It is possible to extrude lightweight metals and alloys (e.g. aluminum and magnesium alloys) in cold extrusion with high extrusion ratios compared to conventional hot extrusion. The work presents mechanical behaviour of various metallic materials under different conditions resulting from localized plastic flow in shear bands and intensive generation of point defects (self interstitials) This phenomenon is the result of the oscillatory movement of the die by a certain angle and frequency The influence of the die geometry on process realization, parameters and the properties of the extrudate. were performed using dies with different face portion geometry. The extrudate obtained from billets of various internal structure was examined for mechanical properties and macro/microstructure, showing that, with adequate modifications to the tool face part geometry, it is possible to reduce the extrusion force and obtain extrudate with desired properties. Basing on analysis of microstructure and mechanical features of the product obtained in Kobo extrusion it was shown effect of superplasticity represented e.g. by high elongation.(about 800% of aluminum alloy 7075) but in this case microstructure does not require nanometric sizes of the grains and metal can undergo extremely large, uniform deformations without breaking. In case of deformation in KoBo extrusion the superplastic flow of metals requires verification especially in relation to the traditionally accepted conditions of superplasticity: fine grain size, high temperature, low strain rate, low stress. The specific conditions of the plastic deformation in the low-temperature KOBO process, with particular emphasis on the original plastic flow mechanism and the role of point defects and concentration of atoms, excessive concentration of interstitial atoms preserved in extruded products (nanoclusters) as well as taking into account the demonstrated significant impact of the die geometry on the mechanical behavior of the deformed metal, show the possibility of use KoBo extrusion as SPD process.

Paper 1974 5 Mechanical and electrochemical analysis of AA5083- AA7075 dissimilar alloy joints fabricated by friction stir welding
Dr. Atul Kumar, India
Oral Presentation (20')

Abstract

This present study aims to produce high-strength (AA7075), high-corrosion resistant (AA5083) dissimilar joints of Al alloys through friction stir welding (FSW) technique for marine applications. The dissimilar joints of Al alloys were fabricated with standardized FSW process parameters (i.e., 1100 rpm of tool rotational speed, 50 mm/min of welding speed, and 2° tilt angle). Detailed analysis of weld characteristics, mechanical properties, and corrosion behaviour are carried out to establish the effectiveness of the FSW technique for dissimilar welding. The hardness profiles across the weld regions revealed a significant increase in hardness within the stir zone compared to the base metals, attributed to the fine-grained microstructure generated during the FSW process. The ultimate tensile strength of the optimized FSW joint is found to be 80% of the AA7075 base metal, indicating good joint efficiency. Microstructural analysis through optical microscopy and SEM provides insights into the grain structure and phase distribution within the weld zone. The stirred zone exhibits a refined equiaxed grain structure as a result of dynamic recrystallization during FSW. Corrosion behavior was assessed using Tafel plots and Electrochemical impedance spectroscopy (EIS). The Tafel plots illustrated that the welded joint exhibited a corrosion potential and current density the same as base metals, suggesting that the FSW process did not lower the corrosion resistance of the materials. EIS results provided further evidence of the weld's stability in corrosive environments, with impedance spectra indicating better corrosion resistance.

Enhancing mechanical properties of NbTi alloys by thermomechanical processing

Dr. Aleksandra Bartkowska, Switzerland

Oral Presentation (20')

Abstract

Ductile NbTi alloys are prominent superconducting materials that exhibit superconductivity under high magnetic fields, making them suitable for particle accelerators, fusion reactors and magnetic resonance imaging (MRI) systems. For example, Nb-47wt.%Ti alloy is utilised in the superconducting magnets of the Large Hadron Collider (LHC) at CERN and in the poloidal field and corrector coils of the ITER magnet system, while Nb-55wt.%Ti alloy is employed in components of the superconducting radiofrequency crab cavities for the High Luminosity LHC (HL-LHC) upgrade. Compared to other high-performance superconductors, NbTi alloys are more cost-effective, have more suitable mechanical properties, in particular ductility, and are easier to fabricate, making them the practical choice for most applications. Metallurgically, both Nb-47wt.%Ti and Nb-55wt.%Ti are full β -phase alloys, due to their high niobium content. However, compared to α -phase or α + β -phase titanium alloys, these bcc β -phase alloys exhibit lower mechanical strength and Young's modulus.

This study focuses on enhancing the mechanical properties of β -NbTi alloys through thermomechanical processing, specifically cold working (CW), heat treatment (HT), and their combination (CW+HT). The goal was to refine the grain structure, minimize contamination, and achieve a hardness exceeding 170 HV1. Nb-47wt.%Ti and Nb-55wt.%Ti alloys were subjected to compressive deformation to 40% strain and rolling reductions of 35%, 65%, 82%, and 94%, respectively. Subsequent HT was performed at various temperatures to analyse the combined effects of CW and HT. As-received and processed samples were analysed using computed tomography (CT) to verify the absence of flaws or imperfections induced by CW. Further characterization of the materials was conducted using light microscopy (LM), scanning electron microscopy with energy-dispersive spectroscopy (SEM+EDS), X-ray diffraction (XRD), microhardness testing, and nanoindentation to evaluate phase composition, microstructure, and mechanical properties as functions of HT temperature and applied strain.

The findings demonstrated that cold working followed by heat treatment significantly enhanced the mechanical properties of both alloys. For the Nb-55wt.%Ti alloy, different levels of CW followed by HT at 400°C resulted in a 50% increase in hardness. Similarly, for the Nb-47wt.%Ti, a rolling reduction of 65% combined with HT at 375°C led to a 20% increase in hardness. These improvements were attributed to the synergistic effects of second-phase precipitation and cold work-induced strengthening mechanisms.

Paper 741 1 Porous and luminescent coordination networks from new tailored ligands

Prof. Lucia Carlucci, Italy

Keynote (Oral Presentation 40')

Abstract

Coordination Polymers (CPs) and Metal-Organic Frameworks (MOFs) continue to attract great scientific interest due to their application in many different fields. Alongside well-known and studied MOFs the search for new materials through the development of tailored organic ligands is still an active topic in the field.

In our long standing interest in the synthesis, structural and topological characterization of new CPs and MOFs we are exploiting the coordination ability of new organic ligands to obtain homo and heterometallic porous networks. In particular, MOFs assembled with β -diketone and derived ligands which show large crystallographic void and structural flexibility will be presented. Their synthesis, crystal structures and porous properties will be discussed.

In addition, will be also presented the use of the triimidazo[1,2 a:1',2'-c:1'',2''-e][1,3,5] triazine (TT) molecule as a platform to develop new organic ligands of trigonal symmetry for the assembly of new CPs. The interesting luminescent properties of TT together with the great versatility in chemical functionalization is very promising for obtaining new luminescent and porous CPs.

Paper 714 2 **Silica derived from Industrial Waste as Catalyst Support: Characterization of Morphological and Surface Properties.**
Dr. SERGIO MOLINA-RAMIREZ, Italy
Oral Presentation (20')

Abstract

The sustainable recovery of Silica from industrial waste presents a promising opportunity to develop high-performance materials with tailored properties, which can be applied and functionalized as catalytic support for Carbon Dioxide Capture and Re-Use Process (CCSU). This contribution is focused on the investigation and development of the synthesis, characterization, and application of silica derived from hexafluorosilicic acid (H_2SiF_6), a hazardous by-product of the phosphate and aluminum fluoride industries. Through controlled precipitation using ammonia and the incorporation of organic templates, silica nanoparticles, mesoporous, and macroporous silica supports were produced with diverse morphological and surface characteristics. Silica nanoparticles exhibited spherical morphology with diameters of 20–40 nm and surface areas of 115–130 m^2/g , and fluoride impurity levels reduced below 0.5 wt.% through optimized washing and drying procedures. Porous silica synthesized with organic templates achieved specific surface areas in the range 1100–400 m^2/g , pore volumes of 0.94–1.15 cm^3/g , and ordered pore sizes ranging from 3 to 30 nm. Also, macroporous silica have been prepared using different organic templates, obtaining materials with a pore diameter between 150–350 nm and a surface area of 110 m^2/g . FTIR-spectroscopy confirmed the presence of diverse silanol groups across all samples, with surface characteristics modulated by porosity and residual fluoride species. The FT IR analysis of hydroxyl (OH) groups revealed a combination of free, geminal, and hydrogen-bonded silanol groups, with weak protonic acidity evaluated using pivalonitrile adsorption-desorption studies. These waste-derived and recovered silica-samples demonstrated physicochemical properties comparable to commercial silica benchmarks. The tunable porosity, high surface areas, and weak acidity indicate these material as promising candidates for advanced applications such as a sustainable catalytic support. These materials, once functionalized with suitable promoters (metals, basic oxides), will be tested for environmental remediation processes through CCSU.

Hierarchical pore formation in iron nitride foils investigated at nano-scale by phase-contrast tomography

Dr. Sandra Benter, France

Oral Presentation (20')

Abstract

Metallic materials displaying a high porosity in form of sponges or foams have gained increasing interest since the turn of the century. It is widely understood that the presence of pores within a material can alter the range of applications significantly. In more detail, pore size, morphology and volume fraction govern the function of the respective material. Catalytic materials, for example, benefit significantly from an increased surface area based on open-pore systems. Recent studies suggest the suitability of iron nitride as a catalyst due to its high activity¹ and long-term stability². Experimentally, a quantitative analysis of pore connectivity, size and distribution remains challenging for pores in the submicron range. Therefore, this study investigates systematically the pore formation during nitriding and denitriding of 38 μm thin, free-standing iron foils. For this, the samples were treated in an NH_3/N_2 atmosphere with different temperature sequences^{3, 4}. Subsequently, the samples were analyzed by employing phase-contrast tomography at the ID16B beamline at the ESRF allowing for a voxel size down to 25 nm. Individual scans of the full foil thickness were recorded for areas of up to $125 \times 125 \mu\text{m}^2$. This combination of high resolution and large scan volume are significant advantages compared to standard scanning electron microscopy and focused-ion beam tomography. The overall results indicate an open-pore system with hierarchical pore formation dependent on the process temperature. The foils exhibit μm - and nm-sized pores towards the edge and middle of the foil, respectively. Additionally, elongated pores oriented parallel to the surface are visible in the center, in contrast to perpendicular pores allocated towards the surface. The study demonstrates the potential of the ID16B beamline to facilitate quantitative data for materials exhibiting hierarchical pore systems in an easy manner. Furthermore, it sheds light on the overall pore formation in iron nitride foils dependent on the process temperature. The results can be a valid stepping stone to further finetune the porosity properties for specific applications such as catalysis.

Assessing the mechanical strength of multi-channelled flat-sheet ceramic filters

Mr. Manuel Antonio García Galán, Spain

Oral Presentation (20')

Abstract

A methodology is presented for assessing the mechanical strength of multi-channelled flat-sheet ceramic filters, and applied to a flat-sheet SiC filter designed for submerged outside-inside vacuum-driven filtration. To this end, four-point bending, tensile, and compressive tests were performed, and the experimentally measured failure loads were converted to failure stresses and analysed by Weibull diagrams. This ceramic filter was found to be ~1.4 times stronger and ~2.9 times less reliable under compression than in bending, and in turn ~3.3 times stronger and ~5.4 times more reliable in bending than in uniaxial tension. These differences in mechanical performance are explained in terms of the corresponding fracture modes and the critical flaw populations responsible for failure. Finally, relevant implications for ceramic “membranologists” interested in mechanical characterization are discussed.

Paper 1702 5 **Influence of Microstructure on Dealloying Kinetics and Nanoporosity in AgAu Thin Films for Electrocatalytic Applications**
Mrs. Ezgi Hatipoglu, Germany
Oral Presentation (20')

Abstract

Dealloying corrosion is a well-established technique for fabricating high-surface-area nanoporous metals, which hold great potential for catalytic applications, particularly in alkaline water electrolysis [1]. This process selectively dissolves the less noble metal from a solid-solution alloy, resulting in a chemically enriched, three-dimensional open-pore nanostructure primarily composed of the more noble metal [2]. These nanoporous metals offer a highly tunable platform for optimizing composition, morphology, and surface-to-volume ratio—key factors influencing catalytic and electrochemical performance. Utilizing thin film precursors presents several advantages over bulk solid-solution alloys, including reduced production costs by minimizing noble metal consumption, the introduction of a high density of microstructural defects that act as preferential sites for dealloying initiation, and enhanced integration into energy storage and catalytic devices due to their inherent substrate-support characteristics [3]. Moreover, thin films deposited via magnetron sputtering enable precise control over thickness and composition, making them highly adaptable for targeted application [4]. Therefore, a fundamental understanding of the microstructure of precursor samples is essential for optimizing dealloying mechanisms and tailoring critical nanoporous features, such as ligament size and composition.

In this study, we investigate the influence of microstructure on the dealloying behavior of AgAu thin films deposited at 400°C with either a (111)-textured or a non-textured grain orientation. Electron backscatter diffraction (EBSD) confirms the distinct crystallographic textures. At the same time, atom probe tomography (APT) reveals that the textured film retains a higher Ag content in the nanoligaments after chemical dealloying. In contrast, the non-textured film undergoes more pronounced coarsening and exhibits lower residual Ag concentration. These findings underscore the critical role of microstructure in controlling dealloying kinetics, and final ligament composition. Understanding such structure-property relationships is essential for optimizing nanoporous metals in catalysis, where stability and active surface area are crucial for long-term performance.

Paper 824 6 Unraveling Ion-Exchange behavior in ZnAl LDH: The Impact of Functional Substituents and Isomeric Variations

Mr. Youmin Qiu, Germany

Oral Presentation (20')

Abstract

This study provides a comprehensive investigation into how both functional substituents and isomeric arrangements influence the intercalation and ion-exchange behavior of ZnAl layered double hydroxides (LDHs). Two distinct systems were examined. In the first, isophthalic acid (IPA), 5-aminoisophthalic acid (AIPA), and 5-nitroisophthalic acid (NIPA) were intercalated into ZnAl LDHs via a co-precipitation method to understand the impact of $-NH_2$ and $-NO_2$ substituents. UV-Vis quantification revealed that loading capacity followed the sequence $NIPA \geq AIPA > IPA$, whereas release kinetics in NaCl solution proceeded in the order $AIPA > IPA > NIPA$. Density functional theory (DFT) simulations attributed these differences to varied binding affinities driven by deprotonated carboxylates on the aromatic ring, showing a higher affinity for NIPA2- than AIPA2- or IPA2-. Moreover, $-NO_2$ group stabilized the intercalated species by additional interactions with hydroxide layers, while the $-NH_2$ group led to weaker interlayer stability due to the positively charged hydrogen atoms.

In the second system, three isomers of pyridinedicarboxylic acid (PDA)—2,3PDA, 2,5PDA, and 3,4PDA—were intercalated into ZnAl LDHs via ion exchange to examine the role of molecular geometry. Structural characterizations showed distinct interlayer orientations leading to varying stabilities, release profiles, and chloride ion uptake capacities. ZnAl-2,3PDA exhibited the highest stability and minimal release due to nearly vertical orientation and strong electrostatic interactions, whereas ZnAl-2,5PDA showed moderate stability with the highest chloride ion uptake. Conversely, ZnAl-3,4PDA demonstrated rapid release and instability owing to a disordered interlayer arrangement. DFT analysis supported these findings, highlighting the correlation between binding strength, charge distribution, and isomeric configuration.

Overall, these results underscore the pivotal influence of both functional substituents and isomeric arrangements on the ion-exchange and intercalation properties of LDHs. Such insights pave the way for the development of predictive models and the rational design of LDH-based materials for targeted applications in controlled release, environmental remediation, and catalysis.

Paper 1927 2 The structure-mechanical properties relations of nanoporous Ag as obtained from molecular dynamics simulations

Prof. Dan Mordehai, Israel

Oral Presentation (20')

Abstract

The mechanical behavior of nanoporous gold (NPG) is governed by a complex interplay of ligament-scale deformation mechanisms, topology-dependent elasticity, and size-dependent plasticity. In this study, we employ molecular dynamics (MD) simulations to investigate the compression and creep response of NPG nanopillars and nanowires, focusing on their size-dependent mechanical properties, plasticity evolution, and deformation mechanisms. Compression simulations of NPG nanopillars reveal that their elastic modulus depends not only on solid fraction but also on ligament topology and nanopillar dimensions. The elastic response is primarily governed by ligament compression, with the effective number of load-bearing ligaments influencing the modulus. In the plastic regime, compression stress-strain curves exhibit an initial nonlinear response, followed by a plateau and a strong hardening stage. Our analysis of dislocation activity shows that the elastic-plastic transition occurs at lower strains than previously assumed. By skeletonizing the ligament structure, we track the evolution of load-bearing ligaments and find that at the onset of the plateau, 40% of ligaments have already yielded, suggesting the plateau stress corresponds to the topology of the unyielded ligaments. Furthermore, tensile creep simulations of NPG nanowires highlight the interplay between dislocation slip and atomic diffusion, revealing a transition from diffusion-dominated deformation at low creep stresses to a mixed displacive-diffusive mechanism at higher stresses. The contribution of dislocation activity decreases as ligament size increases, which manifests as changes in creep exponents. Remarkably, the calculated activation volumes and creep stress exponents align with those measured in indentation creep experiments, despite differences in length and time scales. Our findings provide a comprehensive understanding of how ligament-scale plasticity, structural topology, and diffusion-mediated mechanisms contribute to the mechanical response of NPG structures. This study advances the predictive modeling of porous materials and offers insights for the design of NPG-based functional and structural applications.

Paper 618 3 Bulk nano-structured porous martensitic alloys: a sustainable synthesis attempt via reactive vapor phase dealloying-alloying
Dr. Shaolou Wei, Germany
Oral Presentation (20')

Abstract

For millennia, alloying has been the greatest gift from metallurgy to humankind: a process of mixing elements, propelling our society from the Bronze Age to the Space Age. Dealloying, by contrast, acts like a penalty: a corrosive counteracting process of selectively removing elements from alloys or compounds, degrading their structural integrity over time. In this presentation we will show that when these two opposite metallurgical processes meet in a reactive vapor environment, profound sustainable alloy design opportunities become accessible, enabling bulk nano-structured porous alloys directly from oxides, with zero carbon footprint. We will discuss thermodynamically well-grounded treasure maps that turn the intuitive opposition between alloying and dealloying into harmony, facilitating a quantitative approach to navigate synthesis in such an immense design space. We demonstrate this alloy design paradigm by synthesizing nano-structured Fe-Ni-N porous martensitic alloys fully from oxides in a single solid-state process step, and substantiating the critical kinetic processes responsible for the desired microstructure.

Paper 1540 4 **Hydrogen storage in nanoporous carbons: A path towards sustainable and scalable solutions**
Mr. Stefan Zeiler, Austria
Oral Presentation (20')

Abstract

Hydrogen is a crucial clean energy carrier with a high gravimetric energy density. However, its low volumetric energy density presents significant storage challenges. Beyond energy-intensive methods such as compressed hydrogen (700 bar) or liquid hydrogen (20 K), physisorption-based storage in nanoporous materials offers a promising alternative at moderate pressures and cryogenic temperatures. Nanoporous carbons have shown great potential for hydrogen storage due to their high specific surface area and tunable pore structures. However, research has largely focused on lab-synthesized materials with limited scalability. This study systematically investigates 16 commercially available nanoporous carbons, derived from various precursors and in macroscopic forms (granules, pellets, powders, spheres), to assess their viability for large-scale hydrogen storage applications. Structural characterization via Raman spectroscopy and X-ray diffraction confirmed the turbostratic nature of the studied materials, while N₂ (77 K) and CO₂ (273 K) adsorption provided insights into their pore structure characteristics. Hydrogen storage capacity was initially evaluated at 77 K under low pressures (<1 bar), followed by high-pressure measurements (up to 100 bar) at 77, 87, and 111 K for a subset of five promising materials with varying microporous and mesoporous structures. The storage performance was analyzed in both gravimetric and volumetric terms, considering bulk densities to assess the practical storage potential. The obtained results are compared with pore structure characteristics. In addition, a techno-economic analysis determined material costs per unit of stored H₂, correlating the findings with the U.S. Department of Energy targets. Several commercially available nanoporous carbons demonstrated hydrogen storage capacities competitive with these targets, underscoring their potential for scalable hydrogen storage applications.

Paper 1564 6 Fixed-bed column adsorption of activated biochar towards purification of landfill leachate

Prof. Apostolos Giannis, Greece

Oral Presentation (20')

Abstract

The purpose of this study was the purification of landfill leachate collected at the output of Sequencing Batch Reactor (SBR). The adsorption of total polyphenols (TPH) and color was studied using palm leaves biochar after pyrolysis and activation with the addition of KOH. The activated biochar was used in batch adsorption experiments (kinetic studies), and in fixed-bed column adsorption studying the effect of dilution rate of the initial leachate and the regeneration of the adsorbent material. Two-times activated biochar was also produced to perform adsorption at different flow rates. Furthermore, activated biochar with titanium loading was investigated in batch and fixed-bed column experiments. The materials were characterized for specific surface area, morphology and surface structure by BET, SEM-EDS and FTIR analyses. For the fixed-bed column adsorption experiments, performance modeling was studied using the Thomas, Bohart-Adams and Yoon-Nelson models. For the batch experiments, the higher TPH adsorption yield appeared 73-93% at pH 5, while for the activated biochar with titanium loading the TPH adsorption yield reached 98%. For the column experiments, the breakthrough time was 300 min for the 1/20 dilution rate, 240 min for the 1/10 and 130 min for the 1/5. During regeneration experiments (1/20 dilution rate), the 2nd round regeneration lasted 1310 min, the 3rd regeneration 1110 min and the 4th regeneration 1030 min. For the two-times activated biochar (1/20 dilution rate, 1 ml/min flow rate), it yielded a breakthrough time of 680 min. For the activated biochar loaded with titanium (1/20 dilution rate), the 1st round had a breakthrough time of 740 min, the 2nd round regeneration 1130 min and the third 860 min. The models Thomas and Yoon-Nelson described adequately the TPH adsorption in the fix-bed column experiments.

Mn-Doped Ti Coatings for Dental Implants: Effects on HO_b differentiation, Immune Modulation, and Protein Binding

Mr. Carlos Arias, Spain

Highlight (Oral Presentation 20')

Abstract

Titanium (Ti) is a widely used material for dental implants due to its mechanical strength and biocompatibility. However, its bioinert nature limits osseointegration, posing challenges for long-term implant success. To address this issue, silica-based bioactive coatings have been developed using sol-gel techniques, enhancing implant stability and supporting the incorporation of bioactive molecules. Manganese (Mn), an essential element for bone metabolism, has been investigated for its role in promoting osteogenesis and maintaining osteoblast-osteoclast balance. This study evaluates the effect of Mn-doped silica coatings on Ti implants, focusing on physicochemical properties, biocompatibility, immune response, and proteomic interactions. The Mn-doped coatings were synthesized via sol-gel and applied to Ti surfaces with varying Mn concentrations. Their structural and chemical properties were characterized using Fourier-transform infrared spectroscopy (FTIR) and surface wettability analyses. Biological characterization included cytotoxicity assays, osteoblast proliferation, osteogenic differentiation (ALP activity, osteogenic gene expression), and immune response evaluation in macrophages via cytokine quantification and gene expression analysis. Additionally, protein adsorption from human serum was assessed using nano-LC-MS/MS to determine the impact of Mn doping on protein interactions. Results demonstrated that the sol-gel coatings fully covered the Ti surface without Mn accumulation. FTIR confirmed Si-O-Si bond formation, and Mn addition slightly increased hydrophobicity without altering surface roughness. Controlled Mn²⁺ release was observed over 56 days, reducing degradation rates. In vitro studies showed no cytotoxicity, consistent osteoblast proliferation, and enhanced expression of osteogenic markers, including COL1, BMP2, RANKL, and OCN, particularly in Mn-doped samples at 14 days. Immune response analysis revealed increased expression of pro-inflammatory markers (TNF- α , IFN- γ) in higher Mn concentrations, while lower Mn levels favored the expression of anti-inflammatory cytokines (IL-10, TGF- β). Proteomic analysis indicated enhanced affinity for proteins involved in immune response and its regulation (e.g., SLPI, immunoglobulins, SAA1), cell adhesion (CADH1, CADH5), and osseointegration (FETUA, FETUB), suggesting a positive effect on implant integration. In conclusion, Mn-doped sol-gel coatings on Ti surfaces demonstrated promising biological responses, including improved osteogenic differentiation, controlled Mn²⁺ release, and favorable protein adsorption patterns. These coatings enhanced cell adhesion and immune modulation, potentially contributing to better osseointegration. The findings align with existing literature and highlight Mn-doped coatings as a viable strategy to improve the performance of dental implants. Future studies should explore long-term in vivo effects and clinical applications to validate these findings further.

Photothermal and immunomodulatory AIE decorated 3D printed mesoporous bioactive glass/HA scaffolds for infected bone defect repair

太太。Fanrui Zeng, China

Oral Presentation (20')

Abstract

Repairing bone defects infected by bacteria remains a major clinical challenge, primarily due to the complications caused by bacterial infection and the inflammatory microenvironment. To address this, there is an urgent need for novel bioactive materials that can overcome these issues. Mesoporous bioactive glass nanoparticles (MBGNs) are promising materials for bone regeneration. They form strong chemical bonds with host bone and release bioactive ions, such as Si^{4+} and Ca^{2+} , that promote osteogenesis and angiogenesis during degradation. Furthermore, MBGs can be modified through ion doping, allowing for enhancing their biological performance, such as antibacterial activity. However, incorporating antibacterial elements like Ag and Cu into MBGNs may cause cytotoxicity, and their effectiveness against biofilms remains limited [1][2]. In contrast, aggregation-induced emission (AIE) nanoparticles exhibit unique photothermal properties that are particularly effective in combating biofilm-related infections. These nanoparticles generate enhanced fluorescence and heat upon aggregation, which not only supports antibacterial activity but also ensures minimal cytotoxicity by activating their antimicrobial properties only under light irradiation [3].

In this study, we fabricated a 3D-printed hydroxyapatite (HA)/Ce-MBGN scaffold and modified its surface with AIE nanoparticles. We investigated the effects of AIE modification on the scaffold's morphology, physicochemical, and biological properties. The results showed that AIE modification significantly enhanced the scaffold's photothermal properties without altering its morphology or mineralization ability. AIE-modified scaffolds exhibited potent antibacterial activity, effectively eliminating drug-resistant *Staphylococcus aureus* bacteria biofilm. Additionally, the presence of Ce-MBGNs in the scaffold improved its antioxidant properties, promoted M2 macrophage polarization, and created a regenerative immune microenvironment conducive to tissue regeneration. The scaffold also continuously released Si and Ca ions, which stimulated the osteogenic differentiation of bone marrow stromal cells (BMSCs). In vivo studies demonstrated that the modified scaffold exhibited superior antibacterial and bone regeneration. This research highlights the potential of combining AIE nanoparticles and MBGNs in the design of advanced bioactive materials for treating infected bone defects.

Enhancing Bone Regeneration: Macro-porous Metallic Scaffolds Functionalized with SHED-Derived EVs

Prof. Djordje Janackovic, Serbia

Oral Presentation (20')

Abstract

The repair of large bone defects remains a significant challenge in regenerative medicine. While metallic scaffolds provide excellent mechanical stability, they often lack the osteoinductivity required for effective bone regeneration. In this study, we investigated the osteogenic potential of a 3D-printed Ti6Al4V scaffold functionalized with ceramic coatings and extracellular vesicles (EVs) derived from stem cells of human exfoliated deciduous teeth (SHED cells) embedded in a collagen hydrogel. Ti6Al4V scaffolds were coated with graded silicate glasses and hydroxyapatite (HAP) powder doped with silver. The coatings exhibited strong antibacterial activity, with over 98% reduction in *S. aureus* and *E. coli* cell numbers. Cytocompatibility tests on SHED cells demonstrated a higher metabolic rate of SHED cells on coated scaffolds compared to uncoated Ti surfaces, while apoptosis/necrosis rates remained below 5% across all samples. SHED cells seeded directly on coated scaffolds exhibited improved attachment and proliferation compared to those on uncoated surfaces. These results indicate that the coated scaffolds combine both strong antibacterial properties and high cytocompatibility. To introduce osteoinductive properties, EVs were extracted from SHED-conditioned media via differential ultracentrifugation. Characterization of the isolated EVs confirmed the presence of tetraspanin markers CD9, CD63, and CD81 using direct stochastic optical reconstruction microscopy (dSTORM), while their morphology and size distribution were verified by transmission electron microscopy (TEM) and nanoparticle tracking analysis (NTA). To ensure controlled release within the microporous scaffold, EVs were encapsulated in a 0.4% collagen hydrogel. Fluorescence-based NTA analysis demonstrated that approximately 50% of EVs were gradually released within the first three weeks. The osteogenic potential of EV-loaded scaffolds was assessed by qRT-PCR analysis of SHED cells cultured on the material. After 10 days of treatment, significant upregulation of RUNX-2 and BMP-2 gene expression indicated the pro-osteogenic effects of the SHED-EV-enriched scaffold. These findings suggest integrating SHED-derived EVs within a functionalized Ti scaffold is a promising strategy for enhancing bone regeneration in large defects. Development and characterisation of geopolymer and Mg doped hydroxyapatite-based coatings on Ti6Al4V substrate for orthopaedic applications

Mrs. Chiara Rota, Italy

Oral Presentation (20')

Abstract

Titanium and its alloys are widely used as biomaterials in orthopaedic procedures, due to their optimal mechanical strength, corrosion resistance, and biocompatibility [1]. However, the clinical success of titanium implants is often hindered by poor osteointegration and microbial adhesion, leading to implant failure and high morbidity, thereby increasing healthcare costs. To overcome these drawbacks, surface modification techniques, such as coating with bioactive and antibacterial materials, have been proposed to enhance osteointegration while decrease peri-implant inflammation. This study focuses on the development of novel coatings for titanium (Ti6Al4V alloy) aimed at improving osteointegration and providing antibacterial properties. The developed coatings are composed of magnesium-modified hydroxyapatite and chitosan particles (MgHA_CH) [2], and/or geopolymers [3], and mimic the structure and composition of natural bone, allowing for better integration and faster healing of the implant. Specifically, chitosan, a natural polysaccharide, and geopolymer, an inorganic materials, were selected for their ability to prevent bacterial colonization on the implant surface while doped hydroxyapatite was chosen for its potential to stimulate bone growth and mineralization. The coatings were applied to titanium substrates using two different techniques: electrophoretic deposition [4] and dip coating [3]. In the former case an optimization process was carried out to maximize the deposition performance and the impact of different deposition parameters including current density, deposition time and composition of the deposition solution was investigated. The coatings were thoroughly analyzed to evaluate their morphology, microstructure and chemical composition by means of scanning electron microscopy combined with energy dispersive X-ray diffraction (SEM-EDXS), and Fourier-transform infrared spectroscopy (FTIR). In addition, biological in vitro tests, including osteoblast-like cell proliferation and viability tests and antibacterial assays, were conducted to assess the biocompatibility and antimicrobial features of the coated materials. The coated materials display good morphological characteristics and support cell adhesion, proliferation and spreading while exhibit antibacterial activity against clinically relevant bacteria, including both gram positive and gram negative strands, making them a promising solution for addressing critical challenges in the clinic.

Paper 1267 6 Enhancing Patient Comfort in Cranioplasty: Coated Titanium Implants for Better Thermal Regulation
Dr. Beatriz Garrido Domínguez, Spain
Oral Presentation (20')

Abstract

Cranioplasty is a surgical procedure used to reconstruct skull defects resulting from trauma, congenital anomalies, infections, or tumor resection. The procedure aims to restore cranial integrity, protect the brain, and improve functional and aesthetic outcomes. However, cranioplasty presents significant challenges due to the skull's complex morphology and the need for biocompatible, durable, and mechanically stable materials.

Recent advancements in imaging and manufacturing technologies have enabled the development of patient-specific implants, offering enhanced precision and improving clinical results. Among the materials used for cranial implants, titanium remains a common choice due to its strength, biocompatibility, and corrosion resistance. However, its high thermal conductivity can cause patient discomfort, particularly in response to temperature fluctuations. To address this issue, this study explores the enhancement of 3D-printed titanium cranial implants by applying polyether ether ketone (PEEK) and hydroxyapatite (HA) coatings using Atmospheric Plasma Spray. The coatings aim to mitigate the thermal conductivity of titanium while preserving its mechanical integrity. The research evaluates coating quality and thermal properties across different thickness levels to determine their effectiveness in improving patient comfort.

Results indicate that both PEEK and HA coatings successfully reduce the implant's thermal conductivity, with the degree of improvement related to coating thickness. The findings highlight the potential of these coatings to optimize implant performance, presenting a promising approach to enhancing long-term outcomes in cranioplasty. By integrating advanced coating techniques, this study contributes to developing cranial implants that address functionality and patient comfort.

CNC-manufacturing versus ceramic injection moulding for ATZ shoulder resurfacing

Mrs. Claudia Ortmann, Germany

Oral Presentation (20')

Abstract

Alumina and YTZP ceramics have been established in joint endoprosthetics since the 1970s and 1980s. Zirconia rich dispersion ceramics made of alumina and YTZP are known for high strength, high fracture toughness and low wear rates for decades too. Thus, alumina toughened zirconia (ATZ) material was introduced to the endoprosthetics market in 2007. New efforts have been made to use the ATZ for production of shoulder resurfacing implants. CNC-technology will be compared with ceramic injection moulding.

This paper summarizes the designer's elaboration for the respective manufacturing technology, challenges of the two manufacturing processes and economic aspects. Product development began with formulation of clinical needs and material requirements for ATZ on basis of standards (ISO 13356, ISO 6474-2).

The first investigation results for material samples (both technologies) and CNC manufacturing of a ceramic shoulder resurfacing implant are shown. A debinding process and the thermal treatment - sintering and HIP - were carried out. High purity and the removal of any porosity are mandatory. The whole process was accompanied by the determination of properties such as green density, microstructure, investigation of chemical composition, density after sintering and HIPing and investigation of the phase composition.

Furthermore, suitable injection moulding technology was developed, based on the design and construction of a moulding tool and the choice of a commercial ATZ feedstock. A homogeneous microstructure and phase distribution in material samples could be achieved. The first sample parts were investigated according to their size accuracy.

First results for CNC-technology are shown. Green parts with densities $\geq 2,75\text{g/cm}^3$ and sinter densities $\geq 5,4\text{ g/cm}^3$ were prepared. The chemical analysis met requirements. By adjusting the thermal process, the microstructure could be adjusted so that grain sizes for Al_2O_3 and for YTZP met the requirements of standards. A homogeneous microstructure and phase distribution in material samples could be achieved. First shoulder implants made of ATZ ceramic were successfully realized with CNC-technology.

The results were obtained within the project CIMEOS (funded by Thueringer Aufbaubank, Joint project 1000449: FKZ: 2023 VFE 0008).

Paper 2097 4 **Manufacture of tailorable biodegradable Mg/Zn multimaterial by additive friction stir deposition; microstructural and interfacial characterisation**

Ph.D. Juan Guillermo Santos Macías, Spain

Oral Presentation (20')

Abstract

The development of biodegradable materials for the medical sector can bring substantial improvements in numerous applications. An example of this is bone implants. However, it is difficult to create a material that matches bone properties adequately and consistently during the healing process. A combination of Mg and Zn could assemble the advantages of both, that is, rapid degradation and elastic modulus similar to that of bone for Mg, which limits the stress shielding effect, and slow degradation and moderate strength for Zn.

Manufacturing a viable multimaterial with a good interface can be difficult. Additive friction stir deposition (AFSD) is an appropriate solution in this case. This solid state fabrication process has the potential to allow for tailoring the interface thickness and the structure of the intermetallic compounds (IMC) therein.

In this study, a Mg/Zn multimaterial was produced by AFSD from WE43 Mg alloy substrate and cast Zn-Mg alloy bar feedstock. Extensive microstructural analysis including XRD, EDS, EBSD, 3D FIB-SEM and TEM allowed to characterise the multimaterial, with a focus on the interface, which exhibits a 3-layer IMC structure of Mg+MgZn, MgZn₂ and Mg₂Zn₁₁. Significant plastic accommodation was also found in the interfacial IMC layer. The obtained results are promising for the manufacturing of tailorable multimaterials with enhanced interfacial bonding for biodegradable applications.

Paper 1734 5 In-situ x-ray imaging of porosity control by power modulation during additive manufacturing by the directed energy deposition technique.

Dr. Robert Atwood, United Kingdom

Oral Presentation (20')

Abstract

In-situ synchrotron X-ray imaging has been used to directly observe the behaviour and mechanisms of porosity formation during directed energy deposition laser additive manufacturing of a nickel based superalloy material. The flow pattern established in the melt pool can be observed to entrain the porosity and allow coalescence into larger pores. Disrupting the flow pattern by applying modulation to the laser power allows porosity to escape while also minimising the size by preventing coalescence. This behaviour has been observed via X-ray radiography. The variation of these effects under different modulation frequencies and wave patterns can be used to develop optimised deposition procedure and provide data to physical models, to achieve good quality additively manufactured items of such materials.

Effect of static recrystallization on the anisotropy of mechanical properties of Inconel 625 additively manufactured by LPBF process

Ph.D. Hubert Pasiowiec, Poland

Oral Presentation (20')

Abstract

The post processing heat treatment which significantly reduces the anisotropy of mechanical properties of additively manufactured (AM) materials is currently gaining attention. Due to the fact that static recrystallization occurs in Laser Powder Bed Fusion (LPBF) Inconel 625 without any plastic deformation, the heat treatment involving recrystallization might be applied for reduction in mechanical properties anisotropy. Therefore, the aim of this work was to determine the influence of static recrystallization of Inconel 625 LPBF on the mechanical properties and its anisotropy.

The repetitive melting and solidifying of the melt pools during the LPBF process generate a high residual stress level and high dislocation density in AM Inconel 625. Such material subjected to high-temperature annealing may recrystallize. The static recrystallization temperature and the recrystallization kinetics of Inconel 625 LPBF process parameters correlated, whereas different microstructure is obtained after the processes with different sets of parameters. The samples for this experiment were manufactured using the LPBF machines with the laser beam spot size equal to 35 μm (AYAS 120LM) and 55 μm (SISMA MySint100). After manufacturing, the samples were annealed in a temperature range of 900-1200°C for 5 to 90 minutes. Such approach allowed to determine the recrystallization temperature and its kinetics for materials obtained in two different printers. Subsequently, the heat treatment routes allowing to achieve different levels of recrystallized microstructure (approx. 50 and >90%) were designed to determine the effect of recrystallization on the mechanical properties and its anisotropy.

The microstructure of annealed samples was examined using light and scanning electron microscopy. The fraction of recrystallized grains was estimated from the grain orientation spread (GOS) determined by the EBSD analysis. The mechanical properties were evaluated in the tensile test.

The results of the study indicate that the static recrystallization temperature for both variants of Inconel 625 LPBF samples is between 950 - 1000 °C. Some differences in recrystallization kinetics are observed for Inconel 625 LPBF manufacture on AYAS and SISMA machines. Annealing at 950 °C for 90 min involved partial recrystallization of Inconel 625 LPBF-AYAS (~35 %) whereas more significant changes are observed in Inconel 625 LPBF-SISMA (~52%). The heat treatment, which triggers recrystallization, causing a significant reduction in the anisotropy of the mechanical properties of Inconel 625 LPBF, in parallel increases the plastic properties of the samples.

This research was funded by the National Science Centre, Poland, grant no 2024/08/X/ST11/01402.

Paper 1335 1 **4D printing of buckling-induced architected Fe-based shape memory alloys, microstructure and mechanical behavior**

Prof. Mahmoud Nili Ahmadabadi, Iran

Oral Presentation (20')

Abstract

This study focuses on buckling-induced architected materials (BIAMs), a class of materials engineered for enhanced functionality and efficiency by manipulating geometry and base material. Existing metallic BIAMs exhibit a trade-off between energy dissipation and geometrical recoverability, limiting their applications. This research introduces 4D printing of buckling-induced architected Fe-based shape memory alloys (BIA Fe-SMAs) of a designed and optimized geometry using finite element (FE) simulations by Wire-Arc Additive Manufacturing (WAAM). Material characterization, heat treatment, and compression tests of the printed parts from low-alloy carbon steel and Fe-SMA were carried out to assess energy dissipation and geometrical recoverability. The results of the compression tests are used to refine the parametric design of a larger-scale BIAM, which will be printed and tested to evaluate its suitability for practical applications.

To achieve this, single pulse WAAM process parameters were first optimized by printing several single-layer samples of low-alloy carbon steel and Fe-SMA. Various path strategies were then investigated, including back-and-forth layer deposition, zigzag printing, continuous and discontinuous printing of walls and Tee-joint connections. The printed dampers using the optimized strategy were tested using Digital Image Correlation (DIC) to evaluate their mechanical performance.

In the following, in addition to microstructure analysis and hardness testing, the shape memory properties (shape memory effect and pseudoelastic) of BIA Fe-SMAs were first analyzed systematically for the entire dampers and then individually for Tee-joint connections, sinusoidal profiles, and walls.

Paper 1989 4

Altering microstructure and enhancing mechanical properties during additive manufacturing of Ti-6Al-4V via in-process laser heat treatments

Dr. Steven Van Petegem, Switzerland

Oral Presentation (20')

Abstract

In this work, we have explored in-process laser-based heat treatment (LHT) as an alternative to post-process heat treatments such as annealing, in order to alter the hcp α' / α and bcc β phase content in additive manufactured Ti-6Al-4V. To that end, three samples were manufactured with a laser metal deposition machine, a directed energy deposition technique, with the laser operating at 300 W. The reference sample was not subjected to any LHT. For the remaining two samples, each deposited layer was subjected to either an LHT at 100 W (LHT100) for one sample or an LHT at 300 W (LHT300) for the other, without powder addition.

LHT100 showed an overall improvement in the strength/ductility trade-off. Whereas LHT300 resulted in a lower strength but a much higher ductility and toughness than the other samples. In order to understand the origin of these differences in the mechanical response, the contribution of each of the microstructural features and internal strains to the overall mechanical response is studied in detail. A combined analysis via synchrotron X-ray diffraction, scanning electron microscopy and transmission electron microscopy of the as-built samples revealed that the differences in between the different types of hcp phase fractions between the three samples has the dominant contribution to the difference in their mechanical response. These results, which will be presented in this talk, demonstrate the potential of in-process LHTs for altering microstructures and tailoring mechanical properties.

Paper 1278 **5** **Accelerating Thermal History Predictions in Additive Manufacturing with Artificial Intelligence.**
Mr. José Ángel Bejarano Vázquez, Spain
Oral Presentation (20')

Abstract

In the scope of understanding the factors controlling the defects that commonly appear in the microstructures of materials produced by Additive Manufacturing (AM), a first step is the prediction of the thermal history at which the material is subjected by means of different printing parameters. The extremely large number of different combinations of printing parameters (laser power, hatch distance, laser scanning speed...) adds to the different printing geometries which also can vary the influence of such printing parameters. Its computation by means of Finite Element Modelling is the logical choice, but is time consuming and cannot be used in large computational optimization processes.

This work therefore aims at developing a fast and accurate predictive methodology to calculate temperature history during the AM process. First, a Finite Element Method (FEM) model was developed to extract thermal profiles at key points for Selective Laser Melting processes, optimized for computational efficiency for many different combinations of the printing parameters. Subsequently, different Machine Learning (ML) methodologies are tested as predictive models to determine the most robust approach. The models employed include several Tree-based methods and Deep Learning methods (i.e., Neural Networks). These models were fed with the generated dataset, yielding optimal predictive outcomes for both Extremely Randomized Trees (ERT) and Feedforward Neural Networks (FNN) with very good performance. Additionally, by leveraging Long Short-Term Memory (LSTM) networks, the study has enabled the prediction of thermal profiles for any point within a wide variety of scanning strategies. This was achieved through the innovative use of "Constrained random walks" (CRW), an approach specifically developed to train ML models for predicting thermal profiles across diverse scanning strategies and printing geometries.

The results demonstrate that it is viable to develop models based on ML for predicting thermal profiles in AM for a large variety of printing parameters and strategies, offering quasi-instantaneous predictions with minimum error as compared to the computationally expensive FEM simulations.

Paper 918 2 **Toward High-rate Carbon-based Supercapacitors: New Insights into the Structural Characterization and Electrochemical Performance of Hierarchical Porous Carbons**

Dr. Mohammed Subrati, Greece

Oral Presentation (20')

Abstract

Conventional porous carbon materials, such as activated carbons and carbon blacks, are attractive supercapacitor electrode materials due to their low cost of production and ultrahigh specific surface areas. However, their small electrolyte-accessible surface areas and slow ion transport in their micropores at high charging/discharging rates result in low specific capacitances, thereby limiting their energy densities. Recent research has shown that hierarchical porous carbons (HPCs) offer the ultimate solution by combining the high surface area of micropores with the improved mass transport of ions in mesopores and macropores, thus rendering HPCs as promising high-rate supercapacitors.

Herein, we report the facile synthesis of pristine and N-doped HPCs utilizing the ice-templating method coupled with hard-templating using LUDOX® colloidal silica particles. In a typical synthesis, an aqueous mixture of glucose (or glucose-and-urea) and colloidal silica particles is flash-frozen in liquid nitrogen. The ice fronts formed in the flash freezing process act as a soft template for macropores that can be removed by lyophilization, thereby yielding the dry glucose-silica (or glucose-urea-silica) matrix. The latter is then pyrolyzed, and the resulting carbon-silica (or N-doped carbon-silica) matrix is stirred in an alkaline medium under reflux to etch out the hard colloidal silica template and create the mesopores. Microporosity can then be introduced into the carbon matrix via either physical or chemical activation, using CO₂ or KOH as activating agents, respectively. Nitrogen porosimetry and small-angle X-ray scattering were utilized to analyze the porous structures of the HPCs. Elemental analysis and X-ray photoelectron spectroscopy were employed to determine the nitrogen content and bonding configurations, respectively, in the N-doped HPCs. The electrochemical performance of the HPCs was assessed using the cyclic voltammetry and cyclic galvanostatic charge-discharge techniques.

Paper 475 **4** **Carbon fiber Cu/CuO coatings and the effect of composite fabrication methods on the mechanical performance in energy storage multifunctional devices**
Dr. Bianca K. Muñoz, Spain
Oral Presentation (20')

Abstract

Smart mobility has emerged as a solution to reduce carbon dioxide emissions by utilizing cleaner and more efficient energy sources. A key focus is vehicle electrification, where multifunctional supercapacitors and composite-based batteries serve both energy storage and structural functions. Woven carbon fibers (WCF) used as electrodes require modification to enhance electrochemical performance by increasing their specific surface area (SSA). Various modifications using carbon nanostructures or nanoparticles of metals, metal oxides, metal sulfides, and selenides have been explored. Among these, metal oxides stand out as promising materials for pseudocapacitive energy storage mechanisms due to their lower toxicity compared to sulfides and selenides. Copper oxide has been widely studied for enhancing carbonaceous electrodes. It is typically hydrothermally synthesized on carbon fibers using a copper salt (e.g., nitrate) and a reducing agent (e.g., hydrazine or HMTA). While effective for CuO nanowire growth, the toxicity of reducing agents necessitates more sustainable alternatives. Yokohama et al. synthesized copper nanowires from copper chloride using PVP, NaCl, and ascorbic acid as a reducing agent. We recently applied this method to modify high-modulus carbon fibers and demonstrated their use in flexible supercapacitors [1]. For structural composites, mechanical characterization is essential. Traditionally, tensile testing is used, but interlaminar shear strength (ILSS) tests have gained importance due to the role of interfaces in stress distribution. Only a few examples can be found in the literature when the ILSS is study for structural supercapacitors [2]. This study focuses on optimizing hydrothermal growth conditions for Cu, CuO, and Cu/CuO nanoparticles on WCF and evaluating their electrochemical performance as electrodes. Structural supercapacitors were fabricated using two different methods, and their mechanical properties were analyzed. The hydrothermal process was found to be critical, as complete surface coverage is essential for effective performance. These findings open new possibilities for Cu-based nanostructures on WCF in energy storage and multifunctional applications.

Direct evidence of the presence of hybrid charge transfer state in a perovskite nanocrystal -polythiophene blend solid state film

Dr. Tersilla Virgili, Italy

Highlight (Oral Presentation 20')

Abstract

In recent years, metal halide perovskite semiconductors (MHPs) have demonstrated their exceptional capabilities in the optoelectronic field. This can be ascribed to their outstanding intrinsic photoelectric properties, such as high light harvesting abilities, long and balanced carrier diffusion lengths, high defect tolerance, high photoluminescence quantum yields and readily tunable bandgaps. Despite these interesting features, the lack of long-term operational stability still prevents the use of lead halide perovskites in general, and of their nanocrystals [NCs] in particular, in commercially available devices. To overcome this problem interesting is the possibility of blending perovskite NCs with semiconducting polymers, able to stabilize perovskites by improving film morphology and environmental stability. Additionally, their electronic properties enable the creation of hybrid materials that combine the electrical and optical characteristics of both components. In this work we investigate by ultrafast spectroscopy and morphological characterisation the photophysical properties of a hybrid material composed by a conjugated polymer and perovskite nanocrystals. The relaxation dynamics of a drop-casted film from the semiconducting polythiophene (P3HT) and a green-emitting CsPbBr₃ (zwitterionic sulfobetaine -capped) perovskite nanocrystals (NCs) solution is studied. The transient spectroscopy presents a very long photobleaching signal peaked at 516 nm not present in the single components of the blend. The scanning electron and confocal fluorescence microscopy images show that the P3HT and the CsPbBr₃ NCs are finely mixed in the film. We propose the presence of a very efficient charge transfer from the nanocrystal to the polymeric chain which induces the formation of a long -lived charge-transfer state as we see in the pump-probe measurements. The theoretical model reveals the important role of the zwitterionic sulfobetaine copper in this process. The perovskite strongly adsorbs the surfactant, while the polythiophene chain is not directly bound to the perovskite. Instead, it interacts with the surfactant itself, contributing to the electronic properties of the overall system.

Exceptional stability of solid-state radical-anions in perylenediimide-polyethyleneimine polymers for energy applications

Mr. José Juan Chica Armenteros, Spain

Oral Presentation (20')**Abstract**

The search for organic materials with tunable redox properties and high stability is crucial for advancing electro-optical devices for energy conversion and storage. Perylenediimide (PDI)-based radical anion has emerged as promising candidates for solar energy harvesting due to their broad absorption in the visible and near-infrared (NIR) regions and their ability to participate in Consecutive Photoinduced Electron Transfer (ConPET) processes, offering significant potential for applications such as photocatalysis, photobatteries, and dye-sensitized solar cells. However, the limited stability of these radicals under ambient conditions, particularly in the solid state, remains a major obstacle.

In this communication, we present the synthesis and characterization of a series of novel materials based on polymers composed of perylenediimide and hyperbranched polyethyleneimine (PDI-PEI). By varying the PEI/PDI ratios, we achieved the isolation of the radical anion exhibiting exceptional solid-state stability for several months. The presence of the radical anion was assessed in all synthesized materials. Their unprecedented stability was confirmed by various spectroscopic techniques, including electron paramagnetic resonance (EPR) and Raman spectroscopy. We hypothesized that the anion radical is generated through internal electron transfer between the amine groups of PEI and the carbonyl groups of PDI promoted by light absorption. Furthermore, we propose that PEI enhances the stability of the PDI radical anion by providing steric protection. The photoactive behavior of the materials was assessed by solid-state UV-Vis-NIR absorption spectroscopy, revealing strong absorption across the visible and NIR regions, making them suitable for broadband solar light harvesting. Furthermore, the redox properties of the radical anion are also investigated. Structural information about the molecular arrangement and chemical composition of the materials is evaluated by solid ¹³C-RMN and X-Ray diffraction (XRD) and thermal stability is evaluated by Thermogravimetric analysis. Finally, the compatibility of the material with indium tin oxide (ITO) substrates is demonstrated by depositing thin and homogeneous films using spray coating and spin coating techniques, maintaining the anion radical stability at the PDI-PEI/ITO interface. Future studies are planned to investigate device performance, including its evaluation as an interlayer in solar cell prototypes, and modulating the material's properties through chemical modifications to optimize its performance in energy applications.

ZnSnN₂ films with improved optoelectronic features grown by High-Power Impulse Magnetron Sputtering for next-generation tandem solar cells

Ph.D. Cristina Mancarella, Italy

Oral Presentation (20')

Abstract

The pursuit of enhancing photovoltaic (PV) performance while reducing costs has driven towards tandem solar cells, which combine a top cell with an optimized optical band gap (E_{gap}) and a silicon-based bottom cell. These advanced PV systems efficiently harness high-energy photons and, in simulations, show potential beyond 40% efficiency [1], with experimental designs already exceeding 30% [2]. In this context, identifying suitable materials for the top cell of Si-based tandems is crucial. Conventional choices like III-V, CIGS, CdTe, and perovskites, despite their advantages, face limitations such as scarcity, toxicity, high fabrication costs, suboptimal E_{gap}, or stability issues. Therefore, research is targeting towards novel, cost-effective semiconductors with wide E_{gap} (~2 eV), ideal as top cell. Among these, Zinc Tin Nitride (ZnSnN₂, ZTN) emerged due to its tunable E_{gap}, high absorption coefficient, and composition of abundant, non-toxic elements. Additionally, ZTN can be synthesized as thin films via cost-effective methods [3,4]. This study critically compares the synthesis of ZTN using Direct Current Magnetron Sputtering (DCMS) and High-Power Impulse Magnetron Sputtering (HiPIMS). The latter offers improved material quality and tunability due to the more efficient ionization of sputtered species and enhanced gas dissociation. The objective is to assess the role of process parameters in optimizing ZTN. Our methodology involves reactive co-sputtering from Zn and Sn targets in a pure nitrogen atmosphere. The obtained films are analyzed for composition (Zn/(Zn+Sn) ratio), structure, electrical, and optical properties. Different HiPIMS conditions from the material perspective have been extensively studied (high temperature growth and bipolar pulse applied to the Zn cathode). In particular, this work proves that HiPIMS matches DCMS performed at high temperature, while it is capable of reducing oxygen content below 5% at., incorporating more metallic species due to the possibility to avoid target poisoning and allowing additional structural control through the bipolar pulse. Indeed, carrier density is minimized (10¹⁷-10¹⁸ cm⁻³) by optimizing HiPIMS at room temperature, with bipolar. The fundamental aspect is that high temperature growth is even unnecessary, as it detrimentally increases n-type behavior of ZTN. Concluding, our results are expected to advance PV technology, paving the way for more efficient and sustainable solar cells.

Paper 1649 1 **Improving the Performance of Wood Templated Nanogenerators through Functionalization and Elastomer Impregnation**

Ph.D. Madalena Roque, Portugal

Highlight (Oral Presentation 20')

Abstract

Wood has emerged as a promising material for triboelectric (TEGs) and piezoelectric (PENGs) nanogenerators, offering a sustainable and efficient solution for mechanical energy harvesting. Its natural piezoelectric properties, hierarchical porous structure, and mechanical robustness enhance charge generation and energy conversion. As a renewable, biodegradable, and easily functionalized material, wood presents a compelling alternative for energy harvesting devices, driving the development of greener technologies.

Despite their potential, TEGs and PENGs face challenges in achieving stable, high-output power due to material limitations, structural complexities, and reliance on precious fillers. Impregnating wood templates (WTs) with fillers often leads to poor dispersion, weak interfacial bonding, and dependence on non-sustainable materials, limiting both performance and environmental viability.

To address these issues, this work introduces a scalable method to impregnate cellulose nanocrystals (CNCs) into WTs, leveraging their biodegradability, accessibility, and exceptional mechanical properties to enhance electromechanical performance. By combining delignification with TEMPO-mediated oxidation, porous oxidized WTs were impregnated with eco-friendly fillers composed of CNCs embedded in different elastomer matrixes.

The resulting WT elastomer TEGs, studied across varying CNC concentrations, demonstrated that output performance was influenced by compressive pressure, filler concentration, and surface charge density. CNC incorporation significantly increased surface charge density and charge transfer efficiency, doubling triboelectric performance compared to pure counterparts under identical compression conditions. The enhanced performance is attributed to the improved surface charge retention, increased effective contact area, and optimized charge transfer dynamics facilitated by CNCs impregnation. These findings introduce an innovative, sustainable methodology to improve wood-based nanogenerators. The CNC-impregnated WT composite offers a scalable and environmentally friendly solution for next-generation energy harvesting, providing a promising pathway toward efficient, self-powered electronic devices.

Paper 893 2 Enhanced triboelectric performance in 3D-nanonetworks biodegradable PLA metamaterials

Mr. Carlos García, Spain

Oral Presentation (20')

Abstract

Modern electronics, which are essential for human health, safety, and communication, provide a wide array of opportunities to evolve our society into an intelligent world. However, with the rapid growth of the Internet of Things (IoT), the energy supply for electronics and sensors has become a critical challenge. Triboelectric nanogenerators (TENGs) have been developed as a key technology for mechanical energy harvesting, but further improvements in their triboelectric properties are still necessary to meet the demands of practical and functional devices.

Three-dimensional anodized aluminum oxide (3D-AAO) features hexagonal column-shaped cells with cylindrical central holes of varying diameters and transversal channels. Due to this structure, it can be used as a template for nanostructuring processes. This nanostructuring method offers several advantages over lithography-based techniques, such as cost-effectiveness, broad accessibility, and the ability to fabricate with nanoscale precision from the top down.

Poly(lactic acid) (PLA), one of the most promising biopolymers due to its non-toxicity, and excellent mechanical properties, has found industrial and medical applications thanks to its wide range of properties, from amorphous to crystalline states.

This study investigates the potential of TENGs for efficient mechanical energy harvesting through contact-separation triboelectrification and electrostatic induction.

Nanoengineered PLA films with controlled nanostructuring, enabled by the use of 3D-AAO, are utilized in a simple, fast, controllable, and cost-effective process. The influence of 3D nanocavities within PLA films on triboelectric power generation is examined, revealing a correlation with the triboelectric charge density and the polymer's relative permittivity.

Paper 2007 3

Eco-friendly tribo- and piezoelectric nanogenerators based on bionanocomposites

Dr. Bernd Wicklein, Spain

Oral Presentation (20')

Abstract

Circularity and sustainability of energy devices are gaining importance in the face of growing global energy demand, which enlarges the electronics waste as well as increases the scarcity of critical energy materials. Tribo- and piezoelectric nanogenerators have shown great potential in providing renewable energy to IoT and sensing devices, but often lack sustainability as the constituting materials are mostly petrol-based, fluorinated polymers, metals or lead-containing ceramics. Therefore, revalorized biomass like lignocellulosics, agri-food residues and microbial biopolymers are increasingly considered as electro-active components (1).

Here, we present results of eco-friendly nanogenerators based on different bionanocomposites. Biopolymers like cellulose, chitosan, poly-L-lactic acid (PLLA), polyhydroxybutyrate (PHB) and alginate are investigated as matrix with different fillers such as nanocarbons, MXenes, COF, ZnO, potassium sodium niobate and barium titanate particles in order to tune the triboelectric and piezoelectric properties (2,3,4,5,6,7). Special attention is given to the diverse filler-matrix interactions and their impact on the electrical properties of the composites. In addition, the role of porosity is a further parameter under investigation both for the electrical output and complementary properties. Herein, foams are explored for the construction of 3-dimensional triboactive elements with additional insulating and flame retardant behavior, which can be attractive for smart alarm systems, intelligent buildings and other applications. Finally, we will present incipient results of 3D printed PLLA-ZnO bionanocomposites with enhanced piezo-response brought about by the fine adjustment of the 3D printing parameters. Altogether, the results suggest great potential of bio-based polymer nanocomposites for more sustainable nanoenergy harvesting.

Paper 1946 4 **Poly(vinylidene fluoride) enhanced multisource energy harvesting via Plasma and Vacuum-processed 1D nanoarchitectures.**
Ph.D. Juan Delgado Álvarez, Spain
Oral Presentation (20')

Abstract

Nanogenerators (NGs) are promising for sustainable energy harvesting, with piezoelectric (PENG) and pyroelectric (PyNG) types converting mechanical energy and temperature changes into electricity. To overcome their limited output, hybrid NGs have been developed to harness multiple energy sources. Ferroelectric polymers like polyvinyl fluoride (PVDF) stand out for their strong pyroelectric response, flexibility, and inherent piezoelectric properties. [1]. The performance of PVDF can be enhanced by incorporating nanofillers, increasing the electroactive phase and the internal strain [2]. Additionally, the implementation of nanoarchitectures multiplies the surface power density yielded on these NGs by increasing the surface area incorporating flexibility to the system, opening the path for permittivity engineering and multifunctional applications.

This communication reports on the first advances in the development of a multisource piezo/pyro NG, consisting of supported 1D organic nanowires as soft templates, conformally covered by either polycrystalline piezoelectric ZnO or amorphous SiO₂ and fully embedded in a PVDF pyroelectric matrix. Our approach integrates flexible commercial PET substrates with 1D nanostructures by combining low-temperature, clean, industrially scalable vacuum and plasma deposition methods.

In previous works, we have reported paper-based piezoelectric NGs and self-powered multidirectional sensors [3] and durable hybrid piezo-triboelectric NGs [4] by embedding surface supported polycrystalline ZnO nanowires into non-piezoelectric organic matrixes. Herein, we advance one step in developing multisource energy harvesters by incorporating the ferroelectric polymer PVDF. Our results show how this multifunctional device can extract energy from vibrations and temperature changes, both individually or concurrently, and how the 1D nanoarchitecture boosts the output power compared with equivalent bulk devices.

Functionalized PVDF-based terpolymers for pyroelectric energy harvesting

Dr. Eleni Pavlopoulou, Greece

Oral Presentation (20')

Abstract

Polyvinylidene fluoride (PVDF) and its copolymers is recognized as the most performing ferroelectric polymer, with applications in energy harvesting, sensing, haptics, high-k dielectrics, and others. Recently, the relaxor ferroelectric terpolymer P(VDF-TrFE-CFE) that comprises trifluoroethylene (TrFE) and chlorofluoroethylene (CFE) monomers has been functionalized with addition of fluorinated alkyls (FA). The obtained tetrapolymer P(VDF-TrFE-CFE-FA) was found to display an unprecedented electromechanical coupling and a gigantic piezoelectric coefficient of 1000 pm/V [Science 375, 1418 (2022)], similar to the best inorganic materials. It would be interesting to explore the perspective of employing the tetrapolymer in pyroelectric harvesting applications. However, reports on its pyroelectric performance are currently lacking. In this work we functionalized P(VDF-TrFE-CFE) and P(VDF-TrFE-CTFE) terpolymers (where CTFE stands for chlorotrifluoroethylene monomers) with fluorinated alkynes of various fractions. After verification of the successful chemical modification by means of NMR, the phase transitions of the resulting tetrapolymers have been studied by DSC. The polymer structure (crystalline phases, crystallite domain size, crystallinity) has been studied by means of x-ray scattering in bulk and film form. Simple capacitors have been fabricated and the generated pyroelectric current has been recorded. The structure-function relationships are derived and rationalized.

Paper 603 **6** **Nitrogen-based polymeric solid electrolytes for next-generation multivalent batteries: An environmental impact analysis.**
Mr. Miguel Ángel González Lara, Spain
Oral Presentation (20')

Abstract

In the last decade, the growing global energy demand has provoked a need for the use of intermittent renewable energy sources, as alternative and sustainable energy strategies. However, these strategies require the development of innovative efficient and sustainable energy storage methods in order to reduce the carbon emissions in various sectors, as well as to ensure electricity supply in remote and disadvantaged regions, contributing to improved quality of life and significant health benefits.

In this context, current manufactured lithium batteries have significant challenges, from an environmental point of view, because of their manufacturing require scarce materials, with a high environmental impact associated with their extraction and processing methodologies, particularly transition metals. As an alternative, in the last years rechargeable organic batteries have emerged as a promising economical and environmentally friendly alternative; however, they are currently in the early stages of development, and it is necessary to thoroughly investigate new materials for optimizing their efficiency from an energy storage perspective, as well as their environmental impact to medium- long-term application.

In this context, this research focuses on the development of a new concept of organic solid electrolytes, based on nitrogen-based structures, which could solve the current limitations of rechargeable organic batteries. In particular, we investigated an innovative polymer solid-state electrolyte, with good mechanical stability, low heat transfer, high ion conductivity and high stability, based on aminotriazole-type repeating units (monomers), which has rendered promising properties as electrolyte for rechargeable multivalent ion batteries, such as calcium or zinc.

Six different polymers based on triazole-type structures have been obtained using an easily scalable methodology through soft reaction conditions and avoiding polluting solvents. The polymers were characterized by using different techniques such as Nuclear Magnetic Resonance (NMR), elemental analysis and Differential Scanning Calorimetry (DSC). Then, the polymer electrolytes were mixed with different calcium and zinc salts (concentrations ranging from 80% to 50% polymer), resulting in solid membranes, which were assessed as electrolytes for calcium secondary batteries through electrochemical measurements as Electrochemical Impedance Spectroscopy (EIS).

In addition, an evaluation of the environmental impact of the developed solid electrolyte manufacturing process was performed using Life Cycle Assessment (LCA) methodology, with sigmaPro software and the Ecoinvent database. The LCA showed promising results in terms of carbon footprint with values equal or lower than other polymer electrolytes previously reported in literature.

Paper 1939 1 Grain boundary engineering in nanostructured metals

Dr. Marlene Kapp, Austria

Keynote (Oral Presentation 40')

Abstract

The high strength of nanocrystalline and ultrafine-grained materials is commonly compromised by early crack initiation at and easy propagation along grain boundaries. Thus, to increase the damage tolerance of such materials requires strategies to subdue crack nucleation along grain boundaries. We will present two different strategies to increase the damage tolerance of grain boundaries in ultrafine-grained iron and nickel. First, low-angle boundaries with a spacing of hundreds of nanometer can be engineered by cyclic high-pressure torsion. Such dislocation boundaries have a low misorientation, inherently reducing the energy of the boundary and raising its cohesion. Moreover, due to the limited misorientation, slip transfer across the boundary is facilitated. A main advantage of the concept is that low-angle boundaries can be synthesized independent of the crystal structure, in contrast to the prominent concept of nanotwins. The boundary misorientation and grain spacing can thereby easily be tuned via the applied torsion angle and the number of cycles. Second, segregation of specific elements to grain boundaries can either reduce (e.g. S, P) or raise (e.g. C, B) their cohesive strength, as demonstrated for coarse grained materials. We transferred this idea to the nanoscale by synthesizing B and B-C doped ultrafine-grained iron samples via high-pressure torsion. Although strain-induced segregation to the boundaries is already accessible at room temperature, we will show by APT measurements how the interfacial excess can be optimized via high-temperature HPT or annealing. Lastly, we will present first mechanical tests to verify the success of each concept with respect to grain boundary strengthening.

Carbon Nanomaterials Reinforcements in Inconel 718: Enhanced Strength, Thermal Stability, and Tribological Characteristics

Mr. Manoel Kasalo, Austria

Oral Presentation (20')

Abstract

The increasing demand for extended component lifespan and reduced energy consumption requires the development of novel materials. Metal matrix composites (MMCs) reinforced with various carbon nanomaterials have the potential to achieve high strength, superior thermal stability, and enhanced self-lubrication characteristics [1-3]. Carbon nanomaterials might serve as effective solid lubricants at elevated temperatures due to their higher thermal decomposition resistance compared to conventional liquid lubricants. Typically, these materials are applied as coatings to achieve self-lubrication [4]. This study investigates an alternative approach by incorporating carbon nanomaterials into a nickel-based superalloy matrix (Inconel 718) to develop particle-reinforced self-lubricating MMCs for potential application in extreme environments. Bulk composites were fabricated from powders via severe plastic deformation using high-pressure torsion (HPT) of Inconel 718 with different quantities of graphite, graphene, and carbon nanotubes (CNTs). The objective is to find optimal processing parameters and solid lubricant concentrations to achieve optimum tribological and mechanical properties. Despite differences in chemical bonding, a homogeneous distribution of the solid lubricant phase was achieved through a combination of colloidal mixing and HPT deformation. Microhardness measurements were conducted to analyze the evolution of hardness as a function of graphite content, applied strain, and processing temperature, resulting in ~1.6 GPa hardness differences compared to the Inconel 718 reference material. Micro-tensile tests revealed exceptionally high tensile strength values exceeding 2.1 GPa for MMCs reinforced with up to 1wt% graphite, while maintaining ductile deformation behavior. In-situ high-temperature nanoindentation and X-ray diffraction confirmed superior thermal stability of graphite-reinforced composites. Stable self-lubrication and mild wear behavior, with a sixfold reduction in the coefficient of friction for 5wt% graphene- and CNT-reinforced composites as confirmed by micro-tribological testing.

Microalloyed steel wires reinforced with a titanium core

Ph.D. Marcin Kwiecień, Poland

Oral Presentation (20')

Abstract

To achieve the desired combination of strength and ductility, metal-to-metal composite systems are increasingly being used. The primary advantage of such structural materials lies in two aspects: first, the ability to combine the properties of the individual components within the composite, and second, a thorough understanding of their mechanical and physical properties, which facilitates their use under specific operating conditions. This latter aspect means that new metal-to-metal composite materials require fewer tests and preliminary studies before their potential application, particularly for structural components that are critical from a safety perspective.

The presented research results concern a multilayered material produced through multi-stage wire drawing. The resulting heterostructural material is based on microalloyed steel and reinforced with Ti particles formed by fragmentation of the internal layers of the steel-Ti multilayer systems. The wire drawing process was studied for initial diameters of 6.5 mm, 1 mm, and 0.3 mm. Two basic configurations were used for the studies: tube-tube-rod and tube-rod, made of microalloyed steel and Ti. The evaluation of rheological properties, both of the individual components and the final multilayered systems, enabled a discussion of the relationships between the parameters of the wire drawing process and the development of the microstructure and the accompanying strengthening mechanisms, particularly grain refinement.

At a relatively early stage of the experimental studies, variations in the occurrence of severe plastic deformation (SPD) effects, such as continuous recrystallization, were observed in the Ti layers and the steel matrix. Mechanical property studies of wires with diameters of 1 mm and 0.3 mm, supported by microstructural analysis using optical and scanning microscopy, revealed the complexity of the interaction of various strengthening mechanisms on the rheology of the examined multilayered systems. Particular attention was given to the development of strain hardening in the heterogeneous systems under study. Comparing wires drawn without inter-stage annealing to those subjected to heat treatment revealed different impacts of the multi-stage wire drawing history on both the effects of continuous recrystallization and the interactions between neighboring steel and Ti layers.

Based on the obtained results, conclusions were formulated to guide further research on heterostructural systems produced through plastic deformation.

Paper 607 **5** **HPT processing of Cu-Mo composites with tailored properties for thermal management**

Mrs. Daria Pałgan, Poland

Oral Presentation (20')

Abstract

The growing power density of modern electrical devices requires advanced materials with high thermal conductivity and controlled thermal expansion to ensure efficient heat dissipation and long-term reliability. Copper-molybdenum (Cu-Mo) composites are attractive candidates for thermal management applications due to their unique combination of thermal properties. However, conventional processing techniques, such as powder metallurgy, often result in porosity and limited microstructural control, which can negatively impact their thermal performance. An alternative way would be severe plastic deformation which enables to obtain fully dense materials with significant grain size refinement and improved material homogeneity.

The purpose of this study is to fabricate Cu-Mo nanocomposite from an array of individual disks using high pressure torsion (HPT), determine number of turns required to obtain homogenous microstructure, determine mechanism of its formation and characterize the obtained microstructures and resulting thermal properties. Nanocomposite was fabricated from a system of 3 layered Cu-Mo-Cu disks with thickness 0.4, 0.2 and 0.4 mm. The samples underwent HPT processing with varying numbers of revolutions (from 10 to 200). The results indicate that a fully homogeneous nanostructure, with equiaxed Cu grains (~30 nm in diameter) and dispersed Mo particles (~20 nm in diameter) is obtained after 200 revolutions. The grain size reduction of copper matrix is larger by an order of magnitude comparing to pure Cu, whose grain size after HPT is usually about 250 nm. Additionally, thermal conductivity measurements conducted using the laser flash analysis (LFA) method revealed that the processed Cu-Mo composites demonstrated only a slight reduction in thermal conductivity compared to bulk Cu, making them viable candidates for heat spreaders. The absence of porosity and the uniform dispersion of Mo ensured improved thermal stability, which is crucial for applications in high-power electronic devices.

This study highlights the potential of HPT as an effective method for producing Cu-Mo nanocomposites with tailored microstructures and optimized thermal properties. The results suggest that HPT-processed Cu-Mo composites could serve as a promising alternative to conventionally manufactured thermal management materials, offering improved performance and processing flexibility.

Cooling Effect of Remaining Water Layer on Various Steel Surfaces

Ph.D. Ondřej Resl, Czech Republic

Oral Presentation (20')

Abstract

Accurate prediction and control of the cooling process during hot rolling are crucial for producing high-quality steel with the desired mechanical properties. In many steel companies, hot-rolled steel plates or strips are commonly cooled on a run-out table or in a continuous annealing line using laminar jets or spray cooling, which involves a large amount of water impinging on the steel surface. This process forms a water layer on the top surface, which changes the cooling intensity significantly. The water layer is often removed by water wipers or using air knives; however, thin water layer remains on the surface in most cases. Due to surface tension, this thin water layer forms on both the top and bottom surfaces. The remaining water layer is also formed when using light sprays and can significantly affect the final temperature of the steel strip, especially if the target temperature is below 500 °C, as confirmed by steel producers. This study experimentally investigates the influence of the remaining water layer on heat transfer during cooling after hot rolling. Cooling experiments were conducted using a full-cone spray nozzle and moving steel samples with two different surface finishes: a grinded surface ($R_a = 0.9 \mu\text{m}$) and an oxidized surface ($R_a = 3.1 \mu\text{m}$, oxide thickness $27 \mu\text{m}$). The cooling effect of the remaining water on both surfaces was compared to determine the impact of surface quality.

Severe Plastic Deformation for Processing of Additive-Manufactured Alloys

Prof. G. Güven Yapici, Turkey

Oral Presentation (20')

Abstract

The constant need for high performance engineering components supports the efforts for expanding the design envelopes through the realization of complex shapes and geometries by additive manufacturing. Although additive manufacturing (AM) can accurately account for the geometrical features, mechanical behavior is inherently limited by the material properties and how the part is built. Therefore, improvement of additive-manufactured components from a mechanical property perspective has several technological implications. Since severe plastic deformation (SPD) has long been utilized to achieve extraordinary physical and mechanical properties in a variety of material systems, its utilization following AM deserves further investigation.

In this work, multiple cases on the utilization of SPD technologies as post-AM processing tools for mechanical response enhancement are provided by highlighting the recent efforts in various alloys. As such, this study demonstrates the potential of SPD assisted thermo-mechanical processing (TMP) for obtaining unprecedented properties in additive-manufactured alloys with evidence from different materials, whereby optimum selection of post-AM processing parameters and part geometry are crucial.

Paper 159 1 **Plasma-Assisted Fabrication of Metal Oxide Nanostructures Using Phthalocyanines and Porphyrins: A Route to Functional Porous Layers**

Dr. Juan Ramón Sánchez-Valencia, Spain

Keynote (Oral Presentation 40')

Abstract

Developing innovative methods for nanostructural control is key to designing advanced materials with superior properties.[1] In such a context, plasma-activated deposition has shifted from compact thin films to controlled nanoscale materials, including nanoporous layers, low-dimensional carbon, and complex one-dimensional structures.[2,3] These methods offer scalability, low deposition temperatures, wide substrate compatibility, precise compositional control (including doping), and morphological precision (microstructure, texture, alignment).[2,3] However, a critical limitation is the scarce availability of volatile metalorganic and metal halide precursors for nanoscale deposition. This study establishes the bases for a vacuum and plasma-supported methodology for fabricating metal-oxide nanostructured layers with controlled microstructure using metal phthalocyanines and porphyrins as precursors.[4–6] Key strengths of this method are its ample general character from the point of view of the material composition and microstructure, mild deposition and processing temperature and energy constrictions, and compatibility with the direct deposition on processable substrates and device-architectures. Leveraging commercially available metal porphyrins and phthalocyanines, we developed metal oxide layers including CuO, Fe₂O₃, TiO₂, VO_x, and ZnO with morphologies ranging from compact to porous films as well as low dimensional nanostructures such as 2D networks, nanowires or nanocolumns. The synthesized layers demonstrate potential in energy applications, particularly optical and optoelectronic technologies.

Novel interface-engineered nanolaminated Al-X / AlOH thin films towards superior mechanical properties and thermal stability

Mr. Hendrik Jansen, Switzerland

Oral Presentation (20')

Abstract

Recent deposition advances allow interface-engineered multi-layered Al-X- / AlOH (25 / 1 nm) thin films by a combination of physical vapour and atomic layer deposition. These allow systematic evaluation of grain boundary complexion engineering and the unique crystalline / amorphous interface on mechanical properties and thermal stability. Annealing at low homologous temperatures allows rather segregation enrichment at interfaces than grain growth. Thermal stability was investigated based on lateral grain growth– out-of-plane growth being limited by 1 nm AlOH interlayers. Mechanical testing by nanoindentation and micropillar compression at multiple strain rates allowed mechanical property analysis of the high-strength Al-X / AlOH multilayer thin films with nanoindentation hardness of more than 5 GPa. Ultimately, high-resolution analysis by transmission electron microscopy and atom probe tomography allowed the enhanced properties to be linked to interface decoration and secondary phases that hinder dislocation and grain boundary movement.

Paper 1985 3 Hybrid Highly-Porous Photonic Structures for Photocatalysis Fabricated by Atomic Layer Deposition
Prof. Kaline Pagnan Furlan, Germany
Oral Presentation (20')

Abstract

Harnessing the wide spectrum of solar energy for photocatalysis holds a promise for sustainable pollutant abatement with titanium dioxide (TiO_2) being a benchmark material due to its stability and photocatalytic efficiency when exposed to ultraviolet light (UV). Nevertheless, as TiO_2 is mostly activated by UV-radiation, the rest of the solar spectrum radiation remains unutilized, i.e. is “wasted”. Moreover, pure TiO_2 presents a high carrier charge recombination rate, hindering the catalyst efficiency. Earlier studies have focused on material modifications or semiconductor heterojunctions to widen the radiation range towards utilizing of a wide range spectrum in TiO_2 's photocatalysis. Light absorption and interaction can however also be tailored via (nano)structuring of the material systems, such as in the case of inverse opal photonic crystals (i-PhC). These highly ordered 3D structures are able to tailor light-matter interactions due to their structural photonic stopband (PSB), which when in combination with photoactive materials can enhance the generation of free charge carriers due to the activation of the slow photon amplification effect. To further optimize photocatalytic efficiency, semiconductor heterojunctions can be engineered within the i-PhC structure. In this talk, I will present the challenges and developments regarding the fabrication of hybrid TiO_2 - Fe_2O_3 i-PhCs by multilayer atomic layer deposition (ALD). Our results reveal that the complete functionalization of TiO_2 i-PhCs with Fe_2O_3 increase the photocatalytic activity through the slow photon amplification effect and semiconductor heterojunction formation, where a maximum photocatalytic activity of 1.38 ± 0.09 per hour is observed for the i-PhC with a 16 nm-2 nm TiO_2 - Fe_2O_3 bilayer. These results greatly outperform the pure TiO_2 i-PhC, highlighting the potential of hybrid i-PhCs macroporous structures for efficient water pollutant removal, as well as the advantages of precise nanostructuring and heterojunction engineering by ALD.

Paper 1608 4 **Influence of thermal treatments and UV irradiation on anisotropic TiO₂ architectures prepared by oblique angle deposition**
Dr. Bertrand Lacroix, Spain
Oral Presentation (20')

Abstract

The development of advanced surface treatments is essential for enhancing material properties and introducing new functionalities. This is particularly critical in applications requiring efficient light capture in challenging environments, such as photodetection and solar energy. In these cases, coatings must not only optimize optical performance but also exhibit additional features, such as tunable wetting properties, to ensure long-term efficiency.

In this context, this study - conducted in collaboration between the Pprime Institute, the company Safran (France), and the University of Seville (Spain) - aims to enhance the performance of imaging devices in the visible and near-infrared spectrum by developing porous titanium dioxide (TiO₂) films with controlled columnar architectures. These films are fabricated using electron beam evaporation combined with the oblique angle deposition (OAD) technique, enabling precise control over porosity and morphology through deposition angle adjustments. This structural control allows fine-tuning of the refractive index, a key factor in the optical design of photonic systems, such as antireflection coatings and polarimetric filters, integrated into essential optical components.

By carefully adjusting deposition parameters, highly anisotropic nanostructures can be achieved, which are crucial for obtaining significant linear birefringence, a critical property for high-performance polarimetric filtering. To further optimize this characteristic, this research will investigate the effects of thermal treatments at different temperatures on the nanostructure, including morphology, crystalline structure, and overall optical properties of the TiO₂ films. Additionally, to explore the potential for antifogging and self-cleaning functionalities, the study will analyze how thermal treatments influence wetting behavior. Finally, the impact of ultraviolet (UV) irradiation on these properties will also be examined, assessing its potential as a tool for further controlling surface characteristics.

Innovative Cold Spray Solutions for Composite Substrate Metallization

Mrs. Nikita Shukla, Spain

Oral Presentation (20')

Abstract

Metallization of composite substrates enhances their electrical conductivity making them suitable for advanced applications such as aerospace. Methods like Physical Vapor Deposition, Electroless Plating, and Thermal Spraying offer varied advantages but also face challenges, such as thermal degradation, limited adhesion, and environmental concerns. Cold Spray (CS), is a Thermal Spray technology that involves high-velocity particle deposition without melting the powder material while forming a coating, minimizing thermal impact. This makes it particularly suitable for temperature-sensitive substrates like carbon fibre-reinforced polymers (CFRPs).

This study aims to enhance the adhesion in CFRPs metallization by combining Arc Wire Spray for interlayer deposition with CS for top-layer coating. This technique also solves the challenges like erosion and cost -efficiency. Various interlayer materials, including Zn, Al, Zn/Al alloys, Cu, Brass (Cu/Zn), and combinations, were deposited via Arc Wire to enhance bonding between the composite substrate and the metallic coating. Al and Cu powders were then applied as the top layer using CS. Experimental evaluations assessed coating thickness, porosity, adhesion strength, and electrical conductivity, targeting aerospace industry requirements for lightning protection and electromagnetic interference shielding.

Results show that interlayer selection plays a crucial role in improving adhesion, reducing delamination, and enhancing electrical performance. Additionally, top-layer coatings further improved electrical conductivity, making the metallized CFRPs more effective for advanced applications. The combination of AWS and CS enables superior adhesion and performance, demonstrating the potential of combining different thermal spray techniques for composite metallization. Future work will focus on optimizing process parameters, enhancing material compatibility, and exploring scalable industrial applications.

Paper 1207 1 Low-temperature plasma-assisted carburizing of additively manufactured 316 L steel

Dr. Alessandra Palombi, Italy

Highlight (Oral Presentation 20')

Abstract

Austenitic stainless steels are used in several industrial sectors (chemical, energy, biomedical, pharmaceutical, etc.) due to their excellent corrosion resistance, however, they suffer from low hardness and wear resistance. To improve these characteristics without detrimental effects on corrosion resistance, the 316L steel, manufactured by Laser Powder Bed Fusion (L-PBF), was subjected to a plasma assisted carburizing process at 475 °C. The temperature is suitable to avoid the precipitation of $M_{23}C_6$ carbides and η , χ and σ phases.

The work aimed to optimize the more relevant process parameters, namely the composition of plasma gas mixture (CH_4 plus H_2), and the treatment time. In a first stage the effects of different amounts of CH_4 (0.5, 1, 2, 2.5 and 4 %) in the gas mixture were examined by keeping constant the time (7 hours) of treatment. The samples were characterized by Light Microscopy (LM), Scanning Electron Microscopy (SEM), Atomic Force Microscopy (AFM), X-ray Diffraction (XRD), Raman Spectroscopy (RS), X-ray Photoelectron Spectroscopy (XPS), Glow Discharge Optical Emission Spectroscopy (Rf-GDOES), and Vickers micro-hardness tests. The results evidenced that the mixture consisting of 2.5% CH_4 + 97.5% H_2 is the most effective: the surface hardness (547 ± 27 HV) becomes more than double if compared to the one of original material (245 ± 3 HV). Surface hardening is due to the formation of a C-enriched austenite (S-phase) with thickness of $\sim 20 \mu m$. S-phase resulted covered by a very hard and brittle diamond like carbon (DLC) over-layer of $\sim 2 \mu m$ that fractures and detaches during tribological tests and these abrasive particles increase the wear rate.

Therefore, in the second stage of the research the treatment time has been changed step by step to find the conditions for forming the S-phase without the DLC over-layer. The best trade off, in terms of surface hardening and wear resistance, is the treatment with 2.5% CH_4 + 97.5% H_2 for 90 minutes, resulting in a wear rate of ~ 20 times lower than that of the same material before plasma carburizing treatment.

Paper 507 2 Investigation of coating properties in cold-sprayed Ni-base superalloys post processing – long term heat treatment and hot isostatic pressing

Ph.D. Malarvadani Gamberavadanar Thamizharasan, India

Oral Presentation (20')

Abstract

Cold spraying (CS) is extensively employed to fabricate protective coatings, such as Inconel 718 (IN718), owing to its remarkable efficacy in challenging environments. Although the technique has significant versatility but owing to the problem of porosity inclusions in coatings, parts are often subjected to post-processing treatments. This research examines the impact of such post-processing on IN 718 cold-sprayed coatings onto IN 718 substrates. The post-processing techniques employed are Hot Isostatic Pressing (HIP) and prolonged heat treatment of the IN 718 coating with the aim to examine their influence on the microstructure and mechanical properties of CS coatings addressing the challenges related to coating integrity. The CS IN718 coating was heated to 1150°C and then subjected to an isostatic pressure of 120MPa for 4 hours for HIP treatment, while the long-term heat treatment involved exposure to 750°C for 168 hours. The HIP treatment resulted in superior mechanical properties due to the combined effect of recrystallization, twins and MC carbides. Concurrently, it diminished the work-hardened microstructure via recovery, evidenced by a reduction in dislocation density within the coating. The alterations in coating microstructures resulted in an approximate 200 percent increase in the cohesive strength of the coating following HIP-ing. The application of long-term heat treatment significantly decreased the porosity levels of the coating from approximately 4% to 0.8%, signifying an enhancement in the metallurgical bonding among the individual splats. Precipitation hardening, resulting from the formation of intermetallic phases (γ'' and δ) and MC carbides, alongside a decrease in material ductility, collectively contribute to this phenomenon. In general, both the post processing techniques resulted in improvement of coating strengths. In addition to an increased cohesive strength, the HIP-ed coating additionally demonstrated a notable plastic region, in contrast to the heat-treated coating. Ultimately both post-processing techniques altered the microstructures of the coating, leading to enhanced cohesive strength and ductility. This presentation will offer a comprehensive discussion of all notable findings related to the benefits derived from post-processing treatments of CS coatings.

Comparative Assessment of Plasma and Gas Nitriding on Air-Hardening Ductile Steels

Mr. Sitki Can Akkus, Germany

Oral Presentation (20')

Abstract

Steel components subjected to dynamic loads are susceptible to wear and oxidation. The relative movement between contacting surfaces under such loading conditions can trigger various wear mechanisms, including abrasion and adhesion. Additionally, dynamic loads can induce surface damage and deformation, exposing new material to the environment and accelerating oxidation. Nitriding is one of the thermomechanical treatments to overcome these disadvantages. The notable improvement in the properties of steel parts after nitriding is primarily due to increased surface hardness, internal stress, and chemical changes within the treated region.

While nitriding can be performed using different techniques, plasma nitriding provides several distinct benefits. Gas nitriding, which utilizes ammonia as the nitrogen source, is a well-established method for enhancing surface properties. However, plasma nitriding, where nitrogen gas is ionized by applying a high voltage between the furnace wall and the steel component acting as the cathode, offers several advantages. Specifically, plasma nitriding facilitates a faster process due to the accelerated formation of the nitrogen concentration gradient compared to gas nitriding. Additionally, plasma nitriding eliminates the production of harmful by-product gases, making it a more environmentally friendly option. These differences highlight the potential for plasma nitriding to deliver superior performance in terms of process speed, environmental impact, and surface property enhancement for AHD steels.

A recent innovation introduces a new class of martensitic steels that achieve their final properties through air cooling directly from the forging heat. These air-hardening ductile (AHD) forging steels, alloyed with approximately 4 wt.% manganese, develop a uniform martensitic microstructure without the need for quenching and tempering, significantly lowering CO₂ emissions. With the first commercial melts of these steels now available, interest in their performance across various applications is increasing.

This study compares the plasma and gas nitriding performance of newly developed sustainable AHD steels. Within this scope, a comprehensive characterization study, including mechanical and chemical analyses, was conducted following plasma and gas nitriding processes carried out under similar process parameters. Electron Probe Microanalysis (EPMA) and X-ray Diffraction (XRD) were utilized for elemental analysis and to identify phase formations within the nitrided layers. The results revealed that plasma and gas nitriding yielded comparable hardness values at around 1000HV. Given that the mechanical and chemical properties after nitriding were similar, plasma nitriding emerges as a more advantageous option due to its environmental benefits and time efficiency.

Surface modification of titanium components for motorsport industry by diffusion treatments

Mrs. Elisa Ferrari, Italy

Oral Presentation (20')

Abstract

BOZZA ABSTRACT PER EUROMAT 2025

Surface modification of titanium components for motorsport industry by diffusion treatments

In the motorsport industry, the choice of material for manufacturing the heat-resistant components often fall on titanium alloys. Nevertheless, one of the most common problems of titanium alloys is fretting. [1]

Fretting is a complex phenomenon that occurs at the contact interface subjected to cyclic loading. In the case of titanium components, fretting can be particularly problematic because induces fatigue wear.[1]

Currently, carburizing is the predominant treatment employed to enhance the fatigue strength, [2] however, this process is time-consuming and expensive due to the exploited process to diffuse carbon on surface, i.d PVD.

Therefore, the objective of this study is to identify different surface treatment to improve the wear resistance properties inherent within titanium alloys.

To address these challenges, the idea is to develop a new surface treatment that carburize titanium oxide surfaces instead of titanium itself, thank to knowledge that the diffusion rate of carbon in TiO₂ is significantly higher.[3]

Two different titanium alloys have been investigated: Titanium Grade 2 and Grade 5 (Ti6Al4V alloy) . Samples have been coated by controlled oxidation processes, that is anodization, to provide oxide layers with tailored properties. Subsequently the oxidized specimens are performing carburizing, exploiting different process parameter, such as different temperatures. The diffusion of carbon into the oxide layer to form a carburized surface, has been evaluated with the aim to form a uniform and well-adhered carburized layer. Chemical, physical and preliminary mechanical tests were carried out on samples. In details: optical microscopy, a SEM – EDS analysis, a microhardness and nanoindentation test, scratch test and XRD analysis.

The results show that the oxidation thickness was among 2–3-micron layer and the coating composition, structure, and elemental distribution were composed of three different forms of oxide: anastasio, rutile and amorphous phase.

Furthermore, pin-on-disk tests will be conducted on the carburized surface to evaluate the wear resistance of the treated specimens. The wear behavior, coefficient of friction, and surface morphology will be analyzed to assess the effectiveness of the treatment in reducing wear resistance.

The results prove the possibility to overcome the limitations inherent in traditional carburizing processes. Through controlled oxidation and subsequent cementing, we anticipate the formation of a carburized surface with improved wear resistance and reduced fretting-induced damage.

Tunable nano-Rare Earth oxides for pAthogen mitigation (TREAT)

Prof. Sudipta Seal, United States

Keynote (Oral Presentation 40')

Abstract

Since COVID 19 pandemic, there is a huge demand for effective disinfectants to combat pathogens including deadly Viruses and bacteria and has grown significantly. This need extends to addressing both community-associated and hospital-acquired infections, which continue to pose major global challenges to human health. Therefore, novel strategies offering broad-spectrum and non-specific protection are urgently required. In this talk we will explore design of the nanomaterials for radical generating/scavenging nanozyme surface redox chemistry of metal substituted rare earth (ceria)-based materials; the charge transfer behavior and review documented antiviral and antimicrobial properties. Various formulation efficacy studies will also be presented. Most importantly, we will present In situ electroanalytical measurements (impedance spectroscopy, equivalent circuit analysis) highlighted these biological activities with particles from each formulation showing substantial anti-microbial activities towards both enveloped and non-enveloped virus species via physical or chemical inhibition mechanisms. Furthermore, the surface chemistry and morphology of these nanoformulations have been thoroughly examined using high-resolution transmission electron microscopy and X-ray photoelectron spectroscopy. To optimize nanozymatic activity, a combination of ab initio and classical computational modeling, alongside experimental validation, has been employed in designing these potent nanostructures. (Some of the TEM examination was financially supported by the Institute of Metallurgy and Materials Science of the Polish Academy of Sciences within the MOU between the University of Central Florida Board of Trustees and Institute of Metallurgy and Materials Science Polish Academy of Sciences)

Paper 1571 2 New generation copper-based coatings of improved antimicrobial resistance to pathogens

Prof. Joanna Wojewoda-Budka, Poland

Oral Presentation (20')

Abstract

The use and abuse of antibiotics for many years has created very unfavourable living conditions for bacteria, forcing microorganisms to create many defence mechanisms and selecting strains best suited to these conditions. The appearance of bacteria resistant to many antibiotics, so-called "Super bugs" or MDR (multi drug resistant) has been noticed not only by patients, medical doctors, but also by epidemiological services in many countries.

Antimicrobial copper can be used to produce parts often touched by people in hospitals and clinics but also in public places. Copper ions penetrate into bacterial cells and damage nucleic acids, which leads to disruption of the helical structure and DNA denaturation. Copper ions can also bind informational RNA and thus inactivate viruses, whereas copper complexes form radicals that inactivate viruses.

Therefore, in the proposed study, viability of various bacteria and viruses were examined on variety of copper and copper-based coatings. Innovative copper-based composite coatings obtained through the addition of TiO₂ or CeO₂ particles during the deposition process, will constitute an even more effective weapon in the fight against the spread of pathogenic organisms.

It is known that the rate of copper's antibacterial activity depends on the percentage of copper in the alloy. Thus, the use of durable and wear-resistant coatings, in which the copper content is as high as possible, is an economical solution. Three copper deposition technologies are proposed to be applied: electroplating, electroless plating and selective plating. The common advantages of the considered technologies are their simplicity, wide application in industry, economic attractiveness, the possibility of using complicated product shapes and partial or total versatility, when it comes to the base material on which these layers can be embedded. Synergy of expertise of all partners will contribute to in-depth understanding of the relation between the plating process, microstructure, properties and anti-pathogenic response of the copper and copper-based coatings, which will translate into the development of optimal technology to produce surgical instruments, in particular for dental applications.

Acknowledgments: The study on Cu and Cu-TiO₂ coatings was supported by the National Centre for Research and Development in the frame of the M-ERA.NET program under Grant MERA.NET2/2020/AntiPathCoat/4/2021. Part of this work associated with the Cu-CeO₂ composite coatings was financed by the Ministry of Science and Higher Education of Poland as the statutory financial grant of the Polish Academy of Sciences (task Z-5).

Engineering Biocompatible Surfaces with Oligoproline: A Powerful Anti-Biofouling Peptide

Prof. Sachiro Kakinoki, Japan

Highlight (Oral Presentation 20')

Abstract

The surfaces of medical devices are in direct contact with their surrounding environment, making them critical in determining key properties such as durability and functionality. When implanted in the body, the interactions that occur within the first few seconds between the device surface and biological components including proteins, cells, and blood, are decisive in the long-term success or failure of the implant. Therefore, surface engineering technologies that regulate biological interactions play a crucial role in the performance of implantable medical devices. To prevent unfavorable biofouling leads to the blood coagulation, an anti-biofouling surface minimizes biological recognition, allowing the device to function without triggering adverse reactions. To prevent unfavorable biofouling, which can lead to blood coagulation, an anti-biofouling surface minimizes biological recognition, allowing the device to function without triggering adverse reactions. Here, we designed and characterized a novel non-ionic anti-biofouling peptide, oligoproline, inspired by the collagen backbone structure.

Oligoprolines (Ac-CPn-NH₂, n= 6 or 9) were synthesized by Fmoc solid-phase procedure and immobilized on the Au-sputtered coverslip via Au-SH bonding. Oligoproline-immobilized (OP) surfaces were characterized by water contact angle measurements and X-ray photoelectron spectroscopy (XPS). Subsequently, protein adsorption, fibroblast adhesion, platelet activation, blood cell interactions, and bacterial adhesion on OP surfaces were evaluated.

The OP surfaces were successfully prepared with a smooth topology ($R_a \approx 6$ nm) and a low water contact angle ($\theta \approx 30^\circ$). Serum protein adsorption was significantly reduced upon oligoproline immobilization, with albumin and fibrinogen adsorption levels below 10 ng/cm² and 40 ng/cm², respectively. Fibroblast adhesion was strongly suppressed in vitro. After 5 minutes of whole-blood exposure under dynamic in vitro conditions, the surface coverage by blood elements including platelets and blood cells on OP surfaces was markedly lower than that of clinically available polyurethane. Adhesion of CD62P⁺ platelets and CD45⁺ leukocytes was also significantly suppressed. Furthermore, OP surfaces effectively prevented the adhesion of E. coli and Staphylococcus aureus, both of which are known for secreting prolyl aminopeptidase.

Biomimetic Composite Heart Valve with AI-Enhanced Hemocompatible Coatings: Integrated Simulation, Fabrication, and Preclinical Evaluation

Prof. Roman Major, Poland

Oral Presentation (20')

Abstract

The bioVALVE project addresses the critical challenge of thrombo-emboli formation in pulsatile ventricular assist devices (VADs) by developing an innovative biomimetic heart valve based on a metal-polymer composite. Current mechanical valves suffer from suboptimal blood flow dynamics and elevated shear-induced platelet activation, which promote thrombogenesis and compromise patient outcomes. To overcome these limitations, our interdisciplinary approach integrates advanced fluid-dynamic simulations, state-of-the-art material processing, and rigorous in vitro and in vivo testing. A flexible heart valve was fabricated via injection moulding of thermoplastic polyurethane (TPU) with an embedded, delicate titanium mesh insert, combining microscale elasticity akin to native blood vessels with the macro-scale mechanical stability required for effective valve function.

In parallel, ultra-thin, biofunctional coatings were developed using physical vapor deposition (PVD) and plasma-assisted chemical vapor deposition (PACVD) techniques. The coatings, primarily based on diamond-like carbon (DLC) materials, were systematically optimized through nitrogen and silicon doping and further refined via post-deposition fluorination. These tailored coatings exhibit exceptional uniformity, minimal particulate contamination, and precisely tuned surface wettability, thereby enhancing the “washing” effect on blood-contacting surfaces and significantly reducing shear-induced platelet activation.

A distinguishing feature of our project is the integration of artificial intelligence (AI) methods within the material design and evaluation process. Advanced machine learning algorithms were employed to refine numerical simulations, predict material properties, and accelerate high-throughput screening of coating parameters. This AI-enhanced approach not only reduces reliance on traditional trial-and-error methods but also enables simultaneous multi-attribute optimization—addressing mechanical stability, biocompatibility, and hemocompatibility concurrently.

Mechanical characterization via nanoindentation and scratch testing confirmed that the optimized coatings deliver superior hardness, ductility, and wear resistance under cyclic loading. Complementary hemocompatibility assays under dynamic conditions demonstrated marked reductions in platelet adhesion, aggregation, and activation compared to conventional carbon disc valves. The promising preclinical results underscore the potential of this integrated, AI-driven design framework to advance the performance and safety of VADs, thereby improving clinical outcomes and reducing healthcare costs.

Paper 1719 5 Hemocompatibility Assessment Method Based on the Principles of a Radial Flow Chamber

Ph.D. Przemyslaw Kurtyka, Poland

Oral Presentation (20')

Abstract

The hemocompatibility assessment of biomaterials and implants is a crucial element in their qualification for clinical applications. Any material in contact with blood must meet stringent requirements to prevent complications such as thrombosis, hemolysis, or excessive platelet activation. Improper interaction between a biomaterial and blood can lead to severe health complications and even pose a life-threatening risk to the patient. Therefore, it is extremely important to use precise research methods to assess the compatibility of blood with biomedical materials under conditions as close as possible to physiological ones.

In research practice, a widely used method for evaluating hemocompatibility is the Impact-R test, which enables the analysis of dynamic interactions between blood and the biomaterial's surface. To expand the capabilities of this method, an innovative device called SYMMED has been developed, allowing for a more advanced evaluation of the impact of shear stress on the interactions between implants and blood. This method is particularly important in the context of modern coatings used in vascular and cardiac implants, where dynamic blood contact plays a crucial role. Under physiological conditions, shear stresses occurring at the implant-tissue interface can lead to undesirable reactions, including hemolysis or the initiation of thromboembolic processes. Precise regulation of experimental parameters, such as rotational speed, gap width, and the exposure time of the sample to flowing blood, enables controlled analysis of platelet activation, hemolysis levels, and the thrombotic potential of the biomaterial under study. The methodology used in SYMMED is based on advanced diagnostic techniques, such as confocal microscopy to detect platelet activation using specific antibodies, hemolysis analysis, and other quantitative methods that assess the compatibility of the biomaterial with the circulatory system. The results provide comprehensive information about the biocompatibility of the analyzed materials, which is crucial for their further development and clinical application.

In conclusion, the development of modern methods for assessing hemocompatibility, such as the extended version of the Impact-R test using the SYMMED device, represents an important step toward ensuring the safety and effectiveness of new solutions in medical biomaterials. By precisely replicating physiological conditions, reliable results can be obtained, which are crucial for evaluating and optimizing modern materials used in medicine.

The research was funded by the National Science Center, Poland, allocated based on decision No. 2023/49/B/ST11/03301.

Paper 640 6 **Advanced biomaterials for pediatric miniatural heart pumps – characterization and modelling**
Prof. Roman Major, Poland
Oral Presentation (20')

Abstract

Introduction

The heart, this amazing organ can fail, either due to congenital and genetic problems such as inherited heart muscle disease (cardiomyopathy) or secondary to congenital arrhythmias. The intended target was minimal invasive paediatric pump prototype introduced via vascular access, such placement in an aortic vessel would prevent burdensome invasive surgery at the opened chest for short-term heart support (<4 weeks).

Materials

The coatings dedicated for the pump parts were elaborated full filling the following features: ultra-low friction & fully hemocompatible fullerene/diamond-like carbon hard coatings with surface functionalization for high adhesion of athrombogenic oligoproline & polydopamine with superior properties to heparyn.

Modelling

Numerical simulations of the testers were performed before testing the materials. As part of the evaluation of the biological suitability of materials dedicated to cardiac support pumps, multi-analyses were performed on several alternative testers and the flow properties as well as the interactions between the analyzed surface in cells were recalculated theoretically and only in the next step verified experimentally.

Experimental verification

The experimental verification consisted of an originally developed and executed blood-material interaction scenario under the „Organ-on-chip“ technique. The high speed rotors normalized testers dedicated to evaluate of whole human blood quality changes under dynamic conditions were developed. The aggregates of leukocyte-platelet, platelet-platelet, monocyte-platelet formation and platelets activation were evaluated using the flow cytometry and confocal microscopy. For the group of selected coatings, the adhesion efficiency of blood morphotic elements was determined under a shear stress by the radial flow chamber assay. This multistep material selection was based on the broad materials characterization. To evaluate the developed materials in the sample scale a new prototype of a bio-pump dedicated for the 3D shape substrate testing was developed. The system enabled the testing of cardiac assist devices under normal and dysfunctional heart conditions.

Results

In most cases, tested coatings showed good or very good haemocompatibility. Type “nano-onion” fullerene/diamond-like carbon PVD hard coatings with coating proved to be superior in terms of activation, risk of aggregation, and the effects of generating microparticles of apoptotic origin, and also demonstrated excellent mechanical properties. The Surface additional surface functionalization for high adhesion of athrombogenic oligoproline & polydopamine resulted in the achievement of activation parameters at the level of the negative control, i.e. disactivated blood.

Restoration of physiological conditions in the assessment of the biocompatibility of SiO₂ coatings deposited on Nitinol cardiovascular implants through electrophoretic deposition

Ph.D. Karolina Szawiraacz, Poland

Oral Presentation (20')

Abstract

The materials under investigation concern implants designed for heart muscle regeneration. The development of such materials requires comprehensive research, from basic studies to physiological simulations, in vivo testing, and the preparation of certification documentation. Inadequate planning and improper testing techniques can lead to failure. Due to the critical impact of medical devices on human health, this field is heavily regulated.

Nitinol, a widely used material in cardiovascular implants, is known for its excellent properties, including shape memory and superelasticity. However, its biocompatibility remains a challenge due to the potential release of nickel ions. In this study, surface-modified Nitinol was evaluated with silica (SiO₂) coatings, applied via electrophoretic deposition (EPD). The objective of the coatings was to create a protective barrier between the Nitinol substrate and the biological environment.

To optimize the deposition parameters, the zeta potential of the EPD electrolyte was measured. This analysis confirmed stable colloidal dispersions resistant to aggregation. Wettability of surfaces was assessed through water contact angle measurements. Enhanced wettability is beneficial for promoting protein adsorption and cell attachment, which are crucial for better tissue integration.

The microstructure was examined using transmission electron microscopy (TEM) and energy-dispersive X-ray spectroscopy (EDS) to assess the morphology, composition, uniformity of the coatings. Thin foils for TEM were prepared via gallium ion milling. These techniques enabled detailed analysis of the coating's structure, critical since both microstructural and chemical properties influence biocompatibility and cytotoxicity. Cytotoxicity was assessed according to ISO 10993-5. Extracts were prepared by incubating coated Nitinol samples in culture medium for 24 hours. Following this, the medium was replaced with the extracts, cells were incubated for 48 hours. Cell viability and proliferation were assessed by monitoring cell growth. Confocal laser scanning microscopy (CLSM) and live/dead fluorescent staining were used to visualize cell viability and confirm reduced cytotoxicity of the coated samples.

The genotoxic potential of the SiO₂-coated samples was evaluated using the Xenometrix Rapid Micronucleus MoA assay. This assay detects DNA damage in cells exposed to the extracts. Preliminary results indicated the coatings effectively reduced both cytotoxicity and genotoxicity compared to bare nitinol.

The results of zeta potential optimization, improved hydrophilicity, and microstructural analysis contributed to enhancing the biocompatibility of SiO₂-coated nitinol implants. These coatings showed promising results in reducing nickel ion release and fostering a surface conducive to tissue interaction, offering a potential solution for cardiovascular applications.

Presented studies were financially supported by the National Science Centre, Poland: 2023/49/B/ST11/03301.

Paper 357 1 Orientation dependence of serrated flow: insights from microcompressed Mg-Gd single crystals

Dr. Henry Ovri, Germany

Oral Presentation (20')

Abstract

Important aspects of serrated flow, such as the influence of plastic anisotropy and twinning are yet to be fully understood. These aspects are particularly important in alloys systems of the HCP family, including Mg alloys which exhibit strong anisotropy and twinning. Moreover, efforts to identify the dominant slip systems in the serrated flow regime in polycrystalline materials have been challenging, as such investigations are complicated by the presence of grain boundaries and the interaction between grains. To address these challenges, single crystals of a Mg-Gd alloy were tested using a combination of microcompression and microstructural characterization tools, including EBSD and TEM based EDS/STEM measurements. The study also benchmarks the temperature and strain rate dependencies of the alloy against pure Mg crystals in similar orientations. The results reveal that serrated flow in Mg alloys is markedly anisotropic. This anisotropy arises from differences between the Burgers vector for slip/twinning, and variations impurity diffusivity parallel and perpendicular to the basal plane. The work also provides compelling evidence that the solute drag mechanism, rather than the widely accepted dynamic strain aging mechanism, underlie serrated flow in the alloy.

Paper 2104 2 Exploring Mechanical Properties of Soft Materials at the Nanoscale Using Indentation Methods

Dr. Jan Přibyl, Czech Republic

Oral Presentation (20')

Abstract

Soft materials, characterized by elastic moduli typically below 1 MPa, such as biopolymers, gels, and biological tissues, exhibit distinct mechanical properties compared to hard materials. Investigating these properties at the nanoscale offers new possibilities in fields like biomedical engineering, materials science, and nanotechnology. Nanoindentation techniques, including Atomic Force Microscopy (AFM) and nanoindenters, were employed to assess the mechanical properties of soft samples. These techniques were applied to samples such as defined phospholipid bilayers, biomolecules (proteins, DNA), hydrogels, single cells, and tissue cultures. Additionally, correlative approaches using fluorescence and Raman microscopy were demonstrated. The presentation concludes with a discussion on the challenges of standardizing these measurements.

The goal is to develop more efficient methods for characterizing the mechanical properties of complex soft materials and understanding their properties at the nanometer scale. This also involves exploring their relationship to the molecular nature of certain processes, with implications for biological and biochemical sciences. Such characterization can enhance our understanding of the connections between physiological or disease states and changes in mechanical properties at the molecular, cellular, or tissue levels.

Micro-texture dependent variation of microscale residual stresses in Ti-6Al-4V

Mr. Akshay Mundayadan Chandroth, Belgium

Oral Presentation (20')

Abstract

Residual stresses can be detrimental to the mechanical performance of titanium alloys. Research on residual stresses in titanium alloys post-deformation generally focuses on macroscale stress distribution. Nevertheless, microscale residual stresses can vary significantly from the macroscopic behavior in a material like titanium, which has considerable elastoplastic anisotropy. Understanding the influence of local crystallographic texture on microscale residual stresses requires further research. Localized textured regions, also called macrozones or micro-textured regions (MTR's), are prevalent in titanium alloys. These develop during the material's manufacturing process. The anisotropic deformation behavior of MTR's can significantly affect the development of residual stresses in the material.

In this study, the macroscale and microscale residual stress distribution in Ti-6Al-4V bars was evaluated experimentally on sections along the rolling and transverse direction after four-point bending. The macroscopic and microscopic residual stresses were characterized across the bar thickness using synchrotron X-ray diffraction (sXRD) at DESY beamline P07 and the Focused Ion Beam – Digital Image Correlation (FIB-DIC) ring-core milling technique, respectively. The sXRD measurements were used to probe a gauge volume containing several clusters of grains, revealing a typical post-bending macroscale residual stress profile. In contrast, the FIB-DIC measurements were used to probe smaller gauge volumes of 5 μm , enabling the possibility of exploring the residual stress state within individual grains in specific MTR's. The residual stress profiles obtained across the bar thickness using sXRD were observed to be shifted significantly from the neutral axis of the bar, indicating tension-compression asymmetry. The microscale residual stress data obtained via FIB-DIC measurements were shown to have several outliers compared to the macroscopic residual stress values measured at similar locations via sXRD. Localized crystallographic texture analysis was used at locations where such outliers were observed, in order to demonstrate the relationship between grain (or MTR) orientation and microscale residual stress variation in a plastically deformed Ti-6Al-4V bar.

Effect of polishing on near-surface residual stresses in commercially pure titanium

Mr. Kento Takahashi, Belgium

Oral Presentation (20')

Abstract

Polishing is a mechanical process conducted on metallic materials to obtain a smooth, mirror-like surface, exempt from defects. It is usually conducted prior to metallographic observations, as a step in surface treatments or simply as a finishing process. As any mechanical processing method, polishing induces residual stress, which can be beneficial or detrimental to the structural integrity of materials. It is therefore of interest to evaluate the magnitude of residual stresses induced by this process. Studying the polishing process is complex due to its multi-parametric nature as well as the small length scale of occurring mechanisms. While it has been theorized in the past that an amorphous layer is created on top of a polished sample, it was demonstrated with modern tools that chips were removed over time, therefore making the polishing process more analogous to a cutting process. In this study, commercially pure titanium was polished to evaluate the weight of different polishing parameters on the induced residual stresses in the chosen material. These parameters include abrasive particle size, polishing load and polishing time. The samples were first stress-relieved through heat-treatment and electropolished to obtain a fully stress-relieved surface. The samples were then mechanically polished with a semi-automatic polisher using different parameters. Analysis of residual stress was conducted via ring-core FIB-DIC (Focused Ion Beam-Digital Image Correlation). This method enables depth-resolved residual stress analysis of the polished samples with submicron depth resolution. The results show that polishing induces significant compressive stresses in the first few micrometers of the surface. The effect of different polishing parameters is shown through a design of experiments.

Paper 1292 1 **Advanced multifunctional biomaterials supporting bone tissue regeneration and healing**

Prof. Elżbieta Pamuła, Poland

Keynote (Oral Presentation 40')

Abstract

Although bone has considerable ability to regenerate, infected or critical size bone defects do not heal spontaneously and need special therapies and/or tissue engineering approach. Biomaterials that support bone tissue regeneration and healing should be designed to eradicate pathogenic bacteria, followed by facilitating osteogenic cell signalling and bone tissue expression processes. In our research, we design multifunctional biomaterials that provide mechanical support and are integrated with bone tissues (titania and zirconia ceramics) [1,2] or are made of biodegradable polymers, so their disappearance from the treated lesion is correlated with the ingrowth of native tissue [3,4]. Both types of biomaterial can be modified to deliver drugs or biologically active substances to support bone tissue regeneration. We found that the deposition of calcium phosphate, collagen, or sulphated hyaluronan on polymer scaffolds promotes cell osteogenic differentiation and the healing of osteochondral defects [3,4]. We also develop biomaterials dedicated to infected bone in the form of antibiotic-loaded polymeric micro- / nanoparticles [1,2,5,6]. They can be used as a component of injectable matrices [5,6] or be immobilised on the pore walls of scaffolds, to obtain implantable medical devices, when mechanical support is particularly essential [1,2]. The developed biomaterials release the drugs in a controlled manner to be adapted to the clinical needs. Thus, they are promising for bone tissue regeneration and healing.

Paper 1382 2 **Bridging In Vitro and In Vivo Degradation of Biodegradable Implants: An ODE-Driven DoE and Uncertainty Quantification Approach**

Dr. Tamadur Albaraghteh, Germany

Highlight (Oral Presentation 20')

Abstract

Developing biodegradable implants requires extensive in vitro and in vivo experimentation, yet a clear correlation between these degradation scenarios remains unresolved. The inability to establish a robust correlation hinders the prediction of in vivo degradation based on in vitro studies, making experimental validation highly restricted due to strict ethical and regulatory limitations on animal testing. The challenges arise from biological variability, anatomical constraints, and dynamic degradation mechanisms, making the selection of representative sampling points and optimal experimental time points particularly difficult.

To address these limitations, we introduce a hybrid computational-experimental framework that integrates ordinary differential equation (ODE) models with a Design of Experiments (DoE) approach under uncertainty. Our methodology not only predicts degradation kinetics of Mg-based implants but also provides a systematic strategy to optimize experimental design, ensuring that the most informative time points for data collection are selected. This is achieved by integrating uncertainty quantification (UQ) and scenario modeling, expanding the parametric space of key influential parameters using surrogate models to ease the limitations of scarce experimental data.

Previously, we derived a time-independent correlation ratio for Mg-xGd implants using a multi-fidelity model and data-driven surrogate modeling, demonstrating its potential in bridging in vitro–in vivo gaps. However, the computational cost and complexity of multi-fidelity models restrict their applicability. Here, we propose an efficient and interpretable ODE-based framework that leverages data-driven optimization, accounting for both experimental noise and inherent model uncertainty while refining parameter selection and improving predictive robustness.

A key innovation of this approach is its ability to guide experimental planning by identifying the most informative sampling points, reducing experimental redundancy, and minimizing the number of required animal studies. By establishing a quantitative correlation between in vitro and in vivo degradation, this framework enhances the predictive capability of digital twins in biomaterials research, accelerates the clinical translation of biodegradable implants, and improves the efficiency of preclinical evaluation.

Biomechanical and Microstructural Characterization of Biocompatible Metamaterials for Surgical Applications

Prof. Lukasz Major, Poland

Oral Presentation (20')

Abstract

Advancements in medical technologies require innovative materials that enhance surgical precision, improve patient safety, and support sustainable practices. This study presents the biomechanical and microstructural characterization of biocompatible metamaterials for next-generation surgical instruments, particularly for CardioVascular and Thoracic Surgeries (CVTS). These materials ensure controlled force application, real-time stress sensing, and extended durability under clinical conditions. The developed tools incorporate 3D-printed titanium (Ti6Al4V) metamaterials with reversible deformation properties, preventing excessive clamping forces. Integrated piezoelectric sensor arrays (PyzoFlex technology) enable real-time force monitoring, while soft biocompatible coatings minimize tissue trauma. Fluorinated wear-resistant coatings enhance sustainability, allowing over 100 sterilization cycles without degradation. Biomechanical performance was evaluated using an MTS universal testing machine to simulate vessel compression. A prepared vessel model replicated in vivo conditions by applying an external load while maintaining internal pressure. The metamaterial inserts deformed upon exceeding a force threshold, ensuring controlled occlusion and preventing excessive closure. Post-experimental samples were analyzed using scanning electron microscopy (SEM) to assess deformation mechanisms and surface integrity. Imaging was performed using in-lens detectors (Trinity) on a DualBeam SCIOS II microscope (ThermoFisher), with thin foil preparation via AutoTEM 4 software. Transmission electron microscopy (TEM) using a THEMIS (200 kV) FEG microscope enabled high-resolution imaging, selected area electron diffraction (SAED), and energy-dispersive X-ray spectroscopy (EDS) for phase and composition analysis. Integrating biomechanical validation with microstructural analysis highlights the potential of these metamaterials in addressing key CVTS challenges, such as uneven pressure distribution and excessive clamping forces leading to arterial stenosis and tissue damage. The study demonstrates overload protection accuracy exceeding 90% for clamping forces of 2.2–2.7 N, a pressure sensor resolution below 3 mm per unit with over 98% signal accuracy, and reduced tissue trauma validated histologically. The materials comply with ISO standards (10993, 13485) for biocompatibility and safety. This work advances surgical instrument development by combining biomechanical performance with microstructural engineering, improving surgical outcomes while promoting sustainable medical device design.

Paper 1067 4 Microbiological techniques assessing the infection risk associated with materials designed for laparoscopic instruments
Prof. Roman Major, Poland
Oral Presentation (20')

Abstract

Introduction

Laparoscopic surgery provided a giant leap in safety and recovery for patients over open surgery methods, robotic-assisted surgery (RAS) is doing the same to laparoscopic surgery. Laparoscopy is an essential diagnostic and therapeutic tool in modern medicine. It has become the primary method of diagnosing pathologies of internal organs. It is a minimally invasive method, allowing patients to recover quickly and leaving a good cosmetic result. The most common complications of the laparoscopic technique are associated with the insertion of Veress needles and trocars [1]. One of the resulting and possible risks is the development of a bacterial biofilm on the surface. Of course, nowadays this risk is of low severity, but it is still necessary to develop tools towards the detection of bacterial biofilm. Another factor indicating the need to develop microbiological techniques in this direction is the increasing complexity and sophistication of instrument arms, which can also promote microbial growth. Hospital-acquired infections and the increasing resistance of bacteria to antibiotics represent a critical challenge in contemporary medical practice. One strategy to reduce the likelihood of severe infections is the application of antimicrobial coatings on surgical instruments. This study focuses on the microbiological evaluation of the potential for bacterial infection development on the surface of materials designed for tools used in vascular surgery, specifically the flow closure clamp. This paper offers a correlative analysis of the interactions between bacteria and the surfaces of materials intended for surgical instruments. In order to achieve this goal, contact tests in accordance with ISO 22916 and bacterial biofilm formation analyses were carried out. That included Fluorescence In Situ Hybridization (FISH) staining that was analysed using Confocal Laser Scanning Microscopy (CLSM) and furthermore the surfaces were evaluated by Scanning Electron Microscopy (SEM).

It can be noted that the application of various techniques may yield distinct outcomes. Integrating conventional microbiological methods, such as dilution spotting, with contemporary diagnostic technologies proves to be advantageous for evaluating the antibacterial properties of intricate material surfaces.

Artificial staining of 3D X-ray virtual histology of bone implants through deep learning

Dr. Sarah Irvine, Germany

Oral Presentation (20')

Abstract

3D X-ray virtual histology (XVH) techniques leverage the benefits of X-ray tomography (non-invasive, 3D volume-based measurements) for the correlative imaging of biological samples traditionally visualised through conventional 2D histology, thereby removing the need for labour-intensive sample preparation steps including sectioning and chemical staining. However, such XVH approaches yield greyscale 3D data sets characteristic of X-ray imaging, and cannot replicate the same biological specificity provided by different histological stains directly visualised through the selective colouring of biological tissue components. Concurrently, within the separate field of digital pathology, advances in machine learning have led to the emergence of 'virtual staining' whereby histological stains may be virtually transferred onto non-stained (visible light-based) images through the training of neural networks.) In this work we bridge the two concepts of X-ray virtual histology and virtual staining (previously used for visible light-based histology), by applying image-to-image style-transfer models to generate artificially stained X-ray 3D virtual histology data. As part of our multimodal correlative characterisation studies of biodegradable metal implants in bone, we have performed multiple synchrotron-based x-ray micro-CT and toluidine blue histological measurements sequentially on the same samples. We co-registered more than 50 sets of micro-CT and histology image pairs, which were then used for training on a patch-based modified cycleGAN model network suited for limited pair data. Training results were optimised with the goal to replicate the colours present in the histology images whilst retaining most of the high contrast and resolution features.

Paper 1788 3 Laser surface alloying of 316L stainless steel with 316L+20wt% Cu alloy

Dr. Sokkalingam Rathinavelu, Sweden

Oral Presentation (20')

Abstract

In the present study, 316L stainless steel was surface alloyed with 316L+20wt% Cu using laser-based powder bed fusion (PBF-LB) additive manufacturing technique. Alloying of Cu in 316L can enhance the antibacterial activity. The influence of the process parameters, such as laser power and rescanning strategy, on the microstructure, chemical gradient, and homogeneity was investigated. 316L + 20 wt% Cu powder-mix was used as feedstock. The size and morphology of the feedstock powders were characterized with a scanning electron microscope (SEM). Surface alloying of 316L + 20wt% Cu powders was carried out at a range of process parameters: laser power: 175 W to 235 W, and number of laser scans: single scan, double scan, and triple scan, respectively. The layer thickness of the powder and hatch spacing were kept constant at 50 µm and 90 µm, respectively. The surface roughness of the samples was analysed under optical profilometry. Defects like porosity, cracks, and segregation were characterized by using optical microscopy, scanning electron microscopy, and Energy-dispersive X-ray spectroscopy. Chemical homogeneity in the bulk sample improves with higher laser power and remelting. Cu was found to segregate at grain boundaries, which increases the solidification cracking susceptibility. Adopting a triple laser scanning strategy has resulted in a dense and defect-free surface. Hardness distribution was measured and correlated with the homogeneity in the chemistry and the resultant microstructure of the modified surface.

Paper 1858 4 **The influence of laser surface treatment on the microstructure and friction-wear properties of Ti**
Dr. Agnieszka Twardowska, Poland
Oral Presentation (20')

Abstract

The work concerns changes in the microstructure and tribological and wear properties of Ti grade 1 as a result of laser surface treatment. To shape the microstructure of the Ti grade 1 surface layer, a pulsed ytterbium fiber laser operating with a power of 6-60W, pulse length of 100 and 200 ns and frequencies of 10, 20 and 48 kHz was used. The analysis of the microstructure changes included examination of the chemical composition (EDS) and phase composition (XRD) as well as the microstructure of the surface layers using a confocal microscope and scanning electron microscope. It was shown that, depending on the laser surface treatment parameters used, the surface layers clearly differ in their chemical and phase composition and surface roughness. Laser surface treatment allowed for an increase in the friction -wear properties of Ti grade 1, which was tested in the ball-on-disc test in dry contact with a corundum ball as a counter-part material (3.2 mm in diameter, load 1 N). The value of the wear index Wv for laser-processed samples was 10 times lower than for unprocessed samples. The increased wear resistance of laser-processed Ti grade 1 was caused by the partial phase transformation of alpha-Ti into beta-Ti and the grain refinement that occurred as a result of the rapid heating and cooling induced by laser processing in the area of the near-surface layer. As heating and cooling conditions significantly affect the oxidation reactions of the titanium and resulting type of titanium oxide, they presence and amount also influenced on resistance to wear and CoF. Overall, compared to untreated Ti grade 1, the friction coefficient values for the laser-processed samples were two times lower.

Porous ceramics from laser surface melting of eutectic mixtures: Mg-stabilized zirconia

Dr. Rosa I Merino, Spain

Oral Presentation (20')

Abstract

Porous ceramics with connected porosity are relevant in many applications including porous supporting electrodes in high-temperature electrochemical devices, filters, or membrane supports. To tune the pore size, its connectivity and tortuosity different technologies have been developed [1]. By etching a sacrificial phase, the final porosity structure is determined by control of the microstructure of the ceramic composite before etching. Eutectic materials solidified from a melt can give rise to especially homogeneous microstructures of micrometric and submicron size. In this communication we will present results on the porous ceramic resulting from laser surface melting of MgO-ZrO₂ mixtures. The as-solidified composite consists of Mg stabilized zirconia majority phase with around mainly fibrous 30 vol % MgO. The overall alignment of the phases is determined by the melt-pool shape, while the microstructural size and distribution depend also on the solidification rate and dominant cooling mechanisms, either in flat or cylindrical surfaces. Plates and cylinders of the composite with different microstructures have been surface laser melted. Appropriate homogeneous microstructures have been achieved on preheated plates. The achievement of a homogenous solidified layer with appropriate microstructure on the cylinder samples has proven more difficult. Next, the MgO has been etched out in selected ground plate samples. The gas permeability through the porous plates measured using N₂ or a CO₂-N₂ mixtures is in the range from 10⁻⁶ to 3x10⁻⁶ barrer (or 3·10⁻¹⁰ to 10⁻⁹ mol m⁻¹ s⁻¹ Pa⁻¹) with average pore diameters below 1 micron. These are moderate values as correspond to ceramics with 30 vol% porosity. They will be analyzed to the light of the detailed sample microstructure and solidification conditions.

Laser-Based Directed Energy Deposition with Mullite: A Step Forward for Lunar Regolith Printing

Mrs. Ana De Lucena, Denmark

Oral Presentation (20')

Abstract

In-situ resource utilization (ISRU) is pivotal for sustainable space exploration, enabling the use of local materials to construct infrastructure on extraterrestrial bodies. Additive Manufacturing (AM) techniques, particularly Directed Energy Deposition (DED), hold immense promise for fabricating lunar structures using regolith. However, the scarcity of actual lunar regolith necessitates the use of simulants. Mullite, an aluminosilicate ceramic with thermal and chemical similarities to highland lunar regolith, was investigated in this study for its suitability in DED-based applications.

This research explored the high-temperature behavior of mullite within a laser-based DED process. Experiments included optimizing process parameters such as laser power, scanning speed, and substrate material while leveraging in-situ monitoring via short-wave infrared (SWIR) imaging and microstructural analysis. Deposition trials were performed on mullite-based and stainless steel substrates, focusing on single and multilayer tracks.

The study defined a feasible process window for mullite, identified challenges like porosity and thermal stresses, and evaluated the microstructural integrity of printed parts. Results demonstrated mullite's potential as a regolith simulant, providing critical insights into achieving defect-free fabrication and scalable ISRU solutions. These findings advance the application of AM technologies in extraterrestrial environments, contributing to the goal of establishing permanent lunar settlements.

Paper 1627 1 Ultrafast structural transformations of Fe under sub-ps pulsed laser annealing

Prof. Ryszard Sobierajski, Poland

Keynote (Oral Presentation 40')

Abstract

The phase transitions in iron, encompassing their nature, pathways, and driving forces, have long been a topic of debate. Gaining a deeper understanding of this process is crucial to addressing fundamental questions in condensed matter physics and potentially enhancing technological applications. To this end, we investigated the atomic structure of a thin Fe layer following sub-picosecond pulsed laser annealing using ultrafast time-resolved X-ray diffraction (see [1] for method). Due to the strong electron-phonon coupling in iron, the laser pulse energy was transferred to the lattice on a time scale of 1 ps. This rapid heating led to ultrafast melting. Under conditions below complete melting, this was followed by a solid-solid transition in the remaining crystalline phase. Given the extremely high rate of heating (on the order of 10^{15} K/s), the observed transformations do not align with the phase diagram known for slow (equilibrium) heating. The formation of the fcc-Fe phase is kinetically hindered, and the bct-Fe phase appears at the melting temperature. This behavior aligns with static ab initio theoretical simulations, which predict phonon softening at high temperatures and consequent tetragonal lattice distortion. The experimental results presented here provide new insights into the dynamics of martensitic phase transitions.

Paper 1846 2 Femtosecond Laser 3D Printing of Nanocrystals via Two-Photon Absorption for Enhanced Biomedical Chiral Sensing

Dr. Fu Li, China

Highlight (Oral Presentation 20')

Abstract

Chiral-molecule detection and sensing are critical in various fields such as life sciences, chiral drug development and micro-nano optical devices. The ability to detect and differentiate chiral enantiomers is essential for a range of applications, yet current technologies for chiral detection, particularly for trace-level signals, still face significant limitations. In this context, the chiral construction and optical properties of inorganic nanocrystals have emerged as a key research focus for the development of advanced chiral-enhanced sensing platforms.

In this abstract, we propose a novel approach that leverages nanocrystals as chiral building blocks, integrating them through 3D laser printing technology based on two-photon absorption. We employ photosensitive small molecules as molecular "glue" in the printing process to enable the formation of highly ordered 3D chiral structures composed of functional nanocrystals with high purity. These structures aim to exploit the unique chiral optical properties of the nanocrystals to amplify the sensitivity and selectivity of biomedical chiral sensing.

Our research investigates the formation mechanisms of the printed chiral nanostructures, focusing on the molecular-level interactions between lasers and nanocrystals. We optimize key printing parameters such as light intensity, exposure time, and molecular composition to enhance the resolution and homogeneity of the printed structures. Additionally, we explore the relationship between the intrinsic optical properties of the nanomaterials and the optical chirality of the printed 3D structures, aiming to clarify the mechanisms that lead to enhanced chiral signal detection.

To demonstrate the potential of our approach, we conduct in-situ laser processing of various nanocrystal types, achieving regional selectivity and interference-free integration. This will enable the construction of chiral nanophotonic platforms that offer enhanced chiral sensing capabilities, as well as new possibilities for polarization-based sensing and biomedical imaging applications.

Our findings will not only provide valuable scientific insights into the relationship between laser processing and nanomaterials, but also offer a theoretical framework for the future development of biomedical detection technologies. This research has the potential to revolutionize biomedical chiral sensing applications in a wide array of fields, including pharmaceuticals, diagnostics, and environmental monitoring.

Paper 1183 3 On synergy of theory and experiment in ultrashort laser irradiation of bandgap materials

Prof. Nadezhda Bulgakova, Czech Republic

Highlight (Oral Presentation 20')

Abstract

When powerful ultrashort laser pulses couple with the surface or bulk of a bandgap solid, they create a dense, relatively cold free-electron plasma, a forerunner of laser-induced structural modification of materials. Nowadays the techniques employing laser-induced structural modification of materials experience tremendous development with applications in various fields ranging from electronics, photonics, and information storage to microfluidics and biomedicine. Additionally, new types of lasers are under development with higher average power, higher repetition rate, higher energy in the pulse, with shorter pulse duration, in burst mode regimes, covering missing ranges of laser wavelengths. Experimental diagnostics for monitoring laser-induced phenomena with femtosecond temporal resolution and sub-micrometer spatial resolution are still under development and numerical modeling plays an important role in understanding the fundamental mechanisms in ultrafast processes.

This work has been focused on the synergy of theory and experiment in laser irradiation of bandgap materials using spatiotemporal shaping of laser beams and dual-wavelength excitation. Several theoretical predictions based on simulations with state-of-the-art models will be discussed and their experimental verifications will be presented. In particular, a strong enhancement of localized absorption of laser energy inside fused silica glass using a sequence of two laser pulses at different wavelengths will be considered with the analysis of the whole chain of the processes triggered by the laser pulse and continuing until the final imprinting of a modified structure into the material matrix. For multi-shot irradiation regimes, the simulations have revealed the paramount importance of the defect accumulation not only because of easier ionization of material by successive laser pulses but also due to the associated positive change of material refractive index. This enabled to uncover physical mechanisms behind the non-reciprocal writing of waveguide structures inside glasses. For the case of silicon ablation with dual-wavelength irradiation, sophisticated modeling has been shown to describe quantitatively the experimental data on material excitation depending on the sequence of IR and visible laser pulses. This study demonstrates the importance of adequate theoretical models, which enable understanding the processes in condensed matter at an ultrafast time scale.

Paper 1394 **5** **Effect of doping on the formation and coherent propagation of LIPSS in zinc oxide films induced by fs-laser irradiation**
Prof. Javier Solis, Spain
Oral Presentation (20')

Abstract

Transparent Conductive Oxides (TCOs) are materials with low resistivity and optical absorption in the visible spectrum, which makes them of vital importance for numerous applications (displays, photovoltaics, transparent heaters...) [1]. In spite of its large-bandgap, un-doped ZnO shows a relatively large n-type conductivity at room temperature due to the donor character of oxygen vacancies. In addition, it can be easily doped with different elements to improve its conductivity and turn it into a proper TCO [2] while preserving most of its interesting properties, such as biocompatibility, piezoelectric response or antibacterial activity [3].

The presence of dopants can also be used to facilitate its modification via processing with ultrafast lasers. As in the case of other TCOs [4,5], LIPSS formation [6] upon fs-laser irradiation could potentially be used for generating topographic, optical and electrical anisotropies. However, inducing large scale, homogeneous and controllable anisotropies based on LIPSS requires their formation and coherent propagation over macroscopic regions.

In this work, we have analysed the formation and coherent propagation of LIPSS by fs-laser processing ($\lambda = 1030$ nm, $\tau = 350$ fs) in ZnO films doped with different trivalent oxides (X_2O_3 , X being Al, Ga, In, Yb...). Depending on the dopant and doping level both the formation of LIPSS and their coherent propagation can be successfully triggered, evidencing the importance of generating a small amount of linear absorption at the laser wavelength (1030 nm) upon doping. We will analyse the role of the film composition and its evolution upon laser processing in the resulting structures in order to maximize the induced anisotropies while preserving good electrical and optical behaviour.

Multi-Scale Hierarchical Patterns: A New Frontier in Surface Blackening

Dr. Bogdan Voisiat, Germany

Keynote (Oral Presentation 40')

Abstract

The fabrication of durable and multifunctional blackened surfaces on engineering steel is critical for advancing optoelectronic applications, such as infrared sensing and solar absorbers. This study investigates the use of direct laser writing (DLW) and direct laser interference patterning (DLIP) to create hierarchical textures on AISI 304 stainless steel. The process combines DLW-generated honeycomb macrostructures with DLIP-fabricated microgrooves to produce single- and multi-scale patterns. The resulting textures were characterized in terms of topography, optical reflectance, wettability, and mechanical durability.

The hierarchical textures demonstrated significant improvements in optical performance, with enhanced light absorption due to the synergistic effects between macro- and microstructures. Spectral reflectance measurements confirmed a reduction in reflectance across the visible and infrared spectrum, showcasing the effectiveness of the multi-scale designs in creating highly absorptive surfaces. Furthermore, wettability tests revealed that these textures provide multifunctional properties, such as improved hydrophobicity, making them suitable for use in extreme environmental conditions.

Mechanical durability was evaluated through an abrasive wear test, which showed that the DLW-generated honeycomb structures provide critical protection to the finer DLIP patterns. This protective effect enhances the resistance of the textured surfaces to wear, ensuring the retention of their optical and functional properties under abrasive conditions. The surfaces were also subjected to acid etching in citric acid solutions, revealing that multi-scale structures exhibit superior resistance to acid-induced degradation compared to single-scale patterns. The hierarchical textures effectively slowed the penetration of acid into the oxide layer, preserving the surface functionality. The demonstrated scalability, flexibility, and robustness of these laser-based processes make them promising candidates for industrial applications requiring high-contrast, antireflective, and wear-resistant surfaces. These findings pave the way for the broader adoption of laser-textured blackened surfaces in demanding optoelectronic and environmental applications.

Advancing Robot-Based Direct Laser Interference Patterning Through IR Process Monitoring and Neural Networks Evaluation

Mr. Lukas Olawsky, Deutschland

Highlight (Oral Presentation 20')

Abstract

Direct Laser Interference Patterning (DLIP) is a well-established technique for fabricating micro- and nano-scaled structures, enabling surfaces with advanced properties such as reduced wear and friction. This single-step process offers high throughput and significant potential for automation. However, achieving full automation necessitates the integration of robust online process monitoring to ensure consistent quality of the produced structures.

In this study, we demonstrate an innovative approach combining in-line process monitoring with advanced machine learning methods for evaluating and predicting product quality. Specifically, the emission of radiation due to localized heating during DLIP was monitored using an infrared (IR) imaging system, while the captured signals were analyzed using a Convolutional Neural Network (CNN).

To validate this method, stainless steel substrates were patterned by modifying various laser parameters, including fluence, repetition rate, and process velocity. The IR monitoring system measured important thermal effects during the structuring process, including the average temperature and the size of the temperature field. The surface structures created were then examined using confocal microscopy. Relationships between the process settings, the IR data, and the surface structures were identified. This information was used to train the CNN to predict the quality of the surfaces. The integration of IR monitoring within the DLIP process ensures real-time quality assurance by providing immediate feedback on the manufacturing parameters. Furthermore, the trained CNN demonstrated reliable predictions of the resulting surface topography, optimizing evaluation processes and eliminating the need for post-production analysis.

This approach represents a significant step toward fully automated and intelligent DLIP processes, combining precision monitoring with advanced predictive analytics to enhance manufacturing efficiency and product quality.

- Paper 1387 5 Ultrashort pulsed laser-assisted biomineral coating on an additive manufactured Ti64 implant for enhancing osseointegration**
Dr. Sarathkumar Loganathan, United Kingdom
Oral Presentation (20')

Abstract

Surface treatment of bioimplants is essential to control the interaction between implant surface and host environment for successful acceptance of bioimplant by the patient's body. The present study deals with ultrashort pulsed laser-assisted cerium co-doped hydroxyapatite (Ce:HAP) coating onto 3D-printed Ti6Al4V titanium alloy. The flat titanium discs of 15 mm diameter and 1 mm thickness were designed in CAD software and fabricated using selective laser melting (SLM) technique. The fabricated Ti6Al4V discs were spin-coated (5500 rpm, 60 s) with a slurry containing 5 ml of chitosan and 2 mg of Ce:HAP. Further, the coated surface was irradiated using Chromacity Laser (1040 nm, 200 fs, 200 MHz) at the optimized laser processing condition using a CNC-controlled XYZ-table (100 nm resolution). Surface morphology, microstructural properties, chemical composition and interfacial properties of the irradiated biomineral layer were analysed using SEM, XRD and EDX. The results indicate that ultrashort pulsed laser-assisted biomineral coating is a promising method for the production of ceramic coating on 3D-printed titanium which can be aligned with the implant manufacturing process.

Controlling release kinetics from nanotube drug containers - modulated diameters, capped and multi-molecule filled nanotubes

Prof. Manuela Killian, Germany

Highlight (Oral Presentation 20')

Abstract

The integration of drug delivery coatings in orthopaedic applications is attracting interest due to its potential to improve the success rate of implant systems. Several published reports have focused on the aspect of controlled drug release to aid in the optimization of drug delivery. Herein, we report on a novel and simple approach to extending drug release time and limiting the undesirable burst release from zirconia nanotubes (ZrNT) via structural modification.[1] The latter involves fabricating a double-layered structure with a modulated diameter and is achieved via voltage adjustment during electrochemical anodization. The drug loading and release studies from the structurally modified ZrNTs, characterized via SEM and ToF-SIMS were monitored using UV-Visible spectroscopy and compared with their homogenously thick equivalents. We report a significant reduction in the initial burst release phenomenon using this modification and other complementary strategies investigating release inhibition systems,[2] resulting in an overall improvement in release performance. Capping and/or multi-molecule modification of the nanocontainers allows to render the drug release smart and responsive to external triggers. These simple modifications of ZrNT successfully enhance drug release performance, allow for flexibility in designing drug delivery coatings for specific implant challenges,[3] and offer new insights into alternate biomaterials based on metal-oxide nanostructures.

Functional Coatings with Macroscale Nanocontainers: Innovation or Redundant Complexity

Ph.D. Swathi Naidu Vakamulla Raghu, Germany

Oral Presentation (20')

Abstract

ABSTRACT: Metal-oxide (MO) surfaces have successfully been modified to elicit specific responses attributed to either structural variations and/or chemical functionality. Structural modification of a bulk surface is achieved by exploiting the combined effects of top-down and bottom approaches during electrochemical anodization (EA). Imparting nanoscale geometries has reportedly improved biointegration as a result of structural similarities to corresponding biological environments namely, the extracellular matrix.[1] Additionally, an influence on surface reactivity due to chemical variations has also been observed.[2] In this context, nanostructured bulk surfaces are highly relevant as hybrid materials. This work investigates their ability to elicit multi-functional responses. Herein, nanocontainers are fabricated via EA and deposited onto ceramic implant discs.[3] These nanostructures can further be modified via facile application of self-assembled monolayers (SAM) to subsequently seal or 'cap' the nanotube mouths[4] making them ideal for triggered release applications in the biomedical field. Such bulk surfaces modified with nanotubes may be used to store drugs or therapeutics that can selectively release under appropriate conditions as this hybrid assembly can readily transform static bulk surfaces to those capable of dynamic elution from the overlying nanotubular reservoirs. The hybrid material was thoroughly characterized using scanning electron microscopy (SEM), ToF-SIMS, water contact angle measurements (WCA) etc. These nanocontainers would be capable of facilitating 'smart' developmental strategies towards controlled multi-drug release models that can even elicit sequential release of drugs to limit clotting, inhibit infection and ultimately promote healing.

Magnetic Nanostructured Complex with DFO for Dual Imaging Applications

Mrs. Sunčica Sukur, Czech Republic

Oral Presentation (20')

Abstract

The development of a smart system for theranostics represents a promising approach to personalised cancer treatment. The research presented here focuses on the design of a material for diagnostics, integrating magnetic resonance imaging (MRI) and positron emission tomography (PET), with the potential for future functionalisation toward therapeutic applications.

In particular, the successful synthesis and functionalisation of Fe_3O_4 nanoparticles with polyacrylic acid (PAA) via an optimised co-precipitation method was achieved, followed by the conjugation of deferoxamine (DFO) through coupling chemistry. FTIR analysis confirmed successful synthesis and modification by covalent linkage, while SEM revealed spherical Fe_3O_4 /PAA/DFO nanoparticles with a size of 28 ± 8 nm. DLS and ζ -potential measurements confirmed the material's stability over 30 days at pH 7.4.

The potential of the Fe_3O_4 /PAA/DFO complex as an MRI contrast agent was demonstrated through a linear correlation between T1, T2, and T2* relaxation times and magnetic DFO complex concentrations ranging from 1-50 $\mu\text{g/mL}$, with relaxation times of 5.0 ± 0.4 , 444 ± 60 , and 4233 ± 646 mg/mL-s, respectively, confirming the potential for diagnostics. Furthermore, preliminary ^{68}Ga labelling demonstrated successful incorporation, as confirmed by instant thin-layer chromatography, indicating efficient radiolabelling for PET imaging.

To further evaluate the potential of Fe_3O_4 /PAA/DFO magnetic nanostructure as a dual imaging agent, biological evaluation on BM-MSCs, U2OS, and 143B cell lines will be performed. Further modifications, such as functionalisation with Pt-based anticancer drugs, could enhance its theranostic potential, enabling both diagnosis and targeted therapy within a single system.

Tailored-magnetic nanoparticles for theranostics in osteosarcoma

Mrs. Ana Laura Coria Gutiérrez, Italy

Oral Presentation (20')

Abstract

Superparamagnetic iron oxide nanoparticles (SPIONs) have gained significant attention in cancer diagnosis and therapy due to their nanoscale dimensions, surface functionalization capabilities, and responsiveness to external magnetic fields. These properties make SPIONs ideal candidates for theranostic applications (1). While some SPIONs are commercially available as imaging contrast agents, only two have been approved for cancer treatment, and none have been specifically investigated for osteosarcoma therapy. In this study, we explored suitable functionalization strategies of SPIONs using different ligands and coatings, including cyclodextrins (CDs), amino acids, silica, and polyacrylic acid (PAA). A comprehensive physicochemical and magnetic characterization was conducted to assess and compare their properties. Our studies pointed out that water-soluble MagnetoCyclodextrins (SPIONs-CD) exhibited excellent reproducibility, monodispersity, biocompatibility, and stability in water, PBS, cell culture media, and blood plasma for at least 24 hours and they were exploited as multifunctional drug delivery systems for osteosarcoma. Different drugs were included in SPIONs-CD (i.e., Salinomycin, Doxorubicin). Cellular behavior and cell/material interactions were assessed in vitro using various cellular models, including U2-OS osteosarcoma cell line, hFOB cells, bone marrow-derived mesenchymal stem cells (BM-MSCs), MDA-MB-231 human breast cancer cells. Moreover, functionalization of SPIONs with 3-aminopropyltriethoxysilane (APTES) or PAA produced uniform, spherical nanosized particles armed with amine or carboxylic groups suitable for further decoration with ligands for radiolabeling (i.e., DOTA, DFO).

Paper 1810 6 **Neuroprotective profile of carbosilane dendrimers as nanocarriers of Memantine against Alzheimer's disease**
Mrs. Clara Gómez Serrano, Spain
Oral Presentation (20')

Abstract

Nowadays, the prevalence of neurodegenerative diseases (ND) has increased, yet the etiology of these pathologies remains unknown. ¹ Moreover, the harm done of these neurological disorders could be associated to multiple factors occurring simultaneously (i.e., excitotoxicity, misfolded proteins that forms toxic aggregates, oxidative stress, neuroinflammation...). In the field of nanotechnology, dendrimers have been widely explored for disease-modifying treatments, including Alzheimer's disease (AD). These nanoplatforms are well-defined and ramified structures of polymeric nature that provide multivalency and, furthermore, their intrinsic properties could lead them as perfect candidates for drug delivery systems. ²

In this sense, we have demonstrated in previous studies that carbosilane-based dendrimers with ammonium-peripheric groups have the ability to cross the blood-brain barrier and prevent amyloid fibrils from misfolding in diabetes II and Alzheimer's mice model, one of the main toxic effect that leads the neurodegeneration process. ^{3, 4} Based on these results, our research focused on

functionalizing these systems with Memantine, an uncompetitive glutamatergic N-methyl-D-aspartate (NMDA) receptor antagonist. Our interest in this molecule relies on its capacity to reduce excitotoxicity without inferring with other factors implicated in NMDA activation. ⁵ Thus, combining the inherent capacities of dendrimers with Memantine properties, we could achieve structures with an anti-amyloidogenic profile. ⁶

Magnetoelectric, bio-hybrid nanointerfaces as enablers of wireless tissue stimulation and drug management

Ph.D. Giulia Suarato, Italy

Oral Presentation (20')

Abstract

Magnetoelectric nanoparticles (MENPs) are capable of generating highly localized electricity if stimulated with a relatively low-intensity magnetic fields (H). MENPs are core-shell structures with an inner magnetostrictive phase and an outer piezoelectric shell, whose electrical output can be efficiently modulated via their composition, geometrical features, and interface area. Such multi-functional nanostructures have recently attracted a great interest in biomedicine, exhibiting at room temperature the so-called "magnetoelectric" (ME) effect, which is a linear coupling between an external H (in the mT range, human safe) and a generated, highly localized electric field (E, in the order of 105 V/m). Moreover, thanks to the possibility of either functionalizing their surface with bioactive molecules or encapsulating them in soft matrices, these unique nanostructures can be exploited for the fabrication of a plethora of biomedical devices for wireless, spatially-selective tissue stimulation and controlled drug delivery. In the study herein presented, CoFe₂O₄–BaTiO₃ spherical MENPs were embedded within soft, biocompatible polymeric matrices, to develop flexible and functional biointerfaces. By adopting a holistic computational framework, a multi-physics, finite-elements model was established to (i) assess the effects of different materials-related parameters (i.e., MENPs volume fraction, polymeric matrix electrical properties) onto the electrical output of the bio-hybrid nanointerface, and to (ii) predict the optimal device configuration that could potentially interact with a biological surrounding. MENPs' ability to release active drugs upon proper stimulation with external H has been recently experimentally demonstrated. By acting as nano-sources of E, MENPs can actively regulate their molecular interactions with loaded cargos and cells nearby. One of the hypotheses at the basis of this phenomenon lies on two subsequent steps: (1) the local E generated under a static H leads to a temporary dielectric breakdown of the cell membrane and particle penetration (nanoelectroporation); (2) under alternating H, a modulated dipole moment at the MENP outer shell is considered responsible for weakening the electrostatics bonds between particles and drugs. Based on these premises, we used our computational model to define the operational ranges, in terms of static and alternating magnetic fields, to maximize MENPs' nanoelectroporation and drug delivery performances. ME nanointerfaces surely represent powerful tools to develop alternative, cutting-edge therapeutic strategies. Within this framework, our studies not only are providing material-based recipes for an optimal MENPs-system fabrication, but are also contributing to gain thorough insights on the MENPs functioning at the interface with a biological surrounding, to effectively attain their bioresponsive capabilities.

Paper 1214 8 **New insights into the molecular organization of fluorescent nanovesicle-based bioimaging probes from Molecular Dynamics simulations**
Mrs. Núria Pujol-Solé, Spain
Oral Presentation (20')

Abstract

Fluorescent organic nanoparticles (FONs) are emerging as biocompatible nanostructured platforms for biomedical applications due to their high tunability in terms of functionality and optical properties [1]. Among different nanocarriers, quatsomes are unilamellar nanovesicles formed by the self-assembly of quaternary ammonium surfactants and cholesterol, which have been shown to be highly homogeneous in size and morphology over years [2,3].

Quatosome nanovesicles containing fluorescent molecules have shown outstanding photostability and high brightness due to the confinement of a large number of dye molecules in a small space [4]. In previous studies, the loading of a carbocyanine pair in the membrane gave rise to the FRET effect in a nanosized domain for the first time achieving high FRET efficiency (up to 85%) [5,6]. However, the development of ultrabright formulations often remains a challenge due to the presence of aggregation-induced quenching at high fluorophore loadings.

In this work, all-atomic molecular dynamic simulations have been carried out to simulate a quatosome bilayer patch in the presence of different dyes. The main goal is to perform an in-depth structural analysis of the molecular organization in the membrane bilayer and provide insight into the inter-molecular interactions and aggregation states of embedded fluorophores. The new insight gained will guide the design and optimization of new bioimaging probes.

Paper 1369 1 **Performance evaluation of new polymer additives for technical ceramic shaping processes**

Ph.D. Ismaïl M'barki, France

Highlight (Oral Presentation 20')

Abstract

The manufacturing of complex ceramic components faces persistent challenges in powder processing and shaping techniques. This study introduces an innovative approach combining freeze granulation and robocasting, addressing key challenges in colloidal processing and powder functionalization through novel polymer additives[1][2]. High-purity alumina powder (Al_2O_3 , $8.1 \text{ m}^2/\text{g}$) serves as a model material for developing this new processing methodology. The investigation focuses on nine distinct polymers. Aqueous ceramic suspensions (30-50 vol% solid loading) were formulated using these novel polymer additives, following an optimized dispersion protocol. The research evaluates powder characteristics and suspension behavior through comprehensive rheological analysis. Critical process parameters in freeze granulation, including suspension flow rate and air pressure, were optimized to control granule morphology and size distribution. The relationship between processing parameters and powder compact properties was investigated under varying pressing conditions (2-300 MPa), with particular attention to microstructural development. A key innovation of this work lies in the strategic integration of freeze granulation as a pre-processing step for robocasting feedstock preparation. This novel approach enables the creation of functionalized powder granules with pre-incorporated dispersants, binders, and plasticizers, significantly simplifying subsequent paste preparation for additive manufacturing. Results demonstrate the successful development of ceramic granules suitable for both granulation and robocasting processes. This processing route shows promising results in terms of powder flowability, and printability, offering new opportunities for manufacturing complex ceramic components.

On the pressureless sintering of B4C with Si aids at low temperature

Mr. Antonio Fernández Ortiz, Spain

Oral Presentation (20')

Abstract

The feasibility is investigated of fabricating boron carbide–SiC composites by low-temperature pressureless sintering of B4C with Si aids. Firstly, it is demonstrated on powder compacts with different Si aids (5–30 vol%) that low-temperature conventional pressureless sintering is not viable. Secondly, it is demonstrated on the same compacts that fast pressureless sintering is not viable either. And thirdly, it is demonstrated on powders of the model composition B4C with 20 vol% Si aids that fast pressure-assisted sintering is viable at low temperature if a threshold pressure is applied. All these findings are explained considering that molten Si is a short-lived transient phase that reacts rapidly with B4C to form SiC and a B-rich boron carbide, so external pressure is needed for it to be spread quickly and efficiently throughout the entire porous microstructure before being consumed.

3

Study of the Manufacturing Differences in Recycled Material Produced from Mixed Waste Using Different Methods.

Mr. Jose Carlos Rebollo-Alburquerque, Spain

Oral Presentation (20')

Abstract

Fabrication methods are one of the main factors influencing the properties of materials, as well as their potential industrial applications. The viability of different manufacturing methods for the same materials provides versatility for various uses and facilitates industrial adaptability, allowing a broader range of industrial installations to be adapted for the production of the new material. Therefore, comparing the properties of the same material manufactured using different methods is particularly important, as it highlights the advantages and limitations of each approach. In the present study, a comparison of the properties of Construction and Demolition Wastes (CDW) mixed with industrial wastes in different proportions has been conducted using two manufacturing methods. Physical and mechanical properties have been analyzed in materials produced by molding and uniaxial compaction, both of which were consolidated through sintering at the same temperature for each method. Density, porosity, contraction and tensile strength have been tested for the different series and manufacturing methods.

Paper 437 4 **A Colloidal Processing Approach to improve the Photocatalytic Performance of TiO₂-CuO Heterojunctions**
Ph.D. José Manuel Luque, Spain
Oral Presentation (20')

Abstract

This research proposes an innovative solution to overcome the existing agglomeration issues that usually take place during the blending of semiconductors constituting n-type/p-type heterojunctions with photocatalytic activity. As alternative to conventional synthesis methodologies (e.g., sol-gel, co-precipitation, impregnation) and/or the dry mixing procedures, a colloidal processing strategy was addressed to promote higher dispersion degree among the involved species. Colloidal chemistry provides a straightforward approach to achieving highly homogeneous composite materials in well-dispersed systems by controlling key parameters such as pH, ionic strength, and the addition of specific additives. To this end, a comprehensive study of the colloidal stability of commercial TiO₂ and CuO nanopowders was conducted using zeta potential measurements. Based on the surface charge characteristics of both starting materials, a stable charge balance was achieved in suspensions, where electrostatic interactions promoted intimate surface contact between the TiO₂ and CuO nanoparticles, facilitating the formation of the desired heterojunction. The resulting heterojunctions were optimized by preparing mixtures in different ratios of TiO₂:CuO (1:0.10, 1:0.25 and 1:1), and a comparative study of mixing methodologies, both wet and dry procedure, was performed. All composite materials were characterized in terms of their optical, physicochemical, and photocatalytic properties using UV-Vis absorption spectroscopy, XRD, SEM-EDS and De-Nox activity measurements.

Evaluating and optimizing the plastic additive pelleting process with a single-die press

Mrs. Prutha Nagaraja, Norway

Oral Presentation (20')

Abstract

Plastic additives are key components in plastic material. They are essential for protecting the polymers from thermo-oxidation during plastic manufacture and enhancing the properties of the final plastic product, i.e. color, durability, etc. Typically produced in powder or granule form, they are pelletized for efficient handling, transportation, and processing. Pelletization, i.e., the compression of powders into pellets, is an important process in several industries, including animal feed, pharmaceuticals, wood, and food production. Pellets are often produced in ring die pellet mills. Since pelletization in such mills is a large-scale continuous process, optimization of the process conditions with extensive trials is infeasible. Alternatively, a single-die pellet press can be used as a representative model to study the pelleting process offering a low-cost lab-scale testing. The single-die presses have been extensively used to optimize pelletization in feed and wood industries, offering insights into key parameters such as compaction pressure, energy consumption, and pellet properties.

Our study investigates whether single-die presses can similarly be applied to optimize the pelletization process of plastic additives. We observed that while compaction pressure plays an important role in forming the pellets, process temperature is a critical parameter for the pellet quality. If the temperature is too low, the material remains in its powder state; if it is too high, then the material turns into a paste. Hence, achieving and maintaining appropriate process temperatures is vital for ensuring pellet integrity. For some formulations, required hardness and durability could not be achieved even at relevant temperatures. This was due to the material sticking to the compression rod resulting in inconsistent pellet formation further complicating the process. Another challenge that arises in the plastic additive pelleting process is that one of the components in the additive blend acts as a binder, directly influencing the process temperature across all compositions. Therefore, this study showcases the importance of optimizing the process parameters and, binder properties, to achieve consistent pellet quality. Since further work is needed to adapt this methodology for a wider range of formulations, we incorporated simulations to complement our experiments. By validating our experimental findings through simulations, we were able to pave a path for optimizing the pelletization process across diverse formulations.

High-performance Powders via Powder2Powder Ultrasonic Atomization

Mr. Jakub Ciftci, Poland

Oral Presentation (20')

Abstract

Current methods for the production of spherical powders restrict the development of custom particles with tailored chemical compositions. This challenge is even greater when the input material is already a powder. The proposed Powder2Powder ultrasonic atomization process based on plasma melting allows to change the particle size, morphology and form an alloy in-situ.

During processing the liquid, in contact with a surface vibrating at ultrasonic frequencies, forms standing capillary waves that lead to the ejection of fine droplets. As the amplitude of these waves increases, the wave crests can reach a critical height where the cohesive forces of the liquid are overcome by the surface tension, leading to the ejection of droplets from the wave tips.

The material in the form of powder was used to prepare custom alloy from the powder blend which was melted in the plasma stream and atomized from the sonotrode. The obtained material was used in laser powder bed fusion to print high entropy alloy. Additional case studies will be presented using other out-of-spec additive manufacturing feedstocks.

Paper 1703 1 Opportunities of material extrusion 3D printing technology for producing advanced meso-structured steels with improved properties

Dr. Javier Hidalgo, Spain

Highlight (Oral Presentation 20')

Abstract

Mesostructured composite steels with hierarchical patterns offer a promising route to achieving unique combinations of mechanical properties in advanced engineering components. By modifying both the pattern and composition in these mesostructures, it is possible to fine-tune the structural behaviour of steels, enhancing the balance between strength and toughness while improving damage tolerance. Additive manufacturing, particularly material extrusion (MEX), presents a viable approach for fabricating these complex structures. However, due to processing constraints, multi-material printing of metallic alloys remains a significant challenge. Addressing these challenges requires a thorough investigation into key manufacturing factors, starting with developing and optimising feedstocks tailored for multi-material applications.

This study explores the use of MEX for fabricating multiphase steel composed of 316L and 17-4PH stainless steels. The effects of particle size distribution and solid loading on feedstock rheology and printability are examined, as these parameters are critical to ensuring process reliability. Additionally, the dimensional shrinkage of both materials is evaluated as a function of solid loading to achieve a similar contraction rate after sintering, which is essential for minimizing thermal stresses and preventing warping or structural defects in the final parts. Through the optimization of process parameters, defect-free components with consistent shape retention were successfully produced. Beyond processing considerations, microstructural and mechanical characterization revealed a synergistic deformation behaviour among phases, with a beneficial transition of properties at the interface due to compositional and microstructural gradients. Furthermore, the potential formation of a galvanic pair between the two stainless steels is investigated through corrosion resistance assessments, providing insights into the electrochemical compatibility of the material system.

Paper 676 **2** **Characterization of oxygen and nitrogen in SA508 steel powder in the vacuum induction melting gas atomization (VIGA) process**
Mr. Yao Su, South Korea
Oral Presentation (20')

Abstract

Metal powder, as a unique form of metallic feedstock, has been extensively used in structural applications through powder metallurgy (PM) and the emerging field of additive manufacturing (AM). Vacuum induction melting gas atomization (VIGA) is a widely applied method for producing metal powders due to the efficiency and recovery rate. However, the influence of the atomizing conditions not only on the oxygen and nitrogen content but also on the composition of surface and internal oxides remains unclear, especially of the different powder size.

The present study provides a comprehensive characterization of the oxygen and nitrogen content in SA508 powders of varying sizes, produced using Ar and N₂ gases during the atomization process. The relationship between powder size and impurity elements, such as oxygen and nitrogen, was systematically analyzed. Results indicate that the specific surface area and surface oxidation layer significantly influence the total oxygen content in the powder samples. Consequently, the composition and thickness of oxide layer on the powder surface were evaluated through XPS analysis, and the mechanism of the formation of surface oxide layer was investigated using thermodynamic calculations. The correlation between powder size and oxide layer thickness was also explored, as it is critical for understanding and optimizing the properties of metal powders.

Furthermore, non-metallic inclusions such as Al₂O₃, MnSiO₃, and MnS, were characterized in terms of their type and size using SEM. Thermodynamic software calculations elucidate the formation and evolution of the inclusions, offering critical insights for metal powders. These findings are essential for enhancing the production of high-performance powder metallurgy components through the Hot Isostatic Pressing (HIP) process.

Paper 1870 3 **Alternative processing method for fabrication of amorphous/nanocrystalline FINEMET alloy**
Mr. Petr Urban, Spain
Oral Presentation (20')

Abstract

FINEMET is a nanocrystalline soft magnetic alloy with high permeability, low core loss and good thermal stability making it ideal for high-frequency transformers, inductors for power electronics, EMI suppression components and magnetic sensors. The fabrication process of FINEMET involves rapid solidification followed by controlled heat treatment to form its nanocrystalline structure. However, rapid solidification requires an extremely high cooling rate ($\approx 10^6$ K/s) and any deviation can lead to devitrification and degrading the final properties. Moreover, the final product are very thin and mechanically fragile ribbons (20-30 μm), which makes manipulation and further processing difficult. In this paper, mechanical alloying, an alternative powder metallurgy manufacturing method of FINEMET, will be used. Pure elemental powders were mixed to give the desired FINEMET composition and alloyed for different milling times in high energy attritor mill. After 40 hours of milling, a mixture of amorphous and nanocrystalline powder was obtained. Size distribution and granulometric curves were obtained by laser diffraction, the structure and amorphisation progress was characterized by X-ray diffraction, scanning electron microscopy and transmission electron microscopy. The crystallization process of amorphous/nanocrystalline powder was followed by differential scanning calorimeter.

DEVELOPEMENT OF PVD DIFFUSION BARRIERS AGAINST CARBON DIFFUSION DURING SPARK PLASMA SINTERING

Mr. Romain Charvet, France

Oral Presentation (20')

Abstract

The elaboration of metallic parts by powder metallurgy techniques such as Spark Plasma Sintering (SPS), represents a relevant alternative to conventional manufacturing processes [1]. This technology allows the elaboration in a single stage of dense and high-performance materials with high mechanical properties [2,3]. The powder inserted into a mold is densified by the simultaneous application of Joule heating and uniaxial pressure. The sintering duration is limited, due to the use of high heating and cooling rates (of the order of several hundred of °C·min⁻¹) [4,5]. One of the major problems during SPS of metallic powders is the carbon diffusion from the graphite tooling (punches and die), and/or from the graphite foils inserted between the powder and the tools, to the powder. If the carburization is not blocked, it can lead to a degradation of the sintered material properties and to the formation of a surface composition gradients. Up to now, only few studies addressed this issue [6].

In a previous work [7], it has been demonstrated that a titanium coating (about 1 µm thick) deposited by Physical Vapor Deposition (PVD) on the graphite foil was efficient in avoiding carburization of pure iron during sintering. In the present study, thermodynamic simulations were performed using the ThermoCalc® DICTRA module in order to select new promising barriers. It was noted that Ti, Zr, Hf, Ta, and W are good candidates to slow down carbon diffusion. The synergy of these five elements was tested. A TiZrHfTaW-HEA (High Entropy Alloy) coating was deposited by PVD on the graphite foils. SPS tests were performed using a pure iron powder, to assess the efficiency at preventing carbon diffusion in a simple metallic substrate. The coating stability and the coating/substrate interfacial elemental diffusion were carefully investigated by SEM-EDS, and completed by phase identification using XRD. Very promising results were obtained, showing the relevance of this kind of HEA system.

This study was performed in the frame of the ANR OEDIPUS project (ANR-23-CE08-0028).

Paper 1963 1 4D-printing of nacre-inspired ceramic-polymeric composites

Prof. Kaline Pagnan Furlan, Germany

Keynote (Oral Presentation 40')

Abstract

Additive manufacturing of shape memory polymers has attracted significant attention due to their broad potential in applications across fields like biomedicine and aerospace. However, their mechanical properties, particularly stiffness and strength, limit their utilization. In this study, we demonstrate a novel fabrication approach where ceramic platelets and vitrimers' monomers are printed instead of polymers to produce nacre-inspired responsive ceramic-polymeric composites. Printing of monomers instead of polymers often two main advantages: processing at room temperature since no polymer needs to be melted and yet adequate direct writing viscosity despite the high ceramic platelets' solid load. Upon extrusion during the direct writing printing process, solvent evaporation induces polycondensation of the monomers, forming a vinylogous urethane vitrimer in between the ceramic alumina platelets. The resulting composites feature a covalent adaptable network (CAN) after this polymerization during printing, which enables rapid and efficient self-healing, reshaping, and shape memory capabilities without significant mechanical loss. Moreover, they exhibit up to 3.3 and 26.7 times higher tensile strength and stiffness, respectively, compared to the unmodified vitrimer. The proposed strategy represents a straightforward, direct-write 4D-printing method that operates under ambient conditions for the fabrication of smart responsible ceramic-polymeric composites with shape memory capabilities.

Paper 390 **3** **Towards In-Situ Pre-Programming of Transformation Characteristics in Shape Memory Polymers During Fused Filament Fabrication**
Mr. Apostolos Argyros, Greece
Oral Presentation (20')

Abstract

Shape Memory Polymers (SMPs) have gained significant attention in industrial applications due to their ability to transform shapes and recover their original form in response to external stimuli, such as heat. Their integration with 3D printing, particularly Fused Filament Fabrication (FFF), enables the fabrication of complex, morphing structures with spatially controlled properties. SMPs exhibit the Shape Memory Effect (SME) by transitioning between rubbery and glassy phases, governed by their glass transition temperature (T_g). This transition is influenced by reversible polymer bonds, which are affected by thermal, chemical, and mechanical treatments during manufacturing. Effective application of SMPs requires precise programming of their shape memory characteristics to ensure controlled transformation. While prior research has modified SMP properties through material composition changes, reinforcements, and post-processing, recent efforts focus on embedding material programming within the manufacturing process. FFF facilitates this by allowing localized control of material properties through process parameters such as extrusion temperature, speed, and infill geometry. However, the specific impact of extrusion temperature on T_g and shape memory programming remains unclear. This study aims to optimize SMP programming by tuning T_g and pre-programmed transformation strain without altering the material composition or using reinforcements. Through experimental thermal and thermomechanical testing, coupled with thermal-structural modeling, the study investigates how extrusion temperature influences SMP behavior, enhancing control over shape memory properties. This allows the imparting of multiple shape memory properties into printed SMP parts to realize complex shape-morphing behaviors during the manufacturing stage and without requiring a programming stage before applying those parts.

Paper 1966 4

Structural optimization of Fused Filament Fabricated components with biomechanical optimization methods

Mrs. Amelie Schiele, Germany

Oral Presentation (20')

Abstract

Additive manufacturing processes have evolved from rapid prototyping to the production of directly usable components. Extrusion-based processes such as Fused Filament Fabrication (FFF) enable fast and, for smaller quantities, cost-effective productions. FFF can create complex geometries, by extruding filament strands layer by layer.

The limitation of the technology is the low mechanical strength due to the layered structure. Print strands result in orthotropic properties, with strength and stiffness highest along print directions and decreasing in deviating directions. In order to design highly robust components without over dimensioning, it is not only necessary to take the anisotropy through the layered structure and the printing patterns into account, but also to optimize the printing paths themselves.

Computer Aided Internal Optimization (CAIO) is a method inspired by tree growth that aims at optimizing the internal structure of materials. Based on the Finite Element Method (FEM), CAIO iteratively rotates the orthotropic axis of each finite element in local principal normal stress directions and thus aligns the directions of maximum material strength and maximum load. For the example of a perforated plate subjected to a unidirectional tensile load, a FEM analysis was performed. The local orthotropy orientation, calculated by CAIO was translated into printing paths and demonstrators were fabricated in PLA using an FFF printer. Applying this optimization and compared to industry-standard printing patterns with the same amount of printed material, an increase in tensile strength of up to 28% was realized. In addition, the Soft Kill Method (SKO) was used to optimize the topology. The SKO method aims to optimize components for maximum stiffness and strength while minimizing material usage and thus component mass. The method is based on the biomechanical principles found in bone growth, where mineralization and demineralization controlled by mechanical stress vary structure and stiffness. By applying SKO to the FFF printed parts, a reduction in weight of 25% was realized. Even though the material usage was reduced, an increase in tensile strength of 5%, compared to industry standard prints, was achieved. Compared to standard patterned specimen of the same mass, an increase in breaking load of almost 70% was accomplished. The results of both methods show significant improvement in tensile strength of Fused Filament Fabricated parts. This suggests a strong potential for applying CAIO and SKO in optimized manufacturing of highly robust components.

Paper 1401 **5** **Characterization of highly filled PLA-based composite filaments with silica and alumina for desiccant applications**
Mr. Jose Antonio Martínez-Sánchez, Spain
Oral Presentation (20')

Abstract

Additive manufacturing via material extrusion (MEX) enables the direct, single-step fabrication of complex geometries. Recently, this technology has explored for the production of desiccant elements for air treatment systems. To achieve this, composite materials with high water vapor adsorption capacity are required.

This study explores the incorporation of adsorbent ceramic materials into polylactic acid (PLA)-based composite filaments. Two types of filaments were analysed, containing 20 wt% silica and 20 wt% activated alumina, respectively, both known for their high adsorption capacity. The objective of this work is twofold: first, to evaluate the water vapor adsorption capacity of the novel materials; and second, to characterize their thermal and mechanical properties. The filaments were analysed using thermogravimetric analysis (TGA) to verify the actual silica and alumina content. Adsorption-desorption isotherms (N_2 , 77 K) were obtained to assess the porosity and surface area of the materials. Finally, standardized specimens were manufactured using MEX and their tensile and flexural properties were tested according to ISO 527 and ISO 178 standards. TGA results confirmed silica and alumina contents of 19.4 wt.% and 19.3 wt.%, respectively. Furthermore, both composites exhibited thermal stability up to 255 °C (PLA-Silica) and 235 °C (PLA-Alumina), setting an upper limit for their printability. The N_2 adsorption-desorption isotherms revealed a substantial increase in surface area compared to pure PLA, with BET surface area enhanced by 4200% (PLA-Silica) and 1700% (PLA-Alumina). This increase in porosity resulted in a maximum N_2 adsorption capacity 1800% and 550%, respectively, higher than that of pure PLA.

Regarding mechanical properties, tensile tests demonstrated a reduction in maximum tensile stress of 63% and 30% for PLA-Silica and PLA-Alumina specimens, respectively. Flexural tests revealed a similar trend, with decreases of 62% and 27% in maximum flexural stress for PLA-Silica and PLA-Alumina, respectively.

Overall, the incorporation of ceramic fillers significantly enhances the adsorption capacity of PLA-based composites, demonstrating their potential for applications requiring efficient moisture removal. While mechanical properties are reduced compared to pure PLA, this limitation is not critical for passive desiccant applications. These findings provide valuable insights into the feasibility of high-filled composite filaments for MEX-based additive manufacturing, particularly in adsorption-driven engineering applications.

Paper 1732 6 Influence of Printing and Bed Temperature on the Mechanical Strength of Simple PLA Filament Joints

Dr. Jaime Orellana-Barrasa, Spain

Oral Presentation (20')

Abstract

Fused deposition modelling (FDM) 3D printing is widely used in prototyping and manufacturing due to its accessibility and versatility. However, the mechanical properties of printed parts are highly dependent on process parameters. This study focuses on evaluating the mechanical strength of a single joint between PLA filaments and how it is affected by printing temperature and bed temperature. To quantify the strength, tensile tests were performed on specimens printed with varying temperature settings. The results indicate that both printing temperature and bed temperature significantly influence the interlayer adhesion and overall mechanical performance of the joint. Higher extrusion temperatures generally improve filament fusion, leading to stronger joints, whereas bed temperature plays a crucial role improving adhesion during the first layers of printing. Understanding these effects is essential for optimizing printing parameters to enhance the mechanical integrity of PLA structures.

Paper 2037 7

Optimizing printing orientation for improving mechanical performance in multi-material 3D printing: a dual material and interface criterion approach

Mr. Orel Moutemi, France

Oral Presentation (20')

Abstract

In the era of Industry 4.0, where the focus is increasingly on innovative materials, multi-material 3D printing is garnering significant attention. As its name implies, this technology enables the combination of several materials within a single structure, thereby offering enhanced possibilities in design and functionality. However, the poor mechanical performance of the interfaces between materials can compromise the reliability and durability of the final part, despite the physico-chemical compatibility of the constituent materials. This study focuses on polymer parts fabricated by Fused Deposition Modeling (FDM).

First, we highlighted the role of print orientation on the morphology of the interface, notably its effective contact area and mechanical strength. On the other hand, the literature demonstrates that print orientation is a crucial parameter affecting the mechanical performance of FDM-manufactured parts. Thus, there exists a trade-off between the mechanical performance of the individual materials and that of the interfaces in order to optimize the overall integrity of the part. The present study proposes an approach to manage this trade-off effectively.

Two complementary failure criteria were employed to determine the optimal print orientation angle. The first, the Tsai-Wu criterion, is applied solely to the different materials of the part and takes into account the stresses in all directions to address the anisotropy of the printed material. The second criterion, developed specifically in this work, targets the interface by decoupling the normal and tangential stresses. Its formulation is based on tensile and shear tests designed to characterize the various parameters of both criteria.

These two criteria were subsequently evaluated by comparing the predictions with numerical simulations and experimental mechanical tests. The results, obtained notably on a PLA/PLA PETG/TPU & PETG/PC material combination, demonstrate that this approach provides excellent predictive capability relative to the experimentally measured values, thereby validating the robustness of the method. These findings pave the way for an improved design of multi-material parts fabricated. by 3D printing.

Paper 204 1 **Voxel-level control in stereolithography 3D printing: Achieving dual properties from a single material**
Mr. Dominik Laa, Austria
Highlight (Oral Presentation 20')

Abstract

SLA (stereolithography) 3D printing, despite significant advancements, typically uses a single material per print job. Recent developments try to overcome this limitation and allow multi-material printing through different mechanisms: exchanging the vat, inkjet deposition, or by varying the curing parameters. These approaches often introduce new complexities and limitations. Our work presents a novel approach to SLA 3D printing utilizing a single printing formulation with a “switchable monomer”, which changes its functionality based on the printing parameters. Depending on the monomer state at different temperatures and irradiation conditions, its polymerization behavior is changed. This leads to significant variations in obtained material properties such as the degree of stiffness, young’s modulus and translucency. To employ this novel material system in 3D printing, we introduce tailored software that enables 3D modelling and printing at varying reaction conditions (temperature, irradiation) at the level of individual voxels. During the printing process, the temperature and irradiation strategy are adjusted based on the desired properties of each voxel within the current layer, ensuring precise control over the final material properties.

To demonstrate the feasibility of this approach, we create hybrid materials with spatially varying properties. This enables the fabrication of functionally graded structures that are predefined at the level of individual voxels. Contrary to previous achievements in the field of multi-material polymerization, this technology does not rely on the degree of curing, which is unstable over time in the presence of residual monomers due to post-polymerization and hence leads to deteriorating property-differentiation over the use time of the printed object. Furthermore, the property variation is not restricted to just gradient materials but can be switched discreetly between two states and independently of the printing direction. This level of finely graded control opens up new possibilities for design for additive manufacturing. Together with the tailored voxel-based modelling we exploit this for shape-memory 3D printing (4D printing) of the multi-material objects, which could be employed in soft robotics applications.

Our research contributes in the field of multi-material printing by demonstrating a new material chemistry concept, “switchable monomers”, alongside a complete software solution for modelling and printing with voxel-level property control.

3D Printing of bio-based polymeric composites obtained by vat-photopolymerization technology containing biofillers

Dr. Giovanna Colucci, Italy

Oral Presentation (20')

Abstract

Bio-based polymers coming from renewable sources are emerging to replace the traditional plastics derived from fossil sources, because they offer easy processing, fulfill technological and durability requirements, guaranteeing improved properties such as biocompatibility, lower costs and environmental impact. At the same time, additive manufacturing (AM) technologies have been emerging as greener alternatives to production technologies for polymeric materials. 3D printing is considered a rapid prototyping tool due to its high printing accuracy, low raw material uses and wastes, and the ability to realize printed objects with complex geometry and good dimensional stability for many application fields, such as automotive, packaging and biomedical. Among the different 3D printing technologies, vat-photopolymerization (VP), represents an easy method for obtaining accurate objects by 3D printing. It is a light-based technology, which allows to obtain high printing resolution and good level of shape complexity of the printed parts. During the process, the build platform is immersed into the liquid photocurable resin and, thanks to the UV light, the resin in the vat can be photocured and transformed in a uniform layer of solid material according to the previously designed CAD model. The process goes on until the desired object is complete.

The present research work aims to develop novel bio-based composites containing biofillers by using the Liquid Crystal Display (LCD) 3D printing technology. Acrylate epoxidized soybean oil (AESO) resin was used as photocurable polymer matrix, isobornyl methacrylate (IBOMA) was used as reactive diluent, and phenyl bis (2,4,6-trimethylbenzoyl) phosphine oxide (BAPO) was employed as radical photoinitiator. Different kinds of fillers were used to prepare the final composites deriving from agro-wastes corn and wine by-products, and biochar coming from cellulose pyrolysis. The composites were obtained by dispersing the different fillers within the AESO-based matrix and 3D printed via LCD. Then, the specimens were fully characterized from thermal, morphological, and mechanical point of view. Several 3D printed parts were successfully realized showing very complex structures and improved final properties in terms of elastic modulus, ultimate tensile strength, and glass transition temperature due to the reinforcing effect induced to the presence of the filler's particles, without significant effects on the thermal stability.

Paper 1309 3 Advancing 3D Printing with Vacuum Technology: Process Optimization, Material Properties, and Hybrid Manufacturing
Dr. Marvin Kühn, Germany
Oral Presentation (20')

Abstract

In recent years, 3D printing under high vacuum conditions ($<10^{-2}$ mbar) has gained increasing scientific interest, offering new possibilities for advanced manufacturing. This cutting-edge approach holds significant potential for space and in-orbit manufacturing, the production of high-performance polymers, and the fabrication of hybrid material combinations, such as those used in biomedical applications. The vacuum environment provides unique advantages, including enhanced heat flux control for printed parts and significantly reduced heating power requirements. Additionally, integration of a vacuum arc-based coating process into the polymer extrusion process allows for in-situ surface modifications, further expanding its capabilities. This presentation will first outline our extensive research into 3D printing in vacuum, addressing current challenges and proposing solutions to optimize the process. We will focus on temperature management strategies (including sensor integration and heating mechanisms) and examine the critical electrical and mechanical design considerations necessary for successful vacuum-based printing. We will then explore the mechanical properties of printed components, discuss potential slicing software optimizations, and evaluate the hybrid approach of combining 3D printing with in-process coating techniques. Finally, we will present key applications and challenges associated with this novel manufacturing process, paving the way for future advancements in vacuum-enabled additive manufacturing.

Design, manufacturing and development of piezoelectric PLLA-ZnO nanocomposites by 3D printing

Mr. Guillermo Vergara, Spain

Oral Presentation (20')

Abstract

The main objective of this research is the synthesis of nanoparticles for coordination with bio-based polymers for developing composite materials with improved piezoelectric properties that are flexible, more sustainable and efficient for new applications in potentially disruptive related technologies, such as wireless sensor networks and bio-implanted medical devices.

For this purpose, two materials with piezoelectric properties are used, which, through their coordination in a bionanocomposite achieve a higher electrical response. These materials are poly-L-lactic acid with medical grade purity (PLLA) and zinc oxide nanorods. From 2D WAXS, DSC and electron microscopy analysis of 3D printed bionanocomposites we could deduce that the piezoelectric morphology of PLLA is both influenced by the filler and the processing parameters (1,2,3,4).

This observation allows us to address one of the main challenges in the fabrication of piezoelectric materials and devices, which is to achieve a structure and arrangement that favors the piezoelectric response of the produced devices. This challenge has been overcome by 3D printing, through which it has been possible to orient both the polymeric chains of the matrix and the nanoparticles inside it, achieving a high electrical response potentially suitable for implantation and cell growth activation. Both the elongation and the orientation of the printed material are key to increase the final piezoelectric response of the device (4.7 pC/N), for which the 3D printing conditions have been optimized to achieve thin and flexible films that are adaptable to different structures using specialized 3D printing equipment in the medical sector (5).

Fiber-Reinforced Photopolymers - Additive Manufacturing of High-Performance Composites

Mr. Florian Hager, Austria

Oral Presentation (20')

Abstract

Stereolithography based additive manufacturing technologies has enabled the fabrication of a wide range of materials for creating complex and highly individualized products. For some applications, the overall (thermo)mechanical properties of these photopolymers limits the performance. However, to further increase the mechanical properties, this work is exploring the possibility of fiber reinforcement for photopolymers to use in high-performance materials.

A 3D printer based on the digital light processing (DLP) process (used wavelength $\lambda = 385$ nm, pixel size $50 \mu\text{m}$) was used to produce fiber-reinforced photopolymers. Glass fibers with varying length and aspect ratios were employed as reinforcement, integrated into a (meth)acrylate-based photopolymerizable matrix. Fiber orientation within the printed samples was controlled, with options including semi-random orientation or alignment in the direction of applied load. The fiber orientation and content can be adjusted on a layer-by-layer basis. Fiber sizing is a critical component in composite manufacturing as the sizing has a great influence on the mechanical properties. With appropriate sizing for both the glass fibers and photopolymeric matrix material, the adhesion between fiber and matrix can be significantly enhanced.

The 3D-printed photopolymer composites were tested with respect to their (thermo) mechanical behaviour. The influence of fiber content, orientation and location on the (thermo)mechanical properties of photopolymer composites were investigated using tensile testing and dynamic mechanical analysis. Tensile tests and dynamic mechanical analysis revealed significant improvements with fiber reinforcement. Tensile strength increased by over 44 %, and the glass transition temperature exceeded 90 °C. Notably, the storage modulus exhibited a 3.5-fold enhancement. Furthermore, light and scanning electron microscopy analysis of fracture surfaces provided valuable insights into fiber-matrix adhesion and revealing failure mechanisms, including fiber pull-out and matrix cracking.

Negative Poisson ratio glass/ceramic metamaterials by two-photon polymerization

Dr. Enrico Storti, Switzerland

Oral Presentation (20')

Abstract

Metamaterials with multiple anisotropic properties, including negative Poisson's ratios, negative thermal expansion, negative modulus, high strength and stiffness, and double-negative acoustic properties, hold significant promise for applications such as medicine or civil engineering. However, most are based on polymers or metals, with limiting performance at very high temperatures. At the same time, it is difficult for traditional ceramic processing, such as powder sintering, to process complex metamaterial structures or ceramic components.

Two-photon polymerization (TPP) enables the fabrication of intricate 3D objects by scanning a laser beam within a volumetric body, without relying on a conventional layer-by-layer approach as in traditional stereolithography (SLA). A combination of a galvano-scanner and a micropositioning system provides precise control over the manufacturing process, resulting in true net-shape components. TPP is particularly advantageous for producing high added value ceramics with nanoscale structures, making it highly relevant for nanotechnology applications such as microfluidics, micromechanics, and microelectronics.

In this study, hybrid organic-inorganic resin systems were used as precursors, consisting of photocurable polymers and fumed silica. The resin mixtures exhibited high transmittance in a broad spectral range (400–1000 nm), making them compatible with femtosecond lasers operating at different wavelengths.

Auxetic metamaterial geometries were 3D printed by TPP and underwent thermal treatment in air to gradually eliminate the organic fraction and sinter the silica particles, resulting in homogeneous glass/ceramic components. Microstructural characterization of the printed objects was performed using scanning electron microscopy (SEM) coupled with energy-dispersive X-ray spectroscopy (EDS). Shrinkage and geometrical accuracy were assessed via image analysis.

The mechanical performance of the printed structures was evaluated by nanoindentation before and after thermal treatment at different temperatures, to validate the effect of lateral contraction upon axial compression.

This research was co-funded by the German Research Foundation (DFG) under the Walter Benjamin Program, project code STO 1296/2-1.

Paper 647 1 Development of physical vapour deposition coatings for weathering protection of additive-manufactured polymer substrates

Prof. Ramon Escobar Galindo, Spain

Highlight (Oral Presentation 20')

Abstract

The main barrier to the application of disruptive additive manufacturing (AM) is the limited range of materials currently printed using these techniques. Some common materials typically processed by fused filament fabrication (FFF) are high molecular weight polylactic acid (PLA) and acrylonitrile-styrene-butadiene (ABS). The development of new polymeric base materials, such as acrylonitrile-styrene-acrylate (ASA), with better mechanical and UV resistance properties and the use of protective surface coatings have recently emerged as alternatives to overcome these problems.

In this work, protective metallic coatings (Ti6Al4V and 316 stainless steel) of approximately 500 nm of thickness were deposited by physical vapour deposition (PVD) on additive-manufactured ASA substrates. Pulsed DC magnetron sputtering (p-DCMS) and high-power impulse magnetron sputtering (HiPIMS) techniques were used. The conformal deposition of the coatings and the analysis of the mechanical properties, in particular, the evaluation of the local residual stresses without the use of a reference, were carried out using the Focused Ion Beam - Digital Image Correlation (FIB-DIC) ring-core milling technique [1]. The dual beam FIB-SEM performed an annular trench on the samples, isolating a central island. SEM observation of island surface while the trench is further deepened enabled the measurement of the stresses using digital image correlation (DIC) analysis, as the material undergoes gradual stress relief. The optical properties of the coated AM substrates (total and diffuse reflectance) were evaluated by UV-Vis-NIR spectroscopy. UV-Vis-NIR results showed an increase of the total reflectance of coated samples both in the UV (+15%) and NIR region (+35%). The higher reflectance properties enhance the UV and heat resistance of the material. The changes observed in the mechanical and optical properties, before and after exposure to UV-A and UV-B irradiation, simulating weathering conditions will be also discussed in the presentation. In conclusion, using protective PVD metallic coatings on additive-manufactured polymers improves the resistance to degradation by UV radiation and weathering extending the life of AM parts exposed to ambient conditions. Studies made by FIB-SEM-DIC analysis in combination with finite element simulation assess the conformability and local residual stress of the coating/AM substrate interface.

Continuous fiber reinforcing lithography-based additive manufacturing

Mr. Jan Bornemann, Austria

Oral Presentation (20')

Abstract

Stereolithography (SLA) is an additive manufacturing (AM) process known for producing components with highest precision and smooth surface quality. However, the material properties of the photopolymers commonly used in SLA are often insufficient for demanding technical applications.

The integration of glass fibers offers a promising approach to enhance stiffness, strength and creep performance of SLA-fabricated components.

Particularly, the selective use of continuous fibers is of significant interest, as it allows for the customization of material properties based on the geometry, loading type, and direction of the applied forces. This individual adapted reinforcement strategy enables the production of high-performance components for specialized applications.

To integrate continuous fibers during the printing process, specific mechanical and design requirements must be addressed in the SLA machine architecture. This study presents the development of a lithography-based additive manufacturing system using digital light processing (DLP) technology. The system is equipped with a novel module that enables the precise embedding of continuous glass fibers into the geometry of the printed component along defined contours.

The presented work details the machine's fiber deposition process, focusing on the precision placement of fibers within the photopolymer matrix. Various glass fiber deposition strategies are investigated to assess their influence on the mechanical properties of the resulting structures. Experimental results highlight the significant improvements in component performance due to the reinforcement material and provide insights into the optimal integration of continuous fibers within SLA processes.

This work advances the capabilities of SLA for engineering applications by combining the precision of photopolymerization with the superior mechanical properties of fiber-reinforced composites. It opens new avenues for producing high-strength, stiff, and application-specific components, pushing the boundaries of additive manufacturing in material science.

Paper 1457 3 **Interpenetrating phase composites with complex geometries: pressureless infiltration of alumina-based systems**
Dr. Marco Mariani, Italy
Oral Presentation (20')

Abstract

Additive manufacturing (AM) has transformed material design, enabling complex geometries and overcoming the limitations of conventional processing techniques. Among AM methods, binder jetting offers a scalable and cost-effective route for producing high-precision ceramic components with open porosity, paving the way for applications such as interpenetrating phase composites (IPCs). These IPCs exhibit a unique 3-3 connectivity that combines the intrinsic properties of ceramics and metals to achieve an optimal balance of hardness, wear resistance, toughness, and ductility. This study focuses on the binder jetting of alumina preforms as a foundational step for fabricating ceramic- and metal-matrix IPCs. A comparative analysis of spherical feedstocks prepared by plasma spheroidization is performed to evaluate the influence of multimodal particle size distributions on preform resolution, packing density, and overall print quality. Key parameters influencing the evolution of open porosity during thermal debinding and sintering are investigated, with processing temperatures reaching up to 1750 °C. To demonstrate the feasibility of this manufacturing route, alumina preforms with optimized porosity are infiltrated with copper under oxidizing conditions and aluminium in a nitrogen atmosphere. The resulting IPCs are characterized for their microstructural integrity and mechanical performance. Techniques such as scanning electron microscopy, x-ray diffraction, and ball-on-disk wear testing are employed to assess the relationship between preform properties, composite microstructure, and mechanical behaviour. The outcomes highlight the potential of binder jetting for producing complex geometries at scale while maintaining precise control over porosity and material distribution. This approach advances the development of multifunctional composites and aligns with ongoing efforts to address challenges in AM, including process robustness, scalability, and the qualification of materials for industrial applications in challenging environments, as high temperature, corrosive media and severe mechanical stresses.

Paper 2194 4 Additive Manufacturing of Porous Structural Ceramic Supports via Aqueous-Based Direct Ink Writing: Rheological Considerations and Integration of Functional Phases
Dr. Jonas Gurauskis, Spain
Oral Presentation (20')

Abstract

Additive manufacturing (AM) has significantly expanded the design possibilities for ceramic based components, offering possibility to produce structures with more complex geometries. Among the various AM techniques, Direct Ink Writing (DIW) is particularly well-suited for the cost-effective fabrication of complex ceramic structures. That is, this technique enables the manufacturing of structures with hierarchical porosity distribution with complex mass flow pathways which are critical for advanced applications such as energy conversion and heterogeneous catalysis. The implementation of aqueous-based systems in DIW presents numerous advantages, particularly in terms of environmental sustainability and cost efficiency. However, achieving high-fidelity printed structures requires precise tailoring of the paste formulation, particularly its rheological behavior, as well as stringent control over drying conditions to prevent structural defects. Thus, the rheological properties of aqueous-based ceramic pastes must be meticulously optimized to ensure stable extrusion, shape retention, and defect-free layer stacking. The presentation will provide the insights on the optimization of these pastes that must exhibit shear-thinning behavior. In particular, solid loading, surfactant selection, pore former integration and binder interactions will be discussed. Practical details, such as drying control of printed structures will be addressed. Examples post-processing modifications of these porous structural ceramic supports will be presented, such as reactive surface functionalization and hierarchical porosity engineering through in situ synthesis of meso-micro porous materials. Some cases of deployment of these structures in high-performance environments, such as energy conversion and heterogeneous catalytic systems will be discussed.

Paper 1694 5 Thermal Shock-Resistant Cordierite Ceramics: A Breakthrough for Aerospace Optics

Mr. Alvaro Garcia, Spain

Oral Presentation (20')

Abstract

The aerospace industry constantly drives innovation, demanding materials with unparalleled mechanical strength and functional performance. While ceramics offer promising solutions, their inherent low fracture toughness and thermal shock resistance present significant challenges. This study explores the potential of graphene as a transformative reinforcement material to overcome these limitations. The development of cordierite ceramics, renowned for their superior thermal shock resistance, reinforced with reduced graphene oxide (rGO), is investigated.

Using Pellet Material Extrusion (Pellet MEX), a cutting-edge manufacturing technique tailored for creating complex geometries with rapid prototyping and low production volumes, an aerospace prototype specifically designed for optical applications was successfully fabricated. To achieve fine dimensional precision, green-state machining was employed, significantly improving geometric tolerances and surface quality. This work demonstrates the viability of integrating advanced ceramic composites with innovative manufacturing and post-processing techniques, meeting the aerospace industry's high standards for performance, precision, and reliability.

Paper 1886 1 A soft hydrogel for processing and 3D molecular imaging of the human brain

Prof. Juhuk Park, South Korea

Highlight (Oral Presentation 20')

Abstract

Understanding the intricate architecture and function of the human brain is crucial for advancing treatments for neurological disorders. However, conventional imaging and histological techniques are constrained by the fragility and complexity of brain tissue, often requiring small biopsy samples that limit organ-scale investigations. To overcome these challenges, we introduce a functional soft material that chemically transforms intact human brain tissue into a stretchable, transparent biohybrid, termed mELAST (magnifiable entangled link-augmented stretchable tissue-hydrogel). At the core of mELAST is an in situ polymer synthesis strategy that forms highly entangled, superhydrophilic polymer chains within the brain's native nanoporous network. By integrating with endogenous biomolecules, this soft material stabilizes delicate neural structures while preserving molecular integrity, enabling repeated mechanical thinning and controlled physical expansion of large tissue samples for multiscale imaging. This functional soft material seamlessly integrates with existing histological and imaging pipelines, facilitating advanced tissue phenotyping at unprecedented speed and resolution. By maintaining native protein configurations and molecular markers, mELAST enables rapid multiplexed immunostaining and structural interrogation of neural circuits. The expanded tissues provide a high-fidelity platform to study cellular architecture, morphology, and connectivity in both healthy and diseased brain states. Applications of mELAST in neurodegenerative disease research demonstrate its potential to uncover micro/nanoscale pathological features, such as amyloid plaques and neurofibrillary tangles in Alzheimer's disease, within large intact brain samples. The ability to spatially map neuronal and glial populations at an organ scale offers transformative insights into disease progression and neural network dysfunction. By harnessing the principles of functional soft materials, mELAST transcends traditional limitations in brain tissue analysis. Its tunable thickness/size and molecular preservation capabilities redefine how we visualize and understand the human brain, providing an innovative platform for fundamental neuroscience, neuropathology, and precision medicine. This breakthrough paves the way for next-generation approaches in 3D human brain mapping, advancing our ability to decipher complex neural systems and develop targeted interventions for neurological diseases.

Gelatin-Based Hydrogels with Carrageenan and Chitosan for Soft Tissue Engineering

Dr. Chiara Pasini, Italy

Oral Presentation (20')

Abstract

Bioresorbable hydrogels are leading materials in soft tissue engineering for the realization of scaffolds that can promote the reconstruction of damaged or diseased tissue by hosting cells capable of building new functional tissue. Their superior regenerative performance is favored by the close similarity between their hydrophilic macromolecular network and the structure of the extracellular matrix (ECM).

Inspired by the variegated combination of proteins and carbohydrates in native ECM, novel hydrogels were developed with a composition based on gelatin and enriched with polysaccharides of natural origin: one containing carrageenan (G-PEG-CARR), one with chitosan (G-PEG-CH), and one containing both (G-PEG-CARR-CH). These three materials were synthesized by crosslinking with poly(ethylene glycol) diglycidyl ether and freeze-dried, in order to obtain an interconnected porous structure suitable for cell colonization through a green procedure, without using any toxic solvent or foaming agent.

The swelling, degradation, and mechanical behavior of the scaffolds were evaluated along time upon immersion in water at body temperature. G-PEG-CARR, G-PEG-CH and G-PEG-CARR-CH exhibited high water uptake (about 550%, 730% and 830% after 24 h, respectively) and rather fast hydrolysis (~40%-50% mass loss at 6 weeks), nevertheless maintaining their structural integrity up to 6 weeks. During compression tests, the three materials showed a nonlinear elastic response with high compliance (stiffness of 30 kPa, 40–250 kPa and 60 kPa, respectively) and good deformation reversibility for repeated compressive cycles at 50% strain. They also exhibited natural tissue-like viscoelasticity with fast stress-relaxation (half stress relaxation time ~1-3 s), and their mechanical behavior became more and more compliant after prolonged immersion in water, as degradation gradually occurred.

In order to investigate the hydrogels as potential carriers for cell delivery in tissue engineering, they were seeded with human Mesenchymal Stromal Cells (hMSCs), featuring the potential for self-renewal and capacity to differentiate into several cell lineages. hMSCs spread homogeneously throughout the scaffolds and maintained their growth and viability for at least 21 days, with an increasing proliferation trend. Altogether, these findings revealed that encapsulating hMSCs in gelatin-based hydrogels containing carrageenan and/or chitosan could be a promising strategy for cell delivery in regenerative medicine, deserving further studies targeting specific tissue engineering applications. In particular, at the light of their soft viscoelastic behavior, compatibility with cyclic loading, and efficient hydrolysis, these scaffolds showed great potential for the reconstruction of soft tissues such as skin, muscles, cartilage, or adipose tissue.

INJECTABLE SODIUM ALGinate BASED HYDROGEL WITH METRONIDAZOLE FOR PHARMACOLOGICAL APPLICATIONS

Mrs. Arianna Chiappa, Italy

Oral Presentation (20')

Abstract

A drug delivery system (DDS) is a pharmaceutical dosage form that releases one or more active ingredients in a modified manner in terms of site, rate, and time and ensures that certain systemic or local therapeutic concentrations of the molecules are achieved or maintained. In this work a complex reservoir-like vaginal ring was considered as DDS. Fused deposition modeling (FDM) 3D printing was exploited to manufacture the reservoir wall with controlled dimensions, and macroscopic porosity. The drug, Metronidazole (MTZ) was chosen as antibiotic for the treatment of bacterial vaginosis. It had to be transferred into the reservoir by an easily injectable carrier. Further, once in the reservoir, the carrier should not leak through its pores, to obtain a sustained drug release. An alginate-based hydrogel was developed for this task. Alginate was selected for the gel due to its low cytotoxicity; CaCO₃ and glucono-delta-lactone as crosslinking agents allowed for a controlled gelation process, with the aim to fill the reservoir with a flowable precursor solution that reached the solid-like consistency of the hydrogel in the cavity. Given the therapeutic need of a MTZ load higher than the amount soluble in the aqueous alginate solution, a MTZ dispersion had to be considered. The effects of the composition of the drug-loaded precursor dispersion and the resultant filled hydrogel were investigated from a rheological standpoint. In steady state rotational tests, the precursor dispersions exhibited a flow threshold, followed by a pseudoplastic behavior. By combining this information with a purposely developed capillary rheometry approach their injectability was predicted and assessed. The ability of the suspension to crosslink despite the very high MTZ solid content was confirmed performing dynamical mechanical tests. The solid fraction showed a predominant effect on mechanical properties if compared with alginate. Loss factor increased with increasing dispersed drug content probably due to energy dissipation caused by friction between solid particles. The alginate-content controlled hydrogel stability. Further considering the hydrogel as an independent DDS, alginate content controlled the MTZ release rate. However, once into the reservoir, the release rate controlling factor was demonstrated to be the reservoir porosity, with very little effect from the hydrogel composition.

Paper 843 **5** **Biopolymer-modified double-network PVA hydrogels: A comparative analysis of additive effects on material properties**
Mrs. Leonarda Vukonic, Austria
Oral Presentation (20')

Abstract

Abstract:

Polyvinyl alcohol (PVA)-based double-network hydrogels, incorporating agarose, chitosan, or silk fibroin as biopolymer additives, were systematically evaluated for their structural, mechanical, tribological and biocompatibility properties. Although these polymers are commonly used in cartilage tissue engineering, their precise effects on hydrogel properties have not been systematically compared under uniform synthesis conditions, making this study critical for understanding their role in tailoring mechanical and biological performance. Designed using a consistent freeze-thaw process, these hydrogels address limitations of pure PVA, such as insufficient mechanical strength and bioactivity, providing a deeper understanding of structure-property relationships in soft materials.

Mechanical testing revealed additive-specific effects: PVA-agar hydrogels exhibited the highest compressive modulus, PVA-chitosan hydrogels demonstrated improved elasticity and durability, and PVA-silk fibroin hydrogels displayed superior energy dissipation. These findings suggest their suitability for diverse functional applications. All hydrogels exhibited a high water content (>80%), advantageous swelling characteristics, and interconnected porous structures, essential for supporting hydrated, tissue-like environments. Preliminary cytotoxicity studies confirmed minimal adverse effects, supporting their potential for bioengineering applications.

This study lays the groundwork for developing hydrogels with improved mechanical and biological properties, which are crucial for applications such as cartilage tissue engineering. The fabrication techniques and characterization methods used provide insights into how specific biopolymer additives influence the material's structural and functional performance.

Comparison of mechanical and rheological characterization for multifunctional magnetic hydrogels for 3D printing applications

Mr. Elio Cinar San Segundo, Spain

Oral Presentation (20')

Abstract

Developing new material characterization strategies that combine mechanical and rheological methodologies is essential for optimizing biomaterials [1] used in medical applications such as pharmaceuticals, implants, 3D bioprinting, and tissue engineering. The rapid development of 3D printing techniques has been a driving force in personalized material manufacturing, offering the creation of complex structures and versatility in material selection. Such control in material architecture and mechanical properties is crucial in the tissue engineering sector as when engineered biomaterials come into contact with biological materials, it is crucial for them to closely mimic the dynamic natural environment for optimal integration. However, the required mechanical and rheological properties of biomaterials for 3D bioprinting applications have not been systematically correlated to material printability.

This study aimed to compare various mechanical and rheological characterization techniques of soft magnetic biomaterials and explore how combining these methods, can provide a broader understanding of biomaterial properties, ultimately guiding the selection of appropriate biomaterials for tissue engineering, with a focus on 3D bioprinting applications. The mechanical and rheological properties of various magnetic hydrogels, based on polysaccharides and proteins with varying concentrations [2,3], were measured using a universal testing machine, a rheometer, and a Dynamic Mechanical Analyzer to enable a comparative analysis of the collected data. Furthermore, the effects of material anisotropy were studied through magnetic particle structuring within the hydrogel using triaxial magnetic fields [4].

The universal testing machine applied controlled tensile and compressive forces to the biomaterial sample and measured the resulting deformation, accommodating larger deviations in force and displacement. Using oscillatory shear stresses through rheology, the storage and loss moduli were evaluated. DMA provided a more versatile measurement setup that combined the principles of the universal testing machine and rheology to simulate real-world conditions under extension and torsion. Although the maximum achievable force in DMA was lower than that of the universal testing machine, it offered improved resolution. This setup proved essential for a comprehensive analysis of soft biomaterials' static and dynamic mechanical and rheological properties.

Aging and properties of sodium silicate hydrogels in subsurface environments

Mr. Mohammad Valibeknejad, The Netherlands

Oral Presentation (20')

Abstract

Hydrogels made from sodium silicate have been used as grout to reduce soil permeability and reinforce soil in civil engineering projects. However, their application as a grouting material is becoming more challenging due to urbanization and climate change adaptation, which require deeper injections in increasingly complex soil and groundwater conditions. At the same time, recent legislation mandates more comprehensive environmental impact assessments of hydrogels upon application.

Despite these challenges, little is known about the behavior of hydrogels in the subsurface. A thorough investigation is needed to understand how soil and groundwater composition influence their in-situ performance.

This presentation explores the impact of environmental factors on sodium silicate hydrogels, including soil organic matter, iron-bearing minerals, calcite, soil pH, groundwater composition, and hydrogel properties. Our experimental work characterizes gel properties based on rheology, porosity, microstructure, mechanical strength, chemical composition, and deformation rate. Using this characterization, we assess how soil and groundwater composition affect gel performance.

Overall, this study provides a database to support the selection of optimal grout formulations for soft gel applications aimed at reducing permeability, considering both environmental and engineering conditions.

Hydrophobic Eutectics-based Supramolecular Gels and Cellulose-based Nanosponges: Breakthrough Solutions for Water Remediation

Mrs. Gloria Nicastro, Italy

Oral Presentation (20')

Abstract

Clean water is a fundamental goal of the 2030 Agenda for Sustainable Development [1] and the European Green Deal's Zero Pollution Action Plan [2], making water remediation a critical focus in research. Conventional extraction techniques like dispersive liquid-liquid and solid-liquid microextraction (DLLME and DSLME) face challenges, including the use of volatile organic solvents and non-sustainable sorbents with limited capacity.

This study addresses these challenges by introducing new classes of sustainable materials based on hydrophobic non-ionic eutectic solvents (HES) [3]. HES offer several advantages, including being chloride-free, easy to prepare from natural precursors, 100% atom economy, and high sustainability [4]. To expand their use beyond liquid-liquid extraction, two innovative HES-based materials are developed: hydrophobic eutectogels (HEG) and HES-loaded cellulose nanosponges (HECS).

HEG are supramolecular gels formed by the rapid thermoreversible self-assembly of low molecular weight gelators (LMWG) [3]. HECS are hybrid materials obtained by combination of HES with cellulose nanosponges (CNS), eco-safe nanostructured cellulose-based materials made from TEMPO-oxidized cellulose [5], branched polyethyleneimine and citric acid [6,7], a particularly attractive option for sustainable water remediation. Preliminary studies with HES and HEG composed of terpenes, long chain carboxylic acids and phosphine oxides have demonstrated promising extraction abilities in water remediation from phthalates and bisphenol A.

The materials' structure and extraction mechanisms are thoroughly investigated using NMR and UV-Vis spectroscopy, and HPLC-UV. This comprehensive analysis allows for precise control over their properties, making these materials highly adaptable for various water remediation applications.

The development of these materials marks a breakthrough in sustainable water treatment. By overcoming the limitations of current extraction methods, this research offers a safer, more efficient, and eco-friendly solution for removing harmful contaminants. These materials have the potential to play a crucial role in achieving global clean water goals and advancing the field of green chemistry.

Fabrication, characterization and applications of electrospun polymer-inorganic nanocomposites

Prof. Theodora Krasia, Cyprus

Oral Presentation (20')

Abstract

The design and development of functional, polymer-based nanocomposites attracts significant attention nowadays owned to their unique properties, deriving from the combination of polymers with nanostructured materials of either organic or inorganic origin. Electrospinning – which has already reached the industrial sector – is one of the most powerful and versatile fabrication methods used in the production of nanocomposite materials in the form of micro- and nanofibers [1]. Such fibrous nanocomposites are highly attractive in various research fields, owned to their unique properties including high surface to volume ratios, high porosity and multifunctionality. This presentation provides an overview of our recent research activities on the fabrication, characterization and applications of polymer-based electrospun nanocomposites in the form of nano- and microfibers and corresponding microrods. More precisely, the fabrication strategies followed in the preparation of the afore-mentioned systems, along with the materials' characterization and investigation of their potential applicability in various fields including biomedicine [2, 3], catalysis [4], environmental remediation [5], optoelectronics [6, 7] and sensing [8] are presented and discussed.

Rheoelectrical properties of Multi-Walled Carbon Nanotubes-based electrofluids for soft electronics applications

Mr. Sergio Lago-garrido, Germany

Oral Presentation (20')

Abstract

Electrofluids can be understood as conductive liquid composites, where conductive filler particles are suspended in a non-conductive liquid matrix. In order to achieve electrical conductivity, the filler concentration should be enough to create a 3D network that spans through the entire volume, where the particles are in contact with each other. This concentration is defined as the percolation threshold. The addition of filler particles has an impact on the mechanical network of the electrofluids. At increasing concentrations, the particles form a colloidal gel. We adapted the electrical percolation theory with mechanical parameters to determine the transition from liquid to solid-like behaviour of the electrofluids, i.e., the formation of a mechanical network. Here, we will present how the interplay of these two networks dominates the properties of electrofluids and exploit them as soft sensors and conductive interconnections.

Electrofluids composed of Multi-Walled Carbon Nanotubes (MWCNTs) as the conductive filler and glycerol as the liquid matrix at different concentrations were investigated. The electrical resistance was obtained from I-V curves using a 4-point probe setup for each concentration. The mechanical values (storage modulus, G') were obtained from frequency sweeps in the linear viscoelastic (LVE) region at low frequencies. We found that the electrical percolation was reached at a lower filler concentration than the mechanical: 0.04 wt% and 0.16 wt% MWCNTs, respectively. We propose three regimes to describe the electrofluids depending on which networks are present that allows us to predict their mechano-electrical responses. Electrofluids were encapsulated in EcoFlex tubes and underwent uniaxial tensile tests coupled to electrical resistance measurements.

Electrofluids with concentrations between the electrical and the mechanical percolation exhibited a strong electrical relaxation under strain, due to the MWCNT rearrangement, whereas electrofluids with mechanical network retain the electrical response. This behaviour correlates what observed in rheoelectrical tests (amplitude sweeps). Flow curves showed that the electrical resistance remains constant until a shear rate value of 50 s⁻¹, demonstrating that the electrical and the mechanical networks are independent. We employed electrofluids as conductive interconnections for metal joint components and successfully reduce the change in electrical resistance by 80% compared to an empty ball joint during rotation.

Analysis of piezoionic phenomenon in ionic conductive hydrogel materials for the fabrication of innovative self-powered tactile sensors

Mrs. Maria Jose Arias Belduque, Italy

Oral Presentation (20')

Abstract

Nowadays the lack of tactile devices able to replicate skin functions has prompted researchers to look for and create novel technology that takes advantage of the physical properties of specific materials to develop diverse types of sensors. The piezoionic phenomenon is an effect that occurs in ionic conductive hydrogels. When pressure is applied to the material, ions migrate away from the deformed region, inducing a strain-driven ion flux. If anions and cations mobility differs, their diffusion within the hydrogel will also differ under load, causing a charge imbalance measurable as an electrical voltage in the device, leading to a current in the external circuit, both of which are proportional to the applied pressure. This physical mechanism behaves in an analogous way as the mechanoreceptors in the skin, therefore, can be useful to describe the perception of touch, so its study can lead to the creation of new self-powered sensors and a variety of smart healthcare devices. This study analyses the piezoionic effect in a photocurable semi-interpenetrated polymeric network hydrogel composed of Poly (vinyl alcohol) (PVA), acrylic acid (AAc) and Poly (ethylene glycol) diacrylate (PEGDA). The impact of ionic mobility on the electrical response of the material was validated using different chloride salts, keeping the same anion and altering the cations with various alkali metals. To assess the electrical behavior of the various mobile ions, flat samples with parallel and sandwich copper electrodes underwent a variety of electromechanical and electrochemical characterizations. Furthermore, 3D printed samples were subjected to the same studies to evaluate the impact of complex geometry on the piezoionic response. The results demonstrate that complex 3D geometries enhance the electrical response because of mechanical strain concentration induced by the structure with respect to bulk samples. After the functional characterization of the material, the hydrogel was implemented as a biometric self-powered sensor and as a potential mechanical harvester to recover energy from human motion. The findings pave the way to employ piezoionic phenomenon in the development of new tactile sensors as well as innovative devices useful in soft robotics, flexible and wearable electronics and health monitoring.

Tailoring Mechanical Properties of Polymer Foams at Constant Density: The Impact of Pore Shape, Pore Size, and Fabrication Processes.

Mr. Oliver Walker, Germany

Oral Presentation (20')

Abstract

Polymer foams are especially sought after in energy absorbing applications like safety gear or packaging, due to their lightness and mechanical properties. However, adjusting the properties of a polymer foam often involves trade-offs. For example, increasing the density increases the mechanical properties but also the weight [1]. This leads to the question whether the structure of a polymer foam can tailor its mechanical properties while the density is kept constant. In this work, we investigate polymer foams with defined pore shapes, pore sizes and a pore size gradient. The unit cells range from 10 to 2.5 mm in edge lengths and have either spherical pores (7.5 to 1.8 mm in diameter) or cubic pores (7.6 to 1.9 mm in edge length). The unit cells were assembled by a computer aided design (CAD) software into uniform and graded materials with constant density but varying pore sizes, and subsequently fabricated by stereolithography 3D printing.

We found that materials with cubic pores have a higher E-modulus but a lower yield strength compared to materials with spherical pores. In contrast, the graded materials have lower mechanical properties as their uniform counterparts, no matter the pore shape. Moreover, the pore size influences the material's mechanical response, which is linked to the fabrication process. FEM simulations combined with μ -CT scans were used to analyze the stress distribution during compression, and the effects of fabrication-induced geometric deviations. Consequently, our study emphasizes the critical role of identifying and considering fabrication process related defects and deviations for material property characterization. Apart from this, it demonstrates that mechanical properties of polymer foams can be tailored not only via the density but also by the morphology: shape matters.

Development and Weather Aging Evaluation of Thermoplastic Eco-Friendly Composites Reinforced with Pyrolyzed Biochar

Dr. Ioannis Ioannou, Cyprus

Oral Presentation (20')

Abstract

The increasing demand for sustainable materials has spurred interest in eco-friendly composites utilizing renewable resources. This study investigates the impact of aging on the performance of thermoplastic matrices reinforced with biochar inclusions. A carbon-rich material was produced via the pyrolysis of agricultural waste. The biochar was incorporated into the thermoplastic via the twin roll method, to enhance its mechanical and thermal properties, including tensile modulus, tensile strength, bending modulus, and melting point. A key focus of the study was assessing the long-term durability of the composites through a comprehensive aging analysis.

Samples were subjected to accelerated weather aging, simulating prolonged exposure to environmental conditions, and compared with physically aged samples under real-time conditions. This comparison enabled the estimation of an aging factor specific to the material, providing deeper insights into its long-term performance and reliability. The mechanical and thermal properties of pristine, accelerated-aged, and physically aged materials were thoroughly evaluated.

This study highlights the potential of pyrolyzed biochar-reinforced thermoplastics, offering a viable route for repurposing agricultural waste into high-value, eco-friendly materials.[1-3]

Paper 762 **1** **FATIGUE CRACK GROWTH BEHAVIOUR OF POLYACRYLAMIDE ALGINATE DOUBLE NETWORK HYDROGELS**

Prof. Alicia Salazar, Spain

Oral Presentation (20')

Abstract

A hydrogel is an aggregate of water and polymers, and usually contains more water than polymers. This structure makes them very soft and flexible and biocompatible. These materials, traditionally employed in the biomedical field, are emerging as candidates for potential applications in tissue engineering, flexible electronic devices, etc, where they are required to sustain prolonged static and cyclic loads. The main drawback is that the fatigue response of these materials is still limited, and many uncertainties are still unsolved concerning the fatigue analysis. Thus, this work investigates the fatigue crack propagation in polyacrylamide-alginate double-network hydrogels, materials known for their outstanding mechanical properties. Unlike previous studies in the literature, which have been performed under dry or partially hydrated conditions, this study focuses on tests performed under full immersion conditions, an aspect so far unexplored in the scientific literature. Therefore, the objective is to analyze the effect of alginate concentration on the fatigue crack propagation response of polyacrylamide-alginate double-network hydrogels when the specimens are fully immersed in an aqueous medium. The effect of delayed fracture is also analyzed, a phenomenon in which a specimen cracked under the action of a static load, below which fracture would occur, experiences crack growth.

Fracture toughness evaluation for filled rubbers towards the most appropriate energy parameter and test conditions

Ph.D. Isabella Denora, Italy

Oral Presentation (20')

Abstract

Filled elastomers are widely used in industrial products such as tyres, hoses and sealings, whose integrity is essential to maintain their function. A proper characterization of materials fracture behaviour is therefore fundamental for the appropriate material selection. Currently, there is not a standard for the evaluation of fracture toughness of rubber materials in quasi-static loading conditions and different fracture tests are proposed in literature. Their consistency has been verified for unfilled elastomers, for which the critical value of the tearing energy (T) at fracture initiation in mode I fracture tests has been found to be independent of the loading conditions and thus proposed as a measure of materials' fracture toughness. Further, the critical value of the tearing energy of unfilled rubbers at fracture onset resulted to be consistent to that of an alternative energy-based parameter, J -integral. For filled rubbers, literature reports both differences between the results obtained from different loading conditions and between the values of T and J critical for fracture onset (T_c , J_c).

In this work, a study on the fracture behaviour of three filled elastomers differing in the type of rubber matrix (NBR, SBR) and/or filler type (CB, silica) was performed. Single-edge notch tensile tests, biaxial tension on centre-notched squared specimens and fracture tests in pure shear deformation on single-edge notched specimens were performed at 23°C and 1 min⁻¹. The values T_c and J_c were evaluated from the different tests and compared. Analytical formulations and, in some cases, finite element analysis-based solutions were adopted to assess the parameters' critical value for the occurrence of fracture. A quite good correspondence between T_c and J_c has been obtained for a highly CB-filled NBR, irrespectively of the loading conditions. For the more deformable silica-filled NBR, higher T_c and J_c values were obtained from SENT tests. Regarding the effect of specimen geometry on the SENT tests results, it was investigated if the notch length, a_0 , affects fracture phenomenology and the T_c value and whether the observed effects depend on the material (the above-mentioned CB-filled NBR and a silica-filled SBR). A a_0/W ratio value in the range between 0.07 and 0.33 was adopted ($W = 30$ mm is the width of the 120 mm long specimens of SENT tests). For both materials T_c seems to be not significantly affected by a_0/W . However, the two materials seem to differ in the fracture phenomenology, with the SBR showing a crack deviation during fracture propagation.

Paper 1127 3

Thermal treatment on a silica-filled NBR preliminarily softened by stretching: effect on fracture toughness and fracture propagation process

Mrs. Alice Bianucci, Italy

Oral Presentation (20')

Abstract

When filled rubber compounds are deformed, they exhibit a softening depending on the applied stretch level: in subsequent loading cycles, lower stresses are observed for strains below the maximum strain applied in the first loading cycle. Several studies have shown that the pristine uniaxial tensile behaviour of the material can be recovered through the application of appropriate thermal treatments. However, limited research has been conducted on the thermally induced recovery of fracture behaviour after stretch-induced softening.

This work investigates the effect of stretch-induced softening and its thermally induced recovery on the fracture behaviour of a silica-filled NBR. A thermal treatment has been defined that preserves the tensile behaviour of the pristine material but allows an almost complete recovery of the tensile behaviour of the material preliminarily softened through load-unload cycles under uniaxial tensile conditions. The fracture behaviour was assessed by performing quasi-static tensile tests on notched specimens in pure shear deformation conditions. Tests were video recorded to identify the crack onset and measure the crack advancement. Initially, stable crack propagation occurs, which stops if the specimen elongation is kept constant and no further strain energy is supplied to the specimen. Subsequently, crack propagation becomes unstable, causing the crack to propagate even without a further increase in overall deformation. The energy-based J-integral parameter was evaluated until the initiation of unstable crack propagation and plotted versus the crack advancement, obtaining a resistance curve. The stable crack propagation rate was also evaluated and represented as a function of the J-integral, similarly to the Paris-Erdogan representation. The J-integral values at the onset of both stable and unstable crack propagation were considered as a measure of material's fracture toughness. The softening induced by stretching the material up to 350% deformation caused a decrease in the fracture toughness due to the less dissipative behaviour of the softened material. After thermal treatment, the softened material showed a partial recovery of the overall force-displacement response. However, the J-integral values at crack onset and unstable fracture initiation remained comparable to those of the softened material, with the resistance curve even lower than that of the softened material. From the analysis of the crack propagation rate, it was observed that the thermal treatment accelerates the fracture propagation. As a result, the response of the thermally treated softened material derives from the superposition of a beneficial effect (recovery of stretch-induced softening) and a deleterious one (acceleration of crack growth).

4

Enhancing silicone rubber functionality with thermally conductive fillers

Mr. Kevin Klier, Germany

Oral Presentation (20')

Abstract

Soft materials, especially silicone rubber, have gained attention in recent years, with efforts to develop multifunctional materials. Silicone materials now face stricter requirements, particularly in long-term temperature resistance. To manage high temperatures and reduce thermal load, thermally conductive particles are added for heat dissipation. These materials are particularly useful in e-mobility, where faster charging generates more heat that needs to be managed. Despite their advantages, elastomers exhibit low thermal conductivity compared to metals and ceramics, typically ranging from 0.1 W/m²K to 0.5 W/m²K.

This study investigates the influence of ceramic fillers – aluminum oxide (Al₂O₃), boron nitride (BN), and a combination of aluminum oxide and zinc oxide (ZnO) – with different particle sizes, on the thermal conductivity of solid silicone rubber. Additionally, the impact of potential synergistic interactions from the simultaneous addition of selected fillers is explored to identify pathways for enhancing thermal conductivity. In addition to the interactions, the mechanical properties of the thermally conductive silicone rubber are also determined.

Our study demonstrates that by using a combination of different ceramic fillers with optimal particle sizes and distribution, we can enhance the thermal conductivity from 0.2 W/mK to over 2.0 W/mK.

Furthermore, the thermal conductivity of the silicone compounds is examined under various pressure and temperature conditions to better understand its behavior under realistic application conditions. The results reveal that the influence of pressure and temperature on thermal conductivity is linear within pressure ranges from 10 bar to 200 bar and temperatures from 30 °C to 200 °C.

5

Structural integrity of sustainable thermoplastic elastomers

Mr. Stefano Gozzini, Italy

Oral Presentation (20')

Abstract

To be more sustainable and move towards green technology, more and more efforts are being made to use more environmentally friendly materials. In this context this research is proposed, where sustainable thermoplastic elastomers (TPE) are analysed to replace the non-sustainable polymeric materials currently employed for protective mask frames for cleanroom applications. Considering the mask's reuse requirement, the durability is an important concern, especially the fracture resistance of TPEs, to ensure safe and long-term usability of protective masks. Therefore, the main objective of this work is to evaluate the fracture resistance of TPEs with a reduced environmental impact. Due to the marked viscoelastic nature of these materials, it will be necessary to apply the Viscoelastic Fracture Mechanics approach to determine the fracture resistance curves and the specific energy associated with the onset of crack propagation. Load relaxation tests in tensile mode will be performed and the Single Edge Notch Tension (SENT) configuration will be chosen for the fracture characterization. Evaluating fracture parameters, together with other indicators also determined in previous works, will help to discriminate among potential candidates the best TPE to replace the unsustainable material used in the protective mask frames.

Paper 1500 6

A study of the mechanical behaviour of a 3D printed thermoplastic polyurethane: from material-controlled Mullins effect to process-dominated fracture behaviour

Prof. Claudia Marano, Italy

Oral Presentation (20')

Abstract

This work is the result of a collaboration between Politecnico di Milano and Instituto Superior Técnico, Lisboa. The aim is to study the mechanical behaviour of 3D printed components based on a thermoplastic polyurethane and produced through the filament fused fabrication (FFF) technique. The TPU92A from Fillamentum characterised by T_g of -40 °C and T_m of 200 °C was used.

A preliminary mechanical characterization was performed using 3.2 mm thick dumbbell shaped specimens, printed with YXZ (flatwise) printing orientation (ASTM F2921 terminology): in the 7.4 mm wide and 33 mm long gauge area, each layer consists of 19 deposited material beads, aligned along the direction of the specimen's gauge-length. Uniaxial tensile tests have been carried out at 23°C, at different strain rates (0.6 and 6 min⁻¹) to highlight any viscoelastic response of the material. Loading-unloading cyclic tests were also carried out up to different strains, to evaluate the dissipative response of the material and its dependence on the applied strain.

Rectangular-shaped specimen 1.6 mm thick, with a gauge area 100 mm wide and 20 mm long, were 3D printed with the YZX (Edgewise) printing orientation (ASTM-F2921). Each layer consists of 4 beads aligned along the X axis. A 15 mm long notch was introduced on one edge of the specimen, at its mid-plane, using a razor blade. Fracture tests were performed at 23°C and nominal strain rate of 0.6 min⁻¹, stretching the notched specimen in the direction perpendicular to the layer planes. The energy-related parameter, J-integral, was evaluated to characterize the inter-layer adhesion strength. Different nozzle temperature (235 or 240°C), layer thickness ($t_L=0.2$ or 0.3 mm), deposition paths (aligned-rectilinear or concentric), and the use or absence of a cooling fan were considered in the printing process.

The uniaxial tensile tests show: (i) a change in the structure of the material, induced by the preliminary stretching, (ii) a residual strain present at the end of the unloading step, partially recovering with time, (iii) no significant effect of the printing parameters on the 3D printed specimen tensile response within the explored ranges.

From the fracture tests, a higher fracture resistance value was obtained for pure shear specimens printed at 240°C, with $t_L=0.2$ mm and non-use of the cooling fan.

Microscopic observations of the fracture surfaces are in progress to try to correlate the measured fracture toughness with the actual contact area and morphology of the fracture surfaces.

Corrosion mechanisms under phosphate-rich deposits during (co)-incineration of sewage sludge and mitigation strategies for sustainable waste management

Dr. Ceyhun Oskay, Germany

Keynote (Oral Presentation 40')

Abstract

Sewage sludge (SeS) needs to undergo thermal treatment in the European Union due to recent legislation changes targeting sustainable waste management. This thermal treatment results in the formation of sewage sludge ash (SSA), which offers great potential for phosphorus recovery. Approximately half of this process occurs through mono-incineration. The remaining half involves co-incineration, predominantly taking place in coal-fired power plants. Therefore, the influence of such phosphate-rich ash deposits on the corrosion of superheater tubes of power plants needs to be thoroughly investigated since such systems were never designed for this purpose. While (co-)firing of biomass increases corrosion rates significantly due to the formation of low-melting deposits and the superimposition of active oxidation and sulfidation, little is known about the corrosion mechanisms under phosphate-rich deposits.

This study investigated the corrosion mechanisms during the mono-incineration of SeS at 500°C and its co-incineration with bituminous coal at 625°C. Quasi-isothermal corrosion tests up to 7000 h were undertaken for various steels ranging from 9% Cr steels, e.g. P92, to high alloyed steels such as AC66. The samples were exposed in alumina crucibles to gas atmospheres including H₂O, CO₂, HCl, SO₂, representing the mono- and co-incineration of SeS while being embedded into simulated SSA containing Ca₃(PO₄)₂ or FePO₄ and Ca₅(PO₄)₃ among other sulfate and chloride species. Thereafter, water-free metallographic preparation of cross-sections, wall-thickness measurements, SEM and EPMA investigations were used to characterize the corrosion attack. Even though the attack is significantly aggravated when compared to coal ash in the case of co-firing at 625°C, possibly due to the formation of additional low-melting eutectic deposits, the results suggest that balanced Ni/Cr content can provide sufficient protection against both, chlorine-induced corrosion and sulfidation. In the case of mono-incineration of SeS at 500°C, higher PO₄-content in the SSA led to the formation of a dense Fe₃PO₇ outer scale on low Cr-steels, which improved the corrosion resistance compared to the PO₄-lean ash compositions. Cr-Si slurry coatings and Cr-rich alloy claddings substantially elongate the corrosion lifetime in mono-incineration and co-incineration. Their application can enable low-Cr-steel superheater tubes as structural materials in the co-incineration.

Paper 1860 2 **Oxidation of additively manufactured Ni-base alloy IN625: mechanism of intergranular oxidation**

Dr. Anton Chyrkin, Sweden

Highlight (Oral Presentation 20')

Abstract

Ni-base superalloys are state-of-the-art structural materials for high-temperature applications requiring both high creep strength and environmental resistance, e.g., in power generation, jet-engine technology, petrochemical industry, nuclear technologies, heat processing, etc. Additive manufacturing (AM) of high-temperature alloys has been booming in the past decade, especially in aeronautics, where AM offers a significant flexibility of shaping components as well as decreasing material waste

Additively manufactured (AM) LB-PBF Ni-base alloy IN625 suffers from intergranular oxidation (IGO) during air exposure at 900 °C in contrast to the conventionally manufactured (CM) forged alloy. IGO is triggered by oxide buckling over the grain boundaries (GBs) in the alloy followed by oxidation of the open intergranular voids. The Cr₂O₃ scales thermally grown on the AM and CM alloy specimens were analyzed with SEM/EDX, EBSD, GD-OES, TEM and APT. A new mechanism of IGO in AM alloys highlighting the role of oxide scale adhesion is proposed and experimentally validated.

Paper 1744 3 High Temperature Intergranular Oxidation of Nickel Based Superalloy Inconel 718 and Stainless Steel 316L

Mr. Sudhanva Madhusudan, France

Oral Presentation (20')

Abstract

Keywords: Inconel 718, 316L, Intergranular oxidation, Wagner's theory.

In polycrystalline alloys, grain boundaries (GBs) can undergo preferential oxidation [1]: this phenomenon is known as Intergranular Oxidation (IGO). Oxidized GBs can act as initiation sites for cracks, resulting in premature failure. Therefore, in order to predict the behaviour of alloys in harsh environments, it is important to understand IGO. Although there are several works that deal with experimental characterization of IGO [1-3], there is no recognized model for it.

Sanviemvongsak et al. studied the IGO of the Ni-based IN718 superalloy at 850°C [2]. In these conditions, even if forming a Cr₂O₃ external scale, the alloy is subject to IGO: oxides rich in Al and Ti are observed in the GBs. The IGO penetration depth was found to follow a parabolic kinetics. An analytical model was derived to describe the parabolic rate for the evolution of IGO penetration depth, based on Wagner's theory for internal oxidation. The proposed IGO mechanism involves two competing processes. The first one is the inward diffusion of oxygen to the tip of the oxidation front, along the incoherent interfaces between the intergranular oxide and the alloy matrix; the second one is the outward diffusion of Al and Ti.

The objective of the present work is to verify the validity of this model for the IGO of IN718 and the stainless steel 316L. To this aim, oxidation experiments on these alloys were performed at two temperatures, 650°C and 700°C, for durations up to 10,000 hours. Samples were removed periodically and weighed. Then, X-ray diffraction (XRD) and Scanning Electron Microscopy (SEM) characterizations were performed on the samples. These characterizations were performed at three intermediate durations: 1000 h, 3000 h and 5000h. New IGO data were obtained by systematic microscopic characterizations. These data are herein compared to the model described by Sanviemvongsak et al. [2].

Paper 709 4 Effect of heat treatment on the mechanical property and deformation mechanism of a novel cast nickel-base superalloy

Dr. Min Wang, China

Oral Presentation (20')

Abstract

Alloy 718 is one of the most widely used superalloys in the field of aerospace. Thanks to its good casting property, Alloy 718 can be used to fabricate complex large-sized thin-walled structures for aero-engine applications. However, the maximum operating temperature of Alloy 718 is limited to 650°C. In this work, a novel weldable cast nickel-base superalloy named K4800 is developed, which can be used at 800-850 °C. K4800 possesses excellent tensile properties at both room and elevated temperatures with a good combination of strength and ductility. The creep life of K4800 is not less than 100h under 800°C /430MPa, 815°C /379MPa, and 870°C /255MPa. Meanwhile, this material has outstanding microstructural stability with the absence of undesirable phases like σ or η after long-term aging. The microstructure of K4800 consists of γ , MC, M₂₃C₆, and the γ' (~35 vol.%) in two sizes. It is found that a premature aging process, in which the large-sized γ' forms, is beneficial and somewhat necessary to regulate the precipitation feature of small-sized γ' in the secondary aging. It was found that the sub-solvus aging treatment between 1090 and 1060 °C precipitates sub-micron-sized primary γ' phase which enhances the ductility during 800 °C tensile without evidently impairing the strength. The enhancement was rationalized that the precipitation of sub-micron-sized primary γ' phase decreases the volume-fraction and size of the secondary nanometer-sized γ' phase, and promoted the dislocation movement by suppressing the non-planar slip. However, an excessive amount of the sub-micron-sized primary γ' phase led to a faster ripening process of the nanometer-sized γ' during creep. An area fraction less than 7 % of the sub-micron-sized γ' phase is determined to have limited detrimental effect on the creep life of K4800 alloy, which corresponds to a sub-solvus temperature range about 1080–1090 °C. The dominant deformation mechanisms of K4800 at the yielding stage were identified as: APB shearing from RT to 600 °C, SF shearing and Orowan looping at 600 to 800 °C, and Orowan looping/cross-slip/climbing above 800 °C.

Paper 156 **5** **Optimizing the strength of Ni-based superalloy Udimet 720Li through tailored heat treatments**
Mr. Andreas Hausmann, Germany
Oral Presentation (20')

Abstract

The outstanding mechanical properties of superalloys are largely influenced by their microstructure, such as grain size, volume fraction, morphology, and size distribution of the γ' precipitates. The microstructure is determined by the heat treatment, e.g. solution annealing, quenching, and subsequent aging. To study the effect of the heat treatment process, four different solution annealing temperatures, four different cooling rates, and two different aging steps were used to produce diverse microstructures in the polycrystalline, cast-and-wrought disc alloy Udimet 720Li. Characterization of the microstructures is carried out by scanning electron microscopy and transmission electron microscopy investigations. The mechanical properties were evaluated using Vickers hardness testing and compression tests at room temperature. A sub-solvus solution annealing temperature and an intermediate cooling rate led to the highest yield strength. The super-solvus solution annealing temperature led overall to the lowest yield strength at any cooling rate. This research resulted in a better understanding of the effects of the heat treatment process on the mechanical properties and microstructure, which will be useful for designing optimal heat treatment processes.

Paper 2005 **6** **Evolution of microstructure and mechanical properties as a consequence of tensile creep strain of NNS-HIPped nickel-based superalloy**
Mr. Jehanzaib Anwar, Italy
Oral Presentation (20')

Abstract

Nickel superalloys are being widely used in high-temperature applications such as aerospace and power generation due to their excellent mechanical properties. However, long-term exposure to high temperatures under continuous stress leads to microstructural and mechanical degradation, making it unfit for the service. Therefore, in this study, the creep behavior of Astroloy fabricated via near-net shape hot isostatic pressing (NNS-HIP) is analyzed. NNS-HIP is a powder metallurgy technique enabling precise component fabrication by densifying loosen powders in a pre-designed capsule under high temperature and isostatic pressure brought by compressed inert gas. Creep tests were conducted at different temperature (650, 760 & 820 °C) and stress conditions. Optical and scanning electron microscopy (SEM) analysis revealed that increasing temperature influences the transition of primary γ' precipitates from discontinuous to interconnected, facilitating intergranular crack initiation and propagation. Additionally, hardness testing demonstrated a direct correlation between excessive precipitates coarsening and reduced mechanical properties, with a decline in hardness at 820°C compared to 650°C. The results emphasize the necessity of optimizing operational temperature and stress parameters to mitigate detrimental precipitation and cracking, resulting in improved lifespan of the part.

Paper 803 7 **Development of a novel Method for repairing Crack-like Structures in Ni-based Superalloys**

Mr. Vurgun Sayilgan, Germany

Oral Presentation (20')

Abstract

Single-crystal (SX-) turbine blades made of Ni-based superalloys are used in high-pressure stages of jet engines. The harsh operating conditions result in wear and the formation of cracks which impair the engine lifetime. Currently, the repair of SX blades is limited as conventional repair methods are not capable of regenerating the required SX microstructure in the applied region.

In previous investigations, the high potential of the additive manufacturing technique laser- and powder-based directed energy deposition (DED-LB/P) for repairing SX blades has already been demonstrated. By using a two-step approach of deposition and a subsequent remelting of the material, the regeneration of a directionally solidified microstructure was achieved. This two-step approach was developed in baseline investigations using substrate sheet material and then transferred to the tip of high-pressure turbine blades.

In this study, the repair of crack-like structures with different width-to-depth ratios in two different SX Ni-based superalloys has been investigated. The goal of this contribution is to examine a broad range of artificially introduced defects and evaluate their reparability by DED-LB/P. The required SX-microstructure in the substrate material is achieved by the Bridgman-method with a subsequent heat treatment. In order to simulate a broad range of defect dimensions, an ultrashort pulse laser process was utilized to intentionally introduce notches (crack-like structures) into the substrate. The investigated widths range from 0,1 to 0,4 mm with depth from 0,25 to 0,4 mm. For a profound analysis of the interrelations between defect geometry, process parameters and resulting microstructure, a central-composite experimental design was used. The design of experiment includes the process parameters laser power, traversal speed and powder feed rate as well as the area fraction of SX area with the repaired section and degree of closing of the crack-like structure.

This study demonstrates that closing the crack-like structures is possible for depths up to 300 µm. The experiments show that a greater depth of crack-like structures is challenging regarding the closure of the whole volume and with respect to its resulting microstructure. This contribution highlights the conflict of applying a high line energy to achieve greater melting depths and the use of a low line energy, which is required to achieve single crystallinity in the resulting microstructure. In general, high thermal gradient and high solidification rates are required to maintain SX directional solidification. Furthermore, this study highlights the effect of a prior remelting of the crack-like structure before applying material by DED-LB/P.

Modeling of the thermodynamic and diffusivity properties of the Ti-N system

Dr. Enrica Epifano, France

Highlight (Oral Presentation 20')

Abstract

Titanium alloys are excellent materials for aeronautic engines, thanks to their high strength-to-weight ratio. However, their current use is limited below 650 °C, due to issues like environmental embrittlement and poor creep resistance at higher temperatures. When titanium alloys are exposed to oxidizing environments at high temperatures, a TiO₂ scale forms, accompanied by significant oxygen dissolution (up to ~33 at.%) into the alloy [1]. This oxygen-rich layer is approximately three times thicker than the oxide itself and is responsible for a loss of ductility [2-3]. Nitrogen plays an important role [3-6]. For many titanium alloys, oxidation kinetics are slower in air than nitrogen-free atmospheres [3], [5]. This effect has been attributed to (1) the formation of oxynitride/nitrides between the oxide and the metal and (2) competition between oxygen and nitrogen dissolution [5]. Nitrogen has effects similar to those of oxygen on the mechanical properties of titanium; however, it diffuses more slowly, thereby reducing the depth of the affected zone [7]. Consequently, both the (oxy)nitride and the nitrogen-rich zone act as diffusion barriers for oxygen [5], with beneficial effects on oxidation resistance [3]. To predict these complex equilibria and guide the design of new alloys, a comprehensive understanding of the thermodynamic and kinetic properties of the Ti-N-O system is essential. Current thermodynamic databases fail to reproduce our experimental observations [5]. Therefore, as a first step, we conducted an extensive study of the thermodynamic and kinetic properties of the Ti-N system by experimental investigations, DFT, and CALPHAD modeling. Diffusion couples experiments between Ti and TiN have been performed and completed by accurate characterizations, including EPMA, EBSD and TEM. The new data have been adopted to improve the previous CALPHAD thermodynamic assessments of the Ti-N system [8-9]. A diffusivity database is being developed using diffusion coefficients from experiments and DFT calculations.

Paper 1148 2 **Evolution of the microstructure and mechanical properties of TiNbAl (beta+O) alloys with additions of Ta, Mo or W**
Dr. Philippe Vermaut, France
Oral Presentation (20')

Abstract

Ti- Nb-Al ternary system with the precipitation of stable orthorhombic phase in the bcc matrix are potential candidates to replace nickel or TiAl alloys for high temperature application in aircraft engines, between 800°C and 1000°C. These alloys, with a Nb/Ti ratio = 1 and 15%Al present good mechanical properties, combining rather good resistance to damage at room temperature and high resistance at high temperature. In order to increase the service temperature of such alloys, the effects of a partial substitution of Nb by refractory elements such as Ta, Mo and W, on the precipitation of the O-phase have been investigated by scanning and transmission electron microscopy. The evolution of the mechanical properties with the chemical composition and heat treatments has been followed by hardness measurements and compression tests at 800°C, and discussed in relation with the observed microstructures.

Paper 461 **3** **High temperature oxidation behaviour of Ti-nitrides and O or N-enriched Ti model materials**
Mrs. Tripti Gaur, France
Oral Presentation (20')

Abstract

Titanium-based alloys are widely used in the aeronautic industry for their high strength-to-weight ratio. However, their use is limited below 650 °C, due to issues like environmental embrittlement and poor creep resistance [1]. In high-temperature oxidizing environments, alongside TiO₂ scale formation, significant oxygen dissolution could occur in the alloy and lead to reduced ductility [2]. Nitrogen, from air, plays also an important role in the oxidation of Ti alloys [3,4,5,6]. Recent works suggested its beneficial effect on the oxidation resistance of some Ti alloys, due to the formation of nitrides and/or oxynitrides at the oxide/alloy interface [4,5,6], acting as diffusion barrier for oxygen. However, the formation mechanism of these nitrides/oxynitrides is unclear and the oxidation behaviour of Ti₂N is also unknown.

In order to shed some light on these phenomena, two sets of experiments were conducted. First, the oxidation behaviour in air of TiN and Ti samples enriched in O (concentrations from 0 up to 20 at. %) or N (5 at. %) was studied at 650 °C, for durations up to 1000 hours. The mass variation of each sample was recorded with time, during the oxidation tests. However, it was not possible to obtain a sufficiently pure Ti₂N sample to study in these conditions. So, a Ti-TiN diffusion couple (DC) was prepared by spark plasma sintering and was subjected to a heat treatment at 800 °C, under vacuum, for two months, to promote the formation of a Ti₂N layer (approximately 30 µm thick) at the Ti/TiN interface. The DC was then oxidized in air at 650 °C for 500 hours to evaluate the oxidation behaviour of all phases (Ti, Ti₂N and TiN). The oxidized samples were then characterized using X-ray diffraction, Raman spectroscopy and scanning electron microscopy with energy dispersive spectroscopy.

Misfit strains and deformation behavior of lamellar (α_2 + γ) colonies in-Ti-42Al-8.5Nb

Dr. Heike Gabrisch, Germany

Oral Presentation (20')

Abstract

Conventionally used γ -titanium aluminides consist of lamellar colonies formed by the Al-rich γ -phase (tetragonal) and the Ti-rich α_2 -phase (hexagonal). In Nb-containing γ -alloys the α_2 -phase can transform to the orthorhombic O-phase during slow cooling or during annealing between 480 und 650 °C. The transformation is observed if the Nb content exceeds a threshold between 5-7.5 at-%. It is accomplished by stretching the hexagonal lattice along three equivalent α_2 - $\langle 11-20 \rangle$ directions. The orientation relationship between α_2 and O-phase is $(0001)\alpha_2 // (001)O$ -phase and $[11-20]\alpha_2 // [100]O$ -phase. The initially formed O-phase has the identical composition as the α_2 parent phase, Ti-38Al-9Nb. With prolonged annealing time, this metastable phase separates into a mixture of hexagonal α_2 and orthorhombic O-phase. The compositions of the newly formed phases are Ti-37Al-6Nb (α_2 -phase) and Ti-36Al-12Nb (O-phase). The replacement of α_2 -phase by (α_2 + O)-phases introduces strains to the lattice of the former α_2 -phase lamellae. These can be seen by high resolution imaging where the crystal lattice is continuous but deformed across the α_2 -O-phase boundaries. Internal stresses resulting from small differences in lattice parameters can be measured conveniently by high-energy X-ray diffraction (HEXRD), giving average results over a large volume. These measurements show that the lattice parameter of γ -phase stays constant after different annealing times, while the lattice spacings in the O-phase vary. In the TEM, microstructural characteristics can be traced on a more localized scale. We monitor the relative strains between (α_2 /O)-phase lamellae and γ -lamellae in different annealing states by precession diffraction using the Nanomegas© system in a Talos F200i Transmission Electron Microscope. The measurements show an increase in the mismatch between (α_2 /O)-phase lamellae and γ -lamellae with annealing time. In a second experiment we evaluate the effect of the O-phase on the mechanical properties of the alloy. Micro-pillars of lamellar colonies in selected orientations were milled in an FEI Nova 200 dualbeam FIB/SEM microscope and were deformed at room temperature at constant strain rate in a Hysitron TI 980 Nanoindenter. The results of these experiments show a higher yield stress in the annealed alloy than in the alloy without O-phase. Furthermore, the yield stress strongly depends on orientation. Finally, dislocations and twinning activities in the deformed microstructures were observed by Transmission electron microscopy using cross-sections that were excised from the deformed pillars by focused ion beam milling.

Paper 270 **5** **Research Progress in High-Temperature Titanium Matrix Composites and Their Precision Thermoforming Technology**

Prof. Yuyong Chen, China

Oral Presentation (20')

Abstract

Titanium matrix composites (TMCs) have low density, high specific strength, excellent corrosion resistance, as well as superior oxidation resistance at higher temperatures, which can effectively compensate for shortcomings of existing high-temperature alloys, such as their high density or low service limit temperature, and show broad application prospects in aerospace, automobile manufacturing, weapon equipment, and biomedicine. However, due to its unique properties, the thermoforming process faces many challenges. For example, casting defects such as interface reactions, shrinkage porosity, and misrun are easily formed during the investment casting process because of the low fluidity, significant solidification shrinkage, and high chemical reactivity. Additionally, the addition of reinforcements will increase the difficulty of the thermal processing of TMCs, so it is extremely challenging to prepare a large-size thin sheet.

In this work, an in-situ particle-reinforced high-temperature TMCs resistant to 700 °C were effectively developed by optimizing the composition design on the basis of a 650 °C short-time high-temperature titanium alloy. A specific kind of aerospace cabin and skeleton were developed using investment casting technology. After heat treatment, the tensile strength of the part at room temperature is 1200 MPa, with a 7% elongation. At 700 °C, the tensile strength is 650 MPa, and it is 560 MPa at 750 °C. Furthermore, the TMCs thin sheets of 2060 × 680 × 2 mm were prepared by the pack ply-rolling technique, which is the largest size of TMCs sheets reported. Notably, the tensile strength of the sheet at 700 °C is 592 MPa following multi-step heat treatment, which can effectively satisfy the service requirements. In the near future, we have additionally prepared 2150×650×0.8 mm sheets, which will better meet the real engineering demands. More importantly, this work provides novel guidance for future materials design and production to satisfy specific engineering requirements.

Development of Ca-based coatings for vanadium alloys used in high temperature corrosive environments

Mr. Mark Alexander Ulherr, Germany

Oral Presentation (20')

Abstract

The constant aim to increase gas turbine efficiencies is strongly coupled to an increase in service temperature. For that purpose, the materials must retain their mechanical properties at high temperatures and simultaneously be oxidation resistant. As an alternative to state-of-the-art Ni-based superalloys, vanadium alloys are interesting due to their lower density and high strength. They were recently investigated based on the intermetallic-reinforced Mo-Si-B alloying concept with V instead of Mo. Still, the V solid solution matrix is prone to oxidation, making the material unusable for most technical applications due to the melting point (~680 °C), toxicity and corrosiveness of vanadium oxide. The classical alloying elements that form a protective external scale, Cr and Al, are non-protective against molten vanadate corrosion. Alkaline earth metal oxides can suppress this V₂O₅ corrosion as they can form higher melting, more stable vanadates. Ca was found to form more stable compounds than Mg and is interesting due to its low cost and availability. In this work, Ca-based coating systems were developed and tested for V alloys. The composition and morphology were validated via optical microscopy, XRD, Raman spectroscopy, and SEM. Oxidation experiments of the coated V alloys were performed at 600-800 °C to investigate the oxidation resistance of the new material system.

Paper 1585 1 Advanced Polycrystalline γ' -Strengthened CoNiCr-Based Superalloys

Dr. Steffen Neumeier, Germany

Highlight (Oral Presentation 20')

Abstract

Novel complex concentrated CoNiCr-based superalloys with excellent mechanical properties have been developed, which combine the multiprincipal element nature of high-entropy alloys with the precipitation strengthening in superalloys. A series of advanced polycrystalline γ' -strengthened CoNiCr-based superalloys, called CoWAlloys, with varying contents of Al, W, Ti, Ta, Mo, and Nb are investigated in terms of microstructure, thermophysical properties, yield, and creep strength. The microstructure of all CoWAlloys consists of an fcc solid solution matrix phase (approximate γ composition in at. pct: 50Co–20Ni–20Cr–10X (X = other alloying elements)), which is strengthened by a multicomponent γ' (Ni,Co)₃(Al,Ti,Ta,W,Nb)-based precipitate phase with a very high-volume fraction of around 60 vol pct (approximate γ' composition in at. pct: 45Ni–30Co–25X). These alloys have high solidus temperatures above 1300 °C and moderate γ' solvus temperature between 985 °C and 1080 °C leading to a large processing window. The increasing content of γ' -forming elements Ti, Ta, W, and Nb decreases this window, but increases the γ/γ' lattice misfit and the anti-phase boundary energy, which contribute to a significantly higher yield and creep strength. In another series, the effect of substituting Fe for Co was investigated. Despite a decrease in creep strength with higher Fe content, the alloys still demonstrate comparatively good creep properties.

In order to better classify the properties of these CoNiCr-based superalloys, they are also discussed in comparison with conventional polycrystalline Ni-base superalloys and so-called L1₂-strengthened high-entropy alloys, revealing that the creep strengths of the CoWAlloys are significantly higher. This is due to the reduced strain rate sensitivity of the CoWAlloys due to different underlying deformation mechanisms: By increasing the anti-phase boundary energy, a transition to stacking fault shearing and microtwinning occurs. Additionally, high-resolution scanning transmission electron microscopy coupled with energy dispersive spectroscopy measurements reveal that solute segregation towards these planar defects occur and that the stacking faults locally transformed into the ordered hexagonal χ and η phases. This significantly enhances the creep strengths of superalloys during high-temperature deformation. Additionally, this study discusses the kinetic aspects of solute segregation and subsequent local phase transformations at the stacking faults. Based on these results, guidelines and strategies for the design of next-generation advanced high-temperature polycrystalline superalloys are proposed.

Paper 1098 2 Bridging Alloy Design and Processing: Microstructure, Mechanics, and Additive Manufacturing of Hf-Mo-Nb-Ti RMPEAs

Mrs. Julia Chmielewska, Switzerland

Oral Presentation (20')

Abstract

Refractory multi-principal element alloys (RMPEAs) within the Hf-Mo-Nb-Ti system exhibit excellent mechanical properties, high-temperature stability, and thermal resistance, making them strong candidates for structural applications in extreme environments. However, the composition-dependent mechanical behavior of these alloys remains insufficiently understood, necessitating systematic experimental validation. Additionally, conventional processing methods introduce challenges such as elemental segregation and coarse grain formation, which compromise microstructural uniformity and mechanical reliability. Additive manufacturing (AM) offers a promising alternative by enabling rapid solidification, refined microstructures, and near-net-shape fabrication, potentially overcoming these limitations and expanding the processing window for RMPEAs.

This study investigates the mechanical response of RMPEAs through micropillar compression and nanoindentation under controlled loading conditions, correlating experimental results with computational modeling. Thermal stability was assessed via in situ high-temperature X-ray diffraction (XRD), confirming a predominantly body-centered cubic (BCC) phase with minor secondary precipitates. As-cast alloys exhibited a dendritic microstructure with elemental partitioning, while annealing at 1600°C for 10 h followed by furnace cooling led to the formation of Hf-rich precipitates within a solid solution matrix. Yield strength and hardness varied with composition, with Mo- and Nb-rich alloys demonstrating increased mechanical strength due to solid solution strengthening. To address processing challenges, laser-based techniques were employed to evaluate the feasibility of AM for RMPEAs. Laser surface scanning reduced elemental segregation and refined the microstructure, mitigating coarse grain formation as confirmed by electron backscatter diffraction (EBSD) analysis. This approach enhanced manufacturability by minimizing the need for extensive post-processing, such as homogenization heat treatments. By integrating experimental characterization with computational validation, this study establishes a framework for designing RMPEAs with tailored mechanical properties, improved thermal stability, and enhanced processability for extreme environments.

Paper 1139 3 Effect of long-term thermal aging on microstructure and tensile properties of a highly-molybdenum nickel alloy

Dr. Hoang Long Le Tran, France

Oral Presentation (20')

Abstract

Highly-molybdenum nickel alloys exhibit exceptional corrosion resistance in chloride-bearing solutions. For this reason, they are promising candidates for structural materials in molten chloride salt environments, especially for the future Molten Salt Reactors (MSR). However, the effect of thermal aging on the microstructure and mechanical behavior of the high-molybdenum nickel alloy have not yet been investigated and well documented. So the objective of this work is to study the effects of thermal aging on the microstructure of Ni alloys and their possible consequences on the mechanical properties of these alloys. In this study, the microstructural evolution of a high-molybdenum nickel alloy, the Hastelloy B3, was investigated after thermal aging at 600 °C and 650 °C for 1 000, 4 000 and 10 000 hours using complementary techniques such as SEM (Scanning Electron Microscopy), EDX-SEM (Energy Dispersive X-ray), SEM-EBSD (Electron Backscatter Diffraction), and X-ray diffraction. Small punch tests and tensile tests were carried out to study the mechanical behavior of the material at room temperature and at 500°C. Fracture surfaces were characterized by SEM to determine the rupture mechanism. The influence of pre-rolling of the material is also studied. The Inconel 625 was also studied under the same conditions for comparison. The study was supported by France 2030 and BPIFrance in the ISAC (Innovative System for Actinides Conversion) project of the France Relance initiative.

Paper 2103 5 Isothermal Oxidation Behavior of Mo-Ti-Si-B Multiphase Intermetallic Alloys at 1200 °C

Mr. Hrishikesh Ghewade, India

Oral Presentation (20')

Abstract

The refractory intermetallic alloys are of interest for increasing the operating-temperature range beyond that of Ni-based superalloys (≈ 1100 °C) to improve the fuel efficiency of aero-engines. The Mo-Si-B based intermetallic alloys possess a strong potential for hot end aero-engine applications due to the possibility of achieving impressive oxidation resistance and fracture toughness through suitable alloying additions. The alloys of compositions Mo-14Si-10B (MSB), Mo-20Ti-14Si-10B (20Ti), Mo-30Ti-14Si-10B (30Ti) and Mo-40Ti-14Si-10B (40Ti) (at. %) have been prepared by both arc melting (AM) and spark plasma sintering (SPS). The X-ray diffraction analysis has confirmed the presence of ductile Moss and Mo₅SiB₂ (T₂) phases in both AM and SPS alloys of all the aforementioned compositions. The Mo₃Si (A₁₅) phase has been found to be absent with a small fraction of Mo₅Si₃ (T₁) phase being formed in the 40Ti alloy, as detected by electron backscattered diffraction analysis. In addition to that, formation of Ti₅Si₃ (D₈₈) phase has been observed in alloys containing 30 and 40 at.% Ti. The oxide scale has been characterized using XRD and FESEM. The X-ray diffraction and FESEM analysis have confirmed the presence of TiO₂ and SiO₂. Regardless of processing technique, the alloying with 40 at.% Ti has been found to be beneficial for improving oxidation resistance recorded on isothermal exposure at 1200 °C for 24 h. Such a trend is attributed to the presence of T₁ and D₈₈ phases, absence of A₁₅ phase with poor oxidation resistance, and the formation of a protective double-layered oxide scale comprising TiO₂ and B₂O₃-SiO₂. However, arc melted alloys have exhibited better oxidation performance than sintered alloys. The oxide scale thickness on AM alloys has decreased over time, whereas that on SPS alloys has increased with increasing Ti content, likely due to variations in TiO₂ and SiO₂ growth rates. The oxidation of the Mo-40Ti-14Si-10B alloys examined for short durations of 15 and 30 min, revealed a greater mass change in the arc-melted alloy compared to the sintered alloys, resulting in approximately 21% reduction in oxide scale thickness for AM alloys and a 3% increase for SPS alloys from 15 to 30 min. A detailed analysis of the mechanisms influencing the microstructure evolution and high-temperature oxidation resistance in the aforementioned multiphase Mo-Ti-Si-B alloys will be presented.

Oral Presentation (20')

Abstract

Deformation in the intermediate temperature creep regime of Co- and Ni-based superalloys (~700-850 °C) is dominated by shear of planar defects, e.g. stacking faults and microtwins, whereby diffusion and reordering drive shearing processes. Local Phase Transformation (LPT) to η or χ occurs at these defects (χ -SISFs/microtwins and η -SESFs) and prevents rapid strain accumulation by halting further shearing partial dislocations. A CALPHAD-based design approach has been implemented leveraging the LPT strengthening effect; for Ni-based systems this has proven to enhance a polycrystalline alloy to the performance of traditionally used single crystals. This was accomplished by increasing the propensity for only η -LPT. Here, new Co-based superalloys were created by aggressively promoting both η as well as χ -LPT, the latter having shown extremely effective in preventing microtwin thickening and stacking fault ribbon formation, with the goal of creating an optimized alloy for polycrystalline response. Single crystalline analogs of several alloys were also cast to study fundamental deformation and effectiveness of LPT under specific compressive loading conditions, namely along [001] (enabling SESF/microtwinning) and [011] (enabling SISF and SF ribbons) crystallographic directions, which allowed for alloy performance to be mapped as a function of loading conditions. Comparing these to the optimized polycrystalline alloy provided insight on which LPT dominates polycrystalline response; they were also compared to several benchmark Ni-based LPT alloys. HR-STEM observations, including atomic resolution energy dispersive spectroscopy (EDS), of deformation substructures allowed analysis of LPT and its effectiveness; these observations ultimately informed design of an optimal creep-resistant polycrystalline alloy and refined the CALPHAD-based multi-criteria optimization algorithm PyMultOpt.

Paper 272 1 **Pioneering NiTi-Cu Shape Memory Alloys via Binder Jetting Additive Manufacturing: Process Optimization and Microstructural Refinement**
Prof. Mohammad Elahinia, United States
Keynote (Oral Presentation 40')

Abstract This study introduces a novel application of Binder Jetting Additive Manufacturing (BJAM) to produce NiTi-Cu shape memory alloys (SMAs), marking the first exploration of this method for such alloys. Fine pre-alloyed NiTi and pure Cu powders (<20 µm) were utilized to fabricate components, with the process parameters: temperature, Cu percentage, and sintering time carefully optimized to achieve high-performance SMAs. The parts were sintered in a controlled furnace under an inert atmosphere to minimize contamination and enhance microstructural integrity. The investigation revealed that process optimization significantly influenced the resulting microstructure, minimizing defects and ensuring homogeneity. The study also examined the impact of Cu content and sintering conditions on phase transformations, transformation temperatures, and temperature hysteresis. This pioneering work demonstrates the potential of BJAM as an effective and scalable method for producing NiTi-Cu SMAs with tailored properties, offering a new avenue for additive manufacturing of functional shape memory alloys with minimal defects and superior performance characteristics.

Paper 1787 2 **Micro-structural and Mechanical Characterization of Wire and arc additive manufactured Fe-Mn-Si shape memory alloy**
Dr. Maryam Mohri, Switzerland
Highlight (Oral Presentation 20')

Abstract Iron-based shape memory alloys (Fe-SMAs) have attracted considerable interest due to their economical production, pseudo-elastic properties, shape memory effect (SME), and exceptional mechanical characteristics, making them ideal for civil engineering applications. This study proposes that integrating a Fe-SMA lattice structure with advanced micro-structural engineering could enhance the material's recover-ability through SME, potentially resulting in negative stiffness and improved energy dissipation. Thin walls of Fe-SMA were fabricated using Wire Arc Additive Manufacturing (WAAM). To assess the energy absorption capabilities of Fe-SMA lattice structures, it is essential to gain a thorough understanding of the interplay between manufacturing variables, micro-structure, and functional performance. The primary aim of this research is to conduct a micro-structural and mechanical characterization of WAAM-fabricated Fe-SMA samples in both their as-built and heat-treated states. The findings indicate that post-processing heat treatment, specifically aging at 760 °C for 8 hours, significantly enhances the pseudo-elasticity and recovery strain of the samples.

Paper 1132 4 **Phase and microstructure formation of α'' Ti-Nb: Laser powder bed fusion (LPBF) vs. single track laser melting**
Prof. Matthias Bönisch, Belgium
Oral Presentation (20')

Abstract

Titanium alloys containing moderate amounts of β stabilizers (e.g. Nb, Ta) exhibit remarkable functional properties including shape memory effect and tailorable thermal expansion, which are rooted on the orthorhombic martensite α'' . Conventional fabrication of those alloys involves classical ingot metallurgy, thermomechanical processing, and shaping by forming and subtractive methods, limiting geometric freedom and restricting application specific design. In contrast, additive manufacturing techniques like laser powder bed fusion (LPBF) combine the benefits of (near-) net-shape production of complex parts from Ti alloys with the intrinsic potential to locally tailor microstructures to the requirements dictated by the end application. In addition, due to its characteristic rapid cooling rates, LPBF favours the formation of metastable phases as-built, such as hexagonal martensite α' in β stabilizer-lean parts, and metastable β phase in β stabilizer-rich parts. LPBF may also allow controlled formation of orthorhombic martensite α'' – which is an open question that needs systematic validation and exploration. However, the limited availability and relatively high cost of commercially pre-alloyed, atomized powders is a significant challenge for the widespread production of LPBF α'' parts. Taking Ti-Nb as example, this work thus explores the fabrication of α'' Ti-Nb via LPBF from pre-alloyed Ti-29Nb powders, prepared by mechanical alloying of elemental Ti and Nb powders. The powders were characterized for homogeneity, particle size, and phase constitution, and subsequently consolidated into cuboids via LPBF. Various combinations of laser power and scan speed were tested to study their effects on as-built microstructures and porosity. To isolate the influence of the layerwise build process on the resulting phases and microstructures, experiments will be discussed, for which α'' martensitic substrates were remelted along single laser tracks. Single track remelting revealed different microstructures depending on the melt pool location, including planar growth at the roots and cellular-dendritic growth near the surface. The results of this study suggest that proper selection of alloy content and LPBF parameters can lead to α'' martensitic Ti-Nb parts for functional 3D-printed components.

Paper 1038 5 **Improving the thermal hysteresis of NiTi Melt-spun ribbons for faster actuation with the Cu addition and optimized annealing time.**
Ph.D. Anusha Maniganti, India
Oral Presentation (20')

Abstract

NiTi shape memory alloys (SMA) have unique properties that make them very suitable for various electrical actuator and sensor applications. These attributes include the shape memory effect and superelasticity. It is essential to enhance their response to attain faster actuation. Investigating the phase transformation properties of NiTi shape memory alloy (SMA) is crucial for this objective. This study compares the transformation temperatures and thermal hysteresis of Ni50Ti50 shape memory alloy with Ni45Ti50Cu5 shape memory alloy in ribbon form. The ribbons are manufactured using the melt spinning technique at two distinct velocities: 20 m/s and 45 m/s. They undergo annealing at 470 °C for one hour. Analytical methods, including XRD, DSC, SEM, and EDX, have verified the existence of Ni4Ti3-Cu precipitates in all specimens. The DSC results indicate that the incorporation of 5 at. % Cu alloying partially alleviates multistep phase change in the R45 sample. A slight reduction in Ms temperature and Ht values is noted with the incorporation of Cu and subsequent annealing treatment in both R20 and R45. This research offers significant insights into the impact of Cu addition and an appropriate annealing treatment on the transformation temperatures of NiTi shape memory alloys.

In-depth Mechanism of Corrosion and Mechanical behavior of Ni-rich NiTi Alloys through Optimized Heat Treatment and Phase Transformation

Ms. Priyadarshini Nayak, India

Oral Presentation (20')

Abstract

NiTi-based SMAs are widely employed in biomedical applications owing to their distinct properties, such as shape memory effect (SME) and pseudoelastic effect (PE), resulting in extraordinary shape recoverability. Along with high corrosion resistance, impressive biocompatibility plays a significant role. The present study investigates the in-depth mechanism of corrosion and mechanical behavior of a Ni-rich NiTi alloy (50.80 at% Ni) under different heat treatment conditions. The as-received alloy is initially solution treated at 850 °C for 2 h (ST) and subsequently aged at either (i) 350 °C for 2 h, named as HT_1, or (ii) 550 °C for 2 h, named HT_2. Primarily, equiaxed grains of size of $\sim 35 \pm 4.3.7 \mu\text{m}$ are noted to form in both the aged alloy specimens. Transmission electron microscopy analysis confirms the presence of the B2 phase, R-phase, and Ni-rich (Ni_4Ti_3) precipitates in them. However, the volume fraction of these phases and size of precipitates are different in the aged alloys. These microstructural modifications attained through thermal treatment are noted to influence the corresponding corrosion and mechanical properties of the NiTi alloys. Among the aged conditions, HT_2 alloy is effective in altering the microstructure and improving the corrosion resistance of NiTi alloy in physiological solutions like Hank's solution at 37 °C. Notably, after 30 days of long-term immersion, HT_2 alloy develops another Ca-P layer along with a uniform TiO_2 oxide layer, which is beneficial for the cell growth during immersion period. In contrast HT_1 alloy forms a thin and inhomogeneous oxide layer, which leads to pitting corrosion over time. Furthermore, mechanical characterization reveals that HT_2 alloy exhibits optimized tensile properties with respect to the solutionized alloy. Most importantly, HT_2 alloy exhibits larger transformation strain plateau of 2.5 % and lower critical transformation stress ($377 \pm 9 \text{ MPa}$) for stress-induced martensite transformation (SIMT) as compared to that for ST and HT_1 alloys. Careful scrutiny of the tensile deformation behaviour, analysed via digital image correlation. Interestingly, it reveals that SIMT initiates and extends in an inhomogeneous and localized manner through Lüders-like band. Overall, such improved mechanical, functional, and corrosion characteristics of NiTi alloy in the HT_2 condition are of particular significance for its biomedical application.

Development of Bio-Based Photocurable Resins for High-Resolution 3D Printing with the Incorporation of Quantum Dots for Advanced Photonic Applications

Dr. Ismael Romero Ocaña, Spain

Highlight (Oral Presentation 20')

Abstract

Vat photopolymerization-based 3D printing, such as stereolithography (SLA), has become an essential technique for manufacturing complex structures with high resolution. However, the reliance on photocurable resins derived from petrochemical-based (meth)acrylates poses significant challenges in terms of sustainability and toxicity. In this context, research has focused on developing sustainable alternatives using bio-based monomers.

This study presents the synthesis and characterization of novel photocurable resins developed from natural derivatives, with a significantly higher bio-based content than previously reported values for vat photopolymerization. Structural (FTIR, NMR), thermal (DSC, TGA), and mechanical (tensile, flexural) analyses were performed to characterize the properties of the obtained resins. The 3D printing capability of the resins was evaluated by fabricating test objects using a stereolithography (SLA) apparatus. The mechanical properties of the printed objects were analyzed and compared with those of the commercial resins. The synthesized bio-based photocurable resins demonstrated mechanical and thermal properties comparable to those of commercial resins used in stereolithography 3D printing.

Additionally, within the framework of the National QD-PAVANE project, the incorporation of quantum dots (QDs) into these bio-based resins was explored for photonic and optoelectronic applications in the visible and infrared spectrum. QDs, known for their unique tunable emission and absorption properties, offer the possibility of developing functionalized materials with adaptable optical responses. The combination of bio-based resins with QDs expands the range of applications in detection, lighting, and energy devices, promoting sustainable solutions in cutting-edge technologies.

The incorporation of quantum dots (QDs) into bio-based resins allowed for the modulation of their optical properties, opening up new possibilities for applications in photonic and optoelectronic devices. A significant effect of the QDs on the light emission and absorption of the resins was observed, suggesting their potential for the development of sustainable sensors, lighting devices, and solar cells.

This study demonstrates the potential of bio-based photocurable resins as a sustainable alternative to conventional resins in high-resolution 3D printing. The incorporation of quantum dots (QDs) into these resins expands their functionalities and opens new perspectives in the fields of photonics and optoelectronics. This approach promotes the development of advanced materials and more sustainable manufacturing technologies.

Paper 1169 1 Multi-functional Rotating triangular metamaterial for vibration isolation and energy harvesting applications

Ph.D. Ramin Hamzehei, Canada

Highlight (Oral Presentation 20')

Abstract

This work presents novel multi-functional rotating triangular metamaterials designed for simultaneous vibration isolation and electricity generation. The core innovation lies in the incorporation of rotating triangular joints, which introduce bending deformations in the cell walls under compressive loads. This rotational mechanism reduces the structural stiffness from a positive value to a quasi-zero stiffness (QZS) regime, effectively lowering the system's natural frequency and enhancing its ability to isolate external vibrations. The deformation mechanisms within the metamaterial involve bending, compression, and tension of cell walls, each playing a crucial role in energy harvesting. The integration of piezoelectric materials (PZTs) on the tensioned walls enables efficient electricity generation due to applied tensile loads, while the attachment of piezo benders (PBs) on bending-dominant regions further enhances energy conversion efficiency. By leveraging these synergistic mechanical and electromechanical properties, the proposed structure provides a lightweight, efficient, and scalable solution for vibration mitigation and energy harvesting applications at the same time. Potential applications include automotive systems, where the metamaterial can be embedded in vehicle suspension components, car seats, or chassis structures to dampen external excitations encountered during driving. The harvested energy can be used to power small electronic systems, enhancing their overall energy efficiency and sustainability. Beyond automotive applications, these multi-functional metamaterials hold promise for use in aerospace structures, civil infrastructure, and wearable technologies, where vibration isolation and self-powered sensing are critical.

Elastocaloric effect on laser-sintered thermoplastic polyurethanes

Dr. Álvaro Vaz-romero, Spain

Highlight (Oral Presentation 20')

Abstract

Refrigeration has traditionally played a crucial role in several industrial sectors. Almost all current refrigeration systems are based on vapor-compression refrigeration, where a fluid refrigerant evaporates and condenses. Although vapour-compression has been the dominant technology, there is an increasing concern about the primary global warming and environmental impact from air-conditioning and refrigeration systems. It is thus paramount to investigate new plausible alternatives with similar or higher efficiencies than the current refrigeration cycles. In the last few years, some solid-state refrigeration techniques have been analyzed as potential candidates to replace the traditional refrigeration systems. Solid-state refrigeration through elastocaloric cooling leverages the elastocaloric effect (eCE), where certain materials exhibit temperature changes under mechanical stress due to reversible phase transformations.

Although there is a notorious scientific effort in the field of caloric materials, not all materials are great potential candidates from the technical, economical or ecological perspective. Additionally, designing efficient driver mechanisms that can apply and recover mechanical loads effectively remains complex, so the use of new manufacturing techniques like 3D-printing could accelerate the introduction of new cooling systems. The present work investigates the elastocaloric effect (eCE) of a thermoplastic polyurethane (TPU) produced using Selective Laser Sintering (SLS) to explore the potential of 3D-printed TPUs for solid-state refrigeration applications. Mechanical testing, including uniaxial tensile tests, is conducted to characterize the stress-strain response, including the non-linear elastic response and stress softening behavior. Differential Scanning Calorimetry (DSC) measurements are performed to analyze the thermal transitions of the TPU, such as melting and crystallization temperatures, in order to provide insights into the material's microstructural properties, including its phase behavior. Cyclic loading and infrared thermal measurements are conducted at room temperature to evaluate the eCE by measuring the temperature changes during loading/unloading phases. Finally, Small-Angle and Wide-Angle X-ray Scattering (SAXS/WAXS) experiments are conducted during mechanical cycling to investigate the microphase-separated structural changes and possible Strain Induced Crystallization (SIC) phenomena in the TPU. The focus is on understanding how strain-induced crystallization and other microstructural transformations contribute to the eCE. The experimental results obtained through infrared camera measurements show an increase in temperature above ambient temperature during the loading phase of the cycles and a decrease below it during the unloading phase. These results seem to indicate the formation of crystals during strain increase, which melt upon load removal. The SAXS/WAXS tests show a clear correlation between temperature variations and the appearance of new phases in the loading direction.

Paper 1861 3 **Novel triboelectric graphene polymer sensor for risk mitigation in different environments**

Ph.D. José Sánchez del Río Sáez, Spain

Oral Presentation (20')

Abstract

The increasing demand of free energy in modern society, coupled with the urgent need to find clean and sustainable energy sources, the same as monitoring physical magnitudes in order to either improve the life quality of citizens in smart cities or to mitigate risks against catastrophes, have propelled research and development in innovative areas of energy generation and sensing. One of these innovative approaches is harnessing the triboelectric effect as a viable source of electricity generation. The triboelectric effect, based on generating electrical charge from mechanical energy in the form of friction or contact between materials, offers significant potential for energy harvesting in everyday environments and situations where conventional electrical infrastructure is limited or inaccessible. In addition, the use of specific materials that enhances sensitivity and gives novel properties to the sensors such as electromagnetic shielding or fire retardancy is a key challenge for scientists specialized in novel smart materials. In this work novel triboelectric sensor made of different charged polymer layers and with graphene and fire retardancy elements in its polymer matrix is presented. Its use as a risk mitigation warning alarm system in areas with fire or with high radioactive doses in the air makes this novel sensor a very good candidate to operate in smart buildings. An electrical and mechanical characterization was performed and a high efficient mechanical-electrical energy conversion is shown, reaching power values of mW for applied forces of dozens of newtons. Furthermore, its radiation shielding capacity and its applications as a smart sensor resistant to fire conditions was tested with a novel communication system based on LoRA and Wi-Fi protocol.

Paper 1315 5 Carbon-Nanotubes Embedded Strain Sensors for Monitoring of Structural Carbon Fibre Composites
Mr. Moises Zarzoso, Spain
Oral Presentation (20')

Abstract

Carbon nanotubes (CNTs) offer a promising piezoresistive sensing approach and have been extensively investigated as strain sensors in wearables, healthcare applications, and human-machine interaction devices. This study presents the development of piezoresistive strain sensors based on CNT yarns for structural applications.

Typically, CNT-based sensors consist of discrete CNT fillers embedded in elastomeric polymers, designed to accommodate a broad range of deformations—often exceeding the strain levels relevant to aerospace structural materials, which are typically below 2000 microstrain. While these sensors have demonstrated the capability to detect low strains, they incorporate epoxy or elastomeric polymers, such as thermoplastic polyurethane, which exhibit lower thermal stability than the high-performance polyetherketoneketone (PEKK) family.

In contrast, continuous ensembles of highly aligned CNTs joined together into macroscopic fibres or yarns could help eliminate the associated problems by taking advantage of their hierarchical structure and properties not attainable to discrete CNTs. CNT yarns exhibit piezoresistive behaviour and have already been employed in various flexible materials, including self-recoverable artificial muscles, soft bioelectronic sensors, and smart textiles. The piezoresistivity mechanism in CNT fibres differs from that of percolated nanocarbon networks formed by discrete nanoparticles.

The sensors developed in this study consist of PEKK-coated thermoplastic filaments reinforced with continuous CNT yarns, fully integrated into structural thermoplastic-matrix carbon fibre-reinforced laminates. The PEKK coating enhances the piezoresistive behaviour of the CNT yarns by improving internal stress transfer. When embedded in a laminate, the CNT sensors exhibited a gauge factor of up to 10 for strains of 2000 microstrain under both tensile and compressive loading.

The CNT sensors were calibrated and compared with commercial strain gauges at the coupon level through three- and four-point bending tests conducted at room temperature. The analysis was subsequently extended across a range of temperatures to evaluate the feasibility of the proposed sensors under operational conditions. Additionally, high-cycle fatigue tests demonstrated no degradation in sensing performance, confirming the sensors' suitability for long-term structural applications.

Finally, the sensor's ability to detect damage was assessed by subjecting the test specimens to low-speed impact. A change in signal behaviour was observed, enabling clear damage identification while maintaining a proportional relationship between the sensor signal and the experienced deformation.

Paper 1285 1 **Corrosion mitigation strategies in molten lead: coatings and advanced alloys for nuclear LFR systems**

Ph.D. Serena Bassini, Italy

Highlight (Oral Presentation 20')

Abstract

Austenitic steels such as AISI 316L and 15-15Ti AIM1 are being considered as candidate structural materials for nuclear Lead-cooled Fast Reactors (LFRs). However, their chemical compatibility with molten lead represents a major issue due to severe corrosion effects. Non-protective oxidation and solution of steel constitutive elements are commonly observed phenomena, particularly severe in low dissolved oxygen conditions and/or at high temperatures. These limitations restrict the applicability of these materials only to specific operational conditions. In response, the nuclear materials research community is developing strategies to mitigate the corrosion damage. To address these challenges, two main solutions are being considered: 1) the use of high-resistant coatings or surface modifications deposited on the candidate structural steels, and 2) the employment of new advanced bulk alloys with intrinsic corrosion resistance.

This study focuses on assessing the chemical compatibility of ceramic alumina coatings, FeCrAl pack cementation and advanced bulk AFA (Alumina-forming Austenitic) steels when exposed to molten Pb, to be used as potential strategies against liquid metal corrosion. For the purpose, coated-steel specimens and AFA specimens were exposed to molten lead at a temperature of 550 °C for durations up to 8000 hours in the frame of H2020 GEMMA project. The exposures were performed using the experimental facility BID1 at the ENEA Brasimone, consisting in a mixed tank containing 150 liters of molten lead in which the samples were immersed. Post-test examination was performed on the exposed specimens using SEM-EDX and XRD techniques. After the exposures, it was observed that the alumina coatings and the FeCrAl pack cementation showed no evidence of corrosion and mainly conserved their structural integrity, being able to act as a corrosion barrier. AFA steels showed promising and outstanding corrosion protection features in molten lead, demonstrating to be a good candidate solution as bulk structural material in LFRs.

Paper 96 **2** **Thermo-mechanical, lead corrosion and thermal stability assessment of innovative Alumina Forming Austenitic Alloys for LFRs**
Ph.D. Mauro Brignone, Italy
Oral Presentation (20')

Abstract

The development of new generation Lead-cooled Fast Reactors (LFRs) encounters the key challenge of long-term degradation of structural materials when exposed to liquid lead (Pb). Current research identifies alumina-forming austenitic (AFA) steels as a promising material class for structural applications in LFRs. A novel range of AFA steel compositions has been determined through thermodynamic simulations to predict mechanical properties, corrosion resistance, and thermal stability. The experimental activity has been carried out by casting 0.5 kg rods then scaled-up to 80 kg ingot through VIM and VAR processes. Thermo-mechanical tests have been conducted using a Gleeble machine to identify optimum forming parameters afterwards used for the hot rolling of larger sheets. The material corrosion resistance has been assessed through Pb corrosion tests for 1000 hours at 600°C. Additionally, the thermal stability of selected compositions has been evaluated by oven ageing. Comprehensive bulk characterization techniques, including SEM, XRD, and OM, have been utilized to analyze microstructure and phase transformations. Finally, the behavior under irradiation is being studied using an advanced in-situ TEM setup with heavy ion irradiation.

Paper 1102 3 **Liquid metal embrittlement occurrence by lead and Pb-Bi eutectic of Face-Centered Cubic metallic alloys: austenitic steels and Complex Concentrated Alloys**
Dr. Ingrid Proriot Serre, France
Oral Presentation (20')

Abstract

One of the challenges in the development of Lead Fast Reactors or Accelerator Driven Systems is the reliability of the structural materials in contact with the coolant, such as lead or the Lead-Bismuth Eutectic (LBE), and at high temperatures. In addition to damage due to irradiation, one of the major damages for the structural materials could be due to corrosion by liquid metal and, under stress (mechanical stress or stress caused by temperature fluctuations), structural materials can be susceptible to liquid metal embrittlement (LME), i.e. partial or total loss of ductility in the presence of liquid metal and therefore an earlier fracture. Because of the LME sensitivity of the Body-Centered Cubic alloys, the most ductile Face-Centered Cubic (FCC) alloys could be preferred because of their low LME sensitivity below 450 °C and despite the corrosion observed, in particular the selective dissolution of Ni and possible LME sensitivity at high temperatures (500 °C and more). The objective of the presentation is the study of the LME occurrence of different FCC metallic alloys (austenitic steels and Complex Concentrated Alloys), susceptible to be used in the presence of liquid LBE and Pb. To evaluate the LME sensitivity, Small Punch Tests were performed in air and liquid LBE and Pb saturated in oxygen at different temperatures between 200 °C and 500 °C and at different strain rates. Then, the fracture surfaces and cracking were observed by Scanning Electron Microscopy. Additional tensile tests and EDX-EBSD analysis (Energy Dispersive X-ray and Electron Backscatter Diffraction) are carried out to characterize the cracking paths in the presence of liquid metal and possible microstructure transformations. All the materials present ductile behavior and ductile fracture in air. The steels are less susceptible to LME than the studied CCAs. In case of LME occurrence, intergranular cracks were observed and selective dissolution of Ni and Mn were noted in specific conditions. Lower strain rates and higher temperatures promote LME sensitivity. The LME occurrence is discussed taking into account the microstructure, the hardness, and the composition of the alloys. The study was supported by the GEMMA and INNUMAT projects (Euratom research and training programme: respectively 2014-2018 - grant agreement No 755269, and 2021-2022 - grant agreement 101061241).

Paper 642 **4** **Irradiation and corrosion behavior of oxide-forming FeCrAlNi coatings deposited by HiPIMS**
Mrs. Maria Sole Galli De Magistris, Italy
Oral Presentation (20')

Abstract

Lead-cooled fast reactors are considered among the most promising Generation IV nuclear reactors, owing to their inherent safety and high-power density. Nevertheless, liquid lead causes severe degradation of conventional structural and cladding materials, mainly due to oxidation, dissolution and erosion of the steel matrix. Additionally, high-dose irradiation due to fast neutrons can further enhance corrosion, promoting the formation of defects in the material [1]. In this respect, the cladding is one of the most critical components as it faces the highest temperature and radiation fields, while containing the nuclear fuel. Therefore, proper mitigation strategies must be adopted to protect the cladding material, avoiding unwanted modification of the steel matrix properties. In this framework, surface coating technology can be considered a valuable technique. Indeed, without modifying the properties of the bulk material, the surface of any component can be ideally engineered through the deposition of a protective coating [2]. To improve the corrosion, mechanical and radiation resistance of standard nuclear-grade steels, the composition, density, morphology, adhesion, compatibility to the substrate, and self-healing capabilities of the coatings play a crucial role.

This contribution reports about the development of FeCrAlNi coatings deposited by High Power Impulse Magnetron Sputtering (HiPIMS) on steel substrates. Coatings were produced by simultaneously co-sputtering a steel and an aluminum sources. This strategy should allow to control all the aforementioned properties. The co-sputtering process enables, on the one hand, to precisely tune the amount of Al in the coating, which should promote the formation of a stable and protective oxide layer when in contact with liquid lead [3]. On the other hand, the use of a sputtering target with a composition similar to the one of the substrate should improve the compatibility between the two. Additionally, the ion rich plasma characterizing the HiPIMS process can improve growth and evolution of the coating in terms of density, morphology and adhesion [4]. The prepared samples were tested in both ion irradiation and liquid lead corrosion experiments under relevant operating conditions. The coatings were characterized in terms of morphology, microstructure and elemental distribution before and after the tests, exploiting SEM/EDX, TEM, XRD and Raman spectroscopy.

Three new high alloyed AFA steels for LFRs

Dr. Alfons Weisenburger, Germany

Highlight (Oral Presentation 20')

Abstract

Alumina-forming austenitic (AFA) steels satisfy two key criteria for materials suitable for use in lead fast reactors. They can form in-situ alumina scales that can mitigate the corrosion attack of liquid Pb, and they have an austenitic structure that is necessary for avoiding issues with liquid metal embrittlement. Therefore, AFA steels are one of the advanced material solutions that are at time intensively discussed among the designers and developers of LFR's. Within the EU project INNUMAT KIT designed three high alloyed AFA materials targeting phase stable austenitic steels that can withstand liquid Pb at 600°C and above. The composition of the AFA alloys were optimized using thermodynamic modelling. The amount of Al was kept as low as possible in combination with the Ni and Cr content to suppress as much as possible the formation of ferritic phases, but also as high as required to foster alumina formation during exposure. The latter was based on achieving similar Al activity like for already successfully tested AFA materials. Finally, three different steels with the following composition were manufactured at SWERIM in Sweden and hot rolled for testing: AFA-A: 15.2Cr 22Ni 2.7Al 3Mn 0.8Nb 0.2V 0.08C 0.02Y; AFA-B: 15.2Cr 24Ni 3.1Al 3Mn 0.8Nb, 0.2V, 0.08C, 0.02Y, and AFA-B: 14.5Cr, 24Ni, 3.85Al, 3Mn, 0.8Nb, 1.1W, 0.08C, 0.02Y. Nb, V and W were added for higher strength at elevated temperatures.

Following final annealing, all three alloys exhibit a fully austenitic structure, with grain sizes ranging from 50 to 100 µm. The alloys are exposed to liquid Pb with an oxygen content of 1×10^{-7} wt% at three different temperatures: 500°C, 600°C and 700°C. Each specimen is exposed on two differently prepared surfaces: one side is polished, and the other is ground. The specimens exposed at 700°C show signs of surface attack in certain areas. The presentation will provide insights into the corrosion resistance of the three high alloyed AFA steels in liquid Pb at the three temperatures, aiming to forecast their long-term behaviour and explore ways to enhance compatibility, if necessary. Additionally, the susceptibility of the three steels to liquid metal embrittlement (LME) will be addressed taking into account the results of Small Punch Tests performed in air and in liquid Pb at different temperatures and strain rates.

Paper 975 **6** **Durability of W/WC coating on inner surface of 316L steel Venturi tube in contact with high velocity flow of liquid Pb-Bi eutectic at 350 °C after one year of operation**
Dr. Erich Stergar, Belgium
Oral Presentation (20')

Abstract

The durability of structural materials in contact with heavy liquid metals (Pb, Pb-Bi and Pb-Li eutectics) is one of the key issues to be addressed on the way to master liquid metals as a functional media of novel nuclear and non-nuclear installations. This work presents and discusses the experimental results on the durability of W/WC coating exposed to a high velocity flow of liquid Pb-Bi eutectic.

The inner surface of a Venturi segment in the loop was made of 316L steel and coated with a W/WC layer by chemical vapor deposition (HARDIDE-T). The thickness of the coating is about 50 µm. The main purpose of this coating was to avoid the potentially severe erosion processes by the high velocity of the flowing liquid metal. The temperature of the liquid metal was 350 °C. The flow rate entering the Venturi segment of the loop was about 4.9 kg/s, which corresponds to the local maximum velocity of liquid metal at the Venturi throat of 6 m/s. The concentration of oxygen dissolved in liquid Pb-Bi was maintained at 2×10^{-7} mass%. After an one-year test, the Venturi part of the loop was segmented and examined in detail for durability of the preformed coating. The general conclusion is that the coating successfully protected the inner surface of the Venturi segment with respect to the high velocity flow of Pb-Bi eutectic. The morphological and structural features of W/WC coating are discussed based on the surface and cross-sectional metallographic studies.

Qualification of Materials for Lead-cooled Fast Reactors: Testing standardization and experimental results

Ph.D. Antonino Meli, Italy

Oral Presentation (20')

Abstract

In recent decades, Lead-cooled Fast Reactors (LFRs) have gathered significant interest from the HLM (Healy Liquid Metal) scientific community. As a result, different projects were founded in Europe, US and China, with the related experimental activities carried out. However, in the occasion of the 2023 GEMMA (EC Project) conference in Bologna, two key findings were highlighted from the results presented:

- Nuclear-grade conventional structural materials, such as AISI 316 and 15-15Ti austenitic grades, exhibit good corrosion resistance in liquid lead (Pb) environments up to 450–480°C, provided optimal oxygen control is maintained.
- Experimental data show a notable degree of scatter, likely due to variations in experimental setups.

An obvious approach to address the data scattering challenge is the standardization of experimental facilities, protocols, methodology for analysis of data and their interpretation. These are prerequisites for any LFR developer intending to submit material data to the regulator for licensing reactor prototypes for low temperature operations (400 – 450°C).

In this framework, newcleo in collaboration with ENEA has commissioned a high-throughput facility to conduct an initial evaluation of nuclear grades materials of newcleo's interest (regulated in RCC-MRx code) against corrosion in lead at reactor operating conditions. The test bed is a standardized stagnant Pb cell with bubbling gas injection oxygen control system. Preliminary results on 15-15Ti AIM-1 and 316 grade under stagnant conditions are currently under characterization. In this work we will present some insights about the experimental data for nuclear qualified materials at conditions relevant for operations of a low temperature LFR; with these conditions newcleo intends to deploy to fully demonstrate this technology in an operative environment in the early 2030.

Development, Qualification and Industrialization of materials for Lead Cooled fast Reactors – The INNUMAT approach

Mr. Marco Pattarino, Italy

Oral Presentation (20')

Abstract

The harsh working conditions typical of GEN IV fission reactors impose the development of NEW materials or the tailoring of REFERENCE materials to general requirements of nuclear applications and to the specific requisites of the considered technology.

Among GEN IV NPPs under development using Heavy Liquid Metals coolants, LFRs (Lead-cooled Fast Reactors) technology is one of the most promising.

To foster the R&D efforts and the industrialization of such LFR technology, the European Community launched several projects. INNUMAT project aims to develop innovative structural materials for nuclear applications and put them on track towards qualification for fission lead-cooled and molten salt fast reactors as well as fusion DEMO.

The REFERENCE materials studied within INNUMAT for LFR NPP are

- AISI 316
- HEAs
- AFA steel
- Coated 15-15Ti
- Weld Overlay

While the NEW materials are:

- FeCrAl ODS;
- Mo Alloys;
- MAXTHAL and MAX PHASES

In INNUMAT approach, the development of new materials or of referenced ones and their application at prototypical and industrial level is organized in different phases:

- High through-put development of new materials and tailoring of referenced materials for GEN IV LFR applications.

- Pre – qualification campaign performed on a wide range of materials.

During these stages is advisable to use standardized tests and if not possible proceed with the implementation of interlaboratory Round Robin Testing. This methodology aims to mitigate variability stemming from measurement techniques and testing procedures by isolating the material as the sole variable. By enforcing standardized testing conditions across all participating laboratories, the generated data can achieve the desired levels of comparability, consistency, accuracy, and reliability. All mandatory requirements to obtain the recognition as a new standard and helpful to achieve the acceptance within nuclear construction codes ASME BPVC and RCC-MRx at the end of the development process.

- Complete qualification campaign performed on the candidates selected at the conclusion of pre-qualification activity. Qualification shall be performed taking in account also the materials manufacturability assessment at industrial level and the requirements for the acceptance of new materials within ASME BPVC and RCC-MRx construction codes.

Paper 1515 2 Microstructural characterization of advanced doped UO₂ fuels

Dr. Nieves Rodríguez-Villagra, Spain

Oral Presentation (20')

Abstract

Uranium dioxide based nuclear fuels have been widely investigated for their performance in light water reactors (LWRs). The findings of this study provide valuable insights into the impact of doping UO₂ fuel, contributing to the development of high-performance nuclear fuels with improved safety, efficiency, and durability for future reactor applications. Therefore, incorporation of various additives or dopants into UO₂ matrix has been explored to enhance its physical and chemical properties, leading to improved fuel behavior during irradiation.

Dopants serve distinct purposes in modifying fuel characteristics. Grain size growth can be achieved through the addition of Cr₂O₃, Nb₂O₅, Al₂O₃ or V₂O₅. Mechanical properties can be improved with the inclusion of ZrO₂, while Enhanced Thermal Conductivity (ETC) can be obtained by incorporating SiC, BeO, Al₂O₃ or MgO. Additionally, burnable neutron absorbers (BNA), including Gd₂O₃ and rare-earth oxides of Sm₂O₃, Dy₂O₃, Eu₂O₃, and HfO₂, play a crucial role in controlling excess reactivity in nuclear reactors.

Among the promising dopants, europium and zirconium stand out. Europium is an effective, neutron absorber, making it suitable for use as burnable neutron absorber for extended reactor cycles as Eu₂O₃ with less than 10 wt%. This approach optimizes reactor operation by mitigating the initial excess reactivity in fuel assemblies. Meanwhile, zirconium-doped UO₂ ceramic pellets exhibit outstanding performance in LWRs environments (Shippingport, with 26-38 wt% of UO₂), with greater corrosion resistance in high-temperature water or steam, stable thermal conductivity under irradiation, low neutron absorption cross-section, and reduced swelling rates compared to undoped UO₂ fuel, in addition to be a promising matrix for actinides disposal.

Understanding the microstructural properties of optimized nuclear fuel is essential for fuel design, development, qualification, manufacturing, and predicting in-reactor behavior. This research examines the influence of Eu and Zr doping on the microstructure of UO₂ fuel pellets, both capable of withstanding the demanding conditions of nuclear reactors. Pellets containing varying concentrations of Eu₂O₃ (0.02, 0.2, and 2 wt%) and ZrO₂ (20, 40 and 80 wt%) were prepared. The density, phase composition and microstructure of these ceramic samples were characterized using the Archimedes method, X-ray diffraction (XRD), Raman spectroscopy and scanning electron microscopy (SEM).

Paper 850 3 Evolution of the microstructure of neutron irradiated RPV model steels with different content of Ni, Mn and Si

Mrs. Elvira Oñorbe, Spain

Oral Presentation (20')

Abstract

Long Term Operation (LTO) of nuclear power plants is one of the ways followed to achieve the decarbonisation targets contained in the European Strategic Energy Technology Plan (SET-Plan). In this context, it is necessary to understand the mechanisms that lead to a degradation of reactor pressure vessel (RPV) steels exposed to high neutron fluences. Hence, the microstructure of several RPV model steels with different contents of Ni, Mn and Si, has been investigated before and after neutron irradiation by means of transmission electron microscopy (TEM), atom probe tomography (APT), small angle neutron scattering (SANS) and positron annihilation spectroscopy (PAS) in the frame of STRUMAT-LTO project funded by the EU [1]. The combination of all of these characterization techniques leads to a better understanding of the synergetic effect of alloying elements in the damage microstructure and to the correlation with the hardening of the studied materials as the content of Mn + Ni increases. Regarding the study by means TEM, the analysis reveals a decrease of the density of dislocation loops as the content of Mn and Ni mainly increases. In addition to that, microstructural results indicate that Mn effect seems to be more acute. On the contrary no effect in the density of dislocation loops has been noticed when the content of Si varies. According to APT and SANS results, for low and medium contents of Mn in the steel, the number density of Mn-Ni-Si nano-precipitates (MNSPs) increases as Ni content increases and for a given content of Ni the number density of clusters increases with Mn. On the contrary, Si has a low influence on cluster number density. PAS found an association between MNSPs clusters and the behavior of point defects. Finally, there is a good correlation between microstructural results and irradiation hardening of the materials.

Paper 1361 4 **Development of physics-based models for volatile fission products in minor actinide-bearing fuels for generation IV reactors**
Mrs. Elisa Cappellari, Italy
Oral Presentation (20')

Abstract Fission Generation-IV technologies aim to reduce waste generation and enhance fuel efficiency by adopting Minor Actinides (MA)-bearing fuels, which enable the transmutation of MA. In this context, Fuel Performance Codes (FPCs) are necessary to conduct safety analyses and to accelerate the qualification of MA-fuels, but their predictive capabilities must be enhanced by advanced modeling of MA-fuel thermomechanical behavior. This study develops a physics-based model for volatile fission products (FPs), such as cesium, iodine and tellurium, in MA-fuels. Volatile FPs migrate toward the outer fuel pellet, where they contribute to the formation of the Joint Oxide Gain (JOG) that affects fuel behavior and cladding corrosion. The developed model, which comprehensively describes the production, transport, and release mechanisms of volatile FPs within the fuel, is implemented into SCIENTIX, an open-source computer code, developed at Politecnico di Milano, aimed at simulating fission gas behaviour in nuclear fuels at the meso-scale level. Once validated, the model will significantly enhance the predictive capabilities of FPCs thanks to their coupling with SCIENTIX, supporting the design and qualification of advanced nuclear fuels for next generation reactors.

Paper 234 5 **Overview and status of the IFMIF-DONES Facility**
Prof. Angel Ibarra, Spain
Highlight (Oral Presentation 20')

Abstract The International Fusion Materials Irradiation Facility – Demo Oriented Neutron Source (IFMIF-DONES) is a research infrastructure for irradiation the materials to be used in a fusion reactor. The facility would provide a unique neutron source of energy spectrum and flux level representative of those expected for the first wall of future fusion reactors. Materials irradiation data under such conditions are of fundamental interest for the fusion community to consolidate the fusion reactors engineering design and licensing and to validate modelling tools for materials radiation damage. The facility will be also able to address some tritium technologies related experiments. Its Construction Phase started in 2023 in the proposed site of the Escúzar Metropolitan Park (located in the Granada 18 km southwest from Granada city). This paper will present an overview of the implementation, engineering design and main irradiation characteristics of the facility.

Paper 2012 2 High velocity impact on tungsten: molecular dynamics study

Prof. Tomas Polcar, Czech Republic

Oral Presentation (20')

Abstract

We investigate high-energy collisions between tungsten (W) dust particles and tungsten plasma-facing components (PFCs) in fusion reactors. Using advanced Molecular Dynamics (MD) simulations, the study reveals significant material deformation, melting, and vaporization resulting from W projectile impacts at velocities up to 9 km/s. The results indicate that crater volume and dislocation length increase linearly with impact kinetic energy across samples containing over 350 million atoms. Our study involves the effect of impact angle, temperature and crystal orientation of the single crystal W target, with the first attempts to simulate polycrystalline target as well. The analysis of microstructural defects, such as helium bubbles and vacancies, further reveals their impact on crater formation and dislocation interactions. By integrating experimental data with simulation insights, a novel damage model was developed, significantly advancing our understanding of dust-wall interactions needed for refined predictive models to enhance the resilience of PFCs in advanced fusion reactors.

Characterization of cyclic softening effect on EUROFER-97 mechanical properties through combined LCF + tensile tests

Dr. Davide Bernardi, Italy

Highlight (Oral Presentation 20')

Abstract

The reduced activation ferritic-martensitic (RAFM) steel X10CrWVTa9-1 (commonly referred to as EUROFER-97) represents the first candidate as structural material for the ITER Test Blanket Module (TBM) and the DEMO Breeding Blanket. As such, its full characterization and codification is essential for the reliable design of such components and the consequent successful licensing, construction and safe operation of future fusion machines. A strong effort is thus underway at European level to perform an extensive mechanical testing campaign supported by different EU labs within the EUROfusion Consortium with the goal of filling the gaps still existing in the material properties database, updating the Material File required to implement EUROFER-97 in the RCC-MRx design code for the design and manufacturing of the ITER-TBM and contributing to the data collection for the DEMO Material Properties Handbook (MPH). In particular, one of the most relevant point to address is to evaluate the applicability of the existing RCC-MRx design rules and the related allowable stresses to EUROFER-97, considering the well-known softening behaviour of such material under cyclic loading as opposed to the hardening typically associated with austenitic steels for which those design rules have been mainly established. In this context, a dedicated experimental test campaign involving different research labs has been launched in the framework of the EUROfusion Work Package Materials within the TBM subproject (WPMAT-TBM) to investigate how the EUROFER-97 tensile properties are affected by the cyclic softening of the material. In this line, several tests were performed at the mechanical testing laboratory of the ENEA Brasimone Research Centre during the years 2024-2025. The test matrix includes a set of combined tests consisting of uniaxial strain-controlled low-cycle fatigue (LCF) tests, each followed by a tensile test on the pre-fatigued specimen. The LCF tests were executed at 300°C and 550°C until the maximum number of cycles allowed by the latest (2022 Edition) RCC-MRx fatigue design curve was reached. Then, the pre-fatigued specimens were tested in tension at RT, 300°C and 550°C. Additionally, some tensile-only tests at RT, 300°C and 550°C were also carried out, as a reference, on virgin samples machined from the same plate. All the specimens were fabricated from EUROFER-97 batch 3 with transverse orientation with respect to the rolling direction. This paper provides an account of the execution of the above-mentioned tests and the main results obtained along with a brief discussion of the latter.

Paper 1330 4

Correlation between creep and stress relaxation properties in a martensitic steel

Ph.D. Dario Ripamonti, Italy

Oral Presentation (20')

Abstract

The demand for longer service lives for power plants clashes with the difficulty of obtaining reliable material performance data over time. Extrapolation over long timescales of properties determined through accelerated testing is a complex and not risk-free practice, yet sometimes it is necessary because of time consuming experimental testing. In this paper, a strategy to potentially accelerate the characterization of creep properties by performing repeated relaxation tests is suggested. The method, applied on the martensitic high alloyed steel X20Cr13, relies on the similarity of the physical mechanism leading to mechanical stress relaxation (stress reduction under constant strain) and creep deformation (strain increase under constant stress), which is a powerful incentive to correlate the results of creep tests and stress relaxation tests (SRTs). Simple approaches, such as assuming a power law between stress and strain rate are usually unreliable, however it is shown that after a number of repeated SRTs, the rate of the stress drop, proportional to the creep rate via the Young's modulus, decreases and eventually matches the minimum creep rates measured in conventional creep tests. The procedure is not to be considered as a replacement of creep testing, since design codes under creep conditions require proper creep data. However, it could be used to estimate creep rates at stress values too low to be investigated in reasonable time (for example for the determination of the negligible creep regions) or to quickly check if a new batch of a material already known has consistent properties. Another possible field of application could be life assessment, a situation in which only limited portions of material are usually available, since a single relaxation test could be used instead of a set of creep tests.

Paper 1610 5 **Investigating Water Radiolysis and Iron Speciation in Water-Cooled Breeding Blanket for DEMO: Implications for Corrosion Mitigation and Surface Effects**
Ph.D. Camillo Sartorio, Italy
Oral Presentation (20')

Abstract

Understanding the effects of radiation on coolant chemistry is essential for ensuring the long-term integrity of structural materials in advanced nuclear fusion systems. In the framework of DEMO's Breeding Blanket (BB), exposure to neutron and gamma radiation induces water radiolysis, generating reactive species (e.g., O_2 , H_2O_2 , $HO\cdot$) that significantly influence corrosion mechanisms and surface degradation. When additional elements, such as iron ions, are introduced into the system due to dissolution or corrosion of structural materials, their interactions with radiolytic products can significantly alter the chemical equilibria. Understanding how these species influence and are affected by radiolysis is crucial, as it directly impacts material degradation, coolant stability, and overall system performance.

To investigate these effects, we performed numerical simulations assessing the interplay between water radiolysis, iron speciation, and pH evolution in the Water Cooled Lead Lithium (WCLL) Breeding Blanket cooling circuit. The study focuses on the transformations of Fe^{2+}/Fe^{3+} under irradiation and their impact on oxidation-reduction equilibria, with implications for material surface stability in operational conditions.

The results highlight that iron oxidation and hydrolysis strongly influence the local pH, leading to substantial variations that can accelerate material degradation. Additionally, the effectiveness of hydrogen addition in reducing oxidant concentrations has been shown to depend on both iron content and pH.

This study contributes to the broader effort of optimizing water chemistry for advanced nuclear applications, providing fundamental insights into the interplay between radiolysis, surface reactivity, and material degradation. A deeper understanding of these mechanisms is essential for evaluating the effects of irradiation on material surfaces, particularly in relation to corrosion processes, to enhance component longevity in nuclear environments.

Paper 17 **6** **Insight into He trapping mechanisms in implanted 9Cr and 14Cr ODS steel for fusion reactor applications**
Mrs. Jia Meng, France
Oral Presentation (20')

Abstract

Helium (He) accumulation and bubble/cavity formation in structural materials pose a critical challenge for ensuring the long-term stability of fusion reactor components. High-energy neutron irradiation of the structural steels results in He generation through transmutation of iron (Fe) and chromium (Cr) atoms which compromises its mechanical integrity. Few studies have shown that oxide dispersion-strengthened (ODS) steels, which are promising materials for the first wall/blanket, are able to mitigate He-induced embrittlement due to their unique microstructural features for trapping He. However, if the high density of grain boundaries and nano-oxides/matrix interfaces play a key role in the limitation of bubbles formation, the interaction between He atoms and these interfaces is not fully elucidated.

In this study, we comprehensively investigated He bubble formation and its characteristics in 9Cr and 14Cr ODS steels following He ion implantation at three different temperatures: 25 °C, 400 °C, and 600 °C. Advanced microscopy techniques, including the High-Angle Annular Dark-Field (HAADF) imaging and Electron Energy-Loss Spectroscopy (EELS) in an aberration-corrected atomic resolution microscope (ARM) were employed to characterize the bubble size and its distribution, as well as the He atom density and internal pressure within bubbles at various microstructural features.

Our findings reveal significant differences between 9Cr and 14Cr ODS steels in He trapping, bubble characteristics, and its evolution with temperature. These differences are shown to be due to differences in their respective microstructural features such as grain size, oxide distribution, composition and interface characteristics (i.e. coherent or incoherent). These novel measurements provide a comprehensive understanding of the mechanisms governing He trapping and swelling.

By correlating the temperature effects on He bubble behavior with the microstructural features of ODS steels, this work advances our understanding of He-induced damage mechanisms in nuclear materials. The innovative use of EELS, involving careful isolation and analysis of He signal for quantifying He atom density and pressure within bubbles offers a valuable tool for characterizing irradiated materials. The present results instigate future research for further optimization of microstructural stability of fusion blanket steels under extreme irradiation environments.

Paper 1696 1 Ab initio and atomistic simulations of defect induced hydride formation

Dr. Tilmann Hickel, Germany

Keynote (Oral Presentation 40')

Abstract

Climate change motivates the search for non-carbon-emitting energy generation and storage solutions. Metal hydrides show promising characteristics for this purpose. Using systematic ab initio and atomistic simulations, we explore the potential of the abundant defects in the materials such as grain boundaries, dislocations, and microcracks for enhancing the thermodynamics and kinetics of Al-based hydride formation. Firstly, we consider tailoring and employing the negative pressure of microstructural and structural defects to enhance H solubility and thus hydride formation as a novel concept. Using the ab initio thermodynamics method, we created the negative pressure-dependent phase diagram of Alane hydride AlH₃ in the gas pressure and temperature domain. We demonstrate that such an enhancement at the negatively pressurized crack tip region is feasible by increasing the mechanical tensile load on the specimen. The theoretical predictions have been used to reassess and interpret atom probe tomography experiments for a high-strength 7XXX-aluminium alloy that shows a substantial enhancement of hydrogen concentration at structural defects near a stress-corrosion crack tip. Secondly, using the ab initio simulations we studied the effect of grain boundaries on the stability and kinetics of hydride formation in TiFe and Al-based alloys. We calculate the concentration-dependent segregation energies of H to various grain boundaries such as Σ3, Σ9, Σ5, and Σ11 that are proven to have elevated H concentration. We explore the potential of these grain boundaries for enhancing the formation of hydrides by acting as nucleation sites through the results of these calculations. Based on these insights we derive strategies for exploiting metals as H-storage materials.

Paper 1385 2 The impact of hydrogen on mechanical properties of nickel: a hybrid grand canonical Monte-Carlo/molecular dynamics study

Dr. Ageo Meier de Andrade, Sweden

Oral Presentation (20')

Abstract

Despite decades of research, the dominance and co-occurrence of hydrogen embrittlement mechanisms in metals are still under debate. The complexity of such problem is further increased due to the interplay between atomic and microstructural aspects and the interaction with atomic hydrogen that are relevant for both, but not restricted to, the hydrogen enhanced local plasticity (HELP) and hydrogen enhanced decohesion (HEDE) mechanisms. Computer simulations allow the study of these mechanism under desired conditions and provide a detailed atomistic description of hydrogen interactions in the material and its effect of mechanical and microstructural properties. These simulation approaches are, however, under idealized controlled conditions that might not resemble realistic environments in which load-bearing alloys are used.

In this work is presented recent advances on a large-scale fully 3D atomistic simulations of various microstructural domains coupled with a hybrid grand canonical Monte Carlo/molecular dynamics (GCMC/MD) methodology to realistically study heterogeneous microstructures of nickel. This approach shed light on which mechanism, or which combination of those, is dominant and what is the effect of hydrogen in materials properties of Ni-based superalloys. The construction of defect phase diagrams using the chemical potential of hydrogen as the underlying variable is put forward on the interpretation of defect phases associated with H-embrittlement mechanisms in crack systems, type and orientation of grain boundaries, and the interaction of hydrogen with stacking faults and line defects.

Paper 1972 3

Multiscale Modelling of Hydrogen Diffusion in Polycrystalline Metals

Dr. Davide Di Stefano, United Kingdom

Oral Presentation (20')

Abstract

Hydrogen impurities in metals can severely degrade mechanical properties, a phenomenon known as hydrogen embrittlement. While numerous mechanisms have been proposed to explain this effect, their relevance under specific material conditions remains a topic of debate. Nevertheless, a key factor in all hydrogen-assisted damage mechanisms is the role of hydrogen diffusion and trapping, as the accumulation of critical concentrations at failure points occurs rapidly.

Modelling and simulation are essential tools for understanding hydrogen diffusion, but capturing these processes is challenging due to interactions across multiple length and time scales.

In this work, we present a multiscale modelling workflow—from the electronic to the continuum scale—to study hydrogen diffusion in polycrystalline nickel. We begin with an electronic-level analysis of hydrogen migration and trapping at selected nickel grain boundaries. These results inform a kinetic Monte Carlo model to determine effective diffusivities under various conditions, which are then used as input parameters for continuum-scale simulations of hydrogen concentration evolution in polycrystalline materials.

This multiscale approach accounts for key complexities, including grain boundary character and diffusion anisotropy. While demonstrated here for polycrystalline nickel, the framework is broadly applicable to other materials and microstructures, offering a versatile and predictive tool for assessing the effects of hydrogen exposure on metallic materials.

Multi-Scale Computational Study of Hydrogen Adsorption and Phase Transitions in Metal-Hydrides for Energy Storage

Mr. Yash Prakash Mishra, India

Oral Presentation (20')

Abstract

The adsorption of hydrogen on the surfaces, sub-surfaces, and interfaces of metals and alloys is critical for developing solid-state hydrogen storage technologies. A fundamental understanding of these interactions is essential for optimizing hydrogen storage capacity and stability in metal-hydride systems. In this study, we integrate density functional theory (DFT) calculations with a variational framework to systematically analyze the energetics of hydrogen adsorption on various metal and alloy surfaces. Our approach identifies preferred adsorption sites, structural configurations, and phase stability as a function of hydrogen coverage.

The variational framework developed in this work provides new insights into the impact of adsorbed hydrogen on the structural and chemical stability of polycrystalline materials. By capturing phase transitions at surfaces and interfaces, our model explains how different material configurations can facilitate enhanced hydrogen storage. Specifically, we determine the critical hydrogen concentration necessary for phase separation within bulk systems, allowing co-existing surfaces to accommodate higher hydrogen uptake efficiently.

Additionally, we examine the kinetics of hydrogen adsorption and desorption, both at surfaces and in bulk metallic systems, to assess their influence on storage performance. A key aspect of our analysis is the evaluation of chemical strain induced by lattice expansion during hydrogen absorption and its subsequent desorption. This strain significantly affects the mechanical integrity of metal-hydride systems, influencing both storage efficiency and long-term durability. Our findings provide essential guidelines for designing hydrogen storage materials with improved mechanical resilience and optimal adsorption characteristics.

Beyond storage applications, metal hydrides derived from these materials also hold significant potential for energy technologies, including battery systems. Understanding the interplay between hydrogen adsorption, phase transitions, and mechanical stability will be crucial for the development of next-generation energy storage solutions. This study lays the groundwork for future experimental and computational research aimed at optimizing hydrogen storage in metallic systems, bridging the gap between fundamental materials science and practical energy applications.

Characterizing hydrogen in amorphous alumina thin films through integration of modeling, theory, and experiment

Dr. Vladyslav Turlo, Switzerland

Oral Presentation (20')

Abstract

This talk discloses the effect of hydrogen impurities on the local chemical bonding states and structure of amorphous alumina films by predicting measured Auger parameter shifts using a combination of atomistic and electrostatic modeling. Different amorphous alumina polymorphs with variable H-content and density, as grown by atomic layer deposition, were successfully modeled using a universal machine learning interatomic potential. The annealing of highly defective crystalline hydroxide structures with experimental H-contents at the corresponding atomic layer deposition temperatures led to excellent agreement between theory and experiment in the density and structure of the resulting amorphous alumina polymorphs. The measured Auger parameter shifts of Al cations in such polymorphs were accurately predicted with respect to the H content by assuming that all H atoms are present in the form of hydroxyl ligands in the randomly interconnected 4-fold, 5-fold, and 6-fold nearest-coordination spheres of Al. As revealed by a combination of atomistic and electrostatic modeling, the measured Auger shifts with an increase in the H content and an accompanying decrease in the oxide density depend on the complex correlations between local coordination, bond lengths, bond angles, and ligand type(s) around the core-ionized atoms. These findings and fundamental knowledge contribute to advancing the design of e.g. hydrogen oxide barrier films, oxide membranes for H separation, H storage materials, and fuel cells for a hydrogen-based economy.

Hydride-Driven Formation of Zirconium Islands in Irradiated Fuel Claddings: Alloying Element Segregation and Implications for Structural Nuclear Materials

Dr. Huan Liu, Sweden

Highlight (Oral Presentation 20')

Abstract

High-burnup Zr-based nuclear fuel claddings develop c-component dislocation loops under irradiation, which correlate with accelerated degradation mechanisms such as hydrogen pickup and irradiation growth. Recent atom probe tomography (APT) studies by Mayweg et al. (JNM597(2024)155116) reveal that these loops host nearly pure zirconium (Zr) islands, accompanied by segregation of Fe, Ni, and Sn to loop peripheries and depletion of Sn/O within the loops. While these observations suggest a de-alloying behavior in c-loop, the origin of the Zr islands remains unresolved. Building on density functional theory (DFT) studies by Christensen et al. (JNM 445.1-3(2014)241-250), which demonstrated that alloying elements exhibit low solubility in Zr hydrides, we propose that the Zr islands are hydride phases stabilized by hydrogen accumulation in the faulted regions of c-loops.

The intrinsic strain associated with the c-loop structure—a 5-layer FCC-like stacking fault embedded in the HCP Zr matrix—creates an energetically favorable site for hydrogen segregation. Hydrogen migration into these regions relieves lattice strain, promoting hydride formation. This aligns with the pseudo-FCC sublattice of zirconium hydrides (ZrH), mirroring the distorted FCC geometry of the faulted loop. To validate this hypothesis, we perform DFT simulations of Zr-hcp/ZrH-fcc interfaces, systematically evaluating the stability of alloying elements (Sn, Fe, Cr, Ni, Nb) at interstitial and substitutional sites across pure Zr, hydride, and interfacial regions.

Our results reveal distinct destabilization hierarchies for hydrides: interstitial elements follow Nb > Sn > Fe > Cr > Ni, while substitutional elements follow Sn > Ni > Fe > Cr > Nb. This complements the trend in bulk hydride (Sn > Fe > Cr > Ni > Nb) by Christensen et al. (JNM 445.1-3(2014)241-250), highlighting the critical role of interfacial effects. Notably, Sn—depleted in loops experimentally—exhibits the strongest destabilizing effect substitutionally, aligning with its absence in Zr islands. Simulations of hydrogen-free Zr-hcp/Zr-fcc interfaces further confirm that c-loop instability arises from hydrogen accumulation, not intrinsic stacking faults.

These findings establish a mechanistic link between hydrogen trapping in c-loops, hydride formation, and alloying element redistribution. Hydrogen-induced hydrides create Zr-rich zones by expelling solutes to loop boundaries, consistent with APT observations. This work advances the understanding of irradiation-hydrogen synergy in Zr cladding degradation and provides a framework to predict solute behavior in hydride microstructures. By quantifying interfacial energetics and solute-hydrogen interactions, the methodology also serves as a foundation for extending this analysis to Ni- and Fe-based structural alloys, where hydrogen embrittlement and irradiation defects similarly govern performance.

Paper 2108 1 **Atom probe tomography and advanced thermal desorption spectroscopy for atomic scale characterisation of hydrogen in materials**

Prof. Peter Felfer, Germany

Oral Presentation (20')

Abstract

Hydrogen detection at the atomic scale has long challenged materials researchers, primarily due to pervasive background contamination within conventional atom probe systems. In this work, we present a transformative approach that significantly reduces spurious hydrogen signals and enables unprecedented clarity in imaging hydrogen-metal interactions. A central innovation lies in our newly developed ultra-low hydrogen atom probe, featuring a titanium vacuum chamber coupled with non-evaporative getters (NEGs), cryopumping, and optimized vacuum protocols. This novel configuration—departing from the standard use of austenitic stainless-steel chambers—cuts the background hydrogen level by orders of magnitude. In comparative studies using low-field metals (e.g., aluminum), we observe a near-absence of artifact peaks, ensuring that any hydrogen detected indeed originates from the sample itself.

An equally noteworthy aspect of the research is the pivot from traditional electrochemical hydrogen charging to gas-phase exposure, including deuterium. Though electrochemical routes are well-established, challenges such as transient hydride formation, tip fracture, and unpredictable yield drove the adoption of more controlled gas environments. We developed miniaturized “cube” and “cartridge” chambers to safely expose specimens to pressures up to 10 bar and 90 °C, while a specialized high-pressure bunker facility extends exposures to 1000 bar and 300 °C. Importantly, cryogenic transfers preserve hydrogen content, enabling direct atom probe analysis without the risk of out-diffusion. By eliminating electrolyte-induced surface damage and providing well-characterized thermodynamic conditions, this gas-phase method yields more reproducible and accurate data.

In this talk, we will also introduce pulsed laser experiments in the titanium atom probe, significantly expanding the usefulness of atom probe tomography for the investigation of hydrogen in materials.

As a complement, we also introduce a novel thermal desorption spectroscopy method with significantly improved thermal/energetic resolution. This system works in the UHV regime and has improved diffusion dynamics over conventional approaches. This complements the atom probe to provide statistically significant data on hydrogen-defect interactions, especially in fcc systems, where sluggish diffusion limits the interpretability of the TDS data.

Paper 1584 2 Investigating Hydrogen Embrittlement in Superalloys: The Role of Intermetallic Phases

Dr. Steffen Neumeier, Germany

Oral Presentation (20')

Abstract

The most widely used Ni-based superalloy, Alloy 718, shows significant hydrogen embrittlement. The strengthening precipitates γ' and γ'' as well as the grain boundary pinning δ phase play a significant role in the embrittlement of this polycrystalline alloy. In order to investigate whether superalloys with other grain boundary pinning phases show similar hydrogen embrittlement, two different γ' strengthened CoNiCr-based superalloys with additional intermetallic B2-structured β or D85-structured μ phase particles were investigated. NanoSIMS mapping revealed the highest hydrogen concentration localized within the grain boundary pinning μ precipitates, a finding corroborated by synchrotron diffraction measurements showing significant lattice expansion of the μ phase after hydrogen charging. Neutron diffraction experiments further indicate that the γ' phase absorbs more hydrogen than the γ phase, resulting in greater expansion and an increased lattice misfit between the γ and γ' phases. Tensile tests demonstrate a pronounced influence of hydrogen on the mechanical properties of samples charged with high-pressure hydrogen. The enrichment of hydrogen within the intermetallic grain boundary particles and strengthening precipitates promotes considerable crack initiation and facilitates crack propagation along weakened γ/γ' interfaces. These findings deepens the understanding of hydrogen embrittlement in superalloys and help to develop more hydrogen-resistant alloys.

Paper 424 **3** **Tracking hydrogen in metals: permeation and thermal desorption study using a deuterium tracer**
Dr. Aleksandra Baron-Wiechec, China
Oral Presentation (20')

Abstract

It is known that hydrogen can enter the alloy material during service or manufacturing process and significantly deteriorate the mechanical properties of steel. Information on hydrogen permeation and desorption is crucial for better understanding the susceptibility to pitting corrosion and hydrogen embrittlement phenomena in order to obtain improved resistance to hydrogen-induced degradation in future materials development. Stainless steels commonly used in the nuclear industry and modified RAFM steels are preferred as structural materials for fusion reactors due to their good mechanical properties and corrosion resistance under the realistic conditions of the ITER and DEMO reactors. In this work, electrolytic deuterium uptake and desorption behavior in RAFM steels (with increased W and Si content) and 304 stainless steel was studied using thermal desorption spectroscopy (TDS) and electrochemical permeation (Devanathan-Stachursky method), supported by corrosion test before and after charging to evaluate the changes in surface condition during the charging process. A set of electrolytes were prepared from 99.98% heavy water (D₂O) to distinguish between naturally occurred hydrogen and deuterium introduced to the material by electrochemical charging. The overall conclusions are: the current densities as low as 1mA/cm² and time between 70-90 minutes is sufficient to permeate 0.4 mm thick steel in 0.1 M sodium arsenate solution and pure D₂O (pH 8). In these conditions, the best reproducibility of TDS results and the lower damage to the surface were observed. The deuterium (mass 4) and HD (mass 3) spectra of three steels displayed an asymmetric desorption peak at ~385–395 K (probably overlapping two maxima) and HD maxima at ~385–395, ~480-510 K. For all materials and charging conditions tested, the intensity of the mass 3 was higher than that of mass 4, and the deuterium uptake was greater when the electrolyte was stirred, the obtained values were 0.76 x 10¹⁵ at/cm²(stagnant) 2.36 x 10¹⁵ at/cm² (stirred). The Tafel plots for as received and after electrochemical charging samples showed a shift in the corrosion potential towards more noble values by approx. 0.02-0.1 V. The corrosion current density decreased 10 times, which indicates that an oxide layer was formed on the surface. Time intervals ranging from 8 hours to 7 days between the charging process and TDS measurements reduced the amount of retained deuterium for all analyzed steels when stored in air, however the mass 3 retention was not significantly affected. No such difference was observed for samples left in water of a normal hydrogen concentration.

Paper 1045 4 **Hydrogen embrittlement of precipitation hardened austenitic alloys at liquid helium temperature – The role of hydrogen diffusivity and serrated flow**
Mrs. Nina Damm, Austria
Highlight (Oral Presentation 20')

Abstract

The influence of temperature on hydrogen embrittlement of the precipitation hardened Ni-based alloy N07718 has been previously studied down to cryogenic temperatures of 77 K, showing a reduction of the hydrogen induced ductility loss with decreasing temperature. It has been suggested that hydrogen diffusion is mandatory to cause the embrittling effect. However, operating temperatures of cryogenic tanks and valves for liquid hydrogen storage can go down to 20 K, where the effect of hydrogen on tensile properties remains poorly investigated for precipitation hardened fcc alloys. In this study we conduct tensile tests with an initial strain rate of $3 \times 10^{-5} \text{ s}^{-1}$ at liquid helium temperature (4.2 K) and room temperature on two precipitation hardened alloys, namely Ni-based alloy N07718 and austenitic steel S66286, in an uncharged and a pressurised hydrogen charged state. Results show that virtually no hydrogen embrittlement has been determined at liquid helium temperature. This behaviour is discussed regarding the influence of serrated flow and the effect of cryogenic temperatures on hydrogen diffusivity. In addition, a diffusion model is applied to simulate hydrogen distribution within the two alloys at the investigated temperatures considering potential hydrogen trapping sites.

Paper 1012 5 **Digital material design guidelines for mitigation of hydrogen embrittlement**
Dr. Vsevolod Razumovskiy, Austria
Oral Presentation (20')

Abstract

The global shift towards the widespread use of renewable energy sources, including hydrogen and hydrogen-based fuels, necessitates new safety standards and innovative material solutions for both emerging and established energy sectors. Modern multiscale computational methods offer a promising pathway to accelerate material development and address potential safety risks associated with materials early in their development cycle.

In this review, we highlight computational techniques that have been effectively utilized to propose various strategies for mitigating hydrogen embrittlement in high-strength steels and nickel-based alloys. Furthermore, we introduce novel methods developed at our center to study this phenomenon under diverse conditions. Our approach encompasses multiple length and time scales, ranging from atomic-scale quantum mechanical density functional theory calculations to continuum meso and macro scales represented by phenomenological thermodynamic and kinetic models, as well as the finite element method. These techniques enable us to analyze and predict the evolution of hydrogen-material interactions based on material composition, microstructure, time, temperature, and mechanical stress.

Component test for the assessment of in-service welding on/onto pressurized hydrogen pipelines

Dr. Michael Rhode, Germany

Oral Presentation (20')

Abstract

Hydrogen is the energy carrier of tomorrow and requires a reliable large-scale transport infrastructure. In addition to new pipelines, the conversion of existing natural gas (NG) pipeline grids is an essential part. The transport of hydrogen is fundamentally different from that of NG, as hydrogen can be absorbed into the pipeline material. Given the effects of hydrogen embrittlement, the material compatibility (low alloy steels in a wide range of strengths and thicknesses) must be investigated. However, pipelines e.g. require maintenance or the need for installation of additional outlets with the necessity of welding on/onto the pipelines while they are still in service, i.e. with gas flow under high pressure, such as the well-known "hot tapping". This in-service welding poses challenges for hydrogen operations. The challenge can be roughly divided into the possible austenitization of the inner pipe material exposed to hydrogen, the welding itself, which causes an increased temperature range. Both lead to a significant increase in hydrogen solubility and diffusivity compared to room temperature. In addition, possible surface reactions of the present iron oxides (e.g. magnetite or hematite) with the hot hydrogen should be considered. In this context, the knowledge of hydrogen pipelines is scarce due to the lack of operational experience. Fundamental experimental investigations are required to investigate the transferability from NG to hydrogen pipeline grids. For this reason, the present study presents a specially designed mock-up / demonstrator concept for the realistic assessment of the welding process conditions. The mock-up was designed to allow in-situ temperature measurement during the welding process as well as ex-post sample extraction for quantification of the absorbed hydrogen concentration. For safety reasons, the required volume of pressurized hydrogen was limited by inserting a solid cylinder to ensure a 1 cm thick layer of hydrogen gas. Welding experiments on the DN60 and DN200 pressurized mock-ups showed the possibility of safe welding on or onto pressurized hydrogen pipelines. Indeed, the austenitizing temperature was reached on the inner surface of the pipeline, especially on thinner-walled pipelines, using current welding parameter recommendations. This corresponded to an increased hydrogen uptake in the welded area of several ppm. From this point of view, the suggested component concept is a viable strategy for the screening of several materials and welding parameter combinations under realistic operational conditions.

Paper 772 1 Effect of gaseous hydrogen on polyethylene pipe materials

Dr. Florian Arbeiter, Austria

Oral Presentation (20')

Abstract

The shift to renewable energy systems necessitates efficient methods for storing surplus energy, such as converting it into hydrogen (H₂) through electrolysis. One potential solution for storing and transporting hydrogen is injecting it into existing polyethylene (PE) gas networks. However, the impact of hydrogen exposure on the mechanical properties and longevity of PE pipes, particularly in relation to slow crack growth (SCG), is scarcely investigated. While some studies suggest little effect on polymeric pipes, recent research indicates that high-pressure hydrogen may influence SCG behavior. This study explores the effects of prolonged exposure to gaseous H₂ at operational pressures (~10 bar) on PE pipes using fracture mechanics techniques, specifically cyclic Cracked Round Bar (CRB) tests. Two sets of PE100 pipes were examined: one exposed to gaseous H₂ for two years and the other subjected to water pressurization for over 1000 hours. The findings showed comparable SCG behavior between the pipes exposed to hydrogen and those exposed to water, suggesting that pressure, rather than hydrogen itself, may be the key factor affecting SCG performance.

In parallel, the question regarding the interaction of permeation rates and inner structure of the polymer is an intriguing one. Therefore, a study on the influence of processing conditions on the inner structure and subsequent permeation rates at operational pressure was performed. The study examined the impact of seven different cooling and pressure conditions, as well as degree of crystallinity on the permeation rate of gaseous H₂ through PE. While some differences could be found, the maximum change of permeation rate was found to be roughly 10%. This indicates, that regardless of the processing conditions of PE, the amorphous regions in between crystalline domains are the determining factor with regards to permeation and processing conditions alone cannot introduce big differences in permeation rate.

Paper 1447 2

Hydrogen embrittlement mechanism in additively manufactured stainless steel

Mr. Yixiang Jin, United Kingdom

Oral Presentation (20')

Abstract

Laser Powder Bed Fusion (LPBF) is a promising manufacturing technique for advanced engineering components potentially offering improved mechanical properties. However, the performance of LPBFed components in hydrogen-rich environments remains largely unknown, raising concerns about long-term reliability for applications in hydrogen storage and energy conversion. This study investigates the hydrogen embrittlement (HE) mechanisms of LPBFed 316L SS, including experimental testing, microstructural characterisation, and computational modelling to establish a deeper understanding of hydrogen interactions with LPBFed manufactured materials.

Isothermal desorption spectroscopy (ITDS) demonstrates that LPBFed 316L exhibits higher hydrogen diffusivity compared to its wrought counterpart, suggesting an altered hydrogen transport mechanism within its melting pool boundaries and subgrain microstructure. Slow strain rate tensile tests (SSRT) with in situ neutron diffraction confirm that LPBFed 316L maintains a stable austenitic phase under mechanical loading, with no observable strain-induced martensitic transformation, even in hydrogen-charged conditions. It is also found with EBSD that hydrogen activates dislocation multiplication in the early stage of deformation, and the LPBFed microstructure can suppress this trend, reducing embrittlement susceptibility.

Further investigations using digital image correlation (DIC), reveal earlier initiation but slower propagation of cracks in all hydrogen charged specimens and macroscopic hydrogen-induced localised strain in wrought specimens, providing evidence on enhanced localised plasticity in hydrogen-charged samples. SEM also observe typical quasi-cleavage fracture surface in hydrogen charged samples. Mitigation of this phenomenon was found in LPBF specimens.

To bridge experimental findings with theoretical understanding, a dislocation-assisted hydrogen migration model was developed, providing quantitative insights into the hydrogen-trapping behaviour at subgrain boundaries. Simulations reveal that the fine subgrain structures in LPBFed 316L limit hydrogen accumulation at grain boundaries, reducing embrittlement susceptibility compared to wrought 316L. This novel mechanistic understanding supports the superior hydrogen embrittlement resistance of L-PBF 316L, positioning it as a promising material for hydrogen storage and energy applications.

This work provides compelling evidence that LPBF processing enhances hydrogen embrittlement resistance while providing higher mechanical strength, paving the way for the broader adoption of additively manufactured stainless steels in hydrogen-related applications. By integrating experimental findings with multiscale modelling, this study offers new perspectives into hydrogen-material interactions in advanced manufacturing technologies.

Paper 22 4 **Layered nanostructured magnesium alloys for hydrogen storage synthesized by accumulative fold-forging (AFF)**
Prof. Farzad Khodabakhshi, Belgium
Oral Presentation (20')

Abstract

Accumulative fold-forging (AFF) is an innovative severe plastic deformation (SPD) technique used to consolidate magnesium foils, both with and without the incorporation of niobium particles. Advanced microscopy techniques were employed to study the formation of nano-grains and the bonding at the interfaces between the nano-layers. Following this, the hydrogen storage performance of the resulting layered nanostructures of magnesium alloys was evaluated in relation to the microstructural characteristics observed after the AFF processing of Mg and Mg/Nb materials. Hydrogenation and dehydrogenation tests were conducted at various temperatures, revealing that the interfaces formed by SPD, such as grain boundaries and nano-layers, significantly contributed to the results. Ultimately, the maximum hydrogen storage capacity of magnesium was achieved, although the kinetics of storage and release varied based on the testing temperature, the presence of niobium particles at the layer interfaces, and the extent of microstructural refinements induced by the AFF process.

LOW TEMPERATURE CATALYTIC SUPERCRITICAL WATER GASIFICATION FOR CONTINUOUS HYDROGEN GENERATION FROM BIOMASS WASTEWATER

Prof. Edward Lester, United Kingdom

Oral Presentation (20')

Abstract

A continuous hydrothermal process is demonstrated, for the first time, that can operate at low gasification temperature (430 °C) and residence time (20 s) by combining supercritical water gasification (SCWG) and partial oxidation with in situ synthesis of virgin metal oxide nano-catalyst. This process addresses the challenges associated with catalyst deactivation of a fixed bed, tedious homogenous catalyst separation after the process and/or the need for high operating temperatures. Industrial biomass wastewater was used as the feedstock for generating hydrogen and methane-rich syngas, with a metal oxide nano-catalyst as a valuable co-product and cleaner water, lower in chemical oxygen demand (COD) and total organic carbon (TOC), as a liquid product.

Using olive wastewater as the feedstock, this gasification study experimentally investigated the impact of multiple variables: (1) COD feed concentration, (2) the in situ synthesis of different metal oxide nano-catalysts, (3) the partial oxidation coefficient (η) and (4) the nano-catalyst precursor solution concentration. The optimum conditions for the generation of hydrogen and methane from olive wastewater were a feed COD of 38.6 g/L, $\eta = 0.8$, and 60 mM precursor concentration for the in situ synthesis of Fe₂O₃ nano-catalyst. These optimised conditions were further investigated using spent lees and stillage. The efficiency of hydrogen and methane yields and COD reduction were in the order of stillage > spent lees > olive wastewater. The highest hydrogen molar selectivity, hydrogen and methane yields at 18.8 %, 17 and 11.4 mol/(kg biomass) respectively were obtained with stillage feedstock. Gasification, COD and TOC reduction efficiencies were 68.8–71.7 %, 72.6–76.5 % and 53.9–55.7 % respectively, with this process.

Importantly, this process was further validated by showing stable, steady-state gasification performance in terms of gas yields with olive wastewater, stillage and spent lees as the feedstocks during continuous operation for 40 min without any significant drop in performance. This study exemplifies that the co-generation of catalyst during SCWG is a promising and economically feasible direction for large-scale continuous generation of hydrogen and methane from different types of biomass wastewater at < 450 °C, whilst lowering its COD and TOC.

Paper 2030 6

Hydrogen risk mitigation using high-porosity autocatalytic materials

Mr. Kévin Touchet, France

Highlight (Oral Presentation 20')

Abstract

Hydrogen Risk Mitigation Using High-Porosity Autocatalytic Materials

Hydrogen is garnering significant interest as an energy vector pivotal to the ecological transition. While the majority of hydrogen is mainly produced via methane catalysis, the emergence of decarbonated hydrogen produced from low-carbon energy sources is notable. Hydrogen's high energy release upon combustion, emitting primarily water as a byproduct, underscores its potential. However, its high flammability, propensity for detonation, and impact on material structures, elevate accident risks [1], [2]. Additionally, studies indicate that environmental hydrogen release can indirectly exacerbate global warming by extending the atmospheric lifetime of other greenhouse gases, such as methane.

In this project, we have developed microstructured, high-porosity materials designed to convert leaked hydrogen into water vapor through autocatalytic processes. These composites materials allow to convert more effectively the hydrogen into water vapor than the simpler and costly use of bulky metallic palladium and platinum of the Passive autocatalytic recombiners (PARs) [3]. The use of appropriate metallic oxides doped in catalysts enhances reaction efficiency at room temperature even at low concentration [4]. The exothermic nature of this reaction accelerates hydrogen consumption while allowing its detection. In confined spaces, this technology significantly reduces the risk of hydrogen accumulation. Moreover, the resultant water vapor saturation decreases the flammability risk of hydrogen-oxygen mixtures, as delineated in the Shapiro diagram [2]. For outdoor storage or pipeline operations, these materials can be applied to prevent environmental hydrogen release whilst allowing its leakage screening.

Our research focuses on both the chemical composition and physical structure of the material. We optimize the selection and ratio of metallic oxides and catalytic components to enhance reaction kinetics. Additionally, microstructuring techniques are employed to maximize the specific surface area, achieving surfaces exceeding 50 square meters per gram of material allowing efficient neutralization and detection of hydrogen leak.

This approach aligns with current advancements in catalyst technology for hydrogen applications, emphasizing the importance of material selection and structural optimization to mitigate associated risks.

Paper 1535 1 **Improving the data-driven experimental materials science: PASTA-ELN electronic laboratory notebook**

Dr. Steffen Brinckmann, Germany

Oral Presentation (20')

Abstract

Electronic laboratory notebooks (ELNs) revolutionize research data management in experimental materials science by streamlining workflows and improving efficiency. Unlike traditional manual methods of documentation and sharing research data, ELNs save scientists valuable time and effort, allowing them to focus on the core aspects of their work. This presentation introduces PASTA-ELN, a customized ELN solution designed specifically for experimental materials science.

One of the standout features of PASTA-ELN is its innovative approach to raw scientific data storage. By storing raw data locally on the researcher's hard drive, PASTA-ELN ensures data accessibility and application of further analysis protocols, while safeguarding data confidentiality and security. Additionally, metadata related to measurements, samples, etc. is stored in a dynamic SQLite database, which functions like a document database for efficient data management.

PASTA-ELN also includes extractor add-ons that automatically process raw measurement files by scanning the working directory. These add-ons capture thumbnails, data, and metadata, integrating them seamlessly into the project. Researchers can customize these extractors to suit their specific requirements for data and metadata processing.

As a member of "The ELN Consortium", PASTA-ELN facilitates data exchange and collaboration through the RO-Crate standard via a compatible (.eln) file format. This feature enables effective data archiving, migration across platforms, and ensures long-term data interoperability, fostering collaboration across research teams and institutions.

Comparative Analysis of Bainitic Microstructures under Varying Heat Treatment Conditions: Microstructure, Mechanical Behavior, and Yield Surface Estimation

Mr. Dhanunjaya Kumar Nerella, Germany

Oral Presentation (20')

Abstract

Bainitic steels are widely recognized for their exceptional combination of strength and toughness, making them essential in advanced engineering applications. This study presents a comparative evaluation of two distinct bainitic microstructures produced through varying heat treatment conditions. Microstructure evaluation was performed to analyze phase distribution and grain morphology. Tensile tests were conducted to evaluate the mechanical properties, including ultimate tensile strength and yield strength providing insights into the performance variations induced by the differing heat treatments. Additionally, yield surface estimations were performed to investigate the anisotropic stress-strain response and local deformation behavior of the bainitic microstructures. The findings reveal significant correlations between the heat treatment parameters, resulting microstructural features, and mechanical performance metrics. This study underscores the critical role of heat treatment in tailoring bainitic microstructures to achieve desired mechanical properties. The insights into yield surface behavior offer a deeper understanding of localized stress distribution and deformation mechanics, which are crucial for optimizing the design and application of bainitic steels in high-stress environments. These findings contribute to advancing the development of high-performance bainitic materials through precise heat treatment control.

A unique authenticator for additively manufactured parts derived from their microstructure

Dr. Anja Waske, Germany

Oral Presentation (20')

Abstract

The international research community is currently devoting extensive resources to the development of digital material data spaces and the associated digital twins and product passports of materials and components. A common weak link in these projects to date has been the connection between physical components / samples and their digital data and documents. This is where the concept of the unique identification comes in. Components produced using additive manufacturing can be marked for unique identification and secure authentication [1,2]. Serial numbers and machine-readable codes can be used to identify the component, and link digital product-related data (i.e., a digital product passport) to the actual components. The most prevailing solution consists of local process manipulation, such as printing a quick response (QR) code [3] or a set of blind holes on the surface or the internal cavity of hollow components. However, local manipulation of components may alter the properties, and external tagging features can be altered or even removed by post-processing treatments.

This work provides a new methodology for identification, authentication, and traceability of additively manufactured (AM) components using microstructural features that are unique to each part. X-ray computed tomography (XCT) was employed to image the microstructural features of a batch of AlSi10Mg parts. Based on size and geometry, the most prominent features were selected to create a unique digital authenticator. We implemented a framework in Python using open-access modules that can successfully create a digital object authenticator using the segmented microstructure information from XCT. We show that this method allows to authenticate individual parts from the build cycle based on its microstructural fingerprint. This is our contribution to enhancing the security and product protection of additively manufactured components.

Accelerating Discovery of Corrosion-Resistant Alloys Using a Self-Driving Laboratory and Closed-Loop Optimization

Dr. Özlem Özcan Sandikcioglu, Germany

Oral Presentation (20')

Abstract

The development and commercialization of novel corrosion-resistant alloys through conventional experimental approaches is often slow and costly. To accelerate this process, global efforts have focused on creating self-driving laboratories, known as Material Acceleration Platforms (MAPs). These platforms integrate automated material synthesis, characterization, and testing into closed-loop workflows, leveraging artificial intelligence (AI) and machine learning (ML) to optimize experiment design, predict material properties, and analyze data efficiently.

We have developed a MAP for corrosion research by automating liquid handling, electrochemical testing, and data evaluation. The electrochemistry module supports both the electrodeposition of various alloys and subsequent electrochemical corrosion testing. Through a closed-loop optimization framework, test results inform the selection of the next set of deposition parameters autonomously until predefined objectives are met. This iterative optimization is powered by active learning strategies and Bayesian optimization, to efficiently explore the parameter space (bath composition incl. metal ion and additive concentrations as well as the current density) to identify promising alloy compositions. In this project, we utilized the MAP to design new multi-principal element alloys (MPEAs) as corrosion-resistant electrode materials for H₂O, NO₃ and CO₂ electrolysis. The development of the MAP workflow also includes the optimization of electrochemical testing sequences, ensuring that the experimental design maximizes data efficiency, minimizes redundancy and uses multiple metrics for performance evaluation. In one optimization run, open circuit monitoring, electrochemical impedance spectroscopy (EIS), linear polarization resistance (LPR) and chronoamperometry (CA) measurements can be configured in a sequence. In each campaign, the MAP selects promising leads for upscaling, either by means of electrodeposition or powder metallurgy and arc-melting. Spectroscopic and electrochemical characterization techniques are then employed with selected systems to validate the MAP-driven leads.

This presentation will provide an overview of the MAP's design, its integrated modules, and workflow implementation. We will also highlight key findings from our FeNi-X MPEA system and discuss how closed-loop optimization strategies enhance the rapid discovery of corrosion-resistant alloys.

ML-driven optimization of corrosion inhibitor mixtures with an automated platform

Ph.D. Ahmad Rashid Hazem, Germany

Oral Presentation (20')

Abstract

The CorRobot initiative is a pioneering project in materials science that automates corrosion protection material discovery through an AI-driven workflow, integrating Bayesian Optimization (BO) with neural networks. Traditional discovery methods for corrosion inhibitors are often slow, costly, and inconsistent due to variations in testing methodologies and environmental conditions. CorRobot streamlines this process by optimizing the automation platform with intelligent decision-making, enabling efficient and precise inhibitor formulation discovery.

The CorRobot workflow leverages neural networks to model complex electrochemical relationships, while BO intelligently selects the most informative experiments, reducing the number of trials required. This adaptive learning system refines experimental conditions in real time, prioritizing promising formulations and improving the efficiency of corrosion inhibitor screening. By integrating predictive modeling with automated laboratory processes, CorRobot minimizes human intervention while maximizing data-driven optimization.

A key breakthrough of the CorRobot project is the identification of an effective low-concentration mixture of cerium nitrate and sodium fumarate for iron corrosion protection. This result underscores the power of AI-enhanced workflows in uncovering novel inhibitor synergies often overlooked in conventional methods. The seamless integration of BO and neural networks accelerates discovery cycles and enhances reproducibility in corrosion science.

Beyond improving efficiency in corrosion inhibitor discovery, CorRobot aligns with the FAIR data initiative to enhance predictive simulation tools for material properties. By optimizing workflow automation and data utilization, CorRobot's AI-driven platform has the potential to revolutionize materials science applications beyond corrosion protection. This project paves the way for intelligent, sustainable advancements in surface technology and industrial chemistry.

Paper 1833 6 Building a Legacy Lab for Advanced Functional Materials: Integrating Synthesis and Characterization Capabilities
Dr. Sandra Rabaça, Portugal
Oral Presentation (20')

Abstract

The rapid evolution of Materials Acceleration Platforms (MAPs) requires robust, interconnected research infrastructures to speed up the discovery and optimization of new materials. In this context, we are developing a distributed MAP that connects multiple legacy laboratories by integrating the expertise and experimental capabilities of the Solid-State Group through a data pipeline. This initiative aligns with the EU-MACE framework, fostering a data-driven and AI-assisted approach to materials research. The distributed MAP will encompass various synthesis and characterization facilities, including:

- High-Temperature Synthesis and Crystal Growth Laboratory – focused on the preparation and single crystal growth of inorganic-based materials.
- Molecular and Electrochemical Synthesis Laboratory – specialized in the synthesis of molecular-based materials with unconventional electrical and magnetic properties.
- Polymer Synthesis Laboratory – leveraging expertise from the Organic Electronics Laboratory (IT) to explore organic conducting materials.
- Magnetic and Electrical Characterization Laboratory – equipped for measurements at low temperatures and high magnetic fields.
- Mössbauer Spectroscopy Laboratory – providing insights into hyperfine interactions and electronic structures.

By digitally connecting the synthesis and characterization laboratories, we aim to create a highly efficient research environment that enhances reproducibility, data sharing, and machine-learning-driven material discovery. This initiative will serve as a strategic step toward implementing MAPs within the EU-MACE framework, strengthening Europe's leadership in the field of advanced functional materials.

pyironflow - Enhancing user interactivity in advanced materials science workflows

Dr. Tarakeshwar Lakshmipathy, Germany

Oral Presentation (20')

Abstract

To improve efficiency and the user experience of composing, executing, validating and sharing complex workflows in materials science, several modules of pyiron (<https://pyiron.org>) are currently being developed. Workflows included in the scope of developments encompass, e.g., multiscale simulation workflows bridging atomistics with the continuum scale and experimental workflows with machine-learning in the loop. In this presentation, pyironflow, a graphic user interface (GUI) for a node graph approach to workflows in pyiron, is explored. The front-end of the module is based on a combination of React Flow and Jupyter Widgets while the back-end interfaces with various other pyiron modules. The nodes, formatted as Python functions for ease of extension and incorporation of new software, are conveniently listed in a node library and can be introduced into the viewport and interconnected. Furthermore, the input and output ports of the nodes, and the nodes themselves can be semantically annotated according to established ontologies. This enables interoperability between tools and allows for sharing of workflows in research data management platforms while adhering to FAIR (findable, accessible, interoperable and reusable) principles. In the GUI, the uploading of annotated workflows and resultant data can be accomplished with a simple click of a button once the mappings to the platforms are defined. The annotations also enable semantic validation of workflows. The outcomes of these validations, based on semantic restrictions defined on nodes, are reflected in the GUI. All these features are showcased with examples of metallic materials and their properties. The presentation will then conclude with an outlook on future developments, including semantic composition of advanced workflows and a web portal for pyironflow.

A User-Friendly Application for Seamless Material Science and Engineering Knowledge Integration: The Graph Designer App

Dr. Elena Garcia Trelles, Germany

Oral Presentation (20')

Abstract

In the rapidly evolving field of Material Science and Engineering, ontologies play a significant role in digitalizing data and ensuring adherence to FAIR principles (Findability, Accessibility, Interoperability, and Reusability). They enhance interoperability among diverse data sources and formats, enabling the development of automated workflows tailored to specific applications across institutions. However, the implementation of this advanced technology often necessitates data science skills that many production engineers and materials scientists may not possess.

To bridge this gap, we present the Graph Designer App, a user-friendly web-based application designed to make ontology-based semantic digitalization accessible. This app empowers users to create domain-specific knowledge graphs utilizing pre-loaded ontologies (e.g., the PMD-co). Users can visualize these graphs, populate them with process data, and convert them seamlessly into RDF format for storage in graph databases or further processing through SPARQL queries.

A key feature of the Graph Designer App is its application of consistent graph patterns, which support the creation of generic SPARQL algorithms for complex processing tasks, such as generating and retrieving digital process chains. By simplifying intricate ontology workflows, the Graph Designer App enables users to harness semantic technologies without extensive data science knowledge.

The app functionality is illustrated through a dataset focused on high-temperature materials, featuring a use case derived from the Material Digital 2 project, funded by the German Federal Ministry of Education and Research (BMBF). This dataset is utilized to calibrate sophisticated inelastic deformation models. In this context, an ontology domain module is developed to digitalize deformation models and simulation processes, making specialized material knowledge accessible to component design and optimization engineers.

Moreover, the ontology-based knowledge graph ensures traceability of model parameters to individual data points, providing a comprehensive description of the material state. This traceability offers a solid foundation for model validation and further refinement, significantly improving reliability and reproducibility in Material Science and Engineering applications.

Paper 2032 1 Automating Knowledge Graph Composition for Multi-Scale and Interdisciplinary Research

Mr. Osamu Waseda, Germany

Oral Presentation (20')

Abstract

In multi-scale modeling and interdisciplinary research, the integration of heterogeneous data and domain knowledge is essential for achieving comprehensive insights. Ontology-driven knowledge graphs (KGs) serve as a powerful framework for structuring and connecting information across different disciplines and scales. However, manually constructing and updating KGs is a time-consuming and error-prone task. This talk introduces semantikon, a software package designed for automating the composition of knowledge graphs based on user-defined workflows. By leveraging ontologies, reasoning mechanisms, and workflow-driven orchestration, semantikon ensures semantic consistency, enhances interoperability, and facilitates dynamic knowledge integration. This approach enables researchers in materials science to efficiently model complex systems, bridge disciplinary boundaries, and accelerate data-driven discovery. We discuss methodologies for workflow-based KG automation, key challenges, and potential applications in materials science.

Paper 1562 2 EMMO: an ontology based on universal materials science concepts

Dr. Gerhard Goldbeck, Belgium

Oral Presentation (20')

Abstract

The task of building a 'materials science knowledge graph' is intriguing but also appears daunting. However, in materials science we can build on fundamental physical science principles and foundations. That is how the EMMO ontology has been constructed from the bottom up. The paper will discuss these foundational requirements in relation to the ISO standard for Top Level Ontologies, and how materials science desiderata are fulfilled by EMMO. Based on these solid foundations, examples of the EMMO discipline and domain ontologies will be showcased. In particular, we highlight the CHAMEO ontology for materials characterisation, which underlies the updated "CHADA" CWA 17815:2025. Finally the application of CHAMEO to industrial applications including battery testing and automotive coatings will be demonstrated. This work received funding from the European Unions Horizon 2020 programme, Grant Agreements n. 952869, 862136 and 953167

Semantic Technologies for Digital Transformation in Materials Science: From PMDco 3.0 to Prototypical Applications

Dr. Markus Schilling, Germany

Oral Presentation (20')

Abstract

The digital transformation of Materials Science and Engineering (MSE) is accelerating the adoption of structured, interoperable, and FAIR data practices, in particular with respect to an advanced research data management. Semantic technologies play a pivotal role in this transformation, as they enable the integration, contextualization, and automation of diverse data sources across experimental, computational, and simulation domains. Central to these efforts is the Platform MaterialDigital Core Ontology (PMDco), now in version 3.0, which provides a robust mid-level semantic framework tailored for MSE. PMDco bridges abstract high-level ontologies, such as the Basic Formal Ontology (BFO) standardized in ISO/IEC 21838-2, with domain-specific terminologies to ensure consistency and interoperability across applications.

This presentation explores the application of PMDco and its integration into workflows within the Platform MaterialDigital (PMD) initiative. Through its deployment in electronic laboratory notebooks (ELNs), PMDco enables semantic representation of experimental data, such as tensile test results compliant with ISO 6892-1:2019-11, transforming them into machine-actionable knowledge graphs. Prototypical implementations demonstrate how semantic technologies enhance laboratory processes, improve data reuse, and streamline documentation which offers opportunities for automation and education. Further extending its versatility, PMDco serves as a linking point for semantically representing simulation data, enabling comprehensive integration of experimental and computational datasets. This creates structured data spaces that support advanced digital workflows. Beyond PMDco, the presentation highlights the design of graph patterns and semantic shapes, showcasing generalizable methods for managing diverse data in MSE being based on data structuring and formatting.

By presenting best practices in ontology development, data acquisition, and knowledge graph generation, this talk underscores the transformative potential of semantic technologies in MSE. It offers a forward-looking perspective on the role of structured data spaces as a driver for innovation, ensuring that materials science continues to advance through rigorous, interoperable, and automated digital methodologies.

From unstructured to structured data – semantics-driven workflows for multimodal characterization of materials properties

Mrs. Sepideh Baghaee Ravari, Germany

Oral Presentation (20')

Abstract

A meaningful characterization and understanding of material properties depends on structured data from experiments and simulations. To combine information from both sources, a formal language enables the standardization of workflows for meaningful comparisons.

Our strategy to enable this comparison efficiently involves two main steps. First, we curate a dataset of unstructured literature sources that includes results from studies of experimental and simulation origin related to a defect property known as stacking fault energy (SFE). To structure them, we use multiple large language models (LLMs), such as GPT-4o and Mistral Large 2, within the llama-index framework. These models are used to identify key entities and extract their relationships within the structure-process-properties paradigm. The extraction process is ontology-guided, using the computational material sample ontology (CMSO) [1] and atomistic simulation methods ontology (ASMO) [2] for simulation-based studies. For experimental information we use the platform material digital (PMD)-core [3] and PMD-application. To improve the accuracy and relevance of extracted information, we employ prompt engineering techniques. This results in a structured and domain-aware organization of knowledge from literature.

Second, we have a simulation workflow with an ontological track using CMSO and ASMO with the help of the atomRDF [4] package to perform stacking fault energy calculations. This workflow incorporates a variety of computational methodologies, including gamma surface analysis, axial next-nearest neighbor Ising (ANNNI) model, and tilted cell approaches, all implemented in LAMMPS [5]. With the ANNNI model, we explore the composition and temperature dependency of SFE. The simulations are carried out on pure magnesium and aluminum as well as aluminum-magnesium alloys.

By integrating literature-based knowledge extraction with ontology-driven simulations, we construct a comprehensive knowledge graph that allows to connect data from existing experimental and simulation sources as well as new results. Within the llama-index framework, we further improve the usefulness of this knowledge graph by employing a retrieval-augmented generation (RAG) approach. This allows us to systematically extract the different steps of a workflow while preserving the correct sequence of operations. Additionally, the RAG approach enables us to determine the necessary parameters associated with each process step and allows reproducibility. Ultimately, such a knowledge graph can serve as a robust framework for linking experimental findings, computational workflows, and materials properties, thereby improving our understanding of stacking fault energies and their dependencies across different materials and conditions.

Digital representation of physical metallurgical knowledge

Dr. Jesper Friis, Norway

Oral Presentation (20')

Abstract

We will here present a framework for digitally documenting materials knowledge addressing all levels of semantic documentation, including cataloguing as well as structural, contextual and semantic documentation. It ensures that the documented data becomes FAIR with a special emphasis of making it meaningful, linked and actionable. The documentation itself is stored in a knowledge base, while the documented resources (e.g. datasets) may be stored elsewhere. All types of resources (datasets, materials, processes, samples, instruments, models, researchers, etc...) can be documented and related to each other using the Elementary Multiperspective Material Ontology (EMMO) and its domain ontologies. It ensures consistency of data documentation with materials science knowledge. Datasets are furthermore documented using the DCAT-AP vocabulary (making them accessible and useful for DCAT-aware data services) and preferably also with formalised data models mapped to the ontologies (to document their structure and achieve interoperability at a numerical level).

The framework is developed with the perspective of the data producer focusing on making the documentation process as seamless and simple as possible, while ensuring that all aspects of the FAIR principles are addressed. The data producer is only exposed to well-defined keywords that may either refer to literal values or other resources in the knowledge base. Behind the scenes, the keywords are mapped to ontological data properties (literals) or object properties (resources) using a JSON-LD context. The set of available keywords can be extended with a custom JSON-LD context. To keep the required input for the data documentation to a minimum, the framework reuses the mappings and data models to prepopulate all input fields that can be inferred from the documented resource. Complex (potentially nested) inferences and transformations are achieved with the help of so-called mapping functions. They are functions typically implemented in Python, whose input and output are defined from the ontologies. They are documented like any other resource and applied transparently by the framework whenever transformations are needed between different literal representations.

To document a series of similar resources, the framework offers a spreadsheet-like interface. This allows the data producer to prepare the documentation using a familiar tool like Excel and commit the documentation of all the resources in one go. The European Union's Horizon 2020 and Horizon Europe research and innovation programs are acknowledged for funding via OntoTrans (862136), OpenModel (953167), MatCHMaker (101091687) and PINK (101137809). A Generative Adversarial Networks (GANs)-based data augmentation in the context of material testing and predicting strain rate effect

Mr. Sanghyun Yoo, Germany

Oral Presentation (20')

Abstract

The aerospace industry is showing increasing interest to accelerate the certification process of composite aero-structure using machine learning (ML) models since certification often requires extensive testing to validate the safety and reliability. For example, the number of experimental tests, especially at the coupon level, can be reduced using ML models by identifying patterns and relationships while still ensuring the necessary levels of reliability in material characterisation.

However, a large amount of data is essential to train ML models for learning the patterns to correctly predict the target values. The acquisition of training data, more particularly for the identification of strain-rate effects in composite materials, solely through material testing is often difficult due to high costs and time constraints, which often result in data scarcity. The lack of data presents considerable challenges when training ML models, as it can lead to overfitting and poor generalisation.

This study reports the development of a data augmentation technique with a generative model Generative Adversarial Networks (GANs) as one of the potential solutions to alleviate the issues of data scarcity. Firstly, the capabilities of the GANs model are investigated for the generation of synthetic material test data, which should capture realistic physical phenomena. Secondly, the quality of the generated data and its similarity to available experimental datasets are evaluated. Evaluation metrics based on Principle Component Analysis (PCA) are developed to determine the acceptability of the generated synthetic data. Finally, the strain-rate effects on carbon/epoxy composites are exemplarily predicted using a Gaussian Process Regression (GPR).

Furthermore, the management of a high number of heterogeneous datasets raises additional challenges to guarantee FAIR principles. In this work, experimental and synthetic data are parsed and converted into structured JSON data and labelled using an internal ontology. The storage in the research data management system of DLR, Shepard, allows to increase data findability and interoperability.

The predicted results indicate that GPR can accurately forecast the in-plane shear strength of carbon/epoxy composites across various strain rates. This accuracy is achieved using a training dataset generated through a developed data augmentation technique. This framework supports a data-driven approach for creating synthetic data and establishes its acceptance criteria while also facilitating the prediction of the mechanical properties of carbon/epoxy composites.

Paper 1984 1 **Enhancing Data Acquisition in Manufacturing: LLMs for Effective Material Property Databases**
 Mrs. Inés Pérez Couñago, Spain
Oral Presentation (20')

Abstract

Large Language Models (LLMs) facilitate the development of up-to-date material property databases, offering significant potential for identifying materials with target properties, resolving discrepancies in reported values, and automating inputs for tools like Finite Element Analysis. This work explores Retrieval-Augmented Generation (RAG) for extracting material data, particularly from tabular formats in PDFs with varying formats. Parsing methods were evaluated for robustness, and extracted data was processed into structured formats, incorporating automatic conversion into SI units to ensure consistency. LLM-generated outputs were assessed using standard metrics, while a custom metric was designed to assess domain-specific accuracy and reliability.

An Exploration of Specification Methods and Standardization Bodies and their Impact on FAIR Research Data Management in the MSE Domain

Mr. Henk Birkholz, Germany

Oral Presentation (20')

Abstract

Materials scientists and engineers (MSE) aim to share their research findings within their communities to validate, discuss, and highlight their relevance. The current emphasis on rapid and precise material development has driven the field of integrated computational materials engineering (ICME), which relies strongly on computational support for data generation. The resulting data from such research is often large in volume and multiscale, necessitating effective summarization and abstraction methods to ensure the findings are findable, accessible, interoperable, and reusable (FAIR).

A spectrum of venues and formats for representing computationally assisted research findings exist today. As publications of research results often are intended to be FAIR, this intention necessitates representing research results in appropriate formats, complete with necessary metadata, to ensure they are reproducible and understood by other scientists for years to come. These requirements can be satisfied by appropriate specifications or standards in support of semantic interoperability and corresponding data formats tailored to the application. Yet the key question remains: which type of specification or standard is most useful for my specific application and publication?

This presentation elaborates on different aspects and perspectives to that question: (a) Stand-alone specifications are typically chosen by stakeholders who have reached a consensus within the context of a specific application. De-facto standards typically come with a proven track record of usefulness and applicability, while national or international standards have survived the scrutiny of rigorous review processes that can span many years. (b) The number and quality of authorities contributing to a standardized model can range from a central, well-vetted and well-vetting authority to standard designs that allow for multiple authorities contributing independently to the same domain. (c) The qualities of data representations for research results range from inherited requirements of "human readable", over extensibility, post-processing constraints, processing effort, and data size to convey (e.g., using JSON for material databases?).

Exemplary standards-defining organizations (SDOs) are illustrated, and corresponding approaches to registration authority models for interoperable semantics are highlighted. The advantages and disadvantages of registration authority models and data representation formats, as well as the impact of the number of authorities on design and registration procedures, are discussed in detail using examples of SDOs such as ISO, W3C, or IETF, and data representations, such as OWL, JSON, or CBOR.

While there is never one solution that fits all applications and requirements, some guidance is provided to help navigate the options in the semantic interoperability landscape presented.

Advancing Digital Transformation in Material Science: The Role of Workflows Within the MaterialDigital Initiative

Dr. Jörg Schaarschmidt, Germany

Oral Presentation (20')

Abstract

The MaterialDigital initiative represents a significant effort to advance the digitalization of material science. In addition to developing a prototype infrastructure for a shared data space and addressing semantic interoperability, the Platform MaterialDigital (PMD) emphasizes the utilization of workflows to encapsulate data processing and simulation steps in accordance with FAIR (Findable, Accessible, Interoperable, Reusable) principles. Through collaboration with the funded projects of the initiative, the Workflow Working Group is focused on establishing shared standards to enhance the interoperability and reusability of scientific data processing workflows. Central to this effort is the Workflow Store, a platform designed to facilitate the dissemination of workflows within the community, thereby enabling the exchange and replication of scientific methodologies. This presentation will discuss the challenges associated with adapting workflow concepts, offer insights into their development and application across the domains of the funded projects, and highlight the role of the Workflow Store within the initiative. Furthermore, it will outline the future roadmap for the PMD Workflow Group, aiming to further refine and expand the role of scientific workflows in advancing digital transformation and fostering collaborative research in material science.

Paper 1937 4 A seamless dataflow combining material, virtual engineering workflows and production data in the project lifecycle

Mr. Felix Vidal, Spain

Oral Presentation (20')

Abstract

Advancing industrial efficiency in high-mix/low-volume production requires innovative digital solutions that seamlessly integrate simulation workflows, process control strategies and data-driven optimisation algorithms. The development of an open innovation platform and an interoperable digital pipeline is designed to enable a design-by-simulation optimization framework. The approach integrates feedback and inline feedforward control strategies to enhance the performance of industrial systems by linking materials modelling, materials characterization, simulation-based digital twins, and data-driven models. The framework dynamically updates through distributed production data collected from embedded IoT edge devices and product quality metrics.

A unified methodology is established and demonstrated through two case studies. The first focuses on multidisciplinary optimization to ensure certified path-planning strategies for manufacturing topology-optimized structural elements via Wire-Arc Additive Manufacturing (WAAM) in the construction sector, exemplifying a low-volume production scheme. The second explores optimized design and manufacturing strategies for producing Carbon Fibre Sheet Moulding Compound (CF-SMC) components in the automotive sector, representing a high-mix production scenario. These demonstrations highlight the framework's potential to drive efficiency and innovation across diverse industrial applications.

Paper 1992 5 Laboratory Automation Aiding the Design of Multifunctional Nanocomposites

Dr. Maciej Haranczyk, Spain

Oral Presentation (20')

Abstract

Advanced polymer nanocomposites are relevant to a broad spectrum of applications, from clean and efficient industrial separations through innovative medicine to safe commodity products with low-impact life-cycles. We specifically focus on sustainable and multifunctional nanocomposites, which incorporate bio-based polymer matrixes and multiple advanced functional components such as 2D materials and/or metal-organic frameworks. Formulating the composition of such nanocomposites tuned to a specific application poses a significant challenge as they need to include the appropriate components to ensure desired performance while simultaneously addressing constraints regarding the physicochemical compatibility between them as well as the overall dependence on the processing involved. We are streamlining this process by the development of a dedicated material acceleration platform (MAP). The MAP is a closed-loop experimental setup where laboratory work related with preparation and characterization of samples is performed by a robot while machine learning algorithms dictate what experiments to make in order to achieve desired results with minimal number of experiments. Unlike other emerging MAPs that work with solution or thin-film chemistries, our MAP focuses on thermoplastic materials, which are processed in a pelletized form and require solid specimens for property testing. Our presentation will introduce the concepts behind our nanocomposite MAP and summarize the recent progress in its development, which for far have included (i) an automated twin-screw extrusion process for nanocomposite preparation, (ii) a nested Bayesian optimization loop for 3D printing of testing specimen executed on a pellet 3D printer farm, (iii) a collaborative robot-operated analogue Charpy impact test instrument and (iv) an outer Bayesian optimization loop for navigating the nanocomposite formulation space. Such organization of the MAP allow fairly easy extension to other properties such as tensile tests, thermal conductivity, degradation profiles, etc, which are the subjects of on-going work. The latter will also be highlighted in the presentation.

Oral Presentation (20')

Abstract

The development of novel steels is highly demanding due to their complexity in terms of chemical composition and the strong dependence of their mechanical properties on the processing route. Moreover, the development process involves a series of experimental steps, including synthesis, sample preparation, multi-scale structural characterization, and mechanical testing. Therefore, the usage of AI-based methods for optimizing chemical compositions and process conditions, the integration of data-driven and physics-based modeling, and advanced FAIR data management solutions are key to success.

The ALPmat is an Active Learning Platform for MATERIALS design. A hybrid approach is followed for optimal exploitation of the available knowledge, where physical models and expert knowledge are combined with data from observations. The resulting hybrid models are used for an Active Learning Loop (ALL) to improve the addressed properties iteratively via optimization of the material's chemistry and processing conditions while minimizing the number of new samples.

We will present the details of the ALPmat in terms of hardware and software for the platform backbone, the FAIR database, the framework for running physical modeling and Bayesian optimization algorithms, and integrated software services. Moreover, we will present the data model for bainitic steels. This data model is linked to the state of the investigated sample and is used to uniquely identify use case-specific synthesis, processing, and characterization steps. It serves as a basis for ingesting comprehensive metadata and ensures the data are fully FAIR.

Finally, we will demonstrate the capabilities of ALPmat for running ALLs and present our results for bainitic steels, where we did a multi-objective optimization of the uniform elongation and the yield strength as a function of chemical composition and processing conditions.

Paper 539 1 Dual Synchrotron X ray diffraction approach to strain imaging: application to quantum devices.

Dr. Raquel Rodriguez Lamas, France

Highlight (Oral Presentation 20')

Abstract

Accurately imaging and quantifying strain fields at multiple scales is critical for enhancing the performance and reliability of functional devices. In this work, we present a novel approach that combines two advanced synchrotron X-ray diffraction techniques with high strain resolution (10^{-5}). The combination of Laue microdiffraction (μ Laue) and Dark Field X-ray Microscopy (DFXM) provides access to multiscale strain mapping in semiconductor materials. μ Laue, performed at ESRF's BM32 beamline, offers rapid access to the deviatoric strain tensor, mapping with ~ 300 nm spatial resolution. DFXM, conducted at ESRF's ID03 beamline, provides full-field strain maps with angular and spatial resolutions of 0.001° and 150 nm, respectively.

Here we introduce these two synchrotron techniques, illustrating them with an example of strain mapping of the Si layer from a quantum device (Josephson's Junction). Using μ Laue, we identified regions of interest (ROIs) within the device, separated the signal of the substrate, and extracted the deviatoric strain tensor components of the crystalline layers. This information guided the subsequent DFXM measurements, enabling precise strain analysis. Through DFXM, we obtained focused strain maps of the 400 reflection of Si in the region of interest, with measured strains on the Si layer of the device on the order of 10^{-4} .

This double technique approach provides a particularly useful strategy for imaging and quantifying all strain components in embedded layers, provided they exhibit sufficient crystal quality.

Structure-Property Relationships across Gradient Thin Films on Non-Planar Substrate Geometries

Mr. Kevin Kutlesa, Austria

Oral Presentation (20')

Abstract

While functional properties of thin films have been extensively optimized for planar substrates, their behaviour on curved surfaces remains less understood due to characterization challenges. In this contribution, the complex relationship between nanoscale gradients in residual stresses and microstructure in both lateral and depth directions is elucidated for non-planar substrate geometries. Focusing on nanocrystalline protective thin films deposited on cutting tools, our findings reveal a significant impact of the substrate geometry on structure-property relationships in thin films.

Microstructural properties and residual stress gradients across the cutting edge area of an AlTiN thin film, deposited by magnetron sputtering on a cemented WC-Co insert, were characterized by cross-sectional synchrotron X-ray nanodiffraction (CSnanoXRD) at the ID13 beamline of the ESRF in Grenoble. The film-substrate interface was precisely aligned parallel to an X-ray beam, which was collimated to a cross-section of $75 \times 75 \text{ nm}^2$ using multilayer Laue lenses. Two-dimensional diffractograms were collected from approximately $40 \text{ }\mu\text{m}$ thick cross-sectional lamellae using an Eiger 4M detector. The data acquisition involved a field-of-view of $20 \times 20 \text{ }\mu\text{m}^2$, scanned with a step of 50 nm . The collected Debye-Scherrer rings were analysed using the pyFAI software package and revealed compressive residual stresses up to -5 GPa at the cutting edge, marking a 100% increase compared to adjacent areas. This difference can be explained by insights gained from microstructural characterization. Transmission electron microscopy revealed irregularities in grain size, grain orientation and elemental distributions that were correlated to the non-uniform plasma conditions at the curved substrate during the deposition process. Further, the strain across the cutting edge was evaluated using selective area electron diffraction, which allowed a correlation of the evaluated strain heterogeneities in the modulated grain size regions to the residual stress gradients from CSnanoXRD. To successfully unveil the convoluted process structure property interactions at non-planar substrate regions, nanoindentation and bending tests on microcantilevers fabricated using FIB were conducted at the edge region. A fracture stress of $\sim 8.5 \text{ GPa}$ was revealed at the cutting edge and marks an increase of $> 10 \%$ compared to planar substrate regions.

Our findings demonstrate that the substrate curvature significantly affects mechanical properties through its influence on microstructure and residual stress gradients. Successfully unveiling the convoluted process-structure-property interactions opens new pathways for the optimization of thin films at geometrically complex and performance-critical regions. Beyond cutting tools, these insights hold promise for microelectronics and other advanced technologies, where thin film functionality is critical.

3D Mapping of Intragranular Strain and Microstructure in Recrystallized Iron Using Dark-Field X-ray Microscopy

Mrs. Virginia Sanna, France

Oral Presentation (20')

Abstract

Assessing residual strains in metals is crucial for understanding their thermomechanical behavior, but probing them in 3D remains challenging due to the limitations of traditional techniques, which are often destructive or lack sufficient spatial resolution.

In this study, we performed a correlative investigation of intragranular local residual strain and orientation distributions in a fully recrystallized pure iron sample using Dark-Field X-ray Microscopy (DFXM) and Diffraction Contrast Tomography (DCT). Despite the fully recrystallized state, DFXM revealed significant heterogeneities in residual strain, indicating that strain fields persist even in the absence of a well-defined dislocation network. By analyzing multiple grains, we extracted their strain distribution, misorientation, and dislocation density, which was found to be on the order of ~ 0.0005 , 0.1° and 10^{10} m^{-2} , respectively. To complement DFXM results on local strain and orientation measurements at a 100 nm resolution, we probed the same sample using DCT to obtain the 3D grain structure, mapping the shape, size, and orientation of individual grains over a large volume of approximately $300 \times 200 \times 200 \mu\text{m}^3$. The combination of the two datasets allowed us to resolve individual dislocations within specific 3D grains and determine their Burgers vectors. This identification was achieved by combining the grain orientation data from DCT with machine learning-based analysis of the strain and misorientation data extracted from DFXM. Additionally, the full 3D grain structure provided by DCT enabled further discussion on the origins of local residual strains, particularly in relation to interactions with neighboring grains during grain growth.

This correlative approach enabled high-resolution strain mapping across a representative volume, linking bulk characterization with local defect analysis. Our findings demonstrate the potential of integrating these two techniques, DFXM and DCT, highlighting the advantages of a multiscale approach for advanced characterization of strain heterogeneities and grain-level interactions in metallic systems.

Paper 1071 4 3D Intragranular Orientation Mapping in Cold-Rolled Ferrite at Industrially Relevant Deformation Levels
Dr. Aditya Shukla, France
Oral Presentation (20')

Abstract

Thermomechanical processing of metals introduces high dislocation densities, altering material properties through mechanisms such as work hardening. Non-destructive 3D mapping of deformation microstructures remains a challenge due to limitations in characterization tools. This study combines Dark-Field X-ray Microscopy (DFXM) and texture tomography (TT) to investigate and compare deformation structures in 50% and 65% cold-rolled ferrite. DFXM enables non-destructive 3D mapping of intragranular deformation structures, resolving dislocation cells with elevated densities and misorientation values up to 5°, at a resolution of 100 nm. TT complements this by providing 3D grain orientation data, aligning grains relative to the rolling direction and bridging the effects of neighboring grains on deformation. These data are also validated with complementary Electron backscatter diffraction (EBSD) measurements. The combined approach reveals the evolution of intragranular deformation structures, cell size distributions, and strain hotspots as a function of deformation, advancing our understanding of plasticity and the interplay between local and global deformation behaviors. This framework offers critical insights into deformation mechanisms and recrystallization in metals.

Resolving the limits of the J-integral in a nanocrystalline Cantor alloy using multi-method stress-strain mapping

Dr. Michael Meindlhumer, Austria

Oral Presentation (20')

Abstract

In order to interpret irreversible microstructural processes occurring during elastic-plastic fracture of nanocrystalline materials, it is vital to elucidate multiaxial stress and strain fields in the vicinity of a progressing crack. Here, we present a multi-method nanoscale strain- and stress-mapping surrounding a growing crack tip in two identical miniaturized fracture specimens fabricated from a nanocrystalline FeCrMnNiCo high-entropy alloy. by focused ion beam (FIB) milling. The first cantilever was deformed in situ in a scanning electron microscope using the sequential loading-unloading approach to evaluate the incremental J-integral. Additionally, a point pattern was added on the surface of one cantilever using the FIB feature milling system, allowing for the detailed analysis of the complete 2D surface strain components during the experiment. Cross-sectional X-ray nanodiffraction (CSnanoXRD) at the ID13 beamline of the European Synchrotron (ESRF) with a spatial resolution of down to 200 nm was coupled with an in situ indentation device to uncover the multi-axial stress fields associated with crack growth in the second HEA cantilever. Loads of 22, 45 and 34 mN with consecutively increasing displacement were applied, which correspond to conditions of elastic loading, crack tip blunting and general yielding, respectively. At every loadstep, the CSnanoXRD data were gathered in a region of $30 \times 35 \mu\text{m}^2$ centered around the crack tip. In addition to the evaluation of the 3D stress tensor around the crack tip, small-angle X-ray scattering and full width at half microscopy techniques allowed for quantitative analysis of crack growth and to assess the defect accumulation in front of the crack tip qualitatively, respectively. Additionally, the experimental stress data were corroborated by an elastic-plastic finite element model. Furthermore, the stress and strain data were used to evaluate the J-integral around the crack tip and cross-validate it with the sequential unloading approach and the J- and/or K-values computed from the stress data. It could be shown that the sequential unloading approach overestimates the crack growth and the quantitative J-integral, the latter by a factor of ≈ 10 , due to significant amounts of plastic deformation buildup without crack extension. The quantitative experimental strain and stress results suggest a limit to the path-independence of the J-integral concept, which has significant implications in the development and assessment of modern damage-tolerant materials and microstructures.

Paper 1615 6 **High-energy synchrotron X-ray diffraction and its applicability for depth-resolved residual stress analysis**
Dr. David Canelo Yubero, Germany
Oral Presentation (20')

Abstract

Residual stresses (RS) play an important role in many industrial materials and processes. They are of utmost importance as they strongly influence strength, corrosion resistance, and fatigue properties of metallic materials under service conditions. They also lead to excessive waste of material as they are often unknown or only estimated. High-energy synchrotron X-ray diffraction is a suitable tool to explore nondestructively depth-resolved RS in the bulk of materials.

A monochromatic high-energy X-ray beam in combination with a conical slit cell (CSC) enables the determination of the strain components over the whole sample thickness with sufficient spatial resolution. The CSC has several concentric ring slits that are focused on a spot within the sample by their conical shape. The analysis of full diffraction rings enables the simultaneous determination of all strain components in the plane orthogonal to the beam by taking advantage of the 2D detector. This setup allows resolutions that can be customized depending on the beam energy and on the beam size. Despite the advantages of this technique, it is not widely spread.

A white high-energy X-ray beam is well known for RS determination. It can be used either in near surface stress gradient measurements (reflection geometry) or in transmission condition for bulk measurements. Diffraction data are usually collected using energy-resolved HPGe detectors positioned at independent diffraction planes and the gauge volume can be controlled using incident and scattered beam slits. This technique usually requires performing and analysing data with the $\sin^2\psi$ approach.

Helmholtz-Zentrum Hereon operates two beamlines at DESY (Hamburg, Germany): P07-High Energy Materials Science beamline and P61A White Beam Engineering Materials Science beamline, which offer the above-mentioned techniques. In this work we present the characterization of RS in a variety of samples and geometries to observe the synchrotron capabilities for RS determination of normal and shear stresses in the bulk of materials, sub-surface RS analysis, a cross-comparison between both techniques, and the influence of individual diffraction peak or full pattern analysis for coarse-grained materials. The analysed materials are an additively manufactured austenitic steel 316L part in as-built and heat-treated conditions, a Grade S355 hot-rolled structural steel solely elastically loaded or with stresses generated by significant plasticity, a nickel-based alloy plate with a 3-pass slot weld, and a refill friction stir spot welded aluminium sample.

Local Lattice Distortion Analysis of TiVZrNb Lightweight High Entropy Alloys Using Pair Distribution Function (PDF)

Mrs. Juree Jung, South Korea

Oral Presentation (20')

Abstract

High entropy alloys (HEAs) are a novel class of metallic materials consisting of multiple principal elements in near-equiatomic ratios, offering unique properties such as high strength, thermal stability, and exceptional performance in extreme environments. Among HEAs, body-centered cubic (BCC) alloys are particularly notable for their high-temperature performance, but challenges such as high density and limited ductility have restricted their broader applications. This study focuses on designing lightweight BCC TiVZrNb HEAs by optimizing atomic size misfit to enhance lattice distortion and solid-solution strengthening.

The alloys were fabricated using vacuum arc melting and homogenized at 1373 K for 1 hour to achieve chemical uniformity and eliminate segregation. Synchrotron-based Pair Distribution Function (PDF) analysis quantified local lattice distortion induced by atomic size misfit. The analysis revealed significant local lattice strain within the first and third coordination shells of the BCC structure, as evidenced by the full-width at half-maximum (FWHM) of the peaks. These results confirmed a strong correlation between lattice distortion and solid-solution strengthening, driven by atomic size misfit.

This research underscores the critical role of lattice distortion and atomic size misfit in enhancing the mechanical properties of lightweight TiVZrNb alloys. The findings establish the potential of these alloys as high-performance materials for structural applications in extreme environments, including aerospace and energy systems.

X-Ray Stress Tensor Tomography

Prof. Peter Modregger, Germany

Oral Presentation (20')

Abstract

The material properties of poly-crystalline engineering materials, such as fatigue strength and corrosion resistance, are closely linked to local strain and residual stress distributions. Consequently, precise strain measurements on micrometer scales are critical for validating model-based predictions regarding failure and lifespan—particularly for safety in automotive and aerospace applications. Currently, two primary categories of non-destructive techniques exist for depth-resolved strain measurement in poly-crystalline materials, both of which involve complex setups.

An alternative approach utilizes a pencil beam and X-ray powder diffraction for tomographic reconstruction of local strain and stress tensor components. In 2015, Lionheart and Withers mathematically demonstrated that information from six points on a single diffraction ring, combined with six appropriately chosen sample rotations, suffices to reconstruct all six strain tensor components. However, this method presents significant experimental challenges, and they noted the potential for a reconstruction method using fewer rotational axes.

In this presentation, we will illustrate that employing a single rotation with eight segments derived from two diffraction rings provides a robust foundation for the tomographic reconstruction of the six planar strain and stress tensor components. Scans conducted on shot-peened and control martensitic steel samples at the ID11 beamline of the ESRF in Grenoble, France, yielded reconstructed stress tensor components that align with expectations and corroborate laboratory surface results. Integrating data from two different diffraction rings requires the incorporation of X-ray elastic constants into the forward model. We treated these constants as additional free parameters in the minimization process and will showcase the potential of this approach for directly measuring them.

This innovative method for measuring depth-resolved strain and stress tensor components features a simplified setup, making it adaptable to a variety of existing beamlines. Consequently, strain and stress tensor tomography holds significant promise for transforming the field of strain and stress measurement.

Paper 592 1 **Operando Neutron and X-ray Diffraction: A Window into Microstructure Evolution in Laser Powder Bed Fusion**

Dr. Steven Van Petegem, Switzerland

Highlight (Oral Presentation 20')

Abstract

Additive manufacturing (AM) has become an integral part of modern materials processing, enabling the production of geometrically complex components with high efficiency. Among various AM techniques, laser powder bed fusion (LPBF) is widely used for fabricating metallic parts with intricate microstructures. The process involves localized melting and rapid solidification of fine metal powders using a high-energy laser. However, the complex thermal cycles and dynamic phase transformations inherent to LPBF introduce challenges in controlling microstructure evolution, residual stresses, and defect formation. A thorough understanding of these transient phenomena is essential for optimizing process parameters and improving material performance.

Over the past decade, operando neutron and synchrotron X-ray diffraction have emerged as key techniques for investigating the real-time evolution of microstructures within and around the melt pool during laser-based AM processes. These advanced characterization methods provide insights into phase transformations, thermal gradients, and stress development—critical factors influencing the final material properties.

Conducting such experiments requires specialized sample environments that can replicate industrial AM conditions while remaining compatible with synchrotron and neutron beamlines. This presentation describes the approach developed at the Paul Scherrer Institute (PSI) to address this challenge. Several miniaturized experimental setups have been designed and integrated into beamlines at both synchrotron and neutron facilities, allowing operando studies on LPBF systems.

The capabilities of these setups are demonstrated through examples where operando X-ray diffraction is used to track phase transformations and thermal history in different alloys and multi-material systems, while neutron diffraction and Bragg edge imaging provides insights into residual stress evolution in bulk specimens.

By capturing transient phenomena in real time, these techniques contribute to a deeper understanding of AM process dynamics and generate valuable datasets for validating computational models and simulations. The findings help refine AM processing strategies, improve material performance, and enhance the reliability of additively manufactured components.

In situ study of precipitation kinetics in friction extrusion and consolidation of Al alloys using FlexiStir

Ph.D. Elizabeth Mathew, Germany

Oral Presentation (20')

Abstract

Abstract

Understanding precipitation kinetics is essential for modifying the microstructure and properties of aluminum alloys during thermo-mechanical processes such as friction extrusion (FE) and friction consolidation (FC), where both severe plastic deformation (SPD) and frictional heating contribute to phase evolution and precipitate behavior [1,2]. This study utilizes a specialized in-situ setup, FlexiStir, adapted for FE and FC, along with Small-Angle X-ray Scattering (SAXS) and Wide-Angle X-ray Scattering (WAXS), to investigate precipitation behavior in AA7075 and Al-Cu-Li alloys at the high-energy material science beamline P07 at PETRA III (DESY, Hamburg). The combined SAXS/WAXS technique enables real-time tracking and detailed analysis of the evolution of the precipitate size, distribution, and phase fraction throughout the thermo-mechanical process. Additionally, process temperatures were determined using lattice expansion of aluminum measured from WAXS signals.

The study highlights the influence of deformation and temperature in precipitation evolution. Initial results reveal that SPD accelerates precipitation kinetics, with grain size increasing during the process. However, the precipitate volume fraction decreases as the temperature rises. After cooling, an increase in precipitate volume is observed, which significantly affects the mechanical properties of these alloys. The insights gained from this study aim at optimizing FE and FC processes for high-performance aluminum alloys, advancing their applications in aerospace and other industries requiring superior mechanical and thermal properties.

Paper 1502 3 **Influence of trace and tramp elements on the phase transformation behavior of low-carbon steel analyzed by in-situ high-energy X-ray diffraction**
Mr. Marek Gocnik, Austria
Oral Presentation (20')

Abstract

In the effort to decarbonize the steel industry, a shift toward more sustainable processing routes has gained momentum. One such approach involves the use of scrap metal in combination with electric arc furnace (EAF) production route. This method however, introduces higher levels of trace and tramp elements, which can impact the phase composition, microstructure, and mechanical properties of the final steel products. In this study, the phase transformation behavior of low-carbon steel with varying concentrations of trace and tramp elements was investigated. A reference alloy produced via the conventional BF route was compared to two trial alloys processed through the EAF route, with intentionally increased trace and tramp concentration. To assess phase transformation temperatures and phase evolution during heat treatment, dilatometry experiments were conducted in conjunction with in-situ high-energy X-ray diffraction (HE-XRD) measurements. Rietveld refinement was utilized to quantify the volume fractions of ferrite, cementite, and austenite, providing insights into phase stability and transformation kinetics. Additionally, detailed microstructural characterization was performed using light optical microscopy (LOM) and scanning electron microscopy (SEM). Electron backscatter diffraction (EBSD) analysis was employed to qualitatively assess the presence and distribution of martensite. The results indicate that the presence of trace and tramp elements leads to an expansion of the critical transformation temperature range, directly influencing phase formation during cooling. The increased presence of these elements facilitates the evolution of displacive phases, such as martensite and bainite, accompanied by retained austenite. These microstructural changes have important implications for the mechanical properties of steel, particularly in applications requiring controlled phase distributions to achieve specific strength and toughness characteristics.

Paper 879 4 Synergetic use of powder diffraction and electron backscatter diffraction

Prof. Andreas Leineweber, Germany

Oral Presentation (20')

Abstract

Powder X-ray diffraction (PXRD) and electron backscatter diffraction (EBSD) are common techniques to analyse the global phase content and phase distribution locally of solid-state materials. However, particularly in the case of EBSD, little attention is often paid to the use of appropriate structure models employed for indexing, especially when dealing with phases of non-trivial crystal structure. This contribution will give some examples of EBSD analysis of intermetallic phases where X-ray diffraction of the same materials has been able to provide complementary information, e.g., on lattice parameters or to distinguish between different structural variants (ordering variants" or polytypes). In this talk different alloy systems containing different forms of CoSn₃ (ordered and disordered stacking variants) will be dealt with, as well as Cu₆Sn₅ comprising different superstructures or varying long-range ordering. It is also shown how one can derive simplified crystal structure models allowing for robust indexing. Thus, one gets rid of ambiguities of the determined crystal orientation (which may not be of interest anyway) due to pseudosymmetry, however, at the cost of possibly extractable physical information.

Paper 1386 5 Ultrafast melting of polycrystalline Palladium: bridging experiment and simulation with X-ray free-electron laser probing

Dr. Jerzy Antonowicz, Poland

Oral Presentation (20')

Abstract

Due to its extremely short timescale, the non-equilibrium melting of metals is exceptionally difficult to probe experimentally. The knowledge of melting mechanisms is thus, to a large extent, based on the results of theoretical predictions and computer modeling. This work reports on the ultrafast melting of thin polycrystalline palladium films studied by an optical laser pump – X-ray free-electron laser probe technique and two-temperature molecular dynamics simulations. By acquiring, with a sub-picosecond resolution, the X-ray diffraction snapshots, we capture the transient atomic structures of the sample during its transition from the crystalline to the liquid state. The diffraction data are correlated with large-scale molecular dynamics simulations. Bridging the timescales of the experiment and the simulation allows us to formulate a consistent atomistic picture of the melting transition [1]. We find that with increasing density of deposited energy, the melting process accelerates, and its mechanism progressively varies from heterogeneous, initiated inside structurally disordered grain boundaries, to homogenous, proceeding catastrophically in the crystal volume on a picosecond time scale, close to that of the electron-phonon coupling.

Analytical characterisation of nuclear material by multiscale approach

Mrs. Emmanuelle Brackx, France

Oral Presentation (20')

Abstract

Nuclear materials may have several morphologies and speciation in the solid state divided with different oxides or fluorides of uranium for fuel manufacture and reprocessing in the solid state, in ceramic forms (oxides or carbides), such as fuel pellets packaged in sheaths or inserted into glass matrices for waste packaging. Depending on the generation of the nuclear reactor, different fuel/jacket systems can be envisaged with assemblies consisting of heavy elements and light elements such as: (UO₂/Zircaloy), (UO₂, PuO₂/Zircaloy), ((U,Pu)C, SiC/SiC), (UO₂), SiC/SiC). Optimisation of the behaviour of materials in service or in an accident situation for reactor life, safety and security purposes is based on studies and test infrastructures related to operating conditions as well as scenario studies serious accident that could result in the fuel melting at 2000°C with the components reactor (B4C control bar, steel cooling tank, concrete reactor enclosure). In this last theme, the multi-phase material at various spatial scales obtained by simulating a core fusion is called corium. It is the subject of numerous studies, in particular to supply basic data for reactor behaviour simulation codes in terms of design and safety in service, as well as to guide dismantling operations. These behaviour studies require knowledge of the elemental composition and speciation of the materials tested. This allows for the optimization of manufacturing quality as well as the prediction of the physicochemical behaviour of materials over their lifetime under nominal or accidental conditions. This knowledge is enabled by the elementary and structural characterization means of SEM/EDS/STEM/EBSD, EPMA, Laue diffraction and x-ray and neutron diffraction. This talk presents the analytical developments and techniques adapted to these materials, particularly for the quantitative analysis of light elements in heavy matrices, the identification of multi-scale phases by diffraction methods, the elemental quantification on the solids and the powders as well as the consideration of the behaviour of these materials during preparation phases.

Paper 1523 1 Advancing Laboratory-Based 3D X-ray micro-beam Diffraction for Multiscale Materials Characterization

Dr. Yubin Zhang, Denmark

Highlight (Oral Presentation 20')

Abstract

X-ray diffraction-based three-dimensional, non-destructive characterization has become a cornerstone for investigating the internal microstructure, crystallographic orientation, and defect distributions in polycrystalline materials. These techniques provide critical insights into materials' mechanical and functional properties, playing a pivotal role in materials science, engineering, and manufacturing. However, most advanced 3D diffraction methods are available only at large-scale synchrotron facilities, where access is limited due to restricted beamtime availability, logistical challenges, and high operational costs. These constraints hinder routine investigations and broader adoption in academic and industrial research.

To overcome these limitations, the development of laboratory-based 3D X-ray diffraction instruments is crucial. These systems would enable researchers to conduct 3D characterization routinely, significantly increasing accessibility to these powerful techniques. Laboratory diffraction contrast tomography (LabDCT) represents a major step forward, allowing the 3D reconstruction of fully recrystallized materials with grain size larger than 15 μm at a spatial resolution of 5 μm , using conventional laboratory-based X-ray CT systems. However, despite its success, LabDCT remains limited to relatively coarse-grained microstructures, requiring further advancements to extend its capabilities to finer microstructures and more complex materials.

To enhance the capabilities of laboratory-based diffraction techniques, we have developed a new 3D X-ray micro-beam Laue diffraction (Lab-3D μ XRD) technique. By integrating a conventional X-ray micro-CT system and newly developed Pt-coated twin paraboloidal capillary X-ray focusing optics, we have successfully demonstrated its feasibility. Additionally, incorporating a state-of-the-art photon counting detector has enabled the characterization of small grains ($\sim 5 \mu\text{m}$) and additively manufactured materials, the latter being particularly challenging due to their high defect content. By combining Lab-3D μ XRD with LabDCT and micro-CT, we establish a multiscale and multimodal 4D (x, y, z, time) characterization framework for studying microstructural evolution. This approach expands the capabilities of 3D X-ray diffraction beyond synchrotron facilities, offering an accessible and versatile solution for advanced materials characterization.

Oral Presentation (20')

Abstract

Narwhal tusks, mice bones, lizard skin, unfolded batteries, additively manufactured piezoceramics, catalyst nanoparticles on alumina support, and biochar from pyrolyzed sewage sludge are just some of the many materials that have been measured with X-ray mapping techniques at the DanMAX beamline. Common for the previously mentioned materials is their hierarchical nature. "Conventional" powder diffraction provides information on the average atomic structure of the probed powder, but to properly study hierarchical materials we require spatial resolution. The low emittance MAX IV (Lund, Sweden), the world's first 4th generation synchrotron, allows us to easily and fast focus the X-ray beam on the micron scale. Combined with fast linear scanning stages and optimized scanning strategies it is possible to raster scan macroscopic samples of thousands of square millimeters with micrometer resolution. The large area coverage has made it possible to map battery degradation in aged pouch cell batteries, without having to cut or slice the components.

An upstream fluorescence detector and a photon-counting CdTe area detector provides not only contrast from the elemental composition, but also diffraction contrast of the crystalline species as well as texture contrast from the azimuthal variation of the diffraction rings. In biological samples this can be used to map element deposition during growth, hierarchical crystallization, and crystallite orientations, as seen in e.g. bones, shells, and teeth. With texture mapping we can follow template-induced preferred crystallite orientations in additively manufactured ceramics, aiding in the understanding and production of highly specialized piezoelectric components.

Adding rotations to the raster scan gives the opportunity to do X-ray diffraction computed tomography (xrd-CT), giving 3D reconstructed images, where each voxel contains a full diffraction pattern. The diffraction provides contrast between different crystalline phases, even when those phases have the same nominal composition and density. An example includes the aging of MoS₂ catalyst particles deposited on nano porous alumina support pellets, where the depth-profile of the pellets are of interest. Both 2D and 3D diffraction mapping techniques produce large amounts of data, not uncommonly hundreds of thousands or millions of diffraction patterns. The efficient data structure at DanMAX allows live integration of the collected area detector images and data analysis or tomographic reconstruction immediately following the data collection. A wide range of python-based jupyter notebooks makes it easy and quick to perform qualitative analysis of the large mapping datasets.

Welding at the Beamline, the Beamline P61A and it's use for Materials Manufacturing Research

Dr. Guilherme Abreu Faria, Germany

Oral Presentation (20')

Abstract

The development of new metallic materials as well as their manufacturing and processing techniques has consistently benefited from synchrotron X-ray characterization. X-ray diffraction can characterize phase transformations, stresses and texture, while X-ray imaging allow for observation of phase boundaries, defect formation, etc. Particularly, the high intensity provided by synchrotrons allows for in-situ characterization of transient phenomena such as welding. The use of synchrotron X-ray scattering techniques for materials manufacturing applications does have some requirements. On one side, experiments typically cannot be downsized leading to mm to cm thick samples, requiring high X-ray energies. On the other, materials manufacturing techniques typically introduce high spatial heterogeneity, requiring spatial resolution within the material's bulk. The beamline P61A, operated by Helmholtz-Zentrum Hereon at the PETRA III synchrotron in Hamburg is uniquely equipped for performing metallic materials manufacturing experiments. The beamline uses a high flux white beam with usable energies from 20 to 200 keV, and can be used both for imaging or energy dispersive diffraction, which enables the definition of a gauge volume within the sample, allowing for the characterization of samples with through thickness heterogeneity. P61A has been in operation for 4 years, and over its short history, has seen consistent demand for ex and in situ characterization of welding processes. This talk will present the beamline, its instrumentation and key performance numbers. A selection of user science cases will be presented, with focus on how different welding experiments have been performed. Finally, the talk will show future developments and how these can be applied to materials manufacturing studies.

Paper 1412 4

Advanced operando X-ray diffraction to explore power electronics in space and time

Ph.D. Michael Reisinger, Austria

Oral Presentation (20')

Abstract

In the semiconductor industry, the rising demands for higher performance and reliability require the deployment of novel in-situ test concepts to uncover dynamic processes that govern the device functionality. In addition, to current established methods, for the static investigation of power semiconductors, operando characterization techniques will provide a comprehensive understanding that is essential for the advancement of future technologies. Power electronic devices are complex embedded heterostructures, consisting of different materials with different material properties. Consequently, nondestructive techniques are required to investigate fully functional systems. Due to structural features in the size of few nanometers as well as processes in the nanosecond range, most techniques are meeting their physical limits. In contrast, X-ray diffraction (XRD) based techniques fulfill most requirements to explore various dynamic processes occurring in power semiconductor applications. In particular, in-situ stress testing of functional chips was utilized to study (i) the fatigue of Cu metallization layers as well as (ii) the electric fields in high electron mobility transistors (HEMT).

Power electronics undergo cyclic thermal loading caused by short circuit events. Due to mismatches of the thermal expansion coefficient, large thermo-mechanical stresses arise within the individual layers. Such stresses can lead to plastic deformation within the metallization and cause material fatigue. Dedicated test structures were developed to enable thermal-mechanical cycling with application relevant heating rates up to 10^6 K/s. Subsequently, in-situ 20 kHz X-ray diffraction was utilized at the MS-Powder beamline of the Paul Scherrer Institute in Switzerland to reveal biaxial stresses rising within the Cu metallization during a single heating pulse. Subsequently, the microstructural evolution causing Cu fatigue was investigated using in-situ dark field X-ray microscopy (DFXM) at the beamlines ID03/ID06 of the European Synchrotron Radiation Facility (ESRF) in France. Here, several hundred heat pulses were applied to visualize the changes of the intragranular strain and misorientation of a single Cu grain through the course of thermo-mechanical cycling.

HEMTs are based on wide-bandgap semiconductors such as heteroepitaxial (Al)GaN layers grown on Si substrates. Due to the piezoelectric nature of GaN wurtzite, the change of the electric field during hard switching generates significant lattice strain within few nanoseconds. This effect can be utilized for real time visualization of the local electric field within the active device area. Operando DFXM measurements at the beamline ID01 of the ESRF were used to map the piezoelectric strain field during device switching down to 1 ns temporal and ~150 nm spatial resolution.

Advancing 3D/4D Diffraction Imaging: ESRF's New ID03 DFXM Beamline

Dr. Can Yildirim, France

Oral Presentation (20')

Abstract

The ESRF's Dark Field X-ray Microscopy (DFXM) beamline at ID03 represents a major leap forward in 3D and 4D mapping of crystalline orientation and strain, significantly enhancing multi-scale imaging of embedded microstructures. As part of the ESRF's EBSL2 Upgrade Project, ID03 introduces new possibilities for high-resolution, non-destructive characterization of bulk materials. Relocated and upgraded from ID06-HXM, the beamline is now equipped with state-of-the-art X-ray optics capable of delivering both pink and monochromatic beams, a newly developed high-precision goniometer, and an advanced detection system optimized for capturing subtle microstructural features with a spatial resolution on the order of 100 nm. This capability allows for detailed investigations of thick crystalline samples, providing new insights into their microstructural features.

DFXM is a diffraction-based imaging technique that maps the magnified diffraction signal from a crystalline element using an objective lens. This enables the direct visualization of 3D orientation and strain fields at the submicron scale, offering unique capabilities for studying complex microstructural phenomena. A key strength of ID03 lies in its integration of DFXM with complementary techniques, including 3DXRD, diffraction contrast tomography (DCT), and classical tomography, on the same experimental platform without the need to dismount the sample. This multi-modal approach allows researchers to study hierarchically ordered systems across multiple length scales, providing a more holistic understanding of microstructural behavior.

Since opening to users in April 2024, ID03 has supported a wide range of studies, from strain mapping in metals to functional material analysis in semiconductors, biominerals, and energy systems. We present examples from diverse material systems, including deformation and annealing structures in metals, which highlight the beamline's ability to resolve 3D grain structures and strain distributions with high precision. By enabling comprehensive, in-situ investigations, ID03 facilitates a deeper understanding of intricate structural, orientation, and strain-related phenomena, positioning itself as a powerful tool for advancing research in structure-property relationships across materials science disciplines.

In Situ Deformation Experiment at the Swedish Materials Science Beamline at PETRA III

Ph.D. Zoltan Hegedues, Germany

Oral Presentation (20')

Abstract

Deformation induced microstructural changes are frequently investigated in the literature using a large variety of different techniques. Observing these changes and the evolution of the microstructure in situ is much less common, due to the limited number of techniques providing insights non-destructively into metallic materials. The Swedish Materials Science beamline at PETRA III utilizes high-energy synchrotron radiation to obtain diffraction and/or imaging information. For several applications high energy synchrotron radiation hits the balance between penetration power and temporal resolution providing information from volumes of engineering relevance with a speed suitable to investigate real word conditions. In this talk, the combination of different techniques will be shown through examples of deformed microstructure characterization.

Paper 1258 1 **Effect of air, vacuum, and liquid metal environment on fatigue crack growth in 316L stainless steel at 450 °C**

Dr. Milan Konstantinovic, Belgium

Highlight (Oral Presentation 20')

Abstract

Despite numerous demonstrations that the mechanical properties of austenite steels remain largely unaffected in liquid lead-bismuth eutectic (LBE) environment, the effect of LBE on the propagation of fatigue cracks in 316L stainless steel is not yet fully understood. The main reason is that the immunity of 316L stainless steel has been established from relatively short time exposure testing campaigns at temperatures below 400 °C, therefore limiting corrosion effects. Additionally, low cycle fatigue tests in LBE often suffer from experimental inconsistencies, causing the large data scatter. In this study, the fatigue crack growth rates (FCGRs) in 316L stainless steel, measured in air, vacuum and LBE at 450 °C, are contrasted with the microstructural properties at the crack tips investigated by transmission electron microscopy (TEM). FCG tests were performed on the compact tension (CT) specimens following the ASTM standard. The specimens were pre-cracked under the same environment as those used for the FCGR tests. TEM lamellas with the crack tips were extracted from the fracture surface.

For all the samples, the strong deformation field in the form of multiple low angle grain and twin boundaries are observed along the cracks and at the crack tips. Morphological characteristics of crack branching are in agreement with the slip plane activation mechanism, with irregular crack paths that closely follow the striation pattern observed at the fracture surface. Interestingly, the chemical mapping of the region in front of the crack tip revealed the enrichment of deformation induced low angle grain and twin boundaries by oxygen, and lead/bismuth in the samples that are measured under air and LBE, respectively. These changes, governed by the stress enhanced diffusion, affect chemical bonds, and could potentially lower the material strength locally, causing early fracture. At the macroscopic scale, this results in higher FCGRs in 316L exposed to air and LBE with respect of FCGRs in vacuum. Even though we observed almost two orders of magnitude higher FCGRs in 316L stainless steel exposed to LBE in comparison to those measured in vacuum, the fracture surface investigation clearly indicates that the fracture mode of 316L remains ductile in the whole ΔK range explored in this work.

Assessment of early-stage degradation of coil coated steel

Dr. Ville Saarimaa, Finland

Oral Presentation (20')

Abstract

Continuous coil coating lines have been producing materials for domestic appliances and building industry for over a century. The synergistic combination of metal sheets with organic coatings (polyvinyl chloride (PVC) in the 1960's, followed by polyester in the 1970's and epoxy, polyvinylidene fluoride (PVDF) and polyurethane from the 1980's onwards has spawned a multitude of end applications with tailored properties for aesthetics, corrosion resistance and durability. Currently, the European coil coating industry produces about 1600 million m² of coated metal per year. The industry faces pressure to cut costs in the curing section, pushing for novel radiation curable coating formulations and sustainable practices, such as reducing fossil-based constituents and incorporating recycled and biobased binders and additives.

Some of the bottlenecks related to introducing these novel coating formulations to the market are related to relatively long testing and verification procedures. Currently, quality control during development of coil coatings for steel is carried out with extensive accelerated exposures, UV-weathering, constant salt/humidity resistance and cyclic corrosion tests, followed by gloss and color measurements, and finally assessment of blister density, delamination and paint adhesion. One of the reasons behind the slow pace of approval is that the testing relies heavily on changes in macroscopic coating properties. For a long time, paint deterioration can remain invisible to the naked eye and undetectable by commonly used evaluation techniques. Formation of any visual signs of the degradation may take many several years even at highly corrosive sites. A significant improvement would be to be able to observe and understand the degradation mechanisms at an earlier stage.

This paper explores weathering-induced chemical degradation in coil-coated steel using modern techniques like high-throughput ion beam milling, high-resolution SEM-EDS imaging, and depth-resolved FTIR. Using examples from exposed coil coated materials, it is illustrated how hidden interfaces and molecular-level changes appear before macroscopic signs of corrosion. Being able to observe and understand these mechanisms enables tailoring of more corrosion-resistant coatings and speeding up the lab-to-market cycle.

Paper 508 **3** **In-situ investigation of the influence of corrosion protection systems on microbially influenced corrosion inside offshore monopiles**
Mrs. Carolin Skottke, Germany
Oral Presentation (20')

Abstract

Offshore wind parks are crucial to a successful energy transition towards renewable energy. With a financial break-even point close to the service lifetime, offshore wind energy is expensive. In addition, microbially influenced corrosion further shortens the service time. While the issue of electrochemical corrosion is already addressed by the corrosion protection system, microbially influenced corrosion and its inhibition are little studied for offshore wind farms, resulting in a substantial need for further investigations. Monopiles, tube-like structures anchored in the seabed, are common foundations for offshore wind turbines. The water column within these structures exhibits only a limited mixing with ambient seawater, which can lead to decreasing oxygen levels in greater water depth and therefore offers a unique environment for microbially influenced corrosion. Currently, deployed corrosion protection systems are designed for electrochemical corrosion and do not take microbially influenced corrosion into account. However, previous studies show a dependence of the incubation depth on the overall corrosion patterns and associated microbial corrosion. In the present in-situ study, two test series were incubated for several months to determine the effect of corrosion protection systems on microbially influenced corrosion. Both test series contain commonly used structural steel incubated at three water depths. The first water depth at -6 m shows fully oxic environmental conditions. Seasonally, the water parameters start to transition at -15 m (second water depth) until they reach anoxic conditions close to the seabed at -21 m (third water depth). Test series 1 was incubated without any corrosion protection system, while test series 2 was electrically connected to the mass potential of the monopile, thus being connected to the corrosion protection system. To determine the influence of the corrosion protection system, corrosion rates regarding incubation depths were measured gravimetrically. The obtained corrosion products were then analysed further using 3D and scanning electron microscopy as well as X-ray diffraction. In addition, the environmental water conditions and the microbial communities associated with the incubated steel specimens were investigated. First results demonstrate the dynamic and depth-dependent corrosive situations inside offshore monopiles with and without corrosion protection system. In a later stage, these findings will also be used to calculate the lifetime of offshore monopiles, taking microbially influenced corrosion into account, as well as to find suitable coating strategies. This investigation is carried out as part of the joint project "MiCorFe" funded by the German Federal Ministry for Economic affairs and Climate Action.

Paper 711 **4** **The enrichment behavior of Ni in austenitic stainless steel during the corrosion in liquid lead-bismuth eutectic at 550 °C**
Dr. Min Wang, China
Oral Presentation (20')

Abstract

Currently austenitic stainless steels (AuSS) are viewed as promising candidate structural materials for key components of lead-based fast reactors (LFRs), owing to their exceptional high-temperature mechanical properties, processability, and resistance to liquid metal embrittlement. However, as a crucial major element for the structural stability of AuSS, Ni has a very high solubility in the coolant of LFR, namely liquid lead-bismuth eutectic (LBE). Moreover, Ni typically exhibits a significant segregation tendency in the oxidation zone, and numerous researchers have observed Ni-rich structures within the inner oxidation layer (IOL) of AuSS. This may pose risks of solution corrosion and LBE penetration to AuSS. At present, the enriching behavior of Ni and the effects of Ni-rich structures on the oxidation and solution processes of AuSS in LBE remain unclear. In this study, the internal oxidation behavior of 15-15Ti alloy in oxygen-saturated static LBE at 550°C (up to 6000 h) was systematically investigated, focusing on the initial corrosion behavior and evolution process of Ni in the matrix in front of the oxide/metal (O/M) interface. A new Ni-rich structure was found at grain boundaries in the unoxidized matrix using the method of small-angle inclination polishing. This structure is coherent with the grain on one side and grows into the incoherent grain on the opposite side driving grain boundary migration. A sharp compositional difference is present at the coherent interface. The Ni-rich structure stores Ni, facilitates the participation of Cr in oxidation processes, and alters the composition of oxides as well as distorts their growing path. In this study, with an intact oxide film and no LBE penetration, Ni-rich particles augment the intergranular oxidation resistance of 15-15Ti. However, their impact is constrained by their limited size and number. By increasing the quantity and enhancing the size of Ni-rich particles, further suppression of the preferential oxide thickening along grain boundaries could be achieved. Furthermore, investigations on the interactions between Ni-rich structures and the infiltrated LBE along grain boundaries are currently ongoing.

Influence of the mesostructure on the cyclic fracture-mechanical behavior of Al/Cu-Laminates

Mr. Sebastian Vollath, Deutschland

Oral Presentation (20')

Abstract

Damage tolerance is a critical aspect designing components subjected to cyclic loading for various commercial applications such as the aviation industry. Especially in safety-relevant areas, increasing the service life of components without compromising on safety is of fundamental importance. For this reason, laminated metallic composites (LMC) are of particular interest due to their numerous advantages including an improved strength-to-weight ratio and tailored mechanical properties compared to monolithic materials [1,2]. Among others enhancing the resistance against fatigue crack propagation due to toughening mechanisms is very promising. This feature is based on the so-called material inhomogeneity effect at interfaces. By introducing a gradient in hardness or elastic properties at the interfaces, the resistance against crack propagation is increased due to the formation of a complex 3D-crack network with toughening mechanisms such as crack deflection, bifurcation or bridging [3].

In this work, monolithic materials and Al/Cu-LMCs with a hardness and Young's modulus gradient were fabricated via the accumulative roll bonding (ARB)-process. The LMC samples were heat-treated after the fabrication in order to create a continuous intermetallic layer along the interface. The mesostructure formed was characterized in more detail in terms of hardness, Young's modulus and chemical composition using nanoindentation and EDS. In addition, fatigue tests were carried out using a 3-point bending setup on samples that show no or, respectively, different thicknesses of the intermetallic layer. The fatigue crack growth rates are effectively reduced compared to those of the monolithic materials in crack arrester orientation. Monitoring of selected experiments using a far-field microscope setup and post-mortem light microscopy investigations revealed the formation of various fatigue crack paths. Toughening mechanisms like crack deflection, crack bifurcation and crack bridging are strongly pronounced when defined intermetallic layers in the LMC exist.

Type I-Pitting of Copper Tubes in Drinking Water Supply Networks - Recent Insights into Damage Patterns and Corrosion Mechanism

Dr. Gunther Pajonk, Germany

Oral Presentation (20')

Abstract

Pitting corrosion is a kind of corrosion that again and again is observed on copper tubes in water supplying networks. It appears when there are no stable protective layers developed on the copper tubes' contact surfaces exposed to water.

DIN EN 12502 distinguishes between different types of pitting, especially cold water pitting (type I), warm-mild water pitting (type II) and microbial-influenced pitting (MIC). That classification corresponds on the water temperature, the water composition and some conditions of operation.

According to DIN EN 12502 type I-pitting is generally "characterised by hemispherical cavities at and of green pustules above the corroded area, that consist of basic copper carbonate. Below these spots, the cavities are always covered by a continuous copper(I) oxide film at the previous surface level. Beneath this copper(I)oxide-film ruby-red copper (I)oxide-macrocrystallites and sometimes finely white copper chloride crystals are observed."

Type I-pitting occurs in cold water systems or hot water circuits having cold water characteristics due to long-term stagnations. The Type I-pitting rate is particularly high. For usually tube wall thicknesses of 1 to 2 mm, first damages are soon observed after 3 to 5 years after commissioning.

There are various reasons that trigger pitting corrosion only by interaction. In the case of type I-pitting, the chemical composition of water is essential. Water having a $\text{pH} \leq 7.5$ containing high concentrations of sulphate and nitrate is considered to be corrosive. However, the pitting likelihood decreases if chlorides and hydrogen carbonates are increasing. Due to water quality dependence type I-pitting frequently occurs in certain water supply areas.

This publication presents a case of damage caused by copper pitting in the service line of a single-family house located in Cologne on the left bank of the river Rhine. There, the sulphate content of tap water is $\approx 70 \text{ mg/L}$. As expected, the regional damage incidence is very high. The damage pattern, the appearance of the corrosion phenomena and the morphology of corrosion products are visualised by high-resolution light-optical and electron-optical procedures. The chemical compositions are analysed using EDX analysis and Raman microscopy. This enabled to identify specific compounds and their associated morphologies at the respective sites, to explain how and why they develop and, last but not least, to describe the entire mechanism of type I-pitting from the bare copper metal via the hollowed surfaces to the perforated pipe. It could be explained, too, why sulphates in tap water are so harmful to copper and increase its pitting likelihood.

Paper 1082 2 **Design and realization of a tribometer for journal bearing applications in non-lubricating fluids**

Mr. Francesco Cammelli, Italy

Oral Presentation (20')

Abstract

Friction and wear phenomena are now viewed as a key area of research in support of the European Union's sustainability objectives. Recent studies suggest that tribological advancements could lead to a potential reduction of up to 24% in primary energy consumption [1]. In the extensive domain of tribology concerning shaft-journal bearing systems, the mechanics of non-lubricating fluid environments remains a largely uncharted scientific territory. Numerous industrial sectors grapple with the challenge of transporting and storing non-lubricating fluids, often employing mechanical technologies that prove to be insufficient for this task. Poor material selection and unbalanced operating conditions not only shorten the lifespan of numerous mechanical components but also force users to adopt inefficient technologies to address industrial challenges. This situation becomes even more problematic when non-lubricating fluids contain solid particles, which can act as abrasive agents against materials.

The present study is based on an industrial problem to analyze this engineering issue. A novel, custom-designed tribometer is proposed to simulate the performance of various materials, treatments, and coatings for shaft and journal bearings in non-lubricating environments. The instrument is designed to operate under high rotational speeds, heavy radial loads, and fixed operative temperature. A statistical approach is proposed to correlate torque and heat outputs with operating parameters, according to models proposed in previous literature [2]

Paper 1048 3 **Ground WC-Co hard metal grades evaluated under service-like working conditions: mechanical and microstructural evolution**
Dr. Joan Josep Roa Rovira, Spain
Oral Presentation (20')

Abstract

The unique combination of hardness, toughness and wear resistance exhibited by heterogeneous hard materials (e.g. PcBN systems, cemented carbides, among others) has made them preeminent material choices for extremely demanding applications, such as metal cutting/forming tools or mining bits among others, where improved performance together are required. This presentation is focused on WC-Co cemented carbide material surface integrity evolution at high/intermediate temperature. A systematic micro and nanomechanical study of several WC-Co (in terms of metallic binder content and WC particle size) ground materials is presented. In general, three different aspects are investigated to accomplish the main goal of this research: (1) assessment of the intrinsic hardness of the deformed layer from room temperature up to 600 °C, (2) correlation of the compressive residual stresses with the hardness and elastic modulus maps by high indentation speed tests at the different temperature tested and (3) evaluation of the damage and plastic deformation mechanisms induced in the deformed layer. It was found that for different WC-Co composites, the intrinsic hardness of the deformed layer starts to slightly decrease at temperatures ranging between 400 and 500 °C, depending on the amount of metallic binder. This effect is attributed to different effects which take place simultaneously when the testing temperature increases: dislocation motion, reduction of compressive residual stresses and layer oxide generation mainly constituted by CoWO₄, WO₃ and Co₃O₄.

Paper 441 5 **Fretting wear of a B4C-SiC composite spark-plasma-sintered at 1400°C from B4C+Si**
Mr. Antonio Fernández Ortiz, Spain
Oral Presentation (20')

Abstract

The fretting wear of a B4C-SiC composite fabricated by spark-plasma-sintering of B4C+ 20vol.%Si at 1400°C is investigated in various friction pairs with other ceramics. To this end, fretting tests of 50 mm stroke were performed against diamond, Al₂O₃, and borosilicate glass, at 1 and 5 N loads for up to 100000 cycles. The resulting fretting tracks were characterized in detail by optical microscopy, scanning electron microscopy, energy-dispersive X-ray spectroscopy, and optical profilometry, which was used together with the fretted volumes and the friction coefficients to identify the corresponding fretting modes and mechanisms. Finally, implications arising from the study are presented.

Paper 983 1 Analysis of Austempered Ductile Iron Castings Reinforced with Titanium Carbides

Mr. Jan Marosz, Poland

Oral Presentation (20')

Abstract

The aim of the presented research was to produce a new cast composite material based on the attractive engineering material ie. ADI (Austempered Ductile Iron). The transformation of ADI cast iron into a composite material was based on SHSB (Self-Propagating High-Temperature Synthesis in Bath) reaction. This was a "solid Ti" – "solid C", which ensures that TiC particles are obtained in the microstructure of the alloy. The titanium carbides are thermodynamically stable as a result of their covalent bonding nature, so they do not undergo transformation during the heat treatment process. In the present work castings with different wall thicknesses ranging from thin-walled, i.e. 3 mm, up to 25 mm were attained. The study showed that it is possible to produce a ADI using the SHSB reaction in which titanium carbides of up to 5µm in size are evenly distributed in metallic matrix. Heat treatment was carried out to attain upper and lower ausferrite, reinforced with titanium carbides. The characterization of novel ADI material in terms of mechanical and performance properties was carried out using XRD (synchrotron radiation), light microscopy, scanning microscopy and mechanical properties. Finally, it was shown that ADI strengthened with TiC using SHSB synthesis makes it possible to obtain an attractive material that can be used in demanding areas such as defence, railroad or automotive.

Key words: ADI, heat treatment, "in situ" composites, MMCs composites, SHSB reaction, titanium carbides.

Solidification and structure of thin-walled austenitic ductile iron castings

Prof. Marcin Górny, Poland

Oral Presentation (20')

Abstract

Austenitic ductile iron, with a nickel content of 20% to 36%, is characterized by nodular graphite that is relatively uniformly distributed within a face-centered cubic matrix. This unique microstructure gives the material relatively high strength, ranging from 380 to 550 MPa, along with exceptional ductility, often achieving elongation exceeding 45%. In addition to its excellent mechanical properties, Ni-Resist ductile iron offers high resistance to creep, corrosion, and wear. It also boasts outstanding castability and machinability, making it a versatile material for various industrial applications. Capable of performing reliably across a broad temperature range from -200°C to 850°C, it is widely used in demanding environments. Typical applications include gas turbine housings, gas compressors, motor components, and other critical engineering parts that require both structural integrity and durability under harsh conditions.

This study presents research findings on the primary structure and graphite eutectic formation in castings with wall thicknesses characteristic of thin-walled components (≤ 5 mm), compared to thicker castings (25 mm). The investigation explored the use of Ti, Zr, Nb, and CeO₂ as potential grain refiners. Metallographic analyses, including electron backscatter diffraction (EBSD), were conducted to examine the macro- and microstructural characteristics during the primary and eutectic solidification of austenitic ductile iron. Additionally, novel quantitative assessments were performed to evaluate the morphology and distribution of graphite nodules. The results demonstrated that in thin-walled castings, the primary structure can be effectively refined using Ti and CeO₂, promoting a transition from columnar to equiaxed grains. This transformation is strongly influenced by metallurgical process parameters and the cooling rate at the onset of solidification.

Deformations in large aluminium automotive subframes

Mr. Dag Mortensen, Norway

Oral Presentation (20')

Abstract

In the automotive industry there is a market trend toward producing larger cast structures, as this reduces the need for mechanically joining numerous metallic pieces and decreases weight by minimizing the use of joining materials. At the same time the demand for lightweight automotive parts is increasing together with the market for electric cars. Lighter cars are necessary in order to compensate for the heavy weight of batteries and to enable longer range by smaller batteries. Aluminium components in cars last longer than steel, reduce wear on road infrastructure due to lighter weight, and are more energy-efficient to recycle than steel or composites, supporting sustainability. The larger parts that are made with only one material type will be easier to recycle, which promotes sustainable production patterns. However, to produce the larger one-piece cast structures in aluminium, deformations must be controlled. Aludyne Norway is the largest producer of safety critical aluminium automotive subframes in Europe, and is developing new tools and technologies together with customers to reach this goal. In addition to defects like porosity and cracking it is especially the distortions that have to be controlled in order to increase the size of single piece products. The casting process includes the solidification in a mould, cooling after ejection from the mould, sand core knock-out and removal of the feed gates followed by the heat treatment process including quenching and artificial ageing. Generally, we will then have a deviation from the detailed CAD geometry. Remark that the deviations do not only appear from thermal gradients and internal stresses developed during solidification, cooling and degating, but also from the mould distortions. The mould will be hot and thereby thermally expanded when the liquid metal solidifies against the mould walls. The mould distortions are typically the main cause of the as-cast deformation. After solidification the heat treatment with creep at high temperatures will add to the distortions, and large thermal gradients can lead to deflections and warping during water quenching. Industrial data shows very large variations in quench distortions dependent on the position in a rack with automotive parts. The whole process chain is modelled with a finite element model, developed in-house by the authors, and results are compared with industrial data from several different products, both regarding as cast deformations and regarding movement during quenching with respect to positions in the heat treatment rack.

HIP effect on superalloy casting weld repair

Mr. Ignacio Fernandez, Spain

Oral Presentation (20')

Abstract

Hot Isostatic Pressing (HIP) is a process that involves simultaneous application of a high pressure and elevated temperature in a specially built vessel. HIP is a process used to densify powders and sintered parts, but it is also a standard ancillary operation in superalloys to reduce porosity in casting and health microcracks in welding process, and more recently, in additive manufacturing (AM). Thus, HIP improves mechanical properties of final component. This work is carried out within a welding process and microcracks related to this process in a nickel base superalloy.

Traditionally, there are two ways to measure HIP effectiveness for evaluation of microcrack healing in welding operation:

- 1) Metallurgical cut ups.
- 2) Mechanical testing.

In both cases, a sample with a certain number of specimens is manufactured with the same welding process for all the specimens. Then half of the population is HIPed and the other half is left as it is. Finally, specimens are evaluated for any or both methods mentioned above.

This procedure shows an evident weakness which is that in no case, HIP effect is checked over the same volume of material. Besides, in the case of metallurgical cut ups it is well known that a random number of cut ups is not representative of microcracks population unless, cut up sample size will be big, which is not the case in most of the studies.

The proposal to overcome these issues is to use Computed Tomography System (CT-scan), which is a non-destructive technique (NDT), and evaluate the same volume of material before and after HIP operation. Thus, the evolution with HIP of a set of microcracks can be studied and results analysed depending on their particular characteristics of each microcrack in terms of location, size, width or others.

An Easytom XL equipment from RX Solutions will be used for this study with micro and nano capabilities. The equipment has a potential voxel resolution up to 400nanometes which leads to a defect resolution around 1,2microns. However, measurement parameters and sample size will be optimized for expected crack size seen during previous screening through metallurgical cut ups.

In summary, this work shows an effective new way to evaluate HIP effect in those processes, such as welding, where HIP operation is used for improving metallurgical condition.

5

Chemical and microstructural evolution of the interface during simulated HIP diffusion welding of 316L and Inconel 625 alloys

Mr. Kévin Dugénie, France

Oral Presentation (20')

Abstract

Diffusion welding is a solid-state joining process by which two or more surfaces are welded using high pressure and temperature. This process allows welding of entire surfaces to fabricate large-scale components for fission or fusion power plants. During the process, the interface formed by surfaces evolves: densification and voids closure occur by diffusion and visco-plastic deformation mechanisms. Bounding joint migration is also observed thanks to grains coarsening and triple junctions movement. In most cases, the interface disappears after welding diffusion bonding plateau and the mechanical properties of the final component are sufficient to meet the required specification. However, joining materials in which stable oxides or carbides form easily is not straightforward. This is the case of nickel rich stainless steels as alloy 800 or nickel based alloys as Inconel 625. These materials contain a low amount of aluminium and titanium, which diffuse and segregate at the welded interface into stable oxides and carbides. These reduce grain boundaries mobility across the interface, reducing its final mechanical strength. Despite this drawback, these materials are of a great interest due to their excellent high temperature mechanical properties and their high corrosion resistance compared to conventional 316L austenitic stainless steels.

The goal of this work is to study the evolution of the surface chemistry of the two investigated alloys (laminated sheets) by interrupting several heat treatments, simulating the HIP cycles envisaged. For this purpose, a full study of chemical surfaces evolution with temperature (up to 1100 °C) is done on a 316L stainless steel and on an Inconel 625 nickel-based alloy. Heat treatments are realized under vacuum in order to have a diffusion welding representative atmosphere during the heat treatment of each sample. Surface characterisation techniques as scanning electron microscope (SEM) coupled by energy dispersive X-ray spectroscopy (EDX), X-ray photoelectron spectroscopy (XPS) and glow discharge optical emission spectroscopy (GDOES) are used to observe from surface to the bulk the variation of the alloy's chemistry after each heat treatments.

This study aims to better understand the chemical evolution of the joining interface during the diffusion welding cycle in order to optimize the process for materials containing carbides or oxides forming elements.

Paper 1522 6 **Influence of brazing parameters on the microstructure and mechanical properties of nickel-based superalloys joints**
Mrs. Laura Mathieu, France
Oral Presentation (20')

Abstract

Furnace brazing is a well-established process in the aerospace industry, especially for the assembly of turbine components. The joint is created thanks to the diffusion of elements between the base metal (the parts to be assembled) and a liquid filler metal of similar composition. This complex process leads to the formation of numerous phases in the joint and a modification of the base metal in its vicinity.

The present work, a collaboration between Safran Aircraft Engines and the Institut des Matériaux de Nantes Jean Rouxel, aims to study the impact of brazing parameters, such as the brazing duration and temperature, on the microstructure of the joints and its mechanical performances. To gain a better understanding of the role of grain boundaries on the diffusion process, two base metals are being compared: a polycrystalline nickel-based superalloy and a single crystal. This study also examines how boron and silicon, used to lower the melting point of filler metals, affect the joint microstructure and properties. As reported in previous studies, they tend to form hard and brittle phases, particularly detrimental to the mechanical properties. Therefore, two filler metals with different melting point depressant elements are compared.

The microstructures were characterised using Scanning Electron Microscopy (SEM), Energy Dispersive X-ray Spectroscopy (EDS) and Wavelength-Dispersive Spectroscopy (WDS). Electron BackScatter Diffraction (EBSD) was also performed to identify the different phases encountered within the joint. The mechanical properties were assessed thanks to microhardness testing.

Paper 38 **1** **Numerical simulation of weld heat input effect on microstructure and hydrogen diffusion in thick-walled S690 submerged arc welded joints**

Dr. Michael Rhode, Germany

Keynote (Oral Presentation 40')

Abstract

High-strength, low-alloy (HLSA) steels such as S690 are an attractive option for heavy industries such as offshore wind turbines and peripheral equipment due to their combination of excellent mechanical properties and weldability. The construction of these thick-walled structures requires highly efficient welding processes such as submerged arc welding (SAW). However, SAW presents challenges related to delayed hydrogen assisted cold cracking (HACC). Despite its importance, the effect of different diffusion coefficients on the cold cracking susceptibility of different microstructures within SAW-welded S690 steels is not fully understood. For this reason, the present study focuses on comparing the cold cracking susceptibility of thermomechanically rolled (TM) or quenched and tempered (QL) variants of S690 steel. SAW was performed on specimens of both steel grades to produce weldments consisting of weld metal, heat-affected zone (HAZ), and base metal. Electrochemical hydrogen permeation tests (ISO 17081) were performed to determine the microstructure specific coefficients. Using the obtained coefficients, a numerical model was developed to identify the time- and microstructure-dependent local hydrogen diffusion and its influence on the distribution within the welds. The results showed that the TM grade exhibited slightly accelerated hydrogen diffusion compared to the QL grade, which is beneficial for hydrogen reduction and increases the HACC resistance. However, the further simulations with different ply sequences showed that the welding heat input (i.e. welding ply sequence) had a significantly higher effect on hydrogen accumulation. Specifically, increased welding heat input and increased thicknesses decrease hydrogen diffusivity. For this reason, microstructure-specific hydrogen diffusion played a minor role in thick-layer SAW joints compared to the need to control the welding parameters (layer sequence, individual layer thickness, welding heat input).

Paper 1178 2

Investigation of medieval arquebuses made from malleable iron

Prof. Christof Sommitsch, Austria

Oral Presentation (20')

Abstract

In the 15th and 16th century, arquebuses played a decisive role for military operations. Several arquebuses were provided for non-destructive testing, such as ultrasonic testing, hardness testing and borescope measurements in order to investigate the forge welding processes in this medieval age. In addition, one piece of an arquebus was investigated by light optical microscopy and wet chemic analysis and was compared to wall closure parts from the same age.

Pig iron was produced by a wolf furnace where roasted iron ore and charcoal was fed. The iron was reduced in the solid state and further beaten out.

It was found that the carbon content of the pieces is very low, and the slag amount and composition differ in dependence of the application. The production of the arquebuses under investigation was done by mandrel forging. The initial material was beaten out to a rectangular blank, which was twisted on a mandrel and further forge welded. Apparently, different blank geometries have been used, i.e. stepwise and beveled, which, together with the pre-material and forging conditions has a strong influence on the final geometry and quality of the forging welds.

The Pögl family was a famous family at that time in Styria/Austria with several hammer mills. They developed an advanced forge welding procedure which resulted in outmatching material and product quality.

Paper 1638 3

Influence of weld-related thermal cycles on the sensitization of AA5XXX

Ph.D. Vasilis Loukadakis, Greece

Oral Presentation (20')

Abstract

Aluminum alloys, particularly AA5XXX, find widespread application in critical sectors like maritime and automotive industries. However, their susceptibility to stress corrosion cracking (SCC) following welding processes poses a significant risk of premature failure. This phenomenon is attributed to the formation of a brittle beta phase during post-weld cooling, a process known as sensitization. This study employs advanced computational tools to investigate the influence of welding-induced thermal cycles on the kinetics of beta phase formation in AA5XXX alloys. By simulating the evolution of microstructural phases and predicting the extent of sensitization, this work aims to provide valuable insights for optimizing welding parameters and developing robust post-weld heat treatment strategies to mitigate SCC risk and enhance the long-term reliability of these critical components.

Paper 1720 4 **Microstructure comparison of welded Nitinol thin foils with linear, oscillating and pulsed laser beam**
Prof. Christoph Hartl, Germany
Oral Presentation (20')

Abstract

Nitinol is meanwhile a well-known smart material with its superelastic and shape-memory behaviour. It is a good choice for demanding applications from medical, aerospace, robotics and other important technological fields. One significant stumbling block is through its poor workability. Welding may be a good solution for producing complex shapes. Especially if very tiny parts are needed, laser welding of thin foils of Nitinol may open the way for new challenging applications like antennas and other innovative products. In previous work of the authors it was shown that oscillation of the laser beam was favourable for welding Nitinol components with regard to the mechanical properties, microstructure and alteration of transformation behaviour of the weld. As for the welding of thin foils pulsed laser beam has also have been advantageous for the resulting microstructure, the goal of the presented study was the investigation of the microstructure development and the properties of Nitinol thin foils welded with pulsed in comparison to continuous laser beam. The combination of laser beam oscillation and pulsed operation has not yet been investigated for welding thin Nitinol foils.

Experimental Study of Dissimilar Yb: YAG Laser Beam Welded Inconel 718 to Ti-6Al-4V

Mrs. Dimitra Ioannidou, Greece

Oral Presentation (20')

Abstract

The present study investigates the microstructural evolution and characterization of dissimilar metal lap welds between copper-plated Inconel 718 and Ti-6Al-4V alloys, focusing on the influence of varying copper plating thickness and laser power density on the resultant joints' microstructure. Each weld involved copper-plating one of the two base metal (BM) plates employing an acid bath, varying the plating duration to control the final copper thickness. Dissimilar welding was performed on 2 mm plates using a Yb: YAG laser at two distinct power densities, namely 1.3 and 1.5 kW, allowing an assessment of heat input variations on weld integrity. The microstructural analysis of the fusion zone (FZ) and heat-affected zones (HAZs) was performed using visible light microscopy (VLM) and scanning electron microscopy (SEM) coupled with energy dispersive spectroscopy (EDS), while the joints' crystallographic structure was examined via X-ray diffraction (XRD). Mechanical performance estimation was carried out through Vickers microhardness testing. The metallographic examination revealed defects such as keyhole porosity and cracking, particularly at the BM interface, as well as lack of penetration in specimens welded at 1.3 kW power. Moreover, macrosegregation was observed, especially in welds where the Ti-6Al-4V BM formed the upper section of the lap joint, a phenomenon attributed to the different solubilities and diffusivities of Al and V. Additionally, Marangoni convection further influenced the non-uniform distribution of these elements due to cooling rate variations and directional solidification, which contributed to crack initiation. Microstructural examination indicated that the joints were primarily characterized by the precipitation of ternary intermetallic compounds (IMCs) consisting of Ni, Cu, and Ti, findings that also correlated with the Vickers microhardness results. In conclusion, a higher laser power density was observed to improve weld penetration while reducing the occurrence of crack formation.

Keywords: electroplated copper interlayer, dissimilar metal welding, Yb: YAG laser beam welding, Inconel 718, Ti-6Al-4V, microstructure, Vickers microhardness.

Paper 1738 6 **Experimental evaluation of TIG lap welds made from 316L sheets for use in liquid hydrogen storage tanks.**

Mrs. Stavroula Maritsa, Greece

Oral Presentation (20')

Abstract

The shipbuilding industry is currently facing challenges in the development and construction of onboard liquid hydrogen (LH₂) storage tanks. Austenitic stainless steels (e.g., 316L) are among the materials considered suitable candidates for use as the inner part of the tank in direct contact with LH₂. In the context of the current work, AISI 316L TIG welds carried out on thin sheets, which were previously subjected to certain levels of uniaxial pre-strain (10%, 20%, 30%, and 40%), were evaluated in terms of their microstructure and hydrogen uptake. The investigation covers a range of selected heat input rates in relation to the welding conditions. Cathodic charging was used to introduce hydrogen into the weld metal and the heat-affected zone. The effect of hydrogen was evaluated in two aspects: the amount of hydrogen absorbed and its impact on the mechanical properties of the weld. In this regard, Thermal Desorption Spectroscopy (TDS) analysis and hardness tests were performed for selected combinations of the experimental conditions employed. The results obtained so far allow for the correlation of microstructural features and hydrogen absorption with the welding conditions used for the welds. It is anticipated that the experimental findings will shed light on the mechanism of hydrogen uptake and its interaction with the weld metal (WM) and the heat-affected zone (HAZ) exposed to liquid hydrogen (LH₂). This is expected to contribute to the development of structures with tailored properties for LH₂ storage and marine transportation applications.

Paper 1513 7 **Optimization of A-TIG welding for X5CrNi18-10 stainless steel**

Ph.D. Matija Bušić, Croatia

Oral Presentation (20')

Abstract

The paper presents the influence of the activation flux type on activated flux tungsten inert gas welding (A-TIG) of the X5CrNi18-10 stainless steel. In introduction part properties and application in energy production sector of X5CrNi18-10 stainless steel was investigated. The A-TIG process was explained and the possibility of welding stainless steels using the A-TIG process to maximize productivity by applying reduced or completely without edge preparation was presented. In the experimental part 3 mm thick X5CrNi18-10 stainless steel sheets have been welded in butt joint configuration using TIG and A-TIG welding methods. Three substances were examined as single component fluxes in this experiment: calcium oxide (CaO), silicon dioxide (SiO₂) and ferric oxide (Fe₂O₃). The welding process was performed by automatic guiding system driving a TIG welding torch. With selected A-TIG welding technology machining preparation of plates and consumption of filler material have been avoided. Specimens sectioned from the produced welds have been subjected to bend testing according to the standard ISO 5173:2023, macrostructure analysis and corrosion resistance analysis. The results have confirmed that this type of stainless steel can be welded without edge preparation and addition of filler material when silicon dioxide (SiO₂) as single component flux is used.

Paper 1354 1 In-space 3D printing of Li-ion batteries by Fused Filament Fabrication

Ph.D. Félix Bourseau, France

Highlight (Oral Presentation 20')

Abstract

The Moon and Mars are the next targets for space exploration. However, launch costs and resupply delays have made inconceivable manned long-duration missions. In-Space Manufacturing (ISM) appeared as the essential breakthrough to remove these barriers. This approach would allow the production and repairs of critical systems to answer astronauts' needs independently from Earth resupply. Additive manufacturing processes (AM) are at the heart of this strategy thanks to their versatility, low cost, and ease of use (1). Indeed, Fused Filament Fabrication (FFF) has been successfully deployed in the International Space Station (ISS) to print spare parts and tools (2). 3D printing in microgravity of more complex systems is the next challenge to take up. In Space, energy supply is a critical issue as it is one of the main causes of the space systems lifespan limitation. Energy mainly comes from solar power so rechargeable Li-ion batteries (LIBs) are involved at all spacecraft levels : from the ISS primary power system to portable communications devices, going through life support systems (3). Thus, in-orbit manufacturing of batteries represent a necessary milestone to carry out the ISM approach.

This work aims to make in-space 3D printing of Li-ion batteries feasible. For seven years, our group has optimized composite filament formulations to successfully 3D print Li-ion batteries by FFF. The challenging task of this study was the transition from liquid electrolytes to solid polymer electrolytes suitable for microgravity. We have created and characterized new formulations to obtain a process that fits the security requirements of the spacecraft's environment (4). Materials choices, process parameters, and formulations have been ingeniously studied to obtain the best compromise between printability and electrochemical performances. 3D printing alleviating gravity constrain environments has been performed at European Space Agency (ESA) facilities to demonstrate in-space printability and to understand microgravity's influence on the morphology and the performances of our 3D-printed batteries.

Paper 1897 2

Advanced Sustainable Composite Materials Based on Renewable Resources for Space Applications

Prof. Alice Mija, France

Oral Presentation (20')

Abstract

As the global population continues to grow, so does the demand for resources, making conservation and efficient industrial management more important than ever. A shift towards a sustainable economy is crucial, with bioenergy, biofuels, and bio-based materials playing a key role in reducing reliance on fossil fuels and addressing environmental challenges. This study focuses on developing eco-friendly composites reinforced with carbon or vegetable fibers, engineered to meet the strict requirements of industrial applications. These high-performance materials are particularly suitable for demanding environments, especially in aerospace and space exploration.

At the center of this innovation is a polymeric matrix derived from renewable sources, formulated with an aliphatic compound extracted from vegetable oils, such as epoxidized linseed oil (ELO). By reinforcing this matrix with carbon or vegetable fibers, the resulting composites achieve a unique combination of strength, durability, and adaptability. These materials can be recycled, repaired, and reshaped while maintaining their structural integrity, offering an environmentally responsible alternative to traditional petrochemical-based materials.

Comprehensive testing was conducted to assess their mechanical and thermal properties. Dynamic Mechanical Analysis (DMA) confirmed their exceptional stiffness, while mechanical strength tests demonstrated their durability under stress. The bond between the fiber and matrix was analyzed through Interlaminar Shear Strength (ILSS) tests and visually examined using Scanning Electron Microscopy (SEM), providing insights into the material's internal structure. Thermogravimetric Analysis (TGA) showed that these composites have good thermal stability, with a T5% (temperature at which 5% mass loss occurs) exceeding 300°C. Additionally, a Limiting Oxygen Index (LOI) above 30% highlights their strong fire resistance, making them reliable for applications where safety is a priority.

In space exploration, materials must withstand extreme conditions, including high temperatures, radiation, and vacuum environments. These composites offer promising solutions, as they are designed to endure the challenges of space environments.

In summary, these advanced polymeric composites present a sustainable, durable, and high-performance alternative to conventional materials. With their ability to combine environmental benefits with superior mechanical properties, they hold great potential for use in space missions and other high-tech applications, paving the way for innovative, long-term solutions in material science.

Gravity independent Additive Manufacturing of an Al-Si alloy by Molten Metal Deposition (MMD)

Dr. Andrea Mistrini, Italy

Oral Presentation (20')

Abstract

Space exploration missions continue to push the boundaries of technology into far future. Additive manufacturing (AM) enables on-demand production, maintenance and repair in space, offering a valuable capability and bringing the possibility for deep space exploration closer to reality. The concept of in-space manufacturing (ISM) is driven by the need to overcome the severe constraints of payload capacity, design complexity increasing the risk for failure and the excessive costs associated with launching materials from Earth. Since 2014, extrusion-based 3D printers on the ISS have produced over 200 parts, highlighting AM's potential for space missions. However, metals AM's, particularly Laser Powder Bed Fusion, faces challenges due to powder handling in microgravity. Molten Metal Deposition (MMD), the technology used in this research, is a liquid metal printing process where wire feedstock is melted and deposited as molten metal tracks. This study examines gravity independence by printing samples in standard and inverted orientations (with print head and substrate flipped). Support from the European Space Agency (ESA) enabled setup modifications. The selected material is a 4xxx aluminium alloy, specifically AlSi5 (wt.%). Bulk samples were printed with different parameter combinations (nozzle temperature, substrate temperature, print speed, layer height and track width) to study their effects on materials properties and microstructure. Porosity, microstructure and mechanical properties are compared between both gravity orientations.

Dense and uncracked bulk samples (density > 99%) were achieved. Gravity orientation showed any impact on metal density. The microstructural analysis of sample cross-sections revealed a cellular microstructure, suggesting solidification and cooling rate higher than those typical of conventional casting processes. However, the average grain size is smaller than that of AlSi alloys produced by Laser Powder Bed Fusion. A reduction in grain size is observed from the bottom to the top of the sample section, without differences between regular and inverted samples. In the bottom layers, closer to the substrate, the thermal gradient during solidification is lower due to the influence of substrate preheating, leading to a lower cooling rate that in turn lead to coarser grains. Moreover, the layer deposited on top of the previously deposited layers, can contribute to grain coarsening, leading to a gradient microstructure. Microhardness tests were conducted, revealing variations corresponding to the material's microstructure. Hardness increased from the bottom to the top of the samples, with a rate of 0.18HV per millimetres of height, as grain size decreased. No notable differences in hardness were observed between regular and inverted samples.

Paper 1359 4 Unveiling δ Phase Strengthening Mechanisms in LPBF-Processed Inconel 718 at Elevated Temperatures

Prof. Hyokyung Sung, South Korea

Oral Presentation (20')

Abstract

The highest-strength Inconel 718 alloy, widely used in aviation and increasingly in jet turbine engines (operating up to 650 °C), relies on high-temperature stable solid-state co-precipitation for strengthening. However, conventional co-precipitation is prone to service-induced degradation, particularly due to δ phase formation at elevated temperatures, which leads to significant deterioration in Inconel 718 alloys manufactured via transitional casting or laser powder bed fusion (LPBF). Here, we challenge the conventional understanding of δ phase precipitation in LPBF-produced Inconel 718 alloys, demonstrating that a high density of δ particles can actually enhance mechanical performance. Specifically, LPBF-induced δ phase promotes dynamic precipitation along cell boundaries within internal grains, leading to an optimal combination of strength (~1.2 GPa) and ductility (~23%) at 650 °C. We reveal that δ particles inside the grains exhibit temperature-dependent strengthening mechanisms: at room temperature, δ particles undergo shearing through dislocation slip, resulting in step formation along shear planes. In contrast, at 650 °C, dislocations bend δ particles without forming steps, instead accumulating at γ''/δ interfaces, which triggers a localized disordering transition of the δ phase. This novel δ bending and disordering mechanism arises from a combination of modulus mismatch and stacking faults. The high density of bent δ particles disrupts dislocation motion, inducing inhomogeneous deformation and reducing the yield strength and strain-hardening rate at 650 °C. Our findings provide new insights into the role of δ phase in LPBF-processed Inconel 718, offering a pathway for designing high-temperature stable alloys with enhanced mechanical performance.

Enhancing thermal performance of micro-nano Al/SiC/cBN hybrid composites made for satellite applications via nitride-induced self-forming method

Prof. Hyunjoo Choi, South Korea

Oral Presentation (20')

Abstract

The aerospace industry, especially in the satellite environment, requires low thermal expansion, high heat dissipation, and lightweight materials for maintaining structural integrity and effective thermal management in harsh space conditions. Achieving this combination of properties is more challenging for aluminum metal matrix composites (AMCs) with a single reinforcing phase than for hybrid composites, which provide synergistic properties from multiple reinforcements. Therefore, it is essential to explore AMCs with various grain structures and multiple reinforcements to control the mechanical and thermal properties of hybrid composites.

In this study, SiC- and cBN-reinforced aluminum matrix hybrid composites were fabricated to examine their mechanical and thermal properties. Pure aluminum powder (108–150 μm) was blended with 5 vol.% SiC (1 μm) particles using attrition milling at 550 rpm for 12 hours to create nanocrystalline powders (n-Al/5% SiC). This attrition-milled powder was then mixed with pure aluminum (10 μm), 8.55 vol.% SiC (10 μm), and 10–30 vol.% cBN (36–54 μm) to form various hybrid composite powders. For instance, 5 vol.% of n-Al/5% SiC powder was combined with 65 vol.% pure aluminum and 30 vol.% cBN using a turbula mixer to create a 5% (n-Al/5% SiC)/30% cBN/65% mAl hybrid composite powder. Additional hybrid composite powders were developed similarly. These composites were manufactured using the nitride-induced self-forming process at 660 °C for 1 hour in a nitrogen atmosphere and subsequently densified by hot pressing at 580 °C for 1 hour under a 24-ton load.

After hot pressing, the hybrid composites were examined to analyze their mechanical and thermal properties, including microstructure. This study achieves a relative density greater than 98% for all composites. The uniform distribution of SiC particles and microstructural integrity of reinforcements with Al matrix was analyzed using SEM micrographs. Hardness and tensile strength were increased with the increasing vol.% of nanocrystalline powders and reinforcements. Most importantly, the thermal performance of these hybrid composites was investigated by measuring the conductivity (TC) and coefficient of thermal expansion (CTE). The highest TC and low CTE have been achieved for a hybrid composite of 10% (nAl/5% SiC)/30% cBN with 60 vol.% of mAl. According to preliminary results, composite materials' thermal and mechanical behavior is greatly influenced by the addition of reinforcements and tailored nitridation levels, which may result in innovative approaches for satellite systems. Further investigation is required to understand the interaction between microstructure and thermal properties, aiding the development of high-performance materials for future satellite applications.

Paper 1817 6 Alloy Design for Magnesium Alloys in Aerospace Applications: Optimizing Strength and Thermal Conductivity
Dr. Jae-Yeon Kim, South Korea
Oral Presentation (20')

Abstract

Recently, an interest in low Earth orbit (LEO) communication satellites is growing, and the miniaturization and weight reduction of satellite structures have become essential. Accordingly, the development of advanced lightweight materials with optimized performance characteristics in the space environment has become a critical challenge. Materials for satellite structures require multi-properties of high specific strength, low thermal deformation, and efficient heat dissipation. Fabricating metal matrix composite can be an effective way to enhance these multi-properties; however, the optimization of the matrix alloy is essential to fully exploit the potential of such composites. In general, specific strength in magnesium alloys can be improved through alloying and precipitation hardening. However, the introduction of alloying elements significantly degrades the intrinsic thermal conductivity of pure magnesium (156 W/m·K), reducing it by up to 50%. To address this trade-off, this study systematically investigates the influence of alloying elements and heat treatment on the mechanical and thermal properties of magnesium alloys. Thermodynamic simulations using Thermo-Calc Python were conducted to predict the thermal conductivity and mechanical strength of binary magnesium alloys. Based on these results, alloy systems with optimal strength and thermal conductivity balance were identified. Selected alloys were fabricated via a casting-extrusion-aging treatment route, and their microstructural evolution, specific strength, and thermal transport characteristics were thoroughly evaluated. Among the investigated matrix alloys, Mg-6Zn demonstrated excellent mechanical and thermal performance. Furthermore, metal matrix composites were fabricated using both commercial and newly developed matrix alloys, and their properties were comparatively analyzed.

Paper 1532 1 TEMPUS - A microgravity electromagnetic levitation facility for parabolic flights

Dr. Georg Lohöfer, Germany

Highlight (Oral Presentation 20')

Abstract

During the ~22s lasting free fall phase in an aircraft flying a parabola, the aboard installed electromagnetic levitation facility "TEMPUS" is used to investigate contactlessly and undisturbed of gravity induced convection thermophysical properties and microstructure formations of hot and highly reactive metal or semiconductor melts. The completely contactless handling and measurement of a liquid by the levitation technique keeps the melt free of contamination and enables the extension of the accessible sample temperature range far into the undercooled liquid state below the melting point. Additionally, the state of reduced weight during parabolic flights allows us to considerably decrease the strongly disturbing electromagnetic levitation forces acting in ground-based facilities on the suspended liquids. The present talk explains the basic principle and the technical realization of the TEMPUS levitation facility and its attached measurement devices. Furthermore, it presents some typical experiments performed in TEMPUS, which also show the advantages resulting from the combination of reduced weight, electromagnetic levitation and contactless measurement techniques.

EML – Electromagnetic levitator onboard the ISS: investigation of thermophysical properties & solidification of liquid metals

Dr. Stephan Schneider, Germany

Oral Presentation (20')

Abstract

EML is an electromagnetic levitation facility of the European Space Agency (ESA) onboard the ISS for the containerless processing of conductive materials under microgravity conditions, which is now since 10 years in operation in the Columbus module. Due to the absence of container walls the meta stable state of the undercooled melt can be reached and investigated. The facility allows the measurement of thermophysical properties as surface tension, viscosity, density, specific heat, emissivity & electrical conductivity. Solidification processes can be investigated by the measurement of the growth velocities, the delay time between metastable and stable phase formation and the investigation of the microstructure of the solidified sample after the experiments. In microgravity heating & positioning can be decoupled, so that measurements can be performed at reduced field strengths or the field and electromagnetic stirring can be used as parameter for the measurements. The presentation will give an overview of the technical aspects of the facility, the measurement principles and some results from the ISS experiments. It will be shown how the experiments are planned and performed and will present an overview of the experiments in the last decade.

Paper 1310 5

Thermal conductivity and dynamic oxidation resistance of additive-free silicon carbide ceramics

Dr. Ondrej Hanzel, Slovakia

Oral Presentation (20')

Abstract

Fully dense (t. d. > 99 %) silicon carbide ceramics without any sintering additives were successfully prepared by combination of freeze granulation of silicon carbide powder, annealing of granulated powder and subsequent rapid hot pressing at 1900°C with dwell time from 5 to 80 minutes under a uniaxial pressure of 70 MPa in vacuum. Different ratio of alpha and beta silicon carbide has been achieved by adjusting dwell time during sintering. Thermal diffusivity, specific heat capacity, thermal conductivity, density, microstructure of additive-free SiC with various α/β content has been investigated. The thermal diffusivity of additive-free SiC ceramics increased from 47.3 to 68.4 mm²/s with increasing holding time and therefore increasing α -SiC content from 63 to 94 % and increasing grain size. The highest thermal conductivity ($\lambda=165$ W/m.K) among the SiC ceramics sintered at temperatures $\leq 1900^\circ\text{C}$ was achieved for additive-free SiC sintered at 1900°C under vacuum for 80 minutes. To the best of our knowledge this is the highest value of thermal conductivity for silicon carbide ceramics sintered at $T \leq 1900^\circ\text{C}$ up to now. In addition, such prepared materials were tested in oxy-acetylene torch at 1700°C, 1800°C and 1900°C for 5 minutes. In the dynamic regime the ceramics sustained 1900 °C for 5 minutes. It seems that this material is suitable for ultra-high-temperature applications.

Fully-recyclable CNT sheets for multifunctional thermoset and thermoplastic composites

Dr. Anastasiia Mikhalchan, Spain

Oral Presentation (20')

Abstract

The carbon nanotube (CNT)-based high-tenacity fibres, multifilament yarns, nearly transparent nanotextiles, and thick paper-alike sheets can be synthesized in a single-step gas-phase chemical reaction via floating catalyst CVD process (FCCVD) [1]. With the most recent advantages in FCCVD synthesis conversion, international Carbon Hub R&D initiatives [2], and ongoing efforts in industrial scale-up, the annual capacity to produce CNT as high-performance macromaterials may increase from today's kilo ton per year to the megaton scale through co-production of CNTs in the generation of turquoise hydrogen [3].

These macroscopic CNT ensembles constitute a new class of carbon-based materials, combining the high graphitic carbonaceous nature with high structural ductility similar to high-performance polymers [4]. However, in contrast to conventional all-solid "monolithic" carbon fibres (CF), CNT macromaterials have hierarchical network structure built of ultralong interconnected CNTs, responsible for the remarkable fracture energy and through-thickness and longitudinal electrical and thermal conductivity, enabling their usage in novel multifunctional materials [3]. Such a unique combination of properties with the macroscale format (fibre, yarn, sheet) makes them prominent candidates for novel electrical conductors, thermal management, structural reinforcement, and other areas where they can displace CO₂-intensive materials. The CNT macromaterials could be used in 3D FFF printing and combined with AFP manufacturing of novel structural composites to leverage the design freedom and innovative multifunctional parts with integrated sensors for structural health monitoring, de-icing, lightning-strike protection, EMI shielding for aerospace, automotive, and other industrial sectors.

In this work, we discuss the structural features of macroscopic CNT sheets, their properties, composite processing with high-performance thermosets and thermoplastics (PAEK, PEI), and their recycling capability. The nanostructured CNT materials can be recycled from their thermoset [5] and thermoplastic composites without any notable chemical degradation and with nearly full retention of mechanical and electrical properties. The recycled CNT sheets retain their original shape and CNT alignment after polymer removal, which is hardly attainable for conventional CF recycled mainly as short discontinuous filaments. We correlate the high recycling potential with the intrinsic toughness and structural ductility of CNT sheets, which can be evaluated through the concept of the Essential Work of Fracture (EWF). We evaluate the EWF by testing the laser-cut double-notched samples of CNT sheets to pursue the models for predicting their behaviour and ductile fracture essential for understanding mechanics and recycling potential.

Paper 1168 2 Negative charged covalent organic framework (N-COF)-based Li ion filtering protective layer for stable Li metal anodes

Mr. Jung Sang Won, South Korea

Oral Presentation (20')

Abstract

Lithium metal is considered as a promising candidate for the anode of next-generation batteries, such as lithium-sulfur and lithium-air batteries, due to its high theoretical capacity (3,860 mAh cm⁻³), low standard reduction potential (-3.04 V vs. Standard Hydrogen Electrode), and low density. However, it faces several challenges, including high reactivity, volume expansion, unstable solid-electrolyte interphase (SEI) layer, dendrite formation, and the formation of dead lithium.

To address these chronic issues, extensive research is being conducted, and one notable solution is the development of an artificial protective layer on the Lithium metal surface. In this study, an artificial protective layer was developed using a covalent organic framework(COF), which selectively allows the stable diffusion of lithium ions. Previously developed COF materials for lithium metal protective layer have been reported to enhance cycling stability by facilitating the uniform deposition of Lithium ions beneath the protective layer. However, their high initial resistance leads to poor initial performance, and low ion conductivity increases instability during high-rate charge/discharge cycles.

In this study, a COF material with high-ion-conductivity functional groups(N-COF) was developed to overcome the limitations of conventional COF materials. These functional groups enhance ion conductivity and impart a negative charge to the nanochannels. To synthesize N-COF, a constant temperature was maintained to induce the spontaneous reaction of precursors, and its successful synthesis was confirmed through XRD, FTIR, Raman, and XPS analyses. Compared to other COF materials, N-COF features smaller pore sizes and is composed of abundant lithiophilic functional groups, which not only reduce overpotential during prolonged and continuous lithium plating/stripping but also promote uniform lithium deposition and dissolution. Furthermore, the mechanism of lithium anode behavior with N-COF was elucidated through first-principles calculations (DFT) and comprehensive electrochemical analyses. As a result, the N-COF protective layer facilitated stable lithium deposition beneath the protective layer, enhancing the long-term performance of lithium metal batteries. The symmetric cell and full cell tests demonstrated low overpotential and long-term stability. Additionally, due to its high ion conductivity and negatively charged nanochannels, stable cell performance was achieved even during high-rate charge/discharge cycles.

Multimodal Microscopy and Spectroscopy for Battery Characterization: Understanding Degradation Mechanisms

Dr. George Sarau, Germany

Oral Presentation (20')

Abstract

Batteries play a crucial role in grid-scale energy storage and in powering modern technology, from portable electronics to electric vehicles. However, the gradual degradation of battery performance presents significant challenges to their reliability, safety, and economic viability. In this study, we combine high-resolution complementary analytical techniques to investigate the underlying causes of material degradation in solid-state metal-ion batteries after charge and discharge cycles. The resulting multimodal and multiscale data is analyzed and correlated using customized machine learning algorithms within the same software platform (XamFlow, Lucid).

Our focus is on lithium-ion battery stacks, a representative energy storage technology, consisting of a Nickel-Cobalt-Manganese (NCM) cathode, a polyethylene separator coated with an inorganic layer, and a graphitic anode. First, X-ray Microscopy (XRM) (Xradia 620 Versa, Zeiss) is utilized to non-destructively visualize the 3D micro- and nanoscale structure of NMC cathodes (spatial resolution ~500 nm). XRM data is then employed for the statistical analysis of NMC particle size and shape, porosity, as well as crack and void distributions. These are key parameters associated with degradation due to mechanical stress and cycling fatigue, which lead to increased interfacial resistance and reduced battery capacity.

Second, Scanning Electron Microscopy (SEM) (Crossbeam 550, Zeiss) provides even higher-resolution morphology and defect analysis in both 2D and 3D (spatial resolution ~10 nm). The 3D structure is reconstructed using Focused-Ion-Beam (FIB) milling in SEM, yielding high-resolution FIB-SEM tomography datasets. Additionally, elemental analysis is performed using Energy-Dispersive X-ray (EDX) spectroscopy, while Time-of-Flight Secondary Ion Mass Spectrometry (ToF-SIMS) enables the spatial mapping of lithium distribution. This allows for the assessment of irreversible lithium ion loss, primarily attributed to degradation mechanisms such as electrochemical reactions and thermal effects, which contribute to Solid Electrolyte Interphase (SEI) formation, lithium plating, and electrode saturation.

Third, micro-Raman spectroscopy (spatial resolution ~1 µm) is employed for chemical analysis, enabling the precise differentiation between various crystalline phases of NMC and carbon materials, as well as lithium compounds such as lithium cobalt oxide (LiCoO₂), lithium carbonate (Li₂CO₃), and lithium hydroxide (LiOH), while also providing insights into lithium intercalation and deintercalation processes.

These characterization techniques are broadly applicable to other energy storage materials, including those requiring an inert atmosphere for sample preparation and analysis. In such cases, transfer shuttles are used to safely transport samples between different instruments for slicing, polishing, and measurements.

Paper 534 5 **Development of Additively Manufactured Anodes for Aluminum-Air Batteries: Influence of Microstructure on Performance**
Mr. Ajaykumar Udayraj Yadav, India
Oral Presentation (20')

Abstract

Aluminum-air (Al-air) batteries are promising high-energy-density power sources for applications such as electric vehicles and portable electronics. However, conventional aluminum anodes face challenges including high self-corrosion, hydrogen evolution, and limited mechanical durability, which hinder their efficiency and lifespan. This study explores the electrochemical and microstructural properties of a 3D-printed AlMgScZr alloy as a potential anode material for Al-air batteries.

The AlMgScZr alloy exhibits a unique bimodal microstructure with a fish-scale morphology, characterized by equiaxed grains along the scales and a core of columnar grains. The grain size distribution ranges from 1 to 12 μm , contributing to enhanced mechanical strength and electrochemical performance. The addition of Sc and Zr promotes grain refinement, strengthening the alloy through grain boundary pinning and increasing its durability compared to pure aluminum.

Electrochemical testing was performed in a three-electrode setup using a platinum counter electrode in 4M KOH electrolyte. The open circuit potential (OCP) was measured at -1.7 V, confirming its suitability for Al-air battery applications. Additionally, the corrosion current density of 10^{-3} A/cm^2 indicates improved resistance to self-corrosion. A key challenge in Al-air batteries, the parasitic hydrogen evolution reaction (HER), was significantly mitigated by the presence of Mg, which stabilizes the structure and suppresses unwanted side reactions. Heat-treated alloys were also evaluated, demonstrating that microstructural optimization further enhances electrochemical performance.

The combined effects of microstructural control, alloying elements, and additive manufacturing contribute to improved electrochemical stability, reduced corrosion, and enhanced mechanical integrity. This study highlights the potential of 3D-printed AlMgScZr alloys as next-generation Al-air battery anodes, offering a pathway toward high-performance and long-lasting energy storage solutions.

Paper 1514 6

Back to Basics: using conventional techniques to characterize graphite blends components for applications as anode in batteries

Dr. Asya Mazzucco, Italy

Oral Presentation (20')

Abstract

Graphite blends are rapidly gaining popularity in anode production for batteries, due to their ability to optimize performance, cost, and durability. By combining different types of graphite, manufacturers can enhance conductivity, life cycle, and structural stability, while maintaining low cost. Additionally, blends offer customization of electrode properties and supply chain flexibility. These advantages make graphite blends a key focus for advancing next-generation energy storage solutions. Understanding the structural properties of selected graphite is essential for the characterization of these blends.

Graphite exists in two crystalline forms: hexagonal and rhombohedral [1]. The hexagonal form is the most common and thermodynamically stable, while the rhombohedral form is unstable and always found mixed with the hexagonal one. The rhombohedral features, such as (101) and (012) reflections in powder X-ray diffraction (PXRD), are observed in natural graphite. On the contrary, they are absent in synthetic varieties, due to the high temperature of the production process, which leads the rhombohedral phase to gradually convert into the more stable hexagonal phase when heated above 1300 °C [1]. These structural differences influence the electrochemical properties of graphite blends, highlighting the need for advanced characterization techniques to clearly identify the components of graphite blends.

The aim of this study is to standardize routine analysis methods for characterizing graphite blends. We synthesized 15 graphite blends with varying natural-to-artificial ratios using ball milling under different conditions, including varying milling times and using wet (water, ethanol) or dry milling. Blends were characterized using synchrotron PXRD, at the ID22 beamline at ESRF. Data analysis revealed that a unique method for distinguishing the components within graphite blends involves examining defects in the crystalline structure. Specifically, we investigated how stacking fault density and interplanar distance vary in the blend, using structural parameters of both natural and artificial graphites as standards. This approach allowed us to quantify the percentage of natural and synthetic graphite present in the blends. The PXRD data were complemented with pair distribution function (PDF) analysis to examine how the C-C distances vary in the blends, while FE-SEM measurements provided insights into observed morphologies. The combination of data from applied techniques was used to simulate and validate the crystal structure of the graphite blends. The impact of stacking faults was further explored through atomic-scale simulations, using XaNSoNS software [2]. Preliminary results suggest that using defects as unique fingerprints of different graphites could be a winning strategy.

Paper 1697 1 **Characterization of microencapsulated phase change materials developed from waste for sustainable constructive materials.**

Dr. Jessica Giro-Paloma, Spain

Oral Presentation (20')

Abstract

This study presents advancements by the DIOPMA research group in developing sustainable construction materials (SCM) and optimizing Microencapsulated Phase Change Materials (MPCM). With science, technology, and innovation as key drivers toward the 2030 Agenda's Sustainable Development Goals (SDG), our research explores alternatives to Ordinary Portland Cement (OPC), focusing on Magnesium Phosphate Cements (MPC) incorporating waste-derived raw materials and MPCM. We investigate MPCM with polymeric shells from waste materials such as polyethylene terephthalate (PET), polystyrene (PS), and acrylics (PMMA), evaluating their compatibility with MPC for enhanced building performance. Key requirements include resistance to pH and temperature fluctuations, as well as mechanical strength to withstand the mixing processes. The materials undergo comprehensive chemical, physical, thermal, mechanical, and environmental assessments, including porosity analysis. A life cycle analysis (LCA) is essential to ensure these materials support climate change adaptation and decarbonization efforts in the building sector at both national and European levels. By reducing raw material consumption, enhancing thermal comfort, and lowering reliance on HVAC systems, this research contributes to energy efficiency and the circular economy, driving a sustainable transition in construction.

Paper 1577 2 **Environmentally sustainable alternatives to Portland cement optimized with phase change materials (PCMs) for low temperature thermal energy storage**
Mrs. Jara Martínez Ramírez, Spain
Oral Presentation (20')

Abstract

The production of one of the base materials in modern construction, Portland cement, is associated with significant emissions of polluting gases, mainly CO₂, and with an important demand of water and fossil fuels. Thus, the search for ecological alternatives to Portland cement (PC) has intensified, leading to the development of new systems that allow not only to reduce the impact of the contamination but also to reutilize industrial wastes and to open up these systems to new applications. The recent studies on this field explore the potential of several alternatives, such as alkali activated and hybrid materials based on the use of blast furnace slag or blends of limestone and calcined clay (LC³ materials). Moreover, these alternative materials are observed in recent studies to serve as potential thermal energy storage (TES) systems, taking advantage of similar thermal conductivity and specific heat and better mechanical properties compared with PC, serving as bases for the development of renewable energies [1].

In the study of the optimization of these systems, phase change materials (PCMs) exhibit great thermal properties that make them attractive for the development of TES applications due to their ability to undergo a phase transition, absorbing or releasing a significant amount of heat during this process [2]. This allows the development of medium-to-low temperature TES systems with higher thermal storage capabilities for several applications. The research carried out consists of the study of the effect on thermal and mechanical properties of the PC and alternative systems doped with nylon and of their viability in construction and TES applications. For that purpose, the systems were exposed to low temperature cycles as well as to constant temperatures to determine their performance, stability and viability. The research highlights the potential of PCMs when integrated in both traditional and alternative cementitious systems, being a promising pathway towards a more sustainable and efficient construction.

E4 – Energy storage

Seminario 8 Room (Level +1)

Paper 583 **3** **Study of the degradation mechanisms of a thermal energy storage system based on molten metal**
Dr. Nuria Navarrete, Germany
Oral Presentation (20')

Abstract

Energy storage systems are an essential part of the energy transition towards more sustainable sources. In comparison to electric batteries, thermal energy storage can be a more competitive option depending on the characteristics of the system (applications involving heating, solar thermal energy, heat waste recovery, etc.). The quest of storing the biggest amount of energy possible goes through storage at higher temperatures. Metallic Phase Change Materials (mPCMs) can present high energy densities and high thermal conductivity which make them suitable for their use in high temperature energy storage systems, especially when the volume available for the storage is limited, or fast charge and discharge are required.

Many other criteria need to be considered when designing a high temperature thermal storage system beside the thermophysical properties of the storage material. Compatibility between the mPCM and the container must be ensured throughout the lifetime of the components. This also implies that the storage must be able to withstand a high number of charge/discharge cycles without compromising its performance.

In the present work, a methodology to estimate the lifetime of the components of a thermal storage system is developed. For that purpose, systems based in Al-12.5wt.%Si used as storage material and several iron-based container materials have been tested. The reaction rates between the mPCM and its housing were calculated by keeping the alloy molten for different durations inside a crucible of the container material. Post-mortem analyses were used to determine the extent of the reaction taking place. In parallel, the reaction rates when the system is submitted to numerous melting/solidification cycles were also studied, allowing to estimate the influence of cycling in the degradation mechanisms. This influence was also assessed by measuring the variation in the storage capacity of the mPCM using Differential Scanning Calorimetry. The combination of these experimental results served to establish a methodological first approach for the prediction of component lifetime in latent-heat based thermal energy storages.

Shape-stabilized phase change materials based on natural rubber

Mr. Marc Neira-Viñas, Spain

Oral Presentation (20')

Abstract

To target the problems related to the containment of organic solid-to-liquid phase change materials (PCM), research has led to several solutions mainly focused on their encapsulation at the microscale and macroscale. However, the leakage of liquid PCM can also be prevented by its embedding in a matrix such as porous aggregates or polymeric materials to form shape-stabilized PCMs (SSPCMs). Although thermoplastic polymers are usually chosen as a matrix, the use of elastomers brings the opportunity to obtain flexible and soft composite materials that can be potentially used as SSPCMs.

In this work, we investigate the feasibility of obtaining elastomer-based SSPCMs by incorporating commonly studied commercial organic PCMs with near room temperature phase change into a natural rubber (NR) matrix without the need for previous encapsulation. Thermal analysis of the prepared composites was performed to evaluate their performance as thermal energy storage (TES) material. A decrease in the melting point of the confined PCM was observed and was found to be dependent on the PCM concentration. Although this phenomenon is mainly attributed to the confinement of PCM in the NR network and its polymer-solvent interaction, further structural and thermal characterization of the PCM extracted from the matrix was performed with the aim of evaluating possible changes in its structure and thermal properties as a result of its interaction with the NR network.

Evaluation of the TES performance of the composites over time concluded that despite the initial ability of NR to incorporate great amounts of PCM in its network, the composite material tends to an equilibrium concentration of PCM at room temperature. Once the equilibrium is reached, SSPCMs were proven to be stable without leaking over time or melting-crystallization cycles, although the transition temperatures were shifted towards lower values in comparison to those of the bulk PCM.

The apparent difficulty in the prediction of the transition temperature range of the developed SSPCMs can be seen as a novel potential route for the design of SSPCMs with a customizable phase transition temperature.

Paper 1347 6

3D Simulations of Ultra-High Temperature Phase-Change Material Storage for Thermophotovoltaic Conversion: The SUNSON-BOX Approach

Mr. Alfonso Hernández, Spain

Highlight (Oral Presentation 20')

Abstract

Searching for more efficient, high-temperature energy storage solutions, phase-change material (PCM)-based thermal energy storage (TES) systems have gained significant attention due to their ability to store and liberate heat on demand. As part of the Horizon Europe SUNSON project, we performed comprehensive 3D computational simulations in COMSOL Multiphysics® to investigate the thermal behaviour and energy conversion performance of a novel ultra-high-temperature PCM-TES prototype: the SUNSON-BOX. This system uses concentrated solar power (CSP) to store thermal energy, subsequently converting it to electricity via a thermophotovoltaic (TPV) unit (doi.org/10.1016/J.ENERGY.2016.04.048).

The developed model incorporates a multi-physics approach to account for all elements of this innovative system, investigating how different PCM properties and design modifications influence overall system performance, while providing essential data for optimising material selection, geometry, and operational strategies. The simulations combine heat transfer, radiation, fluid flow, and phase-change modelling under charging (with and without simultaneous discharge) and discharging (with and without active power production) modes. Various metal-silicon PCMs (doi.org/10.1016/B978-0-12-819955-8.00004-1) were analysed regarding latent heat capacity ($> 1 \text{ MWh/m}^3$), melting temperature range ($> 1150^\circ\text{C}$), and thermal conductivity, with the prototype having a 12l PCM volume. Results indicate that certain high-melting-point alloys, such as 24Mn-64Si-10B-2Cr, enable higher TPV operating temperatures, thus enhancing the electrical output. However, these attributes also increase heat losses, reducing system efficiency. Other alloys (43Fe-57Si, 41Fe-51Si-3B-5Cr) provided balanced performance by ensuring relatively high peak power output while limiting losses during extended storage periods. The key performance indicators evaluated include solar-to-thermal conversion efficiency (ratio of accumulated heat in the PCM to total solar input), thermal-to-electric conversion efficiency (product of TPV absorption efficiency and TPV cell efficiency), and charge/discharge cycle times. In charging modes, the system stored up to 19kWh of thermal energy in one cycle, with melting durations of 0.5h-1.3h depending on the PCM alloy. During discharge modes, solidification times ranged from 3h-10h, with electricity outputs of 70-300W. Additionally, optimisation studies were conducted to evaluate the effect of design modifications (doi.org/10.2991/978-94-6463-455-6_18), such as varying crucible wall thickness and incorporating fins into the crucible walls. While adding fins slightly enhanced melting and solidification rates, the projected gains were insufficient to offset the added design complexity and cost.

Overall, this study provides essential insights into the interplay of PCM thermophysical properties, operating temperature, and system design in maximising energy conversion efficiency. These findings will guide ongoing refinement of the SUNSON-BOX prototype, support material selection, and ease subsequent experimental validation and scale-up for real-world renewable energy production.

Paper 1490 1 **Efficient perovskite-based high-temperature hybrid sensible-thermochemical heat storage systems for integration with renewable energy sources**

Dr. Christos Agrafiotis, Germany

Highlight (Oral Presentation 20')

Abstract

The present work presents a holistic approach on development of efficient high-temperature heat storage systems for integration with renewable energy (RE) sources as well as industrial waste heat recovery. The concept pursued is that of hybrid sensible-thermochemical storage implemented on porous, flow-through ceramic monolithic structures like honeycombs and foams, manufactured entirely or substantially from earth-abundant, inexpensive, environmentally-benign perovskites. Ca-Mn-based perovskites in particular, are capable of cyclic, reversible reduction-oxidation (redox) under air atmosphere, accompanied by significant endothermic/ exothermic heat effects, according to the scheme: $\text{CaMnO}_{3-x} \leftrightarrow \text{CaMnO}_{3-x} + x/2 \text{O}_2$. The necessary "renewable" heat for the endothermic reduction step can be supplied from, otherwise to-be-curtailed, surplus electricity from PV or wind systems, concentrated solar energy or hot industrial waste gas streams. This heat is recovered by the inverse, exothermic oxidation of the reduced oxide when the RE-source is not available. With redox oxides, air can be used as both the heat transfer fluid and the reactant (O_2) coming into direct contact with the storage material (oxide).

The development of CaMnO_3 -based redox structures is addressed starting from high-throughput computational screening of such A- and B-site doped perovskite compositions to extract via Density Functional Theory (DFT) theoretical key metrics like heat capacity (extremely important for sensible heat storage), redox reactions enthalpy and thermo-mechanical properties within the temperature range of interest, as a function of kind and concentration of dopant elements. The so-identified shortlisted multi-cation perovskite compositions are synthesized by scalable routes, optimizing selection of precursor powders and sintering conditions with respect to the targeted properties of merit like phase purity of the obtained perovskite, heat capacity, extend and reversibility of reduction, heat effects of the redox reactions, coefficient of thermal expansion, and dimensional changes due to thermochemical expansion/contraction, among others. Of significant importance is the absence of phase transformations, which, even though reversible during heating/cooling in the temperature range of 300-1100°C, are nevertheless detrimental on the thermomechanical strength and longevity of structured ceramics. Finally, rigid monolithic porous honeycombs and foams were manufactured from such optimized compositions in a variety of sizes spanning from few mm to tens of cm. Long-term cyclic redox tests (>200 cycles) on such structures have demonstrated for the first time the ability of a perovskite – or in general of a redox oxide operating via partial reduction (oxygen vacancies) mechanism – to generate repeatable heat effects

Uncovering CSP-TES Synergies Aligned with Global and European Roadmaps in the COOPERANT Project

Dr. Patricia Royo, Spain

Oral Presentation (20')

Abstract

Global energy transition roadmaps include concentrated solar power (CSP) and thermal energy storage (TES) systems as key technologies in the decarbonisation of the energy sector and the development of renewable energies in the medium and long term. The global average LCOE (levelized cost of energy) of these promising technologies dropped by 70 % between 2010 and 2023 (from 0.38 to 0.11 €/kWh). However, this cost is still far from mature renewable technologies such as photovoltaics (0.04 €/kWh) and onshore wind (0.03 €/kWh)¹. In 2024, the global total CSP capacity exceeded 7 GW, and the International Energy Agency (IEA) estimates that 35 and 390 GW of CSP capacity should be added by 2030 and 2050, respectively, to achieve net zero emissions in the energy sector.

We have reviewed different European strategic roadmaps and identified the strategies that CSP-TES systems must follow to play a pivotal role in the uninterrupted supply of renewable electricity and high-temperature heat in alignment with the European Green Deal. The SET Plan includes specific targets to develop innovative and cost-effective systems unlocking the third-generation of CSP technologies.

In this vein, CSP-TES integration can significantly improve the dispatchability of solar energy, i.e., commercial molten salts-based TES achieve up to 18h storage capacity at 560 °C. We have identified and compiled current challenges linked to operation, compatibility and durability at high temperatures as well as reliable thermal cycling stability and concluded there is a need to develop new advanced materials, novel concepts and energy management technologies to ease CSP-TES integration across industrial sectors.

Aligning with the global and European roadmaps, the COOPERANT project introduces key innovations in a new CSP-TES conceptual design operating at high temperatures (>1000°C). To do so, a high-performance open volumetric receiver with a distinct cellular morphology made of silicon-carbon composites is used. Furthermore, the high-temperature hybrid TES with a large storage capacity (600 kWh/m³) will incorporate both latent and sensible heat storage mechanisms. Metal alloys and inorganic salts are investigated as phase-change materials (PCM) to operate up to 900°C while solid-state mixtures can withstand temperatures up to 1300°C. These innovations unlock the potential to reach an overall system efficiency over current benchmarks (>42%), accomplishing the second SET PLAN target.

Overall, COOPERANT's innovative energy storage solution will enable CSP plants to provide renewable high-temperature heat and power on demand, bridging the production/demand gap and aligning with EU and global climate and energy agendas.

Joule-Heated Perovskite Metal Oxides for Thermal Energy Storage

Dr. Mathias Pein, Germany

Oral Presentation (20')

Abstract

High-temperature thermochemical cycles based on redox metal oxides offer great potential to utilize heat from renewable sources such as concentrated solar irradiation or produced from excess renewable electricity and industrial waste heat. All these have in common that the metal oxides are heated by an external heat source. In this work an innovative approach to power-to-heat conversion by joule heated perovskite metal oxides is presented. While typical thermal storage units required a heat transfer fluid such as air to be charged and discharged, joule-heated storage units neither require a heat transfer fluid nor an external source of heat to be stored in the unit. Instead, all it required is electric power and current flowing through the storage units. This concept can not only serve as a means to overcome the inherently fluctuating power supply by PV and wind, but also as solution to electrification of large scale heat supply to industry with high-temperature heat demand.

Perovskite metal oxides of the general formula ABO_3 are a versatile material class, which is considered for various applications due to its tunability and flexibility. Substituting elemental fractions on either A- or B-site can not only govern thermodynamic and kinetic properties, but also electrochemical properties and can improve structural and mechanical stability. Perovskite metal oxides are capable of fully reversible cyclic reduction and oxidation during thermal cycling at high temperatures, which they undergo non-stoichiometrically without any major phase transition. The large variety of possible composition allows precise fine-tuning of desired properties in multi-cation perovskites, including the electric conductivity. This allows perovskite metal oxides to be directly heated by electric current flow through the material, so called joule heating. The presented work investigates Mn- and Fe-rich perovskite compositions as functional materials for such a combined power-to-heat and thermal energy storage approach. From Density Functional Theory (DFT) calculations, a sophisticated doping strategy is derived and chosen material compositions are synthesized and characterized for validation. Electric conductivity, thermodynamic redox activity, heat capacities as well as reaction kinetics are determined experimentally in the desired temperature range of RT – 1100°C and are used to validate the previous theoretical calculations and evaluate the performance of novel material compositions for the described power-to-heat approach. Finally, based on this works results the potential of this novel concept is evaluated and outlook on follow-up work is drawn.

Paper 1360 4 Hybrid Sensible-Latent Heat Thermal Energy Storage for Concentrated Solar Power Applications
Mrs. Adina Hochuli, Switzerland
Oral Presentation (20')

Abstract

The integration of Thermal Energy Storage (TES) systems in Concentrated Solar Power (CSP) plants is crucial for enhancing their efficiency and dispatchability. This study presents a novel hybrid sensible-latent heat TES system designed for high-temperature CSP applications. The proposed system combines advanced solid-state materials with phase change materials (PCMs) to optimize thermal storage capacity and heat transfer performance. We aim to investigate innovative structured fillers, such as honeycomb designs, incorporating new solid mixture materials as PCM matrices and/or macroencapsulated PCM. These components are studied to be strategically arranged to maximize heat transfer and storage density.

Key aspects of the study include:

1. Defining input/output requirements and boundary conditions for the CSP-TES system, including energy flows, power, pressure, capacity, and temperature ranges.
2. Designing a volumetric receiver for efficient solar energy capture and transfer to the heat transfer fluid.
3. Developing alternative TES configurations with optimized material distribution and heat transfer enhancement techniques.
4. Establishing target requirements for storage materials, emphasizing cost-effectiveness and sustainability.

The study also considers key performance indicators (KPIs) to evaluate the TES system's effectiveness, including energy density, thermal efficiency, operational stability, and long-term durability. Various design alternatives are assessed to identify the most viable configuration for large-scale implementation. The work sets a foundation for future optimization efforts, ensuring the proposed system aligns with industrial scalability and economic feasibility.

The results of this study will be presented at the conference, focusing on design considerations, material selection, and performance benchmarks. This research contributes to advancing CSP technology by supporting the development of next-generation TES systems, this research supports the broader goal of improving CSP technology, making it more viable and cost-effective for widespread implementation.

NEWIRONAGE: IRON AS A FUEL IN NEW ENERGY STORAGE CYCLES

Dr. Carmen Mayoral, Spain

Oral Presentation (20')

Abstract

Metallic iron can serve as an energy-dense fuel, CO₂-free producing a regenerable oxide in combustion. The regeneration of the oxide to FeO through an industrial process of reduction with H₂ from renewable sources allows the direct storage of energy in the form of metallic iron. In this way, metallic iron falls into the category of recyclable electro-fuel, also called 'energy carrier'. The process of self-sustaining combustion of iron has been studied and demonstrated at laboratory and pilot plant scale, however there are still some uncertainties about the behaviour of the materials in realistic cycles. The NewIronAge project studies the realistic combustion for industrial implementation in combustion boilers, and the behavior of particles in successive cycles, which is a novelty compared to theoretical and thermobalance scale studies. We have described the detailed physicochemical evolution of iron particles burnt under controlled, realistic conditions. In addition, the use of alternative iron sources is studied. The characterisation of the particles after the successive stages is carried out by XRD, SEM-EDX, TGA and size distribution. The results obtained under the appropriate conditions to ensure the viability of the decoupled storage cycles are presented.
