Paper 1249 1 **Role of precipitates on deformation processes in Al alloys**

Dr. Michal Jambor, Czech Republic

Oral Presentation (20')

Abstract

Advanced high-strength Aluminum alloys owe their mechanical properties to microstructure, typically consisting of aluminum matrix and strengthening secondary particles. The size distribution, volume fraction and number density as well as the type of secondary particles determine the nature of the particle-dislocation interactions and, thus, resulting properties of the alloys. The present study aims to describe the role of different precipitate types upon uniaxial plastic deformation in wrought Al alloys. Modern Al-Cu-Li alloy was subjected to various heat treatment regimes, resulting in different microstructures with various types of strengthening particles. The five series of specimens strengthened with GP zones, θ' , T1 were prepared and subjected to the incremental uniaxial tensile loading while employing digital image correlation (DIC) and various electron microscopy techniques to follow precipitating particles – dislocations interactions and overall dislocation slip character. The results help to understand the role of different precipitate types on dislocation slip character and allow to establish a more accurate prediction of contribution to mechanical properties from certain type of particles.

Paper 1019 2 In-situ time resolved synchrotron X-ray imaging and tomography at Diamond I12-JEEP

Dr. Robert Atwood, United Kingdom

Oral Presentation (20')

Abstract

The high energy (50-150keV) synchrotron beamline I12-JEEP has the capability to install a variety of large and complex user-supplied equipment in support of the study of materials processing and testing in-situ. Experiments under high pressure, elevated temperature or in full mechanical testing machines use radiography, tomography and diffraction to observe the behaviour of materials during processing and testing at the micron-to-millimeter scale and subsecond to multi-seconds time scales.

Radiography at millisecond timescale is used to observe the behaviour of the active zone during additive manufacturing ; the development of porosity and the flow of fluid in the liquid pool under various conditions as well as ejection of material and other defect forming behaviours.

Tomography on the scale of seconds or several seconds reveals the growth behaviour of crystals from liquid of complex mixtures, alloys or natural geological materials under the pressure found in magma chambers.

Large tomography of samples held in a 100kn mechanical testing machine allows the internal observation of damage accumulation in metals or civil engineering materials. Combined synchrotron diffraction and imaging studies elucidate the processes occurring in the multiple phases present in such materials

Paper 1060 3 **High-Throughput Mapping of Dislocation Recovery in Low-Carbon Graded Alloys via In Situ HEXRD**
Mr. Vuk Manojlovic, France
Oral Presentation (20')

Abstract Alloy design requires exploring a wide parameter space where both composition and processing routes dictate the resulting microstructure and material properties. To streamline this process, a high-throughput methodology, termed COMPASS, has been by the SIMaP laboratory of Grenoble INP. This approach integrates space- and time-resolved High-Energy X-ray Diffraction (HEXRD) with in situ thermal processing in a continuously translating sample environment, creating graded samples that facilitate space-resolved diffraction and enabling rapid mapping of microstructure evolution kinetics over various heat treatment conditions.

The aim of the present work is to determine the influence of substitutional solutes on dislocation recovery in low carbon steels. For this purpose, we investigate low-carbon steels with graded molybdenum, manganese and silicon compositions to understand their recovery behavior under thermal treatments following a cold rolling step. A dedicated furnace, designed by researchers at the Institut Jean Lamour (IJL) and operated at ID31, enables real-time tracking of dislocation density through modified Williamson–Hall and modified Warren–Averbach methods.. By synchronizing continuous sample translation with fast data acquisition (10 Hz), the methodology provides an efficient route to quantify the dislocation density evolution as a function of local composition and temperature.

Preliminary results confirm that the in situ measurements successfully capture how solute additions slow down the recovery kinetics across compositional gradients. The ability to monitor dislocation structures in real time reveals how subtle variations in molybdenum content influence recovery kinetics. This integrated approach offers a significant advance over traditional ex situ techniques, reducing experimental timescales and preserving critical transient states that often go undetected in post-mortem analyses.

Overall, this new methodology opens the door to a more comprehensive understanding of alloy behavior by linking compositional variations to microstructural evolution in real time. The insights gained will serve as valuable input for refining computational models of material behavior and guiding the design of next-generation alloys with optimized properties.

Paper 2181 1 Exploring Texture and Residual Stress in Additively Manufactured Steels Using Advanced Diffraction Techniques

Dr. Steven Van Petegem, Switzerland

Keynote (Oral Presentation 40')

Abstract

The crystallographic texture of a material plays a crucial role in determining mechanical properties, deformation behavior, and residual stress development. In additively manufactured (AM) metals, rapid solidification, complex thermal histories, and repeated heating-cooling cycles strongly affect texture, often leading to highly heterogeneous and anisotropic microstructures. Importantly, AM techniques allow not only for shaping components but also for manipulating local texture, offering opportunities to tailor mechanical performance in specific regions. However, the resulting microstructures are often complex and three-dimensional, making it critical to develop methods that can capture both the texture evolution and the coupled residual stress development under processing and loading. This contribution presents two complementary case studies that apply advanced diffraction techniques to tackle these challenges. The first investigates residual stress formation and its link to texture during AM processing, while the second focuses on grain-resolved texture evolution under mechanical deformation.

The first case study examines the evolution of residual stresses and crystallographic texture in 2205 duplex stainless steel during laser powder bed fusion (LPBF) additive manufacturing. Operando neutron diffraction experiments were performed using a neutron-optimized LPBF machine to monitor real-time strain evolution during the layer-by-layer build process. Complementary Bragg-edge imaging mapped texture variations shaped by local thermal history and solid-phase transformations. Results show that stress redistribution occurs predominantly in the earliest printed layers and that crystallographic texture has a direct and significant influence on the magnitude and direction of residual stresses. Ignoring orientation-dependent elastic constants can lead to residual stress calculation errors of up to 96 MPa, emphasizing the importance of integrating texture into stress analysis models.

The second case study focuses on the use of texture tomography to study deformation behavior in additively manufactured TWIP (twinning-induced plasticity) steels. This non-destructive x-ray-based approach was motivated by the need to probe three-dimensional, grain-resolved texture evolution in microstructures with high local complexity and large intergranular misorientations, where conventional 3D diffraction methods struggle. By scanning a micro-focused x-ray beam and reconstructing orientation distribution functions (ODFs) across the sample, texture tomography enables tracking of reorientation mechanisms such as slip and twinning during interrupted tensile loading. The method provides critical insight into how texture evolves under mechanical strain, complementing stress-focused measurements by revealing the grain-scale deformation pathways that contribute to macroscopic material behavior.

Influence of heat-treatment-induced microstructural evolution on the low-cycle fatigue behavior of 316L stainless steel fabricated by laser powder bed fusion

Dr. Patricia Suárez Ocano, Germany

Oral Presentation (20')

Abstract

Additive manufacturing, particularly the laser powder bed fusion (PBF-LB/M) process, has gained significant attention in recent years due to its ability to produce complex geometries with enhanced mechanical properties. Among the various materials used, 316L stainless steel (SS) is highly favored for cyclically loaded components due to its exceptional mechanical strength, high-temperature performance, and corrosion resistance, making it widely applicable across various industries. 316L SS fabricated by PBF-LB/M (PBF-LB/M/316L) exhibits a unique hierarchical microstructure, with high density of low-angle grain boundaries (LAGBs), nano-dispersed silicates, chemical micro-segregations, and solidification-induced cellular structures. Particularly, the submicron-sized cellular walls that enriched with chromium (Cr) and molybdenum (Mo), along with high dislocation densities, contribute to a superior strength-ductility balance compared to conventionally manufactured 316L SS. The dispersed silicate particles act also as a strengthening phase, impeding dislocation movement and enhancing plastic deformation resistance.

This study explores the effect of heat treatments on the low-cycle fatigue (LCF) behavior of PBF-LB/M/316L at room temperature (RT) and 600 °C. First, three heat treatments were applied to the as-built material: 450 °C for 4 hours (HT450/4), 800 °C for 3 hours (HT800/3), and 900 °C for 1 hour (HT900/1) to investigate their influence on microstructural evolution. Microstructural analysis revealed that the HT450/4 condition preserved the cellular structure with high dislocation density, while the HT800/3 condition showed partial dissolution of cells together with reduction in both segregated elements along the cell walls and dislocation density. The HT900/1 condition resulted in complete segregation and cellular structure dissolution with comparable dislocation density to HT800/3 while maintaining the crystallographic texture and grain morphology. Intermetallic χ phase was mostly observed at the grain boundaries in HT800/3, but not in HT900/1. Fully reversed LCF tests were conducted under strain-controlled conditions with a strain amplitude of 0.8 %. Tests were interrupted at specific intervals to analyze the interaction between hierarchical microstructural features and deformation mechanisms in the three heat-treated conditions. Due to the pronounced dislocation cell structures and elemental segregation, the microstructure of the HT450/4 condition significantly impacts deformation and damage mechanisms during cyclic loading, which in turn, differ from the conventionally produced counterparts. The results provide insights into the relationship between microstructural features and fatigue performance, highlighting key deformation and failure mechanisms under cyclic loading. A comparative analysis with conventionally manufactured 316L SS is also made. These findings help optimize post-processing strategies to enhance the structural integrity of additively manufactured components.

Paper 641 **3** **In-situ synchrotron X-ray diffraction study on the deformation mechanisms of advanced steels under various load paths from cryogenic to high temperatures**
Dr. Biao Cai, United Kingdom
Oral Presentation (20')

Abstract

In-situ synchrotron x-ray diffraction was applied to investigate the mechanical and microstructural responses of advanced steels such as TWinning Induced Plasticity (TWIP) steel and Quenching and Partitioning (Q&P980) steel under monotonic uniaxial tensile and cyclic loading-unloading from 173 K to 523 K. It is well known that in fcc materials the temperature-dependent stacking fault energy (SFE) dictates the prevailing deformation mode such as dislocation sliding (i.e., $SFE > 45 \text{ mJm}^{-2}$), twinning (i.e., $SFE \approx 18\text{-}45 \text{ mJm}^{-2}$) and fcc-austenite to hcp/bct-martensite transformation (i.e., $SFE < 18 \text{ mJm}^{-2}$) [1-3]. Despite the well documented studies on deformation under uniaxial tension, this work aims to address the deformation behaviour in these materials under complex thermomechanical conditions, which is critical in predicting and controlling microstructure for engineering alloys.

The diffraction peak profile convolutes microstructural parameters such as stacking faults, twinning, and dislocations [4]. The deviation of lattice strains of successive grain families in fcc phase indicates stacking fault. Diffraction peak profile analysis was carried out to calculate the SFE based on stacking fault probability and mean-square strain. The dislocation density and character (edge/screw) was determined based on the modified Williamson-Hall method, taking into account the effect of stacking faults and twinning. The twin fault probability was drawn from peak asymmetry parameters (Lorentzian and Gaussian peak width of left and right side). Transformation was tracked by evaluating the phase specific integrated intensity. Coupled with in-situ texture analysis via Rietveld refinement of the 2D diffraction images and post-mortem EBSD, the temperature and load paths dependent deformation behaviour is interpreted in terms of phase specific planar faults, dislocation glide and reversal, twinning and detwinning, transformation and their synergistic activities.

X-ray diffraction for characterization of materials in nuclear industry

Ph.D. Claudia Aparicio, Czech Republic

Oral Presentation (20')

Abstract

X-ray diffraction (XRD) is an effective technique for studying different kinds of materials, providing valuable information about their crystal structure and phase composition. One of the main benefits of XRD is its ability to detect even small amounts of secondary phases that can affect the mechanical and chemical properties of materials. This method also allows for monitoring changes in the crystal structure over time or under non-standard conditions (e.g. high temperature, high pressure, or gamma/neutron irradiation), for example concrete aging or changes due to irradiation. Knowing how the phase composition changes on/in a material is important because from that we can conclude about their physical properties, which is especially important in the nuclear industry ensuring the safe operation of the components.

In this work we would like to present examples of how XRD help us to “see” the expansion of unit cell on granite after neutron irradiation, changes of the phase composition on the surface of cement-matrices, and corrosion of steel surface after years embedded in cement-matrices under water in anaerobic conditions.

Paper 1244 5 Advanced Characterization of Coating Microstructure for CERN Future Circular Collider

Miss Yasemin Askar, Switzerland

Oral Presentation (20')

Abstract

The Future Circular Collider (FCC) study aims to advance next-generation, high-performance particle colliders and accelerating structures, with a focus on optimizing the performance of Superconducting Radio Frequency (SRF) cavities. These cavities, typically made of niobium (Nb), operate at superconducting temperatures (below 2 K), enabling highly efficient energy transfer with minimal RF losses.

At CERN, research on Nb-coated, copper-based cavities with thin-film deposition techniques such as diode sputtering and DC-Magnetron Sputtering (DC-MS) were successfully developed and implemented in projects like LEP-II, LHC, and HIE-ISOLDE. These methods demonstrated enhanced RF performance by reducing residual surface resistance while also lowering costs. However, for future accelerators, further understanding of the effects of deposition parameters on the microstructural and mechanical properties of these coatings remains essential to optimize their RF performance.

The study utilizes state-of-the-art preparation and characterization techniques to thoroughly evaluate the microstructural features and stress states of Nb films deposited on Cu via bipolar High Power Impulse Magnetron Sputtering (HiPIMS). Large cross-sectional views were prepared using laser-focused ion beam (FIB) technology, while characterization was carried out through Scanning Electron Microscopy (SEM) and Scanning Transmission Electron Microscopy (STEM). Additionally, advanced diffraction techniques such as Electron Backscatter Diffraction (EBSD) and Grazing Incidence X-Ray Diffraction (GI-XRD) were employed for dislocation density evaluation, texture analysis, and residual stress assessment.

This comprehensive approach facilitates the selection of optimal deposition parameters, enabling the development of high-quality coatings with controlled microstructural and mechanical properties. Consequently, it enhances the efficiency and performance of Nb-coated, copper-based SRF cavities. The findings of this study will contribute to cost-effective designs, which are essential for large-scale accelerators like those envisioned at CERN, while also advancing thin-film coating applications in related fields.

Paper 2183 6 Laser-Driven Surface Design of Ti-Alloys: A Path Towards Biofunctionality and Beyond

Dr. Oktawian Bialas, Poland

Oral Presentation (20')

Abstract

Titanium and its alloys are among the most prominent materials in biomedical engineering, especially for load-bearing implants, due to their favorable mechanical properties and biocompatibility. However, achieving optimal biofunctionality—encompassing osteointegration, antibacterial resistance, and long-term stability—requires precise control over surface characteristics. In this context, laser-based surface engineering has emerged as a promising strategy for tailoring surface topography, chemistry, and phase composition at micro- and nanoscale levels. In this work, we investigate the effects of laser machining of the near-surface modification of titanium-gold (Ti-Au) alloy system. Using a laser treatment under ambient conditions, surface remelting, oxidation, and alloy redistribution phenomena were systematically examined. The resulting laser-affected zones exhibited significant morphological and microstructural transformations, including the formation of surface ripples, grain refinement, and the emergence of metastable Ti oxides and intermetallic phases such as Ti₃Au. These features are known to influence biological interactions, including improved cellular interaction and antibacterial properties. Advanced characterization techniques such as SEM/EDS, EBSD, and XRD were employed to elucidate the phase transformations and crystallographic orientations induced by laser treatment. Moreover, the complex interplay between thermal gradients, convection, and rapid solidification was analyzed to understand the driving forces behind the observed surface architectures. The results underscore the versatility of laser-based approaches in designing functional surfaces on biomedical alloys. By fine-tuning process parameters such as power, scan speed, and repetition rate, it is possible to engineer surface zones with tailored morphology and chemistry aimed at specific biological outcomes. This study lays the groundwork for developing next-generation implant surfaces that go beyond passive biocompatibility toward active biofunctionality, highlighting the role of laser-material interaction in the emerging field of surface bioengineering.

Paper 1640 1 **Mechanical Testing at Elevated and Cryogenic Temperatures with Concurrent Acoustic Emission and Electrical Resistivity Monitoring**

Ph.D. Jan Čapek, Czech Republic

Highlight (Oral Presentation 20')

Abstract

Understanding the deformation mechanisms of materials under extreme temperature conditions is crucial for their reliable application. This study presents an advanced mechanical testing methodology that integrates acoustic emission (AE) and electrical resistivity measurements during tensile loading at both elevated and cryogenic temperatures. The combination of AE and resistivity monitoring provides real-time insights into microstructural changes, and phase transformations. The results highlight the correlation between mechanical behavior, and defect evolution, offering a comprehensive approach to material characterization under non-ambient conditions.

Paper 1479 2 Small-specimen methods for extreme temperature and plastic strain rate material characterisation

Dr. Richard Evans, United Kingdom

Oral Presentation (20')

Abstract

Material processes like fusion and friction welding expose materials to extreme conditions, requiring detailed characterisation of properties such as high-temperature conductivity and plastic flow behaviour for accurate finite element modelling [1,2]. The integration of novel small-specimen testing, co-simulation FE methodologies, and high-temperature DIC has demonstrated an effective approach for determining high-temperature material properties with reduced uncertainty. The research presented here introduces small-specimen testing methodologies and co-simulation techniques designed to optimise experimental setups for high-temperature material characterisation. Building upon prior research conducted to establish temperature fields through material emissivity and optimised speckle patterns using high-speed digital thermography [3,4], this research integrates these methodologies with small-specimen tests to characterise material properties under extreme conditions. A coupled electromagnetic-thermomechanical simulation is developed to optimise both the specimen geometry and experimental setup, ensuring accurate strain field capture while minimising uncertainties such as electromagnetic noise and thermal gradient variations. The simulation results are validated against experimental digital image correlation data to ensure accuracy. The experimental and simulation results reveal that the proposed setup reliably captures complex plastic strain fields and thermal gradients under extreme conditions. These findings contribute to more accurate constitutive models for high-temperature materials, which are critical for simulating processes such as friction welding in finite element models. The methodology provides a robust framework for advancing material characterisation techniques at high temperatures, with potential applications in manufacturing processes requiring precise plastic flow and residual stress predictions.

Effects of specimen geometry and tensile testing system on the ductility and stability of ausferrite

Ph.D. Giuliano Angella, Italy

Oral Presentation (20')

Abstract

Ausferrite is a metallic matrix consisting of Widmānstatten acicular microstructure of bainitic ferrite and metastable austenite reach in C. In ductile irons, where graphite nodules are imbedded, it results from the two-step industrial heat treatment of austempering, coming into a first step of austenitization at high temperatures for high carbon austenite, followed by quenching in salt bath for an isothermal austempering transformation to produce proper ausferrite, and a final slow cooling to room temperature. The resulting Austempered Ductile Irons (ADIs) have outstanding physical and mechanical properties, with excellent strength-to-density ratio, and so ADIs are valid substitutes to steel castings and forgings in many weight-saving transportation applications with considerable cost and CO₂ production benefits, like in heavy trucks, military, railroad and agricultural applications. However, the main concern in the use of ADIs, is the stability of ausferrite, as during loading the metastable austenite may transform into martensite causing rupture. So, the assessment of the stability of ausferrite in industrial thin-walled ADI components is paramount, but, first of all, it is needed to assess the eventual sensitivity of ausferrite ductility and stability to the tensile specimen geometry and the tensile testing system. So, different tensile specimen geometries (round and 2 mm flat with different gauge geometries) have been tested with different gripping systems to investigate the ductility and stability of ADIs. A procedure based on the tensile strain hardening analysis has been implemented to assess the stability of ausferrite, and microstructure investigations have been carried out through Scanning Electron Microscopy and XRD measurements, while Digital Image Correlation (DIC) technique and Finite Element Modeling (FEM) have been used to investigate the local plastic behavior of ADI with different specimen geometries and gripping systems.

Dynamic Response and Challenges in High-Frequency Testing of Elastomeric Specimens

Ph.D. Jose Calaf-Chica, Spain

Oral Presentation (20')

Abstract

The accurate characterization of elastomeric materials under high-frequency dynamic excitation is fundamental for applications requiring vibration isolation, energy dissipation, and structural damping. However, the behavior of these materials at frequencies above 1 kHz shows singular challenges, as the interaction of viscoelastic properties, resonance phenomena, and wave dispersion effects becomes increasingly significant. This study focuses on the dynamic response of elastomeric specimens subjected to excitation frequencies up to 3 kHz, highlighting the mechanical impedance behavior, the strain field distribution, and the limitations of conventional testing methodologies.

Using a custom-built test bench designed for high-frequency applications, the dynamic response of elastomeric specimens was evaluated through an indirect measurement approach compliant with ISO 10846-3. This setup incorporates a seismic mass to decouple external interference, ensuring accurate measurements of force and displacement. Piezoelectric accelerometers and force transducers were employed to capture dynamic data across a wide frequency range, revealing critical phenomena such as resonance-induced strain concentrations and transitions from stiffness-dominated to inertia-dominated behavior. At resonance frequencies, significant deviations in mechanical impedance were observed, attributed to non-uniform deformation patterns and internal energy dissipation mechanisms.

Finite element modeling (FEM) was used to validate experimental results and analyze the strain field under high-frequency excitation. The simulations confirmed the resonance-induced strain localization observed experimentally and provided further insights into the deformation modes of elastomeric specimens. The analysis demonstrated how standard elastic models fail to capture the material's dynamic behavior at high frequencies, requiring more advanced viscoelastic or fractional-order modeling approaches. This research identifies several challenges in high-frequency testing, including the influence of resonance on measurement accuracy, the role of boundary conditions, and the limitations of current testing standards. The findings underline the importance of integrating experimental and numerical approaches to fully understand the high-frequency dynamics of elastomeric materials.

The outcomes of this study have implications for multiple industries, including automotive, aerospace, and civil engineering, where elastomeric components are crucial for mitigating high-frequency vibrations and ensuring structural reliability. By addressing the challenges of high-frequency testing, this work provides a foundation for optimizing the design and performance of elastomeric systems in demanding dynamic environments.

Paper 252 **5** **Sample shape effects on the experimental characterization of compressive and shear moduli**
Mr. Julen Cortazar-Noguerol, Spain
Oral Presentation (20')

Abstract

Accurate determination of the elastic properties, such as the compressive and shear moduli, is essential for understanding the mechanical behavior of materials. While the influence of specimen geometry on compressive modulus measurements is well-documented, its effect on shear modulus measurements in torsion tests has not been studied in-depth, and no correction models are currently available. The present work investigates the geometric dependencies of these moduli and introduces a novel correction model for torsion tests. The elastic properties of cylindrical samples of silicone rubber were evaluated using compressive and torsion experiments. Compressive modulus measurements were conducted with a Dynamic Mechanical Analyzer (DMA), and shear modulus measurements were performed via torsion tests using a rheometer. The results confirmed that both moduli are influenced by the shape factor of the cylindrical samples. To address these effects, a correction model was developed for torsion tests, while an existing model was applied to compressive tests. Application of the proposed correction model led to physically consistent values for both the compressive and shear moduli, demonstrating the reliability of this approach for accurate characterization.

Paper 106 **6** **Evaluation of Damage Models for Predicting Bending Failure in Advanced High-Strength Steels (AHSS)**

Mr. Kyuchool Jeong, South Korea

Oral Presentation (20')

Abstract

The prediction of bending failure in conventional constitutive models and numerical analysis remains underexplored, particularly for advanced high-strength steels (AHSS). These materials present unique challenges in bending fracture, as surface cracks initiate without necking, raising doubts about the applicability of traditional ductile damage models. This study evaluates two advanced damage models across three AHSS grades with tensile strengths ranging from 980 MPa to 1500 MPa to predict the macroscopic onset of failure. The micromechanical-based Gurson-Tvergaard-Needleman-Shear (GTNS) model was modified to better calibrate and distinguish between pure shear and plane-strain tension fractures. Additionally, the Hosford-Coulomb model, integrated with the Generalized Incremental Stress-State Dependent Damage Model (GISSMO), was employed—a framework frequently used in industrial shell analysis for sheet metal forming. A finite element analysis (FEA)-free calibration method was developed to rapidly and systematically identify the coefficients for each model. Calibration was conducted for shear, plane-strain bending, and biaxial tension paths. Both models showed good agreement with experimental load-displacement results for AHSS with low bendability in shear, bending, and tension modes. However, significant errors were observed for AHSS with high bendability due to their unique fracture behavior. The result shows that even with small three-dimensional elements, current ductile fracture models fail to accurately predict the onset of failure in high-bendability AHSS, as these materials exhibit very slow propagation of microcracks at the bending tip. These findings highlight the need to account for slowly propagating bending cracks when developing finite element-based failure models for AHSS.

Microstructural and Mechanical Characterization of Ultra-Pure Aluminum for Low-Vibration Cryogenic Applications

Ph.D. Mirko Pigato, Italy

Highlight (Oral Presentation 20')

Abstract

Sensors operating below liquid helium temperatures are highly sensitive to vibrations, which can affect the sensitivity of high-performance particle detectors. Pulse Tube cryocoolers [1], while generating vibrations lower than those of conventional refrigerators, may still introduce disturbances in delicate applications [2]. Flexible thermal connections are commonly used to mitigate these effects [3]. In the present study, a comprehensive investigation was undertaken to characterize the mechanical and microstructural properties of three ultra-pure aluminium alloys intended for the fabrication of thermal links with low stiffness, specifically designed to reduce vibration transmission in cryogenic environments. Static mechanical behaviour was evaluated through detailed tensile tests, providing insights into yield strength, ultimate tensile strength, and ductility. Complementarily, dynamic elastic moduli were determined by measuring the natural resonance frequency, thereby assessing the alloys' response to vibrational loads [4]. Moreover, dynamic modulus measurements were extended to temperatures approaching those of liquid nitrogen, offering a deeper understanding of the temperature dependence of the elastic properties under conditions that closely simulate practical cryogenic applications. Concurrently, an extensive microstructural analysis was conducted using Electron Backscatter Diffraction (EBSD) and X-ray Diffraction (XRD). These techniques facilitated the development of detailed crystallographic texture maps and enabled the identification of specific preferential orientations within the material. The correlation between the observed microstructural features and the elastic properties was systematically examined [5]. The findings of this study underscore the pivotal role of microstructural characteristics in dictating the elastic behaviour of ultra-pure aluminium alloys. The integrated analysis advances the understanding of the fundamental relationships between microstructure and mechanical performance and provides valuable guidelines for optimizing materials employed in cryogenic systems, where stringent vibration control is critical for maintaining high operational performance.

Paper	2131	2	Ultra-Low Temperature Tensile properties and Fracture Toughness of L1₂ Precipitation-Strengthened Medium-Entropy Alloy Mr. Seong-June Youn, South Korea Oral Presentation (20')
Abstract			With growing concerns about global warming, the demand for eco-friendly energy sources, such as liquid hydrogen (LH₂), has been increasing. Consequently, ensuring the reliability of structural materials in cryogenic temperature ranges has become crucial. Medium-entropy alloys (MEAs) with a face-centered cubic (FCC) structure are promising candidates for cryogenic applications because they have excellent mechanical properties and fracture resistance at low temperatures. However, MEAs have low yield strength, and at temperatures below about 20K, they experience discontinuous plastic flow, causing sudden stress changes. This makes it difficult to predict the material's reliability. In this study, Aluminum and titanium were added to a CoCrNi-based MEA to form L1₂ precipitates. The newly developed alloy was tested under 77K and 4.2K to evaluate its tensile properties and fracture toughness. Compared to the equiatomic CoCrNi alloy, the modified MEA showed a significant increase in yield strength and a lower serration amplitude. Additionally, the KJlc fracture toughness value at 4.2K was measured to be over 300 MPa·m^{1/2}, which is higher than that of austenitic stainless steel commonly used in cryogenic applications. The deformation and fracture behavior of L12 strengthed MEA was also identified based on the deformed microstructure and fractography observation results.

Paper 1899 3 **Influence of the crystallographic orientation on the crystal rotation under tribological load**

Mrs. Bonita Beichert, Germany

Oral Presentation (20')

Abstract

Tribological loading leads to a change in the microstructure of metallic materials, resulting in nucleation points for defects, ultimately resulting in wear particle formation and component failure. The sequentially first microstructural change is crystal rotation, followed by sub-grain formation. A fundamental understanding of these microstructural changes, which form the basis of the friction properties, is required to increase component life time and to design more efficient metallic materials employed in tribological contacts. It is known that the microstructure develops differently for different-orientated normal directions. In order to investigate this orientation dependence in more detail and to understand the influence of the crystallographic orientation parallel to the sliding direction, single trace tribological experiments were carried out on a copper single crystal with [110] normal direction. The sliding directions were systematically varied according to the following criteria: crystal symmetry and the reduction of activatable slip systems. For analyses, the topography of the wear track was measured, SEM images of the wear tracks and cross-sectional STEM images were taken. The crystal rotation was measured using EBSD and TKD. We found that sliding directions that create a mirror plane together with the normal direction result in symmetric material pile-ups on both sides of the wear track, whereas off-symmetry sliding directions result in asymmetric pile-ups. Slip steps form inside the wear track which can be assigned to the same crystallographic orientation in each experiment. The crystal rotation occurs in all cases around an axis perpendicular to the sliding and to the normal direction of the single crystal. The rotational misorientation increases towards the surface and is most pronounced directly underneath the sliding interface. In the microstructure, different features such as a grain boundary-like structure parallel to the surface or a more continuous transition to a higher misorientation are formed depending on the sliding direction. Our results are a first step towards a strategic texture engineering for tribologically loaded materials.

Characterisation of a cast iron alloy produced with the addition of TiC nanoparticles

Mrs. Garazi Ereña Beti, Spain

Oral Presentation (20')

Abstract

The simultaneous improvement of strength, ductility, and toughness in cast iron alloys is a key goal in the metallurgical industry. A promising strategy to achieve that is to modify the alloys by adding nanoparticles (NPs) with high hardness and thermal resistance. An example of valuable NP is titanium carbide (TiC), which has been reported to originate microstructural changes in the Fe-base alloys and to enhance their mechanical properties. A base cast iron with a high Mg content and a low Si content was first produced and then remelted with different additives in a centrifugal casting furnace to cast two medals in a metallic mould. One of them was produced with no addition of NPs and the other one with 3.8% of TiC NPs (about 20 nm in diameter). These NPs were previously introduced in Ni crucibles to promote good wettability (homogeneous dispersion of the particles) and to prevent agglomeration effects. The microstructure and the particles present in each medal were characterized using optical microscopy and Scanning Electron Microscopy (SEM). Both cast medals show a matrix composed of a high fraction of carbides, areas with martensite and low amounts of graphite particles with some having degenerated shape. The casting produced with an addition of TiC NPs comparatively show a microstructure with slightly lower amounts of graphite particles than that in the casting without any NPs addition. These graphite particles are mainly located in the central areas of both castings due to the low solidification rate at that location. For the case of non-graphitic particles, they were analysed using EDS-SEM microanalyses and then classified into six composition classes, very often containing Mg or Ti as main elements. Although the average density of non-graphitic particles are in the range 20000-25000 mm⁻² for both castings, the most frequent composition strongly depends on the addition of the NPs. Thus, the highest density of particles corresponds to compounds (Mg, Si, O, P, RE) for the casting produced without NPs addition, while class (Ti, C) is predominant in the case of the casting with the addition of TiC NPs. Further, it is observed that the size of the (Ti, C) particles present in the matrix ranges between 140 and 430 nm, i.e. about 7-20 times bigger than the size of the added TiC particles.

DURABILITY TESTING OF NEXT-GENERATION MATERIALS FOR SOLAR REFLECTORS

Mrs. Daniela Molina-Hernández, Spain

Oral Presentation (20')

Abstract

The global transition toward more sustainable energy solutions has driven exciting innovations in solar reflector production. Manufacturers are moving away from traditional materials like copper and lead, opting instead for more environmentally friendly alternatives. At the same time, there is growing interest in using glass with higher impurity levels to reduce production costs and enhance the competitiveness of concentrating solar thermal (CST) technology compared to photovoltaics. These new materials haven't been studied yet, especially when it comes to how well they perform optically or how durable they are in real-outdoor exposure conditions. The long-term performance of solar reflectors for CST systems is closely related to the interplay between their material structure (comprising the chemical composition and layer stack) and the environmental factors they are exposed to.

In this study, several different silvered-glass solar reflectors were evaluated, including state-of-the-art samples and several advanced materials combining copper-free samples with varying silver layer thicknesses, enhanced lead-free back protective paints and innovative front glass layers (with different impurity levels). These specimens underwent accelerated aging tests, in addition to outdoor exposure at several global locations, to assess the degradation of their optical properties over time. The accelerated aging test selected in this experimental campaign was the UV radiation exposure in a controlled UV chamber, since it is the most representative for analyzing the potential degradation of this type of novel materials.

The results showed that the initial optical properties of all the materials studied are equivalent, with the maximum difference in solar hemispherical reflectance being less than 0.1 percentage points. This suggests that the use of an innovative silver layer allows the removal of the copper layer without affecting significantly the initial optical performance of the reflector material. However, the composition of the glass layer directly influences the initial reflectance, with a maximum decrease of 0.5 percentage points observed in samples containing higher impurity levels. Additionally, materials with thinner silver layers showed a decrease in solar hemispherical reflectance over time, primarily due to tarnishing (a surface deterioration of the silver layer that impacts reflectance across the visible and near-infrared spectra).

These results emphasize the need for a comprehensive approach to the design of the new generation of solar reflectors, balancing optical efficiency, durability, sustainability, and cost, highlighting the critical role of both material composition and environmental factors in ensuring long-term performance.

Paper 755 **6** **Kinetic degradation determination of the Ion Exchange Resins used as a solid-active media for dry-electropolishing applications**
Dr. Joan Josep Roa Rovira, Spain
Oral Presentation (20')

Abstract

The increasing use of ion exchange resins in the industry presents the need to determine the main mechanism of loss of efficacy for dry-electropolishing applications. Ion exchange resins for the polishing process of titanium alloys are used to study the effectivity reduction in terms of surface quality and therefore reduce the polishing cycles. Two different resins will be employed, one new (considered as a reference) and the other after reaching the end-life (around 100 hours of dry-electropolishing). Along the process, the electrochemical activity of the solid particles decreases, due to several factors; as: moisture retention, saturation of the ionic exchange points, closure of the porosity due to Joule's effect, among others.

The main goal behind this study, is to evaluate the degradation process of cationic-based ion exchange resins to highlight the chemical, physical and thermal properties along the life-time of the electrolyte. Furthermore, the functional groups evolution as well as the mean decomposition temperature of the solid/liquid part of the ion exchange resins investigated will be characterized by using Fourier Transformed Infrared (FT-IR), thermogravimetric analysis, and Time-of-Flight Secondary Ion Mass Spectrometry respectively. Finally, the microstructure of the ionic exchange porosity will be evaluated by means of scanning electron microscopy.

To conclude, after the dry-electropolishing process is possible to appreciate, a reduction of the acid and water content filled in the internal porosity due to the Joule's effect induced during the dry-electropolishing process. The dehydration process presents two different rates: (1) high-dehydration rate induced during the initial dry-electropolishing process mainly attributed to the local temperature change near the surface of the resin and (2) at lower dehydration rates, mainly attribution to a diffusion process of the liquid media, from the central to external part of the resin. These hypotheses agree with the O-H groups present in the FT-IR spectra.

Corrosion resistance of water borne epoxy/carbon dots coatings on aluminium alloy

Prof. Annalisa Acquesta, Italy

Highlight (Oral Presentation 20')

Abstract

The widespread use of various metals, whose degradation produces serious economic losses and environmental pollution, requires continuous solutions to improve their corrosion resistance. Simultaneously, the increasing attention to the sustainability issues has been emphasizing the importance to avoid toxic products. Carbon dots (CDs), as a new zero-dimensional member of the carbon family, possessing the advantages of low toxicity, high solubility, good stability, inhibition properties, are attracting a great attention of researchers in the field of corrosion and protection of metallic materials. In this investigation a low amount of carbon dots was incorporated into a water-based epoxy resin, and then the hybrid coating was used to cover Al 2024-T3 samples. Electrochemical techniques in a 3,5 % by weight of aqueous solution of NaCl, weight loss, surface characterizations are combined to investigate the inhibiting effect and corrosion mechanism.

Paper 74 **2** **Effect of doping on the structure and mechanical properties of anti-wear TiB₂ coatings**

Prof. Agnieszka Kopia, Poland

Oral Presentation (20')

Abstract

TiB₂-based coatings have been intensively developed due to their physical and mechanical properties, including excellent thermal stability and high hardness with good abrasion and corrosion resistance, which appear to be the most beneficial in industrial application. Previous investigations have shown that doping TiB₂ with Ni and C can significantly reduce residual stresses and improve adhesion, making these coatings ideal on tools to machining aluminum alloys. The aim of this study was to analyze the effect of interlayer on the durability (adhesion) of the deposited Ti_{1-x}MxB₂ (x = 0; 0.03; 0.06; 0.10) M=W, Cr, Zr coatings and determine the influence of W, Cr and Zr on their microstructure and mechanical properties. The structural characterization of Ti_{1-x}MxB₂ (M=W, Cr, Zr) coatings was carried out using X-ray diffraction, X-ray photoelectron spectroscopy, transmission electron microscopy and atomic force microscopy. To investigate the mechanical properties, nano-scratch and—hardness tests (NST,NHT) were performed, and fracture toughness of the substrate layer systems was determined. The use of an adhesive layer of pure W, Cr or Zr increased the adhesion of the coatings to the substrate. It is shown that the changes in W, Cr or Zr content not only affect the microstructure, mainly by decreasing the crystallite size (column width), but also the texture (preferred coatings orientation) and phase composition. The addition of W, Cr or Zr also has an effect on the mechanical properties of TiB₂ coating by reducing their hardness and Young's modulus and increasing their fracture toughness (KIC).

Paper 1206 3 **LDH synthesis on AZ31 alloy: effect of microstructural modifications of substrate processed by ECAP**
Prof. Alessandra Varone, Italy
Oral Presentation (20')

Abstract

The high corrosion rate of Mg alloys in biological fluids limits their use in biomedical applications. Several strategies have been adopted to mitigate this issue, among them many researchers investigated the effects of grain refinement and the deposition of different protective coatings. Layered Double Hydroxide (LDH) coatings not only lead to beneficial effects of the AZ31 corrosion resistance but are also of particular interest due to their tuneable structures and ion-exchange properties, which enable them to load and release drugs.

This work investigates the effect of microstructural modifications of AZ31 alloy substrate caused by Equal Channel Angular Pressing (ECAP) process on LDH nucleation and growth. The LDH deposition process was performed on AZ31 alloy substrate, subjected to 0, 1, 2, and 4 ECAP passes, with two different synthesis times (30 minutes and 12 hours). The samples were analysed using light microscopy (LM), scanning electron microscopy (SEM), and X-ray diffraction (XRD).

The results show that the microstructure of the substrate significantly impacts the LDH deposition process. Nucleation of LDH occurs on screw dislocations at the substrate surface, with a fine and uniform distribution of LDH crystals achieved when surface diffusion takes place, enhanced by particular textures component. For the AZ31 alloy subjected to a single ECAP pass with a synthesis time of 30 minutes, a complete surface coating was formed, and the resulting crystal morphology seems to be promising for medical and biomedical applications.

Paper 1910 **5** **Synthesis and characterization of thermochromic $V_xW_{1-x}O_2$ coatings: A scalable approach using multilayer co-deposition and flash annealing**
Dr. Antonio Jesús Santos Izquierdo-bueno, Spain
Oral Presentation (20')

Abstract

This work reports on an original and scalable approach to the fabrication of 25 and 50 nm thick W-doped VO_2 -based coatings which comprises the initial co-deposition, at glancing angles and in the presence of reactive oxygen, of alternating $VO_y/V_{0.85}W_{0.15}O_y$ multilayers with average W/V ratios between 1/99 and 5/95, and their subsequent rapid thermal annealing in air atmosphere. Exhaustive micro- and nanostructural, compositional, and optical characterizations of samples treated at reaction temperatures of 475 and 550 °C for times below 30 s confirmed the synthesis of homogeneous $V_xW_{1-x}O_2$ -based films with unique thermochromic features strongly dependent on the dopant amounts. In general, a gradual lowering of the critical temperature to 37 °C during heating was achieved for the maximum doping of $x = 0.95$, albeit at the expense of some detriments in optical performances. The best and most balanced results were accomplished in a 50 nm layer doped at $x = 0.97$ (i.e. ~1 at% W) subjected to flash annealing at 550°C, presenting a remarkable light transmittance (63.4%), solar modulation capability (6.2%) and critical temperature drop (44°C). In addition, the hysteresis width and smoothness achieved make this coating potentially suitable for application in glazing exposed to direct solar radiation. The proposed methodologies, involving green-like reactions and single-layer designs, postulate as an attractive, plausible and cost-effective alternative for large-scale manufacturing of $VO_2(M)$ -based smart coatings.

Oxetanes as a new class of additives for PEDOT:PSS providing high conductivity and water-resistance

Dr. Ana Charas, Portugal

Keynote (Oral Presentation 40')

Abstract

Conducting polymers, such as poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS), are very promising for organic electronics, performing as charge transport layers, flexible electrodes, resistive sensors, among others. However, for applications where the devices interface aqueous or humid environments (e.g. in bioelectronics), both high conductivity and water resistance are essential. In this communication, we introduce oxetanes as a novel class of additives that significantly enhance both the electrical conductivity and structural stability in water of PEDOT:PSS films.

We investigated the structural properties of oxetanes responsible for these enhancements. It was discovered that oxetanes undergo polymerization in the acidic medium of PEDOT:PSS, leading to the formation of polyether compounds [1]. Additionally, hydroxyl-substituted oxetanes can create covalent cross-links or hydrogen bond interactions with the negatively charged PSS. These interactions screen the electrostatic forces between PEDOT and PSS, reducing Coulombic interactions and promoting PEDOT segregation and structural rearrangements that enhance charge transport. We demonstrate that PEDOT:PSS ink formulations containing oxetanes, applied through spin-coating or inkjet printing, can produce highly conductive thin films on both rigid (glass) and flexible (PET) substrates. These films can serve as water-resistant electrodes in electronic devices, including photovoltaic cells [2] and electrochemical field-effect transistors operating with aqueous electrolytes [3]. In addition to thin films deposited on substrates, we successfully developed flexible, free-standing PEDOT:PSS films, with enhanced water resistance and conductivity, by incorporating an oxetane compound as an additive. The obtained flexible films demonstrated good potential as health-monitoring electrodes [4].

Metal/polymer nanofluids prepared by nanoparticle-beam deposition for unconventional resistive switching

Dr. Daniil Nikitin, Czech Republic

Oral Presentation (20')

Abstract

The growing demand for computational power with lower energy consumption has made the development of novel materials for brain-inspired computing essential. Currently, most artificial neural networks rely on memristors - devices that change their resistance in response to an electric field mimicking biological synapses. However, the top-down fabrication of memristive arrays, typically achieved via techniques like lithography, is approaching limitations due to challenges in miniaturization and wiring complexity. Additionally, the structural organization of these networks diverges significantly from that of biological neuron assemblies, limiting their adaptability, robustness, and learning potential. As a result, the exploration of alternative material systems for brain-inspired computing remains a critical and ongoing research focus.

Gas-phase synthesized metal nanoparticles (NPs) have been utilized to create percolating networks exhibiting neuromorphic functionality. These networks were fabricated by depositing NP beams onto planar substrates equipped with electrodes. Under constant electric fields, the networks produced avalanches of current spikes, displaying scale-free dynamics and long-range spatiotemporal correlations reminiscent of biological neural activity. We advanced beyond the state-of-the-art by creating memristive nanofluids through the deposition of NPs beams into vacuum-compatible dielectric liquids, such as polyethylene glycol (PEG). In an electric field, the NPs underwent electrophoresis and self-organized into long-range conductive paths, growing from anode to cathode. It was demonstrated that the electrophysical properties of the nanofluids and the kinetics of path growth could be finely tuned by modifying the properties of PEG. Fundamental differences in electrical behavior were observed among three types of metal NPs: silver, gold, and nickel. Precious-metal NPs exhibited resistive switching effects during current/voltage cycling, as the voltage applied across electrodes connected by the path revealed memristive behavior. In contrast, nickel-based nanofluids showed no resistive switching, with the resistance matching that of the host liquid, which was attributed to the surface oxidation of the NPs. Detailed analysis of memristive switching in Ag/PEG nanofluids revealed multiple switching events along the path, corresponding to distinct conductivity mechanisms, including Ohmic conduction, tunneling, and space-charge-limited conduction.

4D Printable Metamaterial and Terahertz: A Pathway to Next-Generation Devices for 6G Technologies

Mrs. Beatrice Tosetto, Italy

Oral Presentation (20')

Abstract

The next generation of wireless communication (6G), foreseen for the 2030s, will be based on terahertz (THz) radiation. 6G is predicted to aggregate multiple types of resources, becoming a digital ecosystem that connects the digital, physical, and human worlds. [1] To achieve this goal, it is thus necessary to minimize the existing gap between cyber and physical worlds, with distributed and adaptive devices' interactions with THz. Beyond 6G, THz frequencies are also gaining interest in many applications in different areas, such as biomedical, quality control, security, and defense. [2] In this work, the possibility of creating a stimuli-responsive metamaterial that can interact with THz in a programmable and controlled way was investigated to develop 4D printable sensors for 6G technologies or, in general, for THz radiation. This was possible by combining polymeric material characteristics, pattern designs, and responsive dyes.

Despite the pivotal role that this part of the electromagnetic spectrum will play in the next future, the knowledge on matter/radiation interaction is lacking, especially for polymeric materials. To address this, experiments on various photocured (meth)acrylates and thiol-ene resins with different chemical compositions were conducted, evidencing a precise relationship between polymers' chemical composition and THz interaction. The definition of this dataset was the cornerstone to design new formulations that could meet the transparency criteria request for the development of THz-active metastructure, having user-defined interaction with the radiation given by specific pattern designs. For those metamaterials, geometric features of hundreds of microns are necessary due to the high wavelength involved, and those characteristics are perfectly compatible with 3D printing capabilities, particularly with Digital Light Processing (DLP) technology, the one used for this work. [3] Finally, the integration of photoresponsive compounds within the printed formulation allowed the enhancement of the printing resolution and, additionally, the possibility to trigger the THz transmission, resulting in a THz-active 4D printed metamaterial with a light-controlled THz interaction. These findings open new perspectives for the advanced manufacturing of multifunctional materials in strategic fields such as electronics and telecommunications.

Paper 1941 1 Solvent-free Remote Plasma Assisted Vacuum Deposition of Organic Nanometric thin films with Tailored Dielectric Properties

Mrs. Triana Czermak Álvarez, Spain

Oral Presentation (20')

Abstract

Organic high-k dielectric materials have garnered significant attention due to their use as gate dielectrics in flexible organic field-effect transistors (OFETs). Achieving the desired performance requires precise control over the dielectric properties (relative permittivity and dielectric strength) and morphological properties (surface topography and thickness).

Plasma deposition and treatment methods are manufacturing techniques widely present in different industrial sectors, including mass-scale manufacturing in microelectronics and large-area roll-to-roll processing of flexible and wearable materials. The current communication presents the plasma fabrication of high-k organic thin films using a remote plasma-assisted vacuum deposition (RPAVD) technique.[1] This method consists of the vacuum sublimation of functional molecules within the afterglow area of a remote plasma discharge, providing precise control over the fragmentation and poly-recombination processes involved in the plasma polymerization processes. Furthermore, it is a room-temperature and solvent-free procedure compatible with a wide range of flexible and delicate substrates (paper, textiles...).

Previous developments achieved the synthesis of advanced functional plasma-polymer-like thin films that preserve the molecular structure and integrity of complex precursor molecules for: photonics,[2] sensing,[3] lasing,[4] antimicrobial surfaces,[5] conformal protective coatings,[6] and strain engineering of 2D semiconductors.[7] This communication extends this technique to the development of high-k organic thin films for gate dielectrics applications. A luminescent dye with a very high dipole moment, DCM, is used as a precursor molecule. The results of the dielectric characterization show the development of ultra-flat (RMS roughness < 1 nm) nanometric organic thin films (thickness down to a few tens of nm) with controlled relative permittivity, with values between 3.5 and 6.3. The presence of integer dye molecules and the film's optical properties (refractive index) were also studied to determine the origin of this controlled permittivity. Furthermore, dielectric breakdown results confirm the high dielectric strength with breakdown fields in the range of 5 MV/cm.

Deposition of combinatorial oxide thin films by Spatial Atomic Layer Deposition for optoelectronic applications

Dr. Vijaya Shanthi Paul Raj, France

Oral Presentation (20')

Abstract

Nanoscale films are playing a major role in all modern applications such as photovoltaics and display technologies. Optimization of such films to enhance device performance can be a tedious process. Combinatorial high-throughput (CHT) thin film deposition is an approach for producing films presenting a gradient in at least one property (chemical composition, thickness, etc), for the accelerated optimization of material properties. Although traditional Atomic Layer Deposition (ALD) use have mostly targeted the uniform thin film deposition, several ALD approaches have been developed to perform combinatorial deposition. These procedures take into account the process temperature, non-uniform flow of pulsed gases[1], and saturated/non-saturated cycles[2] to optimize different properties of the films. Spatial-ALD (SALD) is a faster (two orders of magnitude) version of conventional ALD, and is a simpler and affordable approach to obtain high quality nanoscale films at ambient environment[3,4]. Indeed, SALD can be engineered to produce combinatorial films at high deposition rates. It has been implemented to produce ZnO and Al₂O₃ thin films with a thickness gradient for the fast optimisation of metal-insulator-metal diodes (MIM) and perovskite solar cells by using a custom-designed SALD reactor head[5]. The gradients were obtained by the design of the SALD head, with the assistance of computational fluid dynamics (CFD). In this communication, we will present recent CFD results of new reactor-head designs to deposit ZnO and Al₂O₃ films thickness and composition gradients as encapsulation layers of Ag nanowire (AgNW) networks. AgNW networks are alternative indium-free transparent electrodes that present state-of-the art optoelectronic properties but that need to be encapsulated due to AgNW's instabilities (thermal, electrical and chemical)[6]. We will also present experimental results of the impact of oxide encapsulation layer thickness and composition on the stability and properties of AgNW networks. The CHT approach for AgNW networks is intended for low-emissivity coatings[7] in energy-efficient smart windows.

Key words: Combinatorial thin-film deposition, Ag nanowires, SALD, Computational fluid dynamics.

Synthesis of KNN with tailored morphology to be used as fillers in composite materials for piezoelectric applications

Mrs. Vanessa Sánchez, Spain

Oral Presentation (20')

Abstract

Keywords: KNN, synthesis, composites, biopolymers, 3D printing, PENG

Piezoceramics based on Pb have been used for different electronic devices because of their excellent piezoelectric properties. However, nowadays, advanced materials with low impact on the environment and human health is a priority (1). As a promising substitution, sodium potassium niobate (KNN), $(K_{0.5}Na_{0.5})NbO_3$, has attracted much attention due to good piezoelectric properties and excellent biocompatibility. KNN ceramics are prepared by sintering of particles obtained by solid-state and hydrothermal synthesis routes. However, ceramic materials have insufficient flexibility for wearable applications like piezoelectric nanogenerators (PENG) and IoT devices. Therefore, ceramic nanoparticles are combined with biopolymers that contribute interesting properties like flexibility, light weight, and even electrical properties (2,3). In this communication, we present the results of different synthesis methods for KNN particles with tailored morphologies and their combination with the piezoelectric biopolymers poly-L-lactic acid (PLLA) and polyhydroxybutyrate (PHB). Particular attention is given to the filler-matrix interactions by meticulously tailoring the chemical surface properties of KNN through organic surface modification and their impact on the dielectric properties and the piezoelectric response of the composites. The results suggest that precise dielectric coupling together with 3D printing can enhance the performance of energy harvesting and sensing devices.

SELF-HEALING GLASS SEAL FOR HTE/SOFC

Mr. Raphael Voivenel, France

Oral Presentation (20')

Abstract

A current main challenge in High Temperature Electrolysis and Solid Oxide Fuel Cells (HTE/SOFC) technologies is the glass / metal sealing to prevent gas leak. In the literature, various types of seals are studied including compressed, brazed and glass seals. Glass and glass-ceramics seals appear to be the most promising technologies, provided if the glass / glass-ceramic remains stable over time.

A close matching of the thermal expansion coefficient (TEC) between seal and metal support is essential to prevent crack formation, which can lead to a loose of hermeticity (10^{-12} to 10^{-6} K⁻¹). To reach these high TEC values, BaO is often added to the glass composition. The main problem is the reaction between the barium and the environment of the seal at working temperature.

In the present talk, we present our results on a new barium-free glass-ceramic (SCABS) designed for sealing solid oxide fuel cells. Thermal properties, electrical resistivity, thermal ageing, and crystallisation were investigated and related to the glass-ceramic structure, which was characterised by NMR. XRD analyses indicate that crystallisation occurs with the formation of phases such as anorthoclase, feldspar and α -quartz. The SCABS glass-ceramic exhibits thermal and chemical stability under SOFC operating conditions for 960 hours and autonomous self-repair capability at 800°C.

Paper 422 **6** **Formation and Emission Properties of J-Aggregates in Molecularly-Oriented Bisazo Dye Films**
Mr. JIAN YU, Japan
Oral Presentation (20')

Abstract

J-aggregates are known for their unique optical properties and have been studied as various functional materials, including biomedical imaging and phototherapy. We have developed highly oriented J-aggregates of bisazo dyes and investigated their formation mechanisms.[1-4] In this study, we report on the local formation and photophysical properties of J-aggregates in molecularly-oriented bisazo dye films.

A bisazo dye (BZ-5)[4] was vacuum-deposited on polytetrafluoroethylene (PTFE) alignment layers, resulting in molecularly-oriented films containing J-aggregates of BZ-5. When the film was observed by a polarized optical microscope (POM) employing monochromatic light matching the J-band, the regions absorbed by the J-aggregates resembled 'islands'. This observation confirmed that J-aggregates were locally formed in the film. In a comprehensive study using atomic force microscopy (AFM), we found that these J-aggregates are located at quasi-stable branching points between stable crystalline grains.

In general, azo dyes hardly exhibit fluorescence because non-radiative decay due to molecular motion is dominant. However, a sharp peak at 615 nm could be observed in emission spectra for our films. Little emission was actually observed when the crystalline phase was excited in the short-wavelength region. Therefore, the sharp peak must originate from the J-aggregates. In addition, a broad emission peak around 800 nm was also observed, which may originate from a different type of aggregates. However, its intensity is lower than the sharp emission peak at 615 nm, suggesting that energy transfer between different types of aggregates is suppressed. The different types of aggregates are presumably separated by distances exceeding the Förster radius.

In summary, these results show that J-aggregates of the bisazo dye BZ-5 are formed locally in the thin films, and exhibit fluorescence in spite of the azo dye.

Paper 665 **1** **The Effect of Si Additions to an Industrial 7xxx Aluminium Alloy in the Context of Recycling**

Dr. Calin Daniel Marioara, Norway

Keynote (Oral Presentation 40')

Abstract

Using post-consumer scrap in the manufacturing of industrial aluminium alloys is becoming increasingly attractive for the implementation of a circular economy due to decreased energy consumption, lower CO₂ emissions and lower production costs. However, this practice leads to accumulation of unwanted elements which may degrade the performance of such alloys, especially if sorting of scrap is not done properly. In the case of industrial 7xxx alloys the main alloying elements are Mg and Zn, and the most likely pollutant is Si, a major solute element in the composition of 6xxx Al-Mg-Si alloys. In the present work it was investigated the effect of 0.3 wt% Si addition to an industrial Cu-free 7xxx alloy with composition 0.90Mg, 5.70Zn, 0.20Fe and 0.15Zr (wt%) on hardness evolution during artificial aging and connection with the precipitate microstructure. It was found that the Si added alloy had slower precipitation kinetics, achieving a lower peak hardness after a longer aging time than the base alloy. While the base alloy in the peak hardness condition contained the expected metastable η precipitates, two types of precipitates were observed in the Si added alloy. The first type was metastable η phases forming a coarser microstructure, while the second type was L laths with $\langle 100 \rangle_{Al}$ growth directions present in the volume in-between the η precipitates, with a dense microstructure. The L-phase is a thermally resistant precipitate observed in Mg-rich Al-Mg-Si-Cu alloys. High angle annular dark field scanning transmission electron microscopy imaging showed bright contrast atomic columns in the composition of the L-phase, and atom probe tomography confirmed the presence of Zn. It was therefore concluded that the decreased performance of the Si-added alloy was caused by Si binding with Mg to form L-phase, stabilized by the presence of Zn in its structure. Accumulation of Si in Al-Mg-Zn alloys is therefore detrimental to their mechanical properties and must be avoided. Another interesting observation of this study was the presence of up to 10 at% Zn, Si and Mg in the composition of Al₃Zr dispersoids.

MICROSTRUCTURAL AND MECHANICAL CHARACTERIZATION OF A NOVEL SECONDARY ALUMINUM ALLOY FOR AUTOMOTIVE INDUSTRY

Ph.D. Chiara Soffritti, Italy

Oral Presentation (20')

Abstract

Up to 95 % of aluminum currently used in the automotive industry can be recycled and, considering the multiple harmful by-products created during its production from ore, this recycling practice needs to be strongly encouraged. Aluminum recycling consumes only about 5 % of electricity and produces lower amounts of CO₂ compared to the amount generated during primary aluminum production. However, the use of secondary aluminum certainly has some disadvantages, mostly due to undesirable levels of metal impurities that often occur in the melt; among them, iron is the worst due to its detrimental effects on the mechanical properties of aluminum castings. This work aims to evaluate the microstructural and mechanical properties of a novel AlSiMgCu secondary aluminum alloy specifically tuned for the automotive industry, with the iron content controlled by the addition of manganese and poured in permanent mold casting. The equivalent primary alloy was also considered for comparison purposes. The chemical composition of both alloys was determined by optical emission spectroscopy, whereas the microstructural features in the as-cast condition, i.e., secondary dendritic arm spacing (SDAS), eutectic Si morphology, mean average grain size and intermetallic phases were evaluated by optical microscopy and scanning electron microscopy equipped with energy dispersive spectroscopy (SEM/EDS). The mechanical properties were investigated on samples drawn from the castings in as-cast and T6 heat-treatment conditions by tensile and impact tests, and Brinell hardness measurements. Impact tests were carried out through a 50 J instrumented Charpy pendulum to calculate the total impact energy (Wt), the maximum load (Fm), the energy at maximum load (Wm) and the crack propagation energy (Wp). At the same time, the energy absorption was estimated through the measurement of the pendulum's angle of rise (CV). After tensile and impact tests, the fractured specimens were observed by scanning electron microscopy to identify the main failure mechanisms. The results emphasized that the microstructural features and tensile properties of primary and secondary alloys, in the same metallurgical state, were almost comparable. The impact properties of the secondary alloy were slightly lower than those of the primary alloy. In any case, the morphology of the fractured surfaces suggested a ductile fracture mechanism even with different amounts of fractured intermetallics phases according to the different iron contents.

Paper 136 1 **Effect of Zn content on tensile properties and fracture toughness in Al-Zn-Mg-Cu alloy**

Ph.D. Yong Hee Jo, South Korea

Highlight (Oral Presentation 20')

Abstract

To investigate the effect of zinc (Zn) content on the yield strength and fracture toughness of high-strength Al-Zn-Mg-Cu alloys, systematic investigation was conducted using three alloys with Zn contents increasing. The yield strength increased from approximately 500 MPa to 600 MPa as the Zn content increased from 5.6 to 7.8 wt.%. However, the fracture toughness decreased from 28.1 MPa√m to 23.0 MPa√m with the same increase in Zn content.

Optical microscopy observations showed that the fraction of secondary phases was similar across the three alloys. Microstructural analysis performed using EBSD revealed that the grain size, recrystallization fraction, and texture were also comparable among the alloys. Furthermore, XRD analysis of dislocation density indicated that the three alloys had a similar dislocation density of approximately $3.8 \times 10^{14} \text{ m}^{-2}$. The increase in yield strength with higher Zn content was attributed to the precipitation strengthening effect of the additional Zn. Regarding fracture toughness, the increase in Zn content, which enhanced the yield strength, resulted in a reduced Stretch Zone Width (SZW) and an increased presence of cleavage facets on the fracture surface, leading to decreased fracture toughness. Fractographic analysis conducted after fracture toughness testing showed a reduction in the Plastic Zone Size (PZS). According to the Arrhenius equation, the reduction in PZS contributed to the observed decrease in fracture toughness. In summary, while the increase in Zn content in Al-Zn-Mg-Cu alloys has minimal influence on factors such as the fraction of secondary phases, grain size, recrystallization fraction, and texture, it significantly enhances yield strength through the precipitation strengthening effect. However, this increased yield strength reduces the SZW at the pre-fatigue crack tip during fracture toughness testing, resulting in a lower crack initiation fracture toughness value (KIC). This study demonstrates that while increasing Zn content in Al-Zn-Mg-Cu alloys can improve tensile strength via precipitation strengthening, it simultaneously reduces fracture toughness.

Paper 1675 2 **Impact of microstructure heterogeneities and casting defects on the very high cycle fatigue of Aluminium components**
Dr. Marion Kreins, Germany
Oral Presentation (20')

Abstract

Aluminium cast components play a key role in achieving sustainability goals and CO₂ emission targets due to their low specific weight. However, this great potential remains partially untapped, as the limited fatigue strength of cast aluminium components shortens their service life and requires high safety reserves in component design. The main reasons for early failure of cast aluminium components in the very high cycle fatigue (VHCF) regime are casting defects and microstructural heterogeneities, including secondary dendrite arm spacing (SDAS), eutectic silicon, and porosity. The inhomogeneous cooling conditions in complex industrial components lead to locally different characteristics of these inhomogeneities, as could be shown using the example of cylinder heads and engine blocks for automotive engineering. Pores were identified as particularly critical, as they can serve as crack initiation sites and can lead to early failure, especially in the case of large, fissured shrinkage pores. Avoiding shrinkage pores through sufficient feeding is usually not possible with technical components due to multidirectional solidification. Therefore, a targeted modification of the pore shape and size was carried out by hydrogen up-gassing of the melt prior to casting, aiming to reduce large fissured shrinkage pores by small spherical hydrogen pores. Ultrasonic fatigue testing and resonance bending crack propagation tests were performed on cast aluminium specimens with different alloy composition, cooling conditions and pore modifications in order to investigate correlations between microstructure and fatigue performance. High resolution analysis, including μ -CT, STEM and EBSD mapping, revealed that cracks are likely to initiate at near-surface fissured pores and propagate along {111} slip planes. Large α -aluminium cells as well as a short SDAS have a positive impact on crack propagation. Spherical hydrogen pores are beneficial compared to fissured shrinkage pores, as they can retard crack propagation by crack deflection, crack splitting and crack tip blunting. The insights provide a deeper understanding on fatigue mechanisms in cast aluminium alloys and demonstrate the potential of future microstructure optimization for improved fatigue life.

- Paper 1593 3** **Effect of iron on the crystallographic texture and mechanical properties of extruded 6xxx aluminium alloys**
Dr. Fazlollah Sadeghi Hosnijeh, United Kingdom
Oral Presentation (20')

Abstract

This study examined the effect of three different iron (Fe) levels on the grain structure and texture of AA6xxx extrusion alloys. Microstructural analysis was carried out to measure the micro texture and the results were correlated with tensile and bending properties. Results demonstrated that the fragmented intermetallic particles after extrusion were found to act as the nucleation sites of new grain refinement changing the dominant texture from standard deformation and/or recrystallisation textures both at the centre of thickness and peripheral grains. In alloys with dispersoid-forming elements such as Mn, fibre texture components were dominant with a small fraction of Cube recrystallisation that increased from 7 to 10% by increasing iron content from 0.2 to 0.5 wt.%. In the recrystallized alloys the Cube texture was dominant at the centre of profile thickness accompanied by a fraction of Rotated Cube texture, which increased with Fe content. The thickness of the peripheral grain surface layer decreased with increased Fe content in the fibrous alloy due to increased amount of dispersoid precipitation which prevents grain growth. The tensile properties of both alloys were reduced by increased Fe content due to consumption of Si in Fe-based intermetallic compounds which led to reduced free Si required for precipitation hardening.

- Paper 137 4** **Optimizing Over-Aging Resistance in Al-Mg-Si-Cu Alloys through the Addition of Trace Elements**
Dr. Kwangjun Euh, South Korea
Oral Presentation (20')

Abstract

This study focuses on enhancing the thermal stability of Al-Mg-Si-Cu alloys by incorporating trace elements such as silver (Ag) and scandium (Sc), while carefully controlling copper (Cu) content. The primary strengthening phase in these alloys, β'' (Mg_2Si), is prone to over-aging at elevated temperatures, leading to a loss of strength and reliability. Microalloying with Ag and Sc improves thermal stability by preventing the coarsening of precipitates and delaying hardness degradation. Ag promotes the formation of disordered atomic structures and stabilizes the alloy during over-aging, while Sc prevents the growth of the β'' and β' phases, maintaining high hardness. The combined effects of Ag and Sc, along with an optimized Cu content, result in a synergistic enhancement of thermal stability, particularly in alloys subjected to prolonged thermal exposure. This novel approach offers promising improvements in the high-temperature performance of Al-Mg-Si-Cu alloys, making them suitable for demanding applications such as electric vehicle battery enclosures.

Tensile instabilities in 6xxx series aluminium alloys

Ph.D. Julia Olszewska, France

Oral Presentation (20')

Abstract

Tensile instabilities are well known within the 5xxx (Al-Mg) series of aluminium alloys, giving rise to serrated tensile, namely the Portevin – Le Chatelier (PLC) effect. High Mg content, typical for this series, is responsible for blocking the dislocations in the Cottrell atmospheres increasing strength until the dislocation is released and the strength is lowered. 6xxx (Al-Mg-Si) series alloys, with lower Mg contents than most 5xxx alloys, are generally considered to be insensitive to this phenomenon. Yet, at high strains, instabilities of tensile curves have been reported [1,2]. Presence of such serrations is an indication of potential for premature cracking at stamping linked to strain localisation. Additionally, surface aspect and quality can be degraded. 6xxx alloys widely used in the automotive industry for both outer and inner panels could be impacted by this neglected phenomenon.

A focus on detection and understanding of tensile serrations was made in this study at both laboratory and industrial data. It has been noted that the occurrence of instabilities results in high scatter of elongation measurements, up to +/-8% absolute for total elongation and up to +/-5% for uniform elongation. Elongation measurement scatter was chosen as an appropriate parameter to analyse at both laboratory and industrial scales. Various 6xxx alloys, with Si/Mg ratios between 1 and 4, were tensile tested 1 to 10 days after quench. Three major findings were observed: 1) Elongation scatter decreases with natural ageing, reaching the typical measurement scatter within a few days; the scatter is reduced as the solid solution is depleted of Mg atoms by clustering and precipitation. 2) Increased ratio Si/Mg accelerates the stabilisation of the tensile curves and decreases the observed scatter of elongation. For particularly high Si contents (Si/Mg > 4) the serrations and elongation scattering are nearly absent. 3) The tensile instabilities are present despite a pre-ageing treatment.

Clear relation between Mg content and the occurrence tensile serrations was observed in various 6xxx alloys suggesting that the mechanism responsible for these instabilities is of the same nature as in 5xxx alloys.

Recrystallization Mechanisms in an AA2024 Sheet Alloy

Mr. Moritz Theissing, Austria

Oral Presentation (20')

Abstract

The mechanical properties of the aluminum alloy AA2024, which is commonly used in the aerospace industry, depend heavily on the microstructure e.g., grain shape and crystallographic texture. During industrial processing, the material is subjected to various thermomechanical treatments that determine the grain properties due to mechanisms such as recrystallization. Recrystallization itself is a complex transformation that depends on several influencing parameters such as the degree of deformation, secondary phases, precipitation kinetics, dispersoids, etc.

In situ electron backscatter diffraction (EBSD) was used to investigate the recrystallization process. With this technique, it is possible to study the entire transformation on a sample by recording scans during the annealing process. The correlation of the initial crystallographic microstructure and precipitation state with the fully recrystallized state after annealing is also determined. Three samples with different degrees of deformation were prepared and in-situ heating experiments were carried out with different heating rates from 1 K/min to 70 K/min. These experiments were used to determine the dependence of recrystallization on mechanical deformation and annealing heating rate. After annealing, a strong recrystallization texture was observed, consisting mainly of Cube and S grains and a smaller fraction of Goss grains. The in situ experiments showed an inconsistent growth behavior of recrystallized grains, with some showing strong growth while others remained almost unchanged after nucleation. Regarding the texture components, no obvious advantage of the cube over the other texture components was found. In addition to studying the microstructure and texture evolution, the behavior of secondary phases during the annealing treatments was investigated using scanning differential calorimetry (DSC). It was found that the S phase shows a change in the temperature window of recrystallization. The work described provided a detailed picture of the recrystallization mechanisms in AA2024, which will help to further improve the microstructure and thus the mechanical properties.

Paper 1191 7

Microalloying Al-Mg-Si alloy with indium as a new approach to control precipitation processes

Ph.D. Witold Chrominski, Poland

Oral Presentation (20')

Abstract

Microalloying has been proven to be an effective method for modifying conventional precipitation hardening in aluminium alloys. The constant quest for novel compositions accelerates the development of alloys with an improved strength-to-density ratio. This study specifically focuses on the addition of indium to a commercially available 6082 alloy. The manufacturing procedure involves melting the master alloy with the addition of new alloying elements, a process that is straightforward and applicable, for instance, during recycling processes.

The 6082 alloy has been remelted with various amount of indium and then casted into copper moulds. The heat treatment process, crucial for precipitation hardening, revealed that indium does not significantly affect hardness following direct aging compared to the original alloy. However, an alternative treatment, including room temperature storage (common in industrial practice), indicated that for a certain indium content, it is possible to restore the peak hardness level typical of the non-alloyed 6082 alloy with a simple one-stage aging process. This unexpected effect was thoroughly investigated using techniques such as differential scanning calorimetry and atomic resolution scanning electron microscopy. The study demonstrated that the properties of indium, including its melting point, vacancy binding energy, and solubility in aluminium, have a critical impact on the nucleation and growth of strengthening phases in the AlMgSi system. The overall precipitation sequence depends on the diffusion efficiency of the indium which binding energy to vacancies is the highest within alloying elements. Two factors influence tendencies to form indium clusters and deplete solid solution from vacancies – indium content and room temperature storage time. It has been shown that the former should be kept small when direct ageing is required but the latter enable to mitigate unwanted natural ageing hardness loss. The tendency to form clusters with other alloying elements and vacancies appears to be a potent tool for the development of new alloys and heat treatment procedures aimed at achieving controllable precipitation strengthening

Lightweight Alloys for Material Circularity and Manufacturing Sustainability

Prof. Alan Luo, United States

Keynote (Oral Presentation 40')

Abstract

A significant portion of our carbon footprint comes from production of light metals such as aluminum, magnesium and titanium. Increasing the circularity of these nonrenewable metals and reducing energy consumption in their manufacturing activities would significantly contribute to a carbon-neutral society and a circular economy. This presentation reviews some of new light alloys and manufacturing technologies being developed towards material circularity and manufacturing sustainability in the automotive industry. Examples are given on aluminum and magnesium sustainability. While aluminum is increasingly used for lightweighting applications in the transportation industries to reduce energy consumption and carbon footprint, primary production of aluminum is energy-intensive with extensive CO₂ emission. However, recycling aluminum scrap only uses ~5% of the energy and has 95% reduced emission compared to primary aluminum extraction from bauxite ore. The wide use of recycled aluminum in structural applications will improve the sustainability of the supply chain in aluminum and manufacturing industries. Magnesium, as the lightest structural metal and one of the most abundant metallic elements on earth, has been used for lightweighting in the transportation and electronics industries. However, the primary production of magnesium, especially the carbothermal (Pidgeon) process, is also a climate liability due to its large carbon emissions. The future of magnesium industry and applications will largely depend on how we address this sustainability challenge. For structural applications, research is needed to improve the mechanical and corrosion properties, manufacturing processes, and integrated computational materials engineering (ICME) tools.

For manufacturing processes, the development and evolution of energy-efficient large thin-wall die casting (also called mega/giga casting) will enhance the sustainability of automotive manufacturing. The alternative energy vehicles tend to have more simplified body structures, enabling the use of large and consolidated castings which significantly reduce welding, joining and assembly. The development of large thin-wall die casting, using solidification-based ICME tools, will improve the sustainability of transportation manufacturing. Microstructure models for light alloys have been developed based on computational thermodynamics and kinetics, coupled with manufacturing process models. These ICME models are integrated to predict location-specific mechanical properties, based on location-specific microstructure of solidification (casting, welding and additive manufacturing) products, for lightweight and sustainable applications. Ultimately, the combination of recycled/renewable materials and energy-efficient manufacturing processes will drive the automotive industry towards circularity and sustainability.

Paper 499 **2** **Influence of Fe concentrations on the improvement of the recycling content of Al-Mg-Si wrought alloys.**
Mrs. Chaitrali Panchal, Germany
Oral Presentation (20')

Abstract

The recycling capability of Al-Mg-Si wrought alloys is limited by the contents of some alloying elements. Increased Fe concentrations, particularly, have an adverse effect on the mechanical properties of the alloy. To better comprehend this, CALPHAD simulations using Thermo-Calc were conducted on multiple Al-Mg-Si alloys with varying Fe contents. Casting samples at laboratory scale were fabricated to corroborate the obtained simulation results. Standard microstructure investigation methods were used to analyse phase formation in the castings. The effects of homogenization on phase transformation were also examined, followed by mechanical analysis. The results specifically focus on having a better understanding of the relation between Fe concentrations, parameters influencing the alloy microstructure and the alloy mechanical properties through a preliminary study. Through these findings, the recycling strategies in the aluminium industry can be positively informed.

Paper 55 **3** **Microstructural Investigation of β - and π -type Fe-rich phases in Al-Si cast alloys**
Mr. Peer Decker, Germany
Oral Presentation (20')

Abstract

Primary-based A356 casting alloys with increased transition metal concentrations were produced to represent the use of increased amounts of scrap in primary-based alloys, as this production approach requires higher Fe and Cu contents to maximize the proportion of scrap types that can be used. This leads, inter alia, to a pronounced phase proportion of Fe-rich phases, which are often also referred to as AlFeSi phases. These phases usually have a detrimental effect on the mechanical properties due to their undesirable platelet-shaped morphology.

The fabricated alloys were analyzed in the as-cast and annealed state using scanning electron microscopy methods (EBSD, EDS) to determine the transformation of Mg- and Fe-rich π -type phases to Fe-rich β -type phases during annealing. The shape change of the phases during this transformation and the crystallographic properties are described, supported by thermodynamic calculations using Thermo-Calc Software package. The major finding was the shape change of AlFeSi phases caused by a π - to β -phase transformation during annealing. This results in the formation of a more rounded AlFeSi phase morphology revealing a potential method to cover for the detrimental effect of transition elements regarding mechanical properties in recycling-based materials.

A new Al-Si casting alloy with high elastic modulus

Dr. Young-Hee Cho, South Korea

Oral Presentation (20')

Abstract

Elastic modulus, a.k.a. Young's modulus is a measure of the stiffness or rigidity of a solid material, determined by the interatomic bonds. Pure aluminium has an elastic modulus in the reign of ~70 GPa and there have been extensive attempts to increase the modulus of aluminium alloys by introducing either ceramic particles or intermetallic phases having relatively higher elastic modulus than that of the aluminium matrix. We have recently developed new Al-Si based casting alloys with high elastic modulus in the range of 90-100 GPa and low density less than 3.0 g/cm³, by alloy design and microstructural refinement approaches. Based on the preliminary study of alloying elements on the elastic modulus, microstructure and castability, we have selected new candidate alloys, hypereutectic Al-Si alloys with Ni additions, where large volume fractions (~40 vol.%) of hard primary Si and primary Al₃Ni phases were present. However, coarse primary Si and primary Al₃Ni formed upon solidification can interfere with the melt flow, reducing the castability and also were deleterious to elongation. By the assessments of the crystallographic misfit between a nucleant substrate and a nucleated solid, therefore, we discovered modifying elements to refine such coarse and brittle primary phases, particularly Al₃Ni. More importantly, along with the improved elastic modulus, an elongation of about 1% was achieved alongside advantageous yield strength of over 230MPa. Candidate application fields where the new high modulus aluminium casting alloys can be utilised are also suggested.

Tailored Nanocrystalline Aluminium Grain Size in a Nanolaminated Architecture: New Horizons

Mr. Hendrik Jansen, Switzerland

Oral Presentation (20')

Abstract

Grain growth limits the applicability of engineering metals alike Aluminium (Al) alloys. Coarse-grained Al microstructures usually result in reduced mechanical properties – risking catastrophic failure [1,2]. In this work, we are reporting interface-engineered AlNi - AlOH (25 – 1 nm) thin films with tailored impediment to Al grain growth in two dimensions - expanding the application of engineering Al alloys. The thin films were deposited by means of combined hybrid physical vapour (PVD) and atomic layer deposition (ALD) in a SwissCluster AG SC-1 cluster deposition chamber. Mechanical testing was conducted by Nanoindentation with a Berkovich tip. High-resolution analysis of the microstructure was performed by means of combined transmission electron microscopy and atom probe tomography. As-deposited Al95Ni5 – AlOH (25 – 1 nm) thin films are reported to possess a lateral FCC Al grain size of only 10 nm with fine 1 nm Ni-rich segregations and roughly 1 nm AlOH interlayers. This unique microstructure is set to explain the > 5 GPa Nanoindentation hardness of the thin film stack. Vacuum annealing at various temperatures is gradually lowering the hardness until reaching 2.6 GPa for vacuum annealing at 450°C for 1 h, where interlayers set to broaden and Al-Ni phase separation completes. AlNi - AlOH (25 – 1 nm) thin films with > 5 GPa as-deposited hardness show superior mechanical response, even at elevated temperatures. Thus, the system serves as blueprint for further developing Al-based engineering materials towards higher strength and thermal stability with novel combination of deformation mechanisms.

In-situ synthesis of Metal Matrix Composite (MMC) by Laser Powder Bed Fusion

Dr. Jérôme Andrieux, France

Highlight (Oral Presentation 20')

Abstract

The in-situ synthesis of Aluminium Matrix Composites (AMC) via the Global Reactive Synthesis (GRS) has already been demonstrated as a promising approach to control reinforcement size and distribution, as well as to obtain sharp matrix/reinforcement interface. Based on the use of chemical precursors, the GRS is driven by controlled reactivity and thermodynamics enabling the in-situ formation of both the matrix and the reinforcement under basic geometries (cylinders or plates). It has been applied successfully to conventional AMCs like Al-TiC [1] and Al-TiB₂. It has also paved the way to a new class of AMCs and the most advanced studies have been focused on Al-Tau3 AMC, where Tau3 is a ternary borocarbide (Al₃B₄₈C₂) [2,3]. Nowadays the challenge is to combine both the GRS and novel Additive Manufacturing techniques in order to get near-net shape pieces of AMC with complex geometries, where both the matrix and the reinforcements are formed in-situ during the manufacturing process.

The synthesis of AMC via GRS was studied with the Laser Powder Bed Fusion (LPBF) and focused especially on the Al-B-C ternary system. In this talk, we will present the interesting and complex microstructures so obtained and we will discuss the different process parameters, such as precursor composition, high heating and cooling rate, laser speed and power that influence the phases formed, their sizes and distributions as well as their morphologies. Two main AMC will be presented: Al-AlB₂ AMC from a precursor mixture of 98 %wtAlB₂-2%wtC and the Al-Tau3 AMC from a 90 %wtAl-9.8 %wtAlB₂-0.2% wt C mixture.

Paper 754 2 **Modeling Strain Hardening in Al Alloys: Effects of Solutes and Microstructure Across Binary and Technical Alloy Systems**
Mrs. Anna Krejci, Austria
Oral Presentation (20')

Abstract

Understanding the influence of microstructure on the evolution of dislocations is fundamental for accurately simulating material behavior during plastic deformation. This study investigates the effects of solutes, clusters and precipitates on the strain hardening behavior of aluminum alloys. Compression tests are performed on the aluminum alloys 6016 and 6061 after various artificial and natural aging treatments, as well as on two binary systems, AlSi and AlMg, which are solutionized to evaluate their fundamental microstructural properties. This approach assesses how changes in solute concentration and microstructural states affect dislocation dynamics, particularly focusing on dislocation generation and annihilation processes critical for work-hardening and dynamic recovery.

Measured flow curves are modeled using the thermo-kinetic software package MatCalc and an extended Kocks-Mecking approach to evaluate the dependency of model parameters on the material state. The study specifically examines the roles of silicon (Si) and magnesium (Mg) solutes on the dislocation behavior, emphasizing their impact on the mechanical response in aluminum. The findings are cross-referenced with state-of-the-art constitutive modeling theories, offering enhanced insights into the interaction between microstructure and deformation behavior. This work contributes to a deeper understanding of how tailored microstructural engineering can improve formability and overall performance in aluminum alloys.

Paper 1601 3 **Microstructure evolution via 3D printing parameter development of ScAlloy/SiC metals matrix composite**
Ph.D. Yi Chao, Taiwan
Oral Presentation (20')

Abstract

Lightweighting has long been a critical focus in industries like aerospace, automotive, and healthcare. Two common approaches to achieving this are using materials with higher specific strength and employing well-ordered porous structures. Among metallic materials, aluminium alloys play a key role due to their light weight, strength, heat dissipation, corrosion resistance, and ease of processing. Composite material development holds significant potential in meeting lightweighting goals. Silicon carbide (SiC), a third-generation semiconductor, is often chosen as the reinforcing phase for its high strength, thermal conductivity, and resistance to high temperature and pressure. Building on prior research in developing aluminium-magnesium-scandium alloys, this study incorporates SiC to enhance both mechanical and thermal properties. However, manufacturing these composites poses challenges. Traditional processes are costly and struggle with structural complexity. Layer-based manufacturing technologies, particularly Powder Bed Fusion (PBF) in metal additive manufacturing, address these limitations and have become essential in lightweight metal applications. Compared to traditional methods, adding SiC to aluminium-magnesium-scandium alloys through additive manufacturing enables more uniform SiC distribution in the matrix, improving reinforcement effects. However, issues with aluminium-silicon carbide intermetallic compounds can weaken material strength and elongation. To address this, the study will optimize printing parameters for aluminium-magnesium-scandium-SiC composites using Selective Laser Melting (SLM) technology. A key objective is to minimize intermetallic compound formation by identifying optimal printing parameters. The mechanical properties—including strength, Young's modulus, energy absorption, and thermal conductivity—will be evaluated through tensile, compression, and thermal conductivity tests on all samples. This work aims to enhance the performance of lightweight Aluminium-SiC composites and expand their application potential in advanced industries. And moreover we also look forward to find out the relationship between the printing parameter and mechanical properties and microstructure.

SiC nanowhisker reinforced lightweight metal composites: a detailed study of the interface

Dr. Qianqian Li, United Kingdom

Oral Presentation (20')

Abstract

The interest to use nanoparticles and nanocarbon to reinforce light metals has attracted attention in recent years due to their potential application as lightweight high performance materials for both environmental and economical benefit, in applications including aeronautics and automotive. Challenges in successfully producing lightweight metal composites are to achieve a homogenous dispersion of nanoparticles in the metal matrix and to build a suitable interface between those nanoparticles and lightweight metals.

Nano- β -SiC is a promising reinforcement for Mg-Al alloy matrices. However, past research paid less attention to the interfacial behaviours between β -SiC and Mg-Al matrix, with most reports stating the interfaces were 'clear' and exhibited an 'absence of interfacial reactions'.

In this study, β -SiC nanowhiskers were introduced into Mg AZ91 matrix. The interfacial behaviours in this nanocomposite were thoroughly investigated using multiscale characterisation techniques including X-ray phase contrast tomography (X-PCT), scanning transmission X-ray microscope (STXM) and advanced electron microscopy. The analysis identified a less commonly reported ternary carbide, T2-Al₂MgC₂, adjacent to the nano-SiC, providing strong evidence of interfacial reactions during manufacturing. The effects of this ternary carbide on the composite microstructure, e.g. phase distributions and interfacial texture were also investigated. This comprehensive understanding of the interface of the β -SiC reinforced Mg and its correlation to nanocomposite properties is crucial for optimising manufacture and provides key inputs for modelling studies on interfacial mechanics.

Paper 276 **5** **Thermal properties of Aluminum Matrix Composites reinforced with pitch carbon fibers fabricated via hot pressing**
Dr. Ioana Carmen Vladu, Austria
Oral Presentation (20')

Abstract

Aluminium matrix composites (Al-MMCs) reinforced with pitch-based carbon fibers have gained significant attention due to their exceptional thermal properties, making them suitable for advanced thermal management applications. This study investigates the thermal behavior of Al-MMCs reinforced with various types of pitch carbon fibers fabricated via hot pressing. The parameters of the hot-pressing process were tailored in order to achieve full densification. Detailed microstructural analyses were conducted on the fabricated samples to understand the material characteristics. The influence of fiber type, volume fraction, and interfacial bonding on thermal conductivity, and thermal expansion, was systematically analyzed. Experimental results establish a clear relationship between the type and volume fraction of carbon fibers and the resulting thermal performance of the composites. Furthermore, the incorporation of pitch-based carbon fibers significantly reduced the coefficient of thermal expansion (CTE) of the Al-MMCs, enhancing their dimensional stability during thermal cycling. These findings highlight the potential of tailored pitch carbon fiber-reinforced Al-MMCs for aerospace, electronics, and automotive applications requiring advanced thermal performance.

Paper 2045 **6** **Structural application focused characterization of Continuous Fibre based Aluminium MMCs**
Mr. Stephen Kyle-henney, United Kingdom
Oral Presentation (20')

Abstract

Metal Matrix Composites (MMC) are viewed as a better recyclable alternative to Polymer Composites, however established manufacturing methods are not comparable with the time and process efficiency of the latter, and remains a challenge. Over the past decades Continuous fibre based Metal Matrix MMCs have been intermittently used for bespoke structural applications in the aerospace and automotive industries, alongside Particulate MMC. Along the route to establishment of better standardized production methods lie several challenges including the definition of befitting applications. While Aluminium MMCs offer the advantage of weight and relative sustainability when compared with Titanium MMCs, there is little published data for Continuous Fibre based Aluminium MMC from the perspective of structural application at an end-user. A discussion focused upon salient observations from testing of two approaches to this type of MMC is presented. The approaches in focus are: (1) Solid-state processed Silicon Carbide fiber based in Al-Mg-Si (6061 type) alloy. (2) Liquid state processed Alumina fibre in Al-Mg-Si alloy and primary Aluminium. Initially targeted applications, resultant microstructure, select material properties and expectations for maintainability in-service are focused upon.

Paper 13 **1** **In-Situ Alloying through 3D printing of Ti-15Nb alloy and MMC of β Ti-42Nb/TiC**

Prof. Conrado Ramos Moreira Afonso, Brazil

Oral Presentation (20')

Abstract

β Ti alloys are considered for biomedical applications due to their mechanical properties, good biocompatibility and corrosion resistance. Based on that, Ti and its alloys have been applied as biomedical implants, especially the Ti-6Al-4V alloy. However, such alloy presents problems regarding cytotoxicity of Al and V elements related to neural disorder and Alzheimer's disease, although it presents good mechanical properties. Regarding orthopedic applications there is a considerable difference between elastic modulus of Ti and $\alpha+\beta$ alloys, from $E = 100$ to 110 GPa, and that of human bone, around $E = 30$ GP, having β Ti alloy lower $E = 50$ to 80 GPa closer to that of the bone. In this context, the metastable β alloy Ti-15Nb (% by weight) appears, which will be processed through laser powder bed fusion (LPBF) and arc melting, since this is free of cytotoxic elements and shows lower Young modulus. Another approach is LPBF of metal matrix composite (MMC) of β Ti-42Nb powder with micrometric graphite (C) addition for in-situ TiC precipitates formation for increase of hardness, mechanical strength and wear combined with slightly increase of elastic modulus maintaining in low levels. Characterization of LPBF β Ti-15Nb alloy and MMC of β Ti-42Nb with graphite (C) addition for in-situ TiC formation, were done by optical microscopy (OM), X-ray diffraction (XRD), scanning electron microscopy (SEM) and transmission (TEM) techniques, Vickers microhardness, and modulus of elasticity via excitation will be used. by impulse or nanohardness. Phase identification was done by X-ray diffraction (XRD), scanning (SEM) and transmission (TEM) electron microscopy coupled to ASTAR - automatic crystal orientation mapping (ACOM). hardness. The LPMF of β Ti-15Nb alloy formed $\alpha' + \beta$ microstructure, the Vickers microhardness and elastic modulus measured by nanohardness and impulse excitation technique were evaluated, showing suitable modulus of $E = 60$ GPa. The MMC of β Ti-42Nb + TiC resulted in Vickers microhardness of 215 to 239 HV and elastic modulus of $E = 57$ to 65 GPa for (Ti-42Nb alloy and MMC being suitable for bulk and coatings for biomedical implants, respectively.

Study of Recyclability of Metal Powders, Debinding and Sintering in Binder Jetting

Mrs. Andrea Alonso Romero, Spain

Oral Presentation (20')

Abstract

The recycling of metal powders, along with debinding and sintering, constitutes critical processes in the context of additive manufacturing using Binder Jetting technology. This study focuses on the analysis of powders for their recyclability and the optimization of debinding and sintering processes in industrial furnaces to achieve final parts with a relative density exceeding 98% for stainless steels 316L and 17-4PH.

The research emphasizes the characterization of recycled powders to understand their suitability for Binder Jetting. The study focuses on analyzing the oxide layer of the particles formed after various printing cycles using transmission electron microscopy (TEM). This analysis provides detailed insights into the thickness, composition, and distribution of oxide layers, which influence the recyclability and performance of the powders in the Binder Jetting process.

To further understand and refine the debinding and sintering steps, sintered parts are characterized using techniques such as SEM, EDS, EBSD, and XCT. Besides, a step sintering approach is also implemented to analyze the evolution of the sintering process and understand the mechanisms involved. This comprehensive analysis aims to enhance process reliability, parts densification, and to optimize material performance. Moreover, the microstructure of sintered parts subjected to different atmospheric conditions and temperature variations in industrial furnaces is analyzed and discussed. Using these non-optimized conditions sintered densities up to 98% are achieved. Additionally, work focuses on improving the cost-efficiency of these processes by exploring the use of specific controlled atmospheres, including vacuum and argon, to reduce expenses while ensuring the process is efficient.

Keywords: Metal Jetting, Additive Manufacturing, Sustainable Materials, Recycled Metal Powders, Debinding, Sintering.

Ternary NiTi-Nb eutectic alloys by laser powder bed fusion (LPBF): In situ phase formation by design of energy density

Prof. Farzad Khodabakhshi, Belgium

Oral Presentation (20')

Abstract

Alloying of niobium into the pseudoelastic NiTi alloy upon laser powder bed fusion (LPBF) of a eutectic stoichiometry was investigated under the impact of various volumetric energy densities. Specifically, the research examined the effects of volumetric energy density (VED) ranging from 56 to 89 J/mm³ on the potential in situ phase formation. The mechanisms behind the formation of these in situ phases, influenced by the applied VED during processing, were analyzed and compared with the results from micro-mechanical testing. To achieve this, nanoindentation testing was performed, and the resulting hardness distribution was mapped and correlated with microscopy findings related to the possible phase formations.

Paper 1020 1 **PBF-LB of a non-weldable Ni-base superalloy CM247LC: from conventional to non-conventional parameters**
Prof. Eduard Hryha, Sweden
Keynote (Oral Presentation 40')

Abstract Additive manufacturing (AM) of the non-weldable γ' -strengthened Ni-base superalloy CM247LC via powder bed fusion – laser beam (PBF-LB) faces significant challenges due to its susceptibility to both solidification cracking during fabrication and strain age cracking during post-processing heat treatments. Solidification cracking arises from thermal stresses and interdendritic strain accumulation in the final stages of melt pool solidification, while strain age cracking (SAC) is driven by residual stresses from PBF-LB and γ' precipitation during heat treatment. This study integrates multi-faceted approaches to mitigate these issues, combining process parameter optimization, novel scan strategies and microstructure control.

Initial work focused on optimizing laser parameters (power, speed, hatch spacing) to minimize porosity and cracking. Low line energy density (<0.2 J/mm) and strong melt pool overlap (50–80%) reduced solidification cracking by promoting shallower melt pools and minimizing thermal gradients. Residual stress analysis via X-ray diffraction revealed that volumetric energy density (VED) directly correlates with residual stress magnitude, emphasizing the need for lower VED parameters to alleviate SAC. This is however not a possible solution as processing with lower VEDs lead to higher fraction of lack of fusion indicating the need to find other ways to solve the SAC problem. SAC Electron Backscatter Diffraction (EBSD) identified $<100>$ -textured columnar grains in crack-resistant samples, suggesting grain orientation reduces high-angle grain boundaries that are susceptible to solidification cracking.

Building on these findings, novel scan strategies were explored to address residual stress limitations. Reducing laser stripe width from 5 mm to 0.2 mm lowered the crack density by promoting $<100>$ texture and reducing residual stresses by 30%. A demonstrator component manufactured with 0.2 mm stripes survived post-build heat treatment without strain age cracking, unlike components with conventional 5 mm stripe width. Additionally, other strategies such as in-situ remelting strategies showed promise in minimizing solidification cracking with some promise to mitigate SAC.

Ongoing work investigates the role of advanced scan strategies (e.g., laser beam shaping) to have better microstructure control to suppress both the forms of cracking. Results underscore that CM247LC's processability requires tailored approaches distinct from weldable alloys like IN718, with grain structure and texture playing pivotal roles in defect mitigation. These insights provide a framework for alloy and process designers to

Development of Sustainable Fe-based Composite Powders for Highly Wear-Resistant Coatings

Mrs. Agata Kulig, Germany

Oral Presentation (20')

Abstract

The automotive industry faces growing dependence on raw materials, which is caused by the rise of electromobility. In producing wear-resistant components and sheet metal forming tools, coating materials and processes are crucial for performance, sustainability, and lifespan.

This work focused on developing sustainable composite powders and innovative manufacturing processes for highly wear-resistant coatings. A novel Fe-based coating composition (Fe-Cr- X) was designed to reduce dependence on critical raw materials such as nickel, cobalt, and tungsten. A thermal arc atomization process was introduced, achieving an 80% efficiency for particles within the 40–150 µm range, without formation of hollow spheres, and lowering gas consumption by 15%. The microstructure and properties of the composites and the coatings will be presented.

Application of Twin Wire and Arc Additive Manufacturing (T-WAAM) process for manufacturing of Invar 36 by in-situ alloying

Mrs. Amaia Iturrioz Zabala, Spain

Oral Presentation (20')

Abstract

Metal Additive manufacturing (AM), where metallic materials are added to the parts layer by layer, has attracted high attention over the last years due to its design freedom ability and short lead times. Among the metal AM processes are the so-called Directed Energy Deposition (DED) technologies, where a focused thermal energy source is used (laser beam, electron beam or electric arc) to melt materials as they are deposited. This research work analysed the possibility of creating the Invar 36 alloy using the DED-arc metal AM process or better known as WAAM (wire and arc additive manufacturing), more specifically in its Twin mode using two metallic wires as raw materials. The T-WAAM process is characterized by the use of two fully synchronized and independent power sources. From these two power sources two metallic wires are fed into a single torch, by means of two separate wire feeders, through two fully insulated contact tips. A single shielding gas nozzle is employed, and the two arcs generate a single weld pool. The possibility of isolating the power sources and at the same time their operation is synchronized increases the possibility of combining different synergistic curves, such as Cold Metal Transfer (CMT) mode, pulsed or other innovative synergistic curves. In this way, the deposition rate or welding speed can be doubled. In this work, the Twin-WAAM technology is used to obtain the Invar 36 alloy by mixing a steel and a Ni-Fe wires with in-situ alloying approach. Invar36 is an interesting material for skins in molds but its cost is high. With this manufacturing method it would be possible to manufacture steel parts with Invar 36 in desired areas by introducing tailored compositions in the manufacturing process. The microstructure and the mechanical properties of the in-situ manufactured Invar 36 alloy by T-WAAM has been investigated. The obtained results are compared with the ones obtained with commercial Invar 36 alloy wire manufactured by WAAM. The results revealed that there is a difference of 4-6% of the strength between the commercial Invar36 and the obtained T-WAAM alloy, been lower in the obtained alloy. The opposite is true for elongation, which is higher for the obtained alloy (10-15% higher than the commercial Invar 36).

Niobium alloy C-103 for high-performance space applications – first results with using Cold Spray Additive Manufacturing – CSAM

Mr. Markus Brotsack, Germany

Oral Presentation (20')

Abstract

Space propulsion applications require lightweight materials that can withstand high stresses at elevated temperatures. Niobium has a very low density compared to other refractory metals but high strength, i.e. a high strength-to-weight ratio. The material also shows high thermal conductivity and a low ductile-to-brittle transition temperature. This low transition temperature is advantageous for space applications because it shows excellent resistance to high-frequency vibrations at cryogenic temperatures. Furthermore, C-103, a niobium, hafnium, and titanium alloys used for space propulsion applications, have a high melting point at around 2.350°C and show strong stability at elevated temperatures, too.

Currently, many investigations around C-103 material for in-space propulsion systems for satellites are happening in the space industry. This work shows the feasibility of Cold Spray Additive Manufacturing (CSAM) technology to produce a C-103 test part as a first step for future nozzle designs for different space applications. It is essential for the application to have as thin walls as possible to get down the take-off weight of the satellites. A tube of around 135 mm in length and 2 mm in wall thickness has been manufactured using CSAM. Secondly it will be presented a first Cold Sprayed nozzle with a length of about 600 mm and a diameter of about 500 mm and a wall thickness of around 1,5 mm only. The manufacturing process will be presented in detail, in pictures and videos. The work also shows the integration of Cold Spray equipment in a highly automated manufacturing environment, including automated mandrel manufacturing and machining capabilities.

It has been proven that C-103 can be sprayed with high deposition efficiency using cold spray technology. Deposition efficiency of around 92% with a 4 kg/h deposition rate was observed. Both properties make cold spray cost-effective for manufacturing in-space propulsion nozzles with C-103 niobium alloy. Furthermore, microstructural and mechanical properties of cold-sprayed C-103 have also been investigated.

Influence of PBF-LB and in-situ alloying on the microstructural features of refractory-based complex concentrated alloys

Dr. Petra Spoerk-Erdely, Austria

Highlight (Oral Presentation 20')

Abstract

Refractory-based complex-concentrated alloys (R-CCAs), i.e. metallic materials relying on a multi-principal element alloying approach, are attracting increasing interest because of their promising high-temperature properties. Yet, these alloys are often difficult to manufacture, especially when they consist of elements with widely diverging melting points or miscibility gaps. Conventional casting has been linked, for instance, to coarse-grained microstructures and severe segregation phenomena, necessitating costly long-term homogenization heat treatments at high temperatures. In this work, we explore the potential of the metal additive manufacturing technique of Powder Bed Fusion – Laser Beam (PBF-LB) for the fabrication of fine-grained and homogeneous R-CCAs. In addition, by using a pre-mixed blend of elemental powders as feedstock material, we adopt the approach of in-situ alloying. Forming the respective alloy directly in the powder bed of the 3D printer, we make use of the small melt pools and high localized heat input inherent to the PBF-LB method, to create the best possible homogeneity in combination with a great freedom in selecting the respective alloy's chemical composition for further alloy development.

The present work focuses on the R-CCA alloying system Ti-Al0.1-Cr-Mo-Nb0.5 (in at.%). Different printing parameter sets were tested, varying, e.g., the laser power, scan velocity, hatch distance, layer thickness, and number of scan repetitions. Based on microstructural analyses including light-optical as well as scanning electron microscopy, energy-dispersive X-ray spectroscopy, and X-ray diffraction, these parameters were correlated with the microstructural features of the printed parts. By assessing, in particular, the porosity, homogeneity, proximity to the desired chemical composition, and, if applicable, fraction of unmolten particles, several promising printing strategies could be derived. Eventually, the microstructures of the as-built parts were optimized further in selected short-term heat treatments. In this regard, in-situ high-energy X-ray diffraction experiments in a dilatometer setup at a synchrotron radiation source offered valuable insights into the microstructural stability and characteristic features of the prevalent phases. On the example of the alloying system Ti-Al0.1-Cr-Mo-Nb0.5, this presentation will critically discuss the advantages and pitfalls of employing PBF-LB and in-situ alloying in the development of R-CCAs.

Optimization of Binder Infiltration Mechanisms in Metal Jetting for High-Quality Stainless-Steel Components

Mr. Hari Narayanan Karuppaiya, Spain

Oral Presentation (20')

Abstract

Industries today increasingly demand advanced manufacturing techniques that revolutionize production while adhering to clean, energy-efficient practices. Metal Additive Manufacturing (MAM) has emerged as a transformative solution, enabling the creation of complex, customized products with improved efficiency, reduced material waste, and lower production costs. Among various MAM techniques, Binder Jetting, or Metal Jet technology, stands out for its scalability and production efficiency [1]. This powder-based method selectively applies the binder layer by layer to the powder to create intricate parts in the green state, which are subsequently post-processed through sintering to achieve the final product [2].

Binder Jetting addresses many scalability challenges in additive manufacturing, making it a viable option for large-scale production. However, achieving 100% density remains a key challenge to ensure the production of high-quality components. Stainless steels like SS316L and 17-4 PH, renowned for their exceptional mechanical properties, corrosion resistance, and strength, are widely used across industries such as aerospace, automotive, and medical devices. Despite their advantages, when processed via Binder Jetting, these materials often encounter inconsistencies in print quality [3]. Variations in green density, binder saturation, infiltration efficiency, and surface finish can lead to defects in the final part. These inconsistencies can lead to defects, affecting both the mechanical properties and the final part quality.

This study experimentally investigates binder infiltration mechanisms in metal powders and the binder under varying thermal conditions using advanced techniques such as confocal microscopy. The fluorescence behavior of binders will be utilized to visualize and analyze infiltration patterns, layer adhesion, and binder distribution. The temperature-dependent viscosity of the binder will be examined to understand its impact on infiltration efficiency. The study will also explore how these factors influence part density and overall print quality. The findings aim to provide a deeper understanding of binder-powder interactions and their effect on the quality of green parts, facilitating the optimization of process parameters to achieve consistent, high-quality components in large-scale Binder Jetting production.

Additive Manufacturing of CuCrZr Alloys for Nuclear Fusion Applications

Mr. Hasan Huseyin Hayat, United Kingdom

Oral Presentation (20')

Abstract

CuCrZr alloy has significant potential for a wide range of fields, such as the nuclear and aerospace industries, due to its outstanding thermal and mechanical properties. Due to the high infrared laser reflectivity and high thermal conductivity of Cu, it remains a challenge to produce CuCrZr alloy using the Laser Powder Bed Fusion (LPBF) technique. In this study, CuCrZr alloy was produced using the LPBF method, and the optimum printing parameters were obtained. Heat treatments were applied to improve the strength and electrical conductivity of the additive-manufactured CuCrZr samples, and the mechanical, thermal, and electrical properties of the samples were examined. The results are presented by comparison for both as-built CuCrZr alloy and heat-treated CuCrZr alloy.

Grain growth and mechanical behaviour of a solid-state additively manufactured Mg-4Y-3RE alloy

Dr. Dikai Guan, United Kingdom

Oral Presentation (20')

Abstract

Ultrafine-grained (UFG) materials exhibit high strengths due to grain boundary strengthening, but grains can grow rapidly if post heat treatment is required, making it challenging to achieve grain boundary and precipitation strengthening simultaneously. Grain growth stagnation at 525 °C (0.87 T_m, melting point) was observed in a Mg-4Y-3RE alloy fabricated by additive friction stir deposition (AFSD), a novel solid-state additive manufacturing technology. The AFSD processing produced a bimodal grain structure with UFG grains and coarse grains (around 10 microns). After solid solution treatment (SST) at 525 °C for 72 h, no noticeable grain growth occurred. The observed grain growth stagnation is attributed to Zener pinning by these thermally stable nanoparticles. Moreover, the mixture of coarse and UFG grains efficiently improved the ductility of the alloys compared to the corresponding casting and extruded samples. These new findings offer a novel approach to designing Mg alloys with exceptional thermal stability for high-temperature applications.

Application of Thermo-Calc's Additive Manufacturing Module for LPBF of Steel, Aluminium, and High-Entropy Alloys

Dr. Andre Schneider, Sweden

Oral Presentation (20')

Abstract

Thermo-Calc has developed new models to predict thermophysical material properties with unprecedented accuracy, using the CALPHAD method. While the treatment of heat and fluid flow is state of the art in current FEM models, material properties are treated in a highly simplified manner. This gives us a unique possibility to address the solidification problem in AM, with the focus on a unified treatment of both process parameters and alloy dependent thermophysical properties. The first module for Additive Manufacturing, using this approach, was implemented in the Thermo-Calc 2023b release. The latest developments aim at creating a fully predictive module that requires minimal user input. This module automatically generates physics-based properties, including absorptivity and captures the transition from conduction to keyhole modes, including the impact of fluid flow.

This talk will give insight into these developments and their applications to process and materials optimization. Examples of the AM module applied to laser powder bed fusion (LPBF) processing of steel, aluminium, and high-entropy alloys are shown. Recent and ongoing developments, such as key-holing prediction and process maps, are demonstrated, along with simulations of precipitation reactions during heat-treatment of as-built structures using TC-Prisma and DICTRA.

Effect of solidification mode on the resulting microstructure of 304L steel produced with L-PBF

Prof. Efthymios Polatidis, Greece

Oral Presentation (20')

Abstract

Laser Powder Bed Fusion (L-PBF) is not only renowned for its ability to produce intricate shapes and complex geometries, but it is also a powerful tool for tailoring and optimizing the microstructure of metallic parts. By precisely adjusting the process parameters, L-PBF enables fine-tuning of crystallographic textures, grain orientations and microstructural features, offering unprecedented control over material properties [1,2].

Austenitic stainless steels, such as the widely used 304L and 316L grades, can benefit significantly from this capability, as these alloys exhibit distinct deformation mechanisms, i.e., the Transformation Induced Plasticity (TRIP) and Twinning Induced Plasticity (TWIP), which are influenced by the crystallographic texture. As such, specific orientations can either promote or suppress these effects under different loading conditions, making site-specific microstructural tailoring a promising approach for enhancing mechanical performance [3].

This study investigates how the choice of atomization gas, i.e., nitrogen (N) versus argon (Ar), affects the microstructure of 304L stainless steel processed via L-PBF. Despite using identical processing parameters, the two powders exhibit significantly different microstructures due to variations in their solidification behaviors. N-atomized powder predominantly forms strongly textured, columnar grains with pronounced elemental segregation, following a primary γ -austenite with secondary ferrite solidification mode. In contrast, Ar-atomized powder produces less textured, equiaxed grains with a more uniform composition, adhering to a primary ferrite with secondary γ -austenite solidification mode.

In this study we employ operando synchrotron X-ray diffraction during L-PBF processing, which provides valuable insights into the critical role of solidification modes in shaping the final microstructure. The results are coupled with detailed electron microscopy investigations and thermodynamic calculations. The findings of this study underscore the importance of precise control over solidification conditions to achieve the desired microstructural characteristics in austenitic stainless steels.

Powder Reuse in Additive Manufacturing of Titanium Alloy: Effects on Corrosion Performance

Prof. Endzhe Matykina, Spain

Oral Presentation (20')

Abstract

Additive manufacturing (AM) of metal components is a transformative technology that currently shows the fastest growth rate than any other manufacturing industry. Compared to traditional manufacturing methods, it enables production of near-net shapes and complex geometries, often unachievable by any other way, as well as a significant reduction in material waste. The latter is particularly relevant to titanium components, where post-machining can lead up to 80% of material removed. Laser powder bed fusion (LPBF) is the most common AM technique for Ti. Metal powders are produced by costly and high energy-consuming atomization processes. Many manufacturers and end-users prefer to rely only on virgin powder to be able to avoid powder contamination or degradation and guaranty the adequate performance of the components. Nevertheless, there is also a considerable drive to reuse powders during AM as that presents economic and environmental benefits. There are several powder reuse strategies, including single batch and collective aging methods, top-up method and powder refreshing method. The procedure common to them all is sieving the non-consolidated powder between the builds to remove the agglomerates from previous runs, using the rest for the next run. When the sieved powder falls out of specifications, it is discarded. The reuse strategies are not standardized, i.e. the number of reuse cycles is not strictly limited and each manufacturer uses their own trial-and-error based know-how. It has been established that oxygen pick-up and other contaminant levels in powder increase and the powder density and flowability decrease with reusing cycles, all of that leading to increased porosity in the printed parts. However, manufacturers often do not know exactly to what extent powder reuse deteriorates the performance of the components.

The present work investigates corrosion performance of AM Ti6Al4V as a function of the number of powder reuse cycles. Specimens corresponding to cycle 0 (virgin powder) and 20 are characterized by common metallographic techniques, X-ray diffraction, SEM-EDS and optical profilometry pre- and post-corrosion. Corrosion resistance is evaluated using electrochemical impedance spectroscopy (EIS) and cyclic potentiodynamic polarization (PDP) tests. Two different corrosive media relevant to airspace and health applications were studied. Harrison's solution at 25°C and Hanks' solution at 37°C represented acid rain and physiological conditions, respectively. The effect of the powder reuse cycles on localized corrosion of Ti6Al4V is discussed.

Enhancing the Processability and Mechanical Properties of 2618 Al Alloy via Powder Functionalization for Additive Manufacturing

Mrs. Giorgia Lupi, Italy

Oral Presentation (20')

Abstract

The application of Additive Manufacturing (AM) is rapidly expanding, enabling the creation of complex geometries unattainable with traditional technologies. Among AM methods, Laser Powder Bed Fusion (LPBF) is gaining prominence across various industries. However, existing alloys were designed for conventional manufacturing, presenting challenges in AM due to issues like solidification cracking and high-laser reflectivity. For instance, high-strength Al alloys like 2618 are prone to hot-cracking. One solution is modifying the chemical composition of the powders by introducing suitable alloying elements. The addition of Ti and B to form TiB_2 particles has proven to be an effective grain refinement strategy, reducing hot-cracking susceptibility. TiB_2 particles not only improve the processability of the alloy and enhance its strength, but they also significantly increase the elastic modulus of the material when added in considerable quantities. However, producing composite powders with a high ceramic fraction through gas atomization is challenging due to the reactivity of B with Ti, which causes early boride formation, nozzle clogging, and uneven particle distribution. An alternative approach involves modifying only the surface properties of the powder through powder functionalization. In this work, we propose a mixed powder configuration where the 2618 Al powder is pre-alloyed with Ti and B to promote the in-situ formation of TiB_2 particles. This approach is combined with a high-energy mechanical mixing method to functionalize the surface of the pre-alloyed powder with TiB_2 particles. The goal is to fabricate a Metal Matrix Composite (MMC) containing 7 wt% TiB_2 , with enhanced LPBF processability. This high ceramic content is expected to increase the material's elastic modulus and improve its overall mechanical strength. The coated powder was processed by LPBF to produce bulk samples. These samples were heat-treated according to different schedules to investigate their effect on the microstructure and tensile properties of the MMC material. The microstructure was analysed using SEM, EBSD, and TEM to evaluate TiB_2 particle formation and distribution. The results showed that high-density printed composites were achieved, exhibiting homogeneous dispersion of TiB_2 and an absence of cracks. The borides effectively promoted heterogeneous nucleation of the α -Al phase, suppressing epitaxial growth and leading to a fine, equiaxed microstructure. Hardness and tensile tests were performed to assess the impact of TiB_2 formation and heat treatments on the alloy's strength and ductility. Results show significant enhancements in yield and ultimate strengths post-heat treatments, along with an increase in Young's modulus, despite a reduction in ductility.

Development and Additive Manufacturing of an Al-Ni-Mn Alloy using Laser Beam Powder Bed Fusion (LB-PBF)

Mr. Talal T. Alshammari, United Kingdom

Oral Presentation (20')

Abstract

Additive manufacturing through Laser Powder Bed Fusion (LPBF) has revolutionised the production of complex geometries, particularly in lightweight materials such as Al-alloys. However, balancing mechanical performance and thermal stability in Al-alloys remains a challenge. In this study, a novel Al-Ni-Mn alloy system is designed to enhance the properties of Al-Ni alloys by incorporating Mn, a key element known for its high solid solution strengthening, utilising the high cooling rate in LPBF causes rapid solidification in improving the mechanical performance. Building upon previous work demonstrating significant improvements in Al-Ni alloys, this research explores the effects of varying Mn content to optimise the alloy's mechanical properties and thermal stability. The alloy design process integrates thermodynamic analyses, including Phase and Schiel diagram assessments, to predict and control phase stability and composition. The microstructural evolution of the alloys is characterised using advanced techniques such as SEM, EBSD, XRD, DSC, and TEM. Mechanical properties are evaluated through tensile and hardness testing, highlighting the role of Mn content in increasing the solid solution and improving material strength. Furthermore, the thermal stability of the alloys is assessed, focusing on their resistance to degradation at elevated temperatures. This work highlights the potential of Al-Ni-Mn alloys as a sustainable solution for LPBF applications, promoting efficient material usage and reduced environmental impact. It will contribute to developing next-generation Al-alloys with enhanced performance characteristics tailored for LPBF.

Development and processing of the Al 5356 aluminium alloy by additive manufacturing using wire laser-based DED technology (DED-LB/M)

Dr. Julia Ureña, Spain

Oral Presentation (20')

Abstract

Additive manufacturing (AM) is widely recognized as an innovative and revolutionary technology. Metal AM enables the manufacturing of parts with unique shapes and exceptional mechanical properties. The AM process is complex with numerous variants like temperature gradients, high cooling rates, which allows process parameter development for processing materials with tailored properties. Microstructure and mechanical properties of metal AM materials differ significantly from those produced by conventional methods.

Aluminium alloys are difficult materials to be processed by additive manufacturing due to its high energy reflectivity. Only few research studies about aluminium processing throughout DED-LB/M have been found.

In this work, the feasibility of processing the aluminium alloy Al 5356 (AlMg5Cr) by Wire Laser-based Directed Energy Deposition (DED-LB/M) technology has been carried out as the first stage of developing a new metal-polymer multimaterial family within the European funded "MULTHEM Project (Multimaterial additive manufacturing for lightweight and thermal management)" for applications mainly related to lightweight and heat dissipation.

In this process Al5356 welding wire has been used as feedstock. This approach offers a significant competitive advantage by employing an affordable material and reducing material waste compared to traditional machining methods.

The process window has been investigated to reach dense samples with a material densification up to 99.84 %. Microstructural analysis revealed a very fine microstructure composed of equiaxed grains between 3-5 μm and small precipitates homogeneously distributed. Microhardness measurements were performed in horizontal and vertical directions to study the anisotropy of the aluminium alloy developed. A microhardness measurement of 99 HV0.2 was obtained in the horizontal direction while a microhardness profile from 70 HV0.2 to 82 HV0.2 was measured from the surface to the bottom in a sample of 20 mm height. Higher microhardness values have been obtained compared to values from traditional joining methods (70-80 HV0.2) or WAAM studies (60-70 HV0.2). Horizontal and vertical thin walls were also processed to machine cylindrical tensile samples according to ISO 6892 standard. Tensile strength values of 275 MPa and 262 MPa in the horizontal and vertical directions were obtained, respectively. These promising properties could lead to an innovative method for processing Al5356 alloy by wire DED-LB/M. Different geometries and thermal properties are also under evaluation.

Operando X-ray Investigation of Cracking in Copper-Steel Multi-materials

Mr. Andaç Özsoy, Switzerland

Oral Presentation (20')

Abstract

Additive manufacturing (AM) of multi-material alloy combinations is attractive for many industries that require a combination of material properties such as thermal conductivity, corrosion resistance and mechanical strength. However, the printability of these combinations can be hindered by macroscopic defects such as cracks. One such combination is copper-steel multi-materials that greatly suffer from cracking at the interface when processed using fusion-based additive manufacturing methods. Therefore, understanding the underlying mechanisms of cracking constitutes the first step towards obtaining sound copper-steel multi-material parts.

This study aims to reveal the mechanisms of cracking in copper-steel alloy combinations manufactured via fusion-based methods. For this aim, operando X-ray diffraction and imaging, as well as computed tomography techniques were employed during laser powder-bed fusion (LPBF) of CuCrZr and 316L stainless steel to gain a fundamental understanding on the events taking place at the onset of cracking. The miniature LPBF equipment developed at Paul Scherrer Institut (PSI), i.e. miniSLM, was employed in MS and P21.2 diffraction beamlines at the Swiss Light Source (SLS) in Switzerland and PETRA III in Germany, respectively. Moreover, ID19 beamline at the European Synchrotron Radiation Facility (ESRF) was utilized for operando X-ray radiography and computed tomography characterization. Operando X-ray experiments coupled with auxiliary characterization methods have shown that two main mechanisms are responsible for cracking at the interface between copper and steel. First, liquid-liquid phase separation between CuCrZr and 316L was observed upon melting, which led to the formation of species of vastly different freezing ranges and subsequently solidification cracking. Secondly, it was observed in operando X-ray radiography that cracking can occur either further away from the melt pools or right at the heat-affected zone next to the adjacent tracks. Scanning electron microscopy (SEM) characterization revealed that the second type of cracking stems from the copper segregation at the steel grain boundaries during solidification.

In the light of these findings, a new method for mitigating cracking has been proposed and experimented as proof-of-concept. The results have shown interfaces with greatly reduced cracking, although they were not completely eliminated. Nevertheless, the results provide a deeper understanding regarding the processability of copper-steel multi-materials using fusion-based methods, and hold promise for further optimization of multi-material components produced by fusion-based processes.

Paper 296 1 **High-Throughput SEM for Microstructural Analysis in Additive Manufacturing**

Prof. Joerg Jinschek, Denmark

Keynote (Oral Presentation 40')

Abstract

High-throughput microstructural characterization is critical for understanding and optimizing the complex, inhomogeneous microstructures formed during metal additive manufacturing (AM) processes such as Plasma Arc Additive Manufacturing (PLAAM). Rapid thermal cycles in these processes leads to microstructural heterogeneities, including defects (e.g., lack of fusion, porosity, cracks) and complex grain structures, which significantly impact material performance.

This study focuses on optimizing data acquisition speed in scanning electron microscopy (SEM) while resolving critical microstructural details. By optimizing the selection of critical imaging parameters, such as dwell time and pixel size, acquisition times are significantly reduced while maintaining a controlled error rate. This approach enables large-area imaging comparable to optical microscopy but with the significantly higher resolution of SEM.

A Python-based framework automates defect detection in secondary electron (SE) images, extracting key metrics such as defect area, roundness, and orientation. Meanwhile, backscattered electron (BSE) imaging leverages channeling contrast to analyze grain structures. A deep-learning model, trained on electron backscatter diffraction (EBSD)-derived labels, facilitates grain segmentation and detailed assessments of grain area and aspect ratio. This method eliminates the need for chemical etching, preserving the sample surface for further analysis while providing comprehensive insights into grain structures.

The proposed high-throughput SEM framework integrates automated defect detection and grain segmentation to deliver comprehensive microstructural insights. By balancing data acquisition speed and accuracy, this scalable approach improves our understanding of microstructural evolution in additive manufacturing by uncovering the underlying relationship between processing parameters and resulting microstructure and properties.

Paper 860 2 **Optimized Electrodeposition of Multi-Principal Element Alloys through Automation by Material Acceleration Platform**
Dr. Özlem Özcan Sandikcioglu, Germany
Highlight (Oral Presentation 20')

Abstract

Multi-Principal Element Alloys (MPEAs) are garnering significant academic and industrial interest due to their exceptional mechanical and anti-corrosion properties, making them promising materials for engineering applications. Characterized by a disordered atomic distribution within their crystal lattice, MPEAs offer high catalytic efficiency, excellent thermal stability, and sluggish diffusion kinetics, depending on their composition and crystal structure. Notably, several MPEAs, such as the CrCoNi alloy, exhibit excellent corrosion resistance and potential for electrocatalytic applications.

This project aims to develop an automated optimization process for the electrodeposition of first-row ternary MPEAs, investigating their electrochemical properties and testing their application as electrodes in electrocatalysis within a lab-automation loop. While binary and ternary alloy electrodeposition has been achieved, the electroplating of MPEA films with desired bulk properties remains in its infancy. The vast compositional space of MPEAs and the development of respective electrodeposition methods add to the complexity of this topic. Achieving MPEA films with inherent bulk alloy properties requires precise bath compositions and the selection of appropriate additives.

Initially, the development and selection of bath components is based on existing literature to identify bath compositions that facilitate the deposition of the desired MPEA film. However, the challenges of system optimization reported in the literature for MPEA electrodeposition present an opportunity to utilize an automated lab approach. Consequently, initial bath compositions are refined based on the performance of the MPEA film in terms of composition, electrochemical properties, and surface-specific parameters.

The characterization of the deposited films is both automated and manual. Key electrochemical characterization methods include Electrochemical Impedance Spectroscopy (EIS), linear resistance polarization, and potentiodynamic polarization. Scanning Electron Microscopy (SEM) is primarily used for surface morphology analysis, while in-situ Atomic Force Microscopy (AFM) is conducted on optimized electrodeposition systems to investigate deposition mechanisms. Film compositions are determined using Glow Discharge Optical Emission Spectroscopy (GDOES). Additionally, PM-IRRAS and Raman spectroscopy data on additive adsorption at the metal surface support the automation process database. The results of this study will be presented herein.

Paper 984 1 **Phase transformations during post-processing of metastable β titanium alloys fabricated through additive manufacturing**

Mr. Peter Ibrahim, United Kingdom

Keynote (Oral Presentation 40')

Abstract

The microstructural evolution and phase transformations in the metastable β titanium alloys, widely used in aerospace applications such as aircraft frames and landing gear, were investigated in the context of wire arc additive manufacturing (WAAM). This alloy offers exceptional strength and corrosion resistance with an elastic modulus of approximately 110 GPa, making it a promising candidate for advanced manufacturing techniques. Due to the unique microstructural characteristics produced by WAAM, including large columnar β grains and the absence of the nodular and acicular α -phase typically observed in forged alloys, mechanical properties may deviate from standard values to lower strength values of approximately 800 MPa and an elastic modulus of ~ 80 GPa.

This study analysed the as-deposited WAAM microstructure to characterise grain size, morphology, and phase composition. Also, post processing heat treatments were optimised to bring the mechanical properties of the alloys closer to the nominal values. The β microstructure of WAAM-ed parts was found to be clean and free of significant element segregation, allowing shortening of the solution treatment stage to minimise unnecessary grain growth and further reductions in alloy strength. Aging treatments promoted the precipitation of fine α -needles within the β matrix, significantly enhancing mechanical strength. TEM analysis confirmed the careful selection of the aging temperature avoided the formation of the isothermal ω phase during aging, which can deteriorate the deformation range of the alloy. The optimised Heat treatment parameters controlled α -phase growth in β grains while limiting the formation of α -phase at grain boundaries, which has a detrimental effect on the ductility of the alloy. The heat-treated samples achieved a broad range of tensile strengths comparable to the forged alloy while maintaining an acceptable strain range of up to 5%, providing flexibility for tailored mechanical performance in specific applications.

The findings highlight that the introduction of optimised heat treatments can achieve near-forged mechanical properties in WAAM-ed metastable β titanium alloys with reduced energy and time investment. This work underscores the potential of WAAM for manufacturing aerospace-grade components while minimising the need for extensive machining and multi-step thermal processes.

Paper 1729 2 **Laser metal deposition additive manufacturing combined with high-flux in situ X-Ray analysis for high-throughput materials characterization**
Prof. Thomas Niendorf, Germany
Highlight (Oral Presentation 20')

Abstract

Additive manufacturing (AM) is characterized by the evolution of unique microstructures upon processing. Due to the distinct thermal history imposed by rapid solidification and intrinsic heat treatment, i.e., layer-wise re-heating of already solidified volumes, microstructures of well-established alloys such as Ni-base superalloys, austenitic steels or Ti-base multi-phase alloys differ significantly from their cast and forged counterparts. In several alloys, properties of AM-processed conditions are characterized by superior properties, however, numerous alloys suffer from process induced cracking, residual stress and presence of unwanted phases. To overcome prevailing challenges, novel alloys being adapted to the specific boundary conditions of AM have to be developed. To be able to fully exploit these boundary conditions, in situ and operando techniques are the key toward in-depth understanding, e.g. in research studies conducted at synchrotron facilities. Here, radiography and diffraction allow to not only study melt pool dynamics but also phase changes occurring during any specific process step. Unfortunately, beam time at such research facilities is very limited and, thus, the investigation of entire material libraries in one campaign is hardly feasible. As a consequence, availability of lab-based equipment allowing for such kind of studies is urgently required. The present work focuses on the design, realization and implementation of a novel system being installed at University of Kassel. Laser metal deposition, combined with in situ X-Ray analysis using a high-flux source will allow for tackling prevailing gaps in this field. Initial experiments are presented and prospects as well as limitations are discussed.

Paper 1772 3

Combined high-throughput computational and experimental screening of aluminum alloys suitable for additive manufacturing from scraps

Dr. Katrin Bugelnig, Germany

Highlight (Oral Presentation 20')

Abstract

To meet societal goals like climate neutrality by 2050 and a circular economy, material discovery must be faster and more flexible, especially as raw material costs and supply chain issues increase. Advanced technologies like computational screening, 3D/4D characterization, and machine learning enable rapid responses to these challenges. A new Al-based alloy suitable for additive manufacturing (AM) derived from scrap metal mixtures was developed using high-throughput alloy screening paired with synchrotron radiation based experimental validation. The new alloy is intended for aerospace applications and has to meet requirements such as low sensitivity to hot-cracking, minimal solidification interval, appropriate strength and elongation, etc. In high-throughput computational screening, up to 10k alloy compositions were generated by mixing the scrap alloys at different ratios. The CALPHAD method was used for equilibrium and non-equilibrium simulations to assess key parameters, including phases, solidification intervals, and mechanical properties like yield strength and hot-cracking sensitivity. A random forest model predicted properties from simulations and literature, while a multi-objective evolutionary algorithm filtered alloys with target characteristics. Uncertainty calculations addressed compositional variations in scrap, ensuring robust designs. For experimental validation, selected alloy compositions were synthesised by conventional casting, remelted and subjected to laser line scan testing to investigate the effect of different solidification rates on the material. Satic synchrotron tomography scans were taken to analyse the microstructure in 3D. Finally, a potential composition suitable for additive manufacturing was selected for powder production and in-situ laser powder bed fusion experiments were performed during microtomography to confirm the processability of the alloy.

High-Throughput Materials Informatics Integrating Ab Initio, Machine Learning, and CALPHAD Data

Dr. Philipp Keuter, Germany

Oral Presentation (20')

Abstract

Traditional CALPHAD modelling (CALculation of PHase Diagrams) has been proven effective in accurately predicting phase stabilities and material properties as functions of temperature, pressure and composition. However, this approach has notable limitations, including the significant time required to develop comprehensive databases and a scarcity of available relevant experimental data.

To address this challenge, we present a Machine Learning (ML)-enhanced, high-throughput approach that leverages the aiMP and aiOQ databases to bridge the gap between first-principles calculations (DFT) and CALPHAD-based metallic alloy design. The aiMP and aiOQ databases integrate ML predictions of entropy and heat capacity, derived from large-scale datasets of thousands of compounds, offering a significant advantage over typical models trained on more limited datasets of only hundreds of compounds. These databases facilitate three key applications that align with high-throughput materials discovery:

1. Data Cleaning & Reliability assessment: Anomaly detection in curated databases, as well as inconsistencies within aiMP itself, ensuring more robust predictions for CALPHAD modeling.
2. High-Throughput Alloy Screening: Enabling the rapid evaluation of a wide range of material compositions to identify promising candidates for further experimental and computational investigation.
3. Phase Diagram Estimation and Optimization: Providing an efficient starting point for phase diagram development through traditional CALPHAD optimization approaches.

While curated databases continue to hold an advantage in terms of accuracy and reliability for specific applications, aiMP and aiOQ represent a transformative approach to materials data management. These databases bridge the gap between DFT 0 K data and the need for 298 K data for CALPHAD modelling, while maintaining a relatively small error margin, which is likely influenced primarily by the functional used in DFT calculations, the machine learning models, and errors in experimental values. By supporting highly automated workflows and encompassing a far broader range of materials than is feasible in manually curated databases, aiMP opens new possibilities for large-scale materials discovery and thermodynamic analysis.

To illustrate the practical impact of this approach, we demonstrate the combined application of curated CALPHAD databases and aiMP in the high-throughput design of a novel Fe-based hardfacing alloy.

Combinatorial Screening of Magnesium-Scandium Thin Film Alloys

Dr. Hüseyin Zengin, Austria

Oral Presentation (20')

Abstract

Mg-Sc thin film library was produced by thermal evaporation technique focusing a compositional spread of Sc up to 20 at.%. Microstructural investigations were carried out by scanning electron microscopy (SEM), X-ray diffraction (XRD) and Atomic Force Microscopy (AFM) analyses and the results demonstrated that microstructures primarily consisted of hexagonal facets corresponding to (0002) basal planes. The wall size of these facets showed a significant alteration with increasing Sc concentrations. Nanoindentation tests revealed that the hardness of Mg showed enhancements up to around 10 at.% of Sc, above which it decreased. Electrochemical characterizations were conducted through Scanning Droplet Cell Microscopy (SDCM) performed at specific Sc concentrations. Potentiodynamic polarization and Electrochemical Impedance Spectroscopy (EIS) tests showed that increasing Sc content up to specific composition shifted corrosion potential of Mg toward positive direction and improved the corrosion resistance of Mg. Sc led to the improvement on the protectiveness of the surface layer formed during their exposure to the electrolyte.

High-throughput hard X-ray reflectometry to investigate interfaces in materials

Dr. Samuel Tardif, France

Oral Presentation (20')

Abstract

The ability to probe interfaces in complex hetero-materials is paramount to fully understand and control the properties of the materials in question. Yet, accessing such interfaces is usually difficult as they represent only a small volume fraction of the samples of interest. Typically, phase fronts or grain boundaries have often been studied using direct-space imaging techniques, such as electron or X-ray microscopy or tomography. Even though spatial resolution has much improved over time, imaging at the ultimate resolution comes either at the cost of sample preparation (e.g. TEM lamellae, FIB milling) or complex measurements (e.g. ptychography), severely hindering high-throughput considerations.

In this presentation, we will discuss how recent developments on the GMT instrument at beamline BM32 at the European Synchrotron Radiation Facility have enabled the investigations of solid-solid or solid-liquid interfaces with a high resolution and at a high sample rate, using Hard X-ray reflectometry (HXRR). HXRR basically consists in measuring the reflection of X-rays on an interface between two materials of different refraction index (i.e. different electron density), as a function of the angle of incidence. The hard X-rays used (27 keV, 0.4592 Å) easily penetrate matter and can access buried interfaces, i.e. going beyond the limitations to surfaces. The measured HXRR signal probes of the electron density gradients across interfaces, with a resolution across the interface that is a fraction of the wavelength, effectively achieving sub-Angström resolution.

We will show how the principal requirement of reflectometry, namely well-defined interfaces, can actually be harnessed to investigate a broad range of topics, from model systems to evidence surface reactivity, to industrially relevant materials for advanced microelectronics substrates. The technical developments recently funded by the French DIADEM program now offer the opportunity to mount up to 650 samples on a single sample stage, enabling the high-throughput, fast screening of interfaces at the sub-atomic monolayer scale. Examples in a broad range of application fields, ranging from chemical separation of strategic elements to interfacial reactivity in electrolytes or direct bonding interfaces in semiconductors, will illustrate the new capabilities of the GMT instrument, open to the community.

Ion beam engineered earth-abundant electrocatalysts for Hydrogen generation

Dr. John Kennedy, New Zealand

Keynote (Oral Presentation 40')

Abstract

Electrocatalysts are at the heart of green hydrogen and ammonia production. Cost-competitive hydrogen requires GW-scale electrolyser production coupled with a significant drop in current manufacturing costs. Earth-abundant alternatives to platinum compatible with large-scale manufacturing is therefore highly desirable. On the other hand, realising electrochemical ammonia production demands highly selective catalysts for dinitrogen activation. In this work, we present a novel electrocatalyst fabrication approach based on ion implantation that can be optimised for both hydrogen evolution reaction (HER) and nitrogen reduction reaction (NRR).

Transition metal carbides (TMC) and nitrides (TMN) have attracted significant interest as cathode electrocatalysts for HER and NRR, respectively. The inability to manufacture TMCs as ultra-fine nanoparticles (to achieve high surface area) has hindered their catalytic potential for HER. Conventional routes require high synthesis temperatures leading to uncontrollable agglomeration, drastically reducing their active surface area. Using ion implantation, we demonstrate synthesis of tungsten and molybdenum carbides with high activity towards HER (TOF > 10 H₂ s⁻¹) [1-3]. With high-resolution TEM and X-ray photoelectron spectroscopy, we demonstrate synthesis of rare metastable phases of TMCs (e.g., γ' -MoC known for HER activity comparable to Pt) at dimensions as low as 2-3 nm. We show that by careful selection of synthesis parameters, the phase and size of the TMC particles can be controlled consequently affecting their HER activity.

Multiscale porous carbon supports for PEMFC electrocatalysts

Dr. Madeleine Han, France

Highlight (Oral Presentation 20')

Abstract

Proton Exchange Membrane Fuel Cells (PEMFC) are devices that produce electricity and heat from hydrogen and oxygen. They are foreseen to replace combustion engines in the future. However, they currently lack strong performances and durability. The cathode, one of the most critical component, is made of a nanostructured porous carbon layer decorated with electrocatalysts. Such mesoporous materials provide high specific surface area and encapsulates the electrocatalysts nanoparticles (Pt NPs), slowing down the degradation coming from NP coalescence, detachment or Ostwald ripening. However, upon electrochemical cycling, their small pores hamper the diffusion of species to the electroactive sites, thus limiting the performances of the PEMFC.

In our laboratory, we aim at developing graphene-based aerogels (GBA) which are carbons that are expected to show high durability since they display larger graphitic domains than regular porous activated carbon and could provide more stable anchoring sites for NPs. They are characterized by a hierarchical porosity, which should enable the fast diffusion of species through the larger macropores (up to 100 μm) to the interconnected micro and mesopores (1-100 nm) where the electrocatalysts NPs are located. We functionalize these carbons with Pt nanoparticles controlled in size and dispersion for the electrocatalysis of the oxygen reduction reaction. We then investigate the impact of the materials porosity on the electrochemical performances and durability of the PEMFC.

In this presentation, we will describe the different synthesis process specifically developed to design these materials with controlled surface chemistry and structure. The correlation between these materials porosity and electrochemical performances will then be discussed.

Fluorine-Free Materials for Sustainable-By-Design Electrolysis Cells

Dr. Andrea ROSATI, Italy

Oral Presentation (20')

Abstract

FASTCH2ANGE aims to pioneer a sustainable-by-design method for developing TRL4-compliant 100% PFAS-free proton exchange membrane-based electrolysis (PEMEL) cells. It will focus on developing four fluorine-free components: proton exchange membranes, catalyst-supporting layers, transport and gas diffusion layers, and new sealing components like gaskets and insulation plates.

FASTCH2ANGE will achieve this by designing, developing, and testing new PFAS-free PEMs at TRL4. These PEMs will be made using TEOS-based hybrid organic-inorganic ionomers, targeting an operating current density of 3.0 A/cm² at 1.8 V cell voltage, with a degradation rate under 5 μV/hr by 2030. Innovations in catalyst coating technologies will be explored, including an optimized ink deposition technique.

Additionally, fluoroelastomers-free liquid-gas diffusion layers will be prepared using a sol-gel process with silicon alkoxides to improve hydrophobicity and thermal stability.

FASTCH2ANGE also plans to develop PFAS-free sealing components using silicon-based sol-gel formulations and advanced materials like stainless steel, polyetheretherketone, and polyphenylene sulfide, employing high-performance coatings such as diamond-like carbon and ceramic.

Hence, an advanced testing platform utilizing multisingle cells proprietary technology will test the newly developed catalyst-coated membranes (CCMs), achieving a first-of-its-kind PFAS-free 5-cells stack with optimal components.

Harmonized European testing protocols will be used, and the cross-integrability with fuel cell technologies will be assessed in close synergy with SUSTAINCELL and EVERYWH2ERE projects.

FASTCH2ANGE new components will allow the replacement of 10-11% by weight of a new generation of electrolysis systems with harmless materials, that for the envisioned European 140 GW capacity would mean saving up to 10500 tons of PFAS crafted into PEMEL components by 2030.

The authors are presenting this work on behalf of the FASTCH2ANGE Consortium".

Direct Ink Writting of NiFe electrodes for the Oxygen Evolution Reaction

Mr. Pablo Lagar, Spain

Oral Presentation (20')

Abstract

Water splitting is a critical process for generating the so-called green hydrogen. Specifically this green hydrogen can be produced by water electrolysis as far as sustainable energy is used in the process. In order to accomplish the viability of this technology, affordable electrodes with improved performance are required for both the hydrogen and oxygen evolution reactions (HER and OER, respectively). Focusing in the OER in alkaline conditions, Ni and NiFe electrocatalysts have demonstrated competitive results. On the other hand, additive manufacturing (AM, aka 3D printing) is revolutionising the design and fabrication of electrocatalysts by enabling tailored architectures that improve efficiency and durability while reducing costs. In this work, we explore the possibility of enhancing the performance of Ni and NiFe electrodes in alkaline conditions for the OER by customising their geometries. Specifically, electrodes with different lattice patterns were designed and printed using a custom-made direct ink writing (DIW) 3D printer. The first challenge was thus to obtain Ni pastes that could be printed by DIW. This was successfully overcome using adequate F127 Pluronic®/water formulations that allowed high Ni powder loads (over 75 wt% solids content). The rheological properties of the resulting aqueous Ni pastes were optimal for DIW, showing shear-thinning and self-supportive behaviour. The equilibrium storage moduli (G'LVR) were high enough to assure a good printing resolution. The printed electrodes were thermally treated under inert atmosphere up to 900 °C to completely remove the paste carrier and sinter the Ni micro-particles. After post-processing, the different geometries of 3D printed Ni electrodes exhibited good mechanical properties and further NiFe electrocatalysts were electrodeposited by a chronopotentiometry (-3mAcm⁻² 10 min 60°C) using chlorides as metallic precursors. Finally, they were tested by linear sweep voltammetry (LSV) for the OER reaction and compared to a benchmark NiFe catalyst electrodeposited onto a commercial Ni-foam. The 3D printed electrodes showed a 10% reduction of the OER overpotential with respect to the benchmark.

Understanding electrocatalyst degradation at the atomic scale

Dr. Aparna Saksena, Germany

Oral Presentation (20')

Abstract

Climate change has accelerated the demand for cleaner and sustainable fuels. Hydrogen is the most popular candidate for clean energy and its generation through electrochemical water splitting is considered an efficient C-free route. Electrocatalysts play a vital role in reducing the activation energy barrier (1) for the water-splitting reaction for hydrogen and oxygen production. Platinum and iridium (2, 3) (or its oxide) are known for their high catalytic efficiency for hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) respectively. Despite them being the highest-performing catalysts to date, their limited abundance and high cost necessitate greater focus on minimizing their degradation over time.

In this study, we investigate PtIr thin films deposited by physical vapor deposition (4) for OER. Magnetron sputtering and post-heat treatment at temperatures between 700 to 950 °C for 12 hours, allowed for microstructural and local composition variation as investigated by electron channeling contrast imaging and atom probe tomography (APT). During OER, dissolution species are characterized by a scanning flow cell working in conjunction with an inductively coupled plasma mass spectrometer. The as-deposited thin film shows the highest catalytic activity which diminishes by a third after just 50 cycles while the thin film heat treated at 950 °C shows a lower catalytic activity which consistently stays stable. In this regard, we discuss the activity–stability paradox with respect to the role of defects and their local composition for designing better catalysts.

Paper 453 1 **Ambient deposition of single atoms for enhancement of nanostructured metal oxide electrodes**

Prof. Manuela Killian, Germany

Highlight (Oral Presentation 20')

Abstract

Cutting-edge technology utilizes single-atom decoration to enhance heterogeneous catalysis at the atomic level. However, single atoms often aggregate into nanoparticles due to high surface energy. To counter this, we modify surfaces with nanostructured support layers like TiO₂ nanotubes, nanosheets, and NiO nanosponge. Anodization facilitates precise fabrication of well-ordered oxide nanostructures and nanotubes. Gentle defect-engineering methods like room-temperature sonochemical treatment, UV-light irradiation or pH-control are employed to trap Pt, Ir and V single atoms effectively. UV-light radiation induces Ti³⁺ and oxygen vacancies onto TiO₂ nanosheets, enabling efficient Pt single-atom decoration. Sonochemically treated TiO₂ nanotubes exhibit promising performance in H₂ evolution catalysis. Thermal annealing in a reductive atmosphere facilitates the anchoring of single Ir atoms onto NiO nanostructures, further stabilized by ultrasound-driven methods. Characterization involves microscopy (FESEM, TEM, HAADF-STEM) and spectroscopy (XPS, ToF-SIMS). Especially time-of-flight secondary ion mass spectrometry (ToF-SIMS) shows a unique capability of identifying co-catalysts in a single-atomic state on the support. Gas chromatography evaluates H₂ photocatalytic performance, while linear sweep voltammetry assesses H₂ and O₂ electrochemical activity. The demonstrated deposition techniques significantly enhance the efficiency of nanostructured oxide electrodes modified with stable single-atom co-catalysts through gentle treatments.

Paper 1070 2

Fabrication and characterization of 3D printed ceria structures for solar thermochemical water splitting reactors

Dr. Stefan Brendelberger, Germany

Oral Presentation (20')

Abstract

Solar thermochemical cycles are considered for the production of renewable fuels at large scale. The direct conversion of heat, generated by concentrated solar radiation, into chemically stored energy and the usage of the full solar spectrum enable in theory high process efficiencies and respectively low fuel production costs. One of the most investigated redox cycle in this area is the two-step ceria cycle with temperature-swing, pressure-swing operation. In this process ceria is partially reduced at moderate vacuum conditions and temperatures of around 1500°C and oxidized at around 1000°C. In recent years substantial improvements of related receiver-reactors have been experimentally demonstrated [1]. Further improvement potential is claimed for advanced receiver-reactor concepts like R2Mx [2].

The redox material is often applied as an open porous monolithic structure to allow deep penetration of solar radiation and a high surface area for fast kinetics during reduction and oxidation. While the most efficient systems so far have been using reticulated porous ceramics, 3D printing is seen as an option to further improve and tailor the design of the redox structures [3]. First tests have been reported for structures used in directly irradiated receiver-reactors.

R2Mx creates a different set of requirements for the redox structures and adapted designs have been developed. For the fabrication 3 different printing methods are investigated: Binder Jetting, Material Extrusion, and Vat Photopolymerization. Ceria pellets and rods have been printed and characterized in order to iteratively elaborate and improve the fabrication methods. More advanced designs which are closer to the application as well as a proof-of-concept test rig for the testing of the 3D printed ceria structures including first experimental results will be presented.

Paper 1572 3 **Exploring the role of non-metal and metalloid inclusions in transition-metal electrocatalysts for direct seawater splitting**
Dr. Jyoti Gupta, Slovenia
Oral Presentation (20')

Abstract

Hydrogen, the green and sustainable energy carrier, can be produced through a zero-carbon technology such as water electrolysis without any emission of toxic by-products. As the freshwater sources are very scarce on earth, the utilization of seawater as the feedstock for water electrolysis has become a topic of great interest. However, seawater electrolysis has its own challenges, such as the kinetic competition between chloride oxidation reaction (COR) and oxygen evolution reaction (OER) (+1.36V: COR, +1.23V: OER) at the anode. Currently, the most efficient electrocatalysts for the HER (Hydrogen Evolution Reaction) and OER, are those based on precious metals like Pt, Ir, Ru, etc. But because of their high price and scarcity, they cannot be upscaled. Due to their abundance, low cost, and versatile characteristics, Co and Ni based electrocatalysts exhibit remarkable catalytic activity and stability in challenging seawater conditions and have emerged as one of the most promising bifunctional materials for efficient seawater splitting, offering an environmentally sustainable route to green hydrogen production. In our work, we have explored a series of Co and Ni-based catalysts combined with a non-metal (such as P) or metalloid (such as B) or a combination of both (B and P). The improvement in electrocatalytic activity and selectivity for OER in simulated and natural seawater was investigated. The experimental studies were thoroughly complemented by computational tools to not only assist in materials screening but also gain fundamental understanding of the competing reaction mechanisms over the catalyst surfaces and the role of the non-metal/metalloid in the catalyst. We also explore the degradation mechanism using a combination of transmission electron microscopy and inductively coupled plasma mass spectroscopy, providing information on improving the long-term catalyst stability in seawater-based electrolytes. The present study provides the basis for developing high-performing functional materials for green energy generation through seawater electrolysis that can eventually replace the precious metal catalysts in commercial setups.

Paper 653 **5** **Improvement in the production of green hydrogen from a freeze-cast porous Fe₂O₃ material by the use of small amounts of Al₂O₃ and TiO₂**
Mr. Miguel Paul Navarron, Spain
Oral Presentation (20')

Abstract

Hydrogen has become the new energy vector because its combustion produces neither pollutants nor greenhouse gases.

Current production is still based on fossil fuels, with a small but growing proportion coming from renewable resources. However, storage and transport remain a challenge. Iron oxide is a low-cost raw material that can be used to produce high-purity hydrogen through the Chemical Looping Water Splitting (CLWS) process. First, a carbonaceous fuel from organic waste such as biogas, bioethanol or biomass reduces the hematite to wustite (FeO), which is later re-oxidised with steam to produce pure hydrogen.

However, the efficiency of this reaction is dominated by the available surface area, the formation of coke due to the use of bioethanol as a reductant source, and the deactivation phenomenon caused by the high working temperature after numerous redox cycles.

Here we show an Fe₂O₃ freeze-casting porous material doped with Al₂O₃ and TiO₂ capable of yielding 8 mmolH₂/g sample on each redox cycle with negligible traces of CO. We found that TiO₂ has the potential to enhance the reduction reaction of the iron oxide, while Al₂O₃ helps to withstand the prolonged heat treatment. These properties, which double the hydrogen production reported for similar systems are relevant to the proper operating of PEM fuel cells. Our porous materials were fabricated using a camphene-based suspension of synthesised nanoparticles with different compositions. Fe₂O₃ nanoparticles doped with Al₂O₃ and TiO₂ oxide (95 wt% Fe₂O₃ - X wt% Al₂O₃ - (5-X) wt% TiO₂; X= 2, 2.5 and 3) were prepared by the co-precipitation method. This procedure produces a single solid solution matrix with an interconnected porosity of approximately 70%. After redox test, the formation of coke deposit over the surface is neglected at 675°C for samples with 3 wt% TiO₂, leading to a high-purity hydrogen produced during steam oxidation. This study is important to further improve the chemical design of oxygen carriers and also to improve the mechanical strength of porous catalyst materials. As the surface reactions produce a significant stress due to volumetric changes.

Experimental assessment of computationally designed Complex Concentrated Alloys (CCAs) for Molten Salt Reactors (MSR)

Mr. Mounzer Nasser, France

Oral Presentation (20')

Abstract

Compositionally Complex Alloys (CCAs) have recently emerged as attractive structural materials in the nuclear sector, primarily due to their suggested superior irradiation tolerance when compared to conventional alloys [1]. Their expansive compositional space allows for fine-tuning of diverse properties, including electrochemical behaviour, making them interesting for demanding reactor environments [2].

This study focuses on the evaluation of newly designed corrosion- and irradiation-resistant CCAs for Generation IV Molten Salt Reactors (MSRs), where materials must endure chloride-based molten salts at temperatures ranging from 550 to 750°C. Building upon the work of Herschberg et al. [3], both novel CCAs and literature-based "reference alloys" were fabricated through cold crucible induction casting. The obtained Ni-rich alloys incorporate Al or Mo as principal alloying elements along with Cr. Comprehensive microstructural characterisation of both as-cast and homogenised samples employed X-Ray Diffraction (XRD), Scanning Electron Microscopy (SEM), Energy Dispersive Spectroscopy (EDS), Electron Backscatter Diffraction (EBSD), and Transmission Electron Microscopy (TEM). In addition, the predictions made by ThermoCalc software were compared with the experimental findings in order to assess phase stability and guide alloy development.

Mechanical properties were examined via Vickers hardness measurements, room-temperature tensile tests, and hot compression tests. So as to investigate corrosion resistance, prolonged static immersion tests were performed in eutectic LiCl-KCl salt at 450°C for 24 and 168 hours. Heavy-ion irradiation experiments utilised 6 MeV Ni ions at 450°C, and subsequent TEM analyses evaluated resulting microstructural changes. Furthermore, the interplay between irradiation and corrosion was explored through sequential heavy-ion irradiation and corrosion testing.

Preliminary results highlight that these "MORA" alloys not only display robust high-temperature phase stability and favourable mechanical performance but also exhibit commendable resistance to corrosive chloride salts.

Paper 1223 1 **Investigation of the nanostructure of TiSiN coatings using high resolution methods**
Dr. Nina Schalk, Austria
Keynote (Oral Presentation 40')

Abstract Owing to its excellent mechanical properties TiSiN is commonly used as hard protective coating in cutting applications. However, the nanostructure of TiSiN is controversially debated and the detailed investigation is a challenging task, requiring the application of advanced high resolution characterization techniques such as transmission electron microscopy and atom probe tomography (APT). While APT would be a valuable method to illuminate the local elemental distribution with close to atomic resolution, peak overlaps of Si and N in the mass spectrum do not allow for an unambiguous differentiation, resulting in poor elemental accuracy and imaging precision. In the present work, different approaches to improve both, elemental accuracy and imaging precision are shown. In addition, the nanostructure of magnetron sputter deposited as well as cathodic arc deposited TiSiN coatings is illuminated, showing the effect of varying Si content and deposition parameters on the evolving structure.

Paper 1341 2 **The Role of Substrate Roughness and Chemical Composition in HiPIMS-Coated Cutting Tools**
Mrs. Beatriz Sousa Monteiro, Portugal
Oral Presentation (20')

Abstract

The European Union's target of reducing greenhouse gas (GHG) emissions by 55% until 2030 has driven innovations in the mobility sector, leading to the development and application of lightweight alloys and composite materials. This transition is essential for achieving environmental targets; moreover, the efficiency and cost-effectiveness of machining processes of the new materials under development within the mobility sector remain equally important. In this context, a more efficient machining process for these hard-to-cut materials is essential, which can be achieved through the development of advanced cutting tool materials, the optimization of tool geometry, or through modifications in coating design, aiming to improve tool performance, service life and increase retooling time. This is particularly challenging, as the tools must combine wear and oxidation resistance at high temperatures without compromising their toughness, in order to withstand demanding machining conditions.

In the present work, multilayer thin films with different compositions – including TiN, TiAlN, TiSiN, AlCrN and/or ZrN – were deposited through High-Power Impulse Magnetron Sputtering (HiPIMS), on polished and unpolished Si₃N₄-based cutting tools, to assess the substrate roughness and chemical composition influence on structural, morphological, adhesion and wear properties of the ceramic multilayer coatings. With thickness values ranging between 1.5 and 2.5 µm, these films were thoroughly characterized. The structure and morphology of the thin films were analyzed by SEM/EDS, along with roughness measurements, and mechanical properties assessed through adhesion and wear tests. Overall, preliminary results indicate that both substrate surface roughness and coating composition significantly impact multilayer deposition. Unpolished samples exhibit higher roughness values, leading to uneven material deposition and, consequently, less consistent thickness values. These differences in surface roughness, along with the coating composition, also pose a great influence in the adhesion and wear properties of the coatings. Nevertheless, the surface roughness does not seem to affect the presence of defects on the coating topography or the adhesion between layers.

Paper 902 1 **Unravelling solid self-lubrication mechanisms of B₂O₃ in TiB₂±z and WB₂±z based thin films**

Mr. Daniel Pözlberger, Austria

Oral Presentation (20')

Abstract

Transition metal borides (TMBs) represent a highly promising family of materials for functional coatings due to their abundance, cost-effectiveness, and exceptional mechanical properties. These include a high melting point, hardness of up to 60 GPa, excellent chemical and thermal conductivity, and outstanding resistance to wear. TMBs have distinct self-lubricating properties due to the formation of boron oxide, which helps to reduce friction. The temperature plays a significant role in the formation of boron oxide. However, the fundamental mechanisms behind this tribo-reaction are not yet fully understood, especially concerning TMB-based thin film materials. Understanding the oxidation behavior of physical vapor deposited TiB₂±z and WB₂±z thin films is essential for comprehending their friction and wear properties in high-temperature tribo contacts. Tribological tests reveal that sputter deposited super-stoichiometric TiB_{3.5} exhibits a significantly lower friction coefficient (~0.25), roughly half compared to that of sub-stoichiometric TiB_{1.67}, tested at 500°C. This reduction is attributed to the higher oxidation rate of super-stoichiometric TiB_{3.5} and the presence of B-rich tissue phases at the column boundaries. Similarly, α-WB₂±z coatings also exhibit self-lubrication properties. However, they tend to stabilize in the sub-stoichiometric form, resulting in reduced amounts of boron available for oxidation. Additionally, we conduct an in-situ investigation of the oxidation process in sub- and super-stoichiometric TiB₂±z and WB₂±z thin films using elastic backscattering spectrometry (EBS). This technique provides detailed depth profiles of the chemical composition over a temperature range from room temperature to 800°C. The oxidation data are further correlated with tribological, XPS, XRD, and TEM analyses, offering new insights into the lubrication mechanisms of boron oxide in TMB thin films across a wide temperature range.

Paper 117 **2** **Reactive Magnetron Sputtered Cr1-xTaxN and Cr1-yNbyN coatings: Microstructure and mechanical properties**
Mr. Jan-Ove Söhngen, Germany
Oral Presentation (20')

Abstract

Nitride films based on refractory metals can exhibit unique properties which make them suitable candidates in wear resistant applications. The model systems chosen for this study are Cr1-xTaxN and Cr1-yNbyN coatings with various Ta or Nb contents ($0.105 \leq x \leq 0.727$, $0.106 \leq y \leq 0.458$). They were synthesized by reactive magnetron sputtering utilizing a combinatorial experiment in thin film deposition. We used a segmented circular target consisting of two half plates of pure Cr and Ta or Nb for the deposition at 250 W DC target power, 0.4 Pa pressure with a mixture of Ar and N2 (31:23, 41.5:16 and 54.5:5), 0 V substrate bias and $\approx 150^\circ\text{C}$ substrate temperature. The gas mixture was adjusted to achieve nearly stoichiometric nitride coatings. Polished steel substrate samples of 10x10x1 mm3 were placed in a horizontal line opposite to the target. Thus, we obtained different Cr1-xTaxN and Cr1-yNbyN coatings with various Ta or Nb content in a single deposition experiment.

The elemental composition of the coatings was determined by electron probe micro analysis and their phase composition was characterized by X-ray diffraction. Based on these results and according to the atomic concentrations of Cr and Ta or Nb, the coatings can be classified as follows:

1. All coatings are crystalline.
2. All XRD reflections exhibit a similar shape and suggest that all coatings grow in a single-phase fcc (face-centered cubic) solid solution structure.
3. The solid solution (Cr1-x, Tax)N exists in a range $0.105 \leq x \leq 0.727$ while the solid solution (Cr1-y, Nby)N is found in a range $0.106 \leq y \leq 0.458$.

Transmission electron microscopy and scanning electron microscopy analyses will resolve the microstructure further.

Mechanical properties of the coatings were studied by micro-indentation. The hardness and Young's modulus of the Cr1-xTaxN and Cr1-xNbxN in dependence of their Ta or Nb content and as well of the pure CrN and TaN or NbN coatings will be discussed. It was found that both the Cr1-xTaxN and Cr1-yNbyN coatings have a higher hardness than pure CrN. For Cr1-xTaxN, the hardness values range from 1789 to 1952 HV and for Cr1-yNbyN from 1244 to 1777 HV.

Paper 799 3 Pulsed Electron Beam Irradiation of AlSi alloys as Pretreatment to Grow Modified Anodic Oxide Layers
Dr. Andrea Lucchini Huspek, Italy
Oral Presentation (20')

Abstract

Aluminum alloys play a crucial role in several engineering fields, like aviation, aerospace, automotive, construction and marine industries. They are employed thanks to their low density, high strength-to-weight ratio, excellent electric and thermal conductivity, good castability and machinability, and easy recycling. In aluminum-silicon alloys, the content of Si usually varies between 4 and 25 wt. % and other alloying elements, such as Cu, Mg, Mn, and Fe, may be added in smaller amounts to improve the mechanical properties of the alloy [1]. In order to improve the corrosion resistance and the surface mechanical properties, anodic oxidation is usually employed to form a protective coating. However, the anodizability of Al-Si alloys is strongly influenced by the presence of alloying elements, that make the achievement of a homogenous and durable anodic layer a challenging task. The presence of coarse silicon structures, in particular, causes the formation of a highly defective anodic oxide in which unoxidized regions, gas-filled porosities and cracks are frequently encountered [2]. In the present work, the Low-Energy High-Current Electron Beam [3] is employed for surface modification of Al-Si alloys as a pre-treatment for anodic oxidation. In this way, thanks to the rapid melting and solidification induced on the metal surface by the electron beam irradiation, the redistribution of silicon can be achieved, obtaining a small and fine dispersion. In particular, the influence of different energy densities ($2\text{--}5\text{ J/cm}^2$) and different number of pulses (4–32) was investigated. Oxides were produced by anodic oxidation in H_2SO_4 , at 0°C for 15, 30 and 45 minutes. Surface and cross-sectional morphology were investigated using a Zeiss EVO 50VP SEM equipped with a Bruker Quantax X-ray spectrometer for EDS chemical microanalysis. The crystalline structure was characterized by X-ray diffraction in Bragg-Brentano (BB) configuration utilizing a PANalytical EMPYREAN PW1830 diffractometer. Vicker microhardness and elastic modulus were assessed by a Helmut Fischer HVX100 at different loads. The electrochemical behavior of coatings was characterized by Linear Sweep Voltammetry and Electrochemical Impedance Spectroscopy with a Solartron Modulab XM ECS potentiostat in 3.5% NaCl solution at room temperature.

Paper 409 **5** **Tailoring Zr-Cu-based thin-film alloys by W and Nb additions: from metallic glasses to supersaturated solid solutions**
Mrs. Deepika Thakur, Czech Republic
Highlight (Oral Presentation 20')

Abstract

Zr-Cu-based thin-film metallic glasses (TFMGs) have emerged as a promising class of materials due to their exceptional properties such as high glass-forming ability, superior elastic strain limit, enhanced hardness and plasticity. Moreover, these TFMGs offer the potential to be combined with nanocrystalline materials (transition metals or metal nitrides) to create heterogeneous dual-phase nanocomposite structures and thus achieving a better balance of toughness and hardness and/or unlocking new functionalities.

Therefore, this study explores the effect of gradual addition of W (negative mixing enthalpy with Zr but positive with Cu) and Nb (positive mixing enthalpy with both Zr and Cu) on microstructure and properties of Zr-Cu-based thin-film alloys. Two film series, W-Zr-Cu and Nb-Zr-Cu, were prepared by magnetron sputtering technique, keeping Zr:Cu as 1:1 and gradually varying the W and Nb content in the respective series.

A systematic investigation revealed that W and Nb additions have a significant impact on microstructure and other properties of the films. The films remain amorphous with smooth surfaces (roughness < 2 nm) up to 65 at.% of W or Nb, displaying vein-like features typical of metallic glasses upon fracture. W-Zr-Cu films with 67 at.% W are characterized by a combination of featureless structures (amorphous-like) close to the substrate and thin columns in the upper part of the film. Films with even higher W contents grow in a V-shaped columnar microstructure corresponding to the bcc α -W crystalline structure. Nb-Zr-Cu films with 70 at.% Nb clearly exhibit a dual-phase structure with thin columns surrounded by vein-like features. Further increase in the Nb content above 70 at.% leads to the formation of a crystalline structure with parallel columns and very small voids. These voids tend to vanish with increasing Nb content. A gradual increase in hardness and reduced Young's modulus is observed with increasing W content for the amorphous W-Zr-Cu films and the crystalline films show an enhancement in hardness of up to 15% compared to films with pure W due to solid solution hardening. In the case of Nb-Zr-Cu films with up to 70 at.% Nb, the hardness remains nearly constant. However, further addition of Nb results in a decreased hardness and this reduction might be attributed to a less dense structure of the films.

Results of ongoing analysis and experiments on W-Zr-Cu and Nb-Zr-Cu films based on ZrCu will also be presented, providing new insights into the material's phase transitions, mechanical strength, and electrical properties.

Paper 1076 6 Design and Investigation of DC Magnetron Sputtered TiN/TaN superlattice structures

Mrs. Katharina Weiss, Austria

Oral Presentation (20')

Abstract

Thin films based on transition metal nitrides (TMNs) are versatile materials suitable for a broad range of applications. Cubic NaCl-type titanium nitride (TiN), in particular, is a paradigm coating material with excellent mechanical properties. Tantalum nitride (TaN) offers intrinsic ways of tuning mechanical performance via its metastable cubic phase (NaCl-type): providing access to a wide range of stoichiometries and (beneficial) lattice defects, including stacking faults, which may hinder the onset of crack initiation and propagation.

Contrarily to TiN, ab initio calculations indicate the ability of TaN to nucleate mechanical twins and activate twinning-induced plasticity effects. To verify and complement these predictions, we deposited TiN and TaN in the form of superlattice coatings (alternating nano-layers) via unbalanced DC magnetron sputtering. Thereby we take advantage of the TiN template effect and generate numerous interfaces, providing a basis for subsequent analysis of stacking fault and twinning activities in TiN/TaN superlattices, as well as related interface effects. The combined micro-structural analysis using XRD and SEM reveals the expected nano-layered structure of the TiN/TaN coatings, while mechanical tests corroborate the enhancement of hardness and fracture toughness (superlattice effect). In the long run, the insights gained from this study contribute towards a comprehensive knowledgebase for the design of materials with unique property combinations.

Mechanical properties and adhesion of $W_{1-x}Al_xB_2+z$ coatings

Mrs. Ewa Wojtiuk, Poland

Oral Presentation (20')

Abstract

The quest for advanced materials with outstanding properties has brought tungsten borides into the spotlight, thanks to their exceptional hardness, thermal stability, and resistance to wear. The crystallographic structure of these materials is crucial in shaping their physical, mechanical, and antioxidation behavior. Notably, borides doped with aluminium have emerged as a standout option, exhibiting excellent mechanical and antioxidation characteristics [1]. These materials hold significant potential for use as protective coatings that can remain stable under high-temperature conditions. To achieve the desired material structure, a novel magnetron deposition technique was used, integrating direct-current magnetron sputtering (DC) with High Power Impulse Magnetron Sputtering (HiPIMS). The films were deposited using two distinct targets: AlB_2 (DC) and $WB_{2.5}$ (HiPIMS). Mechanical testing demonstrated exceptional hardness (~30 GPa for aluminum doping below 10% atomic). As the aluminum content in $W_{1-x}Al_xB_2+z$ coatings increased, a slight decrease in density and hardness was observed. The experimental findings were compared with theoretical values derived from DFT calculations. All $W_{1-x}Al_xB_2+z$ structures examined using DFT were confirmed to be both mechanically and thermally stable. The experimentally measured hardness values surpassed those predicted by DFT, highlighting the notable impact of aluminum doping. Due to the use of hard coatings mixed with a soft substrate, it is important to achieve good adhesion. Coatings were applied to nitrided steel QR90 with tungsten interlayer. For this purpose, the films were subjected to two methods of adhesion measurement: scratch testing and laser spallation.

Paper 397 1 **The change in tribological properties of aluminum thin films deposited by magnetron sputtering with an additional cooled anode**

Mrs. Daniela Shealsey Jacobo Mora, Mexico

Oral Presentation (20')

Abstract

In this work we studied the effect of adding an anodic plasma to DC magnetron sputtering discharge; we demonstrated that the anodic plasma could generate additional argon ions in the magnetron discharge. Aluminium thin films were deposited on glass substrates, and the anodic plasma was generated by a cooled graphite electrode. The changes in the two plasmas were studied by optical emission spectroscopy (using an Avantes AvaSpec-DUAL spectrometer). In particular, we studied the effect of the anode position (from 5 cm to 8 cm) respect to the cathode and the temperature of the anode (cooled and uncooled electrode). Finally, we studied the changes in the hardness and wear resistance, obtained by scratch tests (NANOVEA ST-500), of the deposited film, as a function of experimental parameters: argon gas pressure (from 5 to 15 mTorr), magnetron sputtering voltage (250 V) and anode voltage (80, 100 and 120 V) applied, as well as deposition rates measured by optical profilometry.

Paper 2071 3

Multifunctional Coatings for Harsh Environments

Prof. Jolanta Klemberg-Sapieha, Canada

Highlight (Oral Presentation 20')

Abstract

Materials exposed to extremely demanding environments in applications such as aerospace, automotive, mining, petroleum and consumer products, continue to face increased technological, environmental and economic challenges, especially since the performance of modern equipment, systems and components is pushed to and beyond their limits. This frequently leads to material deterioration accelerated by excessive wear, erosion, tribo-corrosion, and other mechanisms related to surface damage, resulting in increased operation and maintenance costs, decreased efficiency, premature failure, and compromised safety in the case of critical applications.

A good understanding of materials deterioration processes allows one to develop appropriate strategies to protect technologically relevant substrates taking into account the complete life cycle of the component. Advanced nanostructured coatings call for an “ideal” combination of mechanical, elasto-plastic, tribological, corrosion, thermal and other characteristics. Such requirements can only be satisfied by using specifically tailored coating architectures while considering nanocomposite, nanolaminate, multilayer and graded layer systems. Specifically, the combination of multiple coating types obtained by different complementary processes (called “hybrid” coatings) provides much promise for combined functional characteristics including multifunction, adaptive or smart performance.

Throughout the talk, I will illustrate the relationships that exist between the microstructure, the mechanical properties and the tribological performance of protective coatings by presenting different examples of coatings used in three areas: aerospace, manufacturing and energy.

ZrN-Cu coating by hybrid magnetron sputtering for maritime applications

Sandra Carvalho,

Oral Presentation (20')

Abstract

Maritime transportation is a central player in the worldwide economy. Problems with marine shipping always directly impact the final price of merchandise. Currently, this industry deals with two significant issues: biofouling and corrosion. Both represent maintenance and operating costs increasing. The ban imposed on tributyltin paint, the most used product to fight these problems, seeking a multifunctional solution was open. Magnetron sputtering could represent a big step forward in solving this inconvenience. The present work aims to gather the desired characteristics in one surface: antibiofouling action, corrosion resistance, and mechanical reliability. A ZrN-Cu nanostructured coating was obtained through hybrid magnetron sputtering technology, employing DCMS and HiPIMS simultaneously under a reactive atmosphere (Ar + N₂). Stainless steel 316L was utilised as substrate. Different techniques assessed the fundamental features of the coating (SEM, EDS, XPS, XRD, TEM, EELS). Zone of inhibition tests and quantification of colony-forming units (both with *Cobetia marina*) were employed to evaluate the antibiofouling action. Electrochemical impedance spectroscopy (up to 30 days) and potentiodynamic polarisation measurements were conducted in a 3.5 wt. % NaCl solution to assess the corrosion resistance. Likewise, nano-indentation, scratch tests, and tribology measurements established the mechanical characteristics of the coating. The results demonstrate that Cu diffusion to the surface and the presence of CuO species provoked the antibiofouling action, regardless of the activation mechanism (electrochemical or chemical). Cu²⁺ Ionic releasing (ICP-OES) after 24 h did not represent a toxic agent for *C. marina*. Also, the deposition method effectively limits the influence of Cu over ZrN properties (i.e., anticorrosion and mechanical reliability) due to the increase of compactness provoked by HiPIMS. With coating activation, the mechanical properties of the coating diminished, though the corrosion resistance increased. These findings represent a viable alternative for the marine industry, replacing other harmful products in ship components.

Paper 589

5

Design of an innovative cathodic arc source with high deposition rate and low macroparticles generation

Mr. Raul Bonet, Spain

Oral Presentation (20')

Abstract

Within the group of PVD techniques, Cathodic Arc Evaporation technique stands out for its performance, which is characterized by an almost 100% ionized, high-energy plasma. Its versatility, lower economic cost compared to other deposition techniques and ease of industrial scaling have led to massive industrial implementation for the production of coatings and thin films of various types. One of the disadvantages of the cathodic arc technique is the generation of macroparticles due to the arc discharge on the cathode surface. This fact can be an important technological limitation in cases where a good surface finish, low friction coefficient or good wear and corrosion resistance is required. Traditionally, this problem has been solved by using magnetic filters to separate the macroparticles from the plasma ions. However, this solution is associated with a significant reduction in the deposition rate, which makes it difficult to implement on an industrial scale. On the other hand, to reduce the costs of the coating process, cathodic arc sources that allow a high deposition rate are required.

In this work, an innovative cathodic arc source was designed to achieve a deposition rate of up to 20 microns/hour with an 80% reduction in macroparticles. To increase the deposition rate, a high current pulsed source (100-500 A, 10-20000 Hz) was used to generate the arc discharge between the anode and cathode. On the other hand, aimed to reduce the generation of macroparticles, an optimized magnetic field configuration around the cathode has been obtained by means of Finite Element Method (FEM) simulation, which allows to induce a fast and homogeneous movement of the arc on the cathode surface. Standard transition metal nitride (CrN, AlTiN) hard coatings obtained using this source show excellent surface finish and improved mechanical properties in terms of adhesion and hardness.

Paper 1274 6 **Laser Surface Treating WSC Coatings to Optimize WS₂ Crystallization-to-Carbon Phase Graphitization**
Prof. Albano Cavaleiro, Portugal
Highlight (Oral Presentation 20')

Abstract

WSC coatings i.e. WS₂ phase immersed in an amorphous carbon matrix, provide low friction and wear in several environments (e.g. humid air, vacuum, dry N₂, etc.), attributed to WS₂ phase crystallization and basal plane reorientation along sliding, together with a high structural integrity, mainly attributed to the harder amorphous carbon. However, before WS₂ is able to provide a stable low CoF, a running-in period with unstable CoF is generally unavoidable, especially when sliding against soft materials (e.g. rubber), for which contact stresses are low. Spatially precise laser energy inputs could potentially allow for local crystallization of the WS₂ phase in surface regions, with little structural degradation (e.g. by graphitization) of the amorphous carbon matrix. However, given the multitude of laser systems and input parameters that can be varied during the process, laser treating a new material typically entails the need for time-consuming trial-and-error iterations before the process is easily understood and controllable. Therefore, we set out to find if a single laser parameter could govern WSC phase transformations at specific thresholds. WSC coatings with ~50 at. % of C were thus deposited by magnetron sputtering and subsequently treated with a fiber laser, and an adequate interplay between the most relevant input parameters (found to be the peak power, pulse duration and repetition rate) was reached, with five final treatment conditions (WSC-IR1 to WSC-IR3*) obtained from independently varying each of the latter. Different experimental techniques were then employed to help identify phase transformations, namely: i) optical microscopy, 3D optical profilometry, white light interferometry and calotests to study morphological and cross-sectional features; ii) Raman spectroscopy and nanoindentation to study the level of structural and mechanical transformations, including its spatial variation along treated spots (center, edges, and in-depth). Average power, power density, energy per pulse and fluence were estimated for each treatment condition, as they are known to describe certain laser-matter interaction phenomena in other materials. Increasing each of the latter, treated regions darkness, diameter (10-23 µm), heights (29-118 nm), transformed depths (0.07-0.17 µm), degree of amorphous carbon graphitization and WS₂ crystallization concomitantly increased (former seems to occur at slightly lower exposure thresholds, though almost concurrent with the latter), with mechanical properties like the hardness and elastic modulus reducing little (~3-4.5 GPa compared with ~5-6 GPa in non-treated zones), such that mechanical integrity of the coating should remain high.

Patterned slippery surfaces for efficient and consistant fog harvesting

Prof. Rui Feng, China

Pre-recorded video presentation. Highlight (Oral Presentation 20')

Abstract

Currently, water shortages are one of the most serious social crises that threaten human life. Notably, in moist air, numerous microdroplets exist in fog, from which many creatures are capable of collecting water in clean and efficient ways. Inspired fog harvesting materials have been developed for efficient water collection in recent decade. The fog harvesting surfaces were mostly focused on (super)hydrophobic surfaces which are beneficial for water transportation, however, such surfaces are unstable in fog flow environment and thus difficult to realize long-term stable applications. Both the water collection efficiency and stability are significant for applications of fog harvesting materials. Here, four kinds of surfaces, including superhydrophobic surfaces, lubricant-infused slippery surfaces, liquid-like slippery surfaces and smooth solid surfaces, are investigated by simple method for long-term fog harvesting. The effect of surface structure and wettability on fog harvesting efficiency/stability and the corresponding mechanisms are systematically discussed. At the same time, by learning and cooperating from the fog capture, droplets coalescence, water transportation and collection of multiple creatures, a series of hybrid surfaces are prepared through optimizing surface structures and patterns. As a result, synchronously improved fog harvesting stability and efficiency are realized. For the most excellent surface, it is highly stable during 30-day test and the daily water collection efficiency can reach 90 L m⁻² day⁻¹; and the transparent patterned surface is able for large area fabrication assisted by printing technology. Moreover, a simple device is developed by integrating the patterned surface and a solar evaporator. A cooperative mechanism between fog harvesting surface and solar evaporator is preliminarily verified, and efficient vapor condensation efficiency and vapor collection efficiency are achieved, providing new ideas for the development of water collecting technology in future.

Paper 1057 3 **Decoating process by using the DLyte® Technology of TiAlN/TiSiN and AlCrSiN coatings: insights from chemical analysis using XPS measurements**

Dr. Joan Josep Roa Rovira, Spain

Oral Presentation (20')

Abstract

TiAlN/TiSiN and AlCrSiN are advanced coatings employed in a wide range of industries due to their remarkable properties, including enhanced wear resistance, hardness, and excellent high-temperature performance. One of the most used applications is in cutting tools, since they provide an increase in tools' life under service like working conditions. However, over time the used parts degrade and need to be reconditioned. In that sense, stripping or decoating process is a key point in order to remove the coating and re-coat again to reuse the cutting tool. In addition, decoating process can be used to remove defective coatings produced during the production process, and restore the initial substrate of the tool. Currently on the market, the decoating process for the TiAlN/TiSiN and AlCrSiN can be conducted though chemical (such as acid etching or chemical stripping) or with physical methods (e.g., laser ablation or plasma stripping). However, in both cases substrate could be affected, and as a direct consequence the surface integrity is deteriorated. In the particularly case of cemented carbide (WC-Co) tools, this effect is magnified, since the metallic Co binder undergoes corrosion in acidic or even neutral mediums.

Within the aforementioned information, recently, a new technology can be employed to decoat materials without damaging the substrate and being able to preserve the geometries. In this regard, through this presentation the DLyte® Technology will be employed to decot TiAlN/TiSiN and AlCrSiN coatings deposited over WC-Co material. Furthermore, the thickness of the coating removed along the decoating time will be investigated by using the focused ion beam technique (FIB) in order to determine the decoating kinetics for ternary (TiAlN/TiSiN) and quaternary (AlCrSiN) systems. In addition, as chemical analysis plays a pivotal role in order to understand the process and to control de substrate integrity, X-ray Photoelectron Spectroscopy (XPS) analysis thought the entire decoating process has been conducted. During the decoating process, XPS provides information about the superficial chemistry, identifying the coating's removal elements, and detecting any contaminants or oxidation that may occur. This surface-sensitive technique can be used to track the reduction in signals corresponding to coating elements (e.g., Ti, Al, Cr, Si) as the process of the decoating process by using the DLyte® Technology progresses. This real-time monitoring ensures that the coating is completely removed without damaging the underlying material.

Paper 1541 1 MecaNano COST Action - European Network for the Mechanics of Matter at the Nano-Scale

Prof. Benoit Merle, Germany

Oral Presentation (20')

Abstract

The European Network for the Mechanics of Matter at the Nano-Scale (MecaNano) is a European Cooperation in Science & Technology (COST) Action (CA21121). The network has successfully connected over 400 researchers from diverse fields, including experimentalists, simulation and machine learning experts, and data scientists, fostering knowledge exchange and collaboration. MecaNano aims to advance the multiscale understanding of the mechanical behavior of materials, unlocking new possibilities for the development of novel materials with enhanced performance and durability. This presentation will provide an overview of MecaNano's past achievements and upcoming events. Beyond bringing together researchers from different scientific backgrounds, the Action has placed emphasis on promoting inclusivity, with strong representation from Young Researchers and Innovators in the network and leadership. The establishment of lasting transnational collaborations through Short-Term Scientific Missions, general meetings, and workshops has further strengthened the European Research Area. These efforts position MecaNano to continue advancing micro- and nanomechanics research, addressing emerging challenges through interdisciplinary approaches that integrate machine learning and data science.

A combined experimental-computational study of the compression of hemispherical nanoporous gold nanoparticles

Prof. Dan Mordehai, Israel

Oral Presentation (20')

Abstract

Nanoporous gold (NPG) exhibits unique mechanical properties due to its high surface-to-volume ratio and intricate ligament network. In this talk, we present an integrated experimental and computational approach to investigate the inhomogeneous deformation of sub-micrometer scale hemispherical NPG nanoparticles (NPG-NPs) under compression. Using a combination of the dewetting method and dealloying of Ag-Au alloys, we fabricated NPG-NPs with an average ligament diameter of 13 nm and overall diameters ranging from 200 to 800 nm. Structural characterization revealed a limited number of grain boundaries, predominantly twin boundaries. Compression experiments using a flat punch showed an initial linear load-displacement response, followed by a significant slope increase beyond a critical depth. To elucidate the underlying mechanisms, molecular dynamics (MD) simulations were performed on NPG-NPs with varying sizes, porosities, and ligament diameters. The simulated load-displacement curves closely matched experimental results, confirming the validity of our computational approach. A key finding of this study is the inhomogeneous densification of NPG-NPs, which is localized beneath the compressing punch. By analyzing the dislocation density profiles, we correlated the densification region with the mean-free path of dislocations and their depletion due to the nanoporous structure. The observed increase in slope in the load-displacement curves is attributed to interactions between the densified region and the substrate. Based on these insights, we propose a model for inhomogeneous deformation that enables the evaluation of contact stresses in experiments. Furthermore, we discuss the broader implications of this model for understanding the mechanical behavior of NPG structures under nanoindentation. This work provides a deeper understanding of the mechanical response of nanoporous materials at the nanoscale, offering valuable insights how to analyze indentation of NPG structures.

Atomistic Mechanisms of Dislocation Motion and Reaction in Laves phases

Dr. Zhuocheng Xie, Germany

Oral Presentation (20')

Abstract

Recent studies have revealed new slip mechanisms in Laves phases [1] and highlighted the thermally activated nature of synchro-shear partial dislocation glide [2-3]. However, the atomistic mechanisms underlying dislocation reactions, twinning, and phase transformations remain unclear. In this study, we investigated dislocation motion and reactions in C15 NbCr₂ Laves phases through high-angle annular dark field scanning transmission electron microscopy and atomistic simulations. Experimental observations enabled the reconstruction of dislocation core and lock structures, while simulations provided insights into underlying mechanisms of dislocation motion and reaction. Using nudged elastic band calculations, we characterized the mechanisms of individual partial dislocations forming intrinsic stacking faults, coupled partial dislocations forming extrinsic stacking faults, and their reactions forming Lomer-Cottrell and Hirth locks.

Atomic scale simulations of plasticity in Cu/Ag nanolamellar systems

Mrs. Sandrine Brochard, France

Keynote (Oral Presentation 40')

Abstract

Combining several materials to improve the mechanical properties of the assembly is a longstanding approach, used for example in lamellar composites systems. In the last decades, modern synthesis methods, such as severe plastic deformation, were developed and applied to metallic lamellar composites, allowing for a reduction of their layers width to less than 100 nm. The remarkable mechanical properties that these nanolamellar systems show are mainly imparted by the increasing role played by the interfaces in their plastic behavior. In that context, the nanolamellar bi-metallic Cu/Ag composite is particularly interesting. Indeed, experimental observations reveal in this system the coexistence of two different kinds of interface, whose interaction with extended defects such as dislocations and mechanical twins is very different. On the one hand, the "heterotwin" interface is a strong obstacle to the transmission of dislocations or twins. On the other hand, these defects are easily transmitted across the "cube on cube" interface. Because of the high lattice mismatch between copper and silver (around 12%), both interfaces are semicoherent and characterized by a network of misfit dislocations, which interact in a specific way with extended defects coming from the layers. The interfaces can also be sources for extended defects.

We thus performed molecular dynamics simulations of the deformation of Cu/Ag nanolamellar systems. These atomistic simulations are particularly well suited to the nanometric scale and to the study of the plasticity mechanisms at play in such nano-systems. We considered different stress fields applied to the systems and analyzed in particular the nucleation of dislocations or twins from the interfaces. The role of defects at the interface, such as atomic steps, observed experimentally, was also investigated by introducing them in a controlled way into the simulated systems.

The origin of interface stress transition in Cu/W nanomultilayers

Dr. Yang Hu, Switzerland

Oral Presentation (20')

Abstract

Controlling intrinsic stresses in nanomultilayers (NMLs) is essential for reliable mechanical performance and multifunctional properties. In Cu/W NMLs, a shift from positive to negative interface stresses arises under varying deposition conditions, yet the underlying atomic-scale mechanisms remain insufficiently understood. Here, we employ a neural network potential with ab initio-level accuracy to elucidate how intermixing at Cu/W interfaces drives this stress transition. Follow-up simulations further reveal that although interfacial intermixing is thermodynamically unstable, it enhances resistance to interface sliding and fracture. By directly linking interface chemistry to intrinsic stress, our approach bridges the gap between atomic-scale interface phenomena and the macroscale mechanical behavior of NMLs. These insights enable the design of NML coatings with tunable stress states and improved mechanical performance, opening new avenues for applications ranging from flexible electronics to protective coatings.

Multiscale Modelling of Superplasticity of Ti-6242

Mr. Muritala Arowolo, France

Oral Presentation (20')

Abstract

The superplastic forming (SPF) process enables the manufacturing of complex-shaped aerospace components in a single operation (e.g., air inlets, engine pylons). However, its implementation requires high temperatures, around 900°C for titanium alloys, and very slow forming cycles, making the process highly costly. Optimizing SPF involves reducing forming temperatures, which in turn requires the development of alloy microstructures that enhance ductility at lower temperatures. To achieve this optimization, numerical simulation appears to be an effective approach, as it provides a detailed understanding of mechanical behavior at different scales. This work presents the results of a multiscale (micro and macro) numerical analysis conducted on the polycrystalline dual-phase alloy Ti-6Al-2Sn-5Cr-2Mo (Ti-6242) to improve its superplastic properties. The microstructural mechanical properties of the different phases were characterized through in-situ thermomechanical experiments performed at various temperatures using High Energy X-ray Diffraction (HEXRD). This technique enabled real-time monitoring of microstructural evolution in addition to macroscopic mechanical behavior. The local heterogeneity of the material, in terms of microstructural length scale, is discussed. A crystal plasticity model coupled with various homogenization techniques was implemented to account for local grain rotation and deformation. This work highlights the contribution of microstructural characterization on the accuracy of numerical models and as well the capacity of the constitutive model to predict superplasticity in Ti-6242 alloy.

Multiscale Modeling of Creep Deformation in 30CrMoNiV11-5 Steel: Integrating Mean-Field Theory, Dislocation Dynamics, and Experimental Validation

Dr. Fan Chen, Belgium

Oral Presentation (20')

Abstract

30CrMoNiV11-5 is a high-strength, low-alloy steel recognized for its excellent mechanical properties, including high tensile strength, toughness, and good fatigue resistance. This material is widely used in demanding applications, such as aerospace components, where durability and reliability are essential. Its composition—comprising chromium, molybdenum, nickel, and vanadium—enhances its performance under extreme conditions, making it a preferred choice for industries requiring materials capable of withstanding high stress and harsh environments. However, prolonged exposure to high temperatures and stresses results in creep deformation, that accumulates over time. Accurately predicting the creep behavior of 30CrMoNiV11-5 is therefore of paramount importance.

The existing literature on the creep behavior of 30CrMoNiV11-5 includes studies utilizing machine learning techniques to predict creep rupture time, tensile mechanical properties, and microstructural evolution. These studies rely on reliable datasets derived from experimental measurements or numerical simulations. However, experimental creep tests are inherently time-consuming, often requiring several years to complete. While numerical simulations provide an efficient means of creep deformation and rupture predictions, they present significant challenges due to the complex microstructural evolution of the material under high stress and temperature conditions. To address these challenges, we applied a Mean-Field Creep (MFC) model for creep analysis. Based on Ghoniem's modeling framework and further developed by F. Riedlsperger, it integrates dislocation dynamics with a mean-field methodology to describe creep phenomenon. The MFC model simplifies the complexity of dislocation interactions by averaging their collective behavior and tracking the evolution of dislocation density over time. Central to this approach is the modified Orowan equation, which relates the creep strain rate to dislocation density, Burgers vector, and dislocation velocity. This framework links microscale dislocation behavior to macroscale material performance. To enhance the accuracy of predictions in the tertiary stage of creep, we incorporated the damage evolution equation from the phenomenological elasto-visco-plastic creep law developed by Morch (ULiege PhD 2022).

Given the limited availability of experimental data for parameter identification of the MFC model and its validation, we conducted a series of standard creep tests (SCT) to extract creep curves at various stress and temperature levels. The microstructure states at different material stages, is a key feature for the MFC model too and it was characterized. This experimental campaign validates the MFC model, enabling more reliable predictions of the long-term creep behavior of 30CrMoNiV11-5 under operational conditions.

Paper 2034 5 Delineating thin-film microstructure contributions during ultrafast laser irradiation using atomistic simulations
Dr. Hariprasath Ganesan, Germany
Oral Presentation (20')

Abstract

Atomic and close-to-atomic scale manufacturing demand progress underpinned by enhanced precision and optimization of laser-controlled nanostructuring. Depositing a high-energy laser beam on metallic film results in microstructure changes that invalidate the laser process parameters and influence how the laser beam interacts with the target material, costing numerous energy and time-consuming trial and error experiments. To this end, capturing thin films' crystallographic orientations and microstructure effects becomes crucial for optimizing the laser-metallic thin film interactions; however, these effects remain largely unexplored at the atomic scale. We combined two temperature model and molecular dynamics to simulate ultrafast laser-metal interactions for gold thin films with varying crystallographic orientations and microstructure configurations. Additionally, the effects of underlying silica substrate and chromium adhesion layers were also investigated using experimentally validated material and laser parameters to include the effects of interfaces. Our simulations revealed that microstructure features, namely grain size, grain topology, and local crystallographic orientation, controlled the rate and extent of lattice disorder evolution and phase transformation, particularly at lower applied fluences. We obtained comprehensive insights encompassing both the nanomechanical and thermodynamic aspects of ultrafast laser-metal interactions at atomic resolution. These insights reveal that microstructure-aware/informed thin film fabrication and targeted defect engineering could improve the precision of nanoscale laser processing and potentially emerge as an energy-efficient optimization strategy.

Paper 1688 1 **Unsupervised learning of nanoindentation data of complex materials**

Prof. Ruth Schwaiger, Germany

Highlight (Oral Presentation 20')

Abstract

Nanoindentation is a key technique for characterizing the mechanical properties of materials at small length scales, providing high-resolution measurements of hardness and elastic modulus. While traditional approaches average results over a limited number of tests, statistical nanoindentation captures property distributions, revealing microstructural heterogeneity. Recent advancements in machine learning have further improved the analysis of large nanoindentation datasets.

In this study, Cu-Cr composites with controlled heterogeneity were used to assess the effectiveness of statistical nanoindentation in detecting mechanical property variations. Hundreds of nanoindentation measurements were performed across large sample areas to evaluate Young's modulus and hardness at varying indentation depths. To analyze the data, we applied the Gaussian mixture model (GMM), an unsupervised learning technique, to deconvolute mechanical property distributions and identify distinct mechanical phases within the composite.

A major challenge in statistical nanoindentation is determining the minimum dataset size needed for reliable predictions. To address this, we used a cross-validation approach to systematically assess how dataset size affects statistical reliability. By monitoring the convergence of mechanical property distributions, we identified the required number of indentations for meaningful results.

Our findings demonstrate the importance of data quantity and advanced analysis techniques in nanoindentation studies. The use of GMM enhances the interpretation of mechanical property distributions, offering a robust framework for characterizing multiphase materials. This work underscores the potential of machine learning in nanoindentation and provides insights into data sufficiency for reliable materials characterization.

Paper 745 2 Accelerated discovery of novel materials: The need for high-throughput analysis of crystal structure, chemical composition, mechanical and functional properties integrated into a single instrument combined with machine learning
Prof. Johann Michler, Switzerland
Oral Presentation (20')

Abstract

Combinatorial synthesis methods such as co-deposition of thin-film material libraries enables high-throughput and cost-effective discovery of novel materials. While synthesis is done typically in hours, a comprehensive chemical and microstructure characterization of the library can take several months in a typical lab environment. In this work we've developed the long missing companion technique for rapid materials screening: A high-throughput characterization instrument that combines automated mapping of chemical composition, phase analysis, as well as mechanical, optical and electric property mapping. The novel instrument integrates X-ray diffraction (XRD), X-ray fluorescence (XRF), nanoindentation (NI), optical (LM), and electrical 4-point probing (4P) into a single stand-alone, automated system with a total footprint of 2m². Typical screening experiments consist of 500 measurement positions covering an entire 4" wafer; with a typical duration of 15 hours for XRD, XRF, NI, 4P and LM measurements that result in a comprehensive database on each of these 500 points. We will present an overview and detailed analysis of this database exploiting smart evaluation algorithms. These include correlation to open-access database of materials properties such as the "Materials Project" based on calculations using Density Functional Theory (DFT) as well as advanced machine learning algorithms to improve predictive models for material properties.

As a first case study we investigated the mechanical properties of thin film combinatorial material libraries of the CuAgZr metallic glass system. Our findings indicate that the presence of high oxygen levels in Cu-rich areas, resulting from post-deposition oxidation in regions of less dense packing, markedly influences the mechanical performance of these alloys. Additionally, our research uncovers that nanoscale structural nuances play a significant role in determining the plastic yield and flow behavior of the alloys. Among various machine learning models evaluated, the multi-layer perceptron algorithm excelled, delivering accurate predictions of hardness for alloys not previously tested, thereby offering insightful directions for ongoing material research.

Paper 1633 3 Identification of material parameters by analyzing indentation test data using neural networks

Mr. Sebastian Knorr, Deutschland

Highlight (Oral Presentation 20')

Abstract

The determination of the stress-strain curves of materials as well as the corresponding material parameters Young's modulus, yield strength, tensile strength and strain hardening exponents is an essential part during the design and calculation of components under applied loads. However, the accuracy is significantly limited by the applied material model, the accuracy of the associated material parameters and the used measurement method. If more detailed metallic properties are to be represented, such as isotropic and kinematic hardening as well as creep, more complex material models are required. This is even more difficult if the measurements have to be non-destructive and therefore no standard specimens made from existing components are available.

Therefore, as part of the "SEEKI" research project involving the partners ASMEC, ICAMS, IKTS and SENGICON, indentation tests with spherical indenters are used to generate the measurement data. In order to ensure the sensitivity of the material parameters with regard to the experiments, not only force-displacement curves but also time-dependent curves and indentation profiles are obtained and used for identification. Furthermore, the data is normalized according to the sphere diameter. In this way, the application of the method is independent from the indenter size after possible size effects are ruled out.

In order to avoid the high computational cost of the necessary, time-consuming FE simulations for the numerical parameter identification, these were replaced by a machine learning algorithm, specifically a neural network. This is realized by training such a neural network using FE simulations of indentation tests as training data. It is then possible to predict the required force-displacement curves and indentation profiles in way less time during the identification process itself. Consequently, the restriction on gradient methods for minimizing the function value determinations is no longer necessary, and other robust methods, such as genetic algorithms, can now be used effectively.

It is shown that with the appropriate optimization of the hyperparameters within the neural network, the accuracy of reproducing the FE simulation results is remarkably high and therefore suitable for practical use. The reduction of the time required for a complete parameter identification process from several hours or even days to just a few minutes also makes the approach attractive for mobile applications. Therefore, a mobile measurement head is developed within the project, which, in combination with the new identification approach, allows the direct identification of the material parameters in field use.

Paper 1580 4 Multi scale micromechanical testing for new Polymer Core Solder Ball (PCSB) interconnections reliability in operating conditions

Dr. Yvan Marthouret, France

Oral Presentation (20')

Abstract

Microelectronics manufacturers are in constant research of optimization of their processes and materials in order to miniaturize further, increase reliability and comply to European directives.

New solders balls are proposed for BGA (Ball Grid Array) interconnections [1,2]. These Polymer Core Solder Balls (PCSB) are made of polymers coated by several metallic layers obtained by electroless plating. They are brazed on circuit boards with a lead-free alloy to attach microelectronics components. The ball/braze system is studied to assess its reliability and gather accurate input for numerical modelling. A multi-scale analysis is performed on the PCSB to understand their mechanical behaviour at the ball/braze system level and characterize the materials at the layer level.

Indeed, the metallic layers exhibit different microstructures and mechanical properties than their bulk macro-scale counterparts. Micromechanical tests (micro pillar compression and nanoindentation) are made on Cu and Ni coatings. This micro-scale characterization of mechanical properties such as Young's modulus and yielding stress enables the numerical simulation of the PCSB and clearly shows the difference with results obtained with bulk material properties [3]. The study is now focused on the lead free brazing alloy (SAC fo Sn, Ag, Cu). Nanoindentation mapping is used to monitor the homogeneity of its mechanical properties.

Then, the ball and its braze make a complex system which is studied as a whole at mesoscopic level. Simple compression of PCSB validated the initial approach in [3] but the system undergoes vibrations and repeated stress in operating conditions. Cycling compression tests are thus carried out on soldered balls with a flat punch on a nanoindentation apparatus. They help understand the ball/braze system answer to fatigue and hopefully forecast potential failures. Subsequent numerical simulation of these tests should provide insight on mechanical phenomenon at stake.

Finally, the operating conditions exhibit temperatures from -40°C to 100°C. Hence, the results of aforementioned tests should be checked at different temperatures to provide accurate input to numerical models.

Plasticity beyond Fundamental Building Blocks: A Case Study of Sm-Co Intermetallics

Dr. Nisa Ulumuddin, Germany

Oral Presentation (20')

Abstract

Intermetallic materials often consist of structurally related phases, as complex crystal structures contain repetitions of fundamental building blocks. In this study, SmCo₂ and SmCo₅ are investigated as the building blocks of SmCo₃ and Sm₂Co₁₇. The activated slip systems in these phases were examined using slip trace analysis, micropillar compression and Density Functional Theory (DFT). It was initially hypothesized that SmCo₃ would follow the lowest-energy slip pathway observed in SmCo₂ and SmCo₅. However, our results suggest that the stacking of the SmCo₂ and SmCo₅ units alters the electronic bonding between interatomic layers, thereby modifying the most favorable slip system. Additionally, the activation of non-basal slip systems is significantly restricted in SmCo₃ and Sm₂Co₁₇, limiting their contribution to plastic deformation. Further analysis using DFT revealed deviations from simple shearing in non-basal slip pathways. Bonding analyses were performed to elucidate the underlying factors influencing slip behavior. Ultimately, our work builds a connection between complex intermetallic phases and their structurally related building blocks by characterizing their slip mechanisms and correlative bonding properties.

Nanoindentation and Defect Dynamics in Irradiated Fcc NixFe1-x Alloys: Insights from Experiments and Atomistic Modeling

Dr. Francisco Javier Dominguez Gutierrez, Poland

Oral Presentation (20')

Abstract

Fcc NixFe1-x single-crystal alloys are key model systems for studying defect evolution under self-ion irradiation at room temperature, with fluences ranging from 4×10^{13} to 2×10^{15} ions/cm² [1,2]. This study investigates the effects of irradiation-induced defects on the nanomechanical response of NiFe alloys through a combination of experimentally guided nanoindentation and atomistic simulations. Defects in the irradiated materials were characterized using transmission electron microscopy (TEM), providing essential input for molecular dynamics simulations of overlapping collision cascades to prepare irradiated samples at various doses [3].

The simulations revealed mechanisms of defect formation and evolution, including the emergence of an A15 Frank-Kasper phase within the {111} plane in pure Ni, Ni_{0.88}Fe_{0.12}, and Ni_{0.77}Fe_{0.23} at fluences up to 2×10^{14} ions/cm², serving as a precursor to Frank loop nucleation. The findings also highlight the critical role of Fe atoms in influencing dislocation nucleation and evolution. In Ni_{0.77}Fe_{0.23}, compact 3D precipitates heavily decorated with Fe atoms were observed. However, these precipitates remained too small to evolve into Frank loops, even at elevated fluences.

Nanoindentation experiments and simulations demonstrated a notable increase in hardness in irradiated alloys compared to their pristine counterparts [4,5]. From the atomistic modeling, we provide detailed analyses of the irradiated samples revealed surface morphologies, dislocation densities, and strain mappings to discuss the mechanisms of dislocation pinning during mechanical loading due to irradiation-induced defects. These defects were found to obstruct dislocation motion, contributing to the enhanced hardness of the material.

Overall, this study provides critical insights into the interplay between composition, irradiation-induced defect structures, and their mechanical consequences in NixFe1-x alloys. These findings enhance our understanding of the mechanisms underpinning radiation resistance in these materials, supporting their potential applications in radiation-intensive environments.

Paper 1686 1 Micro scale fracture and fatigue of electrolytes for solid state lithium ion batteries

Prof. David Armstrong, United Kingdom

Highlight (Oral Presentation 20')

Abstract

An all-solid-state battery would revolutionise the electric vehicles of the future. The successful implementation of an alkali metal negative electrode and the replacement of the flammable organic liquid electrolytes, currently used in Li-ion batteries, with a solid would increase the range of the battery, reduce recharging time and address the safety concerns. Current efforts to commercialise such batteries worldwide are failing and will continue to fail until we understand the fundamental failure processes taking place in these devices, which are inherently driven by mechanical failure on the nano- and micro-scale. In this talk I will show our development of both testing methodologies and understanding of materials behavior in key materials for solid state batteries. This will focus on micro scale fracture testing of oxide and halide ceramics for use as solid state electrolytes. We will show indentation fracture toughness measurements and in situ microcantilever fracture testing. This is performed on LLZO, Li6PS5Cl and Li6PS5Cl based composite solid electrolytes under a range of processing conditions to show the often understated (in the battery community) effect of processing on battery performance. Micro cantilever fatigue testing results will then be shown showing the S-N curve behaviour of the same materials out to thousands of cycles. The implications of these results for future battery design will be discussed.

Investigating humidity-driven variations in fracture toughness of alumina using microcantilever testing and Gaussian regression approach

Mrs. Martina Birocco, Switzerland

Oral Presentation (20')

Abstract

Slow crack growth (SCG) is a critical phenomenon in ceramics, caused by stress-dependent cleavage at the crack tip and enhanced by the interaction of environmental humidity with atomic bonds at the fracture site. This causes cracks to propagate slowly over time, even under stress levels below the material's nominal strength, often resulting in catastrophic failure. Understanding SCG is essential for ensuring the long-term reliability of ceramic materials.

Although extensively studied in macroscopic specimens, this phenomenon has only recently been investigated at the microscopic scale. While recent microscale studies have provided some insights, they remain limited in the range of environmental conditions tested.

This study aims to investigate the fracture toughness of monocrystalline and polycrystalline alumina under varying environmental humidity conditions and to develop a comprehensive model of its performance across these conditions.

Stress intensity factors (K) are measured in laser-ablated and focused ion beam (FIB)-milled bridge-notched microcantilevers and micropillars using a nanoindenter that provides precise control over a broad range of humidity levels. Finite Element Method (FEM) simulations are conducted to explore the mechanisms of SCG in microcantilevers. A Gaussian regression process (GRP) is employed to optimize the experimental design and quantitatively modeling the relationship between stress intensity factors and environmental humidity.

The combination of laser ablation and FIB milling has proven to be an effective method for rapidly and precisely producing a large number of samples, enabling extensive testing and enhancing statistical robustness. Preliminary results obtained applying the GRP on previously reported data ($K=3.5$ MPa $m^{1/2}$ in vacuum, $K=1.5$ MPa $m^{1/2}$ in air, $K=0.9$ MPa $m^{1/2}$ in water) reveal a non-linear decrease in fracture toughness with increasing humidity. While earlier studies assumed a linear trend, GRP indicates a steeper decline at lower humidity levels, stabilizing around 75% of relative humidity. This behavior is likely due to the saturation of water molecules interacting with atomic bonds at the crack tip, where K is reduced by moisture-assisted SCG.

This study presents a novel integrated approach for analyzing fracture toughness at the microscale under varying environmental conditions. The method enhances accuracy in characterizing fracture behavior across a broader range of humidity levels than previously studied and significantly accelerates the testing process compared to conventional techniques. This approach offers a new framework for future investigations into the environmental effects on fracture mechanics and SCG across a wide range of materials.

Paper 1575 3 **Impurities Affecting Grain Boundary Cohesion in Nanostructured Tungsten: A Micromechanical Study**
Mr. Julius Keckes, Austria
Oral Presentation (20')

Abstract

The exceptional properties of tungsten, including its high melting point, low vapor pressure, and outstanding high-temperature strength, make it a prime candidate for plasma-facing components in fusion reactors. However, its application is limited by inherent brittleness and sensitivity to impurities, particularly at grain boundaries. While grain refinement to ultrafine- and nanocrystalline regimes substantially increases strength and improves helium swelling behavior, these fine microstructures exhibit predominantly intercrystalline fracture, indicating that grain boundaries are the weakest microstructural link. Consequently, modifications to grain boundary cohesion significantly impact material strength. This study investigates the influence of a DFT (density functional theory) informed element selection at grain boundaries on the mechanical properties of ultrafine-grained tungsten. Ultrafine-grained and nanocrystalline tungsten was synthesized containing elements predicted to strongly segregate at grain boundaries and affect grain boundary cohesion. Specimens were manufactured through multiple processing routes, including spark-plasma sintering, high-pressure torsion (HPT), and thin film sputter deposition. Due to the fine microstructure and limited material volume, mechanical properties were characterized using small-scale testing techniques. In-situ microcantilever bending experiments were conducted, enabling straightforward specimen preparation via focused ion beam, while allowing tensile loading of the material to probe grain boundary cohesion. Results demonstrate a correlation between the content of doping elements and the mechanical response, revealing the profound impact of impurities at tungsten grain boundaries. This study advances the understanding of structure-property relationships critical for developing more damage-tolerant tungsten components for the extreme conditions in future fusion reactors.

Oral Presentation (20')

Abstract

Traditional methods for determining the brittle-to-ductile transition temperature (BDTT), such as Charpy impact testing, require multiple samples and involve costly preparation. To overcome these challenges, we developed an innovative approach using nanoindentation with continuous stiffness measurement (CSM). This technique allows for the evaluation of the stiffness ratio, i.e. the ratio between the loading slope and the unloading stiffness, during a single indentation test. Since loading involves both elastic and plastic deformation while unloading is purely elastic, this ratio provides valuable insights into the relative fractions of plastic and elastic deformation. Previous studies have used similar methods to assess constraint factors and derive flow curves via spherical indentation. In this study, we extended the approach by conducting nanoindentation experiments across the temperature range from -150°C to 25°C . Our results show that the stiffness ratio of an austenitic alloy remains nearly constant across this temperature range, whereas a ferritic alloy exhibits a pronounced increase at lower temperatures. This trend indicates a shift toward more elastic deformation, consistent with the expected brittle-to-ductile transition. A key advantage of our method is its robustness against thermal drift, a common challenge in non-ambient nanoindentation testing. As a result, it ensures highly reliable measurements with minimal stabilization time. In summary, our approach provides a cost-effective and efficient alternative to conventional BDTT testing. Future work will focus on refining the transition temperature estimation by applying this method to a broader range of materials.

Slide-Ring Materials for Circular Economy

Prof. Kohzo Ito, Japan

Keynote (Oral Presentation 40')

Abstract

We have developed the SR materials with polyrotaxane (PR), in which polymer chains are topologically interlocked by figure-of-eight cross-links. 1) SR materials show active and smart multi-functional properties responsive to various external stimuli. Recently, we have reported the stretch induced crystallization of the SR gel, which leads to extremely high toughness and recoverability. 2) When the SR gel is largely stretched, the movable crosslinks uncover and orient PEG axis chains, followed by the stretch induced crystallization of PEG chains: PEG chains drastically change the structure from amorphous to crystal. The nano-size PEG crystals prevent SR gels from fracture and yields the extremely high toughness.

On the other hand, we have found that PR drastically improved the mechanical properties, self-healing, chemical decomposition, and marine biodegradability of vitrimers. 3) The optimal epoxy resin vitrimer incorporated with PR exhibited enhanced toughness, with an elongation at break 5.3 times greater than that of a vitrimer devoid of PR; it also showed self-healing properties, was chemically recycled 10 times faster, and was recovered twice as fast. These results are ascribable to the sliding diffusion motion of the PR, which lowers the energy required for transesterification. Furthermore, vitrimer-containing PR showed 25 wt.% biodegradation following exposure to seawater for 30 d. These findings may lead to the development of environment-friendly plastics that exhibit most of the properties required for a circular economy.

Paper 644 **2** **Highly dispersed iron sites on silica nanoparticles as sustainable curing activator for elastomeric nanocomposites**
Mr. Lorenzo Alberti, Italy
Oral Presentation (20')

Abstract

Rubber vulcanization is a key process for crosslinking rubber polymers by polysulfide chains and producing nanocomposites with high mechanical properties for many applications, e.g., tyres. The industrial vulcanization process commonly employs ZnO as curing activator; however, its low affinity for rubber requires a high consumption, causing possible environmental concerns due to zinc leaching from the final material. This work proposes Fe@SiO₂, featuring Fe(III) sites on silane-functionalized SiO₂ nanoparticles, as a sustainable alternative to ZnO. Fe@SiO₂ is a double-function filler as SiO₂ nanoparticles act simultaneously as substrate for single-site iron activator and as reinforcing agent for the rubber nanocomposite.

Fe@SiO₂ was produced through a two-step synthesis: i) SiO₂ nanoparticles were functionalized with (3-aminopropyl)triethoxysilane in toluene; ii) functionalized SiO₂ was dispersed in a Fe(III) salt containing ethanol solution, to anchor Fe(III) on the surface. Fe@SiO₂ activators with amount of Fe(III) ranging from 0.25% to 5.5% were prepared. Fe@SiO₂ was characterized through a multi-technique approach. First, the presence of Fe on silica surface was confirmed by mapping in Scanning Electron Microscopy (SEM-EDX). Besides, Electron paramagnetic resonance (EPR) showed signals at g~4.3 and at g~2.0, corresponding to isolated Fe(III) centers and coupled Fe(III) centers, respectively. The latter is likely due to electrostatic or chemical interactions, e.g., oxygen bridging, and becomes predominant when Fe loading is increased.

Fe@SiO₂ was tested as vulcanization activator in isoprene rubber (IR) nanocomposites, prepared in a Brabender mixer and cured at 170°C. Dynamic mechanical tests were performed in a Rubber Process Analyzer (RPA). Generally, Fe@SiO₂ exhibited a faster kinetics and a more efficient vulcanization process respect to ZnO, with equal amount of Fe and Zn, while maintaining comparable reinforcement and mechanical properties. Fast kinetics is likely a consequence of the immediate availability of Fe(III) centers on silica surface to react with curatives. In fact, both the effective interaction of the surface Fe(III) centers with sulfur and curatives, as well as their stability during the curing reaction, were confirmed by studying Fe@SiO₂ by XPS in a Model Compound Vulcanization. No difference in reactivity was detected between isolated and coupled Fe species, as RPA tests demonstrated that vulcanization performances depend solely on the total amount of Fe.

Concluding, the activator Fe@SiO₂ was characterized in its structure and reactivity, showing high availability of the active center, good interaction with the curatives, outperforming ZnO in terms of vulcanization degree, and therefore demonstrating to be a valid and sustainable alternative to ZnO for rubber vulcanization.

Paper 1895 1 **Precise control over nanocomposite mechanics via polymer branching and grafting**

Mr. Andrea Giuntoli, The Netherlands

Keynote (Oral Presentation 40')

Abstract

Novel developments in polymer synthesis have allowed in recent years precise control over polymer branching and grafting, techniques that can be used to control the nanoscale structure and dynamics of new polymer-based nanomaterials. This includes a wide variety of materials such as grafted nanoparticles, thin films, composites for applications such as protective coatings, adhesives, membranes, and many more.

Theoretical and computational investigations in this field allow for a great level of control and insight into the nanoscale structures formed from different building blocks often inaccessible to experiments, guiding predictions of structure-property relationships and rational material design.

I will broadly discuss recent advancements in this area and the key principles behind them, and I will then focus on our contribution, particularly in manipulating the glass transition behavior and mechanical response of bulks and thin films using star polymers, polymer-grafted nanoparticles, or polymer-grafted graphene sheets. I will show that polymer grafting offers a unique avenue to control the dispersion, local dynamics and gradients in mechanical properties around nanofillers.

Nanoscale Strengthening and Toughening of Polymers

Prof. Hungjue Sue, United States

Highlight (Oral Presentation 20')

Abstract

Strong and tough polymers are always highly desirable for engineering structural applications. However, many well-established approaches for polymer toughening and strengthening are usually accompanied by unwanted compromises in other properties, such as drops in T_g and modulus, poorer processability, and inadequate low temperature performance. The emergence of nanotechnology has led to attempt to develop novel strong and tough polymers through incorporation of nanoparticle tougheners. In many cases, incorporation of nanoparticles does not show benefit over the micro-sized. Fundamental knowledge on nanoscale phenomena of polymer toughening and strengthening is still lacking. In this talk, a few intriguing examples of nanoscale phenomena that show great benefits in toughening and strengthening of polymers are presented. Issues regarding the preparation of strong and tough polymers will be discussed.

Paper 1803 3 Identification and evaluation of interphase properties of polymer nanocomposites based on a multiscale approach
Dr. Sebastian Pfaller, Germany
Oral Presentation (20')

Abstract

It is known from experiments that adding nano-sized filler particles to polymers shows a pronounced strengthening of the material compared to larger filler sizes. To understand the mechanisms behind this observation, simulations can supplement experimental studies and provide insights into the processes taking place at time and length scales hardly accessible by experiments. In addition, numerical techniques may help to develop targeted strategies to improve the material performance and reduce the effort and cost for material development. In this regard, numerical models of high precision are required that can appropriately capture the processes of relevance.

This contribution presents a numerical methodology based on the Capriccio method, which integrates molecular dynamics and finite element simulations in a multiscale framework. In this approach, the elementary interactions between atoms form the foundation to eventually obtain matrix-filler interphase profiles, which can be used for higher level investigations based on continuum techniques. In our approach, we first characterise the material behaviour separately for the neat polymer and the filler particles using pure molecular dynamics. To this end, we perform numerical “pseudo” experiments to obtain the material properties and to set up appropriate constitutive relations. In the next step, we numerically manufacture nanocomposite samples at purely molecular resolution together with their finite element counterparts exhibiting the same nanoparticle arrangement. From an inverse parameter identification, we extract spatial profiles of the material properties changing throughout the interphase.

Eventually, we use these interphase profiles to set up simulations at the level of representative volume elements and compare the overall material behaviour to that obtained in experiments. Together with subsequent parameter studies, we demonstrate that our methodology is able to reproduce trends observable in reality based only on the elementary interactions between atoms. Hence, it provides a suitable mean to link the material behaviour at the nanoscale to the resulting macroscopic properties. As such, it paves the way to targeted material development which integrates experiments and simulations across a wide range of scales.

Paper 1058 4 **Non linear mechanical and thermal properties of polymer nanocomposites : an atomistic point of view**
Dr. Samy Merabia, France
Highlight (Oral Presentation 20')

Abstract

The first part of the talk will be devoted to the modelling of the non linear mechanical properties of polymer nanocomposites (PNCs). One of the most studied phenomenon is the so-called Payne effect, a drop in storage modulus with increasing amplitude, which occurs for deformation amplitude as low as a few percent. Several mechanisms have been put forward to rationalize such effect, including filler network breaking, polymer chain desorption and yielding of the polymer confined between the nanofillers [1]. In this contribution, we demonstrate that for PNCs involving fractal-like aggregates, the Payne effect may originate from the shear-induced alignment of the aggregates. We reach this conclusion by using a coarse-grained model, which combines an explicit representation of fillers with an implicit description of the polymer matrix [2]. We systematically characterize the effects of aggregate size and polydispersity in the amplitude of the Payne effect [3]. Moreover, we probe the mechanical response of the model PNCs after a first cycle of deformation. We observe slow recovery kinetics of the original storage modulus of the PNCs and relate this memory effect to the alignment of the aggregates. Our findings should contribute to clarify the relation between the macroscopic mechanical response of the PNCs and the mesoscopic state of the filler.

The second part of the talk will be devoted to the thermal transport properties of polymer nanocomposites. Polymeric materials generally display relatively low thermal conductivity, which restricts their use in microelectronics and more generally in thermal management applications. Dispersing conductive nanoparticles in a polymeric material is a common strategy to enhance the thermal conductivity of the nanocomposite, but the resulting conductivity hardly increases due to the existence of a thermal resistance at the interface between the nanofiller and the matrix. Here we investigate the thermal transport properties of grafted silica based polystyrene nanocomposites using non-equilibrium molecular dynamics simulations. We first show that grafting silica with polystyrene chains reduces significantly the thermal resistance between at the nanoparticle/matrix interface. We further demonstrate that this reduced resistance helps increase the total conductivity of the nanocomposite and discuss the effect of the silica nanoparticle diameter.

Paper 972 **5** **Some recent progress on filler structure and interfacial layer dynamics of polymer nanocomposites**

Prof. Julian Oberdisse, France

Highlight (Oral Presentation 20')

Abstract

The macroscopic properties of polymer nanocomposites (PNCs) depend in a crucial way on the microscopic state of the filler nanoparticles (NPs) and the polymer. In particular mechanical properties are strongly affected by percolation of hard phases, which may be NP networks, or dynamically modified (i.e. hardened) polymer regions. In this talk, we will review some recent progress in small-angle scattering associated with simulations to study nanoparticle dispersions, and broadband dielectric spectroscopy (BDS) to investigate polymer dynamics at the NP interface.

Nanoparticles used in industrial applications may be very polydisperse, and form agglomerates of complex geometry. The conceptual difficulty of their analysis goes hand in hand with their superior performances. We will present one of the first self-consistent models of their structure based on a combination of electron microscopy with scattering [1]. We did not realize it back then, but this approach was the first based on a correlation hole analysis [2], which is a measure of the strength of interaction between particles or small aggregates, and thus the local concentration. In collaboration with Vera Bocharova and Alexei Sokolov [3,4], we then moved to an in-depth characterization of the dynamic state of the polymer using BDS in strongly attractive model systems. Here the combination of structural analysis based on scattering, with a careful look on interparticle distances, with BDS turned out to allow for a better quantitative determination of the thickness of the interfacial layer. The experimental system under scrutiny is a surface-modified PNC (C8 or C18 silane grafting), where the NP structure and the interfacial layer dynamics can be followed simultaneously as a function of grafting density and particle content. The strongest dynamical slow-down in the polymer is found for unmodified NPs, while grafting weakens this effect progressively. The combination of all three techniques enables a unique measurement of the true thickness of the interfacial layer, which is ca. 5 nm. Finally, the comparison between longer (C18) and shorter (C8) grafts provides unprecedented insight into the efficacy and tunability of surface modification. It is shown that C8-grafting allows for a more progressive tuning, which goes beyond a pure mass effect.

Dispersion and Self-assembly of Nanoparticles in Polymers for Multifunctional Applications

Prof. Hungjue Sue, United States

Oral Presentation (20')

Abstract

Challenge to commercial implementation of many nanotechnology-inspired products are the lacking of robust approaches to decorate, disperse, and assemble nanoparticles in polymer matrices for specific targeted applications. To achieve desirable multi-functional properties, it is necessary to successfully manipulate nanoparticle dispersion and assembly in polymer matrices without compromising intrinsic nanoparticle properties and their intended purposes. In this talk, several successful examples of approaches in achieving dispersion and assembly of nanoparticles in polymer matrices for desired functionalities and mechanical properties are presented. These examples include dispersion and self-assembly of α -zirconium phosphate (ZrP) in epoxy, dispersion of carbon nanotubes in epoxy, and dispersion of ZnO quantum dots in epoxy. Fundamental principles responsible for manipulation of nanoparticle dispersion and assembly are described. Usefulness of the above research for functional and structural applications, especially for electrical conductivity and barrier properties, is also discussed.

Internal Structure and Cycling Performance of Atomized Silicon Composite Anodes for Lithium-Ion Batteries

Mr. JunHui Han, South Korea

Poster Presentation

Abstract

Silicon is a promising anode material for high-energy-density lithium-ion batteries due to its high theoretical capacity. However, its practical application is hindered by significant volume expansion during charge-discharge cycles, leading to mechanical degradation and capacity fading. To address this challenge, we synthesized multicomponent silicon composite powders using gas atomization. These powders were primarily composed of silicon, aluminum, copper, nickel, and boron, with tailored composition ratios designed to optimize their internal structure and electrochemical cycling stability. This study discusses how the internal structure of each powder, influenced by differing compositions and manufacturing process conditions, affects their initial specific capacity and capacity retention over 35 cycles. It further explores the relationship between the internal structure and electrochemical cycling stability, tested in coin cells using lithium metal as the counter electrode and an electrolyte containing LiPF₆, with formation and cycling conducted in a voltage range of 0.005–1.5 V vs. Li/Li⁺.

Focused Ion Beam (FIB) milling at 300 nm intervals, combined with Energy-Dispersive Spectroscopy (EDS), was employed to characterize the internal structure and composition of the powders with a diameter of 2 μm. The cross-sectional structure of the multicomponent silicon powder consists of discrete silicon-rich regions of approximately a few hundred nanometers embedded within a continuous silicide matrix. The volume fraction of silicon within this matrix was quantitatively assessed. Additionally, cross-sectional nanoindentation tests were conducted to evaluate the mechanical properties of each powder and their relationship to structural features.

Results indicated that powders with higher silicon volume fractions exhibited greater initial specific capacity. However, powders with higher nano-hardness exhibited lower capacity retention after 35 cycles. This phenomenon is attributed to the lack of deformation capability of the silicide matrix in high-hardness powders, which hinders its ability to buffer the volume changes of silicon during cycling. The silicide matrix likely acts as a mechanical buffer, mitigating the volume changes of silicon during charge-discharge cycles and enhancing the structural integrity of the composite. This study provides insights for further optimizing atomized multicomponent silicon composite anodes in next-generation LIBs, contributing to the development of durable and high-capacity silicon anodes for more efficient and reliable energy storage systems.

Machine Learning Assisted Dark Field X-Ray Microscopy Data Analysis

Mr. Abderrahmane Benhadjira, France

Poster Presentation

Abstract

Mapping dislocations is essential to understand the mechanical behaviour of crystalline materials, as they critically influence mechanical, electrical, magnetic, and optical properties. Dark Field X-ray Microscopy (DFXM) is a diffraction imaging technique that enables three-dimensional mapping of dislocations in millimetre-sized samples with a spatial resolution of 100 nm and superior angular resolution compared to Transmission Electron Microscopy (TEM). However, analysing DFXM datasets is data-intensive and requires significant supervision. Moreover, dynamical diffraction effect can influence reconstructed maps in thick crystals, rendering data interpretation difficult. To address these challenges, we propose a workflow using machine learning techniques to facilitate DFXM data analysis. Specifically, we introduce:

1. A data reduction approach based on labelling DFXM rocking curves to identify the weak beam condition for defect analysis, followed by dislocation segmentation.
 2. An artificial neural network coupled with geometrical optics simulations to predict the Burgers vector of the dislocations.
- This workflow offers an efficient, automated, and rapid approach for analyzing dislocations in DFXM data, achieving a data size reduction of 70%. Beyond its application to DFXM images, the methodology is versatile and can be implemented agnostically for X-ray topography and TEM, broadening its potential impact across various imaging modalities. These advancements pave the way for more streamlined and accessible analysis in crystallographic research.

Gas adsorption meets deep learning

Mr. Antonios Sarikas, Greece

Poster Presentation

Abstract

Metal-organic frameworks (MOFs) are promising materials for gas adsorption due to their ultra high porosity and surface area. However, their vast combinatorial space makes traditional material discovery methods inefficient. Recently, machine learning (ML) approaches have been proposed for large-scale screening of MOF databases but their efficacy rely heavily on hand-crafted features.

We propose a deep learning (DL) framework [1] for predicting gas adsorption properties of materials, using as one and only descriptor the potential energy surface (PES). The latter uniquely combines the structural properties and the electronic structure of a material in real space, rendering the proposed scheme applicable in any host-guest system for predicting any adsorption property of interest.

Furthermore, we have developed a generalized deep learning framework [2] that predicts gas adsorption properties from raw structural information using a point cloud representation of the material. Combining this simplified yet complete representation with DL, introduces a versatile paradigm for data-driven material science, bypassing the obstacles of manually crafted descriptors.

Our algorithms were tested for CO₂ adsorption in MOFs, outperforming conventional ML models in the literature, which rely on geometric descriptors. The proposed methodologies were further validated across different host-guest systems, demonstrating broad applicability in diverse materials and properties.

Advanced Microstructure Characterization to Decode Solidification and Phase Transformation Induced in Additively Manufactured Tool Steel

Dr. Nathalie Gey, France

Poster Presentation

Abstract

This investigation demonstrates the power of integrating cutting-edge characterization methodologies for comprehensive understanding of microstructure genesis in additively manufactured 33CrMoV12 tool steel [1]. Microstructure, microtexture, and chemical microsegregation of the as-built steel are explored through a multi-scale approach integrating X-ray diffraction (XRD), electron backscatter diffraction (EBSD) including parent austenite reconstruction [2], secondary ion mass spectrometry (nano-SIMS) [3], and a novel chemical analysis technique coupling backscattered electrons and X-rays within a scanning microscope (SEM-BEX) [4].

As expected, the as-built microstructure consists predominantly of a fine martensitic matrix; however, a surprisingly high fraction of retained austenite also remains (approximately 25%). A secondary structure is detected—superimposed on the primary matrix—comprising colonies of roughly cylindrical cells marked by strong intercellular segregation of C, Cr, Mo, and Mn. Characteristic of cellular solidification under high cooling rates, this microstructure has been frequently reported for metallic alloys with austenite matrix produced by AM (stainless steels, Ni-based alloys), but occurs much more rarely in steels undergoing subsequent solid-state transformations, and has never been observed in this grade.

EBSD analysis enables investigation of relationships between key microstructural features resulting from solidification: the parent austenitic structure, growth directions of segregated cellular colonies, and retained austenite preferentially localized between cells. Notably, the principal axes of solidification cells align with $\langle 100 \rangle$ directions of parent austenite grains reconstructed from final martensite orientation maps. This alignment suggests that steel solidification occurs entirely within the austenitic phase, contrary to the ferrite-then-austenite sequence predicted under equilibrium conditions. Non-equilibrium solidification calculations using the Gulliver-Scheil model enable quantitative correlation between the exceptionally high retained austenite content and chemical segregations that depress the M_s temperature in intercellular regions.

Hydrogen effects on the scratch-induced deformation of pearlitic steel

Dr. Kaili Feng, Germany

Poster Presentation

Abstract

Hydrogen-induced degradation presents a significant challenge to materials and infrastructure in the context of hydrogen energy utilization. Hydrogen embrittlement in steels arises from interactions between solute hydrogen atoms and microstructural features. During production, transportation, and assembly, steel components inevitably develop surface scratches, which can become areas sensitive to hydrogen embrittlement. Pearlitic steel displays excellent mechanical properties, like tribological properties, due to its lamellar structure composed of alternating layers of ductile ferrite and brittle cementite. In this work, micro-scratch tests were performed on a pearlitic steel using an in situ backside hydrogen charging setup assembled on a standalone nanoindentation instrument. This allowed for the examination of scratch behavior during electrochemical hydrogen charging. The interactions between hydrogen and scratch-induced deformation under different scratch directions, that is, parallel to cementite lamella, perpendicular to cementite lamella, and inclined with cementite lamella were studied. The deformation response of ferrite-cementite interface varied across these directions. This work contributed to the understanding of hydrogen-induced damage in materials.

Valorization of grape marc extract to develop active gelatin films

Prof. Pedro Guerrero, Spain

Poster Presentation

Abstract

The development of active films is essential for extending food shelf life, minimizing spoilage, and reducing food waste. In this context, a novel approach was explored to create gelatin-based active films using choline chloride and citric acid natural deep eutectic solvent (DES) to dissolve chitin (Chi), valorized from fruit fly pupae. Films were manufactured by compression molding, a processing method that can be easily scaled-up, and Chi/DES amounts were varied from 20 to 80 wt %. Resulting films were homogenous, showing no agglomeration and a compact structure, as observed by SEM analysis, providing good mechanical properties in terms of film resistance and flexibility due to the new interactions formed among the components of the film forming formulation, as provided by FTIR and DSC analyses. In particular, a notable decrease of α -helix/random coil and an increase of β -turn were observed in gelatin with the increase of Chi/DES, irrespective of the DES content. Moreover, the incorporation of high percentages of Chi/DES (> 40 wt %) caused a slight decrease of β -sheet. These variations of the secondary structure indicate the physical interactions between gelatin and Chi/DES, which modify the protein secondary structure and, consequently, the film properties. Since the films prepared with 40 wt % Chi/DES showed high UV protection and good mechanical performance for food packaging (tensile strength of 10 MPa and elongation at break of 31 %), these films were selected to prepare active films. In particular, to provide the films with antioxidant properties, red grape marc extract was incorporated into the film forming formulation. The incorporation of this extract not only maintained the mechanical properties of the films but also improved its barrier properties and created a network that promoted the sustained release of the extract. These bioactive-containing films demonstrated oxidation inhibition capacity and, thus, their potential to extend food shelf-life.

Overcoming the Strength-Ductility Trade-Off in FCC Metals: TWIP Effects in Cu-Al and Cu-Si Alloys

Mr. Mingyu Lee, South Korea

Poster Presentation

Abstract

The strength and ductility of metals are traditionally constrained by a trade-off relationship, governed by the dislocation mechanism that dominates plastic deformation in crystalline metals. Achieving high strength often necessitates suppressing the generation and movement of dislocations that contribute to ductility. This trade-off, however, can be mitigated by employing deformation twinning as a complementary strengthening and deformation mechanism. This concept is exemplified by TWIP steels, where deformation twinning in single-phase austenitic steels results in exceptional strength and ductility. Since the TWIP effect arises from deformation twinning behavior rather than intrinsic chemical composition, other FCC metals capable of deformation twinning hold potential for similar enhancements.

Building on recent insights into Cu-Al alloys [1], where deformation twinning supports plastic deformation, this study explores the potential of Cu-Si alloys. Silicon, a known reducer of copper's stacking fault energy (SFE), was incorporated to enhance twinning activity. Cu-Al and Cu-Si binary alloys were fabricated, including pure copper, Cu-8at% Al, Cu-16at% Al, Cu-2.2at% Si, Cu-4.4at% Si, and Cu-6.6at% Si, using vacuum arc melting. Following homogenization heat treatment, cold rolling, and annealing at 600°C for 30 minutes, the mechanical properties were assessed via tensile tests and microstructural analysis. Deformation behavior at low temperatures (−80°C) was also evaluated. Experimental results demonstrated that increasing alloying element content in both Cu-Al and Cu-Si alloys enhanced strength and elongation, confirming the TWIP effect. Notably, Cu-Si alloys exhibited greater improvements in strength and elongation compared to Cu-Al alloys under similar conditions. This is attributed to Si's superior ability to reduce copper's stacking fault energy, enabling more effective twinning. Additionally, work-hardening rates increased with strain in both alloys. Microstructural analysis revealed active deformation twin formation during plastic deformation, with the TWIP effect persisting at low temperatures.

These findings underscore the potential of Cu-Si alloys as high-performance TWIP materials, demonstrating their ability to achieve superior mechanical properties through optimized deformation mechanisms. This research contributes to advancing FCC metal applications by addressing the strength-ductility trade-off and enhancing understanding of microstructural evolution.

Electropulsing-Assisted Deep Drawing: Challenges and Key Results

Mrs. Angelika Cerny, Austria

Poster Presentation

Abstract

Electropulsing is an innovative approach for improving formability in sheet metal forming. Direct current pulses are employed to influence forming forces and improve material properties during forming, for example in deep drawing. The process holds significant potential for sustainable manufacturing, as it may reduce energy consumption compared to hot forming. However, despite the promising possibilities, electro-pulsing-assisted deep drawing faces significant technological challenges that need to be solved in order to achieve consistent and scalable results.

One of the biggest obstacles is ensuring effective electrical contact between the forming tools and the workpiece. Reliable contact is essential to deliver high current densities evenly across the forming area. Another significant hurdle is reaching the required current densities to produce a beneficial electroplastic effect. Precise control of the pulse parameters, including amplitude, frequency and duration, is key. These parameters must be optimized with regards to the material properties and the specific geometries of the forming process.

We developed an electrically assisted deep drawing setup, capable of delivering high-current pulses with amplitudes in the kiloampere range and millisecond-scale durations. Aluminum alloy EN AW-5083, known for its excellent corrosion resistance and moderate strength, was selected for the experiments. The selected geometry was successfully formed at different depths. The results show that pulsed electric currents significantly influence the forming forces compared to conventional methods. These improvements are attributed to local thermal and electroplastic effects.

Our research demonstrates the feasibility of electropulsing-assisted deep drawing. Future research will focus on further optimizing the process, scaling it up for industrial applications and investigating its feasibility for other materials.

Paper 1050

Multi-modal in-situ electron microscopy and spectroscopy of high-temperature structural evolution in phase-change and nanostructured materials

Dr. Daan Hein Alsem, United States

Poster Presentation

Abstract

Elevated temperature increases atomic mobility and promotes structural re-ordering kinetics, driving phase evolution, chemical reactions, atomic diffusion, and surface degradation processes. On-chip thin-film heating and temperature sensing technology for in-situ transmission electron microscopy (TEM) holder systems has enabled highly localized specimen heating, greatly improving heating time and sample stability during in-situ heating experiments investigating temperature-induced transformations. This has enabled rapid heating experiments up to over 1000°C with stable imaging and spectroscopic signal collection over timescales greater than 150 hours. Improvements to double-tilting mechanisms have allowed for minimized backlash and increased stability and orientation accuracy for imaging and diffraction of temperature-induced structural evolution.

In-situ heating experiments under TEM are presented for various nanoscale systems. Au nanoparticle surface rearrangement and sublimation at high temperature [1], Mo-W-Se 2D superlattice, heterostructure, and alloy evolution at high temperature [2], and Ge-Sb phase-change memory nanowire restructuring at intermediate temperature [3] are presented. This work highlights the use of in-situ ultrafast heating under TEM to gain crucial mechanistic insights into structural transformations in nanoscale and 2D materials.

Heating and biasing in both scanning electron microscope (SEM) and X-ray synchrotron systems using MEMS chips cross-compatible across all three platforms is now possible. The new multi-modal compatibilities allow correlation of microscopic and spectroscopic results across techniques and length scales, supporting investigations into mechanistic relationships between microstructure, chemistry, and temperature.

Paper 356

Impact of different types of fillers into the UV-ageing behavior of rotomolded PE composites

Dr. Zaida Ortega, Spain

Poster Presentation

Abstract

Composite samples were produced by rotational molding, using a polyethylene (PE) matrix and different proportions of mineral dust (ignimbrite) and lignocellulose fibers (Arundo donax L.). Ignimbrite is based on silica, with high proportions of alumina and iron oxides (60-65%, 18-20%, and 3-5 %, respectively) [1]. The interfacial interactions between the fillers and the polymers are critical for achieving optimal performance, including the lifetime of the composite when exposed to various environmental factors, including UV light [2]. A good interfacial adhesion contributes to distribute stress more evenly throughout the material, thereby reducing the likelihood of crack propagation and degradation.

While the integration of different types of fillers into PE-based composites is expected to yield improvements in mechanical, and thermal properties (for silica), the evidence specifically supporting significant enhancements in UV-aging behavior is limited, finding even less studies for rotomolded items. For this purpose, composites with 5 and 10 wt% filler were prepared and characterized (tensile properties, FTIR spectroscopy and thermal behavior by DSC) before and after accelerated weathering in a UV-chamber for up to 500 h, analyzing the test samples properties every 100 h of exposure. Similarly, 5 and 10 wt% composites were prepared with a combination of both fillers (2.5 and 5 % of each filler). The tensile properties (tensile strength, elastic modulus and elongation at break) were determined for all formulations in the 6 analyzed times, also calculating their carbonyl and vinyl index to determine the extent of the degradation. As expected, modulus increases for the composites, keeping this behavior for the entire analyzed period of time, except for lignocellulose. Elongation at break has been found to decrease with exposure time, in general, although some distinct behavior occurs for the different composites, as also happening for maximum strength and elastic modulus. The neat matrix increases rigidity with UV-exposure, for a later decrease, thus evidencing that the incorporation of the fillers has a significant influence in the photodegradation of the PE. Hybrid composites at 5 % loading shows in general the highest properties, while 5 % composites (with single filler) exhibits the lowest variations along the exposure.

Paper 366

Influence of cooling rate and Mo/Fe-ratio on solidification path in a secondary Al7Si alloy with focus on structural appearance of phases.

Mrs. Neelima Sri Priyanka Gottumukkala, Germany

Poster Presentation

Abstract

Iron (Fe) is a detrimental impurity element in secondary (i.e., recycled) Al-Si alloys, as it adversely affects their castability and mechanical integrity. Its presence promotes the formation of Fe-containing intermetallic phases, particularly the brittle, plate-like β -Al_{4.5}FeSi phase, which significantly increases the susceptibility to cracking. Secondary aluminum alloys typically contain additional elements introduced either as residuals or intentional additives to refine the microstructure. Among these, manganese (Mn) and chromium (Cr) have been extensively studied and are commonly employed as effective modifiers to mitigate the adverse effects of Fe by the formation of harmless α -Al-(Fe,Mn,Cr)-Si phase.

Molybdenum (Mo) is also commonly found in recycled aluminum alloys. Although Mo is claimed to have similar effects as Mn and Cr in promoting the formation of α -Al-(Fe,Mo)-Si over β -Al_{4.5}FeSi, detailed research on its role in forming and partitioning of these phases is limited. Moreover, the possibility of Al₁₂Mo and (Al,Si)₂Mo phase formation must be carefully considered. This knowledge gap emphasizes the need for further research to better understand the effects of Mo on the microstructure and mechanical properties of recycled aluminum alloys.

In the present study, the formation of intermetallic phases in Al7.1Si(1.5-x)Fe(x)Mo alloys (in at%), with x = 0.3, 0.45, 0.6, and 0.75 at%, was investigated under cooling rates spanning the orders of 0.01 to 100 K/s. The alloys were synthesized by arc melting pure elements and subsequently remelted at 950°C in an Ar atmosphere using Al₂O₃ crucibles, prior to defined cooling. The resulting microstructures were analyzed in detail using scanning electron microscopy (SEM) including energy-dispersive x-ray spectroscopy (EDS) and electron backscatter diffraction (EBSD).

The study highlights the significant influence of cooling rate and Mo/Fe ratio on the phase formation in a secondary, Fe-containing Al7Si alloy during solidification. Faster cooling rates effectively refined the microstructure, reducing the size and altering the morphology of Fe-rich intermetallic phases. The addition of Mo, particularly at higher Mo/Fe ratios, promotes the formation of compact or dendritic α -Al-(Fe,Mo)-Si particles instead of plate-like β -Al_{4.5}FeSi particles. Thereby, Mo partitions mainly in the α -Al-(Fe,Mo)-Si phase competing with formation of Al₁₂Mo and (Al,Si)₂Mo while it is almost not solved in the β -Al_{4.5}FeSi phase. These findings underline the critical role of process parameters and alloy composition in tailoring the microstructure and improving the performance of secondary aluminum alloys.

2D Nanostructures from bulk solids. A sustainable treatment based on sonication in aqueous solution.

Prof. Vasilios Georgakilas, Greece

Poster Presentation

Abstract

Ultrasonic processing has become an important tool for the development of environmentally friendly methods for the construction of low-dimensional structures. In recent years the interest has been focused on two-dimensional materials or even better on monolayer nanostructures which are usually characterized by the -ene suffix. In the present work, emphasis is placed on the use of aqueous dispersions to assist the exfoliation of monolayer structures from groups IIIA - VIA of the periodic table and their derivatives. The low-dimensional materials produced in this way can be exploited in biological applications as well as in energy applications depending on their individual properties. The systematic study of the treatment of such materials shows that ultrasonic treatment can be applied to many classes of materials with positive results. However, oxygen groups often appear in the products depending on the chemical activity of the materials.

We have so far studied elements such as tellurium, antimony, bismuth, tin, silicon, aluminum, and minerals such as hematite, magnetite, or solids like tungsten and molybdenum sulfides. The derivatives resulting from the exfoliation are often 2D and have interesting chemical and optoelectronic properties.

The aim of this work is to identify suitable natural extracts that, in combination with ultrasonic treatment, yield sufficient quantities of nanomaterials without affecting their basic properties. Also, often the functionalization of nanomaterials with natural products that have biological activities such as curcumin can act synergistically to increase the therapeutic properties of the materials.

Paper 797

Superfast stripping of DLC coatings from WC-Co cutting tools using a Low-Energy High-Current Electron Beam.

Dr. Andrea Lucchini Huspek, Italy

Poster Presentation

Abstract

Diamond-Like Carbon (DLC) coatings are extensively applied to enhance the durability and cutting efficiency of Hard Metal (HM) cutting tools, particularly under demanding operating conditions. Over time, these tools inevitably develop defects and wear, requiring their disposal. To extend their lifespan through resharping and reuse, an efficient decoating process is essential. In the present research, a vacuum plasma technology is implemented to tackle the issue of cutting tools decoating, with an eye on avoiding the use of harmful chemicals in the process. Low-Energy High-Current Electron Beam (LEHCEB) [1] was employed to remove DLC coatings from WC-Co₂ milling inserts. Pulsed irradiation by LEHCEB allows to completely evaporate the carbon coating from the substrate by exploiting the fast (10^9 K/s) induced thermal gradient and the lowered sublimation point of the coating at the vacuum working pressure. The electron accelerating voltages were 20, 25 and 30 kV, with an associated energy density of 2.5, 3.3 and 4.9 J cm⁻², respectively. The number of pulses were 5, 10 and 20, with a 0.2 Hz repetition frequency. The working pressure ($1.8 \cdot 10^{-4}$ Torr) and the ionized gas (Ar) were kept the same. Stripped substrates were then reground, recoated and tested to demonstrate the full regeneration of the cutting tools. Samples were characterized in terms of surface morphology by Scanning Electron Microscopy (SEM, Zeiss EVO 50P). Chemical microanalysis was performed by Energy-Dispersive X-Ray Spectroscopy (EDS, Bruker Quantax 200 spectrometer). The crystalline structure was assessed by X-Ray Diffraction (XRD, PANalytical EMPYREAN PW1830. Coating thinning was assessed by Raman Spectroscopy on DLC and X-Ray Fluorescence on TiN. Vickers microhardness was assessed by instrumented indentation at different loads (Helmut Fischer, HVX100).

Accelerating Materials Innovation: The Role of Materials Platforms and Databases in EU-Funded Projects

Dr. David Mercier, France

Poster Presentation

Abstract

Material informatics is transforming the innovation landscape by integrating data science, machine learning, and multiscale modeling to accelerate materials discovery and deployment. This study explores how these advanced methodologies enhance technology transfer, with a particular focus on the development and impact of materials platforms and databases across EU-funded projects. These initiatives have successfully enabled seamless data integration, interoperability, and predictive modeling, fostering collaboration between academia, industry, and policymakers. By examining key case studies, we open the discussion on how these platforms are streamlining the transition from fundamental research to commercial applications, driving efficiency, and reducing time-to-market for novel materials.

Paper 2041

New generation of porous composites titanium/ Hap biomaterials.

Mrs. Julia Sadlik, Poland

Poster Presentation

Abstract

Modern societies are faced with an increasing demand for orthopedic implants, which is challenging both medicine and materials engineering. The dynamic growth of the implant market is driven by the need to develop biomaterials with improved durability and biocompatibility. This thesis focuses on improving the properties of titanium alloy (Ti6Al4V) based surgical implants to extend their lifetime and improve their functionality. The primary research hypothesis is that the combination of titanium alloys with hydroxyapatite (HAp) and the laser texturing (LST) of the surface of the samples can result in a biomaterial with exceptional mechanical and biological properties. Hydroxyapatite, as the main mineral component of bone, enhances the bioactivity and osteointegration of the implant, while the use of laser surface treatment allows the microstructure and topography of the material to be precisely modified. The porous structure encourages the penetration of cells, resulting in rapid osteointegration, and moreover offers the possibility of applying drugs and antibiotics directly to the implant, which also speeds up recovery. The implant surface is further structured by laser to increase the specific surface area. The research of the present work is comprehensive, as it includes the development of a method to obtain the aforementioned composites for accurate physico-chemical analysis. The powder metallurgy manufacturing process consisted of several steps, starting with the preparation and obtaining of powder compositions in different proportions, followed by isostatic cold pressing and then sintering. The characterization of the obtained materials was carried out using different analytical techniques such as Fourier transform infrared spectroscopy (FT-IR), optical microscopy and X-ray diffraction analysis. The research focuses on the analysis of the tribological and biological properties of the newly developed Ti/HAp/LST composite. Microstructural characterization and biocompatibility tests in an environment simulating biological conditions were performed. The XTT tests carried out confirmed the lack of toxicity of the resulting composites both before and after laser structuring. The results show significant improvements in properties and bioactivity, suggesting that the proposed material could find application in modern orthopedic implants. The development of a new generation of

Paper 2172

Research on medical Ni-Ti alloy with ZrC coatings deposited by PVD technique

Ph.D. Mieczysław Pancielejko, Poland

Poster Presentation

Abstract

The studies were conducted on Ni-Ti medical shape memory alloy, with characteristic temperature of $30 \pm 5^\circ\text{C}$. To deposition of ZrC coatings on Ni-Ti and Si alloy substrates, one of the PVD techniques was used, the reactive magnetron sputtering method in an atmosphere of a mixture of argon and acetylene gases. The coatings were deposited under different conditions, the acetylene flow rate was changed in the range of 1.5-6.3 sccm, the substrate polarization bias voltage was changed in the range of -10 to -100V and the temperature in the range of 200 - 400°C.

Phase and chemical composition tests (XRD, XPS, EDS) were carried out, the structure (SEM) of the coatings was examined. The hardness and the E module were tested using the load-unloading method, internal stresses and adhesion (scratch test, Rockwell test) were determined. Tribological tests (ball-on-disk) of ZrC coatings and substrates were carried out in combination with an alumina counterspecimen. XRD and XPS analyses confirmed that the coatings contained ZrC phase crystallites. The highest hardness of ZrC coatings (26.1 GPa) was significantly higher than the hardness of Ni-Ti alloy (2.3 GPa). Scratch tests and Rockwell tests indicated good adhesion of ZrC coatings to Ni-Ti alloy substrates. The dry friction coefficient of ZrC coatings against alumina counterspecimen was many times lower (0.1-0.3) compared to Ni-Ti substrates (0.96). Coatings deposited at acetylene flow above 3.5 sccm showed wear indicator values one order lower than Ni-Ti substrates. EDS chemical composition analyses of the surfaces of friction pairs were carried out after ball-on-disk tribological tests. The structure and properties of ZrC coatings produced by the reactive magnetron sputtering method indicated the possibility of using them to coat, for example, endodontic tools made of Ni-Ti alloy. Initial comparative operational tests of files without coating and coated with ZrC coating were conducted.

The studies showed that the use of ZrC coatings increases their hardness and resistance to wear of Ni-Ti alloy substrates, while maintaining good adhesion. Therefore, ZrC coatings produced by the reactive magnetron sputtering method can be used in various fields of technology and medicine to increase the durability of objects/tools made of Ni-Ti alloy.

Paper 905

Wetting properties of titanium surfaces tuned by duplex treatments combining nanosecond laser treatment and chemical functionalization

Prof. M. C. Marco de Lucas, France

Poster Presentation

Abstract

Duplex treatments combining different processing methods open up a wide range of possibilities for modifying the surface properties of materials. In the case of titanium, nanosecond laser treatments have demonstrated their ability to induce a surface oxidation layer whose stoichiometry and properties depend on treatment conditions [1-2]. The covalent grafting of organic molecules onto the surface of titanium oxide films [3-4] opens up interesting prospects for controlling the hydrophobicity and biocompatibility of titanium surfaces, as well as for developing self-cleaning surfaces, sensors, photocatalytic supports, etc. [3].

The aim of the present work is to tune the wetting properties of metallic titanium by laser-assisted surface oxidation followed by chemical functionalization to produce hydrophobic to superhydrophobic surfaces.

A Q-switched and frequency-doubled Nd:YAG green laser (KALUTI) operating at 532 nm and delivering 5 ns pulse duration was used for laser treatments on CP-Ti plates. They produced a saw-tooth patterned surface covered by an oxidized surface layer containing mainly TiO₂-anatase [5]. The chemical modification of laser-treated surfaces with octylphosphonic acid (OPA) in form of tetrahydrofuran (THF) or boiling water solutions was performed. The effect of concentrations of modifier going from 0.01 to 100 mM on the resulting organic load, layer structure and contact angles was investigated. The duplex-treated surfaces were characterized by SEM-EDS/WDS, XPS, XRD and Raman spectroscopy.

OPA solutions in THF were found to give rise exclusively to monolayer formation (16 ± 5 Å), with surface coverage completed at a phosphorus concentration of around 4.8 at.% according to XPS results. Concentrated OPA solutions in water produced an additional layer of titanium (IV) octylphosphonate, bringing the total thickness of the organic layer to 37 ± 11 Å at a maximum phosphorus concentration of approx. 8 at.%. Despite the different nature of the organic layers, all surfaces containing at least 2.2 at.% P showed a similar static contact angle of around 155°. Based on dynamic contact angle measurements, superhydrophobic behavior was confirmed for surfaces bearing a full OPA monolayer and titanium phosphonate (IV) overlays.

Selective Dinitrogen Electroreduction to Ammonia on Zn₂V₂O₇ Pyrochlore

Mrs. Naina Goyal, Germany

Poster Presentation

Abstract

Electrochemical ammonia synthesis offers a sustainable alternative to traditional nitrogen fixation, providing high energy density, low storage costs, and greenhouse gas-free combustion. However, the process faces significant challenges due to the slow kinetics of N₂ activation, highlighting the development of highly efficient electrocatalysts. This study investigates the sol-gel synthesis of bimetallic oxides, focusing on zinc pyrovanadate (Zn₂V₂O₇) for its potential in nitrogen reduction reaction (NRR). The pyrochlore framework of Zn₂V₂O₇ provides structural integrity through zinc, while vanadium serves as the active site, facilitating the reduction of molecular nitrogen (N₂), a thermodynamically stable molecule. Density functional theory (DFT) simulations indicate that Zn₂V₂O₇ facilitates the nitrogen reduction reaction (NRR) through a surface hydrogenation mechanism centered on vanadium active sites. The reaction intermediates were identified and characterized using in-situ attenuated total reflectance surface-enhanced infrared absorption spectroscopy (ATR-SEIRAS). The catalyst achieved selective ammonia production with a faradaic efficiency of 76.5 % and a yield of 101 µg h⁻¹ mgcat⁻¹ in 0.1 M Na₂SO₄ electrolyte, demonstrating its potential for practical applications in sustainable NRR processes.

Utilization of Waste Triglycerides and Sulfur for the Production of Triboelectric Nanogenerators

Prof. Petr Slobodian, Czech Republic

Poster Presentation

Abstract

In recent years, there has been a significant increase in the interest in sustainable materials aimed at reducing environmental impact and promoting efficient resource utilization. A promising approach involves the reuse and recycling of industrial byproducts to create functional materials, minimizing waste and transforming residues into valuable resources. This study focuses on the production of high-sulfur-content materials with sustainable properties, utilizing elemental sulfur and waste triglycerides from plant oils representing traditional low-value residues. These materials are synthesized through inverse vulcanization, where sulfur copolymerizes with unsaturated compounds such as waste vegetable oils, acting as a solvent, initiator, and monomer in the process.

The resulting sulfur-based polymers exhibit outstanding properties such as thermal stability, chemical resistance, and thermoplastic behavior. To comprehensively analyze the produced material, various characterization techniques were employed, including scanning electron microscopy (SEM), X-ray diffraction (XRD), Fourier transform infrared spectroscopy (FTIR), Raman spectroscopy, 3D profilometry, differential scanning calorimetry (DSC), dielectric analysis (DEA), and mechanical property evaluation. A key aspect of this study is the assessment of the triboelectric properties of the synthesized sulfur-based copolymers. The copolymer was paired with two different waste-derived materials to form triboelectric pairs: discarded goat leather and a blend of recycled refuse waste polymers (RRWP), primarily composed of polyolefins. The triboelectric response was found to be highly dependent on the pairing material. When combined with goat leather, the composite exhibited a tribonegative character, whereas when paired with RRWP, it demonstrated a tribopositive nature. Notably, this trend intensified with cycling during the triboelectric experiment, stabilizing after approximately 150 cycles under conditions of 14 kPa applied pressure and a sliding velocity of 0.6 m/s. The findings provide valuable insights into the relationship between copolymer composition and triboelectric behavior, demonstrating the potential of sulfur-based thermoplastics for sustainable energy harvesting applications.

Paper 1422

Establishing a processability window for laser processing of regolith simulants: Ex-situ analysis and in-situ monitoring

Mrs. Emma Porsbjerg, Denmark

Poster Presentation

Abstract

Laser Powder Bed Fusion (PBF-L) is one of the few additive manufacturing (AM) technologies with potential for constructing large structures on the Moon using only in-situ materials. Space agencies such as ESA and NASA have outlined roadmaps that include lunar landing pads, blast shields, and habitats built via AM. In-Situ Resource Utilization (ISRU) is critical to these efforts, as the cost of launching large amounts of material from Earth remains prohibitive. This research builds on a preliminary study that successfully demonstrated 2.5D printing in the high-fidelity lunar regolith simulant (LRS) LHS-1, directly on a loose powder bed. An extensive experimental campaign will now investigate a viable process window for PBF-L of LHS-1 parts with the mechanical qualities required for the construction of large structures. The printed components will be evaluated for geometrical accuracy using a benchmark model developed in collaboration with SAGA Space Architects. Extensive ex-situ characterization will provide a fundamental understanding for optimizing the process window alongside in-situ monitoring via high-speed imaging to analyze laser-substrate interaction in real time. Lunar regolith has highly irregular morphology, a wide particle size distribution, and variable chemical composition, making closed-loop process control, and consequently in-situ monitoring, likely necessary for large-scale construction without extensive pre-processing or site restrictions. While high-speed imaging has been used to optimize PBF-L for metallic materials, it has never been demonstrated for an LRS. In conclusion, this work aims to optimize PBF-L for lunar construction by addressing engineering constraints and setting the scene for a closed-loop control framework.

Paper 1725

Post-processing effects on surface integrity of C300 subjected to different finish machining conditions.

Mrs. Anna Barrero, Spain

Poster Presentation

Abstract

Additive Manufacturing (AM) techniques have attracted much attention due to the capability to produce unique and complex geometries with high productivity rates. Selective Laser Melting (SLM) is one of the most widely used techniques due to its versatility with various materials. It allows the production of complex three-dimensional parts, the production of functional components and is economically viable [1]. As a result, SLM are becoming increasingly used in several industries as in the aerospace, automotive or biomedical industries [2]. Nevertheless, one of the limiting factors of AM processes is the part surface quality closely related to service performance and durability. Therefore, the as-produced metallic AM parts cannot be used directly, and subsequent post-treatments are required. In this work, the influence of different finish electrical discharge machining (EDM) strategies to improve the surface integrity quality and mechanical properties of a C300 maraging steel with a simple geometry was studied. Damage characterization of the machined subsurface was analysed in terms of microstructural changes and micromechanical behaviour.

Surface integrity of both AM and AM machined samples were characterized on surface and cross-section view. A combination of nanoindentation techniques and advanced microscopy techniques including, 3D Optical profilometry, scanning electron microscopy (SEM-EDX) and electron backscattered diffraction (EBSD) were used to study the effect of the post-processing strategy on both the surface and the subsurface levels. Results are presented in terms of micromechanical changes (hardness and elastic modulus) and micro-damage discerned at the edge of the post-processed surface.

The results from these tests will allow for the prediction of the most effective post-processing methods to enhance the mechanical performance of additive manufactured components. Additionally, this study will offer valuable guidance for future advancements in the field, particularly in optimising the mechanical properties of components with inhomogeneous microstructures commonly found in additive manufacturing.

UV-Curing-Assisted Drop-Casting as a novel approach in the production of ceramic beads

Dr. Radoslaw Zurowski, Poland

Poster Presentation

Abstract

One of the primary challenges in the manufacturing of ceramic materials is achieving the shaping of microbeads with high sphericity and uniform size distribution.

This research aims to produce alumina materials with spherical geometry using UV-curing-assisted drop-casting, a novel shaping technique introduced by Falkowski and Zurowski [1]. In this approach, droplets of photocurable ceramic dispersions with hydrophilic properties are exposed to UV irradiation while falling through a hydrophobic non-solvent.

This study presents the results of optimizing the composition of photocurable ceramic suspensions. The effects of varying amounts and types of dispersing agents, monomers, and photoinitiators on the rheological properties were investigated. Extensive rheological measurements led to the development of a water-based ceramic suspension with desirable properties: a high water-to-monomer ratio, high solid content, shear-thickening behavior, and relatively low viscosity. Additionally, the authors focused on selecting process parameters to produce ceramic microbeads with high circularity, uniform densification, and no microstructural defects.

Paper 166

Investigation of Thermophysical Properties and Chemical Compatibility with Alumina of High-Entropy Zirconates

Mr. Manuel Schenker, Germany

Poster Presentation

Abstract

Thermal Barrier Coatings (TBCs) are used in the hot zones of airplane turbines. They protect metallic components and prevent damage caused by the high combustion temperatures and corrosive atmospheres. Since the 1980s yttria stabilized zirconia (YSZ) has been used as standard TBC material. However, its properties limit the operational temperature to around 1200 °C. It is necessary to find new materials to overcome those limitations and therefore increase the efficiency of the engine by increasing the working temperature.

In the last decade, high-entropy oxides (HEOs) are investigated as a new material class. HEOs are single-phase oxides with a configurational entropy higher than 1.5 R that can be established using five or more cations in equimolar ratio and statistical distribution in one or more sublattices. The high configurational entropy could lead into a phase stabilization over a broad temperature range and has further beneficial effects like low thermal conductivity (phonon scattering due to disorder), low sintering rate (sluggish diffusion), and adjustable properties depending on the used ions.

Single cation zirconates show promising properties as future TBC materials in gas turbine applications. Based on that, the high entropy effect can improve the usability of the zirconates as a TBC material. Therefore, zirconates with the general formula $A_2Zr_2O_7$ with five different rare-earth elements on the A sublattice were investigated in this work. Their thermophysical properties, including thermal conductivity, thermal expansion, and sintering behavior were investigated. The results show comparable behavior with YSZ or better properties.

In the application, the TBC material is in contact with alumina, which forms as a thermally grown oxide on the bond coat. Therefore, the reactions of the high-entropy zirconates with alumina were investigated in this work as well. Besides the reaction in a bulk material, the behavior at the interface of the compounds as layers needs to be investigated to explore the kinetics of the reaction in detail. Furthermore, a coating technique and the mechanical and chemical compatibility with alumina in a layer system should be investigated to estimate the lifetime of a HEO coating as a TBC.

Defect Engineering in MoS₂ Nanomaterials via Low-Energy Ion Implantation for Next-Generation 2D Functional Devices

Ph.D. Rabia Nawaz, Finland

Poster Presentation

Abstract

The exploration of two-dimensional(2D) materials, such as molybdenum disulfide(MoS₂) and other transition metal dichalcogenide(TMDs), has gained significant attention due to their extraordinary electronic, optical, and mechanical properties. These materials hold immense potential for applications in electronics, optoelectronics, catalysis, and energy storage.

Ion implantation has emerged as a promising technique for modifying the structure and properties of 2D materials by introducing dopants and defects into the atomic lattice. This enables precise control over substitutional dopants, vacancies, and interstitials, allowing for tailored modifications in electronic, optical, and mechanical characteristics. This study explores how low-energy ion implantation can modify MoS₂, unlocking applications in catalysis, optoelectronics, and other advanced fields.

Existing research primarily focuses on the effects of high-energy ions on 2D materials. In contrast, the impact of ultra-low-energy ions, such as argon(Ar) and xenon(Xe), on MoS₂ has not been as thoroughly investigated. This research aims to fill this gap by studying the effects of ultra-low-energy ion implantation on MoS₂ at varying ion energies by experimental (Scanning Transmission Electron Microscopy STEM and Raman Spectroscopy) and computational(Molecular Dynamics MD) approaches. By combining these approaches, this research aims to deepen the understanding of how ultra-low-energy ion implantation influences the properties of MoS₂.

Employing the KIIA ion accelerator at the University of Helsinki, mechanically exfoliated MoS₂ samples were irradiated at controlled doses (1×10^{14} – 1×10^{15} ions/cm²) and energies ranging from 15–200 eV. STEM analysis revealed significant structural alterations, including defect formation at energies 40, 45, 50, 55, 80, and 200 eV. A clear indication of trapping the ions in the van der Waals gap is seen in the simulation at 40, 45, 50, and 55 eV, but the experimental confirmation is still underway. The transition from AB stacking to mixed AB/AA/AC stacking was observed, with stacking transformations occurring at the sub-nanometer scale.

MD simulation results showed that at 20 and 30 eV, no defects were introduced in the MoS₂ lattice. However, at 35–40 eV, defect generation in the top MoS₂ layer began. When the energy increased to 40–50 eV, Ar ions penetrated the first MoS₂ layer, leading to interlayer trapping, nanoscale pore formation, and stacking disorder.

A key finding is that 15 eV Ar implantation achieves clean and well-preserved MoS₂ surfaces, presenting a promising method for surface cleaning before property engineering. This study provides critical insights into how ultra-low-energy ion implantation enables precise defect engineering in MoS₂, fine-tuning its properties for nanoelectronics, optoelectronics, and catalytic applications. Future research will focus on refining implantation techniques, optimizing defect configurations, and further expanding MoS₂'s applicability in nanoelectronics and sustainable energy solutions.

Paper 116

The effect of Mo segregation on the grain boundary precipitation behavior in Fe-Ni-Mo-X alloys

Mr. Dong-hyun Kim, South Korea

Poster Presentation

Abstract

Maraging steel shows superior strength and toughness through the significant precipitation of intermetallic compounds. Its development started from high amounts of Ni- and Co-containing alloys, but nowadays, the entire or partial substitution of high-cost elements (Ni, Co) to cheap ones is being studied to reduce its cost. Fe-Ni-X (X=Mn, Ti) alloys show excellent hardening responses during aging treatment. However, these alloys suffer grain boundary embrittlement and show no tensile ductility even after very short aging treatment. Precipitation of intermetallic phases, θ -MnNi in Fe-Mn-Ni alloys and η -Ni₃Ti in Fe-Ni-Ti alloys, at grain boundaries was suggested as the reason for the weakening of grain boundary strength. After extended aging, grain boundary strength is recovered when these precipitates transform to austenite. Dislocation glide or dislocation climb was critical in converting these grain boundary precipitates to austenite. To overcome the grain boundary embrittlement at the early stage of aging treatment, adding Mo is considered to strengthen the grain boundary. Although the Mo effect improving strength and ductility was reported, the effect of Mo segregation on the change of the grain boundary precipitation behavior has not been elucidated yet. This study clarifies the roles of Mo segregation on the grain boundary precipitation behavior and its related recovery of grain boundary strength in Fe-Ni-Mo-X alloys.

Paper 487

Improving thermoelectric properties of calcium manganites using co-doping strategy

Dr. Maria Madre, Spain

Poster Presentation

Abstract

Due to the relatively low thermoelectric properties of oxide ceramics, fixed A-, and variable B-site doped CaMnO_3 materials were prepared and studied for raising their thermoelectric performances. $\text{Ca}_{0.97}\text{Y}_{0.01}\text{La}_{0.01}\text{Yb}_{0.01}\text{Mn}_{1-2x}\text{Nb}_x\text{Mo}_x\text{O}_3$ ($0 \leq x \leq 0.03$) samples were prepared using planetary milled precursors, to reduce the initial particle size and increase their reactivity. The mixture was calcined at 1050°C for 1h, milled again, cold uniaxially pressed in form of pellets (about $3 \times 3 \times 15 \text{ mm}^3$), and sintered at 1310°C for 12h. Powder XRD patterns showed that sintered samples are nearly single phase, with only small amounts of CaMn_2O_4 . SEM analysis performed on the samples surfaces revealed that grain size decreases with Nb, and Mo dopant content, while porosity variation with dopant content is negligible. This was confirmed through density measurements using Archimedes' method, which indicates that all samples are around 91-94% of the theoretical density of CaMnO_3 . Electrical resistivity (ρ) of samples decreases with the dopant content, reaching the minimum at 800°C ($6.1 \text{ m}\Omega \text{ cm}$) in $x=0.03$ samples, 60% lower than that of the pristine ones. On the other hand, Seebeck coefficient (S) decreases with doping, and the highest values at 800°C among the doped samples have been determined for $x=0.005$ ($210 \mu\text{V/K}$). The highest power factor ($\text{PF}=S^2/\rho$) at 800°C has been obtained for $x=0.01$ samples ($0.46 \text{ mW/K}^2\text{m}$) due to their best compromise between electrical resistivity and Seebeck coefficient. Thermal conductivity (κ) measured in the same direction as ρ , and S , did not significantly vary with composition, but the combination of PF and κ , leads to the highest figure of merit ($\text{ZT}=S^2/\rho\kappa$) values at 800°C for the $x=0.005$ samples (0.27), which is among the best reported in the literature. These results clearly show that co-doping approaches are very useful to raise the thermoelectric performances of CaMnO_3 materials, and open new paths for integrating high-performance calcium manganite-based materials in TE modules for power generation at high temperatures.

Paper 484

Design of high-strength medium manganese zinc-coated steel for the automotive industry

Ph.D. Mattia Franceschi, Spain

Poster Presentation

Abstract

The demand for reduced fuel consumption, lower CO₂ emissions, and improved vehicle safety is driving the development of advanced high-strength steels (AHSS). Hot stamping of coated C-Mn-B steels dominates automotive applications due to its ability to produce ultrahigh-strength components. However, these steels exhibit poor elongation, limited crash energy absorption, and require Al-Si coatings with inadequate corrosion resistance. Medium manganese steels (3–12 wt.% Mn), a key material in 3rd generation AHSS, offer superior mechanical properties, lower transformation temperatures, and compatibility with Zn coatings, making them a promising alternative for warm stamping applications. In this study, new Zn-coated medium manganese steels were developed with the following objectives:

- a) Achieving total elongation (TE) $\geq 10\%$ and ultimate tensile strength (UTS) ≥ 1500 MPa for intrusion-resistant components.
- b) Achieving TE $\geq 18\%$ and UTS ≥ 1200 MPa (UTS $\times$ TE ≥ 21 GPa%) for energy-absorbing components.

The alloy system consisted of varying amounts of C, Mn, Al, Cr and B.

A total of 72 different variants were identified and analyzed using thermodynamic simulations to evaluate phase volume fractions and chemical compositions. Nine alloys were selected for experimental validation, based on the results of the phase transformation characteristics from the thermodynamic simulations. These alloys were prepared at a laboratory scale, subjected to hot and cold rolling, and subsequently processed through annealing and hot press forming. Based on quasi-static tensile testing, two alloys were identified as promising candidates for pilot scale experiments simulating the industrial heat treatment procedure.

Funding received for this work from the European Research Executive Agency (REA) under the Grant Agreement No. 101112425 is gratefully acknowledged.

Combining In Ovo Testing and MicroCT Imaging to Assess Tissue Integration and Angiogenesis in Porous Scaffolds

Prof. Angel Concheiro, Spain

Poster Presentation

Abstract

Preclinical in vivo studies are widely used to evaluate the compatibility and performance of a wide range of materials for biomedical applications, but ethical concerns and challenges in translating animal data to humans have spurred the search for animal-free alternatives. The FDA Modernization Act 2.0 has accelerated this shift by promoting the 3Rs principles and supporting the development of innovative methods for medical device and pharmaceutical approval [1].

This study explores the use of the chorioallantoic membrane (CAM) of fertilized hen eggs as a promising alternative for evaluating the blood compatibility, angiogenesis, and tissue integration of a wide range of biomaterials, from contact lenses to bone scaffolds. The in ovo CAM test is cost-effective, reliable, and reproducible, and is not considered an animal experiment under Directive 2010/63/EU until embryonic day (ED) 17, as the chick embryo does not experience pain before ED 14. Visual monitoring of the CAM allows for the classification of biomaterials based on their potential ocular irritation (since the CAM resembles the conjunctiva) [2] and their ability to promote or inhibit microcapillary development around and over the scaffolds [3].

Additionally, this work aimed to combine in ovo testing with microcomputed tomography (microCT) imaging to provide precise, non-destructive, 3D visualization of tissue integration within porous materials. Bone scaffolds and wound dressings were tested on fertilized eggs within the timeframe when the experiment is not considered an animal experiment. After incubation, the CAMs were fixed, stained, and imaged with microCT to assess blood vessel formation and tissue integration. The method enabled accurate quantification of tissue ingrowth and vessel formation across various biomaterials [4]. Bone scaffolds with open porosity showed extensive vascularization and integration with the CAM, while wound dressings did not integrate, indicating that they can be safely removed without disrupting the underlying tissue. In conclusion, this combination of in ovo testing and microCT imaging offers a promising animal-free alternative for evaluating biomaterials in tissue engineering applications.

Phase Stability and Impurity Detection in TiO₂(B) Synthesized by Soft Chemical Route: Implications for Preparation and Application

Ph.D. Monika Vilémová, Czech Republic

Poster Presentation

Abstract

In this study, we investigated the phase stability of TiO₂(B) synthesized using ion exchange and dehydration with K₂Ti₄O₉ as a precursor. The presence of potassium within the material, particularly in TiO₂(B), remains undetectable by conventional techniques such as X-ray diffraction (XRD) or energy-dispersive spectroscopy (EDS), even at concentrations exceeding those typically classified as "minor impurities." One focus of the research was to evaluate the potential of differential scanning calorimetry (DSC) for detecting residual potassium content. Another focus was the examination of the phase stability of TiO₂(B) when incorporated into a different metallic systems such as steels. This work aims to contribute to the production of single-phase, chemically pure TiO₂ nanoparticles, enabling the investigation of their intrinsic properties without interference from secondary phases or impurities. Furthermore, an improved understanding of phase stability can guide the selection of suitable processing methods and facilitate exploration of the material's use in emerging applications.

Magnetite nanoparticles coated by hydrochar-like structure: the influence of synthesis methods on drug delivery and magnetic hyperthermia effect

Mrs. Agnieszka Ciuraskiewicz, Poland

Poster Presentation

Abstract

Polysaccharide-modified magnetite nanoparticles are a growing research focus due to their potential in targeted and controlled drug delivery. Surface functionalization is crucial, with organic modifiers like polysaccharides (e.g., dextran, starch) enhancing biocompatibility, stability, and targeted drug conjugation. These biopolymers create a biocompatible environment, minimizing toxicity and immune responses while enabling prolonged circulation and selective tissue targeting. The choice of polysaccharide significantly impacts drug release kinetics, allowing for sustained or triggered release, which improves therapeutic efficacy and reduces side effects. Starch, a widely available, low-cost, and biodegradable polysaccharide, is particularly promising for drug carriers and nanoparticle coatings. Functionalized starch-coated iron oxide nanoparticles enhance stability by balancing magnetic and van der Waals forces, while polymer surface complexing agents help control particle size during magnetite formation.

In our research, we created magnetite-based materials modified with wheat starch using a high-temperature decomposition process. This study explores how synthesis methods influence physicochemical properties. Structural analysis was conducted using X-ray diffraction to determine phase composition and crystallite size, while scanning and transmission electron microscopy provided detailed insights into morphology. UV-VIS spectroscopy assessed drug adsorption on ferrite nanoparticles, and drug release studies revealed significant differences in adsorption capacity based on the applied modifiers. The polysaccharide layer proportion was determined using thermogravimetric analysis. Additionally, we evaluated the magnetic hyperthermia effect of polysaccharide-modified magnetite nanoparticles and compared it with unmodified magnetite.

Paper 432

Molecular dynamics study of nanotwinned gold thin films deformation

Mrs. Sandrine Brochard, France

Poster Presentation

Abstract

Crystal defects may play an important role in improving the properties of materials. This is the case for twin boundaries, which impart to nanotwinned materials a remarkable combination of high mechanical strength and good ductility, without loss of electrical properties, their resistivity being identical to that of coarse-grained materials. Indeed, the twin boundaries, that divide the matrix into two symmetric orientations, can hinder the motion of dislocations, making it more difficult for plastic deformation, leading to the desired mechanical strength. However, because of the high symmetry of the associated microstructure, the scattering of conducting electrons at a coherent twin boundary is reduced, preserving the electrical conductivity of the metal, conversely to what happens for other grain boundaries.

In that context, we performed tensile tests on gold thin films with nanotwins, in-situ under X-ray diffraction and we observed, for some loading axes, the growth of twins in the crystal. To better understand the deformation mechanisms occurring in these materials, we conducted atomic scale simulations for systems as close as possible to the experimental ones. Such simulations are tools particularly well suited to this type of study, making it possible to accurately describe the configurations of defects such as dislocations, grain boundaries, twins, etc. They naturally reproduce key material properties such as elasticity coefficients, stacking fault or twin boundary energies. Moreover, atomic scale simulations and experiments tend to converge to similar size scales. However, special care must be given to the selection of the interatomic potential used in molecular statics and molecular dynamics simulations. For this study, we selected two interatomic potentials on the basis of the correspondence of their gamma curves to the ones obtained with ab initio calculations.

Then, we first investigated the stability of a nanotwin in a gold thin film, before submitting it to applied stress in a direction similar to the experimental one. The preliminary results on the thin film deformation show the glide of partial dislocations along the coherent twin boundary and the detachment of partial or extended dislocations from the junction between coherent and incoherent twin boundaries.

Customizing Luminescence in REPO₄ Nanocrystals via chemical synthesis routes

Mrs. Rocío Molina-Motos, Spain

Poster Presentation

Abstract

REPO₄ materials (RE= La, Ce, Pr, Nd, Sm, Y, Er, Gd) present interesting properties such as photochemical and thermal stability, high quantum yield, low photobleaching and toxicity, and long lifetime. These features make them promising hosts for up-converting Ln³⁺ ions, which have led to consider them in optoelectronic applications, as well as biomedicine, clean energy, or sensors, among others. Their processing in the nanoscale is key for their incorporation in next generation of smart optoelectronic devices. Controlling the structural and microstructural characteristics of REPO₄ and RE_{1-x}Ln_xPO₄ nanoparticles through the synthesis is essential to tune and enhance their luminescence response. Despite the great interest of these nanostructures and the possibility of crystalizing them in different crystalline structures (hexagonal, monoclinic and tetragonal) and with varied morphologies and particle sizes, there is still a scarce comprehension of the different parameters that interfere during their growth throughout synthesis process. Particularly, Er³⁺ doped and Er³⁺/Yb³⁺ co-doped REPO₄ nanoparticles would be of interest for optical telecommunication applications due to their NIR emissions; however, they have been hardly studied to date.

In this study, we report the synthesis of hexagonal, monoclinic and tetragonal REPO₄ (RE = Eu, Er, Y) and RE_{1-x}YEr_xYb_yPO₄ (RE = Eu, Y; x=Er) nanocrystals using different chemical synthesis routes in order to customize their structural and morphological features and thus their luminescence response from the visible to the NIR range. Special attention is paid to the morphology and particle size, for it, the use of different surfactants, chelating agents and phosphate sources is considered, which determines the growth in certain crystallographic directions and impact on the dispersibility of the nanocrystals. With the aim of successfully evaluating the performance and properties of the nanocrystals, an in-depth structural, microstructural and thermal characterization study is carried out by techniques such as X-ray diffraction (XRD), Raman spectroscopy, scanning electronic microscopy (SEM), Differential Thermal Analysis and Thermogravimetric Analysis (DTA/TGA) and correlated with the photoluminescence response.

These results suggest that REPO₄ hosts are very versatile and promising for the modulation of the luminescent response in nanocrystals, which places them in a privilege position for the fabrication of anti-counterfeiting security markers that emit at specific wavelengths. The tunable emission properties and high stability of these nanoparticles make also them a promising material for future developments in advanced optoelectronic applications, display technologies, and optical sensors.

Superb cold-drawn deformability of NiCoCrFeMo high-entropy alloys mediated via planer defect engineering

Prof. Xidong Hui, China

Poster Presentation

Abstract

Metal fibers are essential key materials in the fields of textiles, aerospace, petrochemical and electronic machinery. And composite and micro refinement have become the development trend of new materials. However, the fabrication of micron-scale alloy fibers remains a challenging subject. Recently, high-entropy alloys (HEAs), also known as multi-principal-component alloys (MPCAs), have received widespread attention due to their unique characteristics such as high strength and hardness, excellent low-temperature fracture toughness, high-temperature stability, corrosion resistance, and impact resistance. Herein, we present a novel Ni-Co-Cr-Fe-Mo high-entropy alloy (HEA) fiber with a reduction rate of 99.9995% and a strain (ϵ) of 12.19 prepared by cold-drawn process without requiring intermediate annealing. The exceptional deformation strain within the fiber leads to extraordinary tensile strengths at room temperature and liquid nitrogen temperature. The in-depth investigation of the microstructure of fibers has been conducted. And the cold drawing deformation mechanisms mediated by the synergistic effects of plane defects have been studied. It has been shown that various geometrically necessary dislocation interfaces, such as dislocation walls and microbands, along with deformation twins and long-period 9R structures, was formed in response to external stress when $\epsilon \leq 2.7$. As the strain increases, the saturated layered structure emerges and progressively evolves into a 3D equiaxed crystal. Moreover, the formation and evolution of the 9R structure (i.e., the migration of incoherent twin boundaries), coupled with the interaction of partial dislocations and the role of deformation twins, are crucial factors determining the fiber's plastic response. This work is supposed to provide an alternative approach for the process of high-strength metallic fibers with excellent deformability through plane defects engineering.

Processing, microstructure development and mechanical properties of reactively sintered SiC ceramic composites reinforced with various NbC fillers

Dr. Richard Sedlák, Slovakia

Poster Presentation

Abstract

Our fast developing world has ever greater demands on the development of new progressive materials and technologies for a very wide range of applications across the aerospace, defence, energy, medical and transport sectors. The main reason for attracting attention to ceramics as is mainly due to its excellent properties such as high hardness, refractoriness, exceptional wear resistance and resistance in aggressive corrosive environments. However, ceramic inherent brittleness strongly limits its widespread, reliable technical application. Nowadays, we are increasingly faced with the inevitable need to design and develop new advanced ceramic composite materials with increased damage tolerance. The presented systematic study investigates the influence of the sintering parameters on microstructure development and basic mechanical properties of reactively sintered SiC ceramic composites reinforced with various NbC fillers. The main attention of the research is focused on the in-situ synthesis of SiC matrix during reactive sintering through the SPS technique, with the addition of reinforcing NbC phase in the form of globular particles and synthesised ceramic fibers in the range from 5 to 20 wt.%. The reactive sintering conditions were optimised, the temperature varied from 1800 to 2100 °C, and dwell time from 10 to 20 mins. Microstructural characterisation was performed by scanning electron and transmission electron microscopy with EDS, and phase composition by XRD. Basic mechanical properties, such as nano/micro/macro hardness, fracture toughness, bending strength, and elastic modulus were measured. The combination of in-situ reaction and SPS resulted in the prepared high damage tolerant ceramic composites. The relationship between microstructural development and basic mechanical properties has an important role in the further development of these perspective materials.

Paper 393

Microstructure and micromechanics evolution of β -Ti gum metal (TNTZO) during cyclic loading using synchrotron diffraction

Mr. Peter Ibrahim, United Kingdom

Poster Presentation

Abstract

β -Titanium alloys have gained interest in the past few years for their excellent mechanical properties, including high strength and low elastic modulus. A considerable number of these alloys are a perfect fit for medical applications as they consist of elements with excellent biocompatibility, such as Ti-Nb-Ta-Zr alloys known as TNTZ. TNTZ alloys offer elastic modulus values as low as 56 GPa and strength up to 1 GPa. Using additive manufacturing techniques, such as LPBF, to build customised TNTZ medical implants increases the potential for a better patient-specific healthcare concept. However, inevitable oxygen pickup during powder atomisation and the LPBF process results in a high-oxygen version of these alloys referred as TNTZO (Gum metal) with altered mechanical properties and deformation mechanisms, as oxygen is found to block the stress-induced phase and twinning transformations during loading. Post-processing heat treatments have been found to alter the microstructure and the micromechanics of TNTZO alloys, leading to a wide range of macro-mechanical properties. The fact that most loading on load-bearing implants, such as hip and knee joints, is cyclic loading raises special concerns about the material response to this loading case. These changes in the micromechanical behaviour of the material under cyclic loading are crucial for fully enhancing the predictability and reliability of the alloy for medical applications. In this study, synchrotron diffraction was used to analyse the microstructural properties of the as-built TNTZO in comparison with the solution-treated and aged versions of the alloy. The effect of heat treatments on the lattice-scale elastic moduli and dislocation density of the alloy was analysed. Moreover, the microstructural texture evolution and the dislocation density of the different samples were assessed along with cyclic loading using the Williamson-Hall technique for peak analysis. The structure-property relationship was studied by examining the aforementioned micromechanical changes against the measured elastic modulus softening through successive loading cycles. Similarly, the presence of α -phase after aging is related to a noticeable increase in the recoverable strain value along the test accompanied with hysteresis loop between the loading and unloading elastic regions. These findings provide insight into the deformation mechanisms governing cyclic superelasticity in β -Ti alloys and highlight the role of microstructural refinement in optimising mechanical performance. The results contribute to the broader understanding of fatigue behaviour in β -Ti alloys and their potential for high-strain applications requiring enhanced recoverable deformation.

Paper 1471

Shaping of ceramic beads via UV curing assisted drop-casting method

Dr. Pawel Falkowski, Poland

Poster Presentation

Abstract

One of the key challenges in manufacturing ceramic materials is shaping beads with high sphericity and a uniform size distribution. Ceramic microbeads are typically formed by dropping a ceramic suspension containing alginates (as a gelling agent) into solutions with calcium ions. However, this approach often results in residual calcium ions in the sintered bodies, which can negatively impact their properties.

This study aims to produce ceramic materials (alumina and zirconia) with spherical geometry using UV curing-assisted drop-casting [1]. This method exposes droplets of photocurable ceramic dispersions with hydrophilic properties to UV irradiation while falling through a hydrophobic non-solvent. Ceramic beads have diverse applications, such as in ultrafine grinding of non-metallic minerals, printing inks, pharmaceuticals, and food. However, producing these beads in a controlled, repeatable, and cost-effective manner, with perfect sphericity and uniform size distribution, remains a significant technological challenge. Additionally, the possibilities for final machining are often limited. The proposed method addresses these challenges effectively. Moreover, the process is easily automated, and the UV-curable dispersions use water as a solvent, making the approach more environmentally friendly.

In this study, the authors present results on optimizing the photocurable ceramic suspensions' composition. The influence of various dispersing agents, monomers, and photoinitiators on the rheological properties was evaluated. Extensive rheological measurements led to water-based ceramic suspensions with desirable properties, including a high water-to-monomer ratio, high solid content, shear-thickening behavior, and relatively low viscosity. Additionally, the study focused on determining the optimal shaping process parameters to produce ceramic microbeads with high circularity, uniform densification, and minimal microstructural defects.

Graduate School Circular E-Cars: Development and establishment of a circular economy for e-cars in the Rhenish Mining Area

Mrs. Hannah Naber, Germany

Poster Presentation

Abstract

The Graduate School Circular E-Cars aims to develop and establish a circular economy for e-cars in the Rhenish Mining Area. For this purpose, the entire value chain is addressed, from material preparation and design to questions of reuse.

Circular E-Cars is organized across four locations: RWTH Aachen University, the University of Siegen, FH Münster, and the Wuppertal Institute. Within this framework, the Steel Institute (IEHK) of RWTH Aachen University focuses on resource recovery, metal refining, and the innovative design of materials and products.

Key aspects include non-destructive assessment of damage status in structural and functional components, as well as the design of new high-strength, recyclable alloys. Additionally, the melting of recycled materials with comparable quality standards and comprehensive material testing are core tasks of the IEHK within this Graduate School.

Alkali Metal-Promoted Ru/Al₂O₃ for Optimized NH₃ Decomposition and Electron Density Control

교수 Sungsu Kim, South Korea

Poster Presentation

Abstract

Ammonia is considered a potential hydrogen carrier due to its higher volumetric hydrogen density than liquid hydrogen and its ability to be stored in a liquid state under stable conditions [1]. Hydrogen production through ammonia decomposition has gained significant research interest in recent years [2]. Since ammonia decomposition is an endothermic reaction, high temperatures are required to maintain efficiency. Recent studies have focused on the development of low-temperature catalysts, with Ruthenium (Ru)-based catalysts being reported as the most effective for ammonia decomposition [3]. Various support materials have been evaluated for catalytic activity, with Alumina being widely used in catalysis due to its high specific surface area and tunable physicochemical properties [3]. However, compared to MgO and rare-earth oxides, Al₂O₃ has been reported as a less effective support due to its lower Ru nanoparticle dispersion, which negatively affects catalytic performance in ammonia decomposition [4]. Recent studies have demonstrated that the incorporation of alkali metals into catalysts can induce surface basicity, significantly enhancing catalytic performance in ammonia decomposition [5].

In this study, Al₂O₃ was modified with various alkali metals to create highly basic surface sites. The Ru/Me-Al₂O₃ catalysts (Me = K, Na, Ca, Mg) exhibited enhanced activity in ammonia decomposition compared to Ru/Al₂O₃. A series of characterization analyses were conducted to investigate the correlation between the presence of highly basic surface sites and the catalytic performance of Ru/Me-Al₂O₃ catalysts. The NH₃ decomposition reaction over Ru-based catalysts is structure-sensitive, with catalytic performance highly dependent on the size of Ru NPs on the support. The formation of optimally sized Ru NPs on the surface of Me-Al₂O₃ in Ru/Me-Al₂O₃ catalysts was found to be beneficial for NH₃ decomposition. Catalytic activities were assessed at a weight hourly space velocity of 60,000 ml·gcat⁻¹·h⁻¹, and the temperature-dependent NH₃ conversion results are presented in Figure 1.

The addition of alkali metals (K, Na) significantly enhanced catalytic activity compared to unmodified Ru/Al₂O₃, whereas the incorporation of alkaline earth metals (Mg, Ca) led to a decrease in activity. These variations were attributed to differences in the super-basic properties induced by the respective metal additives, as confirmed by X-ray diffraction, Brunauer-Emmett-Teller surface area analysis, and CO₂ temperature-programmed desorption studies. The findings indicate that modifying Al₂O₃ with alkali metals can significantly improve its suitability as a support material for ammonia decomposition catalysts. Al₂O₃-based catalysts can be applied to various industrial processes, and their utilization is expected to enhance the diversity of ammonia decomposition catalysts.

Structural and mechanical properties of refractory alloy thin films: TiZrHfTa system

Prof. Gregory Abadias, France

Poster Presentation

Abstract

Complex concentrated alloys (CCAs), including medium- and high-entropy alloys, offer attractive thermomechanical properties which make them promising candidates for various technologies such as corrosion resistant or radiation tolerant structural materials. Among the various CCAs, alloys with multi-principal refractory elements (RCCA) have drawn significant attention for hydrogen (H) storage applications [1-3] due to their ability to reversibly absorb H in the form of metal hydrides. However, up to now, studies on RCCA for H storage have only focused on bulk materials, with limited attention to thin film counterparts, which could be considered as model materials enabling an easy tailor of composition, phase and microstructural features (grain size, porosity or texture), providing valuable insights on the mechanisms of hydride formation and dissolution in RCCAs. In this work, (TiZrHf)_{100-x}Ta_x thin films, with thickness up to 700 nm and Ta content ranging from 0 to 60 at.%, were synthesized by co-sputtering deposition. The phase composition, crystal structure, morphology and elemental composition was determined using a combination of analytical techniques (XRD, SEM/TEM, EDS), while the intrinsic stress was measured in situ during deposition by wafer curvature method. The mechanical properties of the films were assessed by nanoindentation and opto-acoustics (Brillouin light scattering and picosecond laser ultrasonics) methods. By tuning the Ta content, different phases were stabilized in these quaternary alloys, from hcp to bcc and amorphous. These structural changes are accompanied by variation in growth morphology (evolving from nanocolumns to vein-like patterns), stress reduction and a progressive softening of hardness, shear and elastic modulus with increasing Ta content. The experimental findings are discussed and compared with results obtained from atomistic models of random alloys and amorphous phases, using ab initio molecular dynamics simulations combined with machine-learned interatomic potentials, as well as relevant data from the existing literature [4]. Preliminary hydrogenation tests will be also reported.

Microfluidic based LC sensor and antennas with tuned performances using liquid conductors

Prof. Goran Stojanović, Serbia

Poster Presentation

Abstract

This study explores the feasibility of constructing LC resonant circuits and antennas using liquid-based media within microfluidic channels. A hybrid fabrication approach combining stereolithography (SLA) 3D printing and xurography was employed to develop these microstructures. The microfluidic channels, printed using Elegoo Standard White resin, were designed for liquid capacitors and sealed with a PVC top layer embedded with aluminum conductive tape to enable capacitance measurements. The capacitor structure exhibited capacitive properties, with channel dimensions of 0.7 mm in width and depth and an active area of 18 × 21 mm. The process of design and fabrication of the following electronics components is presented: capacitor, inductor, LC sensor and antenna. The inductor is designed as square inductor with 5 turns, whereas capacitor as interdigitated electrode system with 13 fingers. Combining of this L and C components, LC sensor is created. In the microfluidic channel, the liquid (ionic) conductor is injected (liquid with electrolytes - Powerade). The quantity of injected ionic conductors can adjust the value of inductance or capacitance and as a consequence the resonant frequency can be tuned. Using impedance analyser, the electrical parameters: inductance, capacitance, impedance and phase angle are measured. For the antenna, xurography was solely used, employing a PVC foil substrate. A conductive loop made from aluminum tape formed the inductive component. A cutter plotter was used to cut the microfluidic channels in the PVC foils in the middle, and again PVC foil at the top with the inlet for the liquid conductor. These layers are laminated using hot laminator under pressure to obtain compact structure. The liquid was introduced into the antenna using a syringe to ensure precise and controlled insertion into the designed channels. Final antenna dimensions were 91 x 40 mm. The antenna's performance was evaluated using a vector network analyzer to determine S-parameters. Compatibility of LC sensor and antenna and their inductive coupling for wireless sensing applications was determined.

The effect of the acid content and the electrical parameters in the dry-anodising process of Ti6Al4V

Dr. Joan Josep Roa Rovira, Spain

Poster Presentation

Abstract

Titanium has low density, high strength to weight ratio and excellent corrosion and wear resistance. When titanium is suspended in an electrolytic bath as an anode and a current is passed through the bath, oxygen is produced at the anode Surface. This oxygen combines with the titanium to form titanium oxide. The interference taking place between the oxide and light results in the appearance of colors on the metal surface and oxides with different thickness generating different colors. This passive oxide film formed on titanium surface is responsible for its high corrosion resistance. Thus it has wide range of applications in aerospace, automotive and biomedical industries. This presentation presents a dry-anodizing technology by using DryLye® Technology. In this sense, the thickness, voltage and current density effect of the acid content is evaluated by different advanced characterization technique. The direct and indirect coating thickness measurement of the anodize layer by using the Focused Ion Beam and reflectometry techniques, respectively; highlight that the anodize thickness layer does not depend on both the acid content and the applied electrical parameters, yielding a homogeneous value of around 60 nm.

Machine learning potentials for simulations of defects in TiN and TaN

Mrs. Kiana Rostamipour, Austria

Poster Presentation

Abstract

Transition metal nitrides (TMNs) are widely recognized for their exceptional hardness, thermal stability, and electrical conductivity, making them irreplaceable in numerous industrial applications such as protective coatings and high-performance materials. Among these TMNs, titanium nitride (TiN) and tantalum nitride (TaN) have gained significant attention for their versatility and performance in wear-resistant coatings. The increasing demand for advanced materials has driven the exploration of methods to fine-tune their mechanical properties, such as through the introduction of structural defects. In this study, we investigate defects in the cubic and hexagonal phases of TiN and TaN using molecular dynamics (MD) simulations. MD provides atomic-level insights into the structure and behavior of materials under well-controlled conditions, which can be challenging and resource-intensive for experiment. To speed-up MD simulations and access length scales beyond that typical for ab initio modeling, we develop machine learning potentials (MLPs), combining computational efficiency with accuracy for defect modeling. To train these MLPs and validate their predictive power, we generate data through finite-temperature density functional theory (DFT) calculations. Our dataset encompasses a wide spectrum of defect types, including vacancies, grain boundaries, and twins. This approach facilitates the development of robust MLPs while enabling direct comparisons between MD simulations and DFT results, ensuring both reliability and accuracy. Our work aims to advance the understanding of defect-driven property modifications in TiN and TaN, paving the way for improved materials design with applications in wear-resistant coatings and high-performance materials.

Microstructural Changes in Zr-4Nb-2Al Alloy During Hot Rotary Swaging

Mr. Adam Strnad, Czech Republic

Poster Presentation

Abstract

Zirconium and its alloys are widely utilised in various industries, from nuclear reactors to biomedical implants, owing to their excellent corrosion resistance, low neutron absorption cross-section, and superior mechanical properties. The low neutron absorption cross-section, in particular, makes zirconium an ideal structural material for nuclear reactor components. To enhance the material's mechanical strength and achieve a favourable microstructure comprising hexagonal close-packed (hcp) α -phase and body-centred cubic (bcc) β -phase, new zirconium alloys have been developed. The studied alloy, Zr-4Nb-2Al, contains a high concentration of α -phase-stabilising aluminium and β -phase-stabilising niobium, resulting in a favourable α + β microstructure. This study examines the microstructural changes in the Zr-4Nb-2Al alloy during thermomechanical processing using hot rotary swaging. A key focus of the research was analysing the phase transformations occurring in the alloy, which were studied using differential scanning calorimetry and resistometry. These methods provided insight into the α -to- β phase transformation, which was later used to establish the temperature parameters for hot rotary swaging. The swaging process began in the β -phase region to refine the typically large β grains. This was followed by processing in the α + β coexistence region to achieve the desired final microstructure. The microstructural changes after each processing step were analysed using scanning electron microscopy, which revealed a transition from a lamellar to a globular microstructure. Mechanical properties were then evaluated through compression and microhardness tests, demonstrating the material's performance enhancement. This research provides insight into the steps involved in the hot rotary swaging of zirconium alloys. It also offers a detailed summary of the microstructural and mechanical property changes that occurred during the thermomechanical processing of the Zr-4Nb-2Al alloy.

Mechanical properties of 304L stainless steel at 4K

Dr. Young-Kyun Kim, South Korea

Poster Presentation

Abstract

In this study, the mechanical properties of 304L stainless steel (SS) fabricated via the laser powder bed fusion (LPBF) process were investigated at room temperature and cryogenic conditions ($\sim -269^{\circ}\text{C}$) under controlled oxygen concentration (0.2%). Compared to conventionally wrought SS304L, LPBF-fabricated SS304L exhibited a significantly increased yield strength, reaching approximately 336 MPa at room temperature and up to 398 MPa at -269°C . Additionally, it demonstrated an additional yield strength increase of approximately 64 MPa at room temperature compared to previously reported LPBF SS304L. This enhancement in strength is primarily attributed to the oxide dispersion strengthening effect induced by controlled oxygen concentration, as well as grain boundary and dislocation strengthening, without a significant reduction in ductility. Furthermore, strain-induced martensitic transformation (SMT) did not occur at room temperature and showed a decreasing trend at cryogenic temperatures compared to wrought SS304L. This behavior is interpreted as a result of the high dislocation density and nitrogen-stabilized austenite. Additionally, the "discontinuous plastic flow (DPF)" observed at -269°C was associated with the adiabatic heating effect induced by plastic deformation, consistent with the material's low thermal conductivity. Based on these findings, the correlation between the unique hierarchical microstructure of LPBF SS304L and its cryogenic mechanical properties at -269°C was thoroughly examined.

Composites comprising additively manufactured lattice structures and resorcinol-formaldehyde xerogels

Mr. Fabian Henn, Germany

Poster Presentation

Abstract

The ever-growing importance of saving energy implies the use of increasingly efficient insulating materials. Particularly for mobile applications, such materials also have to display light-weight characteristics. Owing to their highly open-porous nature, aerogels and xerogels are excellent insulating materials with low density [1-2]. However, their fragility limits direct applications as structural materials, e.g. in vehicles. Lattice structures offer high specific strength and can be readily produced using additive manufacturing techniques including selective laser sintering (SLS). Thus, a combination of lattice structures with aerogel materials represents a promising approach for the development of mechanically robust lightweight insulation materials [3-4].

Here, we report on the development of composites comprising polyamide 12 (PA12) lattice structures and resorcinol-formaldehyde xerogels. While the former was accessed using high-speed sintering (HSS) of PA12 powder, the xerogel filling was obtained by sol-gel synthesis followed by ambient-pressure drying. Specifically, we describe a rational approach of selecting the unit cell geometry of the lattice structure using simulation methods. The production of a variety of composites varying in unit cell dimensions and lattice strut thickness is described. The subsequent characterization of compressive and thermal properties is presented, and the findings are discussed with respect to future applicability.

Methods of Compound Drug Delivery via Porous Collagen Scaffolds

Mrs. Kyriaki Louca, Cyprus

Poster Presentation

Abstract

This research investigates drug delivery through Porous Collagen Scaffolds (PCSs). Scaffolds that are collagen – based are promising biomaterials, offering significant potential in regenerative medicine. Various studies have explored the use of PCS for peptide – based therapeutics, however only a few focus on the utilization of PCS for controllable long- term delivery of hydrophobic small molecules . Here a PCS Drug Delivery System (DDS) designed for small molecule compounds is presented. The system involves embedded biodegradable polyester microstructures (microrods, fibers, microspheres), incorporated in the PCS during the formation of the scaffold. The microstructures are fabricated via electrospinning/electrospraying. The fabrication of the microstructures was followed by systematic studies that were conducted to evaluate the influence of the type of the embedded matrix (long fibers, spheres etc.), composition (different copolymer blends) and surface characteristics on the diffusion mechanism of the selected drug, BNN27. In addition, the maximum drug loading concentration was studied. The drug release kinetics corresponding to each DDS system was quantified, and the non-toxicity of the polymer grafts was confirmed via bioactivity studies carried out on NIH3T3 cells. Ultimately, the polymeric grafts composition and fabrication techniques were optimized to enhance the DDS's half-life and drug loading capacity, paving the way for improved long-term drug delivery systems.

Omics technologies to identify key biochemical pathways involved in the antitumor activity of a mesoporous silica nanosystem containing selenium nanoparticles

Dr. Blanca González, Spain

Poster Presentation

Abstract

Breast cancer is the most commonly diagnosed cancer in women, primarily affecting those aged 50 and older. Among its various subtypes, the Luminal A estrogen receptor-positive (ER+) tumor is the most prevalent and has the best prognosis, as it can be treated with chemotherapy and hormonal therapy. However, these treatments involve significant challenges due to the high concentrations currently required, leading to drug resistance and severe side effects. Therefore, new therapies capable of selectively targeting cancer cells while sparing healthy tissues are still urgently needed. In response to this need, this study proposes a novel nanosystem that combines two antitumor agents: selenium nanoparticles (SeNPs), known for their chemotherapeutic properties, and tamoxifen (TMX), a drug commonly used to treat hormone-responsive breast tumors. Both agents are compressed within a single nanosystem composed of mesoporous silica nanoparticles (MSNs), with transferrin (Tf) anchored to the surface. This functionalization enhances the selectivity of the system (MSNs-TMX-Tf-SeNPs) towards cancer cells that overexpress transferrin receptors (TfR). Following the synthesis and physicochemical characterization of the nanosystem, functional characterization was performed to evaluate its efficacy in an in-vitro model using T47D breast cancer cells (Luminal A subtype). Furthermore, omics technologies were employed to identify the key biochemical pathways involved in the antitumor activity of this novel nanosystem. The results demonstrated a significant antitumor effect, primarily inducing senescence and, to a lesser extent, late apoptosis, likely attributed to TMX activity. Moreover, two critical mitochondrial metabolic pathways were found to be disrupted: the tricarboxylic acid (TCA) cycle and one-carbon metabolism, specifically the folate cycle. Additionally, damage to the endoplasmic reticulum was observed, associated with alterations in the biosynthesis of monounsaturated fatty acids and cholesterol. These disruptions ultimately led to hypoxia and oxidative stress, triggering autophagy and cell death.

Investigating the concept of Complex Concentrated Alloys for a sustainable alloy design of lead-free brasses

Mr. Bernardo L. Ribeiro, Portugal

Poster Presentation

Abstract

Lead (Pb) is a commonly used alloying element in brass alloys (Cu-Zn) to enhance machinability. This improvement primarily occurs due to Pb-particles' deformation into needle-like structures, which promote discontinuous chip formation, as these structures serve as points for crack initiation. However, due to Pb's toxicity and environmental hazards, several organisations have issued regulations and guidelines, such as the DWD, REACH, ELV and RoHS, to limit the maximum Pb content in components for several industries. Different approaches have been implemented to develop novel lead-free brass solutions for various applications, such as direct Pb replacement and heat treatment. Nevertheless, none of the current solutions produce cost-effective alloys with machinability comparable to leaded brasses, therefore representing a significant drawback for the industry. To close this gap, Complex Concentrated Alloys (CCAs) could be explored as a potential solution to achieve the necessary properties and requirements without compromising brass's circularity.

The present work depicts the first phase towards the sustainable development of lead-free CCAs based on the Cu-Zn system, which covers the overall alloy design: (1) literature review; (2) definition of chemical, mechanical, and microstructural requirements; and (3) compositional alloy design based CALPHAD simulations for microstructure prediction. The current literature favours a biphasic structure with low melting point precipitates to replicate the Pb's role during machining operations. A study of the supply risk of the current elements circulating within the brass scrap circular economy versus the elements' relative cost was the first step to narrowing the window of the most attractive elements to consider for a sustainable and cost-effective alloy design. Within this window, Cu, Zn, Fe, Ni, Al, Mn, and Sn are depicted as the most promising main elements to incorporate in the lead-free alloy. Based on thermodynamic assessments, thermo-physical parameters and CALPHAD simulations show that the Cu-Zn-Al-Mn system presents a promising FCC/BCC ratio, as observed for conventional alloys. The incorporation of other elements that favour the formation of soft-phase precipitates will also be presented and discussed. This study summarises the first phase of the co-promotion project 'recyBRASS' - COMPETE2030-FEDER-00576900 - between ASBW Barbosa World Brass, S.A and the Faculty of Engineering of the University of Porto, on the development of novel lead-free brass alloys.

A new stainless steel with microstructural and compositional gradient by selective laser melting

Dr. Lucía Morales Rivas, Spain

Poster Presentation

Abstract

Additive manufacturing (AM) is driving metallurgists to design new alloys and complex microstructures. One of the main restrictions of AM is that, in general, it is not intended for a subsequent thermomechanical process, which motivates the study of alternative hardening methods based on pure heat treatments.

This work proposes the design and manufacturing of a new stainless steel by selective laser melting, in line with the following alloying and microstructural strategies: Nickel content reduction and mechanical composite behavior conferred by a layered structure. The intrinsic heat treatments during the manufacturing process will be explored in order to achieve a controlled microstructural refinement, and, consequently, improved mechanical properties.

This work has been funded by the "ComFuturo Third Edition" Programme, supported by the MSCA-COFUND Agreement No. 101034263.

3D printing of ceramic materials reinforced with metallic nanoparticles

Dr. Joanna Tanska, Poland

Poster Presentation

Abstract

Ceramic-metal composites represent a particularly significant class of materials, as they integrate the beneficial properties of both ceramics and metals, resulting in enhanced properties of the final material. The presence of metallic particles in a ceramic matrix can act as a barrier to crack propagation, thereby improving the fracture toughness of the product. The effectiveness of this reinforcement depends on multiple factors, including the size, distribution, and morphology of the metallic phase. Micrometer-sized particles limit the ability to control the microstructure, as achieving uniform distribution of the metallic phase within the ceramic matrix is more difficult. This can lead to local inhomogeneities and a deterioration in the mechanical properties of the products. However, the use of metallic nanoparticles comes with certain technological challenges due to their strong tendency to agglomerate. Additionally, because of their high flammability, they require special storage conditions (in a cool, dry inert gas to prevent surface oxidation). A promising approach in the fabrication of ceramic-metal nanocomposites involves the use of metallic phase precursors. These precursors decompose and undergo reduction at elevated temperatures, facilitating the in-situ formation of finely dispersed metallic nanoparticles within the ceramic matrix. The aim of the research was optimization of the ceramic pastes composition to obtain zirconia matrix composites, manufactured by Direct Ink Writing (DIW). Metallic phase was introduced to the pastes in the form of metallic powder or metallic precursor. Additionally, thermal analysis (TG/DTG/DTA/MS) was performed for the green bodies, metallic powders, and metallic precursors, which enabled the selection of appropriate sintering parameters. The important stage of the research was the characterization of the obtained samples, which included Vicker's hardness and fracture toughness tests, as well as SEM and XRD analysis.

Research was funded by the Warsaw University of Technology within the Excellence Initiative: Research University (IDUB) programme.

Microstructural Analysis of Fractures in Cementitious Materials: From the Matrix to the Concrete Scale

Señor. Javier Martínez De Iturrate Vicente, Spain

Poster Presentation

Abstract

The mechanical behavior of cementitious materials is directly related to their microstructure and the fracture mechanisms that develop under load. This study conducts a detailed microscopic analysis of fracture surfaces in specimens of cementitious matrix, mortar, and concrete using high-resolution optical microscopy and trinocular microscopy. The primary objective is to characterize fracture patterns and assess the impact of partially replacing Portland cement with wind turbine waste (RAG) and oxy-combustion ashes (OXI). Phenomena such as the formation of interfacial cracks in the paste-aggregate transition zone, the propagation of microcracks within the matrix, and the morphology of hydration products were identified.

The obtained images reveal significant differences between the studied materials. In the cementitious matrix, dispersed microcracks with intragranular propagation predominate. In mortar, an increase in interfacial porosity is observed, affecting the cohesion between the aggregates and the cementitious matrix. In concrete, fractures tend to be more tortuous, with energy absorption zones and plastic deformation areas suggesting optimized mechanical behavior.

The results confirm that incorporating waste materials influences the adhesion between the cementitious paste and the aggregates, modifying fracture energy and material ductility. It is concluded that microstructural analysis is essential to understand the relationship between material composition and mechanical performance, allowing for the design of stronger and more sustainable cementitious materials.

Thermal treatment of beech wood under controlled conditions: Physico-chemical characterisation.

Mrs. Petra Mácová, Czech Republic

Poster Presentation

Abstract

The long-term durability of wood, especially for outdoor applications, depends significantly on effective surface treatments. Among various preservation techniques, thermal treatment is considered an environmentally sustainable alternative. However, to achieve optimal thermal treatment without weakening the structural integrity remains a major challenge [1][2]. Nowadays, various techniques are available, and e.g. plasma-induced surface carbonisation offers a promising approach leading to surface protection with minimal internal degradation [3].

This work is aimed to investigation of the progressive thermal degradation of wood constituents, providing a detailed baseline for future studies focused on carbonisation of solid wood surfaces. Powdered beech wood (*Fagus sylvatica* L.) was thermally treated in a sealed conditions. This approach allowed to get the control over the pyrolysis process, limiting the ignition and combustion. Based on the thermogravimetric analysis (TGA) results, several temperature values were selected within the range of 110°C to 600°C. The physico-chemical properties of the thermally treated samples were subsequently characterised using advanced analytical techniques, including Fourier-transform infrared spectroscopy (FTIR), ultraviolet-visible spectroscopy (UV-VIS), colorimetry, X-ray diffraction (XRD) and scanning electron microscopy (SEM).

The findings showed that the color change could be used as a reliable indicator of the temperature of applied thermal treatments and, thus, may pinpoint out expected changes in the physico-chemical properties of thermally treated beech-based samples. The knowledge obtained for controlled themally treated samples may find utilization for the complex characterisations of the role of thermal treatments on wood properties and may help in the development of optimised wood preservation techniques that enhance its durability, improve weather resistance, and preserve the structural integrity leading to long term sustainability of wood constructions.

Abstract

There exists an increasing trend towards glass materials and enamels to create decorative, durable, and highly resistant architectural solutions. Nevertheless, the common processes to produce glass implies high energy consumption and pollution and therefore, environmentally friendly processes with a view on electrification of the glass industry is now pursued.

With an aim to determine the ultimate relationships between the structural characteristic of a glass composition and its electrical characteristics, there have been prepared several glasses with different Zn contents. The structural characteristics of the glasses were studied by spectroscopic techniques which allowed determining the effect of the Zn in the glass matrix in terms of altering the proportion of bonding and non-bonding oxygens. Zn enters in the network as a network former and induced the formation of BO₄ units, as deduced from the increase of the band centered at about 910 cm⁻¹. These results have been correlated with the viscosity of the glasses, their thermal behavior as the electrical conductivity high temperature.

The complete characterization of the glasses will set up the basis for the development of new glass compositions with selected electrical conductivities to be used in newly developed electrified glass melting technologies.

Revealing fretting wear resistance mechanism under liquid lead-bismuth eutectic of Cr-Al-C composite coatings fabricated by laser cladding

Mr. Yuchen Cao, China

Poster Presentation

Abstract

Laser cladding technology was utilized to construct Cr-Al-C coatings on the surfaces of service materials. Through the fretting wear test in liquid LBE, the fretting wear behaviour of Cr-Al-C composite coatings under different fretting working conditions was studied to elucidate the characteristics of the coating's sub-surface components, chemical composition distribution, morphology, crystalline orientation, and micro-structure after the fretting wear, so as to reveal the protection mechanism of coatings against fretting wear in liquid LBE. Results show that the coating mainly consists of diffuse Cr₂AlC phase, interdendritic Cr₇C₃ phase and dendritic Cr-based solid solution. The wear resistance of the coating is 4.25 times that of the 316 stainless steel substrate at a test temperature of 320 °C, the wear resistance of the coating was 33 times that of the 316 stainless steel substrate at a test temperature of 450 °C. The oxidized layer can block the direct contact between the material and the friction partner and reduce the wear, while also preventing the infiltration of LBE and the dissolution of the base metal elements. In addition, the Cr₂AlC in the coating possesses good self-lubricating properties, which can also effectively reduce wear; the coating's Schmidt factor is statistically distributed between 0.41-0.5, with a high capacity for plastic deformation, which effectively improves the resistance to fretting wear damage of materials. The presence of carbide effectively impedes the movement of dislocations, dislocations stacked around it and can not make it fracture or deformation, thus playing a certain role in strengthening. This study provides a theoretical basis and foundation for the protection design of heat transfer tubes in steam generators.

Microstructure and Mechanical Properties Correlation of Additively Manufactured IN939 Superalloy

Mr. Md Shahwaz, India

Poster Presentation

Abstract

This study evaluates the mechanical performance of IN939 superalloy, fabricated using Powder Bed Fusion-Laser Beam (PBF-LB) and subjected to post-process heat-treatment. The primary focus is understanding how heat-treatment affects the microstructural evolution and mechanical properties of IN939 for high-temperature aerospace and industrial applications. High-temperature tensile and compression tests at 850 °C for heat-treated samples are conducted to gather data on yield strength, ultimate tensile strength, and ductility. Microstructural analysis using scanning electron microscope (SEM) and electron backscattered diffraction (EBSD) reveals significant modifications in grain structure and phase stability due to heat-treatment, which are directly correlated with enhanced mechanical properties. The strain hardening behavior is assessed using the Hollomon and Ludwik equations, showing a decrease in the strain hardening exponent at 850 °C, indicating increased susceptibility to localized deformation. The results demonstrate that heat-treated IN939 exhibits substantially improved mechanical performance at 850 °C, with higher yield and tensile strength while maintaining adequate ductility. These improvements are attributed to refined microstructure and enhanced phase stability from heat-treatment. This study underscores the importance of optimizing heat-treatment parameters to ensure the alloy's reliability and effectiveness in high-stress, high-temperature environments.

Modeling of single crystals and polycrystals of NiAl using the Deformable Discrete Element Method

Dr. Pawel Holobut, Poland

Poster Presentation

Abstract

Many important materials are polycrystals with a cubic crystal structure. Examples are aluminum and copper with the face-centered cubic (FCC) structure, iron and chromium with the body-centered cubic (BCC) structure, as well the BCC intermetallic NiAl which is the main focus of this study. A widespread way of modeling such materials at the microscale is by using the Finite Element Method (FEM). In the present work, an alternative approach based on the Discrete Element Method (DEM) is employed instead. Both methods have advantages and disadvantages, with FEM being potentially less computationally intensive and more accurate in some applications, while DEM being better adapted to handling discontinuous phenomena like fracture.

A DEM model is created by filling a given volume with spherical particles of the same or different sizes and bonding adjacent ones together by cohesion. The effective properties of the ensemble are calibrated by adjusting stiffness parameters of the inter-particle bonds. A single crystal of cubic symmetry can be modeled by using either a random-dense packing of DEM particles or a cubic-symmetric periodic one, both having a cubic-symmetric distribution of bond stiffness coefficients. The second approach is followed in this work, since the first one faces difficulties reproducing properties of highly anisotropic crystals like NiAl. The simple cubic (SC) arrangement of particles is adopted, with deformable DEM (DDEM) particles used instead of standard ones [1] – a change which increases the range of values of effective parameters that can be obtained. In particular, it allows easy representation of the elastic properties of NiAl crystals.

The transition to the polycrystal is made by subdividing a representative volume into grain sub-volumes and filling them with SC patterns of DDEM particles at different orientations, corresponding to EBSD test results. It is ensured that proper attachment conditions at the grain boundaries are created, where SC patterns of different orientations meet. The results of simulations for NiAl in the linear-elastic regime are presented and discussed in connection with future tests of larger deformations leading to grain-boundary fracture.

ACKNOWLEDGEMENT: This work was financially supported by the National Science Centre, Poland, under Grant Agreement No. OPUS 2020/37/B/ST8/03907 for the project "Multiscale investigation of deformation and damage behavior of novel hybrid metal matrix composites. Experimental studies and numerical modeling".

Luminescent Solar Concentrators for Efficient and Sustainable Use of Solar Energy

Dr. Amador Menéndez-Velázquez, Spain

Poster Presentation

Abstract

Solar energy is a renewable source with great potential, clean and sustainable, that reduces the carbon footprint by not generating polluting emissions. Although its use requires high initial investments, it is one of the most economical energies in the long term and the only one capable of generating heat, reducing the use of solid fuels. However, the technology currently available has several technical limitations. Luminescent solar concentrator (LSC) technology is an innovative solution that can provide greater efficiency in capturing sunlight, even in diffuse lighting conditions, allowing better use of solar energy. Its versatile design facilitates integration into windows, facades and other architectural surfaces, promoting the development of self-sufficient buildings. It also reduces costs by minimizing the amount of photovoltaic material required and improves sustainability by taking advantage of a wider spectrum of radiation without generating polluting emissions.

An LSC is transparent device with luminescent particles that absorb and re-emit light at longer wavelengths, guiding it by internal reflection to the edges, where solar cells convert it into electricity, improving photovoltaic efficiency.

In this work, a new second LSC generation will be presented, with the ability to capture a wide range of the visible-UV spectrum, covering wavelengths between 350 nm and 750 nm, and to re-emit at a longer wavelength. This luminescent system is composed by an optimal combination of organic molecules embedded in a polymeric matrix.

The final LSC is obtained by deposition of the luminescent suspension onto glass, followed by solvent removal, which allows the formation of a homogeneous and efficient coating.

As a luminescent system, several molecules capable of absorbing in the UV/visible part of the spectrum and re-emitting at longer wavelengths were selected. The goal is to capture as much of the spectrum as possible with as few luminescent species as possible, so that each absorbs a specific fraction of the electromagnetic spectrum. Together, these species will allow various wavelengths of the solar spectrum to be captured, thus optimizing the use of incident solar radiation.

In addition, the selected species should enable Förster resonance energy transfer (FRET), a non-radiative transfer process that occurs when the emission spectrum of the donor overlaps sufficiently with the excitation spectrum of the acceptor. To maximize the efficiency of the system, it is essential to find the optimal conditions that favor this interaction between the luminescent species.

Investigation of the Tensile Strength of Biochar-containing Thermoplastics

Mrs. Viktoria Theodorou, Cyprus

Poster Presentation

Abstract

Nowadays carbon-rich materials derived from biomass waste known as biochar have gathered increasing attention as sustainable alternatives to carbon-based fillers. Traditional carbon-based nanofillers that are typically employed as additives in polymers to enhance their thermomechanical performance, are neither environmentally friendly nor economically viable. Several scientific studies suggest that the incorporation of biochar into polymer matrices may lead to polymer composites exhibiting superior properties compared to their pristine polymer counterparts, offering comparable or even enhanced mechanical performance compared to those reinforced with expensive carbon nanofillers. This study is structured into two key phases: First, the production of eco-friendly biochar-based thermoplastic composite and second, their mechanical characterization by performing tensile tests under ambient conditions. Sample preparation involved a pyrolysis step that was employed to convert biomass feedstock into a carbonaceous material, followed by a twin-roll milling process to produce composite plates with specific thicknesses. Tensile tests were performed according to ASTM D638 to determine the elastic constant (Young Modulus) and tensile strength of the resulting "green" composites. Overall, this research highlights the potential of utilizing biomass waste to create environmentally friendly products, with biochar emerging as a highly promising, renewable filler in polymer composites. Laser Textured and Bioactive Ti/HAp/MXene Biomaterials

Mrs. Edyta Kosińska, Poland

Poster Presentation

Abstract

Nowadays, abnormalities affecting the skeletal system are an increasingly common problem. This is related to the phenomenon of an aging population, as well as the occurrence of various accidents that cause bone damage. It is often required to implement an implant, which must meet the appropriate requirements to be used in a living organism. Such a material must meet a number of requirements, i.e. biocompatibility and bioactivity. For this reason, metallic implants are increasingly being abandoned, and alternative ceramic-metallic composites are being introduced. Ceramics, i.e. hydroxyapatite, thanks to their structure resembling natural bone, contribute to the regeneration of bone tissue and introduce bioactivity into the system. On the other hand, metals, in this case titanium alloy Ti-6Al-4V, provide adequate mechanical properties. Bone implants, especially of the hip joint, are exposed to constant stress and friction, which contribute to implant wear and often revision due to inflammation. An additional element that will benefit implant longevity is laser texturing, which can affect bioactivity by creating a well-defined and controlled surface roughness. This will allow, among other things, the growth of cells in appropriate areas, which will contribute to bone regeneration. Another way to improve the tribological properties of Ti/HAp composites is to implement MXene coating. These relatively new 2D materials have been identified as solid lubricants and compounds that form beneficial tribofilms. Moreover, they have been noted for their potential due to their large surface area, drug-loading ability, and biocompatibility and non-toxicity to the living organism. The biomaterials were prepared by using the powder metallurgy method and then selecting appropriate sintering conditions. At the initial stage, the percentages of hydroxyapatite, porophore and titanium in the powder mixtures were determined, which were then compressed using the cold method and the samples prepared in this way were sintered. The next step was to perform laser surface texturing (LST) to improve friction and anti-wear properties. A layer of MXenes was also implemented as a lubricant that can improve friction and wear. The performed physicochemical and structural analysis of the obtained composites showed the potential of the designed material for use in bone tissue regeneration.

Advancing Binder Jetting: A Multi-Scale Numerical Approach to Minimize Residual Porosity

Ph.D. Valerio Lampitella, Spain

Poster Presentation

Abstract

Binder jetting has emerged in recent years as a promising Additive Manufacturing (AM) technique, featuring the typical advantages of AM—such as the ability to produce unconstrained geometries and reduce material waste—whilst avoiding the energy cost and challenges tied to rapid solidification and extreme thermal cycles common in fusion-based AM methods. Despite its potential, due to an incomplete understanding of the multi-scale and multi-physics nature of the process, the presence of defects, particularly residual porosity, still limit its broader adoption.

Numerical simulations offer a pathway to investigate binder jetting processes with exceptional spatial and temporal resolution, providing insights that would be extremely challenging to obtain (if feasible at all) through experimental approaches alone. To advance the understanding of sintering mechanisms contributing to residual porosity, this study proposes a novel integrated approach combining the Discrete Element Method (DEM) and Phase Field (PF) models.

The DEM is utilized to predict the powder bed's characteristics post-spreading, such as particle packing density and coordination, which serve as critical inputs for the PF model. The PF model, based on a grand potential approach, is employed to examine the evolution of porosity during sintering under the thermal conditions of the process. The effects of binder residues on diffusion mechanisms—including volume, surface, and grain boundary diffusion—are explicitly incorporated by locally modifying mobilities, offering a more comprehensive depiction of sintering dynamics.

Accurate calibration of model parameters is essential to faithfully represent the underlying physical phenomena. While some parameters can be derived directly from the literature, others require detailed calibration. To address this challenge, a Bayesian calibration framework is implemented in ACBICI (A Configurable Bayesian Calibration and Inference package), an open-source Python library, to identify the most probable parameter distributions for governing DEM and PF models. This probabilistic approach not only refines parameter determination but also quantifies uncertainties in the models and calibration procedures, enhancing their predictive reliability.

The combined framework of DEM and PF models, augmented by Bayesian calibration, establishes a robust methodology for investigating binder jetting processes. By elucidating the underlying mechanisms of defect formation and quantifying uncertainties, this work contributes to the development of strategies to minimize residual porosity, ultimately advancing binder jetting toward the production of high-performance, defect-free components.

AI for Materials Industry: An Open Online Course

Prof. Stefaan Cottenier, Belgium

Poster Presentation

Abstract

We present AI4MI, an open-access educational initiative bridging the gap between materials science expertise and modern AI capabilities. Designed for materials scientists and metallurgists, this curriculum transforms complex AI concepts into practical tools through industry-relevant case studies. The course combines hands-on experience with real industrial datasets and foundational machine learning theory, featuring applications such as automated steel defect classification, materials discovery, and sensor data visualization. Through carefully structured modules, participants learn to identify suitable AI applications in their work, understand implementation requirements, and avoid common pitfalls. Special attention is given to data preparation, model validation, and model insight, ensuring participants gain both theoretical understanding and practical implementation skills.

Deformation Mechanisms in Ti-Nb Graded Materials: Insights from High-Throughput Analysis

Dr. Lola Lilensten, France

Poster Presentation

Abstract

β -metastable alloys have attracted growing interest in recent years thanks to their great work-hardening, allowing to combine strength and ductility. These properties are obtained by triggering the transformation-induced plasticity (TRIP) and twinning-induced plasticity (TWIP) effects, that are related to the metastability of the β -phase, and thus the composition of the alloy. However, despite their promising properties, a large development of these alloys remains. Current design approaches to target compositions of this family are mostly semi-empirical or empirical and rely on a large dataset resulting from numerous papers. The inherent drawback of this approach is that papers do not necessarily study the alloys in the same microstructural conditions (grain size, processing conditions...) or do not provide all the characteristic of the material (oxygen content...). Thus, exploiting such datasets leads to uncertainties. which might limit or postpone the development of this family of materials.

To tackle this problem, we propose using compositionally-graded materials. The Ti-Nb binary system is selected as a case-study. Indeed, depending on the Nb-content, it displays all the deformation mechanisms of interest, and is well documented in the literature. The graded material is prepared by diffusion couple with the two end-compositions Ti-18Nb and Ti-30Nb (at.%), framing the compositions of interest. Triggering the deformation mechanisms is done thanks to a single tensile test, and subsequent analysis of the deformed microstructures is done by electron microscopy. The results demonstrate that this approach allows us to quickly identify the compositional domains where a certain deformation mechanism is obtained. As all the compositions contained in the sample have undergone the same processing route, one sample leads to one solid dataset. The efficiency of the approach, in terms of time, is also discussed by comparing the tensile approach used here, to another one using micro-indentation.

Defect Analysis through Process Monitoring in Screw Extrusion-Based metal 3D Printing

Ph.D. Wonsik Lee, South Korea

Poster Presentation

Abstract

This study explores the detection and analysis of incomplete filling defects in screw extrusion-based metal 3D printing. In screw extrusion 3D printing, suboptimal process parameters—such as extrusion speed, jerk or acceleration—cause voids and unfilled areas in green parts. These defects, after debinding and sintering, lead to reductions in both tensile strength and elongation. Although process optimization can minimize such defects, identifying the precise parameter set depending on product geometries and feedstock materials typically requires nondestructive testing (NDT) of the final printed parts.

To address this challenge, we implemented a real-time process monitoring system that eliminates the need for extensive post-process NDT. During printing, a vision camera installed inside the 3D printer acquired grayscale image of each deposited layer. These images were converted to black and white images and underwent distortion and vignetting corrections to enhance accuracy in quantifying defect sizes and distributions. By comparing each processed image against the corresponding CAD image, we identified voids and partial infills within individual layers. Subsequently, we reconstructed a three-dimensional model from the stack of analyzed layer images, enabling early prediction of the extent of internal defects and their locations within the final product. To validate our monitoring approach, we compared vision-based defect images with computed tomography (CT) scans of the printed parts. The results demonstrated high consistency between the two methods, suggesting that in-process image acquisition can accurately locate internal defects without requiring external inspection tools. It seems that this work provides a practical, real-time strategy for optimizing printing parameters and enhancing quality assurance in screw extrusion-based metal additive manufacturing.

Elimination of stretcher strain marks in high-Mg Al-Mg alloys: deformation behavior and microstructural insights in H16 temper

Mr. Jabir Ali Siddique, South Korea

Poster Presentation

Abstract

The occurrence of stretcher strain marks (SSMs), also known as Portevin–Le Chatelier (PLC) bands, presents a challenge in high Mg content Al-Mg alloys, affecting both surface quality and mechanical properties. This study investigates the effect of Mg content on the deformation behaviour of Al-6Mg, Al-7.5Mg, and Al-8.5Mg alloys in H16 temper (60% cold rolled condition). The alloys were produced using Eco-Al processing, where Mg was alloyed with a Mg+Al₂Ca master alloy to enhance melt stability. Tensile testing and Digital Image Correlation (DIC) analysis reveal a direct correlation between Mg content and SSM formation. Al-6Mg exhibited early SSM initiation, while Al-7.5Mg showed a delayed onset with localized strain concentration. In contrast, Al-8.5Mg exhibited no evidence of SSMs, demonstrating uniform deformation, enhanced strength, and greater elongation than Al-6Mg and Al-7.5Mg. This novel finding suggests that the formation of SSMs can be eliminated in high Mg alloys processed to H16 temper, significantly improving mechanical stability and surface quality. X-ray Diffraction (XRD) and Full Width at Half Maximum (FWHM) analysis indicate that dislocation density increases with Mg content. Electron Backscatter Diffraction (EBSD) provides insights into texture evolution, while Transmission Electron Microscopy (TEM) examines dislocation morphology. These findings offer valuable insights into strain localization and strengthening mechanisms in high Mg Al-Mg alloys, contributing to developing materials with superior mechanical performance and surface integrity for industrial applications.

High-temperature profilometry-based indentation plastometry for nickel alloy development in additive manufacturing

Dr. Konrad Gruber, Poland

Poster Presentation

Abstract

Developing new high-temperature alloys is a challenging and resource-intensive process, partly due to the high costs associated with traditional tensile testing. Standard methodologies require the fabrication of dogbone-shaped samples and specialized high-temperature tensile testing setups, significantly limiting the number of feasible experiments. To overcome these limitations, profilometry-based indentation plastometry at high temperatures (Hot-PIP) has emerged as an efficient alternative. Hot-PIP enables the extraction of stress-strain curves from small cubic samples ($<10 \times 10 \times 10$ mm) by analyzing indentation imprints created at temperatures up to 800°C. This technique reduces material consumption, shortens testing times, and facilitates rapid mechanical property assessment. In this study, we investigate the applicability of Hot-PIP for the mechanical characterization of Inconel 718-TiC alloy produced using a powder bed fusion -laser beam of metals (PBF-LB/M). The alloy is fabricated through in situ composite powder processing, introducing TiC to enhance high-temperature performance, and compared to pure Inconel 718. We evaluate the ability of Hot-PIP to infer key mechanical properties such as yield strength, ultimate tensile strength, and ductility, comparing the results against conventional high-temperature tensile testing data. The findings demonstrate the feasibility of Hot-PIP as a robust tool for rapid alloy screening in additive manufacturing, particularly for high-temperature material development. By offering a more accessible approach to mechanical testing, Hot-PIP may help streamline the evaluation of new alloys in additive manufacturing while reducing material and experimental costs.

Thermohydraulic Performance and Optimization of a Double-Pipe Heat Exchanger with Perforated Annular Fins and clove functionalized GNP nanofluids

Dr. Cheen Sean Oon, Malaysia

Poster Presentation

Abstract

This study proposes a compound heat transfer enhancement method that integrates clove-functionalized graphene nanoplatelet (CGNP) nanofluids with perforated annular fins. The thermos-hydraulic performance and flow structure of a double-pipe heat exchanger fitted with fins of 0.2-0.7 porosity are investigated numerically in the Reynolds number (Re) ranging from 561 to 7,945. The CGNP nanofluid 0.025 wt% and distilled water (DW) were employed as the working fluid. This study filled the gap in research on the porosity of perforated fins. The numerical result showed that all fin designs could induce secondary flows and vortices, which intensified fluid mixing and thinner thermal boundary layers, resulting in heat transfer enhancement. Compared to the full annular fin, although the perforated structure resulted in a slight decrease in the Nusselt number (Nu), it was accompanied by a significant decrease in the pressure drop. A porosity of 0.4 was considered to better balance the heat transfer enhancement and pressure drop. Compared to the smooth circular pipe, the perforated fin with 0.4 porosity increased the Nu by 78% and the pressure drop by 87% at Re = 2270, at which time the highest PEC value of 1.46 was obtained. Furthermore, the CGNP nanofluid improved the heat transfer coefficient by 15.7 % and 19.5 % for a pipe with annular fins of porosity 0.4 and a smooth pipe, respectively, with a negligible change in pressure drop. The compound method strengthened the velocity–temperature field synergy, resulting in optimized convective heat transfer.

Cu-Mo-O mixed oxides as anodes in high performance lithium-ion batteries

Mr. Joaquín Calbet Bernad, Spain

Poster Presentation

Abstract

The mixed oxides of the Cu-Mo-O (CMO) system have attracted significant interest in recent years due to their remarkable redox properties, which enable applications in various fields such as catalysis, photochemistry, sensing, and energy storage systems [1]. Specifically, the 3:2 stoichiometry phase ($\text{Cu}_3\text{Mo}_2\text{O}_9$) exhibits a high theoretical capacity (916 mAh g^{-1}), high electronic conductivity, and a non-toxic nature compared to other metal oxides containing cobalt, which are commonly used in lithium-ion batteries (LIBs). Various synthesis methods and additional strategies have been employed to modify the microstructure and enhance the electrochemical performance of phases with different stoichiometries [2].

In this work, materials with nominal composition $\text{Cu}_3\text{Mo}_2\text{O}_9$, are synthesized using (i) ball milling of metals followed by oxidative heating, (ii) ball milling of metals oxides followed by calcination, (iii) solvothermal synthesis and (iv) coprecipitation method. Structural and compositional characterizations are performed using various techniques: XRD, Raman, SEDX, SEM and TEM. The electrochemical performance as anodes for Lithium-ion Batteries (LIB) is evaluated through cyclic voltammetry, charge-discharge curves at different rates, and impedance spectroscopy. The materials show high rate cyclability and long-term stability. Thus, capacity values of around 910 mA h g^{-1} after 10 cycles at 0.1 A g^{-1} , and 200 mA h g^{-1} after 2000 cycles at 1 A g^{-1} are obtained in some cases. Post-cycling assessments and preliminary kinetic studies further elucidate the electrochemical response of optimized anodes, highlighting their potential for enhancing LIB efficiency and longevity.

Machine learning-enhanced modeling of interactions between diamond surfaces and protein sequences

Mrs. Olena Onyshchenko, Poland

Poster Presentation

Abstract

This work presents an investigation into the application of machine learning (ML) methods for modeling protein structures of microcystin-LR (MC-LR) and diamond-based surfaces for advanced biosensing applications. MC-LR, a highly potent toxin produced by cyanobacteria, necessitates innovative detection strategies to ensure safe water supplies. In response, our research combines computational protein modeling with diamond surface optimization, showcasing the predictive capabilities of modern ML algorithms. Initially, we established a comprehensive dataset of homogeneous and heterogeneous diamond surfaces using QuantumATK software. The heterogeneous diamond structures were simulated as boron-doped diamond (BDD) functionalized with hydrogen, hydroxyl, or oxygen terminations to generate relevant terminations. The Moment Tensor Potential (MTP) was then trained and optimized using an active learning approach, allowing the model to refine itself iteratively as it encountered new or challenging configurations. By selectively adding data and calibrating parameters, the trained MTP exhibited enhanced robustness and predictive accuracy, effectively mitigating overfitting. In the second phase, we employed AlphaFold to predict protein sequences capable of detecting MC-LR. The predicted structures demonstrated high confidence scores, lending credence to the proposed folding motifs and providing a strong basis for subsequent experimental validation. Complementary simulations were performed for DNA aptamers designed for MC-LR detection, highlighting their potential for highly selective and sensitive biosensing applications. Collectively, these results underscore the promise of ML-driven approaches in bridging materials science and biotechnology for water remediation. The primary application of our findings is the development of optimized diamond-based electrodes, which can be seamlessly integrated with protein- or aptamer-based sensing elements to enable reliable detection and further degradation of MC-LR. This work drives innovation in the creation of cost-effective, durable, and scalable biosensors that enhance water quality monitoring and help protect public health. By uniting advanced ML-optimized materials modeling with biomolecular engineering, we provide a blueprint for addressing complex environmental challenges — particularly the urgent need for efficient and sustainable water safety technologies.

Spray-dried polymeric carriers for in-situ mucosal and submucosal regeneration in colorectal disease

Dr. Jacopo Barberi, Italy

Poster Presentation

Abstract

Colorectal diseases accounts for more than 2.2 million deaths in Europe. Among these, familial adenomatous polyposis and ulcerative colitis are two severe conditions, with the former potentially leading to the development of colorectal carcinoma, while the latter showing limited response to pharmacological treatments over time. When surgical intervention is required, proctocolectomy (i.e the complete removal of both the colon and rectum) or its restorative variant are typically performed, compromising patients' quality of life. In this context, minimally invasive removal of damaged mucosal and submucosal tissues and subsequent regeneration by innovative multi-functional engineered biomaterials has the potential to obviate the need for highly invasive surgery. Over the past few decades, drug loaded micro-, and nano-carriers based on synthetic and natural polymers gained increasing interest in the field of regenerative medicine, due to their excellent bioactivity, drug protection effect from environmental degradation and tuneable release kinetics. Their incorporation within an in-situ injectable hydrogel formulation mimicking mucosal and submucosal extracellular matrixes can synergistically promote the physiological tissue restoration while modulating the local delivery of the pharmaceuticals. In this research, chitosan (CHIT) and poly-lactic-co-glycolic (PLGA) based delivery systems were synthesized as micro- and nano-carriers using the spray-drying technique. Specifically, CHIT particles were loaded with neomycin (NEO) to provide a prompt, in situ, broad-spectrum antibiotic effect, while PLGA particles were loaded with pirfenidone (PIRF) to inhibit tissue fibrosis. CHIT was selected for its antioxidant, anti-inflammatory, and antimicrobial properties, which can be further enhanced by the short-term controlled release of NEO. Conversely, PLGA is a versatile and biodegradable polyester used for medium-term drug release systems (i.e., one to two weeks) of hydrophobic drugs. The optimization of the spray-drying process was conducted by testing different sets of parameters, including inlet and outlet temperatures, pump flow rate, and aspiration power, with the aim of achieving a single-step synthesis process for both the materials. Different polymer/drug ratios and molecular weights were evaluated and the resulting particles features, such as morphology, dimension and crystallinity versus amorphous features of the drugs were assessed. Cumulative drug release kinetics, evaluated by HPLC, were further tuned in their therapeutic windows by tailoring sodium-tripolyphosphate ionic reticulation and lactate/glycolate ratios respectively for CHIT- and PLGA-based carriers. To better mimic colorectal environment, release tests were conducted both in saline medium (TRIS-HCl) and in simulated intestinal fluid (SIF). Further tests on carriers' homogeneous incorporation in the in-situ injectable hydrogel will be assessed to ensure a reproducible drug release.

Incorporation of Mine Tailings into diverse industrial waste for the production of Alkali-Activated Cements in Sustainable Construction

Mrs. Lucila Alicia Menacho Rodriguez, Spain

Poster Presentation

Abstract

The sustainable utilization of industrial waste in construction materials is essential for reducing environmental impact and promoting circular economy principles. Alkali-activated cements (AACs) have emerged as a viable alternative to conventional binders, enabling the valorization of industrial by-products while minimizing the consumption of natural resources. This study evaluates the effect of mine tailings (MT) as precursor in AACs formulated with various industrial residues, including Aldebarán bottom ash (CFA), construction and demolition waste (CDW), and bleaching earth waste from the oil industry (TDCoosur). The primary objective is to assess the impact of MT incorporation on the mechanical performance of AACs and identify optimal precursor-activator combinations to enhance compressive strength.

Two types of activators were employed: a commercial activator and an alternative activator, the latter synthesized through the thermal treatment of NaOH and spent diatomaceous earth, a by-product of the brewing industry. Cementitious mixtures were prepared by incorporating 10% and 40% MT by weight into the selected precursors, and compressive strength tests were conducted to evaluate mechanical properties. The results indicate that the incorporation of 40% MT into CDW, activated with the alternative activator, led to the highest compressive strength improvement, demonstrating the synergistic interaction between these materials. Similarly, the addition of 10% MT to TDCoosur using the alternative activator resulted in even greater compressive strength values, highlighting its potential as a precursor. Conversely, when 10% or 40% MT was added to CFA with the alternative activator, a decline in compressive strength was observed, suggesting a less favorable interaction under the tested conditions.

These findings underscore the potential of mine tailings and industrial waste as sustainable raw materials for AAC production, provided that the appropriate precursor-activator pairings are selected. The study highlights the importance of optimizing AAC formulations to enhance mechanical performance and expand the applicability of waste-derived binders in sustainable construction. Further research should focus on long-term durability assessments and microstructural analyses to deepen the understanding of these alternative cementitious systems.

Challenges and new solutions in manufacturing ceramic matrix composites

Prof. Paulina Wieceńska, Poland

Poster Presentation

Abstract

Ceramic matrix composites (CMCs) can be fabricated by traditional ceramic manufacturing techniques, for example: hot pressing, extrusion, colloidal processing, or other methods, such as infiltration of preforms, centrifugal casting and additive manufacturing. Each shaping technique requires using specific processing agents which allow obtaining slurries or pastes of demanded rheological properties or provide other desirable features of the materials. These functional additives are as follows: dispersing agents, binders, monomers, (photo)initiators of polymerization, plasticizers, surfactants, pore-forming agents, precursors of reinforcing phase, etc. Possibilities of using different organic additives in the processing of CMCs will be presented (water-based monomers, sugar-based and polymeric deflocculants, polyacrylic binders, coordination complexes). The following issues will also be discussed: multifunctionality of selected compounds, thermal decomposition of additives during the sintering, fabrication of gradient composites, additive manufacturing of CMCs, ceramics reinforced by metallic nanoparticles.

Research was funded by the Warsaw University of Technology within the Excellence Initiative: Research University (IDUB) programme.

Valorization of phosphate mining waste: Dolomite sand application in durable self-compacting mortar systems

Mr. Hamza Beniddar, Morocco

Poster Presentation

Abstract

Phosphate mining operations generate vast quantities of mixed-type by-products that accumulate and deposit on mine surfaces without proper management, creating severe environmental concerns. Simultaneously, the construction industry faces sustainability challenges due to extensive extraction of virgin materials and diminishing natural resources. This research investigates the durability properties of self-compacting mortar (SCM) incorporating dolomite, a phosphate mining by-product, as a replacement for natural sand at 0%, 50%, and 100% substitution levels.

Durability was assessed through acoustic and thermal property measurements, capillary water absorption, shrinkage, and alkali-aggregate reaction tests. The alkali-carbonate reaction of dolomite aggregates was specifically investigated by subjecting samples to tetramethylammonium hydroxide (TMAH). Resistance to aggressive environments was evaluated by immersing specimens in 5% HCl and H₂SO₄ solutions, with residual mass loss and compressive strength monitored at 7, 28, 56, and 90 days of acid exposure. Microstructural analysis of acid attack mechanisms employed XRD and SEM techniques. Results demonstrate that dolomite-based SCM exhibits enhanced performance with lower thermal conductivity, reduced capillary water uptake, and decreased shrinkage, with no evidence of alkali-aggregate reaction in either mortar type. The minimal amount of brucite produced further confirms that dolomite aggregates are non-reactive. Notably, in acidic environments, conventional mortar lost 26.2% and 46% of mass in HCl and H₂SO₄ respectively, with corresponding compressive strength reductions of 97.3% and 86.6%. In contrast, dolomite-based mortar lost only 8.7% and 10.9% of mass, with strength reductions of just 31.5% and 41.3%. These findings indicate that dolomite from phosphate by-products represents a promising sustainable alternative for durable construction materials.

Dynamic Chemical Milling for Enhancing Internal Surface Quality of LPBF-Manufactured Scalmalloy Components

Mr. Rafael Eugenio Dos Santos, Spain

Poster Presentation

Abstract

In recent years, the additive manufacturing of metal parts using Laser Powder Bed Fusion (LPBF) has gained significant traction in high-performance industries such as biomedicine and aerospace due to its ability to produce complex geometries with high precision. However, a major limitation of this technology is the relatively poor surface quality of the fabricated parts, which can negatively impact their functional properties, including wear resistance, corrosion resistance, and fatigue life. To address this issue, various post-processing techniques, such as mechanical polishing, shot blasting, and chemical or electrochemical treatments, are commonly applied to improve the external surface finish. However, enhancing the surface quality of internal features, especially in complex geometries produced via LPBF, remains a significant challenge due to limited accessibility and the lack of effective treatment methods.

This study presents preliminary findings on the development of a novel dynamic chemical milling methodology specifically designed to improve the internal surface finish of Scalmalloy alloy parts produced by LPBF. Scalmalloy, an advanced AlMg-based alloy developed by Apworks for aerospace applications, offers high strength and lightweight properties, making it a prime candidate for additive manufacturing. An experimental setup was designed to facilitate the controlled circulation of an etching solution within the internal cavities of the parts, ensuring uniform material removal. The etching solution, composed of NaOH, Na₂S, and triethanolamine, was formulated based on established aerospace industry practices for aluminum alloy chemical milling. This study systematically investigated the influence of chemical concentration, treatment temperature, and exposure duration on surface roughness while minimizing unintended reductions in wall thickness. The results provide insights into optimizing the process parameters to achieve significant improvements in internal surface quality, thereby enhancing the overall performance and reliability of LPBF-manufactured Scalmalloy components for critical aerospace applications.

NEW ELECTROACTIVE AND THERMO-REVERSIBLE DIELS-ALDER EPOXY NANOCOMPOSITES DOPED WITH CARBON NANOTUBES

Dr. Monica Campo Gomez, Spain

Poster Presentation

Abstract

The manufacturing of reversible matrix epoxy nanocomposites with Diels-Alder bonds is highly complex and, therefore, constitutes a topic that is practically not treated in the state of the art. Diels-Alder epoxies need the addition of solid reagents, such as bismaleimide, that increase notably the viscosity and hinder the mixing and dispersion of nanofillers. Thus, the combination of network reversibility and self-healing with other smart functionalities such as electrical conductivity and Joule heating is hard to achieve. In this way, the state-of-the-art shows reversible epoxy nanocomposites that need contents of carbon nanotubes near or higher than 1 wt.%, which implies deep handling and economic drawbacks.

In the present work, a new manufacturing route is proposed to manufacture new electroactive Diels-Alder epoxy nanocomposites whose percolation thresholds are below 0.3 wt.%. The target is achieved by an optimized mixing methodology, and the materials show efficient thermo-electric behaviors, compared with previous attempts, that are close to conventional nanocomposites.

Composite ZnO/CeO₂ electrospun nanofibers as efficient antibacterial materials

Dr. Zili Sideratou, Greece

Poster Presentation

Abstract

Infectious diseases from microbial pathogens constitute a major global health problem,^{1,2} which is further intensified by the escalation of the antibiotic resistance rendering the traditional treatments ineffective. Therefore, in quest of new strategies to fight against bacterial infection, metal or metal oxide nanoparticles have emerged as very powerful tool.³ Amongst them, ZnO and CeO₂ stand out on account of their natural abundance, low cost, low toxicity, good biocompatibility and high bactericidal effect.^{4,5} To this end, in the present study highly active composite ZnO/CeO₂ antimicrobial nanoformulations are fabricated through a facile water-based electrospinning method. The composite ZnO/CeO₂ electrospun nanofibers are produced from an initial sol-gel solution employing water as the only solvent, PVA as a carrier polymer and Zn, Ce nitrates as metal precursors. After calcination, according to SEM analysis, the produced materials present a highly homogeneous nanofibrous morphology with small diameters not exceeding 200nm. In addition, elemental mapping measurements reveal a high compositional uniformity with even distribution of both Zn and Ce species, while the ratio of Zn/Ce was 1.2:1. After the structural characterization of the synthesized nanomaterials, their antibacterial activity was evaluated against Gram-negative *Escherichia coli* and Gram-positive *Staphylococcus Aureus* bacteria, while their biocompatibility was investigated through cytotoxicity on mammalian cell lines. It was found that these composite ZnO/CeO₂ electrospun nanofibers exhibited an enhanced, dose-dependent antibacterial activity against both test organisms. Additionally, due to their low toxicity, these nanofibers can be considered as very attractive antibacterial materials.

Carbon nanodisks decorated with triphenylphosphonium-functionalized hyperbranched poly(ethyleneimine) with enhanced antibacterial performance

Dr. Zili Sideratou, Greece

Poster Presentation**Abstract**

It is known that nanostructured carbon-based nanomaterials as well as polymers bearing suitable positively charged groups, such as triphenylphosphonium groups, guanidine groups, quaternary ammonium groups, etc., exhibit enhanced antibacterial properties [1,2]. Combining the above-mentioned categories, new nanomaterials with excellent antibacterial activities have been obtained [3-5]. Carbon nanodisks represent an interesting alternative to bulk graphite, produced through the so-called pyrolytic Kvaerner Carbon Black & H₂ (CB&H) process [6].

In this study, hyperbranched poly(ethyleneimine) of two different molecular weights (i.e. 1300 Da and 5000 Da) functionalized with decyl-triphenylphosphonium groups were developed and subsequently interacted through both covalent and non-covalent bonds with the acid-treated carbon nanodisks (oxCNDs), affording two nanohybrid materials i.e. oxCNDs@PEI(1300)-TPP(C10) and oxCNDs@PEI(5000)-TPP(C10). The successful attachment of polymers onto oxCNDs, was confirmed using various physicochemical techniques, while the polymer content in the hybrids oxCNDs@PEI(1300)-TPP(C10) and oxCNDs@PEI(5000)-TPP(C10) were found to be 20.45 and 24.04 %w/w, respectively. Also, the homogenous attachment of polymers on oxCNDs were confirmed by SEM and TEM microscopies. Subsequently, the antibacterial activity of the as-prepared nanohybrids were evaluated against Gram (-) Escherichia coli and Gram (+) Staphylococcus Aureus. From the obtained results, it can be concluded that all nanohybrids exhibit improved antibacterial properties compared to oxCNDs, especially against Gram (+) S. aureus bacteria, with oxCND@PEI(1300)-TPP(C10) being more efficient. Finally, their cytotoxicity was evaluated against mammalian cells and it was found that the hybrid materials do not exhibit any significant toxicity. These findings indicate that these nanohybrids have great potential to be used as safe and efficient antibacterial agents in various applications, including those in the disinfection industry.

A paper-based, gasochromic Pd-WO₃ sensor for hydrogen detection

Mrs. Maliheh Nazari, Portugal

Poster Presentation

Abstract

A hydrogen-based society requires secure access to technology, WO₃ gasochromic sensors being promising candidates for integrating new equipment¹. Nonetheless, WO₃ sensors are commonly produced via complex and expensive methodologies. In this work, we report a simple and sustainable strategy to manufacture paper-based WO₃ sensors, thus promoting an environmental-friendly route toward the visual hydrogen detection. WO₃ was prepared via a solvent-based synthesis. Briefly, WCl₆ was dissolved in ethanol (1 mg/mL) for 72 h and freeze-dried. The resultant WO₃ was dissolved in water (40 mg/mL) and an Na₂PdCl₄ aqueous solution (27 mg/mL) was added dropwise. The final Pd-WO₃ particles were obtained by centrifugation and freeze-drying. To prepare the paper-based sensor, bench protective paper (1.0×0.5 cm) was dipped in a Pd-WO₃ aqueous solution (5 mg/mL) for either 5 or 20 min. The gasochromic performances of the sensors (S5 and S20, respectively) were tested in a 10 % H₂/N₂ atmosphere. The ATR-FTIR analysis of the Pd-WO₃ particles confirmed O–W–O (605 cm⁻¹) and W–O–W (945 cm⁻¹) bands for WO₃, evidencing an efficient conversion of WCl₆ into WO₃. Indeed, Pd-WO₃ was able to change its color ($\Delta E = 30$; $t_{90} = 130$ s) when exposed to a 10 % H₂/N₂ atmosphere. Similarly, both S5 and S20 changed their colors from green to black during the 3 min test. As expected, the longer dipping time of S20 resulted in a more noticeable ($\Delta E = 8$) and faster ($t_{90} = 80$ s) color change comparatively to S5 ($\Delta E = 6$; $t_{90} = 100$ s). Although these gasochromic responses are still far from recently reported Pd-WO₃ sensors, S5 and S20 showed discernible color change (i.e. $\Delta E > 5$) within a competitive timeframe.¹ Such results encourage further studies to validate paper-based WO₃ sensors as suitable hydrogen detectors. Future work will include optimization of the Pd-WO₃ functionalization and, importantly, a detailed chemical, structural and mechanical characterization of the paper/Pd-WO₃ interface.

ACKNOWLEDGMENTS

Paper 421

Formation Mechanism of J-Aggregates in Two Types of Molecularly-Oriented Bisazo Dye Films

Ph.D. Tetsuya Aoyama, Japan

Poster Presentation

Abstract

[Introduction] We have developed highly-oriented J-aggregates of bisazo dyes.[1-4] In these studies, we found that two compounds differing only in the end group gave completely different results in polarized optical microscopy (POM) images and absorption spectra. These different results are presumably due to the fact that dye 1 is more likely to form J-aggregates, whereas dye 2 is not. In this study, we investigated the formation of J-aggregates by comparing these two compounds.

[Experiment] Bisazo dyes 1 and 2 were vacuum-deposited on the polytetrafluoroethylene (PTFE) alignment layers, resulting in molecularly-oriented films containing J-aggregates. These two films were analyzed by polarized optical microscopy (POM) and atomic force microscopy (AFM). X-ray structure analysis was performed on single crystals of these two compounds, and the molecular packing in their films was investigated using grazing incidence wide-angle X-ray scattering (GIWAXS) measurements.

[Result] Single crystal analysis revealed that the directions of molecules within the unit cell are all parallel for dye 2, but not completely parallel for dye 1. This difference may have affected the formation of J-aggregates because molecular orientation is achieved by trapping along the atomic grooves between adjacent PTFE chains.[2] If all the molecules are parallel and can easily align with the atomic grooves, highly oriented and uniform thin films can form.[1] On the other hand, if the molecules are not parallel within the unit cell, some molecules may be placed across two parallel adjacent atomic grooves, resulting in a reduction in molecular alignment. However, this arrangement could facilitate the formation of J-aggregates because J-aggregates can form under quasi-stable conditions. In fact, when dye 2 was vacuum-deposited onto the glass substrate directly without the PTFE alignment layer, the quantity of J-aggregates formed in the films significantly increased. In summary, a high order parameter is achieved when the molecules fit well into the atomic grooves of PTFE. Conversely, our results suggest that if the molecular arrangement and the atomic grooves are poorly matched, the degree of orientation is reduced and J-aggregates are more likely to form.

In-vitro corrosion tests of Zn and Mg-based wires for biomedical applications

Mr. Jiří Liška, Czech Republic

Poster Presentation

Abstract

Magnesium alloys with Zn addition are promising biodegradable materials for bone fixation implants. However, their corrosion behavior must be optimized to ensure a controlled degradation rate and sufficient mechanical strength. Another key challenge is controlling hydrogen release during corrosion, which is linked to surface quality and material purity. In this study, in vitro tests were performed in DMEM at 37 °C to investigate the corrosion kinetics of Mg-Zn alloy wires (Mg, Mg-0.3Zn, Mg-0.4Zn, wt.%). These wires were braided into strands, and the amount of released hydrogen gas in DMEM was measured. Temperature and pH were continuously monitored, and corrosion products were analyzed using SEM and EDS. The addition of zinc resulted in a more controlled corrosion rate compared to pure magnesium while maintaining adequate mechanical integrity. The results provide insights into corrosion behavior and the role of Zn alloying, contributing to the optimization of biodegradable materials for medical applications.

A Team-Based Framework for First-Year Materials Physics Education

Dr. Kristina Bockute, Lithuania

Poster Presentation

Abstract

Traditional materials science curricula often prioritize abstract theory over early engagement with applied design challenges. However, recent studies have explored innovative approaches to teaching introductory materials science courses, emphasizing active learning and real-world applications. Project-based learning (PBL) has been implemented in first-year engineering curricula, integrating multidisciplinary projects with traditional lecture content [1]. These projects enable students to apply theoretical concepts to practical challenges and connect abstract concepts with real-world engineering decisions.

This study presents a pedagogical model for first-year undergraduate materials physics that integrates active, team-based learning with real-world material selection tasks. Over a half-semester project, student teams analyze applications (e.g., biodegradable packaging, lightweight automotive components) through iterative research, experimental data analysis, and ethical evaluation. The framework employs a structured problem-solving approach, developing through problem identification, experimental validation, and teams' presentations. This phased method fosters critical thinking, teamwork, and effective technical communication.

Key innovations include integrating ethical design principles through case studies on global challenges like material shortage, encouraging participants to balance performance with societal impacts. Failure-driven learning is integrated via reflective reports, promoting resilience and iterative improvement. Authentic assessments, such as peer evaluations and stakeholder pitches, replicate real-world accountability. Data from pre/post surveys indicate that most students improved their ability to connect theoretical concepts with practical constraints, alongside developing stronger collaboration skills. Performance in material selection tasks, assessed through rubric-based grading, also showed notable improvement. This framework illustrates that early exposure to open-ended, ethics-driven design projects strengthens foundational materials science knowledge and enhances professional readiness.

Investigation of Co-doped Iron Oxide Electrocatalysts for AEM Electrolysis

Dr. Kristina Bockute, Lithuania

Poster Presentation

Abstract

Recent advancements in catalyst development for anion exchange membrane (AEM) water electrolysis have highlighted iron oxides doped with cobalt as efficient and cost-effective alternatives to noble metal-based catalysts. Studies demonstrate that Co doping enhances the oxygen evolution reaction (OER) activity and durability of Fe-based oxides, optimizing their electronic and structural properties for improved performance. These findings [1-2] emphasize the potential of Co-doped Fe oxides to boost AEM electrolysis efficiency, offering a promising pathway toward scalable and sustainable hydrogen production.

In this study, we present a systematic investigation into transition metal oxides, specifically Fe₂O₃ thin films doped with cobalt, as highly active and robust catalysts for OER. The thin films were fabricated using reactive magnetron sputtering, a precise deposition technique enabling control over film composition, microstructure, and thickness.

Comprehensive characterization of the Co-doped Fe₂O₃ thin films revealed improvements in catalytic activity and stability compared to undoped Fe₂O₃. Structural analysis using X-ray diffraction (XRD) indicated that cobalt incorporation enhances the crystallinity and modifies the lattice structure, promoting favorable electronic and surface properties. Scanning electron microscopy (SEM) and atomic force microscopy (AFM) provided insights into the surface morphology and uniformity of the films, which directly impact their electrochemical performance.

Laser Powder Bed Fusion of Crack-Susceptible AISI M2 Tool Steel: From Process Parameter Development to Industrial Validation — A Comparative Study of Additively and Conventionally Manufactured Components

Mr. Tousif Anwer, India

Poster Presentation

Abstract

AISI M2 high-speed tool steel is extensively used in the forging and tooling industry due to its exceptional hardness and wear resistance. However, its conventional manufacturing route, which includes casting, forging, complex multi-step heat treatment, and diamond-tool-based hard machining, is both time- and cost-intensive. Additive Manufacturing (AM), specifically Laser Powder Bed Fusion (LPBF), offers a transformative alternative by enabling near-net-shape fabrication with rapid solidification and intrinsic layer-by-layer thermal cycling. This approach can potentially eliminate the need for extensive post-processing, such as prolonged heat treatments and hard machining.

Nevertheless, processing AISI M2 via LPBF remains highly challenging. The high carbon content (~1 wt.%) and complex alloy chemistry lead to poor weldability, causing crack formation, delamination, and high residual stresses due to the formation of hard and brittle martensitic and carbide phases. This work focuses on developing a robust LPBF process parameter set to fabricate crack-free AISI M2 components. A comprehensive parameter optimization strategy was employed to suppress cracking and produce defect-free builds.

The additively manufactured components were characterized using a suite of microstructural techniques including optical microscopy, SEM, EBSD, TEM, and XRD, along with mechanical testing such as hardness, tensile, and compression tests, benchmarked against conventionally manufactured counterparts. Finally, both sets of components underwent industrial cold forging trials to evaluate tooling life and failure mechanisms under real service conditions.

The study demonstrates the feasibility of producing crack-free AISI M2 tool steel via LPBF and establishes its potential to replace conventional manufacturing for high-performance tooling applications, significantly reducing processing time, cost, and energy consumption.

Electrophoretic deposition of Pr³⁺-doped Lu₂SiO₅ thin films for antimicrobial applications

Ph.D. Željka Antić, Serbia

Poster Presentation

Abstract

In this study, we utilized electrophoretic deposition to create antibacterial thin films from Pr³⁺-activated powders. The motivation for this research stems from the unique luminescent properties of Pr³⁺-doped materials. In cases where the Pr³⁺ lowest-energy 4f5d state is located below the 4f2 1S0 state, Pr³⁺ ions facilitate two-photon blue light upconversion to the ultraviolet C (UVC) spectral range. UVC light has widely known germicidal properties, which means it may effectively kill microorganisms such as bacteria, viruses, and fungi. As a result, UVC is employed in a variety of disinfection processes, including water and air purification and surface sterilization in healthcare settings. This study intends to develop functional coatings with biocidal capabilities under visible light using the upconversion properties of Pr³⁺-doped materials. At first, single-phase Lu₂SiO₅ doped with 0.5 mol% Pr³⁺ was produced by a Pechini-type polymerized complex technique. This method involves a polyesterification reaction between citric acid and ethylene glycol, yielding a precursor material subsequently utilized for electrophoretic deposition. Subsequently, we fabricate thin films on conductive aluminum substrates using the electrophoretic deposition of the precursor powder. Both films and precursor powders undergo full characterization employing several analytical techniques. The methods employed comprised X-ray diffraction for analyzing the crystal structure, scanning electron microscopy for examining morphology and surface characteristics, and photoluminescence spectroscopy for evaluating upconversion emission. To assess the efficacy of thin films for germicidal applications, experiments were conducted on gram-positive bacteria (*Staphylococcus aureus*), gram-negative bacteria (*Escherichia coli*), and fungus (*Candida albicans*), chosen due to their relevance in clinical and environmental settings.

Dynamic stimulation using uniaxial compression promotes the osteogenic and anti-osteoclastogenic responses of cellular co-cultures within composite scaffolds

Prof. Maria Chatzinikolaïdou, Greece

Poster Presentation

Abstract

Introduction

The dynamic bone tissue undergoes continuous remodeling through lifetime regulated by different cell types, bone forming osteoblasts and bone resorbing osteoclasts. Mechanical stimulation applied on bone tissue can shift the balance between these two cell populations [1]. In this study, the application of uniaxial compression in a three dimensional (3D) co-culture comprising human bone marrow mesenchymal stem cells (hBM-MSCs) and human peripheral blood mononuclear cells (hPBMCs) was established and validated [2]. The two cell populations were seeded onto 3D scaffolds produced by fused deposition modeling. The scaffolds composition was 90/5/5 %wt of poly-L-lactic acid, polycaprolactone and poly(3-hydroxybutyrate-co-3-hydroxyvalerate) substituted with 2.5% wt strontium-nano-hydroxyapatite.

Methodology

hBM-MSCs (7x10⁴ cells/scaffold) were seeded and cultured under static and dynamic culture conditions for 13 days, followed by the addition of hPBMCs (50x10⁴ cells/scaffold) and application of mechanical stimulation every other day for 25 min at a frequency of 1 Hz and a strain at 8% of the scaffold side (400 µm of displacement). Cell proliferation and morphology were monitored via a reduction-based cell viability assay, scanning electron microscopy (SEM) and confocal microscopy. Measurements of the alkaline phosphatase (ALP) and tartrate acid phosphatase (TRAP) activity were conducted to determine the effect of the scaffolds on the osteogenesis and osteoclastogenesis. Quantitative polymerase chain reaction was applied to quantify gene expression changes of osteogenesis-related markers (osteonectin, osteoprotegerin and osteocalcin), and osteoclastogenesis-related markers (TRAP, dendritic cell-specific transmembrane protein and nuclear factor of activated T cells 1).

Results

The cell viability assessment displays excellent biocompatibility, while SEM and confocal microscopy images display well-spread cells. After 14 and 28 days, the ALP activity is higher in the dynamic co-culture compared to the static one and the corresponding hBM-MSCs mono-culture. The TRAP activity results showed a significantly lower TRAP activity in the dynamic co-culture than in the static co-culture and the hPBMCs mono-culture after 14 days. Gene expression of osteogenesis related markers was significantly higher in the dynamic co-culture than in the static and mono-cultures of hBM-MSCs.

Conclusions

The results confirm that the mechanical stimulation enhanced the osteogenesis and suppressed the osteoclastogenesis in an in vitro cell co-culture of hBM-MSCs and hPBMCs due to the communication of the two cell populations compared to the monocultures and the static co-cultures.

The effect of deformation on Al-Mg-Si(-Cu) alloys

Mrs. Inga Konow, Norway

Poster Presentation

Abstract

By studying the microstructure of aluminium alloys, we aim to optimize thermomechanical processing, possibly allowing for better performance while maintaining their recyclability. Al-Mg-Si(-Cu) alloys are commonly used in automotive, aerospace and construction due to their combination of lightweight properties, strength and corrosion resistance. These alloys strengthen via precipitate hardening, where fine particles hinder dislocation movement. Small additions of alloying elements like zinc and iron can drastically alter the precipitation in a material, changing the performance. This is a common challenge when it comes to recycling of aluminium. Higher recycling rates require broader compositional windows and tolerance for impurities, and it can be crucial to find thermomechanical processing routes optimized for high scrap content.

Plastic deformation improves the tensile strength by introducing dislocations and changing the precipitate formation, but the mechanisms behind are not yet fully understood. In this study we look at two different processing routes, involving plastic deformation after extrusion; the first involves cold rolling before heat treatment and the second has an additional heat treatment before the rolling. We use transmission electron microscopy (TEM) techniques such as conventional bright-field and dark-field TEM along with high-angle annular dark-field scanning TEM (HAADF-STEM) to quantify precipitate size, density and type. The aim is to link the mechanical properties to the microstructure, with an emphasis on sustainable alloy design.

Study on the Electrochemical Characterization of Multi-component Dimensionally Stable Electrodes for Copper Electroplating in PCB Manufacturing

Ph.D. Seong Ho Son, South Korea

Poster Presentation

Abstract

Dimensionally stable electrodes (DSEs), as substitutes for conventional copper anodes, enable precise fine-pattern formation in copper electroplating for PCB circuits. The use of DSEs in PCB electroplating requires high energy efficiency and durability. DSEs are typically fabricated by coating one or more noble metal oxides onto the titanium substrate due to their electrochemical performance and stability. During the PCB electroplating process, oxygen evolution reactions at the anode decompose organic additives in the electrolyte, reducing electrolyte stability and hindering fine-pattern formation. Therefore, research on the fabrication of noble metal coatings for DSEs is required to enhance electroplating performance and electrolyte stability. In this study, noble metal coatings with high current efficiency and reduced organic additive decomposition were fabricated by depositing metal oxides such as iridium, ruthenium, and tantalum in various compositional ratios, followed by optimization of oxidation heat treatment conditions. The composition and surface morphology of the DSE were characterized using field emission scanning electron microscopy (FE-SEM) and energy-dispersive X-ray spectroscopy (EDS or EDX). Electrochemical reactions were analyzed using a potentiostat, and the decomposition characteristics of organic additives were evaluated by cyclic voltammetry stripping (CVS). The copper electroplating process was performed using a sulfuric acid-based electrolyte containing a suppressor, an accelerator, and a leveler of organic additives at a current density of 50 mA/cm² for 60 minutes, and the decomposition rate of organic additives in the electrolyte was measured. The decomposition rate of the suppressor showed minimal dependence on the DSE composition, whereas the accelerator exhibited a higher decomposition rate with increasing Ir content in the DSE coating layer.

Machine Learning Prediction of magnetic properties for Fe-based and Pt-based alloys

Dr. Svitlana Ponomarova, Ukraine

Poster Presentation

Abstract

Fe-Pt intermetallic alloys represent a group of solid-state materials that exhibit interesting physical and chemical properties dependent on their chemical compositions. For instance, Fe-Pt alloys can experience various types of phase transitions, including atomic and magnetic ordering and martensitic transformation, across a wide range of concentrations and temperatures.

Different phase transitions can coexist, and their interactions may alter material properties.

Meanwhile, Pt-based alloys undergo magnetic transitions along with atomic ordering. Fe- and Pt-based alloys are utilized in high-density magnetic storage devices, magnetic recording media, and optical and electronic devices.

There are two different approaches to determining the Curie temperature. The classical method involves preparing an alloy of a specific composition and measuring the Curie temperature through experimental techniques. In contrast, the second approach predicts the Curie temperature before performing experiments, based on the known physical and chemical properties of the material.

In this research, we adopt the second approach and apply machine learning techniques to predict the Curie temperature (T_c) for Fe-based and Pt-based alloys. Control factors include atomic order (formation of the L12-type of superstructure) and variation of the chemical composition of the alloy by adding a small amount of a third element (up to 5 at.%).

The feature set for supervised machine learning includes the alloy's composition, atomic order state, and the atoms' properties.

We identified the best-fit mathematical model and validated the results using experimental methods to measure the Curie temperature.

Our findings indicate that the Voting Ensemble model, combined with the Monte Carlo cross-validation method, achieves the best performance and provides the most accurate predictions. "Normalized root mean squared error" is used as the primary metric for evaluation obtained results.

For our technical toolkit, we select the Azure machine learning framework due to its robust capabilities in machine learning and its user-friendly design.

This study can be extended to include different doping elements in Fe-Pt alloys, as well as applications to Fe-Pd-based and Fe-Ni-based bulk alloys and nanoparticles.

Performance-optimized diatom-SiO_x anodes for Li-ion batteries by preserving the nanostructured SiO₂ shells of diatom microalgae and tailoring oxygen content

Prof. Valeria Blanco, Spain

Poster Presentation

Abstract

Nanostructured silicon oxides (SiO_x) are promising anode materials for lithium-ion batteries (LIBs) due to their high capacity and excellent cycling stability. Nanostructured SiO₂ sourced from diatom microalgae holds great potential as a sustainable template for SiO_x synthesis via scalable magnesiothermic reduction (MgTR), which requires SiO₂ and Mg as reactants. However, the successful application of diatom-SiO_x in LIB technology relies on the ability to achieve precise control over SiO_x oxygen content while preserving the intricate nanoporous structure of diatom-SiO₂. This work explores, for the first time, the use of diatom-SiO₂ from industrially cultured microalgae as a precursor for SiO_x anodes through MgTR. Our findings reveal that partial reduction of diatom-SiO₂ to diatom-SiO_x occurs through the formation of Si nanocrystals embedded on the SiO₂ matrix. Particle nanostructure was found to be highly sensitive to the heat generated during MgTR, and it could only be preserved by adding controlled amounts of NaCl heat scavenger. Distinctive electrochemical performance of SiO_x anodes was achieved by modifying the amount of Mg on the reactants mixture. Anodes prepared with 1:1:2.5 SiO₂-to-Mg-to-NaCl molar ratio delivered optimal electrochemical performance, with superior capacity stability after 200 cycles. These findings provide key enablers for developing performance-optimized sustainable diatom-SiO_x anodes.

Green Synthesis of Magnetic Iron Oxide Nanoparticles Using Agave tequilana bagasse extract and its Application for Toxic Dyes and Cr (VI) removal in aqueous solution

Mr. Javier Alejandro Pérez-Gómez, Mexico

Poster Presentation

Abstract

Magnetic iron oxide nanoparticles (MIONPs) were synthesized using a novel green method consisting of a water-based extract from bagasse of Agave tequilana Weber var. azul (residual from the Tequila industries) used as the reducing agent and iron nitrate nonahydrate as the precursor during the microwave-assisted synthesis. The physical and chemical properties of the MIONPs, along with the ease of magnetic separation after reactions, make them a good candidate for removal of water contaminants. For the MIONPs syntheses, we used different percentages of bagasse extract (from 5 to 10% w/w), and we varied the concentrations of iron nitrate nonahydrate from 0.08 to 0.24 M. The nanoparticles were characterized using UV-Vis, FTIR, and Raman spectroscopies, as well as TGA, XRD, SEM, VSM, and TEM techniques. UV-Vis, FTIR, and Raman spectroscopies confirmed different iron oxide and hydroxide phases of the nanoparticles along with different sizes (10 nm to 36 nm) and shapes as confirmed by the TEM micrographs. The XRD confirmed crystalline and amorphous phases of iron oxide and hydroxide nanoparticles. The VSM technique showed paramagnetic and ferromagnetic-like behaviors of the nanoparticles. The color removal capacity of the nanoparticles was tested for the toxic dyes Maxilon red (MR), methylene blue (MB) brilliant green (BG) and, also for adsorption of Cr (VI) from aqueous solutions. The nanoparticles achieved good performance for Cr (VI) adsorption and color removal of toxic dyes in batch reaction experiments, with complete removal for BG and 90% removal of MB. The performance of the nanoparticles for Cr (VI) adsorption and color removal of toxic dyes was related to the crystallinity of the iron and iron hydroxide phases. The environmental impact of the wasted bagasse is huge in the area, and we are providing here an option to use it with a beneficial purpose.

DED-LB/Mp additive manufacturing of a G91 steel using atomized and mixed commodity powders

Dr. Pilar Rey Rodriguez, Spain

Poster Presentation

Abstract

Among all additive manufacturing (AM) technologies, Directed Energy Deposition, DED, is preferred due to its ability to produce relatively large parts requiring minimal tooling and relatively little secondary processing. In addition, DED processes can be used to produce components with composition gradients, hybrid structures with different materials and microstructures and to repair or add features on pre-existing components. But, probably one of the main interests for some industries is the potential to fabricate spare parts on demand as in the case of the Energy sector. In this sector, G91 ferritic-martensitic alloy is of specially interest due to its stability at high temperatures and creep strength. However, this material does not exist as powder feedstock and parts are not conventionally made using pulvimetallurgy routes.

In this work, we have optimized and printed by Laser Beam Directed Energy Deposition using metallic powder (DED-LB/Mp) several coupons using an atomized G91 alloy in a robot cell consisting in a KUKA industrial table and robot with a PERMANOVA laser head equipped with a FHG-IWS continuous nozzle and a 8kW COHERENT fibre laser. A GTV powder feeder was used to blown the powder carried using an argon flow. On the other hand, a pre-mix of commodity powders (H13 and SS430L) as prepared using a Turbula mixer with a composition close to the G91 one. With this pre-mix, also tracks, overlaps and coupons have been printed and compared with the original alloy. Macro and microstructural observations were made using Optical Microscopy (OM) to assess both quality and microstructure, revealing no noticeable porosity nor cracks for both materials. The microstructure was also studied using Scanning Electron Microscopy (SEM) to detect intermetallic and or segregations on different regions of the coupon. The resulted microstructure present different morphologies and phases depending on the printing parameters and the type of alloy. Finally, mechanical properties using microhardness, tensile and small punch tests (SPT) were obtained. A noticeable increase in resistance was detected in the mixture as a consequence of the higher content of carbon

Recovery and efficiency improvement of a TiO₂-rich waste: the case of tionite

Prof. Barbara Di Credico, Italy

Poster Presentation

Abstract

The depletion of natural resources and the progressive environmental deterioration have emphasized the need for more sustainable chemical processes. A common solution is sustainable remediation, which involves removing pollutants released in the environment. Photocatalysis, particularly using titanium dioxide (TiO₂), proved efficient in degrading a wide range of organic contaminants at ambient conditions. However, due to the high environmental impact of TiO₂ production and market volume, more sustainable practices in TiO₂ preparation are needed. Traditional TiO₂ production, namely mineral extraction and liquid-phase synthesis, require high energy and solvent consumption. TiO₂ extraction from wastes has been considered, but the solution still has a strong environmental impact. Therefore, the direct use of Ti-rich residues or their improvement through mild chemical procedures remain more sustainable options but poorly explored. This scenario prompted us to investigate and optimize a TiO₂-rich waste material, known as tionite, obtained by the recovery and neutralization of the insoluble components from the TiO₂ production by sulfate process. Considering the rising interest toward circular economy, the final goal is to close the loop of TiO₂ industrial production through the application of tionite as a sustainable photocatalyst.

Tionite obtained using Ca(OH)₂ as a neutralizing agent showed NPs with various shapes made of a combination of TiO₂, mainly in the rutile phase, aluminosilicates and a significant amount of CaSO₄·2H₂O. Since preliminary photocatalytic tests conducted on tionite showed no significant photodegradation yields, a treatment based on NaOH neutralization was carried out to simplify tionite composition and improve its photoactivity. The new tionite shows a more homogeneous morphology consisting of titania NPs and aluminosilicate sheets with different counterions. To further simplify tionite composition, mild treatments with HF or NaOH were carried out to remove SiO₂-based components, as confirmed by a multi-technique characterization.

The obtained tionite samples, having different physico-chemical characteristics, were tested for different photocatalytic applications. At first, samples were employed in both traditional photocatalysis and photo-Fenton processes, but no significant decay was observed. On the other hand, remarkable selectivities were obtained in the application of tionite samples for the partial oxidation of ferulic acid to vanillin, an industrially relevant compound. The application of tionites in peroxymonosulfate (PMS)-assisted catalysis demonstrated a remarkable efficiency in PMS activation and 4-chlorophenol (4-CP) degradation for all samples.

In conclusion, TiO₂-based materials not only can reduce environmental pollution by degrading organic molecules, but the development of sustainable strategies for their production and preparation is possible.

ODS Steels Produced by Additive Manufacturing for Materials in Harsh Environments

Ph.D. Irena Paulin, Slovenia

Poster Presentation

Abstract

Oxide dispersion-strengthened (ODS) steels are known for their superior mechanical properties at high temperatures and increased resistance to neutron irradiation embrittlement. These properties favour them for future applications as fuel cladding for next-generation nuclear systems and blanket materials for fusion power systems. We aim to determine whether an ultrasonically gas-atomised precursor steel powder with the addition of oxide nanoparticles or a steel powder with smart surface oxidation, combined with consolidation techniques such as laser powder bed fusion (LPBF), can enhance the performance of ODS steel in extreme, high-temperature conditions. As a proof of concept, we have selected austenitic 316L stainless steel, which has good ductility, workability, and mechanical integrity at high temperatures. Y₂O₃ has been chosen as the nanopowder material to add to the matrix, as it has a higher ultimate tensile strength than other powders. As the project progresses and the strengthening mechanisms associated with the nano oxide dispersion are known, TiB₂ nanoparticles (with a higher melting point) will also be employed.

We prepare ODS steels by mechanical mixing in Turbula, followed by ball milling and LPBF processing. We perform microstructure characterisation, mechanical testing at elevated temperatures, corrosion tests, tribology tests, and Vickers' hardness. The morphology and phase composition of the resulting powders and LPBF samples are analysed using scanning electron microscopy (SEM) with an EDS and EBSD, respectively.

Measuring Circularity in Practice: Insights from Repairability Assessment

Mrs. Setenay Saglam, Switzerland

Poster Presentation

Abstract

Material circularity is becoming increasingly important in today's economy and is a central focus of both industry and policy agendas. Achieving circularity requires robust, consistent metrics that can evaluate circular economy strategies across all levels of a product, beginning at the material level. From design for reuse to functional recycling, each strategy offers different opportunities for circularity. To understand their real impact, these strategies must be measured in a comparable and transparent way.

Within the CE-RISE project, we have developed a set of indicators to support such evaluations. This poster presents the methodology behind these indicators, using the repairability indicator as an example. By applying these indicators, we aim to provide a practical basis for assessing how much circularity products can unlock.

Among circular strategies, repair plays a central role due to its close relation with current and emerging regulations. Policies such as the Right to Repair and the Ecodesign Directive are shaping expectations for how products should be designed to enable easier repair. However, to evaluate how well these regulations are applied in practice, and to assess the efforts made by manufacturers, a common assessment is needed.

One relevant initiative in this area is the EN 45554 standard, which provides a methodological basis for assessing the repairability of energy-related products. Based on this standard, several repairability indexes have been developed, including the French Repairability Index and the iFixit Repairability Score. While these indexes offer useful perspectives, they differ in scope, scoring logic, and applicability across product categories.

Within the CE-RISE framework, these existing indexes have been compared and evaluated using real-world cases from industry partners. As a result, a new tool called the Repairability Indicator has been developed. This indicator uses a scoring system that considers both design-related parameters (e.g., modularity, accessibility of components) and support-related parameters (e.g., availability of documentation and spare parts over time).

Each parameter is scored individually, and the combined result reflects how repairable a product is in practice. The aim is to provide a flexible tool that can be adapted to different product groups while offering a fair, consistent basis for comparison.

In our poster presentation, we will introduce the EN 45554 standard, review key existing repairability indexes, and present the Repairability Indicator developed within CE-RISE. By combining and adapting current approaches, this tool helps move toward a more harmonized method for assessing repairability and supports clearer tracking of circular economy progress across sectors.

Optimising NiCoMn Electrocatalysts for Efficient Hydrogen Production

Dr. Cátia Freitas, Portugal

Poster Presentation

Abstract

Hydrogen evolution reaction (HER) is crucial for renewable energy, requiring the development of cost-effective electrocatalysts. Noble metals like Pt, Ru, and Pd are highly efficient HER electrocatalysts due to their exceptional catalytic activity. Nevertheless, high costs and limited availability make them impractical choices, making it important to find more affordable and readily available alternatives. This study proposes to utilise nickel (Ni), cobalt (Co), and manganese (Mn) synthesised and/or recovered from battery cathodes as electrocatalysts for the hydrogen evolution reaction (HER).

Ternary transition metals compounds (NiCoMn) obtained by hydrometallurgical processes for the treatment of waste lithium-ion batteries (based on Li, Ni, Co, and Mg oxide cathodes) were tested as electrocatalysts for HER in alkaline media and its performance compared with hydrothermal synthesised NiCoMn materials. NiCoMn materials supported in carbon black were also prepared by hydrothermal synthesis to promote synergy between the ternary transition metal compounds and the highly conductive carbon material.

While these metals individually exhibit catalytic activity, the use of NiCoMn complexes, particularly those derived from battery cathode leaching solutions, remains largely unexplored. The electrocatalytic performance of the NiCoMn materials reduced under H₂ flow at 200 °C shows the best electrocatalytic performance, with an overpotential of -0.5 V and excellent electrochemical durability for 100h. The enhanced catalytic stability of NiCoMn mixtures compared to the individual metal compounds is presumably related to the synergistic effect between the Ni, Co, and Mn and the increased number of active sites. Additionally, although carbon black decreases the catalyst overpotential, its general stability remains unchanged.

To the best of our knowledge, the use of NiCoMn compounds, mainly those derived from battery recycling, as HER electrocatalysts has not been previously reported. This approach offers a sustainable solution by minimising environmental impact, conserving resources, and fostering a circular economy.

Paper 875

Finite element modeling of effective mechanical properties of multiphase metal matrix composites with various interphase zone

Dr. Szymon Nosewicz, Poland

Poster Presentation

Abstract

Metal–matrix composites (MMCs) are an important class of materials in which the microstructure can be tailored to have superior properties by comparison with non-reinforced alloys. Depending on the manufacturing process, MMC can be more complicated than just a two-phase material combination. Due to solubility and temperature-driven diffusion, another phase is formed between two phases of the composite, which exhibit properties quite different from those of its surroundings. Such interphase plays a critical role in the composite. It may not only modify the physical properties of the composite but also change the quantitative global behavior of the composite material [1].

The proposed research investigates how variations in the plasticity and damage parameters of the interphase influence the effective mechanical properties of a representative volume element (RVE) representing a metal matrix composite (MMC). This study is driven by the understanding that the mechanical properties of the interphase, often not well characterized, can significantly affect the overall behavior of the composite. To explore this, a finite element (FE) model was employed to simulate the composite's effective response, with interphase properties ranging from highly brittle with low ductility and toughness to highly ductile, resembling the matrix material. The numerical simulations were performed on the example of sintered nickel-silicon carbide composite, where the interphase characteristics depend on the manufacturing process. The modeling approach utilized several advanced frameworks:

- The Gurson-Tvergaard-Needleman model for the matrix
- An elastoplastic model with damage for the interphase/particle
- A cohesive zone model for the interface

It shows the significant influence of interphase properties on stress-strain evolution, fracture modes, and effective composite properties - ultimate tensile strength, fracture strain, and toughness. Each composite component's deformation and damage behavior (matrix, interphase, particle, interfaces) has been studied. As the yield stress, hardening curve, and fracture strain of interphase together with interface strength and its fracture energy evolved, more than six fracture modes have been observed, which is the key to the mechanical performance of a complex three-phase system.

Laser-induced graphene on synthesized polyimides

Mrs. Katarina Tošić, Serbia

Poster Presentation

Abstract

In recent years, laser-induced graphene (LIG) has attracted significant attention due to its excellent physicochemical properties and potential applications in wearable and flexible electronics. This method of graphene production offers a simple, fast as well as cost-effective approach compared to traditional techniques, making it highly suitable for various technological applications. Polyimides are among the most compounds commonly used as substrates for laser-induced graphene formation on polymers. However, most studies have focused on commercially available polyimides, while research involving the prior synthesis of polyimides remains limited. Inducing graphene on synthesized polyimides offers the possibility of tuning the biocompatibility of the substrate, as well as its structural, chemical, and physical properties, which is of paramount importance for optimizing material quality for applications. In this study, graphene has been laser-induced on synthesized polyimides. Different polyimide resins were synthesized using N-[3-(2,5-dioxo-2,5-dihydro-1H-pyrrol-1-yl)phenyl]acetamide and the following compounds with terminal amino groups: urea, 4-[(4-aminophenyl)sulfonyl]aniline, 1,2-diaminoethane, 1,6-hexamethylenediamine, at high temperature by polymerization in the melt. The resulting polyimides were characterized using various physicochemical techniques. Additionally, after the successful preparation of laser-induced graphene, the mechanical and electrical properties of the material were investigated to evaluate its potential application in wearable sensors. The following characterization methods were performed: Raman spectroscopy, Fourier transform infrared spectroscopy (FTIR), scanning electron microscopy with energy dispersive X-ray spectroscopy (SEM-EDS), X-ray diffraction (XRD), cytotoxicity and mechanical testing. The results provide valuable insights into the relationship between polyimide structure and the efficiency of laser-induced graphene formation, highlighting the potential of these materials for future technological advancements. This research was supported by the Science Fund of the Republic of Serbia, #4950, Polymer/graphene heterostructures for physiological sensors – Polygraph.

Calibrating a TRIP crystal plasticity material model from in-situ high-energy X-ray diffraction data considering the uniaxial load direction

Prof. Matthias Bönisch, Belgium

Poster Presentation

Abstract

Transformation induced plasticity (TRIP) steels stand out for their high strain hardening and high formability. Their mechanical properties and performance largely depend on the processing history and resulting microstructural attributes. To optimize application-specific TRIP components, engineering of the microstructure is crucial. Simulation tools capable of predicting the impact of forming conditions and strain path on the mechanical response and resulting part behaviour are becoming inevitable for inexpensive optimization of the related forming processes. Describing the material behaviour under these complex industrial deformation conditions, necessitates constitutive models that define the material response based on microstructural characteristics, such as grain/crystallite sizes of austenite and martensite, dislocation densities etc. Calibration and validation of these models benefit from detailed reference data, such as datasets from in-situ experiments probing multiple scales at the same time.

In this work, we explore the calibration of a physics-based crystal plasticity-based TRIP constitutive material within the DAMASK [1] simulation framework for a metastable austenitic stainless steel. A comprehensive dataset [2] recorded via in-situ high-energy X-ray diffraction at beamline P07 at DESY, giving access to phase fractions, transformation kinetics, crystallographic texture, lattice strains, load partitioning, and dislocation densities next to the macroscopic stress-strain response, served as reference for the model calibration. The model parameters, describing dislocation motion and saturation, initiation and evolution of martensitic phase transformation were calibrated by multi-objective Bayesian optimization while comparing simulation results with experimental observations depending on direction of uniaxial loading. The optimized parameters will be discussed with respect to the identification approach and compared with results of similar models in the literature. The results indicate that the employed crystal plasticity model (although popular among the crystal plasticity community) cannot fully capture martensite evolution and strain hardening when comparing simulations with the in-situ measured local material behaviour. As such, this work stimulates and suggests further work in the near future that would eventually help improve the robustness and comprehensiveness of load direction sensitive models.

Design optimization through a DNN-based FE surrogate model by developing a design and analysis automation

Mr. Dongwoon Han, South Korea

Poster Presentation

Abstract

Developing an appropriate design and manufacturing process that achieves optimal performance while satisfying functional requirements is crucial for ensuring the quality of the product. This study proposes a design optimization method that reduces time and cost in traditional finite element analysis (FEA)-based design optimization by developing a deep neural network (DNN)-based finite element (FE) surrogate model. An algorithm for automatic geometry generation and mesh automation was developed for the creation of an FE surrogate model. Additionally, an algorithm was developed to automatically assign boundary conditions, perform FEA, and collect data automatically. A FE surrogate model was developed using a DNN-based framework incorporating Bayesian optimization and k-fold cross-validation techniques. Optimal design factors were derived using the simple additive weighting (SAW) method and validated using FEA. The optimization results suggest that our surrogate model replicates the high-fidelity FE model at a lower cost and promptly provides accurate optimal results.

Paper 2087

Integrating Sustainable Material Selection in Engineering Education Through a Gamified Learning Approach

Dr. Waleed Ahmed, United Arab Emirates

Poster Presentation

Abstract

Promoting sustainability in education requires integrating environmental considerations into engineering curricula from the early stages of design thinking. This paper explores the incorporation of sustainability principles within an Engineering Ethics Course Project, emphasizing the importance of material properties and recyclability in early stage design decision-making. The initiative engaged students in selecting appropriate sustainable materials by utilizing the Granta Material Intelligence Card Game, an interactive tool designed to enhance awareness of material families and their environmental impacts. Through this gamified approach, students better understood how material selection influences product lifecycle, recyclability, and overall sustainability. The implementation of this methodology fostered critical thinking, ethical responsibility, and engagement, preparing future engineers to make informed, sustainable choices in real world applications. This study highlights the effectiveness of integrating material intelligence into ethics education, demonstrating how hands-on activities can drive sustainability awareness and responsible engineering practices.

Advanced Thermal Insulation Composite Material for Sustainable Construction Using Palm Fiber and Basalt Waste

Dr. Waleed Ahmed, United Arab Emirates

Poster Presentation

Abstract

This research explores the development of an innovative composite material using waste basalt rock, biodegradable polylactic acid (PLA), and palm waste. The study aims to address environmental challenges by repurposing waste into a high-performance material suitable for modern construction applications. A key research focus is the use of waste basalt rock, which is often discarded as domestic waste. Instead of accumulating in landfills, the fine basalt is processed into a concrete aggregate, improving the mechanical properties of basalt-based concrete while reducing environmental impact. This aligns with circular economy principles by converting waste into a valuable construction resource. The second component is biodegradable PLA, a thermoplastic polymer commonly used in eco-friendly packaging. PLA is a sustainable alternative to petroleum-based plastics, offering the advantage of biodegradability while retaining strength and flexibility. Its incorporation into the composite enhances durability while addressing plastic waste concerns. Additionally, the study includes palm waste, comprising leaves and wood, as a reinforcing component. This agricultural byproduct not only reduces organic waste but also contributes to the composite's mechanical performance and aesthetic properties. The resulting material demonstrates promising characteristics for civil engineering applications. It exhibits high compressive strength and excellent thermal insulation, making it suitable for energy-efficient and durable construction materials. Its adaptability allows for applications across various structural components, enhancing sustainability in the building sector. We highlight the significant advancement in waste management and material science. Upcycling basalt rock, biodegradable PLA, and palm waste presents a sustainable and high-performance composite with broad applications in construction and insulation. The findings contribute to the ongoing development of environmentally friendly materials, paving the way for more sustainable and resilient infrastructure solutions.

Nitrogen Ion Implantation in Refractory High Entropy Metallic Glass HfMoNbTaTiVWZr: Structural and Mechanical Effects

Mrs. Karolina Stępniaik, Poland

Poster Presentation

Abstract

High entropy metallic glasses (HEMGs) combine the superior mechanical and chemical properties of metallic glasses with the compositional complexity of high entropy alloys. Among them, refractory high entropy metallic glasses (RHEMGs) stand out for their high thermal stability, oxidation resistance, and superior mechanical properties at elevated temperatures. Despite extensive studies on their thermal behavior, mechanical performance, and glass-forming ability, ion implantation remains an underexplored method for optimizing their surface properties.

This study investigates the effects of nitrogen ion implantation on a thin film of HfMoNbTaTiVWZr, a RHEMG with exceptional stability and hardness. While ion implantation has been successfully employed to enhance hardness and wear resistance in both conventional metallic glasses and high entropy alloys, its influence on RHEMGs is not well understood. Previous studies have shown that argon ion implantation has minimal impact on the hardness of this material, suggesting high radiation resistance. However, nitrogen implantation may lead to significant changes, including nitride formation, densification, and modifications in atomic bonding.

Our research explores the impact of nitrogen incorporation on hardness, elastic modulus, tribological performance, and fracture resistance. Special attention is given to nitrogen diffusion mechanisms, penetration depth, and potential nitride formation. Preliminary findings indicate that nitrogen implantation can significantly alter the material's surface characteristics without compromising its bulk properties. These results provide critical insights for tailoring RHEMGs for high-performance applications in extreme environments, where enhanced surface properties are required without sacrificing structural integrity. Samples with nitrogen incorporated into their lattice exhibited increased hardness compared to the untreated alloy. Furthermore, the deformation mechanisms were altered following the introduction of nitrogen.

Photocrosslinked 3D Foamed Scaffolds Based on GELMA/HEMA copolymers and MBGs: Potential Application in Bone Tissue Engineering

Dr. Sandra Sanchez-Salcedo, Spain

Poster Presentation

Abstract

The treatment of bone defects represents one of the great challenges of orthopedic surgery, with autografting standing out as the best option to address this problem. Therefore, one of the great challenges in the field of Tissue Engineering (TI) is the development of structures that fulfill the same functions as an autograft, but without the limitations that these entail. In this context, bioactive mesoporous glasses (MBG) in the SiO₂- CaO- P₂O₅ system present great potential in the field of TI for bone regeneration, as they offer a large specific surface area and high porosity. To increase the regenerative capacity of the materials, the incorporation of Sr²⁺ and Zn²⁺ or Sr²⁺ and Mn²⁺ ions has been studied. In this project, the in vitro regenerative properties of three-dimensional GelMA-HEMA/MBG hybrid scaffolds have been investigated by 3D printing. On the one hand, mesoporous bioactive glasses (MBG) have been synthesized in the system 85 SiO₂- 10 CaO- 5 P₂O₅, doped on one hand with 4% ZnO and 2.5% SrO and on the other hand 1% MnO and 2.5% SrO and undoped. On the other hand, a biocompatible copolymer of gelatin with a degree of methacrylation of 95% and 2-hydroxyethylmethacrylate (GelMA-HEMA) has been synthesized. Both MBG and GelMA-HEMA copolymer have been blended to obtain bioinks for robocasting with MBG, processable for the fabrication of three-dimensional meso-macroporous scaffolds. Scaffolds exhibiting hierarchical porosity: mesopores (around 4 nm), macropores (1-600 μm) and big channels (1000 μm), were prepared. The maximum swelling of a maximum of 250 wt% of the scaffolds in PBS and alfa-MEM in a few hours indicates their capacity to adsorb nutrients necessary for cell development, and to adapt to the bone defect in which they are implanted. These scaffolds, in addition to their demonstrated cytocompatibility, offer good structural morphology and interconnected porosity, resulting in adequate cell development. In cellular assays, it has been demonstrated that scaffolds with teriparatide-loaded MBGs stand out in cell differentiation and mineralization assays compared to unloaded scaffolds. Scaffolds with strontium- and zinc-doped MBGs show the best proliferation, as well as differentiation above scaffolds with strontium- and manganese-doped MBGs. Furthermore, an improvement in the osteogenic properties of the scaffolds when loaded with teriparatide has been observed, due to the synergy between the inherent properties of the MBGs, therapeutic ions and the effects of the osteogenesis agent.

Synthesis and characterization of biographene oxide@carbon dots derived from agricultural wastes (pomegranate peels and cotton stems): Application for Cr(VI) removal from aqueous solutions

Prof. George Kyzas, Greece

Poster Presentation

Abstract

Increased industrialisation has resulted in the release of immense quantities of wastewater containing heavy metals into the environment. Cr exists as both Cr(III) and Cr(VI), with Cr(VI) being more poisonous causing developmental abnormalities, DNA damage, and cancer in all creatures. As a result, WHO claims that Cr(VI) is one of the heavy metals that pose a major risk to human health, with the maximum allowed concentrations in surface water and drinking water being less than 0.1 and 0.05 mg/L, respectively. Among the methods used for water purification, adsorption is considered an advantageous candidate because its easy operation and high efficiency. In the present work graphene oxide (GO) decorated with carbon dots (CDots, both derived from the same biomass is suggested). Agricultural wastes used are pomegranate peels and cotton stems and are carbon-rich biomass resources that can be transformed into products that work well as heavy metal adsorbents. Here we present a unique approach for synthesising GO from biomass using ferrocene as a catalyst. This method can be used to create high-quality nanostructured materials. GO has a vast surface area and functional groups that bind heavy metals through various mechanisms. CDots have functional groups, such as hydroxyl and carboxyl groups, that enhance adsorption capabilities. Factors affecting the adsorption, such as the pH solution, initial concentration of Cr(VI), contact time, and temperature, were investigated. The composites' morphology and structure were characterized by FT-IR, SEM, BET and XRD analysis. Overall, the results indicate that GO@CDots can be effectively employed for removal of Cr(VI) from aqueous solutions.

Toward enhanced tensile and impact properties in low alloy multiphase TRIP-assisted steels

Mr. Chang-gon Jeong, South Korea

Poster Presentation

Abstract

Multiphase TRIP-assisted steels have emerged as a cost-effective solution offering an exceptional balance of strength and ductility. These steels, characterized by low alloying content (<4 wt.%), consist of ferrite (α), bainite (α_B), retained austenite (γ), and martensite (α'). Their unique microstructure enables enhanced tensile properties through strain partitioning between soft phases (α , γ) and work hardening from hard phases (α_B , α'). Additionally, the deformation-induced martensitic transformation (DIMIT) of retained γ delays necking, further improving tensile performance.

While much research has focused on the effects of retained γ fraction and stability on mechanical properties, the impact toughness of multiphase TRIP-assisted steels under high strain rates remains underexplored. These steels are increasingly applied in the automobile industry for their superior formability and high energy absorption potential, improving passenger safety. Furthermore, their low yield ratio and high post-deformation yield strength make them attractive for wire rod applications, where both impact toughness and tensile strength are critical.

This study investigates intercritical annealing (IA) temperature's role in multiphase TRIP-assisted steel's microstructural evolution and mechanical properties. A continuous heat treatment cycle comprising IA, fast cooling, and bainitic isothermal treatment (BIT) was applied. Controlling IA temperature directly influences the phase fraction of α and the stability of retained γ in the final microstructure. Previous research suggests that an intermediate IA temperature ($(AC1+AC3)/2+20$ °C) maximizes the retained γ fraction. At higher IA temperatures, γ transforms into α and pearlite during cooling, as confirmed through dilatometry analyses.

This research systematically examines the effects of IA temperature on tensile properties and Charpy impact toughness, highlighting the imbalance between ductility and toughness. The findings provide insights into optimizing IA parameters to achieve a desirable combination of microstructural constituents, enhancing formability and impact performance. These results address existing knowledge gaps, advancing the understanding of multiphase TRIP-assisted steels for automotive and wire rod applications.

Paper 415

New insights into the mechanism of direct amination of unsaturated carbon with hydroxylamine derived reagents: possible application toward graphene oxide functionalization.

Dr. Matteo Daino, Italy

Poster Presentation**Abstract**

Amines are organic compounds of fundamental importance due to their application in several fields. They represent the core structure of numerous biologically active compounds, dyes, pharmaceuticals and are vital in producing functionalized organic materials¹. Various synthetic methods for amines have been devised: for example, the synthesis of aromatic amines often involves reduction of nitroarenes, copper-catalyzed substitution reactions, or palladium-catalyzed cross-coupling reactions². The efficient synthesis of amines remains an active area of research, with continuous progresses in achieving high chemoselectivity and yields. In this perspective, we introduce a novel reaction mechanism for the amination of unsaturated carbons with hydroxylamine derivatives (O-(methylsulfonyl)hydroxylammonium ([MsONH₃]⁺) and O-(pivaloyl) hydroxylammonium ([PivONH₃]⁺) in the presence of ferrocene. This mechanism, deeply investigated by DFT calculations, has clarified the interaction that occurs between the ammine reagent, the iron-based species, and the substrate, defining the formation of the nitrogen-based radical species responsible for the addition to the unsaturated carbon. This approach holds potential for the functionalization of graphene oxide (GO): compared to methods that rely on epoxide ring-opening³ or those that attach the amino group to the material via a molecular spacer, the use of hydroxylamine derivatives as aminating agents allows the formation of primary amines directly bound to the nanomaterial's layer, thus enabling the obtainment of both aliphatic and aromatic amines. Moving from the molecular scale of benzene to that of graphene oxide, DFT calculations are performed on carbon clusters of varying sizes, allowing the study of reactivity both at the edges and on the basal plane. GO with aromatic amine domains would allow access to a previously unexplored chemistry of this nanomaterial. By exploiting the functionalizations made possible by the presence of this new functional group, it would be possible to control the nanomaterial's bottom-up lateral growth. Such a functionalized graphene oxide could then pave the way to advanced materials, such as innovative membranes with anticorrosion and electrical conductivity properties⁴.

Residual stress and machining path optimization based on artificial intelligence

Ph.D. Hyunsung Choi, South Korea

Poster Presentation

Abstract

The residual stress in manufacturing of material itself and post-processing to manufacture the aerostructure component has been a crucial issue for the dimensional accuracy of the manufactured aerostructure component. In this research, the application of artificial intelligence has been introduced for the prediction of residual stress and machining path optimization for the 2xxx series aluminium alloy which is outlined in Figs. 1 and 2, respectively. The Bulk Residual Stress (BRS) which is induced by quenching after extrusion was predicted by the ANN model with respect to geometry of material and quenching parameters. The Machining-Induced Residual Stress (MIRS) was predicted by the simple regression model with respect to machining parameters. The data set for each residual stress prediction was prepared by using finite element simulation and experimental results where contour and X-Ray Diffraction (XRD) methods were used for the experiment of the residual stress. Both BRS and MIRS were applied into finite element simulation for the distortion prediction of machining without any fracture model to describe element deletion in machining. In the simulation, the BRS was initially mapped into the extruded material with its geometry and quenching condition. Based on the machining parameters such as tool, feed rate, width of cut, and RPM, the MIRS come to be inserted into the integration points of the element which is located machined surface. Then, through the additional simulation time step to satisfy the force equilibrium which is violated by the BRS and MIRS, the machining-induced distortion could be predicted only by the BRS and MIRS whereby it is possible to perform numerically efficient finite element simulation for the prediction of machining-induced distortion. As far as machining path optimization is concerned, since MIRS includes the machining process parameters, XGBoost regression model was adopted because of its feature which combines several decision tree models to give the best prediction and shows excellent prediction for small datasets.

Spatter Formation Behavior Induced by Machining Chips in Hybrid Additive Manufacturing

Ph.D. Seongtak Kim, South Korea

Poster Presentation

Abstract

Metal additive manufacturing (AM) processes offer the advantage of rapid prototyping and part production without the need for molds. However, the resulting poor surface quality often requires post-processing. To address this challenge, hybrid AM systems have been developed, integrating laser powder bed fusion (LPBF) with three-axis computer numerical control (CNC) machining. Despite their benefits, machining operations inevitably generate byproducts such as chips, which may influence the AM process condition. In this study, we investigate the mechanisms of spatter formation, one of the major impurities in AM, induced by machining chips. It was observed that chips increase the oxygen concentration in the powder, thereby enhancing the Marangoni effect in the molten pool, which subsequently promotes spatter formation. Furthermore, Higher scanning speeds generally reduce spatter, but spatter has been shown to increase due to irregular powder size when there are machining chips in the powder. In conclusion, we proposed a method to achieve optimal process conditions in the hybrid AM. The findings of this study provide valuable insights into impurity formation in hybrid additive manufacturing systems and suggest strategies for optimizing process conditions to minimize defects.

UTILIZATION OF MICROWAVE ENERGY IN ZINC WASTE PROCESSING

Dr. Silvia Dolinská, Slovakia

Poster Presentation

Abstract

The aim of the EU in the area of securing critical and strategic metals is to achieve raw material and energy security. By using domestic raw material resources and recycling waste, the need for their supply from other countries will be reduced. The application of microwave energy in waste treatment represents an innovative way of recovery metals. Flue dust containing Zn, Fe and other metals are a dangerous by-product, arising not only during the production of steel in an electric arc furnace, but also during the subsequent galvanization of steel products. The aim of pyrometallurgical and hydrometallurgical methods of flue dust processing is the recovery of valuable elements in accordance with the most advantageous economic and environmental procedures. However, metal recovery is often limited by the existence of a stable spinel structure of ZnFe_2O_4 phase present in the dust particles. The advantage of microwave radiation is the acceleration of ongoing processes and the heating selectivity on base of dielectric and magnetic properties of irradiated materials.

Microwave absorption materials containing metals, especially Fe, effectively absorb electromagnetic waves, on the other hand, transmission materials allow electromagnetic waves to pass through. The advantage of microwave pretreatment of zinc dust is the transformation of refractory minerals present (e.g. ZnFe_2O_4) into easily leachable zinc oxides. Experiments of microwave-assisted extraction of flue dust from an electric arc furnace in microwave field confirmed zinc recovery above 97%.

A higher yield of zinc compared to conventional leaching was achieved by the interaction between the electromagnetic field and the heated material. Microwave heating offers a promising alternative for zinc recovery from flue dust, combining energy efficiency, environment and high speed of processing. Laboratory tests, thermodynamics and kinetics of the microwave assisted extraction process will help to optimize the parameters of microwave heating. The microwave power regulation, increase in temperature and dielectric properties knowledge of treated materials will lead to the possibility of reducing the amount of leaching agents and to the efficiency of the methodology processing.

Raman I(D)/I(G) Analysis of Carbon-Based Materials Derived from *Mauritia flexuosa* (Aguaje) Residues

Mr. Daniel Obregon, Perú

Poster Presentation

Abstract

There is great interest in obtaining increasingly efficient, economical, and biodegradable materials. Low-cost carbon-rich materials have become a green alternative for producing graphene-like materials for energy storage devices, sensors, and composite materials applications. For this reason, a one-step process for reforming *Mauritia flexuosa* (aguaje) residues under oxidation conditions with ferrocene is proved. Aguaje is a fruit whose pulp demand increases over time, generating residues as its seeds. Ferrocene is applied as an oxidizing catalyst via direct carbonization in a muffled furnace at 450 °C under atmosphere conditions. Contact time (15 to 30 min), particle granulometry (around 180 to 250 µm), and ferrocene ratio (5 to 15 %) influence the transformation of an amorphous carbon phase to a graphene-like structure of sp² hybridization. The ratio of intensity D (structural defects) and G (sp² carbon pairs in chains and rings) bands on Raman spectra was used as a response. Raman, FTIR, and SEM techniques characterized the structure of the obtained materials. It is observed that the D/G ratio increase required a longer time with higher size-particle. Electrochemical properties are evaluated with cyclic voltammetry on a ferro/ferri system with all synthesized materials.

Paper 307

Phase field simulation of segregation in single crystal Ni-based superalloys and its influence on creep properties

Mr. Sean Böhm, Germany

Poster Presentation

Abstract

Ni-based superalloys exhibit inhomogeneous microstructures dependent from the manufacturing route, thus resulting in inhomogeneous properties such as tensile strength and creep strength. Hence, combined FEM and phase-field simulation models are developed. The simulation models allow to determine the influence of casting parameters and subsequent heat treatment parameters on local microstructures of Ni-based superalloys. The combined simulation models are calibrated on the Ni-based superalloy CMSX4. CMSX4 contains gamma-prime-forming elements Al, Ti and Ta, which segregate in the interdendritic regions, and slow diffusing elements Re or W, which segregate in the dendrites. The segregations influence the solid solution hardening and gamma-prime precipitate structure, resulting in local differences in crystal properties. The combined simulation models predict local i.e. position dependent creep properties as well as global creep properties. The combined simulation models thus establish a link between process and heat treatment parameters and creep properties

Development of high porosity bifunctional materials for Sorption Enhanced Steam Reforming (SESR) of ethanol using colloidal process and freezes-casting technique.

Prof. Ranier Enrique Sepúlveda Ferrer, Spain

Poster Presentation

Abstract

Sorption enhanced steam reforming of ethanol is an intensified process, in which it is possible to produce high purity hydrogen with low content of carbon oxides. Ideal for the production of hydrogen for fuel cells applications, minimizing the purification stages downstream the reforming reactor. Considering the production of hydrogen for fuel cells applications, the main advantage of this process is that it allows H₂ production and purification in one stage, minimizing the purification stages downstream the reforming reactor.

Among the most active catalysts for the ethanol reforming reaction are the ones based on Ni as active phase supported on alumina, since they are highly active and low cost. Regarding the CO₂ capture process, the CaO has shown high CO₂ capture capacity under the reforming temperature range, rapid CO₂ capture kinetics, as well as high availability and also low cost. However, both materials have some disadvantage, as Ni is susceptible to deactivation by both carbon formation and sintering, and CaO is prone to sintering at high temperatures (around 850 °C).

Then, the development and synthesis of bifunctional materials with high active surface minimizing the distance between CO₂ generation sites and CO₂ sorption sites has gained relevance. Nevertheless, many researchers are developing bifunctional materials using low-tech techniques such as impregnation method, co-precipitation method, wet-mixing method or, high-tech techniques such as atomic layer deposition method and template-assisted method.

Here we show a simpler method of manufacturing high porosity Ni(Al₂O₃-MgO)-CaO bifunctional material combining co-precipitation and colloidal process, with freezes-casting technique. The resulting structure showed an open porosity of 70% with a significant number of Ni/CaO interfaces. It reached a complete reforming of ethanol without coke formation. The CO₂ capture rate was kept constant throughout the entire test. Also, no microstructure degradation was noticed.

These findings are significant to confirm the improvement in the efficiency of the SESR process, by an adequate design of the manufacturing technique of the active material

Welcome to Materland

Dr. Gloria P. Rodriguez Donoso, Spain

Poster Presentation

Abstract

"Welcome to Materland" is an outreach project in Materials Science, Technology, and Engineering coordinated by the Spanish Materials Society (SOCIEMAT) and the University of Castilla-La Mancha (UCLM). It brings together more than 90 participants from 37 institutions (universities, research centers, and technology centers) across Spain.

The project's main objectives are:

- (i) to enhance public knowledge and understanding of Materials Science, Technology, and Engineering by showcasing its relevance to technological development;
- (ii) to introduce the fascinating world of materials to primary, secondary, and vocational education students, fostering scientific vocations in STEM fields; and
- (iii) to establish and consolidate a national network for the dissemination of Materials Science and Engineering, facilitating collaboration between researchers and educators while promoting research initiation activities for adolescents and young people.

To achieve these goals, a wide range of activities is carried out, structured into three main areas:

- a) Creation of outreach materials and dissemination activities – This includes seminars, talks, competitions, and exhibitions (e.g., Women in Materials; Materland: The Materials Around Us), as well as the podcast Conversations in Materland, which features engaging discussions between researchers on socially relevant, current, and general-interest topics related to materials.
- b) Introduction to research activities – This involves scientific workshops and projects in schools aimed at bringing scientific experimentation and research closer to young students, as well as training courses for non-university educators.
- c) National Materials Outreach Conference "Materdivulga" – A biennial congress dedicated to science communication in the field of materials.

Launched in 2021, the project has been funded by the Spanish Foundation for Science and Technology (FECYT) through various grant programs supporting scientific, technological, and innovation culture:

- Bienvenidos a Materland: Acercándonos al maravilloso mundo de los materiales (Welcome to Materland: Approaching the Wonderful World of Materials), FCT-20-15783 (2021–2022)
- Materland: La aventura continúa (Materland: The Adventure Continues), FCT-22-18133 (2023–2024)
- Descubriendo Materland (Discovering Materland), FCT-23-19226 (2024–2025)

Pioneering Women in Materials Science

Dr. Gloria P. Rodriguez Donoso, Spain

Poster Presentation

Abstract

This work is part of the outreach activities carried out within the framework of two science communication projects funded by the Spanish Foundation for Science and Technology (FECYT) [1, 2]. Its main objective is to recover and highlight the contributions of women who have excelled in the field of Materials Science, Technology, and Engineering throughout history.

In general, the public is familiar with very few female scientists and even fewer engineers or technologists. This is due to several reasons, but primarily because, throughout history, women have been denied both knowledge (access to culture and education) and recognition. Despite these barriers, many historical and contemporary female role models exist, and it is crucial to make their contributions visible—especially to younger generations. Additional goals of this initiative include breaking down gender stereotypes that hinder women's access to STEM fields, particularly in leadership and decision-making positions, and bringing female role models in Materials Science and Engineering to rural areas where access to scientific knowledge is more limited.

Among the women whose lives and work are highlighted in this project are Constance Tipper (UK, 1894), Mária Telkes (Hungary, 1900), Stephanie Kwolek (USA, 1923), Mildred Dresselhaus (USA, 1930), María Vallet Regí (Spain, 1946), Alicia Durán (Argentina, 1950), and Rosa Menéndez (Spain, 1956), among others.

The activities designed to introduce these pioneers to girls, young students, and the broader society include an exhibition featuring informational panels and objects related to their work, talks, workshops, competitions, and more. Additionally, an interactive game, "Discover Women in Materials Science, Technology, and Engineering," has been developed. This game includes videos where Spanish PhD students and researchers present these pioneering women to inspire future generations.

A Digital Platform for Circular Management of Critical Raw Material: Emission Estimation Module

Dr. Sophie Turlur-Chabanon, France

Poster Presentation

Abstract

The management of critical raw materials (CRM) is an important endeavour for the re-industrialization of Western economies in a context of geo-political tensions. European economies need to increase domestic supply to secure the global competitiveness of industries, especially in the EU's strategic sectors (i.e. renewable energies, e-mobility, cloud and cutting-edge technologies). Extraction and processing of material resources (fossil fuels, minerals, non-metallic minerals and biomass) account for over 55 % of greenhouse gas emissions (GHG) and 40 % of particulate matter health related impacts globally. The expansion of the EU mining industry faces several challenges and increased CRM production will lead to the increase of air emissions.

The European Union has co-financed numerous projects related to the mining industries such as the Smart EcoMine Hub. Competition for access to raw materials has led to the need for more efficient management of the raw material supply chain. Therefore, this paper presents recent achievements in raw material management, such as Digital Twins, and proposes a novel collaborative digital platform designed as a part of the ROTATE project. The new platform aims to: i) foster collaboration among mining stakeholders to reduce the environmental footprint associated with the mining and quarrying (M&Q) sector required to obtain these materials; ii) define workflow management for mining-related calculations, such as process and environmental assessment for energy and resources efficiency model and the modules on decision making, energy efficiency, biodiversity, risk assessment and emission estimation iii) allow the integration of several IT tools provided by different stakeholders.

The aim of this work is to present the emission estimation module's outcomes linked to the assessment of atmospheric emissions, including dust, CO₂, and NO_x, which form the basis of roadmaps for the reduction of atmospheric emissions in quarries. Some calculations of this module use near-real time meteorological data provided by WEKEO which is an EU cloud-based platform accessing updated and timely Copernicus data directly from the original sources.

The emission estimation is presented for the Canteras Industriales pilot quarry in Granada, Spain.

Paper 77

Optimal Chemical Composition Ratio of Nb and Ti on the Mechanical Properties of Cold Rolled High Strength Low Alloy Steels

Mr. Changgeun Lee, South Korea

Poster Presentation

Abstract

The balance between Nb (Niobium) and Ti (Titanium) is critical in controlling the recrystallization behavior and mechanical properties of 550 MPa grade cold-rolled (HSLA) High Strength Low Alloys steel. Nb delays recrystallization through solute drag effects and precipitate formation, while Ti not only retards recrystallization but also enhances strength more effectively due to its ability to form fine, stable precipitates. This study aims to determine the optimal Nb/Ti ratio for maximizing yield strength while maintaining ductility.

To achieve this, hot-rolling and cold-rolling processes were simulated, followed by annealing under various temperatures and durations to mimic industrial conditions. The microstructure was analyzed using advanced characterization techniques, including TEM (Transmission Electron Microscopy), SEM (Scanning Electron Microscopy), and EBSD (Electron Backscatter Diffraction), to evaluate the recrystallization kinetics and precipitation behavior in detail. Mechanical properties were assessed through tensile testing, while hole expansion ratio (HER) testing was performed to evaluate the application-specific performance, particularly edge stretchability.

The results show that precise control of the Nb/Ti ratio significantly influences precipitation behavior, grain refinement, and recrystallization delay. Ti-rich compositions demonstrated superior strength due to the formation of finer TiC precipitates, while Nb's role in solute drag contributed to a more uniform microstructure. Annealing conditions were also found to play a crucial role, as longer annealing times at lower temperatures enhanced the formation of desirable precipitates while controlling grain growth.

This comprehensive analysis provides insights into the optimal combination of Nb and Ti to balance high strength, ductility, and application-specific properties. The findings contribute to the development of high-performance precipitation-hardened steels for automotive and structural applications, where both strength and formability are critical.

A joint experimental and computational investigation of $\text{Sr}_{n+1}(\text{Fe}, \text{Ta})\text{nO}_{3n+1}$ ($1 < n < \infty$) catalysts for the Oxygen Evolution Reaction

Dr. Elena Arroyo-de dompablo, Spain

Poster Presentation

Abstract

The design of materials capable of catalyzing the water dissociation reaction is critical for green hydrogen production. Research efforts in electrode materials for alkaline electrolyzers (AEL) focus on (i) enhancing durability, as both the anode and cathode of electrocatalysts degrade over time, and (ii) improving electrocatalytic activity, particularly to accelerate the kinetics of the oxygen evolution reaction (OER). Transition metal oxides (MnO_2 , NiO , CuO , ZnCo_2O_4 , NiCo_2O_4 ...etc), known for their stability in alkaline media, are used as anodes for the OER process in AELs [1]. Oxides related to the perovskite ABO_3 structure (A = lanthanide, alkaline-earth; B = transition metal) are promising materials, and due to their high catalytic activity, cobalt-based perovskites have been extensively studied. However, one of the challenges in the energy transition is the scarcity of so-called critical materials, which drives the development of new OER electrocatalysts based on perovskite-derived structures, where Co is replaced by Fe/Mn. In recent years, Ruddlesden-Popper (RP) phases have emerged as potential alternatives to conventional perovskite electrocatalysts [2]. This work presents a combination of experiments and Density Functional Theory (DFT) calculations to investigate the $\text{RP}-(\text{Sr})_{n+1}(\text{Fe}, \text{Ta})\text{nO}_{3n+1}$ with $1 < n < \infty$. The materials are synthesized via solid-state reaction (ceramic method), and their structural characterization is performed using XRPD and HRTEM techniques. The catalytic activity of the materials for the OER process is confirmed through electrochemical measurements using a 1M KOH solution as the electrolyte. DFT calculations provide insights into the effects of composition (Fe substitution for Ta) and structure (n value) on catalytic performance.

Science for all ages: engaging the elderly in lifelong learning

Dr. Elena Arroyo-de dompablo, Spain

Poster Presentation

Abstract

Universities generate knowledge that fosters progress and innovation. Consequently, it is essential to share this knowledge with society to encourage education and development. While scientific dissemination is often linked to younger generations, learning is a lifelong activity and, therefore, citizens of all ages should be included. Engaging elderly people in scientific activities not only helps integrate them into society but also promotes scientific culture. Presenting our findings to senior citizens has benefits beyond the mere transfer of knowledge. It contributes to their cognitive stimulation, encouraging critical thinking and problem-solving skills. Moreover, it can relieve feelings of isolation and loneliness, providing social interaction and a sense of purpose.

We have developed a science dissemination activity entitled "The energy of the future: A current problem". The activity is part of the program "Ciencia en Residencia" (<https://www.ucm.es/otri/ciencia-en-residencia>), developed by the Office for the Transfer of Research Results of Universidad Complutense de Madrid. The program aims to bridge the gap between academia and society, illustrating the relevance of science to everyday life. The activity includes a talk that addressed the significant societal challenges related to energy, incorporating various interrelated aspects such as energy independence, environmental sustainability, and economics. As a particular example, in a 5-minute video (https://www.youtube.com/watch?v=h_ezQtmtJrg) we illustrate the materials design process for green hydrogen production. The participants were encouraged to engage actively through games, written exercises, and debates. In this communication, we present the results, observations and conclusions of carrying out the scientific dissemination activity with senior citizens in out in two retirement homes in Madrid (Spain).

The authors acknowledge MCIN/AEI/10.13039/501100011033 - "ERDF A way of making Europe" for the project ECSAWE-PID2022-139501OB-C22. This research is also part of the Teaching Innovation Project N° 36 of the 2024/2025 call from Universidad Complutense de Madrid, and of the "Ciencia en Residencia" initiative of Oficina de Transferencia de Resultados de Investigación (OTRI) from Universidad Complutense de Madrid. The authors are grateful to "MANAVA" senior day center and the retirement home "Residencia Isabel la Católica" for hosting the activity.

Vacuum Insulation Panels for Liquid Hydrogen Storage and Transportation Applications

Prof. Anna Zervaki, Greece

Poster Presentation

Abstract

Vacuum Insulated Panels (VIPs) have recently become a focal point of research in various projects worldwide, particularly in the context of cryogenic insulation systems. The primary objective of employing VIPs in such applications is to reduce dependence on conventional vacuum pumps and to enhance the reliability of insulation systems by incorporating smaller vacuum elements. These smaller elements minimize the impact on overall insulation performance in the event of localized vacuum failure.

In this study, the thermal and mechanical behavior of a VIP is evaluated over a wide temperature range—from ambient conditions down to cryogenic temperatures (20 K)—using the Finite Element software Abaqus. The materials selected for the VIP prototype were chosen based on their proven performance across this temperature spectrum, as reported in recent literature. Specifically, AISI 316L stainless steel was employed for the outer envelope (foil), while K1 hollow glass bubbles were selected as the core material. The simulations addresses the thermal performance of an assembly comprising three VIPs arranged in various configurations. Boundary conditions were applied to simulate a temperature gradient from 20 K to 300 K, representative of cryogenic operating environments. A heat flux corresponding to the 20 K side of the assembly was used as a comparative performance metric, as this flux directly correlates with the boil-off rate in practical applications.

The results obtained from these simulations will support the design of corresponding experimental setups intended to validate the numerical models. Additionally, the simulation outcomes will aid in identifying and resolving potential design challenges—such as envelope plastic deformation and non-uniform heat flux—ultimately contributing to the development of an optimized VIP configuration for cryogenic insulation applications.

Exploring multifunctional properties of BaTiO₃ –based ceramics by addition of multi-walled carbon nanotubes

Dr. Felicia Gheorghiu, Romania

Poster Presentation

Abstract

This study investigates the multifunctional properties of Ba_{0.85}Ca_{0.15}Ti_{0.9}Zr_{0.1}O₃ ceramics prepared using multi-walled carbon nanotubes (0 - 70 wt% CNT) as sacrificial templates to generate variable porosity levels (3% - 25%). Comprehensive analyses of dielectric, ferroelectric, pyroelectric, piezoelectric, and non-linear dielectric properties emphasized the influence of porosity on the functional properties and the possibility of exploring potential pyro/piezoelectric applications of such ceramics. Besides the dilution effect due to the porosity increase, the presence of small amounts of residual unburnt CNT, variations of pore morphology and phase interconnectivity, and the ceramic grain size reduction when increasing the CNT addition determine in a complex way the functional characteristics. All the porous ceramics are stable and can sustain the application of high fields. The pyroelectric effect is enhanced around room temperature due to the proximity of orthorhombic-tetragonal phase transformations, giving rise to high values of pyroelectric coefficients of $p \sim 21 \times 10^{-4} \text{ C}\cdot\text{m}\cdot\text{K}^{-1}$ and energy harvesting Figure of Merit of $Fe \sim 211 \text{ J}/\text{m}^3\text{K}^2$ for 10% CNT level. Furthermore, all Ba_{0.85}Ca_{0.15}Ti_{0.9}Zr_{0.1}O₃ ceramics present a piezoelectric energy harvesting potential for self-powered functionality. The non-linear dielectric characteristics demonstrate the advantages of introducing porosity for reducing permittivity while preserving a high tunability level for $x=50\%$ CNT addition.

From pure element powders to protective coatings in industrial applications based on thin W-Ta-B films obtained by SPS-HiPIMS method

Dr. Tomasz Mościcki, Poland

Poster Presentation

Abstract

The forging of lead-free brass alloys is characterized by low tool durability, presenting a significant challenge in industrial applications. To address this issue, unique magnetron-sputtered coatings based on WB2 alloyed with Tantalum [1], were employed to increase tool life. These coatings were produced from spark plasma sintered (SPS) targets using the high-power impulse magnetron sputtering HiPIMS technology. Initially, the coatings underwent laboratory testing, where their microstructure, adhesion to the substrate, and mechanical properties were tested and evaluated. Those studies shows that proposed material is superhard but also has increased fracture toughness. Additionally, ~ 2 µm thick W0.83Ta0.17B2.5 films are thermally and oxidation resistant at elevated temperatures. The next phase involved testing these coatings on tools used in hot flashless forging processes in an industry conditions. The experiments were conducted on dies that were preliminarily gas-nitrided to provide a suitable substrate for the coating application. The results were compared to those of only nitrided dies.

After 102 774 forging cycles with the nitrided tool the wear reaches nearly 0.5 mm, which may represent the maximum acceptable wear limit from the perspective of evaluating the quality of the forged parts. The tool with the nitrided and deposited W0.83Ta0.17B2.5 coating after similar number of forging cycles exhibits less wear, with a depth of approximately 0.15 mm. While this allows for extended service life, it clearly indicates the removal of the protective layer in sensitive areas of tool.

The obtained results confirmed the beneficial impact of proposed coatings on enhancing tool durability. In certain cases, the service life of the tools was extended by up to 50%.

This study demonstrates that the application of newly developed W0.83Ta0.17B2.5 coating which can significantly improve the durability of tools used in the flashless forging of lead-free brass alloys, offering a promising solution for industrial manufacturing challenges.

Paper 144

Applications of surface treatments obtained by ion implantation techniques

Dr. Jaume Caro, Spain

Poster Presentation

Abstract

Ion implantation is a sophisticated surface engineering technique that utilizes ionized atomic species accelerated to high energy in a vacuum environment. This method is used to introduce accelerated particles into the surface of a substrate. Unlike conventional coatings, this process allows the atoms to penetrate the substrate at the sub-surface level. This unique feature avoids the risk of delamination, an issue often encountered with traditional surface coatings. Like other surface treatment processes, ion implantation can improve the corrosion resistance, wear resistance, hardness, electrical conductivity, bioactivity, and antibacterial effect of materials compared to their pristine forms. As it is a surface modification technique, the bulk properties of the substrates are retained. In addition, one of the most valuable advantages of this low temperature surface treatment technique is that the concentration and depth distribution of the implanted ions can be strictly controlled by adjusting the processing parameters.

In this work, Plasma Immersion Ion Implantation (PIII) and Metal Vapor Vacuum Arc (MEVVA) ion implantation techniques have been used for surface functionalization of metallic and polymeric materials.

In the field of dental implants and keratoprosthesis, bactericidal surface treatments on titanium have been developed by co-implantation of silver and copper ions using a MEVVA ion source. Antibacterial activity against *S. aureus*, *E. coli* and *P. aeruginosa* has been demonstrated, as well as resistance to the formation of a biofilm composed of the bacteria *F. nucleatum*, *P. gingivalis* and *A. actinomycetemcomitans*. Fungicidal activity against *C. albicans* has also been validated.

Finally, in the field of hard PVD coatings, an improvement in the adhesion strength of AlCrSiN coatings deposited on WC-Co substrates implanted with Ti and Cr species by PIII has been demonstrated. This improvement is attributed to the introduction of residual stresses in the substrate, which increases its fracture toughness and load bearing capacity.

Upcycling Secondary Al-Si Casting Alloys: Unlocking the Potential of Rare Earth Elements Microalloying to Mitigate Fe Contamination

Mr. Helder Nunes, Portugal

Poster Presentation

Abstract

The global transition to electric vehicles, alongside policies phasing out fossil-fuel-powered cars by 2030, is set to reduce the demand for conventional casting alloys, such as those used in engine blocks. By 2040, this transition could lead to a surplus of up to 8.7 million tons of scrap metal, with 3.6 million tons potentially becoming "dead metal" if innovative recycling methods are not developed. Secondary aluminium alloys (SAAs), derived from mixing different alloy scraps, exhibit inferior mechanical properties due to contamination. In Al-Si casting alloys, contaminants such as Fe and oxides significantly reduce mechanical performance compared to primary alloys. The precipitation of brittle intermetallic phases further deteriorates properties, mainly ductility. Phases such as β -AlFeSi, α -Al(FeMn)Si, or π -AlFeMgSi can form depending on the alloy composition. Some studies have investigated the effect of Mn, Cr, or Mg on morphology optimisation and phase transition. Despite these challenges, the automotive industry must maintain its competitive advantage by minimising raw materials and manufacturing costs. Researching upcycling methods to modify Fe-rich phases is crucial for enhancing the properties of SAAs, ensuring their economic competitiveness with primary alloys. To address these challenges, this research focused on adding rare earth elements (REEs) in SAAs to enhance their overall quality and mechanical properties. REEs additions, typically limited to less than 1 wt.% to avoid the formation of excessive Al-REE phases that can deteriorate mechanical properties, are referred to as "REEs microalloying." Elements such as lanthanum, cerium, and erbium have been shown to refine α -Al grains, modify the morphology of eutectic Si, and improve fluidity. These advancements offer promising pathways for upcycling SAAs.

This study aimed to evaluate the impact of microalloying with La, Ce, and Mischmetal (a 50% mixture of La and 50% Ce) at concentrations of 0.05, 0.10, and 0.15 wt.% on a highly Fe-contaminated AlSi7Mg0.3 alloy, about 3.8 wt.% Fe. The evaluation was conducted on castings with and without T6 heat treatment. Samples were extracted from castings and prepared using conventional metallographic techniques. Optical and scanning electron microscopy with energy dispersive spectroscopy were used to analyse the microstructures and identify the phases. Subsequently, tensile and hardness tests were conducted to evaluate the influence of REE microalloying on the mechanical properties of the alloy. Even a minimal addition of 0.05 wt.% of REEs showed significant potential in refining β -AlFeSi needles, partly transforming them into irregular star-shaped α -AlFeSi. Additionally, the T6 temper enhanced the breakdown of the needle structures.

Thermomechanical analysis of biochar-containing polymer-based composites by Dynamic Mechanical Analysis

Mr. Paraskevas Kyriacou, Cyprus

Poster Presentation

Abstract

Carbon-based reinforced polymers have attracted significant attention among the different composite materials, due to their versatile nature and fascinating physiochemical properties. The incorporation of carbon fillers within a polymer matrix can lead to major improvements concerning the mechanical, electrical, thermal and tribological properties of the composite material, making them materials of choice for a variety of advanced applications [1]. However, the non-environmentally friendly and expensive nature of typical carbon-based additives including carbon nanotubes, carbon nanofibers and graphene, has raised concerns about their potential integration in a variety of larger scale applications.

The necessity of finding eco-friendlier solutions has led to major developments in carbon-based polymer additives derived from natural resources. Such carbon-based fillers usually combine environmental friendliness, recyclability, cost-effectiveness and lightweight structures with excellent thermomechanical and electrical properties. In addition, thermoplastics including polyesters, polyolefins such as polyethylene and polypropylene, polystyrene, nylon and Teflon are gaining increased attention nowadays due to their lower manufacturing costs, high-impact resistance and reprocessing ability and thus recyclability through simple remelting processes [2].

In the present study, biochar fillers deriving from agricultural wastes are utilized as reinforcement materials for selected thermoplastic matrices. More specifically, agricultural wastes are carbonized by employing a large-scale pyrolysis method, followed by their co-processing with thermoplastic materials by means of twin-roll milling, resulting to biochar-containing thermoplastics. The produced composites in which the biochar content was systematically varied, were investigated in respect to their morphological and thermomechanical characteristics by means of scanning electron microscopy (SEM) and dynamic mechanical analysis (DMA), respectively.

Design of metallic Phase Change Materials: Surface properties of liquid Al-Si-Sn alloys

Prof. Donatella Giuranno, Italy

Poster Presentation

Abstract

One of the most promising technologies for efficient Thermal Energy Storage (TES) are Metallic Phase Change Materials (PCMs), characterized by superior thermal conductivity and energy storage per unit volume. Such PCMs are based on solid-liquid transitions, but their limited solutions in the liquid state may represent problem for handling. To produce materials with desired properties it is necessary to understand the relationships between the elements of a quadriade “composition-processing route-microstructure-properties” and based on it, to achieve tailored microstructure associated with a unique combination of properties. Speaking about industrial processes involving the presence of the liquid phase, the solidification is a key step to perform these processes properly. Modelling of solidification and thus, microstructural evolution is directly related to reliable thermophysical property data of metallic melts, needed as input parameters. Direct measurements of bulk and surface properties of liquid alloys at high temperatures are often technically difficult or even impossible, and therefore, theoretical models can be used to estimate missing property values. The energetics of mixing in liquid Al-Sn, Al-Si and Si-Sn systems has been analysed through the study of the concentration dependence of various thermodynamic and surface (surface tension and surface segregation) properties in the combined framework of thermodynamics and statistical mechanical theory.

The aim of this study is to correlate the thermodynamic properties of the Al-Si-Sn system and its subsystems with their surface properties and to compare the model predicted property values to own experimental data and / or to the data available in the literature.

Correlation of ab initio methods with experimental phase exploration of TM-Al/Si-C thin film materials

Mr. Christian Gutschka, Austria

Poster Presentation

Abstract

Thin films, consisting of Transition Metal Carbides (TMCs), are known for their remarkable thermal stability, with melting points reaching up to 4000 °C, and their excellent mechanical properties, including exceptional hardness. These properties make Physical Vapor Deposited (PVD) TMCs indispensable materials for challenging applications in the aerospace and tooling industries. Nevertheless, their limited oxidation resistance inspires the alloying of strong oxide formers such as Al and Si to improve their high-temperature performance. Setting the focus on metastable, fcc-structured, TM-X-C (TM = Ti, Zr, Hf, Ta, W and X = Al, Si) solid solutions, Density Functional Theory (DFT) was used in order to access the metastable solubility trends, by the means energy of formation and unit cell distortion. In a second step, these theoretical findings are correlated with an experimental approach in which over 260 different compositions within these ten material systems are grown by combinatorial magnetron sputtering. Phase formation, mechanical properties, and oxidation resistance are subsequently analyzed by X-ray diffraction, nanoindentation (CSM method), and Transmission Electron Microscopy (TEM) for selected states. The comprehensive analysis of structure-property relationships of these ternary TMC thin films provides crucial insights into the so-far relatively unexplored phase space and opens up opportunities for advanced applications.

Elastic limit and plastic relaxation of GaAs/In(Al,Ga)As core shell nanowires for bandgap engineering

Prof. Philomela Komninou, Greece

Poster Presentation

Abstract

Core-shell nanowires (CSNWs) exhibit pseudo-uniaxial strain along their long axis. Specifically, narrow and flexible GaAs cores can sustain large elastic strain energy without plastic relaxation, leading to a bandgap reduction of up to 40% [1] and a 50% increase in electron mobility [2] when overgrown with sufficiently thick In_x(Al,Ga)_{1-x}As shells. Using high resolution transmission and scanning-transmission electron microscopy (HR(S)TEM) combined with atomistic and continuum calculations, we determined experimentally the critical indium composition for the onset of plastic relaxation and characterized the 3D strain fields and plastic relaxation mechanisms [3]. GaAs/In_x(Al,Ga)_{1-x}As CSNWs (0.2 < x < 1) were grown via the self-catalyzed VLS mode using MBE, with a fixed 20 nm core diameter and 80 nm shell thickness. HR(S)TEM observations were conducted using a 300 kV ThermoFisher Titan Themis 60/300 and a 200 kV JEOL JEM F200 CFEG microscope. The 3D strain fields were measured using geometrical phase analysis and were compared to theoretical finite element analysis and atomistic empirical potential calculations. Density functional theory (DFT) calculations were employed to analyze the electronic properties of the strained heterostructures. It was found that, while axial strains remain uniform, elastic relaxation induces radial and tangential strain gradients in the core and shell due to strain concentration at their interface, even after plastic relaxation of the CSNW. GaAs/In_{0.5}Al_{0.5}As CSNWs sustained the highest elastic strain in their cores while exhibiting a coherent interface [4]. In contrast, CSNWs with higher indium contents in the shell underwent plastic relaxation through specific mechanisms introducing extended defects in the shells. These included Frank partials delineating horizontal intrinsic stacking faults (SFs), misfit dislocations gliding along inclined {111} planes, and stair-rod dislocations forming at SF junctions. The preferential accumulation of specific defects on either side of the core suggested that transient bending, caused by asymmetric shell deposition at the early growth stages, can affect defect formation. Despite the presence of significant strain gradients at the core-shell interface, DFT calculations confirmed that the heterojunction maintained a type-I alignment without significant band bending in the core.

We thank the High-Performance Computing (HPC) Infrastructure and Resources Center of the Aristotle University of Thessaloniki (AUTH) for providing computing resources.

Efficient Microwave-Assisted Synthesis of Copper Chromite Spinel: Structural and Thermal Properties Analysis

Prof. João Batista Rodrigues Neto, Brazil

Poster Presentation

Abstract

Microwave-assisted synthesis has gained attention for its ability to accelerate reaction kinetics and enhance phase selectivity in complex oxides. In this study, we demonstrate that microwave processing not only reduces synthesis time for CuCr_2O_4 spinel but also alters the phase transformation pathway, providing an alternative route to achieve phase-pure materials with improved structural control. By tuning reaction temperature (180–200 °C) and synthesis time (15–30 min), followed by calcination at 400–700 °C, we elucidate the critical role of microwave irradiation in phase development. X-ray diffraction (XRD) confirmed that at 200 °C for 30 min, the tetragonal CuCr_2O_4 phase formed with high purity, while at 180 °C for 15 min, a biphasic mixture of tetragonal and orthorhombic phases persisted, indicating an incomplete transformation. Thermal analysis (DTA/TG) revealed that the 180 °C sample exhibited a sharp exothermic peak with mass loss, associated with oxidation-reduction processes and NO_x exchange, suggesting that phase transformation is chemically driven rather than purely thermal. In contrast, the 200 °C sample displayed a more gradual exothermic response with lower structural water loss, indicating a kinetically favored and more controlled transition. These findings provide compelling evidence that microwave-assisted synthesis not only accelerates phase formation but also influences the underlying redox chemistry, potentially bypassing intermediate states observed in conventional solid-state routes. The ability to tailor the oxidation state and structural evolution through microwave parameters opens new opportunities for designing copper chromite materials with enhanced functional properties for catalytic, electronic, and magnetic applications.

Paper 886

Optical emission spectroscopy of deposition process of W-Al-B coatings obtained by HiPIMS/DCMS hybrid technique

Mr. Rafał Psiuk, Poland

Poster Presentation

Abstract

Tungsten borides because of their properties, like hardness and thermal stability, may be a potential alternative to traditional superhard materials (diamond and cubic boron nitride) or typical materials for tool coatings (TiN, TiAlN etc). Tungsten borides can be furtherly enhanced by alloying with various metals. In this regard, addition of aluminium can increase oxidation resistance of diboride-based materials [1].

High power impulse magnetron sputtering (HiPIMS) technique is already well-used for deposition of high quality coatings. Flux of highly energetics species have a significant influence on deposited coatings and its properties. Due to this, plasma behaviour during HiPIMS should be extensively studied.

In this work we present the study of deposition of W-Al-B thin films by HiPIMS/DCMS technique. $WB_{2.5}$ and AlB_2 targets were co-sputtered in various parameters of $WB_{2.5}$ -HiPIMS/ AlB_2 -DCMS. Plasma behaviour was investigated via optical emission spectroscopy to obtain intensities and distribution of atoms and ions of tungsten, aluminium and boron. Due to lower deposition rate of dual than single magnetron set-up it was very important to perform examination of plasma plume behaviour. Mechanical properties were evaluated by nanoindentation technique, microstructure was observed using scanning and transmission electron microscopy (SEM, TEM). Chemical and phase composition were measured by ToF-ERDA and X-ray diffraction (XRD), respectively.

Addition of Al into WB_2 structure lowered the hardness of deposited films from 29 to 17 GPa at ≈ 0.7 Al/(W+Al) atomic ratio. Crystalline coatings were only obtained for Al/(W+Al) ratio between 0.05-0.2.

Bone-on-a-chip with biomimetic scaffolds

Dr. Isabel Izquierdo- Barba, Spain

Poster Presentation

Abstract

Bone tissue engineering (BTE) is a promising option in the face of the growing incidence of bone diseases that require transplants. BTE uses a scaffold of a biomaterial that mimics bone tissue, but in static conditions we do not achieve the dynamism that exists in vivo. Microfluidic devices can facilitate the development of conditions that closely emulate the in vivo environment by allowing fluidic control of oxygen and nutrient supply and controlled application of mechanical stimulation.

The convergence of biomaterials, stem cells and microfluidics has enabled the fabrication of devices Organ-on-a-Chip (OoC) that replicate the real microenvironment of a tissue or organ. OoCs allow different physical or chemical stimuli to be applied to the tissue that recreate cellular physiology, offering greater control of the cellular microenvironment.

The material selected for the manufacture of these devices, in addition to being biocompatible, must have the appropriate physical and mechanical properties to match the mechanical characteristics of the target organ, which is essential when mimicking bone.

B5Tec has a flow controller designed and developed by the company that allows the flow rate to be controlled with great precision. This has been used to develop a Bone-on-a-chip prototype together with the UCM research group.

We used 3D titanium scaffolds that were encapsulated in resin bases with a PDMS cap. All materials of the prototype and flow controller were found to be biocompatible. We performed a culture of pre-osteoblastic cells, in differentiation medium, observing that in different dynamic conditions we have cell proliferation and that intermittent flow increases osteoblastic differentiation. With this result we performed a co-culture with intermittent flow of preosteoblasts and macrophages, observing that there was proliferation of both cell types and again increased osteoblastic differentiation. These results are novel and promising for achieving a situation of dynamic tissue growth in the laboratory, which would represent a significant advance in the simulation of the complex bone microenvironment. It should be noted that in the future they could be implantable in vivo, since we use biocompatible materials, and they could be developed with a focus on personalized medicine, based on the patient's own cells.

The new technology offers additional advantages such as real-time monitoring in a highly automated way, reducing costs and reallocating the costs necessary for experiments and allowing a large number of reproducible tests to be carried out in a short time and with reliable results, thus reducing research times.

Paper 1791

Advancing of mechanical and exploitation behaviors of steel grinding balls by industrial-scale “Quenching and Partitioning”-based processing

Prof. Vasyl Iefremenko, Slovakia

Poster Presentation

Abstract

A “Quenching and Partitioning” (Q&P)-based heat treatment has been developed and successfully implemented on an industrial scale for 104 mm diameter rolled grinding steel balls (0.75 wt.%C-1 wt.%M-0.5 wt.%Cr). This innovative approach aims to enhance both surface and bulk hardness, improve impact resistance, and, crucially, prevent cracking during heat treatment, a common issue with conventionally processed high-hardenability steel balls. Traditional manufacturing of steel balls involves rolling, followed by direct water quenching interrupted at an average bulk temperature of 220-250°C, and subsequent self-tempering. This conventional method is effective only when the martensitic transformation is limited to a depth of 5-10 mm from the surface. However, with high-hardenability steels, martensitic transformation occurs throughout the entire ball volume leading to surface cracking due to the significant volume change associated with martensite formation in the core. To address this critical limitation, the Q&P principle has been strategically adapted. The modified Q&P process involves two key steps: (a) controlling the quenching duration to ensure that the ball's core temperature falls below the martensite start (M_s) temperature, and (b) replacing the self-tempering stage with a controlled furnace tempering process. The optimal bulk temperature at which the water quench is interrupted has been determined to be within the range of 125-170°C. This specific temperature range ensures a balanced “Martensite/Retained Austenite” ratio within the ball at the moment of quenching interruption. Following the quench, a tempering at 200-250°C is implemented to relieve stresses and facilitate carbon partitioning from the martensite to the austenite. The resulting microstructure exhibits a gradient from tempered martensite in the outer “shell” layers to a “Martensite/Bainite/Retained Austenite” microstructure in the core. Notably, the retained austenite content in the core is significantly increased, reaching 25-30 vol.%, due to carbon enrichment resulting from the partitioning process from martensite (and bainitic alpha-phase) to the gamma-phase (austenite). This controlled increase in retained austenite content from the surface towards the core effectively balances stresses and prevents the formation of cracks. The Q&P-based heat treatment has been successfully implemented on an industrial scale. The Q&P-treated grinding balls achieved a remarkably uniform hardness of approximately 55 HRC throughout their cross-section, and, importantly, no hardening cracks were observed. Furthermore, these Q&P-treated balls demonstrated exceptional fracture resistance under repetitive impacts of 6.8 kJ each, a critical requirement for their demanding operational conditions. This improved performance makes the Q&P process a highly promising route for manufacturing high-performance grinding media.

Atomistic Modelling of Hydrogen Storage in Graphene Using LAMMPS Molecular Dynamics

Mr. Tesfay Berhe Gebreegziabher, United Kingdom

Poster Presentation

Abstract

Hydrogen storage is a critical component for advancing clean energy technologies, and graphene has emerged as a promising material for this purpose due to its unique structural properties. In this study, we explore the hydrogen storage capabilities of graphene through atomistic modelling using the LAMMPS (Large-scale Atomic/Molecular Massively Parallel Simulator) molecular dynamics software. Our methodology involves simulating the adsorption process under various conditions to optimize hydrogen uptake. Specifically, we examine the effects of graphene defects, interlayer spacing, and external pressure to identify optimal parameters. The simulations demonstrate that graphene can achieve a hydrogen storage capacity of 2.8 wt% at room temperature and 10 bar. These findings highlight the potential of graphene for efficient hydrogen storage applications and provide insights for future experimental and theoretical studies in the field.

Development of surface treatments and coatings for the corrosion protection of bipolar plates of PEM fuel cells and electrolyzers

Dr. Jordi Orrit-Prat, Spain

Poster Presentation

Abstract

PEM electrolyzers are essential for the production of green hydrogen as they use renewable electricity to split water into hydrogen and oxygen with high efficiency. Their compact design, fast response time, and ability to operate under variable conditions make them key to enabling a sustainable hydrogen economy. On the other hand, PEM fuel cells are a promising candidate to replace internal combustion engines in today's transport applications. However, in both cases, there are some aspects related to their performance, durability and cost that limit their effective implementation. These technical limitations are mainly associated with the durability of the metallic bipolar plates, a crucial component of PEM fuel cells and electrolyzers.

Stainless steel and titanium alloys are suitable materials for the manufacture of bipolar plates for PEM fuel cells and electrolyzers, respectively. In the case of PEM fuel cells, stainless steel bipolar plates can be produced cheaply, easily and on a large scale in the form of thin sheets by means of forming processes. However, their corrosion resistance is not high enough to withstand the acidic and humid environment under which a PEM fuel cell operates. This fact increases the interface contact resistance and contaminates the proton exchange polymeric membrane, thus reducing the energy efficiency of the cell. In the case of PEM electrolyzers, titanium bipolar plates face several corrosion-related challenges: (i) surface passivation due to the formation of a passive oxide layer (TiO_2), which can increase contact resistance and reduce electrical efficiency; (ii) aggressive environment due to acidic and high potential operating conditions; (iii) hydrogen embrittlement, which can compromise their structural integrity over time.

In both cases, a solution to these problems involves the application of electrically conductive coatings with good corrosion resistance. In this respect, PVD (Physical Vapor Deposition) coatings (e.g. noble metals, transition metal nitrides and carbides, and amorphous carbon-based coatings) have been extensively studied in recent years.

In this work, the preparation and characterisation of carbon-based coatings obtained by PVD cathodic arc evaporation is presented. In addition, the development of corrosion resistant surface treatments obtained by Metal Vapor Vacuum Arc (MEVVA) ion implantation has been explored.

Silicon-based ceramics: influence of sintering atmosphere

Dr. M-Magdalena Lorente-Ayza, Spain

Poster Presentation

Abstract

Silicon-based ceramics, including silicon carbide (SiC) and silicon nitride (Si₃N₄), are advanced materials renowned for their exceptional mechanical, thermal, and chemical properties. These ceramics exhibit high hardness, excellent thermal conductivity, and remarkable resistance to thermal shock, oxidation, and wear. Due to these attributes, silicon-based ceramics are extensively utilized in high-temperature applications, such as components in gas turbines, heat exchangers, and advanced refractory materials.

The sintering atmosphere plays a crucial role in the densification and final properties of silicon-based ceramics. The choice of atmosphere can significantly influence the microstructure, mechanical properties, and thermal stability of the sintered ceramics.

In the present study, the influence of sintering variables without the application of pressure on the properties of silicon carbide and silicon nitride specimens has been investigated. The forming process employed was uniaxial pressing, and the firing was conducted in a graphite resistance furnace without the application of pressure. Thus, the influence of the environmental conditions of the samples, the firing cycle, and the firing atmosphere on the final properties of the obtained samples has been studied, analyzing their impact on the final properties.

The project "Cerámicas avanzadas para motores de propulsión - PROPULCER" is founded by Instituto Valenciano de Competitividad Empresarial (IVACE+i).

Paper 547

The Influence of Ethanol-Fueled HVOF Deposition Parameters for 316L based coatings

Mr. Alexandre Maier Eurich, Brazil

Poster Presentation

Abstract

The thermal spray process is widely utilized across industries to deposit metallic or non-metallic coatings on prepared surfaces, enhancing properties such as corrosion and abrasion resistance. The High Velocity Oxygen Fuel (HVOF) thermal spray process, known for producing coatings with low porosity, low oxide content, and high substrate adhesion, employs liquid fuels like ethanol and powder feedstock delivered through a converging-diverging Venturi nozzle. Ethanol, a relatively recent advancement in liquid-fuel technology, has shown promise due to its safety, efficiency, reduced oxygen consumption, and minimal emissions of toxic fumes and particulates. This study focused on 316L based coatings, an austenitic nickel-chromium stainless steel powder (Fe 17Cr 12Ni 2.5Mo 2.3Si 0.03C). Coatings produced with this material are dense, bright, and exhibit exceptional resistance to corrosion, wear, and impact, as well as tensile strength, making them ideal for applications requiring corrosion resistance, solid particle erosion protection, and dimensional restoration. The experimental design employed a Taguchi L9 orthogonal array to analyze the influence of four factors: working distance, mass flow of combustion gases, combustion stoichiometry, and powder feed rate, each analyzed three levels. Calibration curves were developed to correlate RPM settings with powder feed rates, ensuring precise parameter control. The findings aim to enhance the understanding of the relationships between process parameters, coating microstructure, and performance. To characterize the coatings and compare the effects of different process parameters, the following analyses were conducted: optical microscopy, scanning electron microscopy (SEM), Vickers microhardness, analysis of the porosity and oxide area fraction, and fracture toughness. To evaluate the significant difference between levels were used the Tukey test. The optimal coatings are expected to exhibit lower porosity, lower oxide content, higher microhardness, greater thickness, and higher toughness. The results indicate that porosity was significantly influenced by the mass flow rate, while the oxide content showed no significant influence from any of the parameters analyzed. Microhardness was significantly affected by the standoff distance, whereas the coating thickness was influenced by the combustion stoichiometry and powder feed rate. In contrast, fracture toughness showed no significant relationship with the evaluated parameters. The parameter levels that contributed to improved coating properties were the two highest levels of standoff distance, the highest mass flow rate, the lowest levels of stoichiometry, and the highest powder feed rate. In summary, small variations in standoff distance and stoichiometry did not significantly affect the results, highlighting the robustness of the process under these conditions.

Simulation of the Extrusion of high purity aluminum wires

Mrs. Claudia Luppertz, Germany

Poster Presentation

Abstract

Aluminum wires play a crucial role in nearly all power and control electronics. Being used to connect different materials, aluminum wires are not just subject to high electrical energies but also thermal and mechanical stresses. To enhance the efficiency of named aluminum wires and simultaneously reduce costs in production, new materials and production technologies are investigated by a project at Hochschule Bonn-Rhein-Sieg in cooperation with an industrial partner. As a material, ultra-high purity aluminum is investigated due to its high electrical conductivity. As one part of the manufacturing process, hot extrusion of cast material is investigated. Through hot extrusion, semi-finished products are generated, which will be pulled to the final wire in a later manufacturing step.

To gain deeper insights into the extrusion of aluminum wires, simulations are performed with the software Inspire Extrude Metal. For these simulations, the knowledge of the temperature- and strain-rate-dependent flow stress is of great importance. A suitable constitutive model is fitted to describe the flow stress as a function of temperature and strain rate. Due to a lack of literature data on the investigated material, high-temperature tensile tests are performed at different strain rates and temperatures ranging from 20 degrees Celsius to 500 degrees Celsius.

With the data on flow stress obtained from the performed tensile tests and other thermomechanical properties gained from the software JMatPro, the simulation and optimization of the extrusion process of the aluminum wires are performed. The influence of the process temperature, the extrusion speed, and the wire thickness on the extrusion process are investigated with the aid of simulation in virtual experiments. The results of the research and simulations carried out by this paper can help the industrial partner understand and optimize the real-world manufacturing process.

Acknowledgment

The work described in this contribution was carried out as part of the WireLife project - Lifetime of new aluminum wires for power electronics (FKZ 13FH544KX0) which is funded by the Federal Ministry of Education and Research as part of the Research at Universities of Applied Sciences funding program. Innovative Copper-Based Electrocatalysts: Harnessing 3D Printing for Sustainable Nitrate Management in Drinking Water

Dr. Ana Valero, Spain

Poster Presentation

Abstract

Nitrates are naturally present in the environment. However, anthropogenic activities, particularly the widespread use of fertilizers in intensive agriculture, have led to a significant increase in nitrate levels in both aquifers and soils. This excessive nitrate contamination of groundwater systems poses serious environmental risks, such as eutrophication, and can also threaten human health.

The United States Environmental Protection Agency (EPA) has established a maximum contaminant level (MCL) for nitrate in potable water at 10 mg L⁻¹ necessitating the development of effective nitrate removal strategies for drinking water treatment.¹ Copper and its alloys have demonstrated considerable promise in electrochemical applications, particularly for the electro-reduction of nitrates.² The utilization of additive manufacturing (AM) techniques, specifically 3D printing of metallic electrodes with various surface modifications, offers potential enhancements in electrochemical processes by increasing the active surface area.³ In this context, powder bed fusion (PBF) systems, employing electron beam melting (EB-PBF) as the energy source, are frequently utilized for 3D printing of metallic structures.

This study investigates the development and performance of innovative copper electrodes manufactured by Electron Beam Powder Bed Fusion (EB-PBF) technology. These electrodes undergo subsequent electrochemical and thermal modifications to enhance their catalytic properties. This work evaluates the effectiveness of these modified electrodes by comparing them with unmodified 3D-printed copper electrodes and conventional copper foil, all tested under identical conditions. The performance of these electrodes is assessed as electrocatalysts in the reduction of nitrate to ammonia, a process with substantial potential for fertilizer production.

Following a comprehensive analysis of the parameters influencing the electrochemical reaction, we successfully scaled up operations using a novel, custom-designed electrochemical cell. This cell features fabrication through Multi Jet Fusion technology, utilization of polyamide-based materials, and scaled-up electrodes with surfaces reaching up to 200 cm² of geometric area. Employing various electrochemical techniques on the modified 3D copper electrodes yielded exceptional performances, achieving over 99% nitrate reduction and up to 90% conversion to ammonia within a 3-hour timeframe. These findings underscore the potential of additive manufacturing technologies in revolutionizing the design and production of advanced electrochemical systems. The demonstrated scalability opens new avenues for industrial applications, particularly in sustainable fertilizer production and environmental remediation, highlighting the promising intersection of advanced manufacturing techniques and electrochemical engineering.

Hierarchically Structured Catalysts Via Additive Manufacturing For Emerging Applications

Dr. Ana Valero, Spain

Poster Presentation

Abstract

Additive manufacturing (AM), or 3D printing, has emerged as a revolutionary technology in catalytic applications, offering unprecedented advantages over traditional manufacturing methods. This innovative approach enables the creation of customized electrocatalysts with complex geometries, tailored porosity, optimized active surface and formation of nano-micro levels hierarchical structures. Additive manufacturing opens new frontiers in the field of catalysts, electro-chemical reactions and in the manufacturing of their reactors and peripherals that were previously impossible to achieve.^{1,2} Key advantages include unparalleled design flexibility, rapid prototyping capabilities, material efficiency, and the ability to create highly customized structures with enhanced surface area-to-volume ratios.

The unique benefits of AM in electrode manufacturing extend beyond traditional production limitations, allowing for the integration of multiple materials, cost-effective small-scale production, and precise structural optimization.^{3,4} By enabling the creation of intricate electrode designs with minimal material waste, this technology accelerates research and development processes while providing unprecedented opportunities for innovation in electrochemical applications.

In this work, novel architectures were developed using state-of-the-art powder sintering technologies in additive manufacturing, including Powder Bed Fusion Electron Beam (PBF-EB), Powder Bed Fusion Laser Beam (PBF-LB), and Multi Jet Fusion (MJF). These advanced techniques enabled the successful manufacturing of a wide range of metallic and non-metallic structures. The fabricated components underwent optimized surface modifications through chemical, electrochemical, and thermal treatments to create hierarchical catalytic structures. Furthermore, these metallic structures were thoroughly validated in various electrochemical and photoelectrochemical applications, such as water splitting, electrochemical nitrate reduction, and other related applications.

Paper 140

Microstructure and Mechanical Properties of AlSi7Mg Alloy Deposited on Die-Casting Specimens by the L-DED Process

Ph.D. Hyunkyu Lim, South Korea

Poster Presentation

Abstract

Recent advancements in large-scale die-casting techniques, such as Giga Press, have garnered attention due to their potential to simplify automotive body manufacturing by eliminating the need for welding processes. This innovation reduces the number of components, streamlines processes, and enhances productivity. However, while the production of large components offers advantages, challenges arise regarding the handling and re-melting of defective products due to their substantial size. One potential solution to address defects or reinforce the structure of large die-cast components is the L-DED (Laser-Directed Energy Deposition) process. Despite this potential, studies focusing on the application of L-DED for aluminum alloys remain limited.

In this study, AlSi7Mg alloy powder was utilized to optimize the L-DED process. Mechanical property evaluations and microstructural observations were conducted on thin-wall specimens (90 × 40 × 4 mm). Subsequently, die-cast/L-DED joint specimens were fabricated by depositing AlSi7Mg powder onto die-cast specimens, and their mechanical properties and microstructures were evaluated. Results showed that as the deposition thickness (Z-pitch) increased, the occurrence of balling phenomena at the upper region of the specimens decreased, but wrinkling was observed. Furthermore, the mechanical property variations in the joint specimens increased with the Z-pitch.

Sertraline adsorption on graphite oxide: Kinetic and thermodynamic study

Dr. Catherine Drosou, Greece

Poster Presentation

Abstract

Sertraline is a commonly prescribed medication for the treatment of depression and obsessive-compulsive disorder. It is often released into raw wastewater and subsequently into the environment from wastewater treatment plants (WWTPs) due to insufficient removal. Therefore, it is crucial to eliminate sertraline from aquatic environments. In this study, graphite oxide was used to remove sertraline. Graphite oxide was synthesized using a modified Hummers method. Various characterization techniques, including BET, XRD, XPS, Raman spectroscopy, FTIR, and elemental analysis, were employed to examine the physicochemical and structural properties of the composite material. Graphite oxide exhibited a high adsorption capacity, compared to -commercially available- activated carbon, achieving an adsorption value of $245.1 \mu\text{mol}\cdot\text{g}^{-1}$ for sertraline at 25 °C after 6 hours of contact time. The kinetic study revealed that the non-linear form of the pseudo-second-order model best represented the adsorption behavior of sertraline on graphite oxide. The adsorption isotherms were analyzed using the Langmuir and Freundlich models, in both linear and non-linear forms, at temperatures of 10, 25, and 40 °C. The results indicated that the non-linear form of the Langmuir model effectively described the adsorption isotherms of sertraline.

Additionally, a thermodynamic study was conducted to calculate the free energy, enthalpy, and entropy parameters (ΔG° , ΔH° , and ΔS°). The thermodynamic parameters suggested that the adsorption process of antidepressants was spontaneous and endothermic within the temperature range of 10-40 °C. Moreover, equilibrium experiments were carried out to investigate the effects of various factors, such as the pH, the composition of the water matrix, and the ionic strength. It was found that ionic strength and aqueous medium composition significantly reduce graphite oxide's adsorption capacity. Excess ions, like Na^+ , and the components of the aqueous matrix, respectively, compete with sertraline for active sites on graphite oxide, limiting its effectiveness in water treatment.

Volumetric 3D Printing toward 3D printing complex structures for biomedical application

Ph.D. Francesco Schimmenti, Italy

Poster Presentation

Abstract

Vat polymerization processes, which are based on the photopolymerization of a photocurable resin, in the last few years have broadened their application field from industries, research, healthcare and everyday life [1].

These technologies enable high-resolution prototyping and fabrication but are limited by slow layer-by-layer printing and the need for support structures for complex geometries.

For these reasons, new technologies have emerged in the recent years, also known as Volumetric 3D Printing (VP), to overcome these limitations. They are a light-mediated based on photopolymerization process and on a layer less approach which directly polymerizing a defined resin volume, enabling printing of complex, low-defect 3D objects within seconds and without support structure. Among all, Xolography is brand-new VP technologies that we recently buy in our lab. This is a VP technology where the curing processes is mediated by a photoswitchable photoinitiators, also known as dual-color photoinitiators, added to the resin which are activated by a first wavelength, while absorption of the second wavelength induce a local photopolymerization. Thus, polymerization only occurs at the intersection of lights of the two wavelengths.

Herein we present the development of water-based formulations and all the characterization to assess the suitability of them for the Xolography processes. [2,3]

For this work, Poly (ethylene glycole) Diacrylate (PEGDA) with different molecular weight was employed as photoactive monomer. Indeed, PEGDA is reported to be widely used for the fabrication of hydrogel thanks to its good solubility in water and biocompatibility and, in addition, it allows to obtain complex functional 3D structures.

The proposed approach enables the possibility to obtain 3D complex structures within minute which can be

further functionalize for biomedical application, for example, as bioelectronic interface by inducing a conductive phase exploiting an interfacial polymerization [3].

Paper 1653

Reuse of Plastic Waste in the Agricultural Sector: Another Step Towards Sustainability

Dr. Natividad Antón Iglesias, Spain

Poster Presentation

Abstract

Plastic consumption has experienced exponential growth, leading to the accumulation of waste in landfills around the world. For this reason, various countries and institutions promote the reduction of plastic use and the increase of its recycling to protect the environment. However, although this effort aims to reach all scenarios, some of them are ignored, such as the agricultural sector. The management of plastic waste from agricultural and livestock use is hindered by the lack of interest from companies and institutions, and as a result, a large portion of the waste generated ends up scattered across fields and forests. This research aims to find a new use for the plastic waste generated in the agricultural sector, a solution that is more attractive and encourages companies to recycle it. This study focuses solely on packing ropes or raffia ropes: polypropylene ropes used to compact different types of grasses for livestock consumption. A clear influence of degradation on the properties of this material was observed. To determine these properties, different test specimens were manufactured, and subjected to compression and bending tests, accompanied by optical analysis to understand the behavior of the material throughout the study.

Preliminary Research on the Incorporation of Wind Turbine Blades Wastes into Clay Materials

Dr. Natividad Antón Iglesias, Spain

Poster Presentation

Abstract

The increasing demand for renewable energy has led to the widespread use of wind turbines, resulting in significant quantities of waste materials, particularly from the sanding and finishing processes of turbine blades, thus promoting sustainable practices in the wind energy and ceramics industries. This study investigates the potential of using sanding dust from wind turbine blades as an additive in the formulation of clay ceramics, specifically focusing on its incorporation into kaolin and clays from the Zamora area. Green densities were determined, the sinterability curves of new materials were plotted, the evolution of porosity was analyzed, and the phases present were characterized using X-ray Diffraction (XRD) for a composition with 30% sanding dust addition. The sanding dust, primarily composed of epoxy resins, fiberglass, and to a lesser extent balsa wood, presents unique challenges and opportunities when integrated into clay matrices. Preliminary results indicate that the addition of sanding dust significantly influences the plasticity, shrinkage, and behavior during the firing of clay mixtures. Samples with a 30% addition show greater shrinkage than the base materials, and some temperatures exhibit a certain conical deformation. Regarding the optimal sintering temperature, there are hardly any variations compared to the base materials, although density decreases due to the incorporation of lower density materials like fiberglass. This preliminary study demonstrates the feasibility of using sanding dust from wind turbine blades in conjunction with clay ceramics, creating a new composite material.

Challenges in evaluating the interface between resorbable magnesium materials and bone tissue

Mrs. Jitka Lunackova, Czech Republic

Poster Presentation

Abstract

In biomedicine, significant attention is given to biodegradable metals. Among the most promising candidates are Mg-based materials, as Mg^{2+} cations and Mg corrosion products are well tolerated by the body and naturally degraded through metabolic processes. The biomedical application of these materials could be particularly beneficial for paediatric patients due to their dynamic growth.

The aim of this study was to describe the degradation of Mg-3Y (<3.5 wt% yttrium) and Mg-4Y-4Li (4.0 wt% yttrium, 4.0 wt% lithium) alloys in a real bone environment and their interaction with bone tissue. Mg-based implants were inserted into the condyle of an adult Wistar rat (male, >480 g). Samples were extracted after 8, 12, and 24 weeks of healing, fixed in 4% formaldehyde, and subjected to micro-CT analysis and histopathological examination.

Micro-CT allows for non-destructive 3D evaluation of samples. However, due to the similar X-ray density of the examined Mg-based materials and bone tissue, distinguishing between them in micro-CT imaging is challenging. This distinction becomes increasingly difficult as the magnesium material degrades and bone regeneration progresses. This work focuses especially on the challenges of micro-CT analysis at the interface between Mg materials and bone tissue.

Modification of the stoichiometric and the reduced SnO₂ (110) surface by transition metal doping: density functional study

Dr. Ana Umićević, Serbia

Poster Presentation

Abstract

SnO₂ is a wide gap semiconductor, which has excellent properties for selective detection of various gases, catalysis and optoelectronic devices. Many experimental studies showed that the transition metal (TM) doping is a way to enhance its performances. Using the modified density functional calculations we study the relative stability of the stoichiometric and the reduced SnO₂ (110) surfaces, as well as the influence of transition metals doping on their stability and electronic structure. In our study we consider models of the surface with different positions and concentrations of oxygen vacancies. We find that the substitutional doping of TM for Sn induces the structural relaxation and the charge modification around the involved atoms. In some of the investigated cases it also introduces surface states within the band gap. The obtained results for the structural relaxations and energetics are compared with available previous theoretical and experimental data.

Paper 384

High-Temperature Nanoindentation Behavior of Single-Crystalline Titanium: A Molecular Dynamics Study

Mrs. Gordana Marković, Serbia

Poster Presentation

Abstract

The mechanical responses of the single-crystalline hexagonal close-packed (HCP) metals, such as titanium (Ti), make them highly valuable for applications requiring excellent strength-to-weight ratios and high-temperature stability. Titanium's ability to maintain mechanical performance at elevated temperatures (600–1300 K) has been observed through nanoindentation experiments. Obtained results of the local hardness and elastic modulus values, i.e. nanoindentation behaviour at elevated temperature, reveal the connection of dislocation mechanisms and defect nucleation. The main focus of this work is a computational study of the high temperature effects on the mechanical deformation properties of a single-crystalline Ti during a nanoindentation test. Molecular dynamics (MD) simulations of a spherical nanoindentation are carried out at two indenter tip diameters and crystalline sample orientations [001], [10-10], and [11-20], for a temperature range of 10–1000 K. The study examines how the temperature increment affects the nanoindentation process, altering dislocation densities, slip mechanisms, atomic displacements, and the local hardness, as well as its agreement with experimental findings.

Paper 868

Effect of surface roughness, defects, and residual stresses on the fatigue behaviour of additively manufactured metals

Mrs. Paula Rahm, Germany

Poster Presentation

Abstract

One of the main advantages of additive manufacturing processes, and especially of laser-based powder bed fusion (PBF-LB/M), is that it enables the production of topology-optimised and thus lightweight components. The materials produced via PBF-LB/M usually have a high monotonic strength due to their unique and fine microstructure. However, their fatigue strength is lower in relation to conventionally manufactured materials, which is mainly caused by the process-induced microstructural defects and the additively manufactured “as-built” surface layer, containing a rough surface topography and tensile residual stresses. Note that the “as-built” surface layer often shows a higher density of process-induced defects than the inner material volume.

Therefore, the objective of the presented work is to analyse the influence of the “as-built” surface on the fatigue behaviour of metals produced via PBF-LB/M. For this, specimens made of the austenitic stainless steel AISI 316L were examined in two different surface conditions, “as-built” and polished. To characterize the different surface conditions, the microstructure, the surface topography, and the residual stresses at the surface were analysed, showing huge differences in the surface roughness and especially in the residual stress state.

For both surface conditions fatigue tests were performed to determine the S-N curves. Subsequently, the fracture surfaces of the specimens were investigated to identify the crack-initiating defects. In accordance with previous work [Lehn24], based on the $\sqrt{\text{area}}$ approach the impact of the defects on the fatigue behaviour was assessed using a modified S-N curve, which further enables the consideration of the influence of process-induced residual stresses [Mura19].

These analyses showed that the “as-built” surface significantly reduces the fatigue life. However, considering the defect size and residual stresses at the surface by means of the $\sqrt{\text{area}}$ approach, both surface conditions show nearly identical S-N curves. Thus, these influencing factors were identified as the main reasons for the lower fatigue strength of the “as-built” surface condition, which is in accordance with previous findings for AISI10Mg [Lehn24]. Consequently, the results obtained indicate that the surface roughness is not the most limiting factor for additively manufactured metals.

Microstructural Evolution and Deformation Mechanism Analysis of AlTiVCr High-Entropy Alloy with Varying Al-Ti Ratios

씨. Dong Seong Hong, South Korea

Poster Presentation

Abstract

High-entropy alloys (HEAs) are multi-component metallic systems composed of four to five or more principal elements, each within a composition range of 5–35 at.%. Due to their high configurational entropy, HEAs reduce free energy, promoting the formation of a stable single-phase solid solution while suppressing intermetallic compound formation. Among various HEAs, body-centered cubic (BCC) structured HEAs exhibit superior strength, making them promising candidates for high-performance structural applications such as aerospace components and lightweight automotive parts. However, their inherently low ductility poses challenges in processing, necessitating further research to enhance their mechanical properties.

In this study, a novel lightweight BCC-based HEA was designed to achieve an optimal balance between strength and deformation characteristics. Alloy compositions were systematically adjusted based on experimental evaluations of microstructural evolution to ensure homogeneity and improve mechanical performance. Specifically, Ti, V, and Cr—elements with minimal atomic size differences—were selected as primary alloying components, while Al, a widely used lightweight element, was incorporated to mitigate brittleness. The study aimed to develop an AlTiVCr HEA with enhanced mechanical properties. Furthermore, the influence of Al and Ti ratio variations on the formation of intermetallic compounds was experimentally analyzed, and their impact on mechanical performance was assessed.

The alloys were fabricated using arc melting and suction casting to produce rod-shaped specimens with a diameter of 3 mm and a length of 50 mm, with compositions of Al_xTi_{80-x}V₁₅Cr₅ (x = 35, 40, 45 at.%). Microstructural characterization and phase analysis were conducted using scanning electron microscopy (SEM, JEOL JSM-6390) and X-ray diffraction (XRD, Panalytical). Additionally, chemical composition analysis was performed via transmission electron microscopy (TEM, JEM-ARM200F, Jeol) and energy-dispersive spectroscopy (EDS). Mechanical properties were evaluated through room-temperature compression tests using a universal testing machine (UTM), and the experimental data were analyzed using SEM to establish correlations between microstructure and mechanical properties.

Quenched and Partitioned Steel for Advanced Engineering Applications: Insights into Microstructure and Properties

Dr. Huda Refaiy, Egypt

Poster Presentation

Abstract

The third-generation advanced high-strength steel, Quenched and partitioned steel (Q&P), is a promising grade for advanced high-performance structural applications. It promotes the production of lighter and stronger parts with improved performance, which minimizes the need for additional reinforcement. Consequently, high energy efficiency, saving of resources and costs during the production processes, and industrial applications can be achieved. This is due to its outstanding mechanical characteristics compared to imitative high-strength steels. Q&P steel is more appropriate for the automotive, aerospace, and construction sectors, where performance and safety are essential. Its continued development and application are crucial to cope with the challenges of a rapidly evolving industrial and environmental requirements.

This article presents a detailed examination of the evolution of quenched and partitioned (Q&P) steel, focusing on processing techniques and their influence on mechanical properties. It displays the impact of processing conditions on the resultant phase transformations and the microstructure, particularly the formation and stabilization of retained austenite. Also, the effect of chemical composition and heat treatment parameters on mechanical characteristics such as strength, ductility, and toughness to optimize its performance for specific applications. The weldability and the change in the structure in the heat-affected zone of this steel will be discussed. This study strives to be a foundational resource for researchers and steel producers to increase their understanding of the microstructure and properties of Q&P steel for advanced engineering applications.

Biofunctional magnetic scaffolds that enhance osteogenic differentiation of mesenchymal stem cells through mechanotransduction

Ph.D. Manuel Estévez, Spain

Poster Presentation

Abstract

Magnetic composite biomaterials have garnered significant attention in bone tissue engineering (BTE), as dynamic magnetic fields have been shown to modulate the proliferation and differentiation of various cell types. The aim of this manuscript is the fabrication of biofunctional magnetic scaffolds combining Fused Deposition Modeling (FDM) and thermal Drop-On-Demand (DoD) inkjet printing. The 3D scaffolds were initially fabricated from thermoplastic polymers, including poly-L-lactic acid, polycaprolactone, and poly(3-hydroxybutyrate-co-3-hydroxyvalerate) by FDM and subsequently super paramagnetic iron oxide nanoparticles were incorporated via DoD. The obtained results demonstrated the precision and versatility of the fabrication technique, as well as the scaffolds' stability under physiological conditions and their magnetic capability. Biological evaluation with human bone marrow mesenchymal stem cells confirmed the scaffolds' biocompatibility and enhanced osteogenic potential under the application of a magnetic field, which activated mechanotransduction processes. These findings indicate that the developed 3D magnetic biofunctional scaffolds hold great promise as a tool for advanced and personalized bone regeneration therapies.

Paper 213

Evaluation of the activation energy of hydrogen desorbed from the vicinity of dislocation cores in α -iron

Mr. Keisuke Akiyama, Japan

Poster Presentation

Abstract

Hydrogen embrittlement, which deteriorates mechanical properties such as strength and ductility of metallic materials due to absorbed hydrogen, is a significant issue. It has been well known that hydrogen diffusing into metallic materials is preferentially trapped at sites with high binding energy according to Fermi-Dirac statistics. Therefore, clarifying the activation energy for hydrogen desorption (E_a) from various lattice defects acting as trap sites for diffusible hydrogen is crucial to understanding the states of hydrogen present in metallic materials. However, previous studies on the E_a for hydrogen desorbed from dislocations in α -iron have only been able to determine values considered as average for hydrogen trapped at edge dislocation cores, screw dislocation cores, and the strain fields around dislocation cores. In the present study, we attempted to evaluate the E_a for edge dislocation cores and their vicinity, which have the highest binding energy among dislocations, by reducing the amount of tracer hydrogen as much as possible. Cold-rolled iron containing 6 ppm C (Fe > 99.98 mass%) was prepared. The iron was processed into flat plate tensile specimens with a parallel part of 30 mm and annealed at 900 °C for 30 min. The tensile specimens were subjected to plastic strain of 25 % at a strain rate of $8.3 \times 10^{-6} \text{ s}^{-1}$ at R. T. to induce sufficient lattice defects into the specimens. A 10-mm square specimen was cut out from the parallel part of the tensile specimen and polished to reduce the specimen thickness to 0.3 mm. To detect lattice defects in these specimens, tracer hydrogen was charged by constant current cathodic electrolysis at a current density of $10 \text{ A} \cdot \text{m}^{-2}$ in a 0.1 N NaOH solution containing $0.05 \text{ g} \cdot \text{L}^{-1} \text{ NH}_4\text{SCN}$ at 30 °C for 1 h. Tracer hydrogen spectra were then obtained by thermal desorption spectroscopy at heating rates of 1, 2, and $2.5 \text{ }^\circ\text{C} \cdot \text{min}^{-1}$ and in a temperature range of -200 to $200 \text{ }^\circ\text{C}$. The peak of hydrogen desorption corresponding to dislocations was extracted from the tracer hydrogen spectra, and then the E_a values were calculated from the heating rate and the peak temperature of hydrogen desorption using the Choo and Lee's equation. The E_a for dislocations with approximately 1/40 of the tracer hydrogen amount compared to the previous study was found to be $53.1 \text{ kJ} \cdot \text{mol}^{-1}$, which is higher than $30.4 \text{ kJ} \cdot \text{mol}^{-1}$ reported previously and is considered to be the E_a for the edge dislocation cores and vicinity in α -iron.

Electrical insulation properties of reactive grown AlN thin films at high-temperatures

Mrs. Norma Salvadores, Austria

Poster Presentation

Abstract

Aluminum nitride-based ceramics are known for their insulating properties and high thermal conductivity. Their range of applications is vast, whether as structural components or thin films. As the electrical conductivity is highly depended on the temperature, the mobility of charge carriers at elevated temperatures causes distinct challenges for insulating thin film materials.

Therefore, in this study the growth of insulating AlN thin films via PVD and their electrical insulation up to 750 °C is studied. For the growth various reactive PVD techniques have been used, including magnetron sputtering (DCMS), high-power pulsed magnetron sputtering (HIPIMS), and pulsed magnetron sputtering (PMS). For all depositions a 3" Al target was used in mixed Ar/N₂ atmospheres. Phase formation has been examined using XRD, while the deposition rate and film morphology were investigated through SEM and TEM. The insulating properties of the coatings were analyzed using in-situ impedance spectroscopy, with measurements taken from room temperature to 750°C. The experiment was conducted using Pt/Ti lithography pads.

The electrical properties are influenced by the morphology of the film, with the densest HIPIMS grown films exhibiting the highest electrical resistance over temperature. Nevertheless, the influence of impurities, such as O₂, plays a significant role in reducing the insulating properties of the films.

Effects of cooling rate and tempering on the microscale mechanical properties of heat resistant steel (30CrMoNiV5-11)

Mrs. Paula Chonillo Vera, Spain

Poster Presentation

Abstract

Ferritic/martensitic heat-resistant steels used for high-temperature applications typically have a multiphase microstructure containing ferrite, martensite, and/or bainite, as well as carbides. This microstructure is controlled by the cooling rate during quenching and by tempering parameters. Various microstructural constituents exhibit different mechanical properties, which, along with the microstructural architecture, define the mechanical properties on the macroscale. This work focuses on the effect of local microstructure on the local mechanical properties of 30CrMoNiV5-11 heat-resistant steel.

Samples machined from the as-received material were austenitized at 950 °C for 30 minutes, followed by controlled cooling at the following rates: 0.05, 0.5, 5, and 50 °C/s. Scanning electron microscopy (SEM) and electron backscatter diffraction (EBSD) analyses were performed to identify individual microstructural constituents and conduct their quantitative analysis. Nanoindentation tests were carried out using a Hysitron TriboIndenter TI 950 with a Berkovich indenter, performing measurements on EBSD scans to correlate local microstructural architecture with nanohardness values.

The results showed that higher cooling rates (50 °C/s) produced a martensitic microstructure with the highest average nanohardness (6.1 GPa). As the cooling rate decreased, the microstructure changed, and average nanohardness values also decreased as follows: 5 °C/s resulted in a martensitic-bainitic microstructure with a nanohardness of 5.8 GPa; 0.5 °C/s yielded a ferritic-bainitic microstructure with 4.8 GPa; and 0.05 °C/s produced a ferritic microstructure with the lowest average nanohardness value of 4.5 GPa. Subsequently, simulating an industrial manufacturing process, tempering was performed at 680 °C for 45 minutes, followed by rapid cooling in water. EBSD and nanoindentation analyses were repeated to evaluate the effect of tempering on local mechanical properties in comparison to the quenched material. It was found that the average nanohardness values decreased after tempering. Specifically, the tempered martensitic microstructure (50 °C/s) exhibited an average nanohardness of 4.5 GPa, followed by the tempered martensitic-bainitic microstructure (5 °C/s) with an average nanohardness of 4.7 GPa, the tempered ferritic-bainitic microstructure (0.5 °C/s) with 3.9 GPa, and the ferritic microstructure (0.05 °C/s) with 3.7 GPa. The microstructure-property relationship on the microscale is discussed.

Processing of Ti-10Nb-10Ta alloy foams via powder metallurgy with solar sintering

Dr. Antonio Cañadilla Sanchez, Spain

Poster Presentation

Abstract

Titanium alloys with niobium and tantalum are promising materials for biomedical applications due to their excellent biocompatibility, corrosion resistance, and adaptable mechanical properties. In this study, open-cell Ti-10Nb-10Ta foams with 50 and 60 vol.% of porosity were manufactured using the space-holder powder metallurgy technique, employing NaCl as a pore-forming agent. The novelty of this study was the one step sintering and nitriding of ternary titanium alloy foams using a low-cost Fresnel lens as solar concentrator.

The experimental procedure included powder mixing and compaction with the space-holder, followed by the space-holder dissolution in water and finally solar treatment under N₂-5%H₂ atmosphere to achieve optimal sintering components. Thermal analysis revealed that an exothermic reaction occurred in the range of 470-520 °C, attributed to the formation of titanium nitride (TiN). Additionally, solar heating activates the solid-state diffusion process during sintering, optimized at 1200 °C, which requires much less time than using electric furnaces (15-30 min vs. several hours).

Microstructural characterization confirmed the presence of TiN in the surface of the components, effective metallurgical bonding between powder particles, and homogeneous porosity distribution which fits with the designed parameters. These results demonstrate that the application of solar thermal cycle enables the production of high-quality titanium alloy foams with optimized microstructure, promoting high pore interconnectivity, and the formation of a TiN surface layer that enhances hardness without compromising structural integrity.

All the manufactured foams exhibit an optimal pore size (200–600 µm) that could promote cell growth, rounded cubic pore morphology, preventing stress concentrations, and interconnected porosity network that could facilitate the circulation of bodily fluids, making them particularly suitable for bone implants. This study confirms that the combination of space-holder and solar concentrated energy technologies is an efficient and sustainable methodology for producing titanium alloy foams.

Sustainable processing of metal components by material extrusion additive manufacturing technique and concentrated solar energy

Dr. Antonio Cañadilla Sanchez, Spain

Poster Presentation

Abstract

Material extrusion additive manufacturing (MEX) enables the design and production of complex metal components, optimizing their physical, mechanical and/or thermal properties, with wide applicability in numerous industrial sectors. It is considered a sustainable technology as it minimizes waste generation and natural resources consumption, thanks to its high material utilization rate, without compromising quality and functionality of the final product. MEX is based on a three-stage PDS (Printing-Debinding-Sintering) methodology: the first step involves 3D-printing using filaments composed of binder system and metal powder, then the polymeric content is removed, and, finally, the parts are sintered at high temperatures during prolonged times. The final sintering stage is the most energy-demanding, so the exploration of new clean energy resources and the development of more efficient energy utilization strategies should be prioritized at this stage.

Concentrated Solar energy (CSE) is proposed as a clean, renewable, and non-polluting energy resource that is highly efficient for high-temperature materials processing. In this context, this research studies the feasibility of using CSE in the sintering of metallic components obtained by advanced additive manufacturing techniques. Concentrated solar energy through a low-cost Fresnel lens installation was used in the sintering stage of metal parts produced via MEX in a novelty methodology defined as PDSS (Printing-Debinding-Solar Sintering).

Optimal PDSS processing parameters were established for H13 tool steel, Inconel 625 nickel-based alloy and copper components. Density measurements, SEM microscopic analysis and mechanical characterization were carried out at the different stages of the processing in order to evaluate the porosity and properties of as printed, debinded and final parts. It has been demonstrated that the use of CSE in the sintering stage lowers treatment temperatures and shortens manufacturing times thanks to the activator effect of solar radiation in diffusion processes, reducing total costs and environmental footprint. Furthermore, solar sintered metal components achieved competitive relative density properties up to $\approx 95\%$, as well as adequate dimensional accuracy compared to conventional material extrusion additive manufacturing. Finally, different components with relatively complex geometries and specific applications have been designed and processed via PDSS.

Study on the Reinforcement of Eco-Friendly Basalt/Epoxy Composites with Varying CNT/Graphene Content

Dr. Kyoungsik Cho, South Korea

Poster Presentation

Abstract

Basalt fiber is a naturally abundant material distributed worldwide and is increasingly recognized as a next-generation eco-friendly inorganic fiber that can replace conventional organic fibers. Compared to traditional fibers, it exhibits low toxicity to humans, excellent mechanical strength, and outstanding chemical resistance, leading to extensive research on its applications in composite materials.

Previous studies have shown that Basalt/PET composites outperform glass fiber composites in terms of flexural and tensile strength. Additionally, research indicates that the mechanical properties of epoxy composites improve significantly after the surface treatment of multi-walled carbon nanotubes (MWCNTs). These findings suggest that basalt fiber has great potential as a reinforcement material for high-performance composites.

The objective of this study is to enhance the mechanical properties of basalt fiber composites while maintaining their inherent thermal stability and durability. To achieve this, carbon nanotubes (CNTs) and graphene were incorporated to analyze their effects on composite performance. Both CNTs and graphene are advanced materials with a hexagonal carbon lattice structure and sp^2 bonding, known for their lightweight nature and exceptional strength.

In the fabrication process, basalt fiber was mixed with epoxy resin and a curing agent, followed by the addition of CNTs and graphene to ensure uniform dispersion. The mixture was then compression-molded using a hot press to create standardized test specimens. These specimens were subsequently subjected to mechanical tests, including tensile testing and wear resistance evaluation.

Experimental results revealed that the basalt fiber composites containing CNTs and graphene exhibited a 50% increase in flexural strength and a 25% improvement in wear resistance compared to composites without these nanomaterials. This indicates that the addition of CNTs and graphene plays a crucial role in enhancing the mechanical performance and durability of basalt-based composites.

In conclusion, this study highlights the potential of basalt fiber as a sustainable and high-performance composite material for various industrial applications. Given its durability, lightweight nature, and thermal stability, basalt fiber-reinforced composites present a promising alternative for industries requiring advanced materials, with significant potential for future applications.

Paper 691

Optimizing oxide dispersoid content towards enhancing mechanical properties of ODS Ni-based high entropy alloy

Mrs. Manashi Sabat, India

Poster Presentation

Abstract

The oxide dispersion strengthened high entropy alloys (ODS HEAs) represent an advanced material that integrates the distinctive properties of high entropy alloys with the strengthening effect of oxide nanoparticles. The excellent high-temperature stability, strength, hardness, and corrosion resistance of the ODS HEAs thus offer new avenues for developing structural materials to meet high-temperature applications like aerospace, nuclear power plants, etc. The current research work provides a comprehensive approach for optimizing oxide dispersoids in oxide dispersion strengthened high entropy alloy (ODS HEA) to enhance the strength-ductility alliance, thereby widening its applicability. The study focuses on fabrication of ODS HEA featuring a composition of Ni₄₇Al₆Co₁₈Cr₈Fe₁₂Ti₈W₁ at. % via mechanical alloying (MA) and spark plasma sintering (SPS). The investigation encompasses variations in Y₂O₃ content, including 1 vol. %, 3 vol. % and 5 vol. %. The effect of Y₂O₃ addition on the microstructural evolution and mechanical properties of the sintered alloys was evaluated. Phase analysis reveals that presence of Y₂O₃ promotes the formation of Y₂Ti₂O₇ complex oxide precipitation in ODS HEAs. A significant enhancement in both hardness and strength is evident in the pristine HEA upon Y₂O₃ addition. However, a reduction in these properties is observed in the 5 vol.% Y₂O₃ ODS HEA due to agglomeration of Y₂O₃ nanoparticles. Notably, the ODS HEA containing 3 vol.% Y₂O₃ exhibits exceptional mechanical characteristics, achieving a compressive yield strength of 1517 MPa and a compressive strain of 27%, demonstrating a synergistic combination of strength and ductility. Enhancement of the mechanical properties in the ODS HEA is ascribed to both oxide dispersion strengthening resulting from addition of Y₂O₃ as well as presence of in-situ formed Y₂Ti₂O₇ complex oxide coupled with solid solution strengthening effect of the HEA matrix.

Vacancy-Confined Single-Atom Catalysts on MXenes for Enhanced CO₂ Reduction

Mr. Amil Aligayev, Poland

Poster Presentation

Abstract

MXenes, a versatile class of two-dimensional (2D) materials, exhibit exceptional electronic conductivity, tunable surface chemistry, and catalytic properties, making them promising candidates for sustainable energy applications. This study investigates vacancy-confined single-atom catalysts (SACs) supported on MXenes to enhance CO₂ reduction performance. Using density functional theory (DFT) and experimental techniques, we uncover the role of vacancies and single-atom configurations in optimizing catalytic activity and selectivity.

Our computational analysis reveals that introducing vacancy-confined SACs on Ti₃C₂T_x MXenes functionalized with oxygen, hydroxyl, and fluorine groups tailors the electronic structure and adsorption properties of key intermediates, such as *CO and *CHO. The vacancy sites effectively anchor single atoms, enhancing charge transfer and stabilizing intermediates. This enables selective reaction pathways toward CO and CH₄ production, with proton-coupled electron transfer mechanisms elucidated through transition state calculations. Notably, oxygen-functionalized MXenes demonstrate near-zero Gibbs free energy for intermediate adsorption, ensuring high catalytic efficiency. Experimental validation through scalable synthesis of functionalized Ti₃C₂T_x MXenes confirms the presence of vacancy-confined SACs. Characterization techniques, including X-ray photoelectron spectroscopy (XPS), Raman spectroscopy, and electrochemical analysis, reveal the active site formation and their role in CO₂ reduction. The combination of high surface area, vacancy engineering, and synergistic electronic properties positions MXenes as superior catalysts compared to conventional materials.

This work highlights the transformative potential of vacancy-confined single-atom catalysts on MXenes for enhanced CO₂ reduction, providing a pathway for the rational design of advanced materials in renewable energy and carbon capture technologies.

Ni-9%P+(a:C-H)DLC multilayer coating: a solution to improve the tribological behaviour of complex-shaped AISi10Mg components produced by Powder Bed Fusion-Laser Beam for automotive industry

Ph.D. Gianluca Di Egidio, Italy

Poster Presentation

Abstract

The interest of the industrial and scientific community in Powder Bed Fusion-Laser Beam (PBF-LB) technology stems from its innovative approach to the design and manufacturing of high-performance and complex-shaped components. AISi10Mg alloy is widely used to produce lattice structures and thin-walled parts by PBF-LB technology for the automotive industry, as it combines good mechanical properties and corrosion behaviour. However, it is characterized by poor tribological behaviour, especially under severe environmental conditions.

The application of the Ni-9%P+(a:C-H)DLC multilayer coating is a promising solution to improve the tribological behaviour of PBF-LB AISi10Mg components: the deposition conditions (time and temperature) are compatible with the as-built microstructure, preserving its mechanical performance, and can be integrated with heat treatment cycles used to optimize bulk tensile properties. In addition, the Ni-9%P interlayer is able to coat complex geometries and surface-connected defects, typical of the PBF-LB process, ensuring uniform thickness, good adhesion and continuity, and providing load support to the (a:C-H)DLC topcoat, which is characterised by high wear resistance and low friction. Barrel finishing can be implemented before the deposition of the Ni-9%P+(a:C-H)DLC multilayer coating to obtain a controlled surface finish over the entire surface, ensuring uniform functional properties.

To demonstrate the effectiveness of the whole post-process cycle (barrel finishing + multilayer coating deposition), a complete microstructural and micromechanical characterization was carried out on a motorcycle steering plate in PBF-LB AISi10Mg alloy. Optical profilometry and cross-section observations using FEG-SEM/EDS and ion milling were used to analyse the surface roughness and the quality of the multilayer coating, substrate and interfaces. The adhesion of the Ni-9%P layer on the substrate was evaluated by Rockwell indentation ("Mercedes test") and the practical adhesion of the (a:C-H)DLC on the Ni-9%P interlayer was tested by progressive load scratch testing. Instrumented indentation was used to measure the hardness of both layers (Ni-9%P and (a:C-H)DLC) on the micro/nanoscale.

The results obtained from the microstructural and micromechanical characterization demonstrated the applicability of the Ni-9%P+(a:C-H)DLC multilayer coating on real automotive components produced by PBF-LB. This will enable the production of innovative components with sustainable materials and processes, supporting the ecological transition in the automotive sector.

Optical properties of Sb-Ge and Ge-Se thin films for applications in photovoltaic devices

Mrs. Marina García-Pardo, Spain

Poster Presentation

Abstract

The current global context, marked by growing concern over environmental issues stemming from the overexploitation of conventional energy resources, is driving a research effort focused on developing more sustainable, adaptable, and efficient photonic and photovoltaic devices [1-2]. In this context, advances in the development of semimetal -based and chalcogenide -based materials for sustainable solar photovoltaic cells as a potential energy alternative [3], are particularly relevant. In recent years, efforts have been made to find new solutions to eliminate the toxicity of Cd and the scarcity of elements such as In, Ga, and Te, which are present in traditionally used CIGSe and CdTe-based thin-film solar cells. Among the compounds that have attracted interest for both photonic and photovoltaic applications are those based on SbGe and Sb₂(S,Se)₃ and related materials [4]. They show unique properties as absorbers for thin-film solar energy harvesting.

This work focuses on the optical characterisation of the of Ge-Sb and Ge-Se thin films. These films were deposited by thermal evaporation o co-evaporation followed by a selenization process in the case of the chalcogenides. By using spectroscopic ellipsometry we have determined their dielectric optical function that give access to the determination of the band gap energy and absorption coefficient. We correlate the optical properties to the composition and morphology of the films. This study was carried out at the Optical Characterization of Materials Service (SCOM) of the Institute of Optics (IO-CSIC) [5], using advanced techniques such as spectroscopic ellipsometry [6], reflectance, and transmittance [7] measurements.

Enhancing Properties of Zinc-Based Biodegradable Alloys for Biomedical Applications via Powder Metallurgy

Mr. David Nečas, Czech Republic

Poster Presentation

Abstract

Biodegradable metals have garnered significant attention in biomedical research as temporary substitutes or fixation devices for damaged body tissues. Among these, zinc alloys are particularly promising for applications such as stents and screws due to their excellent biocompatibility and favorable corrosion properties compared to other metals like magnesium and iron. However, to meet the stringent requirements of biomedical applications, these materials must exhibit enhanced mechanical properties. Therefore, optimizing the composition and processing methods of zinc alloys is crucial for developing effective biodegradable devices in biomedical engineering.

In our research, we focused on the preparation of binary and ternary zinc alloys with copper and manganese, starting from pure powders. We employed a combination of mechanical alloying (MA), spark plasma sintering (SPS), and extrusion. Optimization of preparation parameters led to the formation of fine-grained, homogeneous microstructures with intermetallic phases, resulting in improved mechanical properties. This study examines the effects of powder metallurgy preparation on the mechanical and corrosion properties of selected alloys. Our results demonstrated a significant impact of MA parameters on the fineness and chemical composition of Zn-2Cu and Zn-1Cu-1Mn (wt.%) powders. The compacted samples, processed through SPS and extrusion, exhibited fine microstructures with grain sizes in hundreds of nanometers, intermetallic phases such as CuZn₅, and oxide nanoparticles from the original surface of the powder particles. These structural changes played a crucial role in hindering dislocation motion, thereby enhancing the strength of the material and influencing its behavior during corrosion testing. We observed increased hardness, an improvement in ultimate tensile strength from 109 MPa for pure zinc to 180 MPa for the ternary alloy, and the formation of a partial corrosion barrier during testing in a simulated physiological environment. Our findings underscore the potential of this powder metallurgy approach in enhancing the mechanical and corrosion properties of zinc-based biodegradable alloys, thereby advancing their applicability in biomedical devices. Fresh and hardened properties of concrete formulated with enforced carbonated recycled aggregates

Dr. Maria Del Mar Alonso, Spain

Poster Presentation

Abstract

In agreement with the objectives of the European Green Deal, concrete and cement sector aims at reaching zero emissions by 2050 by applying different technologies including carbon capture, utilization and storage. The present research is focused on quantifying the effects of enforced carbonation of recycled concrete aggregates on the rheology and hardened properties of concrete with the final aim at maximizing the level of natural aggregates by recycled one without affecting the technological properties of the material. For this purpose, recycled concrete aggregates of different size ranges were initially characterised and afterwards enforced carbonated by direct injection of 20% CO₂, using different carbonation times and relative humidity.

Concrete specimens were prepared by maintaining the w/c ratio and searching for and target slump. Properties of new concrete in the fresh and hardened state were evaluated using replacements of natural aggregates by recycled aggregates (carbonated and non-carbonated) in the range between 0 and 75%.

The results of this preliminary study established that the ideal exposure time to enforced carbonation of the aggregates was 6 h, and RH was optimized to maximize carbonation. Carbonation treatment improved the rheological properties of the concrete containing recycled aggregates. Different replacements of uncarbonated and carbonated recycled concrete aggregates showed promising results at fresh concrete properties and 7 days compressive strengths

Phase-Field Modeling of Magnesium Alloy Degradation for Biomedical Applications

Mrs. Vittoria Squartecchia, Spain

Poster Presentation

Abstract

Biodegradable metals hold tremendous potential in the field of biomaterials, offering a solution to mitigate post-operative complications associated with permanent implants. However, enabling their commercial adoption requires a comprehensive understanding of the degradation mechanisms of these materials.

Pitting corrosion, for instance, is a critical challenge in the application of magnesium-based alloys for biomedical purposes, particularly for degradable implants. This localized form of corrosion can jeopardize the structural integrity of devices, undermining their mechanical reliability and effectiveness.

Computational models have emerged as powerful tools to support and enhance traditional in vitro studies, offering efficient methods to investigate corrosion phenomena. Among the various computational approaches developed for simulating magnesium-based alloys corrosion, phase-field (PF) models stand out for their versatility, making them a promising alternative.

Here we aim to use PF simulations to investigate the degradation of magnesium alloys used in biomedical applications. The initial approach starts with a simple model that considers uniform degradation; subsequently, the model is refined to account for the phenomenon of localized corrosion (pitting). The methodology employs an implicit description of the metal-electrolyte interface, represented by a smooth phase-field function, and a stochastic variation of interface mobility to capture the inherent randomness in pitting initiation and propagation. Our analysis focuses on the role of key parameters influencing corrosion dynamics, such as the interface thickness and the distribution of interface kinetic coefficients. Additionally, we explore the transition from uniform to localized corrosion regimes and their implications for the degradation rate and mechanical stability.

We expect this work to ultimately provide a comprehensive framework for understanding and predicting the degradation behavior of magnesium-based alloys in physiological environments, advancing the application of biodegradable materials in biomedical devices.

Paper 434

Optimization of aluminum content in the zinc bath to improve wettability and galvanizing performance of AHSS

Mr. Sang-Hoon Shin, South Korea

Poster Presentation

Abstract

Advanced high-strength steels (AHSS) contain Si and Mn, which form surface oxides during annealing, hindering zinc coating. To address this, aluminum is added to the zinc bath to promote oxide reduction. This study investigates the effect of aluminum content by measuring wetting force and Fe-Al coverage across different steel grades. A comparative study was conducted on interstitial-free (IF), high-silicon (P2, Si/Mn = 1.0), and low-silicon (P4, Si/Mn = 0.3) steels. The wetting force and $\text{Fe}_2\text{Al}_{5-x}\text{Zn}_x$ inhibition layer coverage were evaluated.

IF steel exhibited optimal wettability at 0.25 wt.% Al, while higher Al concentrations reduced the wetting force due to the formation of coarse $\text{Fe}_2\text{Al}_{5-x}\text{Zn}_x$ particles. In contrast, both P2 and P4 steels showed a monotonic increase in wetting force with increasing Al content. In both P2 and P4 steels, the aluminothermic reaction facilitated oxide reduction and aluminum consumption, suppressing abnormal $\text{Fe}_2\text{Al}_{5-x}\text{Zn}_x$ growth and improving wettability.

FactSage calculations revealed that the aluminothermic reaction significantly reduced the residual MnSiO_3 coverage, while SiO_2 showed minimal reduction, indicating greater resistance. Even at 0.50 wt.% Al, complete oxide reduction was not achieved, leading to the retention of residual oxides. The penetration of $\text{Fe}_2\text{Al}_{5-x}\text{Zn}_x$ beneath these residual oxides was observed, further enhancing wettability.

Oxide-Based Preceramic Polymers for Dual Protective Coatings on Cast Aluminum Structures: Enhancing Corrosion Resistance in Heat Transfer Applications.

Ph.D. Aurora Pizzinat, Italy

Poster Presentation

Abstract

This study investigates the development of advanced anticorrosive ceramic coatings through an innovative approach that combines multiple protective technologies. Specifically, polymer-derived ceramic (PDC) coatings were applied using Durazane 1800 onto surfaces pre-treated with plasma electrolytic oxidation (PEO). The research focused on optimizing the coating process by incorporating a 70% functionalized alumina nanopowder into the Durazane 1800 matrix, followed by curing the coatings under controlled air atmosphere conditions. Initial experimental results demonstrated significant promise in achieving highly effective ceramic coatings with enhanced durability. To assess the performance, the coated samples underwent rigorous testing in a corrosive environment (the corrosive medium is $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$) over 25 cycles, with periodic measurements of mass to monitor material degradation. Remarkably, almost no detectable mass change was observed across all samples after completing the 25 cycles, underscoring the exceptional corrosion resistance and stability of the developed coatings. These findings suggest a robust and reliable solution for protecting metallic surfaces in challenging environments.

Paper 88

Tribological Behavior of STS316L Sintered Bodies and Cu/STS316L Composites Fabricated via Binder Jetting Process

Dr. Kyung Il Kim, South Korea

Poster Presentation

Abstract

The binder jetting (BJT) process is a promising additive manufacturing technique known for its high material selectivity and ability to create complex shapes. It enables the production of porous and composite materials through sintering and impregnation, techniques commonly used in powder metallurgy. STS316L powder is widely used in BJT due to its excellent weldability, corrosion resistance, and tribological properties. However, research on its tribological behavior is limited.

This study investigates the tribological properties of sintered STS316L bodies and Cu/STS316L composites fabricated using the BJT process. Sintering was performed at three different temperatures: 1100, 1200, and 1300°C. Tribological tests were conducted using the Pin-on-disc method, and friction coefficients along with wear marks were analyzed using scanning electron microscopy (SEM) and energy-dispersive X-ray spectroscopy (EDS). The results showed that for STS316L, both the friction coefficient and wear mark size increased with the sintering temperature. In contrast, Cu/STS316L composites exhibited stable friction coefficients and smoother wear marks under all conditions. Microstructural analysis of the wear traces helped identify the underlying tribological mechanisms.

Pr³⁺-ACTIVATED NaY₉Si₆O₂₆ LUMINESCENT NANOPOWDERS: PREPARATION, STRUCTURE, MORPHOLOGY, AND PHOTOLUMINESCENCE

Prof. Miroslav Dramicanin, Serbia

Poster Presentation

Abstract

Pr³⁺ luminescence centers in solids provide diverse emissions across the ultraviolet, visible, and infrared spectral ranges, originating from both interconfigurational [Xe]4f¹⁵d¹ → [Xe]4f² and intraconfigurational [Xe]4f² → [Xe]4f² electronic transitions. These emissions can be of any type, including scintillation, downshifting, downconversion, and upconversion. They can exhibit fast decay times in the nanosecond range, making them ideal for scintillating applications, or slower decay times in the microsecond range, suitable for lighting phosphors and sensing applications. Additionally, Pr³⁺ optical centers may provide long-lasting luminescence. For these reasons, Pr³⁺-doped materials have found widespread use in a variety of practical applications, particularly in lighting, displays, healthcare, sensing, and security fields.

Here, we report a thorough examination into the structural, morphological, and photoluminescence features of Pr³⁺-activated NaY₉Si₆O₂₆ (x = 0; 0.5; 1; 3; 5; and 7 mol% Pr³⁺) oxyapatite phosphors, prepared using hydrothermal synthesis. Differential thermal analysis was used to determine the optimal calcination temperature, and an exothermic peak was found at 995°C. This peak is attributed to the transformation of the NaY₉Si₆O₂₆ from an amorphous to a crystalline form. The X-ray diffraction patterns of six NaY₉Si₆O₂₆ samples doped with different Pr³⁺ concentrations revealed a single-phase hexagonal structure with the P6₃/m (176) space group. Transmission electron microscopy images of samples showed agglomerates of round-shaped nanoparticles with an approximate size of ~55 nm. The room temperature photoluminescent emission spectra, excited at 450 nm, revealed distinct emission bands in the visible spectral region. These emission bands correspond to the Pr³⁺ electronic transitions, specifically the [Xe]4f² → [Xe]4f² transition. The optimal Pr³⁺ doping concentration, based on observed emission intensities, is 0.5 mol%.

New heterogeneous photocatalysts based on novel 2D materials for photochemical upcycling of plastic wastes

Prof. Dimitris Gournis, Greece

Poster Presentation

Abstract

Much of the research effort on 2D materials focuses on its use as building block for the development of novel hybrid structures with well-defined dimensions and behavior suitable for applications among else in gas storage, heterogeneous catalysis, gas/liquid separations, nanosensing and biology. Towards this aim, here we demonstrate the development of green and sustainable processes using novel 2D heterogeneous catalysts for the photochemical upcycling of plastic wastes, such as polystyrene (PS). Various photocatalytic anthraquinone and thioxanthone derivatives were successfully synthesized and immobilized in different types of 2D matrices to produce novel heterogeneous photocatalysts. 2D Xanes of group-14 [germanane (GeH) and silicane (siloxane)], anionic layered double hydroxides (LDHs), cationic clay minerals and synthetic clay analogues (SCA) with high surface area, tunable pore size and functionalities were prepared using top-down synthetic approaches and applied as supports of the photocatalytic molecules. All materials were characterized by a combination of analytical techniques. Finally, the heterogeneous photocatalysts were tested in the aerobic photochemical upcycling of PS but also in other demanding plastics, such as PET, PE and PP.

Acknowledgments. The research project is implemented in the framework of H.F.R.I Call "Basic research Financing (Horizontal support of all Sciences)" under the National Recovery and Resilience Plan "Greece 2.0" funded by the European Union –NextGenerationEU (H.F.R.I. Project Number: 15949).

Paper 1126

Enhancing the Mechanical Properties of Zn-Based Biodegradable Alloys Through Harmonic Structure Design

Mrs. Anna Boukalová, Czech Republic

Poster Presentation

Abstract

In recent years, zinc alloys have been increasingly investigated as promising biodegradable materials for medical applications, especially in orthopaedics and cardiovascular surgery. Due to their biodegradability and good biocompatibility zinc alloys appear to be an attractive alternative to biodegradable magnesium or iron alloys. Potential applications of these materials include the manufacture of screws and nails for fracture fixation, as well as stents that can be inserted into narrowed blood vessels and other tubular organs to hold them open.

Despite their advantages, zinc alloys have some disadvantages, including poor mechanical properties, particularly low strength and limited ductility. This limits their practical applicability in challenging biomechanical conditions. Therefore, ways to improve these properties without adversely affecting the biocompatibility of the material are being intensively sought. One promising approach to achieve these goals is the creation of a harmonic structure characterised by a combination of soft cores and a hard ultra-fine-grained 3D skeleton. This approach allows for synergistic increases in both strength and ductility, which is key to the successful application of the material in medicine.

This work focuses on the study of Zn-based alloys with a harmonic structure. Advanced powder metallurgy methods, specifically mechanical milling and subsequent plasma sintering, were used to prepare alloys with controlled microstructure. Detailed analysis of the microstructure was complemented by an investigation of mechanical properties to understand the relationship between the microstructure and the resulting material characteristics. After sintering, the alloy contained oxide shells that negatively affected the mechanical properties of the material. During the extrusion process, these were broken, which led to a significant improvement of the structure in terms of efficiency of the processes enabling the synergy of the different domains of the material to be realised. As a result, the alloy achieved a tensile strength above 300 MPa and a ductility of approximately 13 %. This knowledge will allow further optimisation of the properties of these alloys for biomedical applications, which could contribute to the development of a new generation of biodegradable implants.

This research was funded by the Czech Science Foundation (project No. 25-16144S).

Enhanced Electrochemical Sensing of Doxorubicin Using a Polymer Nanocomposite-Modified Screen-Printed Carbon Electrode

Mrs. Iva Dimitrievska, Macedonia

Poster Presentation

Abstract

Advancements in electrochemical sensor design continuously refine surface kinetics, leading to enhanced analytical performance, greater reliability, and broader application potential. Among various sensor platforms, screen-printed electrodes (SPEs) have gained significant attention for sensitive drug detection due to their adaptability for surface modifications. The integration of carbon nanomaterials, noble metals, and polymers has substantially improved electroanalytical performance, leveraging their unique chemical and physical properties to enhance electrode reactivity.

This study presents the development of a novel electrochemical sensor based on a polymer-modified carbon SPE for the detection of doxorubicin (DOX) at low clinical concentrations. The sensor's unique modification involves a nanocomposite of reduced graphene oxide decorated with gold nanoparticles, embedded within a Nafion matrix — a configuration not previously reported in the literature for DOX detection. The synthesized material was characterized using FTIR, Raman spectroscopy, XRD, and SEM.

Electrochemical analysis via cyclic voltammetry demonstrated precise quantification of DOX, exhibiting a linear concentration range of 1.5 to 22.1 μM and an improved detection limit of 9.263 μM , compared to 16.676 μM for the unmodified SPE. The developed sensor also exhibited an enhanced sensitivity of 0.272 $\mu\text{A}/\mu\text{M}$, significantly higher than the bare electrode's 0.152 $\mu\text{A}/\mu\text{M}$. Additionally, its high surface area, efficient functionalization, and rapid response highlight its potential for practical applications in anticancer drug monitoring.

Paper 1620

Electronic and optical properties of GaN/AlN heterostructures in relation to their strain state

Prof. Theodoros Karakostas, Greece

Poster Presentation

Abstract

Heterostructures composed of successive thin mGaN/nAlN bicrystals with a wurtzite-type structure are crucial for the development of optoelectronic devices. Here, (m and (n) denote the periodicity of the thickness along the c-axis [1,2,3]. This study aims to optimize their electronic and optical properties by selecting appropriate m/n ratios with relatively low thicknesses, avoiding the condition of plastic relaxation.

Two structural models are considered in this contribution:

1. Free-Standing Model: This model assumes complete relaxation with zero stress.
2. Pseudomorphic Model: This model includes thin pseudomorphic GaN wells on a thicker AlN layer.

The energetics of both models are investigated through computer simulations using DFT calculations with the Quantum ESPRESSO ab initio package [4]. A series of structural configurations are analyzed with $m, n = 1 \div 10$ for the free-standing model and $m = 1 \div 10$ with $n = 8$ for the pseudomorphic GaN case. Special attention is given to the detailed analysis of the $m=4, n=8$ pseudomorphic configuration, which corresponds to the experimental case reported in [1].

Elastic models are developed to minimize the elastic energies of the bicrystals. These combined DFT and elastic calculations also provide data to extract the interfacial energies. The electronic and optical properties are approximated by including the Hubbard correction for strongly correlated systems using DFT+U and Hubbard parameter calculations [5,6]. The results demonstrate a correlation between the elastic models and electronic structures.

Computation work in this report has been produced using the High-Performance Computing (HPC) Infrastructure and Resources of the Aristotle University of Thessaloniki (AUTH).

Colloidal processing of ceramic matrix composites

Ph.D. Piotr Wieceński, Poland

Poster Presentation

Abstract

Ceramic materials exhibit exceptional properties, including high corrosion, heat, and wear resistance, as well as remarkable hardness. Additionally, they can display n-type and p-type conductivity, piezoelectric and ferroelectric properties, and optical transparency, making them suitable for a wide range of applications in both bulk and coating forms. To ensure high-quality, defect-free microstructures—especially in composite materials where one phase must be homogeneously distributed within the matrix—fabrication methods must be carefully chosen. For bulk ceramics, colloidal processing techniques effectively meet these requirements for both single-phase and composite materials. In this research, colloidal methods were used to produce high-density ceramic materials incorporating metallic particles or reduced graphene oxide flakes. These additives significantly influence the mechanical and functional properties of the final material. For ceramic-metal composites, the metallic phase was introduced using precursors such as acetylacetonates or other metal salts. This approach enables the homogeneous distribution of even small quantities of additives throughout the suspension and, ultimately, the composite. Furthermore, the use of precursors facilitates the formation of metallic nanoparticles, which enhance the material's properties compared to ceramic matrix composites reinforced with microparticles obtained via conventional powder metallurgy techniques.

The wet forming method was also employed to fabricate ceramic-rGO (reduced graphene oxide) composites. However, due to graphene's nearly two-dimensional structure and strong tendency to agglomerate, achieving a homogeneous composite through this technique is challenging. To address this, our research utilized the chemical functionalization of graphene oxide to enhance its dispersion and solid loading in alumina and zirconia suspensions while simultaneously reducing viscosity. This study analyzed the impact of sintering conditions, graphene oxide modification, and the use of metallic precursors on the microstructure and mechanical properties of ceramic-matrix composites.

Surface Quality Analysis of Thermally Treated Wood by Advanced Techniques

Ph.D. Lucie Zárybnická, Czech Republic

Poster Presentation

Abstract

Developing innovative solutions for the thermally surface treatment of wood is a current research topic. In this regard, the flame-charring of wood boards [1,2] represents a good compromise, allowing sufficient protection of the wood surface. The disadvantage of this technique is the low consistency of the process. An alternative option is the use of the contact hot plate method, which shows that the correct application of wood pyrolysis can provide reasonably good effects of wood protection while maintaining sufficient mechanical properties [3,4].

In the presented contribution, an innovative technique utilising arc plasma discharge was investigated. The main motivation for this study is to develop in-depth knowledge and introduce new possibilities that will allow the replacement of the above-mentioned techniques. The structure and roughness of thermally treated wood surfaces were analysed using microscopy techniques. Additionally, the samples were investigated in cross-section to determine and characterise changes in the depth profile. Mechanical properties at the microstructural level were evaluated through nanoindentation, while Fourier-transform infrared spectroscopy was employed to analyse changes in chemical composition after the treatment.

The obtained data provide valuable insights into the structural changes optimising wood conservation and treatment technological processes.

Mechanical Performance and Atomistic Modeling of polycrystal NiFeCrMn Alloy Under High-Temperature Tensile Loading

Dr. Francisco Javier Dominguez Gutierrez, Poland

Poster Presentation

Abstract

High-entropy alloys (HEAs) have emerged as promising materials for nuclear applications due to their exceptional mechanical properties, thermal stability, and resistance to radiation damage. Among these, FCC Ni-based high entropy alloys are particularly notable for their high strength, ductility, and structural integrity, making them ideal for extreme environments such as nuclear reactors.

This study examines the mechanical performance of a NiFeCrMn alloy under tensile loading using a combination of atomistic computational modeling and experimental validation. Analyses were conducted on both single-crystal and polycrystalline samples across room-temperature and high-temperature conditions to explore the effects of grain structure and crystallographic orientation on deformation mechanisms. A refined Embedded Atom Method (EAM) potential, optimized for NiFeCrMn alloys, was employed to ensure accurate representation of the alloy's behavior, with simulations closely replicating experimental conditions for direct comparison of stress-strain responses. Key findings highlight the influence of temperature on ultimate stress, grain structure on twin formation, and crystal orientation on defect propagation during deformation. The study underscores the alloy's ability to maintain mechanical integrity under high-temperature conditions, advancing the understanding of HEAs for demanding applications, particularly in nuclear energy systems.

This work demonstrates the synergy between computational and experimental approaches, offering a robust methodology for evaluating advanced materials under extreme conditions.

Paper 1727

The effect of Zn on grain boundary segregation and IGC in Al-Mg-Si-Cu alloys

Mr. Håkon Longva Korsvold, Norway

Poster Presentation

Abstract

The inclusion of Cu and Zn impurities are often unavoidable in the recycling process of 6xxx aluminium alloys, both of which may result in a decrease of the corrosion resistance of the alloy. Corrosion experiments have however found that the addition of Zn to alloys already containing Cu may in some cases improve IGC resistance. In this study a series of Al-Mg-Si-Cu alloys with varying amounts of added Zn were investigated, with a particular focus on the influences of the impurity element on the solute segregation at grain boundaries as well as the atomic structure and chemistry of age hardening precipitates.

The alloys were investigated using a combination of APT and various (S)TEM techniques, including conventional bright field/dark field, STEM-EDS and HAADF-STEM. To produce site specific APT samples a Xe-Plasma FIB equipped with an EBSD detector was utilized, which allowed high angle grain boundaries to be targeted and analyzed. The results of the characterization experiments were then linked to the results of corrosion tests. The underlying mechanism on the influences of Cu and Zn on the intergranular corrosion (IGC) behaviors are discussed.

UTILIZATION OF MICROWAVE ENERGY IN OBTAINING METALS FROM SULPHIDIC ORES

Dr. Ingrid Znamenáčková, Slovakia

Poster Presentation

Abstract

The processing of the necessary metals as well as the sustainability of their production is currently closely related to the modernization of the technological procedures of their obtaining. Progressive technologies, which are increasingly being used in various industrial areas, include the application of high-frequency electromagnetic radiation. The advantage of the application of microwave energy in the processes of heating materials is the replacement of the conventional heat source. Copper, as one of the main industrial metals, is obtained from naturally occurring ore deposits as a primary raw material, or as a secondary raw material in the form of electronic wastes and wastes generated during production.

In nature, copper occurs in the form of sulphides (chalcopyrite, bornite, tetrahedrite, tennantite), oxides (cuprite), hydroxycarbonates (malachite, azurite, tyrolite), or silicates (chrysocolla).

However, the quality of the primary bearings decreases and the cost of mining and rock transport requires a large amount of energy. The obtaining metals from refractory ores is also difficult process requiring energy-intensive treated processes and leaching in environmentally undesirable leaching agents. When complex sulphide ores are heated in a microwave field, useful components containing metals such as Cu, Fe, Zn, Sb, Ag, Au are heated. There is no heating for tailings components with Si and Ba content.

For this reason, it is advantageous and economically prospective to treat primary ores with a lower metal content. The use of microwave energy thus represents an innovative method of thermal pretreatment of sulphidic ores before the subsequent processes of hydrometallurgical obtaining of strategic metals. The heating complex ores in a microwave field will cause disturbance of minerals structure and break down mineral grains. The result will be an intensification of crushing and grinding processes, reduced requirements for the amount and type of leaching agents, and better leachability of metals.

Competitive low-carbon cements prepared with low-grade kaolinitic clays as SCMs: enhancing strength through C-S-H gel nucleation seeding

Dr. Isabel Santacruz, Spain

Poster Presentation

Abstract

In this study, we expand the potential of LC3-50 binders (52 wt% Portland cement (PC-52.5), 30 wt% calcined clay, 15 wt% limestone and 3 wt% gypsum) by using low-grade kaolinite clays and C-S-H gel nucleation seeding. Different commercially available kaolinite clays, each containing approximately 20 wt% kaolinite, were initially characterised. After thermal activation and milling ($D_{v,50} = 11 \pm 2 \mu\text{m}$), the R3-test (ASTM C1897-20) confirmed that their low pozzolanic reactivity was characteristic of this type of clay, as indicated by heat flow values of approximately 200 J/g SCM.

The pozzolanic reactivity and the effect of seeding were evaluated in LC3-50 (water-to-cement ratio, w/c, of 0.4) pastes through calorimetry, Rietveld Quantitative Phase Analysis (RQPA), thermal analysis, and porosimetry, as well as in mortars through mechanical strength tests. While LC3 mortars exhibited relatively low compressive strengths, particularly at one day, seeding significantly enhanced the early-age strength (>60%), reaching values of up to 20 MPa. Although the strength gains from seeding at 28 days were less pronounced, they remained significant (>10%), achieving mortars with compressive values up to 57 MPa. Consequently, after one day, LC3-50 mortars exhibit higher environmental performance (EP) values compared to plain PC52.5. However, as hydration time progresses, EP values reduce significantly due to the corresponding increase in compressive strength for the same level of CO₂ emissions. Additionally, a competitive LC3-50 concrete was developed using seeding and a w/c=0.5, achieving compressive strengths of approximately 20 MPa at one day and 40 MPa at 28 days. The quantitative analysis of the pastes provided deeper insights into the pozzolanic reactions and the role of C-S-H seeding. Further details will be provided and discussed at the congress.

The role of precipitates in hydrogen embrittlement of precipitation hardened Al_{0.35}CoCrFeNi complex concentrated alloy

Dr. Kateryna Kamyshnykova, Slovakia

Poster Presentation

Abstract

The hydrogen embrittlement (HE) behavior of the precipitation-hardened Al_{0.35}CoCrFeNi complex concentrated alloy (CCA) was investigated as a function of microstructure. The cast alloy was thermomechanically processed and solution annealed at 1330°C to achieve a uniform distribution of equiaxed grains with single-phase FCC crystal structure. Consecutive precipitation annealing at 700°C (PA700) and 900°C (PA900) lead to the different phase compositions: FCC + B2 + L1₂ (PA700) and FCC + B2 (PA900), with occasional formation of Cr-rich particles on the grain boundaries and inside of coarse B2 particles. Tensile tests were performed before and after electrochemical hydrogen charging at 70°C for 72 hours to evaluate the impact of hydrogen on mechanical properties. The PA700 samples exhibited the highest strength after hydrogenation (775 MPa) but suffered from severe hydrogen embrittlement, with ductility dropping from 25% to 8.3%, while the PA900 samples maintained moderate strength (684 to 659 MPa) and ductility (34% to 30.2%) after applied hydrogen charging. The single-phase FCC structure exhibited the best product of strength and elongation and maintained it also after hydrogenation. Fractographic analysis revealed that HE was associated with hydrogen-assisted crack initiation at the surface and on the grain boundaries with the prevalent cracking on the interfaces between B2 and Cr-rich particles in precipitation hardened alloy. The findings highlight the critical role of microstructural features in hydrogen-induced degradation of CCAs and provide insight into designing HE-resistant alloy systems.

Bimodal 316L austenitic steel: Enhancing mechanical performance through ODS strengthening

Dr. Hynek Hadraba, Czech Republic

Poster Presentation

Abstract

Achieving an optimal balance between strength and ductility remains a critical challenge in materials engineering. This study explores a novel bimodal microstructural approach to enhance the mechanical properties of 316L austenitic stainless steel by integrating a fine-grained oxide dispersion-strengthened (ODS) matrix with a coarse-grained austenitic phase. Unlike conventional strengthening strategies, the use of ODS steel provides enhanced stability against grain growth and contributes to improved mechanical performance.

Bimodal microstructures were fabricated by mixing mechanically alloyed fine ODS 316L steel powder with coarse austenitic powder, followed by spark plasma sintering (SPS). Three bimodal compositions with 70%, 75%, and 80% fine-grained ODS steel were investigated alongside unimodal coarse and fine-grained variants. Microstructural characterization, including electron backscatter diffraction (EBSD) and transmission electron microscopy (TEM), confirmed the forming of a distinct bimodal grain structure with an aspect ratio of ~10 between coarse and fine grains.

Mechanical testing revealed that bimodal structures significantly improved the strength-ductility balance compared to unimodal counterparts. Hardness measurements showed a non-linear increase with the fraction of fine ODS grains, aligning with predictions between the Voigt and Reuss bounds, suggesting a non-negligible coupling between coarse- and fine-grained regions. The highest hardness of 2.96 GPa was achieved for the ODS80 composition, compared to 1.46 GPa for the unimodal coarse-grained steel. Tensile tests substantially enhanced yield strength (YS) and ultimate tensile strength (UTS) while maintaining acceptable ductility. The ODS70 and ODS75 compositions exhibited YS of 605 MPa and 673 MPa, respectively, surpassing the 260 MPa of unimodal coarse steel. The UTS of the bimodal variants reached up to 908 MPa, significantly higher than the 605 MPa of coarse-grained steel. Despite the increase in strength, bimodal samples retained uniform elongation between 18.5% and 22.3%, deviating from the conventional Hall-Petch trend.

Comparisons with literature on bimodal steels prepared by alternative methods, such as bimodal or high-energy ball milling, indicate that the proposed approach offers a simple yet effective route to achieving superior mechanical properties. The results demonstrate that tailoring the volume fraction of ODS fine grains enables optimized mechanical performance, making this strategy highly promising for applications requiring a strong yet ductile material.

TEM investigation of hybrid MXene coatings of Ti₃C₂T_x and Nb₂CT_x for lubrication

Dr. Sabine Schwarz, Austria

Poster Presentation

Abstract

Tribology plays an important role in improving the lifetime of mechanical systems with moving components. The aim is the reduction of friction-related losses [1], so the simplest and most efficient solution is the application of a lubricant to separate the interacting surfaces. Two-dimensional (2D) materials with layered structures have emerged as a highly researched class of solid lubricants. 2D materials are thin, sheet-like structures that consist of one or a few atomic layers in thickness. MXenes are 2D-materials consisting of layered transition metal carbides, nitrides, and carbonitrides. The MXenes properties are strongly influenced by factors such as the number of nanosheets, the orientation of the individual monolayers, the lateral flake size, or the film thickness. Two different MXenes, namely Nb₂CT_x- and Ti₃C₂T_x-MXene as pure flakes, as well as a hybrid solid lubricant coating, were examined in more detail. For comparison, uncoated AISI 304 steel substrates were used as reference materials, and the tribological performance of individual Ti₃C₂T_x and Nb₂CT_x coatings was also investigated against an Al₂O₃ counterbody. The excellent lubricating performance of the hybrid coating is attributed to the tribo-induced formation of a compact, patchy tribofilm, which effectively reduces the coefficient of friction and protects the substrate from wear.

Transmission electron microscopy (TEM) was used to study the pure MXene flakes, as well as the tribofilm after wear tests. The detailed microstructural characterization included imaging by transmission electron microscopy, high resolution TEM, phase analysis by selected area electron diffraction patterns (SAD) as well as measurements of the lattice space distances of the HRTEM images. A chemical analysis (elemental mappings) was done by energy dispersive x-ray analysis (EDX).

As a result, one important realization was, that the two-dimensional structure of the MXenes was retained within the tribofilm after sliding, and it kept its crystallinity. This could be proven by high resolution TEM imaging after preparing a TEM lamella cut by Focused Ion Beam (FIB). The crystal structure could be verified with Ti₃C₂ and Nb₂C, respectively.

So in the end it can be concluded, that a hybrid tribo layer consisting of Nb₂CT_x- and Ti₃C₂T_x-MXene flakes, provides a promising basis for future tribological films to reduce friction-related losses.

Integrating SSbD Principles in the Synthesis of Bio-SiO₂ Functionalized with TiO₂ for Sustainable Solutions

Dr. Ana Luísa Alves, Portugal

Poster Presentation

Abstract

Nanomaterials (NMs) have garnered significant attention in recent years due to their unique properties and extensive applicability across diverse industries. However, concerns regarding the potential adverse effects of NMs on human health and the environment have driven the development of the Safe and Sustainable-by-Design (SSbD) framework. This concept emphasizes the intrinsic design of safer NMs while ensuring their sustainability across their Life Cycle (LC). The integration of SSbD principles is paramount for advancing nanotechnology in a manner that aligns with societal and environmental priorities.

In this work, we present the development of bio-inspired silica (bio-SiO₂) nanomaterial functionalized with titanium dioxide (TiO₂) using a hydrothermal synthesis method. This approach aligns with SSbD guidelines by emphasizing environmentally benign synthesis pathways and the production of nanomaterials with tailored functionalities for specific applications. The functionalized bio-SiO₂/TiO₂ materials exhibit a range of desirable properties, including antibacterial, adsorbent, and photocatalytic activities, making them suitable for applications in water purification, antimicrobial coatings, and air quality improvement.

The hydrothermal synthesis process enables precise control over the material's structural and functional attributes, ensuring reproducibility and scalability. Key performance indicators were evaluated, including:

1. **Antibacterial Properties:** The nanomaterial demonstrated antibacterial activity against common pathogens, showcasing their potential for healthcare and environmental remediation applications.
2. **Adsorption Efficiency:** The bio-SiO₂/TiO₂ composites exhibited high adsorption capacities for methylene blue (MB) as a pollutant probe, underscoring their utility in environmental remediation.
3. **Photocatalytic Activity:** Under ultra-violet (UV) and visible light irradiation, the materials achieved effective degradation of MB, highlighting their role in photocatalytic processes for water purification.

A comprehensive characterization of the synthesized materials was performed using advanced techniques, including scanning electron microscopy (SEM), X-ray diffraction (XRD), and surface area analysis, to correlate structural properties with functional performance. Additionally, life cycle assessment (LCA) methodologies were employed to evaluate the environmental impact of the synthesis and application stages, ensuring adherence to SSbD principles.

This study not only advances the design of multifunctional nanomaterials but also provides a roadmap for integrating SSbD principles into the development of nano-enabled products (NEPs). The results contribute to the growing body of knowledge required to achieve a balance between innovation, safety, and sustainability in nanotechnology. Future work will focus on scaling production, validating performance in real-world scenarios, and expanding the applicability of these materials to additional use cases.

Paper 1238

Exploring the effect of phase superposition in BaTiO₃- solid solution ceramics for enhanced functional properties

Dr. Cristina-Elena Ciomaga, Romania

Poster Presentation

Abstract

This study explored the impact of phase superposition on the functional properties of BaTiO₃-based ferroelectric ceramics by substituting the B-site cation with a larger ionic radius component. BaTiO₃ powders were synthesized via a solid-state reaction method, incorporating Zr⁴⁺ (0.72 Å) to replace Ti⁴⁺ (0.605 Å) and induce structural modifications. BaZr_xTi_{1-x}O₃ (x = 0-0.06) ceramics with orthorhombic/tetragonal phases at room temperature were comparatively investigated to understand the role of phase composition for small addition of Zr on their functional (dielectric, ferroelectric, piezoelectric and tunability) properties. Concerning the values of BaTiO₃, the switching polarization, permittivity peak, tunability, and piezoelectric coefficients are changed by doping with 6 % Zr onto Ti⁴⁺ sites. The orthorhombic polymorph amount is larger in the doped ceramic and explains its higher switching polarization. These findings highlight the role of phase superposition in tuning the functional characteristics of ferroelectric ceramics and offer valuable insights for the development of advanced passive components in high-voltage industrial applications and energy harvesting devices.

Paper 452

Enhancing Metal-Polymer Interlocking by Optimizing the Geometry of Micro-Pins

Mr. Mehmet Aladag, Poland

Poster Presentation

Abstract

This study aims to enhance metal-polymer interlocking by optimizing the geometry of micro-pins fabricated on metallic substrates. Polymeric materials, such as PEEK and Trogamid, will be bonded to metal surfaces through axially symmetric, mushroom-shaped interlocking structures produced using Directed Energy Deposition (DED). By varying pin geometry—specifically size, shape, and surface distribution—their impact on interlocking strength is expected to be evaluated. Potential failure mechanisms will be analyzed, including polymer rupture, pin fracture, and separation caused by excessive shear forces. A mathematical model will be developed to predict these failure mechanisms, providing a tool for designing optimal interlocking structures. The model will enable to design optimum interlocking structures for metal-polymer interfaces, while separation tests are expected to yield data on force-displacement and stress values.

Effect of process parameters and feedstock composition on the functional properties of 3D-printed ceramic-based composites

Mrs. Weronika Bulejak, Poland

Poster Presentation

Abstract

Additive manufacturing, commonly known as 3D printing, has emerged as a transformative technology for shaping ceramic and composite materials. Unlike conventional molding techniques, additive manufacturing methods, such as Direct Ink Writing or Fused Deposition Modelling, enable the precise fabrication of complex geometries without the necessity of casting molds. This not only enhances design flexibility but also significantly reduces production costs, particularly for customized or low-volume components. By eliminating the need for extensive tooling, 3D printing is highly suitable for both mass production and the creation of single, specialized elements tailored to specific requirements.

The present research aimed to develop and optimize colloidal systems for the fabrication of functional ceramic-based composite materials using additive manufacturing methods. The study focused on the formulation of stable dispersions with well-controlled rheological properties to ensure their suitability for 3D printing by material extrusion. A crucial aspect of the research was the selection and optimization of organic additives which play a crucial role in stabilizing the suspensions and enhancing their printability. To achieve this, rheological characterization of the prepared dispersions was performed to assess their proper viscosity, shear-thinning behavior, and flow stability. Then, printing parameters were systematically analyzed and adjusted to achieve optimal printing performance, ensuring consistent layer deposition and defect-free structures. The printed ceramic-based composite materials were subjected to detailed physicochemical properties evaluations and microstructure analysis to examine the effect of process parameters and feedstock composition on the functional properties of 3D-printed ceramic-based composites.

Research was funded by the Warsaw University of Technology within the Excellence Initiative: Research University (IDUB) programme.

Radiofrequency plasma spheroidization of mechanically alloyed complex concentrated alloy NbTiVZr

Dr. František Lukáč, Czech Republic

Poster Presentation

Abstract

The recent progress in additive manufacturing increased the demand for high quality metal powders with tailored composition. The refractory complex concentrated alloys are peculiar for conventional metallurgy due to their high melting point and reactivity. Therefore, the cold spray additive manufacturing method is ideal for utilization of this type of material. Radiofrequency plasma spheroidization provides powders with suitable collection of properties for further processing. In addition, the combination of our cold spray additive manufacturing and refractory complex concentrated alloys is suitable for cladding of heat sensitive parts. This work focuses on production of spherical powder of a selected refractory complex concentrated alloy NbTiVZr from a powder produced by high energy milling from elemental commercial powders. Various processing parameters will be discussed in order to optimize the quality, homogeneity and powder size distribution. Each additive manufacturing method requires different size distribution of powder particles. However, powder sieving significantly decreases efficiency of production. Therefore, provided optimization of milling and spheroidization processes are crucial. Main focus of this study is to investigate microstructure and quantitative phase composition of spheroidized powder particles from initially mechanically alloyed powders with the atomic-level homogeneity. High-enthalpy plasma reaction in protective atmosphere liquifies intermixed powder particles and thus interesting microstructures and phase composition are formed during fast cooling in the collector and on the walls of the spheroidization chamber. Such powder does not require complicated heat treatment nor surface reduction annealing and is ready for further additive manufacturing. The first samples of cold spray additive manufacturing method of high entropy alloy NbTiVZr will be presented after thorough analyses of microstructure, quantitative phase composition and mechanical properties.

Thermoelectric efficiency enhancement of sputtered L21 Fe₂VAI, Fe₂V_{0.8}AlW_{0.2} and Ti-doped Fe₂VAI (100) and (110) epitaxial thin films

Mr. Jose María Domínguez Vázquez, Spain

Poster Presentation

Abstract

Thermoelectric materials are capable of transforming thermal gradients into an electrical voltage difference. This quality makes these materials a possible solution to the global energy crisis through the harvest of diffusive heat waste. Thermoelectric efficiency is measured with the figure of merit zT , which is defined as $zT = S^2 \sigma T / \kappa$, being S the Seebeck coefficient, σ the electrical conductivity, T the temperature and κ the thermal conductivity (1). For that reason, materials that exhibit high S , high σ and low κ are very interesting. Thermoelectric thin films are of great interest because they reduce considerably the κ through nano-structuration. Among all thermoelectric materials, Fe₂VAI is a full Heusler alloy that has attracted considerable interest due to its non-toxic and earth abundant constituents and its great thermoelectric properties. The thermoelectric properties in this alloy can be tuned via doping with elements like Ti, Si or W (2,3), making the alloy p or n type, and in some cases, resulting in a significant increase in thermoelectric performance (4). Besides doping, chemical order of Fe₂VAI has an impact on the alloy's band structure. So, a systematic study of the thermoelectric properties according to its chemical order is of high interest. Also, other parameters like crystal orientation may influence the thermoelectric properties, for example, via changes in the grain morphology and size. In this work, we present experimental thermoelectric and structural results of Fe₂VAI and Fe₂V_{0.8}AlW_{0.2} thin films grown by magnetron sputtering from nominal composition targets at deposition temperatures ranging from RT to 950°C, on Al₂O₃ (1 1 -2 0), and on MgO (1 0 0) substrates, exhibiting (1 1 0) and (1 0 0) orientations, respectively, and varying degrees of chemical order. Moreover, a doping optimization of L21 Fe₂VAI with Ti, in a co-deposition configuration was performed, obtaining higher values of Seebeck and power factor ($PF = S^2 \sigma$) reaching the range of 100 μV/K and 2000 μW/(m·K²) respectively.

AM2C3 Twinning Project: Development of Al-based Metal Matrix Composites for Laser Powder Bed Fusion Additive Manufacturing

Prof. Theodora Kyratsi, Cyprus

Poster Presentation

Abstract

The AM2C3 – Additive Manufacturing and Advanced Materials Competence Centre is a Horizon Europe Twinning project designed to establish a regional hub for cutting-edge research in metal additive manufacturing (AM) and advanced materials. The project brings together expertise from leading European institutions to develop high-performance materials tailored for aerospace, space, and high-value industrial applications. At full deployment, AM2C3 will serve regional SMEs by providing customized materials solutions, supporting New Space companies—the emerging private space industry driven by disruptive business models and independent innovation. As part of the University of Cyprus (UCY), the project will also build local expertise in high technology readiness level research, bridging materials science with industrial-scale implementation.

One of AM2C3's core research activities focuses on the development of next-generation high-strength aluminum alloys, optimized for Laser Powder Bed Fusion (LPBF) additive manufacturing. The project explores novel Metal Matrix Composites (MMCs) based on Al2618+, a Zr-modified aluminum alloy known for its improved processability in AM. Going beyond existing solutions, AM2C3 integrates nanoparticle reinforcements via mechanical alloying, aiming to enhance microstructural stability, mechanical performance, and high-temperature resistance. These reinforcements act as heterogeneous nucleation sites, refining the grain structure, reducing columnar grain growth, and mitigating hot cracking. Additionally, their presence contributes to load transfer strengthening and grain boundary stabilization, leading to improved hardness, wear resistance, and overall mechanical response.

Preliminary results demonstrate a homogeneous dispersion of reinforcements within the Al2618+ matrix, validating the feasibility of this novel Al-MMC approach for LPBF. Initial processing trials suggest promising densification behavior, with reduced porosity and enhanced microstructure compared to unmodified Al2618+. These advancements will broaden the AM processing window, making high-performance aluminum alloys more accessible for industrial adoption.

Evaluation of Springback Prediction of the 980MPa High Strength Steel Sheet Using a Yield Function with a Hardening Model

Dr. Junghan Song, South Korea

Poster Presentation

Abstract

The ongoing need for vehicle weight reduction and safety improvement results in many challenges in selecting and replacing automotive materials. Advanced high strength steel (AHSS) remain one of most common materials in automotive applications due to its continuous property improvement. In spite of their major advantage, large springback is one of major drawbacks of AHSS sheets. As a way to overcome such a drawback, the computational method is utilized in the design stage for the proper analysis of springback in the forming process.

In the current study, springback of 980MPa high strength steel sheet was numerically evaluated for U-bending and S-rail component using a yield function with a hardening model. For springback prediction, two types of yield functions - Hill'48 and Yld2000-2d - were considered. Additionally, isotropic hardening and the Yoshida-Uemori model were used to investigate the springback behavior. The parameters for each model were obtained from uniaxial tension, uniaxial tension-compression, uniaxial tension-unloading and hydraulic bulging tests. The numerical simulations were performed using the commercial software, AUTOFORM. The results were compared with experimental data from a U-bending and S-rail component stamping process.

Microstructure and mechanical properties of additive manufactured 18Ni-maraging steel after two-step aging treatment

Prof. Sung Hwan Hong, South Korea

Poster Presentation

Abstract

Additive manufacturing (AM) is an advanced technology used for the manufacture of products that have intricate shapes and complex inner geometries. In commercial metallic material field, various metallic materials have been investigated to use AM processing. The microstructural features such as grain size and precipitates will differ profoundly from those obtained by casting, heat treatment and forming processing, which is resulted from the rapid heating and cooling rates during AM. Therefore, the evolution in microstructure of metallic materials fabricated AM with post-treatment can give an opportunity to discover the enhanced mechanical properties of the metallic materials. In this study, the maraging steel powder with mean particle radius of 36 μm have been used in AM experiment. The specimens with bulk cuboidal shape were fabricated with the optimized laser power and scanning rate conditions. The as-built specimens were composed of α' martensite phase in applied AM condition. The density of as-built specimens reached $\sim 8.03 \text{ g/cm}^3$, which is almost similar to the full density of maraging steel. The as-built specimens was aged at two different temperatures to form nanoscale precipitates in the α' martensite matrix. From the systematic microstructural analysis, it was found that the formation of nanoscale precipitates and its volume fraction depend on the aging temperature and time. After single aging treatment at 733 K exhibited Ni_3Ti type nano-precipitates. On the other hand, the specimens aged at two different temperatures contained two types of nano-precipitates. The microstructural evolution achieved by two-step aging treatment revealed an improved mechanical properties than the specimen aged by single aging treatment. Moreover, the processing time for aging treatment was reduced by two-step aging treatment. From these results, it is suggested that the optimized microstructure and mechanical properties of 18Ni-maraging steel can be achieved by modulating the aging treatment condition.

Electrospun PEO-based membrane enriched with recovered lignin: towards sustainable solid-state electrolytes for Li-ion batteries

Mrs. Laura Coviello, Italy

Poster Presentation

Abstract

Nowadays the demand for rechargeable energy storage devices has increased, driven by the proliferation of electrical applications across various sectors, including household appliances, electric vehicles, computers, smartphones, and stationary energy storage systems coupled with renewable sources. Notably, lithium-ion batteries are broadly diffused due to their high energy density, high specific capacity, operating voltage, relatively slow self-discharge rate, good cycle stability, and fast charging capabilities. However, the use of liquid electrolytes is associated with several potential safety risks including poor heat dissipation, leakage and the uncontrolled growth of lithium dendrites. These issues can provoke short-circuits, fires, and explosions, raising some concerns about safety and environmental impact. Solid state electrolytes (SSEs) have emerged as a viable alternative to address these limitations, owing to their exceptional flexibility, good chemical stability, and high energy density, thereby enhancing battery safety. Additionally, SSEs permit a simplification of the internal structure, which makes the assembly process easier and saving cost. With this perspective, the present contribution aims at demonstrating the potential of a novel and sustainable solid polymeric electrolyte (SPE), based on electrospun PEO-Lignin-LiTFSI membranes. Electrospinning was chosen as manufacturing technology due to its versatility, cost-effectiveness, and potential scalability and since it allows to produce highly porous and flexible nanofibrous membranes with a high surface-to-volume ratio and a controlled entanglement of polymer chains thanks to the rapid evaporation of the solvent. PEO is typically used for the production of SPEs because of its cost-effectiveness, ease of processability, and the capacity to dissolve lithium salts, thus allowing for ion conductivity. The incorporation of lignin proved to be essential to enhance the mechanical strength of the resulting membranes and ensure their stability during electrochemical cycles, due to the excellent thermal stability and favourable rigidity. Moreover, lignin is a by-product of the paper industry, thus offering a sustainable solution for the reuse of a waste polymer in a valuable application, thereby promoting the production of SPE within a circular economy model. As a proof of concept, the PEO-Lignin-LiTFSI membrane was tested in a symmetric Li|Li electrochemical cell at 55 °C, demonstrating compatibility with Li plating and stripping; the addition of lignin turned out to be effective in counteracting the growth of Li dendrites and thus preventing the resulting battery breakdown for a longer time with a reference membrane prepared with only PEO-LiTFSI.

Bilayer electrospun membrane enabling the stimulation of angiogenesis in advanced 3D skin model

Mrs. Laura Coviello, Italy

Poster Presentation

Abstract

The skin, the largest multifunctional organ of the human body, acts as a protective barrier against physical, chemical and biological factors from the external environment, and is responsible for maintaining homeostasis, adjusting the temperature and hydration of tissues. The performance of the skin is a vital function, and any damage has a detrimental impact and requires an effective treatment. However, the market offers a limited number of medical treatments, and the availability of new therapies is slowed down by the difficult advancement from pre-clinical testing to clinical trials. To overcome this issue is imperative to transition from the conventional 2D cell culture and animal models to 3D in vitro models. These 3D in vitro models have the capacity to replicate the organization and physiological function of the natural tissue, are more cost-effective and manageable than animal models. Nevertheless, the development of 3D in vitro skin models presents significant challenges due to the complexity and heterogeneity of real skin, including vascularization, immune interactions and prolonged healing processes. Among these challenges, the formation of an organised vascular network is essential to maintain homeostasis and the pathogenesis of the engineered tissue. The purpose of the present work is to stimulate angiogenesis and the vascularization within a pre-existing dermis-epidermis 3D in vitro skin model¹ can be used as a platform for drug screening. To achieve this objective, electrospinning (ESP) technology has been exploited to fabricate a fibrous structure comprising two overlapping layers, designed to facilitate the formation of endothelial tissue and the sprouting of vessels through various morphological stimuli of cells. The first layer features an oriented pattern, while the second layer has a random pattern. These different architectures are achieved by using different types of fibre collectors (rotating and plate collectors, respectively) during the electrospinning process. The targeted ESP formulations combine natural functional polymers, including collagen and gelatin, which promote cell adhesion, and synthetic polymers, such as polycaprolactone to provide mechanical support. The fibrous structures are intended to release a range of angiogenic factors, such as VEGF and EGF, to promote angiogenesis and sprouting of blood vessels through the skin model. The release of these factors over time will be modulated by several strategies, including the incorporation of degradable polymeric (i.e. polylactic-co-glycolic acid) particles and/or mesoporous silica particles, as well as the direct anchoring to the fibre surface.

Use of Parametric Models and Data in Scenario Based Approach for Materials Education and Professional Training

Prof. Tammam Kaid, United Kingdom

Poster Presentation

Abstract

Modelling at different scales (e.g. Density Functional Theory (DFT), Molecular Dynamics (MD) Simulation and Numerical Modelling) plays an important role in engineering R&D and materials education. The framework of Industry 5.0 requires the workforces with enhanced data-competence, interdisciplinary knowledge and skills, particularly, in materials. Parametric modelling is a powerful tool for many different engineering disciplines from traditional mechanical engineering, manufacturing to medical engineering, for which materials education is a key pivoting knowledge block. The use of parametric tools allows the users to analyse and visualise detailed data for complex materials, as well as evaluating different scenarios, which is important for both materials education and professional training. It can also produce comprehensive data for training and development of complex interdisciplinary knowledge. Data-led framework, equipped with education focused parametric study tools, will help opening new opportunities in establishing user focused framework in materials education and training with optimum impact beyond the traditional direct experience-based research and education approaches.

In this paper, the use of parametric modelling and data system for training and learning development of complex material systems are presented through three cases in different technical areas: modelling and testing of welded structures and precipitations (materials and manufacturing); foot orthotics with a particular focus on biomechanics (medical engineering) and complex porous structures and application (energy sectors). In each case, the use of parametric modelling linked with DFT modelling, MD Simulation and numerical modelling is presented. The key functions and framework of parametric models to empower the end users is analysed. Different approaches for identifying the factor of significance and use of key knowledge blocks are shown in this work. In addition, the key issues in designing parametric studies and material data system for integrated research and education development over different disciplines is comparatively studied and discussed.

Interface Modification in Fe/Pt Spintronic Bilayers for Superior THz Emission

Dr. Andreas Delimitis, Greece

Poster Presentation

Abstract

Layered ferromagnetic/non-magnetic (FM/NM) nanostructures have attracted significant interest for spintronic applications due to efficient spin transport across epitaxial interfaces in Fe/Pt bilayers [1]. These bilayers are promising for THz spintronic devices [2], with interface quality playing a crucial role in spin current transmission. Optimizing interfacial structure and defect density can enhance spintronic THz emitter performance [3]. This study investigates structural modifications of the Fe/Pt interface by varying growth and annealing temperatures, correlating interfacial features with THz emission properties.

Fe/Pt bilayers with Fe (12 nm) and Pt (6 nm) were deposited on MgO(100) substrates via electron beam evaporation. To maintain total thickness, Pt layer growth temperature was varied to modify the Fe/Pt interface. A 12 nm Fe film was deposited at 300°C and annealed for 30 minutes, followed by a 6 nm Pt layer deposited at 300°C, 450°C, or 600°C, with subsequent annealing at corresponding temperatures. THz emission was characterized by using terahertz time-domain spectroscopy (THz-TDS). Structural investigations included X-ray diffraction (XRD), transmission and scanning transmission electron microscopy (TEM/STEM), energy-dispersive X-ray spectroscopy (EDXS), and Z-contrast high-resolution STEM (HRSTEM) imaging along with HRSTEM image simulations. The Fe/Pt(450°C) sample exhibited the highest THz emission, nearly twice that of Fe/Pt(300°C), while Fe/Pt(600°C) showed negligible signal [4]. XRD revealed an almost strain-free Fe/Pt structure for Fe/Pt(300°C), while the 450°C sample showed an additional $L1_0$ -FePt peak, suggesting interface modification. The 600°C sample exhibited new peaks corresponding to the fct lattice of $L1_0$ -FePt, indicating complete transformation into an ordered alloy. TEM analysis confirmed distinct Fe and Pt layers for Fe/Pt(300°C). HRTEM imaging of Fe/Pt(450°C) revealed a 2 nm interlayer (IL) at the Fe/Pt interface with a periodic intensity modulation, signifying a chemically ordered $L1_0$ -FePt structure. Z-contrast HRSTEM imaging and simulations confirmed chemical ordering. STEM-EDXS showed localized Fe and Pt interdiffusion. In contrast, TEM analysis of Fe/Pt(600°C) showed full interdiffusion into a chemically ordered $\text{Fe}_x\text{Pt}(1-x)$ alloy with fct symmetry. The Fe/(2 nm) $L1_0$ -FePt/Pt interface in Fe/Pt(450°C) significantly enhanced THz emission. In contrast, complete intermixing and the absence of a non-magnetic Pt layer in Fe/Pt(600°C) suppressed emission. These findings highlight the potential of engineered interlayers for optimizing spintronic THz emitter performance and advancing spintronic device design.

Paper 1731

Effect of bimetallic Fe-Co catalysts deposited on neodymium oxide on the properties and activity in ammonia synthesis

Mrs. Małgorzata Lemańska, Poland

Poster Presentation

Abstract

Ammonia is a promising compound for hydrogen storage. It can be easily transformed from the gas to the liquid phase, and its decomposition does not produce carbon oxides. These advantages increase the interest in ammonia production [1]. Synthesis of ammonia is an industrial process that requires high temperatures and pressures. These conditions result in using 1,5% of the world's energy [2]. That is why new catalytic systems are widely being searched for. According to literature, metals that have the highest potential in ammonia synthesis are iron, ruthenium and cobalt. However, the high price of Ru is an obstacle to more frequent use of this metal, while iron and cobalt are often used in research [3]. The volcanic curve, which represents the activity of these metals in ammonia synthesis, shows that iron strongly binds the nitrogen molecule, and cobalt weakly binds this molecule. The combination of two metals, one that binds nitrogen molecule strongly and one that weakly does this, leads to the catalytic system showing much higher activity in ammonia synthesis than using only one metal [4]. Therefore, there is a considerable potential for obtaining active bimetallic catalysts using Fe and Co.

This work aimed to obtain iron-cobalt bimetallic catalysts deposited on neodymium oxide using different ratios of Fe and Co.

The method of preparation of the neodymium carrier was precipitation using $\text{Nd}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ in distilled water and solution of KOH and K_2CO_3 as a precipitating compound. Iron-cobalt catalysts with a metal content of 10 wt% were prepared using the wet impregnation method using $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ and $\text{Co}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$. Eight catalytic systems with different molar ratios of Fe/Co were received (1, 0.95, 0.9, 0.8, 0.7, 0.5, 0.2, 0). The obtained catalysts were tested in ammonia synthesis at 470°C and 6.3 MPa. All materials were subjected to physicochemical characteristics using N_2 physisorption, XRD, TPR, TPD- H_2 , TPD- CO_2 , and STEM-EDX.

High-temperature oxidation behavior of Inconel 625 superalloy processed by additive manufacturing

Ph.D. Ana Romero Gutiérrez, Spain

Poster Presentation

Abstract

Inconel 625 is a nickel-based superalloy that stands out for its excellent mechanical and resistance to oxidation and corrosion properties. Thanks to these characteristics, it is widely used in sectors such as power generation, the aerospace industry and the petrochemical industry, where parts are exposed to high temperatures and various corrosive environments or fluids. In these conditions, Inconel 625 components are susceptible to oxidation and corrosion problems and, therefore, deterioration or loss of functionality and safety in service.

In this work, the technology FFF (Fused Filament Fabrication) of additive manufacturing, also known as FDM (Fused Deposition Modeling), is used to produce Inconel 625 parts. This technique has demonstrated the possibility of obtaining metal parts in a much more economical, simple and safe way than other conventional and advanced manufacturing methods. A detailed study of high-temperature oxidation has been carried out to evaluate the mechanisms involved and the effects of oxidation on these components. The Inconel 625 parts manufactured using FDM have been exposed to temperatures of 850, 900, 950, 1000 and 1100 °C for times up to 96 hours, using both a muffle furnace and thermogravimetry equipment. After these tests, the oxidation constant has been calculated and the oxides formed on the surface have been characterized by X-ray diffraction and optical and scanning electron microscopy.

By studying the results obtained and carrying out a bibliographic review and comparison, it is demonstrated that fused filament additive manufacturing technology is a viable and economic alternative for the manufacture of Inconel 625 parts, which allows obtaining fully functional parts with potential for applications at high temperatures where materials with high resistance to oxidation and mechanical properties are required.

Directly Grown CoOx Nanowires Coated with NiOx Nanosheets on Ni foam: A Novel Integrated Electrode for High-Performance Non-Enzymatic Glucose Sensing

Ph.D. Yasmine Izri, Algeria

Poster Presentation

Abstract

Non-enzymatic glucose sensing is critically important in diverse fields, including medical diagnostics, food quality control, and environmental monitoring, due to its simplicity, robustness, and cost-effectiveness. In this context, nanostructured metal oxide-based electrodes have gained attention as prospective electrode materials, delivering promising electrocatalytic performance.

Addressing this need, this study reports the successful synthesis of a CoOx@NiOx core-shell heterostructure, consisting of CoOx nanowires as the core covered by NiOx nanosheets as the shell, directly grown on nickel foam (NF) to form an integrated electrode for non-enzymatic glucose sensing.

The synthesis involved a two-step process: first, the growth of CoOx nanowires on nickel foam via a straightforward hydrothermal method, followed by the chemical bath deposition of NiOx nanosheets to form the CoOx@NiOx core-shell heterostructure. The morphology, structure, and electrocatalytic performance of the electrode were systematically analyzed using comprehensive physicochemical characterizations. Results confirmed the uniform deposition of the CoOx@NiOx heterostructure on the three-dimensional nickel foam framework. Electrochemical testing revealed that the CoOx@NiOx/NF electrode exhibited exceptional performance, with a high sensitivity of $8700 \mu\text{A} \cdot \text{mM}^{-1} \cdot \text{cm}^{-2}$ and $581.15 \mu\text{A} \cdot \text{mM}^{-1} \cdot \text{cm}^{-2}$ across wide linear ranges of $10\text{--}1000 \mu\text{M}$ and $1000\text{--}5000 \mu\text{M}$, respectively. This outstanding electrocatalytic performance can be attributed to the unique CoOx@NiOx heterostructure, which provides a large surface area, enhanced exposure of electroactive sites, richer redox reactions, short ion diffusion paths, and rapid electron transfer. Furthermore, the electrode demonstrated excellent selectivity, high reproducibility, and long-term stability, underscoring its suitability for practical applications. In summary, the proposed CoOx@NiOx/NF electrode offers a highly promising platform for continuous non-enzymatic glucose monitoring.

Paper 1346

The catalytic effect of cobalt and influence of mechanical milling on hydrogen storage system MgH₂ – Co using small milling time

Ph.D. Milica Prvulovic, Serbia

Poster Presentation

Abstract

The addition of cobalt to MgH₂ powder and forming MgH₂ - Co composites was investigated for small milling times. The composite powders were synthesized for 15, 30, and 45 min and characterized by XRD, SEM-EDS, PSD, DSC, and TPD methods. During TPD analysis, a kinetic model for the hydrogen desorption process was also determined. The hydrogen desorption reaction in catalyzed samples is described by the Avrami-Erofeev model with the value of parameter $n=4$. The E_a (apparent activation energy) for the hydrogen desorption reaction was decreased with the increase in milling time and the addition of transition metal. The uniform distribution of transition metal decreases hydrogen desorption temperature by more than 100 °C compared to the pure MgH₂ and purely milled MgH₂. The quantity ratio of released hydrogen reached the highest value ($LT/HT=3.38$) for a sample with the highest amount (20 wt.%) of additive and the longest milling time (45 min). LT maxima appear at 310 °C, significantly reducing desorption temperature compared to commercial MgH₂ (480 °C). The short milling times improve desorption properties by lowering the hydrogen desorption temperature enhancing the effect of catalyst. In this approach, mechanosynthesis can be analyzed as two independent processes—grinding and catalytic effects. For the studied milling times, the catalytic influence of Co is dominant in the hydrogen desorption process.

A novel MTES/polysilazane hybrid polymer coating for corrosion protection of stainless steel substrate

Dr. Yolanda Castro, Spain

Poster Presentation

Abstract

A novel MTES/polysilazane hybrid polymer coating for corrosion protection of stainless steel substrate

Y. Castro¹, E. Merino¹, P. N. Moghaddam², M. Parchovianský², A. Duran¹, A. Pakseresht²

¹ Instituto de Ceramica y Vidrio (CSIC), Campus de Cantoblanco, 28049, Madrid, Spain.

Keywords: Polysilazane, corrosion, stainless steel, thin films

Polysilazane is an attractive candidate of coating materials due to its good adhesion properties to most substrates and its great potential to be modified and to obtain tailored properties for a variety of applications [1] [2]. In this work, the hybrid coating based methyltriethoxysilane (MTES) and poly(methylvinyl)silazane (Durazane 1800) was synthesized by sol-gel route to improve corrosion resistance and lifetime of stainless steel substrate. The MTES/polysilazane solution was synthesized using tetra-n-butylammonium fluoride (TBAF) and n-butyl acetate (NBTA), and was deposited on stainless steel by dip coating method. The structure and thermal stability of hybrid sol were investigated by Fourier transform infrared (FTIR) spectroscopy and thermogravimetric analysis (TGA). FTIR studies demonstrated that the incorporation of MTES to polysilazane backbone the integrity of polysilazane was preserved. Based on Field emission electron microscopy (FESEM) analysis, crack-free, smooth, and homogenous hybrid coatings were obtained on stainless steel. The corrosion resistance of MTES/polysilazane and polysilazane coatings are studied by electrochemical impedance spectroscopy (EIS) and potentiodynamic polarization techniques. The preliminary results confirmed that the synthesized hybrid coatings can be a good option to improve the corrosion resistance of the stainless steel substrate in 3.5 wt% NaCl solution.

Everglass: The new role of glass in a sustainable society. Technology for the integral recycling of glass

Dr. Yolanda Castro, Spain

Poster Presentation

Abstract

Glass recycling uses mature technology limited by high energy consumption to melt tons of glass and the inflexibility of a heavy-duty system. Current technology only allows the recycling of certain glasses and a very small amount of waste generated. A new technology is required to allow the integral recycling of all types of glass, drastically reducing the carbon footprint. EverGLASS proposes to develop a radically new technology called "glass laser transformation" for on-site glass recycling and the generation of customized or technical products. The vision is ambitious, as it aims to bring to the consumer market a novel technology to enable virtually infinite reuse of glass. It proposes an alternative approach to the traditional centralized recycling process (particularly where this model is not possible, generating thousands of tons of glass waste annually taken to landfills). The new technology goes beyond the current limitations of the systems (high energy use, expensive and rigid process, strong logistical requirement), adopting a highly environmentally friendly model that will allow flexibility in the use of the material and in the process. Therefore, EverGLASS has the potential to revolutionize recycling as a concept. It also addresses one of the main problems with recycling, user participation, in an innovative way by allowing the personalization of recycled items of different use. This project brings together experts from advanced laser technologies (UVIGO, Spain), glass and ceramics science (ICV-CSIC, Spain), glass processing and engineering (TnUAD, Slovakia), risk and impact assessment (ACTALIA, France), Social Sciences (ESCI, Germany) and numerical simulation (ITWM, Germany).

Key words: glass, recycling, circular economy, close loop recycling, open loop recycling, laser processing

Analyses of UNSM treatment on mechanical properties and microstructures of Inconel 718 alloy

Ph.D. Eunwoo Yoon, South Korea

Poster Presentation

Abstract

The ultrasonic nanocrystalline surface modification process (UNSM) is a physical surface treatment method in which ultrasonic vibrations are applied directly to the surface. Nanocrystalline grains and compressive residual stress at the surface formed through the ultrasonic nanocrystalline surface modification process improve yield and tensile strength and are particularly effective in suppressing fatigue failure. In this study, the ultrasonic nanocrystalline surface modification process was applied to Inconel 718 alloy and confirmed the mechanical properties at room temperature, and the microstructure was examined using a scanning electron microscope and electron backscattered diffraction analysis. The ultrasonic nanocrystalline surface modification process was treated on the surface of the Inconel 718 tensile specimen. For the mechanical properties analyses, tensile tests at room temperature were conducted, and nanoindentation was conducted to analyze hardness up to 200 μm from the surface. The effect of the nano-surface layer and the compressive residual stress formed during the ultrasonic nanocrystalline surface modification process on the mechanical properties were obtained from this study.

Paper 438

Temperature Gradients for data mining

Dr. Stephanie Lippmann, Germany

Poster Presentation

Abstract

Experimental data on phase diagrams, chemical and thermal diffusion and interfacial energies are required for reliable alloy and database development, the prediction of microstructural evolution and materials properties. Considering the number of alloy systems and alloying elements, efficient experimental methods are needed to characterize metallic materials. Experiments with concentration gradients offer a high throughput. Widely known are methods with diffusion couples and multiples or thin films. Less common are methods that combine temperature and concentration gradients. At the university of Jena, methods for effectively obtaining thermodynamic, kinetic, and thermal data have been developed over the past 20 years. The early methods are related to directional solidification, where temperature gradients are used to adjust microstructures. In sample regions where solid and liquid phase co-exist, locally separated, temperature-dependent phase equilibria are formed and accessible to subsequent characterization. In this way, large sections of solidus, solvus and liquidus lines in binary alloys or paths in multicomponent systems can be determined with a highly reduces experimental effort. The concept also allows for the synthesis of pure intermetallic phases as bulk materials for measuring and modelling heat capacities. Recently, the method development focused on analyzing non-equilibrium or transient states. The efficient characterization of thermal properties is one application, another is the measurement of interfacial energies of alloys from metastable microstructures. The poster gives an overview of the methods and introduced basic concepts.

Metallographic analysis of end-of-test metal components of hydrogen-fueled internal combustion engines

Prof. Giorgia Ghiara, Italy

Poster Presentation

Abstract

The ability to detect hydrogen embrittlement in internal combustion engines is of pivotal importance to ensure the reliability, safety, and durability of engines, particularly those that utilise hydrogen as a fuel source. Metallography can reveal microstructural changes, crack propagation and fracture characteristics in hydrogen-exposed metals. Therefore, it facilitates a comprehensive understanding of the mechanisms underlying hydrogen embrittlement (HE) and the evaluation of material susceptibility.

This study constitutes a part of a collaborative initiative with the company Dumarey Automotive Italia S.p.A., which received financial support from the Italian government in ensuring the full compatibility of internal combustion engine components in the context of transitioning from hydrocarbon-based fuels to hydrogen-powered engines. The objective of the present study is to determine, through metallographic techniques, the susceptibility of metallic components of internal combustion engines (pistons, engine heads and blocks, valves and valve seats, and gas inlet and outlet manifolds) to degradation caused by hydrogen. To this end, equivalent components from diesel and hydrogen-powered engines were examined and compared after engine bench tests lasting approximately one thousand hours. Optical microscopy and scanning electron microscopy were performed to verify the presence of microstructural changes and crack propagation. In addition, microhardness measurements were employed to assess changes in the hardness of the material.

Effects of silicon addition on the microstructure and mechanical properties of austenitic stainless steel

Dr. Min Wang, China

Poster Presentation

Abstract

Austenitic stainless steel is a kind of promising fuel cladding structural material for the lead-based fast reactor (LFR). Recent studies show that silicon addition is an effective way to improve the corrosion resistance of stainless steels in the lead-bismuth eutectic alloy. However, effects of silicon on the mechanical properties of austenitic stainless steels have not been systematically studied yet. Basing on the composition of 15-15Ti, the authors designed and fabricated a silicon-bearing austenitic stainless steel named as 15-15TiSi, and investigated its microstructure and mechanical properties through the methods of thermal-calc calculation, microstructural observation, and uniaxial tensile and creep tests.

Silicon addition decreases the solidus and liquidus temperature of alloy and leads to the precipitation of δ during the solidification of the 15-15TiSi stainless steel with 2.5wt.% silicon. In contrast, δ is absent when the silicon addition is 2.0wt.%.

For the 20% cold-worked 15-15TiSi stainless steel plates, a better strength-ductility combination can be achieved at room temperature by silicon addition. Since silicon has the effect of reducing the stacking fault energy of alloy, during cold work it promotes the formation of deformation twins, which are beneficial for the work hardening behavior of material.

During the creep tests of 15-15TiSi stainless steel, silicon addition causes an intergranular precipitation of σ -phase, which affects the mechanical property of alloy differently at various temperatures. At 550°C, σ particles are fine and discrete and beneficial for the intergranular creeping deformation resistance of 15-15TiSi. At 650°C, however, σ precipitates massively and causes an evident drop in the creep rupture life of alloy.

Briefly, to avoid the precipitation of δ , the silicon content of LFR cladding used austenitic stainless steels should be limited to 2.5 wt.%. In addition, at the temperatures no higher than 550°C, there is no undesirable effect of silicon on the mechanical properties of 15-15TiSi.

The morphology of the INCONEL 686 alloy and WC powder mixtures after mechanical synthesis dedicated for the Cold Gas Spraying process

Ph.D. Slawomir Kac, Poland

Poster Presentation

Abstract

In this work, the mixture of Inconel and WC powders was subjected to the mechanical synthesis process to produce composite powders used as the starting material for spraying coatings using the CGS method. This work, which presents results concerning the morphology of the Inconel 686 superalloy, focuses on a detailed analysis of the powder particles formed during mechanical alloying. The influence of the grinding time and the weight ratio of powders on their morphology and crystallite size was examined. Three powder mixtures were prepared with different Inconel 686 - WC weight ratio (10, 30 and 50 wt.% WC). Inconel 686 was mainly in the form of spherical particles with a diameter of approximately 50 μm . In raw state, analyzed tungsten carbide powder had irregular shapes, the particle size was approximately 1-3 μm , with tended to agglomerate. During the process of mechanical alloying (MA), the powder particles were subjected to a strong collision with the balls in the ball mill, which causes their strong deformation. As a result, the fine and hard WC particles were embedded in the surface layer of the Inconel particles, forming a composite surface coating of the Inconel particles. The powders were investigated before and after the process of mechanical synthesis using the Scanning Electron Microscope and the X-ray Diffraction methods. The mixing time and proportion of powders have a significant effect on their morphology and the degree of grinding. The crystallite size of the pure Inconel686 particles, varied from 30 nm (in the initial state) through 18 nm (after 2 h of milling) to 15 nm after 10 h of milling. At 10% WC content, the crystal size changed from 25 nm to 19 nm after 2 and 10 hours of milling, respectively. Moreover, a significant fragmentation and deformation of Inconel particles, which take the form of a plate with an irregular shape and sharp edges were observed after mixing time longer than 6 h. In the mixture of powders with a high content of WC (50 wt.%) no fragmentation and no significant change in the shape of the Inconel particles were observed at the same time of grinding in a ball mill. Inconel 686 particles with embedded WC particles are very attractive for the CGS spraying process applications, especially as uniform and stable matrix structure in sprayed coatings that increase wear resistance.

CALPHAD-Based High-Throughput Assessment of Scrap-based Metal Powders Printability for L-PBF

Mr. Mohammad Zarghami, Spain

Poster Presentation

Abstract

Steel manufacturing is an energy-intensive process with a significant CO₂ footprint. Scrap recycling plays a significant role in reducing the environmental footprint of steel manufacturing. While the use of scrap in steelmaking is a long-established and widely accepted practice, its variable chemical composition and presence of contaminants often limit its application to steel grades that are less sensitive to composition and microstructure, such as structural steels used in long products like reinforcing bars. However, using steel scrap for manufacturing high-performance, near-net-shape products, (such as additively manufactured (AM) parts) is an ongoing research topic, focusing on understanding the effects of chemical composition variations, impurities, and the development of impurity-tolerant alloys [1,2].

In this work, we perform high-throughput computational thermodynamics (CalPhaD) simulations to evaluate the manufacturability of metal powders derived from steel scrap for the laser powder bed fusion (L-PBF) process. By analysing the phase evolution and material thermal properties across a range of chemical compositions, we assess potential printing issues such as hot cracking, keyholing, balling, and lack of fusion using phenomenological criteria in the literature [3]. This study explores the admissible range of chemical composition for scrap-based steel powder, which could be used to lead the strategies for different scrap selection and mixing and pre-atomization impurity/contamination removal procedures.

Novel aluminium-carbon nanomaterials fabricated by means of friction stir processing and plasma welding

Dr. Petra Spoerk-Erdely, Austria

Poster Presentation

Abstract

The electrical conductivity of a material plays a significant role in many areas including energy transfer, electronics, and electric vehicles. Improvements in conductivity translate into reduced energy losses and, therefore, represent an important focus in materials research for modern society. Yet, for many applications, conductor materials also require a high mechanical strength, and resistance to aging as well as elevated temperatures. Since in many classic alloys these requirements, i.e. high electrical conductivity and high strength, are in conflict to each other, this work investigates novel aluminium-carbon nanomaterials on the basis of alloy Al-6061 and activated carbon nanopowder (nC), which show great potential for simultaneous improvements in both properties. The aim is to create special crystallographic structures by the application of different processes. Friction stir processing (FSP) and plasma welding were combined to achieve these promising microstructures and, thus, material properties. In a first step, FSP was used to produce a homogeneous pre-material by introducing 3 wt.% nC powder into the Al-6061 base material. To this purpose, the nC powder was mixed with ethanol and subsequently applied to grooves in Al-6061 sheets. Upon closing the filled grooves in a pin-less FSP setup, metal-matrix composites (MMCs) were created in a multi-pass FSP process. Different groove geometries and process parameters were tested to ensure high homogeneity in terms of carbon distribution. In a second step, the MMCs were remelted by plasma welding. During plasma welding, the melt pool is subjected to an electric current, which exerts an influence on the crystallographic structure of the nanocarbon within the aluminium matrix. Different welding parameters were investigated and correlated with the resulting microstructures and material properties. A comparative analysis between the properties of the new aluminium-carbon nanomaterials and the initial, untreated Al-6061 sheet material finally evaluates the potential of the created material as well as of the suggested unconventional, yet reproducible and resource-efficient fabrication route.

Hydrogen Storage and Detection in MoSeTe-based Two-Dimensional Structures

Dr. Gema Tabares Jiménez, Spain

Poster Presentation

Abstract

This study explores the potential of two-dimensional MoSeTe (with a composition of 25% Se and 75% Te) structures for hydrogen storage and detection. The material is grown out-of-plane on sapphire substrates using Chemical Vapor Deposition (CVD). The sensor's properties are characterized through Raman spectroscopy, X-ray diffraction (XRD), and scanning electron microscopy (SEM) to analyze the crystal structure, morphology, and material quality. Resistance variations under hydrogen exposure are studied to assess the sensor's sensitivity and response time to changes in hydrogen concentration. MoSeTe's unique properties, along with its high surface-to-volume ratio in its two-dimensional form, make it a promising candidate for hydrogen detection applications. Additionally, hydrogen uptake is evaluated using ERDA-TOF (Elastic Recoil Detection Analysis-Time of Flight) at the Particle Accelerator located at the Microanalysis Center (Cantoblanco).

Multi-functional Smart Soft Materials

Prof. Luyi Sun, United States

Keynote (Oral Presentation 40')

Abstract

Smart soft materials have one or more characteristics that can be significantly altered in convertible fashions by external stimuli. Inspired by the fascinating visual display strategies and adaptive mechanisms in animals and plants, we have fabricated a series of smart soft material-based devices that can respond to external stimuli with instantaneous and reversible fashions in optical, electrical, mechanical, and/or shape deformation signals. The key to successfully achieving those intriguing characteristics in these smart material systems lies in the function-orientated structural design, which integrates bioinspired design and surface engineering with multiscale architecture as the crucial elements. These materials are characterized by convertible topographies like dynamic cracks, folds, stimuli-responsive wrinkles, and other analogous structures. These systems demonstrate high design flexibility, excellent reversibility, and wide applicability.

Modeling and Simulations of Polymeric Nanostructured Materials Across Scales: From Atoms to Macroscopic Behavior

Prof. Vagelis Harmandaris, Cyprus

Highlight (Oral Presentation 20')

Abstract

The computational study of complex polymeric materials is a very challenging field, due to the broad spectrum of the underlying length and time scales. We present a hierarchical multi-scale methodology for predicting the macroscopic properties of polymer-based nanostructured systems, which involves atomistic and coarse-grained (CG) simulations, as well as homogenization approaches and continuum models. The CG models are derived through a systematic “bottom-up” data-driven strategy, using information from the atomistic scale without any adjustable parameter [1]. Moreover, Deep Learning algorithms are developed to reintroduce atomic detail on the CG scale, and obtaining atomistic configurations of long polymer chains [1]. Here, we first provide an overview of the above hierarchical approach that allows the study of macromolecular systems over a broad range of time scales, from a few fs up to ms and the prediction of their properties (structural, dynamical, rheological, etc.) [2].

Next, the proposed computational methodology is applied to provide a fundamental understanding of the mechanism of mechanical reinforcement in glassy polymer nanocomposites, which is of paramount importance for their tailored design. We present a detailed investigation of the coupling between density, structure, and conformations of polymer chains with respect to their role in mechanical reinforcement [3]. We found that the effective mass density and rigidity of the matrix region change with filler volume fraction, while that of the interphase remains constant. The origin of mechanical reinforcement is attributed to the heterogeneous chain conformations in the vicinity of the nanoparticles, which involves a twofold mechanism. In the low-loading regime, the reinforcement comes mainly from a thin, single-molecule, 2D-like layer of adsorbed polymer segments on the nanoparticle, whereas in the high-loading regime, the reinforcement is dominated by the coupling between train and bridge conformations; the latter involves segments connecting neighboring nanoparticles.

Nanostructured Polymeric Matrices for Enhanced Ablative Thermal Protection Systems in Space Exploration

Dr. Rita Bottacchiari, Italy

Oral Presentation (20')

Abstract

The continuous evolution of space exploration missions necessitates the development of advanced Thermal Protection Systems (TPS). Ablative TPSs (A-TPS) are essential for planetary entry missions as they are capable of withstanding the intense aerodynamic heating encountered by the vehicles. Phenolic-Impregnated Carbon Ablators (PICA) have long been the standard for A-TPS in space missions due to their effective thermal insulation and ablation resistance. PICA-like ablators comprise a carbon fiber reinforcement impregnated by a phenolic resin which, when invested by high heat fluxes, undergoes pyrolysis reactions bringing to the consumption of a considerable amount of the incident heat. Phenolic resin is widely used as matrix because of its excellent thermal stability, low thermal conductivity, and ability to form a protective char layer during pyrolysis. Traditional carbon-phenolic ablators, though effective, face performance limitations under the increasingly severe conditions of future missions. Therefore, it is of utmost importance to either improve PICA-like materials, by for example tailoring the microstructure and porosities, or design new A-TPSs exploring different polymeric matrices with higher thermo-mechanical properties.

This study focuses on the exploration of novel, nanostructured A-TPSs with two polymeric matrices: phenolic resin and cyanate ester. The alternative cyanate ester resin offers advantages such as higher char yield, higher decomposition onset temperature, and increased glass transition temperature compared to state-of-the-art phenolic resin. To obtain the nanostructuring of the resin matrix it is possible to use either a cross-linker or a polymeric additive which can alter the length of the polymeric domains formed during cross-linking and gelation. In this work different additives have been tested: hexamethyltetramine (HMTA), polyvinylpyrrolidone (PVP) and polyethylene glycol (PEG) were incorporated into the solutions to tailor the matrices' microstructure. Scanning Electron Microscopy (SEM) was employed to investigate the resin morphology and distribution within the carbon felt: the optimization of the manufacturing was conducted to obtain a homogeneous distribution of the matrix throughout the felt, the formation of micro-nano domains of the polymer structure and the presence of open and interconnected porosities. The as-designed ablators were characterized and compared to non-nanostructured ones. Thermo-ablative performances were assessed with oxyacetylene flame tests, exposing samples to a heat flux of 4MW/m^2 for 60 seconds. Surface and back-side temperatures were recorded, along with measurements of mass loss and surface recession. The exposed samples were further analysed with SEM equipped with an EDS system to compare the oxidation of the exposed carbon fibers and the in-depth formation of a char layer.

Paper 269 1 **Deformation Behaviors of High-Density Polyethylene Characterized by In-Situ Nanodiffraction Imaging**

Prof. Hiroshi Jinnai, Japan

Keynote (Oral Presentation 40')

Abstract

Semicrystalline polymers possess a hierarchical structure that consists of both crystalline and amorphous regions. During the stretching process of these polymers, their internal structures undergo various changes, including the rotation and fragmentation of crystals, elongation of amorphous areas, and the formation of voids. Although these deformation behaviors are closely related to mechanical properties, analyzing their relationship has proven challenging due to nanometer-scale heterogeneity. Nanodiffraction imaging (NDI), an advanced electron microscope imaging technique based on electron diffraction, allows us to observe polymer crystals and map chain orientation with nanometer-scale spatial resolution.

In this study, a high-density polyethylene (HDPE) specimen with well-oriented molecular chains was prepared and subsequently stretched within an electron microscope to investigate its deformation behavior.

We observed many voids generated within the specimen. The TEM image at a certain strain reveals a craze. Because crazes represent a unique form of plastic deformation in polymers, it is essential to clarify the generation and growth mechanisms to understand their mechanical properties. A fibrous region was observed just before the fracture. NDI was performed on the craze and fibrous regions. At the conference, we will present TEM images that illustrate the deformation behavior, along with NDI maps showing relative crystallinity and molecular chain orientation. Additionally, we will discuss the mechanisms of deformation and fracture of HDPE based on the shape of voids and fibrils, the spatial distribution of crystals, and the orientation of molecular chains.

Paper 94 **2** **How to measure properly fracture properties of brittle materials using molecular simulations? Application to mode I and mode III in silica glass.**

Dr. Maxime Vassaux, France

Highlight (Oral Presentation 20')

Abstract

The fundamental understanding of the root causes of failure requires information on atomic-scale processes. Molecular dynamics (MD) simulations are widely used to provide these insights while maintaining chemical specificity. However, the boundary conditions that can be applied in MD fracture simulations are limited to the linear-elastic fracture mechanics far-field solution, which makes it difficult to apply bending or shearing deformations as they occur in classical experimental setups. This has to date prevented the accurate and precise prediction of key fracture quantities such as critical stress intensity factors. We here apply the domain-decomposition Capriccio method to couple a molecular model representing silica glass simulated using MD with the finite element method (FEM) and perform both mode I (tension, three- and four-point bending) and mode III simulations. We investigate multiple criteria to best identify the point of critical crack propagation: decrease in stress, decrease in the number of interatomic interactions, and increase in kinetic energy/temperature. We propose a novel protocol that allows us to determine the critical stress intensity factor of silica glass under mode I and mode III conditions from atomistic data with increased fidelity. Overall, our contribution demonstrates how more than ever MD simulations enable chemically specific quantitative predictions of the fracture behaviour of oxide glasses.

Towards accurate thermodynamics from random energy sampling

Dr. Thomas Schuler, France

Oral Presentation (20')

Abstract

Special Quasi-random Structures (SQSs) are often used to model disordered alloys in small simulation cells and to compute their thermodynamic properties. Yet, SQS-based sampling yields chemical potentials (among other quantities) that do not match the equilibrium values at some finite temperature. This is due to the lack of chemical short-range order in random (or SQS) samples. In this talk, we present a probabilistic analysis of chemical potential calculations based on the distribution of substitution energies and the Widom technique.

This original approach to the thermodynamics of multi-principal element alloy is demonstrated on a model Fe-Ni alloy. Atomic-scale Monte Carlo simulations are performed systematically to check the validity and the limits of our theoretical work across alloy compositions and temperatures.

By sampling either equilibrium configurations or SQSs, we show that they both yield different results, but that it is possible to correct the results from the random sampling in order to get a result which is much closer to the equilibrium values.

The first order correction proposed in this study is quite effective and very simple to apply. Moreover, it does not require additional energy calculations.

Using similar tools, we also show that vacancy formation free energies computed from randomly sampled local chemical environments must be corrected to ensure the consistency between various available calculations. Indeed, irrespective of the choice of the species being replaced by a vacancy, we should arrive at the same value of the vacancy formation free energy. As we did for chemical potentials, we propose a simple way to compute this correction term, and compare the outcome with equilibrium Monte Carlo results and with approximations found in the literature.

In the course of the presentation we shall also discuss the applicability of the method to other quantities of interest and to alloys beyond binary concentrated alloys.

Active learning prediction of the enthalpy of mixing of BCC, FCC and HCP solid solutions

Mrs. Runan Xie, France

Oral Presentation (20')

Abstract

Predicting the formation of solid solution is essential in a large field of research, particularly for high-entropy alloys, for which the properties can be modulated by adjusting the composition and nature of elements. To design these alloys, it is important to know the enthalpy of mixing in the face-centered cubic (FCC), body-centered cubic (BCC), and hexagonal compact (HCP) phases, because this property is key to predict their formation using machine learning [1] or thermodynamic [2] approaches. At present, these approaches rely on enthalpy of mixing data that are either approximations from Miedema’s model [3], which is valid only for the liquid phase, or obtained by Density Functional Theory (DFT) methods, which are time-consuming, and make it challenging to explore all possible configurations and combinations for all phases. In both cases, the enthalpy of mixing of multicomponent solutions is obtained by summing the pairwise interactions of all binary subsystems.

In this study, we develop a machine learning model to predict the enthalpy of mixing in the FCC, BCC, and HCP phases generated by binary combination of dozens of elements. The training dataset is built from literature data, and is completed using active learning to identify where new data is most needed, and the Special Quasi-random Structures methods combined with the DFT method are used to simulate news data. The agreement between experimental and theoretical data, as well as between enthalpies of mixing calculated for complex concentrated solutions and those extrapolated from binary systems, is discussed. Our results can be used to improve and extend to other elements predictions of FCC, BCC and HCP phase formation that are necessary for the design of high entropy alloys.

High-throughput screening of Al-Co-Cr-Fe-Ni-Ti compositionally complex alloys: from CALPHAD simulation to AM-generated component

Dr. Leonid Gerdt, Germany

Oral Presentation (20')

Abstract

The accelerated design of high entropy alloys (HEAs) and compositionally complex alloys (CCAs) aims to expedite the discovery and optimization of these materials through computational techniques and high-throughput experimental methods. By leveraging thermodynamic simulations techniques such as CALPHAD, it is possible to predict phase stability of various alloy compositions, significantly reducing the time and resources required for traditional trial-and-error approaches.

In the research project NovMat-AM a high-throughput screening approach has been utilized and further improved, enabling characterization of more than 60 novel alloys in the Al-Co-Cr-Fe-Ni-Ti system. The aim was to develop a dual-phase alloy comprising FCC matrix and L12 precipitations after age hardening heat treatment for application in harsh environment. From the screened compositions one selected alloy Al₇Ti₆Cr₁₆Fe₁₄Co₁₄Ni₄₃ (in at.%) has been cast and then processed to 20 kg powder for additive manufacturing. This powder was successfully used to produce a turbine stator as a demonstrator part by means of laser powder bed fusion (LPBF). Furthermore, the mechanical properties of the synthesized alloy at elevated temperature of T = 600 °C were determined by means of tensile test.

The alloy Al₇Ti₆Cr₁₆Fe₁₄Co₁₄Ni₄₃ exhibited a phase structure consisting of FCC matrix, L12 precipitations and small amounts of BCC B2, Ni₃Ti and sigma phase in the as cast state. In the as-built state the LPBF-produced samples had a much finer dendritic solidification structure than the as cast samples. However a precipitation of the L12 phase could not be detected in the as-built state of the LPBF samples. After homogenisation heat treatment at T = 1,150 °C for t = 24 h and subsequent age hardening at T = 850 °C phase composition comprises FCC matrix, L12 precipitations and small particles of BCC B2 and sigma phase at the grain boundaries. This is true for both. i.e. cast and LPBF processed material, although the LPBF samples exhibit finer grain structures. With a tensile strength of R_m = 1,056 ± 37 MPa at T = 600 °C the heat treated LPBF samples show promising results for future use in high-temperature application. However, the low ductility of the alloy with elongation at break of A = 0.5 % still needs to be improved. A slight reduce of Al and Ti content could be a possible solution for avoidance of the formation of BCC B2 and sigma phases, which are presumed to be the main reason for the decreased ductility of the material.

Dislocation mechanisms in MPEAs enable simultaneously high strength and ductility

Prof. Evan Ma, China

Keynote (Oral Presentation 40')

Abstract

To expand into new territories in the strength-ductility space, we exploit additional strengthening and strain hardening mechanisms rendered possible by the widened scope of element selection and composition design in multi-principle-element alloys (MPEAs), which also help push the known plasticity mechanisms including TWIP/TRIP towards extreme. In particular, the unusual chemical inhomogeneity in these highly concentrated alloys has three prongs: i) concentration fluctuation/undulation that can be intentionally enlarged [1]; ii) local chemical orders that arise from the varying chemical affinity among the constituent species [2]; and iii) abundant interfaces due to the extraordinarily high volume fraction of nanoscale sized precipitates spaced close to one another [3]. All these help roughen the atomic and energy landscape, elevating hardening via nanoscale segment detrapping in the nano-cocktail solution. The resultant stick-slip renders the motion of dislocations sluggish/difficult, which then tend to stall, react, entangle and accumulate, sustaining the ability to work-harden on the fly with increasing tensile strain. Such defect dynamics delocalize the plastic strain to prolong tensile elongation (to as large ~50%) at >GPa flow stresses [4]. In the absence of embrittling ingredients (such as ceramic and large intermetallic precipitates with inherent dislocation starvation), as long as effective means can be found at the same time to elevate strain hardening to keep up with the strength elevation, the plastic instability such as necking that instigates damage can be suppressed/delayed. This understanding motivated us to keep developing new complex concentrated alloys for better and better strength-ductility synergy [3]. We are now at the verge of realizing yields strength up to ~1.8 GPa, not far from the best super steels, and in the meantime uniform tensile elongation ~27%, similar to that of an elemental metal such as Fe. Putting it another way via a famous/old Chinese saying, this success of having it both ways is like "having fish and bear's paw at the same time".

2

Stability and properties of BCC-B2 refractory “high entropy” alloys

Prof. Maryam Ghazisaeidi, United States

Highlight (Oral Presentation 20')

Abstract

Improving energy efficiency requires the discovery of new materials for use in high-temperature environments. Refractory multicomponent alloys featuring a BCC/B2 microstructure are promising because a microstructure analogous to the famous γ/γ' in superalloys, but with refractory elements, could lead to alloys that can retain high strength at very high temperatures. Given the extensive range of possible compositions in these alloys, a key initial question is whether the B2 phase can develop within refractory metals.

In this talk, I will explain how we tackled this question via our recently developed Multi-Cell Monte Carlo (MC)² method which is suitable for predicting phase stability in multicomponent systems. We used this method to span through the extensive compositional space of these alloys, refine the trends in ordering, and identify the most promising combinations for detailed analysis. We discover that B2 phases form exclusively with the inclusion of elements from groups VII and VIII of transition metals, such as Re, Ru, and we identify these phases among a total of eleven elements. Based on these findings, we develop a machine learning interatomic potential for the most promising combination and study the dislocation structure and transfer between BCC/B2 phases using atomistic simulations.

3

Chemically architected high-entropy alloys: exploring composition space to generalize the concept

Ph.D. Mathilde Laurent-Brocq, France

Oral Presentation (20')

Abstract

In addition to the various strategies already widely known and exploited, a new strengthening mechanism for metallic alloys has recently been proposed [1]. Thanks in particular to the specific features of the Spark Plasma Sintering process, an area with a pronounced chemical gradient, called interphase, was generated between the grains of two jointly sintered powders, one of pure nickel and the other corresponding to the equimolar high-entropy alloy CrMnFeCoNi. Having shown that the characteristics of the interphase were controllable [2] and that an increase in mechanical resistance, attributed to this chemical gradient, was obtained [3], the study is now being extended to other combinations of metals and/or alloys. The main objectives are to generalize the description of the phenomena already observed, while maximizing the effect of the chemical gradient on strengthening. More specifically, the aim is to find alloys with the same crystalline structure (face-centered cubic, fcc) and a significant difference in lattice parameter, which is assumed to be the main driver of hardening.

The exploration of new alloy systems was assisted by the CALPHAD method (CALCulation of PHase Diagrams). Firstly, the accuracy of this tool for lattice parameter predictions, which is not a common use case, was investigated. Next, equilibrium calculations were carried out at a fixed temperature (1373 K) and in such a way as to broadly screen the compositional space within 16 alloy systems: 14 quinary and 2 quaternary, from the 13 elements considered (Al, Ti, Cr, Mn, Fe, Co, Ni, Cu, Zn, Nb, Mo, Sn and W), were explored numerically with a predefined meshing for each. From around 350,000 compositions, we selected those that were fcc single-phase and then calculated their lattice parameter. The aim is to maximize the difference in lattice parameter between the selected alloy and pure nickel. Taking into account other criteria, such as chemical complexity and manufacturability, a limited number of compositions were selected. These were then processed by melting, casting and homogenization treatment, and their microstructure was characterized. Finally, the experimental results were compared with predictions.

Phase transformation and texture evolution in a metastable medium entropy alloy

Mr. Ibrahim Ondicho, Australia

Oral Presentation (20')

Abstract

The metastable Fe₄₅Co₃₅Cr₁₀V₁₀ medium-entropy alloy (MEA) exhibits a single-phase face-centred cubic (fcc, γ) structure after casting and homogenisation at 1100 °C for 6 h. During cold rolling (CR), the MEA undergoes deformation-induced martensitic transformations via $\gamma \rightarrow \epsilon \rightarrow \alpha'$ and $\gamma \rightarrow \alpha'$ pathways with variant selection. Beyond 40% CR thickness reduction, the γ phase develops a Brass-type texture due to the preferential transformation of Cu_γ and S_γ orientations to ϵ and α' -martensite, accompanied by shear banding. The ϵ -martensite texture features $\sim(011\bar{5})$ $[[37\bar{4}2]]$ ϵ and $\sim(112\bar{6})$ $[[([1]\bar{1}21)]]$ ϵ orientations along the {hkil}-fibre, arising from Cu_γ and S_γ orientations via the Shoji-Nishiyama orientation relationship (OR) and variant selection. Similarly, the α' -martensite texture, typical of bcc materials, aligns along the alpha and gamma fibres after 80% CR, with the former originating from G_γ , Br_γ , Cu_γ and S_γ orientations, and the latter mainly from Br_γ and S_γ via the Kurdjumov-Sachs OR and variant selection. Isochronal annealing of the metastable MEA at 625–900 °C for 300 seconds after 80% cold rolling (CR) results in the formation of the Cr- and V-rich sigma (σ) phase between 625–725 °C. Beyond 725 °C, the microstructure consists solely of the γ phase due to $\alpha' \rightarrow \gamma$ reverse transformation, which begins at 675 °C and completes above 725 °C, driven primarily by shear martensitic transformation. Recrystallisation of the reverted γ phase completes at ≥ 850 °C, with nucleation occurring preferentially within shear bands. The reverted γ phase retains a rolling texture with high intensities at G_γ , Br_γ , and GT_γ orientations after annealing between 625–750 °C. Above 750 °C, annealing twinning weakens G_γ and Br_γ orientations while strengthening GT_γ and (120) $[[2\bar{1}0]]$ γ orientations, driven by first-order twinning of G_γ and GBr_γ orientations. Twinning within G_γ and Br_γ also produces new (214) $[[2\bar{1}\bar{1}]]$ γ and RBr_γ orientations, characteristic of low stacking fault energy alloys. Isothermal annealing at 625 °C reveals that the MEA develops B2-like chemical short-range ordering (CSRO) domains within 300 seconds. These CSRO domains gradually transform into a long-range ordered B2 phase after more than 6 hours of annealing at the same temperature. A combination of scanning transmission electron microscopy and thermodynamic calculations indicates that this disorder-to-order transformation is driven by the formation of the σ phase, which depletes the disordered α' -martensite (bcc) matrix of Cr and V elements. The ordered B2 phase is predominantly FeCo-rich, resembling the chemical composition of Fe-Co binary or Fe-Co-V magnetic alloys that undergo disorder-to-order transformations at low annealing temperatures.

Paper 744 6 Development of High Specific Modulus Multicomponent Alloys with An FCC Structure

Mr. Mustafa Seker, United Kingdom

Oral Presentation (20')

Abstract

This project aims to design a new single-phase FCC High Entropy Alloy (HEA) with a high specific modulus, employing a combined computational and experimental approach. The goal is to develop a lightweight engineering material that achieves ductility through an FCC structure, and a high stiffness and low density, using the compositional freedom of HEAs. Firstly, computational modelling methods are used to efficiently explore the vast compositional space and identify promising candidates. After promising compositions are found through modelling studies, these alloys are manufactured experimentally, and the modelling results are verified by characterization studies. In this direction, CASTEP, an atomistic modelling method based on density functional theory, is used in assessing lowest energy phases and their elastic properties. In addition to this method, phase estimation is supported using Thermo-Calc (CALPHAD method software). In the experimental side, Vacuum Arc Melting is used in sample manufacturing. SEM, EDX and XRD are used to characterise the structure, with mechanical properties assessed by nanoindentation.

Despite the power of computation, employing particular search strategies is useful in narrowing the compositional space to explore. To do this, two different approaches are being followed. The first approach designs a new alloy from scratch, while the second manipulates a previously known single-phase FCC HEA to retain the FCC structure while increasing the specific stiffness. Within the scope of the first approach, modelling and experimental studies were initially conducted with aluminium and nickel, with the subsequent introduction of cobalt. The second approach explored the individual effects of copper, molybdenum, vanadium, and aluminium additions to an CoFeMnNi base. The results of modelling and experimental studies on these alloys will be presented.

Paper 28 **1** **L12-type chemical short-range ordering in compositionally-complex alloys**

Dr. Yue Li, Germany

Highlight (Oral Presentation 20')

Abstract

The formation of L12-chemical ordering is a critical phase transformation phenomenon in face-centered cubic (FCC) compositionally complex alloys (CCAs) that can significantly influence their properties. However, quantifying the early stages of chemical ordering is challenging due to the complex elemental arrangements, small domain sizes, similar atomic numbers, and subtle compositional differences from the surrounding matrix. We recently introduced a machine learning-enhanced atom probe tomography (ML-APT) approach to characterize chemical short-range ordering (CSRO) in binary and ternary alloy systems. Here, this methodology is extended to the more complex CoCrNiFeMn alloys, investigating the impact of different compositions and heat treatments on the formation of L12-type CSRO. Our findings offer solid tomographic evidence of L12-CSRO, primarily with Cr repulsion tendency, along with domain size and morphology distributions that align with reported Monte Carlo simulations. The extent of L12-CSRO is strongly dependent on both composition and heat treatment conditions. A standard workflow for applying ML-APT to CCAs is proposed, emphasizing its strengths and limitations, and setting the stage for further exploration and control of local chemical ordering to advance the design of CCAs.

Notable local lattice distortions in BCC refractory high-entropy alloys probed by total scattering

Mr. Yao Hu, Sweden

Oral Presentation (20')

Abstract

The remarkable flexibility in tuneable chemistry and promising application prospects have driven the development of high-entropy alloys (HEAs). One particular category of HEAs, body-centred cubic (BCC)-structured refractory high-entropy alloys (RHEAs), have attracted great interest due to their exceptional mechanical properties at high temperatures. Despite the fast development in the field of HEAs, one of their key features, local lattice distortion (LLD), remains rarely explored and a comprehensive understanding of it is lacking. Considering that there has been plausible evidence suggesting that LLDs contribute to solid solution strengthening, a deeper understanding of LLDs through systematic studies might provide a promising route for decoding the structure-properties relationship and tailoring mechanical properties of RHEAs.

Total scattering and pair distribution function (PDF) analysis have been presented as potent techniques in quantitatively investigating LLDs. The effect of LLDs on the PDF peak broadening provides a way to quantify them by fitting the PDF data. However, since LLDs as static displacements are coupled with thermal displacements resulting from thermal oscillations of atoms, it is essential to separate the thermal component. One approach is to conduct measurements at cryogenic temperatures, which allows the fitting of Debye curves and the quantification of the thermal component as a function of temperature.

In this work, LLDs in BCC-structured RHEAs were quantified through variable temperature neutron total scattering measurements under cryogenic conditions. Notable LLDs were quantified in the studied BCC-structured RHEAs, compared to their face-centred cubic (FCC)-structured counterparts. Results from both a homogeneous bulk sample and inhomogeneous powder were compared to evaluate the combined effects of chemical segregation and vacancy on PDFs. Additionally, Debye temperatures of the investigated RHEAs were experimentally determined, which is one step forward in understanding their thermodynamic properties.

Elucidating the Equilibrium Vacancy Concentration and Diffusion Behaviour in Refractory High-Entropy Alloys from First-Principles

Mr. Damien Lee, Switzerland

Oral Presentation (20')

Abstract

Refractory high-entropy alloys (HEAs) have emerged as promising candidates for high-temperature applications due to their exceptional mechanical properties and thermal stability. Atomic diffusion plays a crucial role in microstructural evolution and long-term stability. In most metallic systems, diffusion primarily proceeds through substitutional diffusion, where diffusion constants are directly proportional to vacancy concentrations. However, accurately determining vacancy concentrations from ab initio methods is computationally demanding due to the vast compositional space of HEAs and extremely low vacancy concentrations. In this work, we investigate HEAs composed of Group 4, 5, and 6 elements and introduce an efficient statistical-mechanical approach for calculating equilibrium vacancy concentrations. By leveraging first-principles calculations and Monte Carlo simulations, we systematically assess how composition and local atomic interactions influence vacancy formation. We then employ kinetic Monte Carlo (kMC) simulations to compute diffusion constants, providing a quantitative understanding of atomic mobility in HEAs. Our results reveal key insights into diffusion mechanisms, emphasizing the role of short-range order and chemical environment. Our work demonstrates how first-principles methods can effectively model diffusion behavior in complex composition space of HEAs.

Mechanical properties of the quaternary high-entropy alloy Zr₄₅Ti_{31.5}Nb_{13.5}Al₁₀ after plasma nitriding or nitrogen ion implantation followed by heat treatment

Mrs. Karolina Stępnia, Poland

Oral Presentation (20')

Abstract

High-entropy alloys (HEAs) are materials of great interest due to their unique composition, consisting of multiple principal elements. This contrasts with traditional alloys, which typically contain only one or, at most, two base elements. The number of possible HEA compositions is significantly larger than that of conventional alloys [1]. HEAs exhibit a range of exceptional properties, including high corrosion resistance, excellent mechanical strength, and remarkable fracture toughness.

In this study, the mechanical properties of the quaternary high-entropy alloy Zr₄₅Ti_{31.5}Nb_{13.5}Al₁₀ were investigated. The alloy underwent plasma nitriding or nitrogen ion implantation and subsequent heat treatment. The primary objective of this research was to examine and compare the effects of these two modifications on the alloy's mechanical performance and microstructure.

Plasma nitriding leads to the formation of a high-entropy nitride phase within the material. In contrast, nitrogen ion implantation introduces a supersaturated solid solution but disrupts the crystal structure, primarily incorporating interstitial nitrogen atoms. To restore the crystalline structure and promote the formation of high-entropy nitrides, heat treatment was applied to homogenize the material.

Mechanical testing was performed using nanoindentation and micropillar compression to evaluate hardness, elastic modulus, and yield strength. The surface of the samples was primarily characterized using atomic force microscopy (AFM), which was employed to measure adhesion, surface roughness and friction. To analyze the microstructural changes induced by the different treatments, thin lamellae were prepared for transmission electron microscopy (TEM) observations. X-ray diffraction (XRD) analysis was conducted to confirm the presence of high-entropy nitride phases. Additionally, energy-dispersive X-ray spectroscopy (EDS) was used to determine elemental distribution both on the surface and in cross-sections of the lamellae.

Samples with nitrogen incorporated into their lattice exhibited increased hardness compared to the untreated alloy. Furthermore, the deformation mechanisms were altered following the introduction of nitrogen.

Paper 638 **5** **Experimental and computational analysis of nanoindentation-induced plasticity in arc-melted equiatomic Mo-Ta-W refractory bcc single-phase alloy**
Dr. Tomasz Stasiak, Poland
Oral Presentation (20')

Abstract

Medium and high entropy alloys (MEAs and HEAs) have been studied for the last twenty years. Many compositions are still unknown due to the vast field of possible systems. Alloys based on refractory elements are very promising for high-temperature applications due to their very high strength. However, their brittleness at room temperature, relatively poor oxidation resistance, and difficulty in preparation due to very high melting points of constituent elements limit the application of refractory multicomponent alloys. Moreover, the deformation mechanisms of refractory alloys are poorly understood, which slows down advancements in the field.

The aim of this study was to investigate nanoindentation-induced plasticity in a single-phase equiatomic Mo-Ta-W alloy. The experimental results were compared with molecular dynamics (MD) simulations. Mo-Ta-W alloy was prepared using the arc melting technique. The alloy was characterized by various methods such as XRD, SEM-EDS, EBSD, TEM, and nanoindentation. After casting, the microstructure of the Mo-Ta-W alloy reveals a segregation of molybdenum, which has a significantly lower melting point than tantalum and tungsten. The annealing at 1550°C for 24 h was performed to homogenize the microstructure. The XRD confirms a single bcc phase structure and large grains of a few hundred micrometers. The nanoindentation was carried out in the grains with different orientations, i.e., [001], [111], and [101], to study plastic response. The effect of grain boundaries was diminished in this study. The pile-up formation and slip traces were analyzed by SEM and TEM and, subsequently, compared with the MD simulations. It was found that experimental and computational results are in good agreement. The dislocations in Mo-Ta-W alloy are distorted compared to pure W. The studies that were conducted deliver new knowledge about the understanding of nanoindentation-induced plasticity of refractory multicomponent alloys.

Size effects and strain rate sensitivity in nanocrystalline High-Entropy CuMoTaWV

Mr. Mateusz Włoczewski, Poland

Oral Presentation (20')

Abstract

High-entropy alloys (HEAs) are materials known for their exceptional mechanical properties, resistance to thermal effects, radiation, and even corrosion, properties, which are often unattainable with conventional materials [1]. From a nanomechanics point of view nanocrystalline structure is particularly interesting [2] and because of that, this work investigated size effects and strain rate sensitivity in nanocrystalline CuMoTaWV prepared using single target DC-magnetron sputtering.

To achieve objective comparison of the behaviour of novel HEA under various loads and different loading rates were investigated with nanoindentation and compression of micropillars in situ Scanning Electron Microscopy with an Alemnis nano-indenter. Therefore data from experiments were correlated with taken images and videos, which extended the analysis. To analyze the microstructural changes induced by compressive stresses due to nanoindentation and micropillar compression tests thin lamellae under indents and in cross-sections of pillars with the use of Focused Ion Beam were conducted. Prepared lamellae were investigated using Transmission Electron Microscopy in order to enhance knowledge of the behaviour of the nanocrystalline HEA after loading.

Experimental work will help with the evaluation of the influence of the different effects on the mechanics of HEAs. The overall project objective is to bring a wider understanding of mechanical properties and underlying rules affecting the behaviour of nanocrystalline HEA.

Chair: Manzoni, Dr. Anna

Paper 155 1 **High-temperature in-situ investigation of refractory high entropy superalloys**

Dr. Anna Manzoni, Germany

Highlight (Oral Presentation 20')

Abstract

The spinodal decomposition in bcc structured refractory alloys can be used as a potential strengthening mechanism, as has been demonstrated over the last decade in research on high entropy alloys and compositionally complex alloys. Early work from the 1990s already showed the possibility of further enhancing this spinodal decomposition by adding the element Al, which in addition to spinodal decomposition also provides an ordering process in the otherwise disordered bcc phases of the alloy. Nevertheless, the knowledge of refractory high entropy (super)alloy systems, is still in its infancy and requires further research to fully exploit its potential for high temperature applications in the future.

Two refractory alloys of the Al-Nb-Ta-Ti-Zr family are investigated via (high temperature in-situ) XRD, in the long run for understanding spinodal decomposition properties. Ex-situ XRD and TEM observations show the formation of at least one bcc phase and an ordered B2 phase. In addition, one or more Al-Zr rich phases are observed, which are not part of the spinodal phases and are unwanted.

The high-temperature observations at 1000°C for 60 h show a remarkable increase in peak width up to 2° FWHM that does not disappear after cooling in the furnace. Ex-situ observations after 1000°C for hundreds of hours and subsequent quenching show narrow peaks (max 0,2° FWHM) at the same position. This and several other observations will be presented in this talk and possible explanations are presented.

3

High temperature oxidation behavior of high entropy alloys elaborated by Spark Plasma Sintering and Hot Isostatic Pressing

Dr. Robin Vallereau, France

Oral Presentation (20')

Abstract

Interest in high entropy alloys (HEAs) has increased in recent years, as they exhibit promising mechanical properties and phase stability at elevated temperatures, making them promising candidates to replace superalloys [1]. The high temperature oxidation behavior of HEAs elaborated by arc-melting, a classical metallurgical process, is widely reported in the literature [2-6]. In the present study, HEAs were elaborated by pressure assisted-sintering techniques (Spark Plasma Sintering (SPS) and Hot Isostatic Pressing (HIP)) from atomized and atomized-milled powders. The alloy under study is Al_{0.3}CoCrFeNi, formed by an FCC single-phase solid solution. Isothermal oxidation tests were performed at 900 °C for several durations up to 3000 h. SEM-EDS characterizations combined with XRD analyses revealed that the oxide scale formed on HIPed samples elaborated from atomized powder is composed of an outer Cr₂O₃ layer and α-Al₂O₃ at the metal /oxide scale interface. A spinel-type oxide containing Cr, Co, Ni, and Fe grew on top of the Cr₂O₃ scale. SEM cross-section analyses showed the formation of Al₂O₃ inside the alloy, at powder particle grain boundaries. Al₂O₃ internal oxidation tends to increase with the oxidation time. Additionally, AlN precipitates were observed inside and below the internal Al₂O₃ oxidation layer. Samples elaborated by SPS from atomized-milled powder showed a completely different oxidation behavior. The oxide scale was only formed by an α-Al₂O₃ layer, presenting two different grain morphologies. No internal oxidation (Al₂O₃) phenomenon was observed. For both HIP and SPS samples, deeper in the bulk, the high temperature ageing promotes the precipitation of B2 AlNi enriched phase inside the grains (in the form of rods) and at the grain boundaries (with equiaxed shape). Finally, the influence of the elaboration process and the initial mechanical state of the powder particles (atomized or atomized-milled) was also investigated.

High temperature corrosion resistance of HEA for application in hydrogen energy

Prof. Wojciech Nowak, Poland

Oral Presentation (20')

Abstract

The constant need to reduce greenhouse gas emissions and the desire to improve the efficiency of gas turbines lead to a continuing trend in increasing the operation temperature of gas turbines. Higher operating temperatures reduce fuel consumption and higher combustion temperatures reduce emissions of pollutants. In addition, hydrogen is increasingly being used as a cleaner alternative fuel. However, the use of hydrogen or hydrogen-rich fuels increases combustion temperatures and increases water vapour content in exhaust gases. Typically used Ni-based alloys reached their operation temperature limit. In addition, the presence of water vapor exacerbates the oxidation behaviour of Ni-based alloys at high temperatures. It is therefore necessary to use a new brand of materials in gas turbines running on hydrogen-rich fuels. High-entropy alloys (HEAs) are a very promising material to replace commonly used Ni-based alloys. HEA is a group of materials composed of at least five major atomic elements. These alloys can be doped with other elements in quantities below 5 at. % in total. Thus, in this study, NiCoCrAlFe-X alloys are studied for oxidation behavior when exposed to dry and humid atmospheres for 1000 h. NiCoCrAlFe-X alloys are doped with alloy elements of 1–5 at. %. The effects of chemical composition on oxidation resistance in dry and wet atmospheres will be explained and discussed.

Paper 392 **6** **Fabrication and characterization of a Ni-based high-entropy alloy for the hydrogen industry**
Mrs. Lucía Castrillejo Robles, Spain
Oral Presentation (20')

Abstract

High-entropy alloys (HEA) are a promising class of advanced materials, whose microstructure and mechanical properties can be optimized through carefully selecting compositions and process techniques. In the present study, a nickel-based HEA with chromium, manganese, and copper additions (NiCrMnCu) was developed and characterized, being its use intended for applications requiring high strength and ductility, as well as low hydrogen permeation, and fabricated using alloy elements easily available.

The HEA was designed according to ThermoCalc simulations, to get a monophasic microstructure, and then synthesized using an induction furnace. Its microstructural characterization involves optical microscopy (OM), X-Ray diffraction (XRD), scanning electron microscopy with compositional analysis (SEM + EDX), and transmission electron microscopy (TEM) to study the crystal lattice characteristics fully. Results revealed a dendritic microstructure predominantly consisting of a face-centered cubic (FCC) phase with localized segregation of the alloy components.

Corrosion resistance was evaluated using electrochemical tests in NaCl and NaOH, including polarization curves, polarization resistance measurements, and corrosion rate calculations, aiming to obtain the right parameters to analyze its behavior towards permeation in hydrogen-rich environments. As for the mechanical characterization, Small-Punch tests (SPT) have been performed, which provide information related to its tensile and fracture properties, allowing us to estimate the ductility and tensile strength of the HEA alloy by making use of small specimens.

1

Microstructural constituents influencing toughness in maraging steels

Prof. Ronald Schnitzer, Austria

Highlight (Oral Presentation 20')

Abstract

Maraging steels are one of the most versatile high-performance materials due to their excellent combination of strength and toughness. They are used for many demanding applications, such as aircraft wheel suspensions and plastic mold materials. The microstructure of these steels consists of uniformly distributed, nanometer-sized, intermetallic precipitates embedded in a Ni-rich martensitic matrix. Depending on the alloy composition and the heat treatment applied, different types of precipitates can form during the ageing process. The investigated steel belongs to the group of PH 13-8 Mo grades and obtains its strength increase during ageing through the precipitation of intermetallic β -NiAl particles. Furthermore, so-called reverted austenite forms during aging, which has a significant influence on the toughness properties.

In this study, particular attention was paid to the presence of δ -ferrite and its influence on toughness. An increase in the proportion of this phase led to a drastic decrease in impact toughness. When examining the microstructure, it was found that the embrittlement is caused by cracks originating from delta ferrite.

In addition to the use of high-resolution methods such as transmission electron microscopy and atom probe tomography to characterize the intermetallic precipitates, in-situ methods such as high-temperature X-ray diffraction and the use of high-energy synchrotron radiation have proven to be beneficial for understanding the microstructural development during heat treatment. For example, the occurrence of the austenite memory effect and recrystallization without prior cold working in PH 13-8 Mo steels could be demonstrated by cross-scale in-situ methods [1]. The latter effect leads to a significant refinement of the microstructure, which has a positive effect on the mechanical properties.

Another part of the investigations was dedicated to intercritical annealing prior to ageing. Targeted analysis of the microstructure using atom probe tomography and transmission electron microscopy showed that this annealing step creates zones enriched with Ni, which promote the formation of reverted austenite during the subsequent ageing process. In-situ high-energy X-ray diffraction tensile tests also showed that this phase exhibits high mechanical stability [2].

In addition to the negative influence of the δ -ferrite, it was shown that the phase fraction of transformed austenite has the greatest influence on toughness, while that of the martensite block sizes is negligible.

FATIGUE CRACK INITIATION AND GROWTH IN ADVANCED BAINITIC STEELS: NOTCH AND MICROSTRUCTURAL EFFECTS

Dr. Lucía Morales Rivas, Spain

Highlight (Oral Presentation 20')

Abstract

Knowing the effect of the microstructural features such as interfaces on the fatigue response of bainitic steels containing retained austenite, is a topic of high interest for, among others, bearing applications. The up-scaling in the development and use of such complex advanced steels in actual components requires a comprehensive study of both microstructural and notches effects, aspects often treated in isolation.

New results from studies based on scanning electron microscopy and electron backscatter diffraction over the crack path, in correlation with the crack growth rate, will be presented, revealing the twofold effect of the retained austenite.

High-throughput method for steel development using directed energy deposition

Mr. Pentti Kalliotiura, Finland

Oral Presentation (20')

Abstract

The advancement of research methods is critical for developing novel steels for demanding applications. Conventional materials research requires significant human effort and time, making it slow and expensive. The Materials Acceleration Platform (MAP) concept aims to revolutionize the field by utilizing high-throughput experiments and characterization combined with data informatics to create automated research cycles. This research explores a high-throughput methodology for stainless steel development, employing state-of-the-art Directed Energy Deposition (DED) equipment with the capability of in-situ mixing of up to six elemental powders.

The use of DED enables the rapid creation of extensive alloy families. Samples are designed to minimize the processing time while utilizing the full potential of automated characterization. This approach significantly accelerates the discovery and optimization of new alloys by allowing learning, rapid iteration and testing. The integration of advanced characterization techniques, such as high-throughput microscopy and spectroscopy, facilitates detailed analysis of the synthesized alloys. The combination of high-throughput synthesis and automated characterization represents a significant development leap in alloy research, promising to deliver novel materials with enhanced performance for a variety of industrial applications.

In this research iron, nickel, chromium, and molybdenum are used as alloying elements to demonstrate MAP concept for stainless steels. These elements were chosen to validate the methodology, as they are common elements in stainless steels and facilitate different phase structures (Ni: austenite; Cr, Mo: ferrite). In the work, DED parameters are optimized, to achieve a homogeneous structure. Therefore, characterization of homogeneity of the samples is done by X-ray diffraction (XRD) and microscopy techniques. For high-throughput determination of mechanical properties, an indentation method is utilized. The used characterization methods are semi-automated, creating grounds for full automation.

By streamlining the research process, MAP not only reduces costs and time but also opens new avenues for innovation in materials science. This research is the first step towards MAP, creating foundations for future research. When combined with data informatics and computational modeling, the methodology has a huge potential for developing novel steels for challenging applications, such as hydrogen production, storage and transport.

Paper 342 1 **Convergence of Pathways to Equilibrium During Tempering of Bainitic and Martensitic Structures in a High-Si Medium Carbon Steel.**

Ph.D. Carlos Garcia-Mateo, Spain

Highlight (Oral Presentation 20')

Abstract

This research reveals the convergent nature of bainitic and martensitic microstructures during high-temperature tempering in a high-silicon medium carbon steel, while examining their distinct transformation pathways across temperatures ranging from 200°C to 650°C. Despite their different initial states - both containing carbon-saturated tetragonal ferrite matrix and retained austenite - these microstructures follow unique routes to a common equilibrium state. The investigation demonstrates that while retained austenite governs the tempering response in bainitic structures, the highly dislocated, carbon-enriched ferritic matrix controls the transformation in martensitic structures. Through comprehensive analysis utilizing high-resolution dilatometry, scanning electron microscopy, and X-ray diffraction techniques, we establish that both microstructures ultimately achieve identical equilibrium states at elevated tempering temperatures (600-650°C), albeit with significantly different kinetics - bainitic structures exhibiting slower transformation rates. This study maps the critical tempering mechanisms in high-silicon steels and quantifies the transformation pathways to equilibrium. These findings provide fundamental insights for optimizing heat treatment protocols, demonstrating that despite different starting microstructures, carefully controlled tempering can yield convergent final states in advanced steel processing.

2

Two-stage isothermal transformation of austenite to nanobainite in chemically inhomogeneous medium alloy steel containing 0.5% C

Ph.D. Jarosław Marcisz, Poland

Oral Presentation (20')

Abstract

Nanobainitic steels have been the subject of research for more than 20 years and are now reaching the industrial implementation stage. In order to facilitate the commercialization of nanobainitic steels, various grades are being developed with chemical compositions that make it possible to adjust technological and performance properties to meet users requirements. One direction is to produce a bainitic-austenitic nanostructure with the lowest possible contents of carbon and alloying elements. A characteristic feature of alloy steels is the segregation of elements during solidification, resulting in microstructural banding and local fluctuation of MS and BS temperatures. When the applied isothermal transformation temperature is lower than the local MS value, an athermal martensite is formed during cooling. The effect of the athermal martensite on the strength, plasticity and ductility of nanobainitic steel can be positive or negative, depending on its content, morphology and degree of carbon supersaturation. The subject of the study was a nanobainitic steel with reduced carbon content compared to classic grades ($C \geq 0.6\text{wt}\%$), containing 0.5C-2.0Mn-1.6Si-1.6Cr-0.55Mo (NBLC-NanoBainiticLoweredCarbon), intended for the manufacture of steel plates up to 20 mm thick. The main purpose was to determine heat treatment parameters that provide a beneficial ratio of strength to plasticity and ductility of the investigated steel characterized by a significant degree of chemical segregation. The steel was melted and cast in a vacuum furnace, the ingot was forged into flat bars and then hot-rolled into 15 mm and 8 mm thick plates. Based on dilatometric studies, the characteristic temperatures of Ac1, Ac3 and MS were determined and a part of the TTT diagram was developed in the temperature range of 205-255°C. The contents of Si, Mo, Cr and Mn in the segregation bands were determined using the EDS-SEM method. On the heat treated samples HV10 and HBW hardness measurements, static tensile tests, Charpy KV impact tests, and microstructural studies by LM, SEM, TEM and XRD methods were carried out. The most beneficial combination of mechanical properties of NBLC steel was obtained after two-stage isothermal heat treatment at temperatures of 235°C and 225°C: tensile strength 2.0 GPa, yield strength 1.3 GPa, total elongation 14%, hardness 600 HV and impact toughness KV: 17J at +20°C, 11J at -40°C and 10J at -60°C. The relationship between microstructure and mechanical properties was analyzed, and a hypothesis was formulated on the possibility of reducing the negative effect of chemical segregation on the mechanical properties of NBLC steel.

Solid-state phenomena in advanced bainitic steel through in-situ S/TEM observations

Dr. Aleksandra Królicka, Poland

Oral Presentation (20')

Abstract

Dynamics in processes and matter observed using in-situ S/TEM microscopy methods provide an outstanding capability for better understanding the complex phenomena in the nanoscale. Solid-state phenomena occurring in steels are mainly observed using a multidimensional approach involving ex-situ conditions. Dynamic microscopy constitutes a research method that supports direct analysis of phenomena that cannot be identified using other research techniques.

Advanced, ultra-fine bainitic steel was designed to stabilize the B2-ordered phase (NiAl) [1]. The chemical composition of tested steel follows Fe-0.4C-8.0Ni-2.8Al-0.8Cu (wt.%), and the design approach was described elsewhere [2,3]. The aim of this study is to understand the precipitation processes of intermetallic during aging processes, the decomposition mechanism of the metastable bainitic structure during reverse transformation [4], and bainite formation during low-temperature transformation. The experiments were performed using the MEMS heating holder and dynamic electron microscopy S/TEM observations. The applied thermal cycles enabled the observation of the precipitation processes of the NiAl intermetallic phase and the reverse transformation of the bainitic structure into austenite. The dynamic precipitation processes of the L12 and B2 phases were evaluated as a function of temperature together with the decomposition mechanisms of the bainitic matrix. Finally, the bainitic transformation at 250 °C was conducted inside the microscope column. The grain boundary and autocatalytic nucleation were observed during bainitic transformation. Moreover, the austenite memory effect was observed. Despite certain limitations of the in-situ S/TEM method, the occurrence of crucial phenomena associated with the bainitic transformation was evidenced.

Decomposition of carbide-free bainite during prolonged holding at bainite transformation temperatures

Dr. Philipp Retzl, Austria

Oral Presentation (20')

Abstract

TRIP-assisted steels rely on retained austenite in their microstructure, which enables the so called TRIP-effect. Alloying with sufficient amounts of Si or Al is employed to suppress carbide formation during the bainite transformation to allow for enrichment of austenite with carbon during bainite formation and thereby stabilizing it down to room temperature. While Si or Al can suppress carbide formation in carbide-free bainite for durations typically employed for bainite transformation (e.g., several minutes), prolonged holding at the transformation temperature eventually leads to carbide formation in the austenite areas. These precipitates reduce the carbon concentration in austenite, destabilizing it and promoting martensite formation upon quenching. To understand this decomposition process is crucial to optimize large-scale production of TRIP steels, where steel often cools down in large coils and therefore the time to reach room temperature can be up to several hours, leading to a reduced TRIP-effect.

To investigate this behaviour, samples of a steel containing 0.4 wt% C, 1.5 wt% Mn, and 1.5 wt% Si were austenitized at 950 °C and then quenched with 50 K/s to bainite transformation temperatures ranging from 450 to 350 °C. The samples were held at these temperatures for up to 10 hours. The heat-treatment was done on a Dilatometer Baehr Type 805. A combination of XRD and EBSD investigations was used to examine the decomposition process.

Thermal Stability of Nanostructured Bainitic Steels: Investigating the Microstructural Changes and Mechanical Properties After Reheating

Dr. Behzad Avishan, Turkey

Oral Presentation (20')

Abstract

Nanostructured bainitic steel, also known as super bainite, represents a significant advancement in third-generation AHSS, combining high strength, ductility, and toughness properties. Exceptional strength and ductility properties result from a unique microstructure consisting of nanoscale bainitic ferrites and austenite films in bainitic sheaves, separated with austenite blocks. It is essential to study the thermal stability of the microstructure and resultant mechanical properties at temperatures higher than that of the bainite forms. This is particularly important for high-temperature applications or in scenarios where the temperature of an engineering component increases during service. This study investigates the microstructural variations and corresponding changes in mechanical properties in super bainite achieved by isothermal bainite heat treatment at 250 and 300 °C after reheating to the temperature range of 300-700 °C. Microstructural features were characterized using field emission gun scanning electron microscope and X-ray diffraction methods, and consequently, hardness, tensile and Charpy impact tests were carried out to study the resultant strength and ductility combination. It has been shown that reheating the originally achieved super bainite up to 400 °C didn't affect the microstructure and mechanical properties, indicating considerable thermal stability. However, cementite precipitation, austenite decomposition to pearlite, cementite spheroidization and complete decomposition of the microstructure to spherical cementite particles distributed within a ferritic matrix occurred at elevated temperatures. While yield strength, ultimate tensile strength, elongation and impact energy of the super bainite remained unchanged until heating to 400 °C, different strength-ductility combinations and impact toughness energy values were achieved at different heating temperatures depending on the corresponding microstructural variations. It has been shown that, big austenite microblocks are susceptible to decomposition to pearlite, despite the austenite films that are thermally more stable. Cementite precipitation was more pronounced in nanobainite with higher dislocation density, as dislocations acted as potential diffusion paths for carbon, accelerating the cementite precipitations. Finally, results approved that the tempering behavior of the same steels with martensite in their microstructure was different from that of austempered materials, indicating the higher tempering resistance of nanostructured bainite compared to that of martensite.

Paper 746 **6** **Phase transformation behaviour in a laser powder bed fusion produced maraging steel**
Mrs. Ana Santana, Spain
Oral Presentation (20')

Abstract

In conventional manufacturing, maraging steels present a martensitic structure hardened by precipitation during ageing at a specific temperature and time period. In contrast, Laser Powder Bed Fusion (LPBF) produced maraging steels consist of mainly martensite and some retained austenite with intrinsic thermal cycles promoting early stages of precipitation for a given set of parameters. As a result, the two manufacturing routes produce distinct microstructures. Understanding how these phase transformation differences affect the microstructure is essential for its control, strategic use and to avoid compromising the mechanical integrity of the final part.

This work investigates how changes in the layer thickness and laser emission mode affect the metallurgical phenomena (i.e., the martensite-to-austenite transformation and precipitation of intermetallic phases) during printing—melting, rapid solidification, and repeated heating and cooling. Microstructural characterisation techniques and multiscale chemical analyses were performed to examine as-built samples and those aged at 480 °C and 540 °C.

Scanning Electron Microscopy allowed to identify layer thickness as a key parameter influencing the solidification cell size in as-built samples. For all conditions, X-ray diffraction results showed that the tetragonality of martensite remained consistent across layers despite successive reheating cycles. Retained austenite was found both at and away from melt pool boundaries at the mesoscale in the as-built structure and its volume fraction increased with ageing temperature. Electron Probe Micro Analysis results showed that mesoscale Cr segregation and Ni and Ti depletion caused by competing mechanisms during printing, persists even after ageing. No significant impact of the printing parameters on microstructural evolution during ageing was observed. However, nanoscale clustering and precipitation in aged samples differ from those found in conventionally processed materials. Finally, hardness values of aged LPBF-maraging steel samples were found to be comparable to those achieved in samples processed by conventional manufacturing methods, highlighting the potential of this technique to produce end-use parts.

Paper 1319 1 Additive Manufacturing of Fe-Mo-W-C high thermal conductivity steel by electron beam and laser powder bed fusion

Dr. Eduard Garcia Llamas, Spain

Highlight (Oral Presentation 20')

Abstract

Metal forming tools are subjected to harsh conditions, including fluctuating temperatures and repeated wear. Additively Manufactured (AM) carbide-reinforced steels have demonstrated significant advantages in such applications, as the added geometrical freedom enables optimized tool design while reducing both production complexity and lead time. This study evaluates a novel high thermal conductivity steel (HTCS) developed using alloying and processing methods patented and pioneered by the Spanish company ROVALMA, aiming for short cycle times and long tool lifetimes in processes such as hot stamping, die casting, and forging. HTCS powder was atomized by INNOMAQ21 and fabricated using two additive manufacturing techniques: Electron Beam Powder Bed Fusion (PBF-EB) and Laser Powder Bed Fusion (LPBF). Samples were produced across a wide range of process parameters and analyzed using microscopy, microindentation, and spectroscopy. For PBF-EB, the as-built microstructure exhibited a hardness of approximately 390 HV, with elongated grains oriented along the build direction and separated by boundaries containing Mo precipitates. The optimal process window for PBF-EB was found to be above 2 J/mm², with no balling observed even at 1200 W and 6000 mm/s, indicating excellent potential for high throughput. LPBF was conducted using high-temperature module to obtain comparable conditions of powder bed as in EBM. Temperature increase allowed to avoid cracking and perform in-situ heat treatment of the material during LPBF. As-build samples presented comparable hardness, while after the post heat-treatment in the dilatometry furnace they featured various changes in the hardness. Both techniques yielded promising results in terms of manufacturing efficiency and unique microstructure features.

Paper 1318 2 **Optimizing Tool Steel Performance through Additive Manufacturing: Exploring PBF-EB and PBF-L Technologies**
Mr. Jakub Ciftci, Poland
Oral Presentation (20')

Abstract

Additive manufacturing, particularly 3D printing, offers significant potential for design optimization and the production of limited series components, aligning well with several industrial and economic sectors. However, the technology is currently constrained by a limited selection of available materials. In the case of tool steels, the choice is often restricted to costly superalloys or high-alloy steels, such as Maraging grades. Despite their higher cost, these materials fall short of conventional tool steels in terms of durability and performance. This study aims to explore and demonstrate strategies using two 3D printing technologies—PBF-EB (Powder Bed Fusion-Electron Beam) and PBF-L (Powder Bed Fusion-Laser)—to produce cost-effective, high-performance steel based on the high-carbon grade 1.2842 (90MnV8). LPBF was conducted using a high-temperature module to achieve powder bed conditions comparable to those in EBM. The increased temperature helped prevent cracking and enabled in-situ heat treatment of the material. Both techniques demonstrated promising results in terms of manufacturing efficiency and the development of unique microstructural features. Additionally, samples from both technologies underwent distinct heat treatment processes. Microstructural phase changes were analyzed using scanning electron microscopy (SEM) and X-ray diffraction (XRD).

- Paper 1272 3** **Understanding the effect of laser powder bed fusion thermal cycles on the microstructure of a tool steel**
Mrs. Nisrine El Hamouchi, Spain
Oral Presentation (20')

Abstract

Laser Powder Bed Fusion (LPBF) is an advanced additive manufacturing technique used to produce complex components layer-by-layer by scanning the cross-sections of a 3D CAD model with a high-intensity laser. During the LPBF process, materials are exposed to extreme and rapid thermal cycles, characterized by high heating and cooling rates, as well as localized melting and solidification. These unique temperature profiles differ significantly from those encountered in conventional manufacturing methods, resulting in highly heterogeneous microstructures in the additively manufactured parts. To simulate the thermal behaviour of the LPBF process and its impact on microstructural evolution, an ultra-fast heating experiment was conducted using a dilatometer on a conventional tool steel sample. This approach aimed to replicate the thermal cycles experienced during LPBF by achieving comparable peak temperatures and rapid temperature transitions. The microstructural analysis focused on a two-layer printed steel model to understand changes in phase distribution, grain refinement, and thermal-induced transformations such as carbide precipitation and variations in dislocation density. These findings provide valuable insights into the thermal response of tool steels during additive manufacturing processes and propose methods for reproducing LPBF-like thermal cycles, enhancing material design and performance optimization in advanced manufacturing contexts.

- Paper 518 4** **Additive Manufacturing of low alloyed 90MnCrV8 tool steel**
Mr. Carlos Botero, Sweden
Oral Presentation (20')

Abstract

The development of an electron beam powder bed fusion (PBF-EB) process for 90MnCrV8 aims to leverage the advantages of additive manufacturing (AM) for producing high-performance tool steels. In PBF-EB, it is possible to utilize microstructural engineering, and the aim is to develop such hardening mechanisms to increase the performance of low alloyed steels, to compete with less environmentally friendly alloys in terms of performance. This study takes a new approach for heating the feedstock powder, where a polar-hexagonal spot heating is used rather than the standard linear rastering. The polar-hexagonal heating and melting strategy were developed and used to produce solid samples from gas atomized 90MnCrV8 feedstock. The optimized EB-PBF process demonstrated the ability to produce fully dense parts which were analyzed using scanning electron microscopy (SEM) and X-ray diffraction (XRD).

Alloy design strategy for the development of nanostructured bainitic surface layer in gear steels for wind turbines applications

Prof. Francisca Garcia-Caballero, Spain

Oral Presentation (20')

Abstract

Wind energy is ideally placed to be the European Green Deal's technology of choice since it is the most efficient solution to reduce emissions in the power sector. Europe installed 18.3 GW of new wind power capacity in 2023, a record amount but only half of what it should be building to meet its 2030 climate and energy targets, which requires to install 260 GW of new wind power capacity over 2024-2030. To meet its 2030 climate and energy targets the EU now needs to build 33 GW a year on average.

It is well-known that turbine towers are becoming taller to capture more energy. The hub height for utility-scale land-based wind turbines has increased 73% since 1999, to about 100 meters in 2022. The average hub height for offshore wind turbines is projected to grow even taller to about 175-200 meters in 2035. Moreover, the average rotor diameter of newly-installed wind turbines was over 150 meters in 2023. Wind turbines have also increased in maximum power rating, or capacity. Today's new wind power developments have a turbine capacity up to 6 MW range onshore and up to 15 MW offshore. Gearboxes are a highly loaded part of wind turbines, which is facing numerous challenges the coming years due to upscaling and torque density increase. In this work we will design new ultra-high strength steels for gears, to ensure the increasing gear operating conditions in terms of reliability, performance and compactness that manufacturers demand by wind turbines with higher mechanical torque.

The aim of our alloying design strategy, based on thermodynamic and kinetics data, is to form nanoscale bainitic structures within the carburised layers of medium and large-size gears for on- and offshore wind turbines, by means of alternative heat treatments on propane and plasma carburising in atmospheric pressure furnace limiting at maximum oxide formation during carburising, and a subsequent austempering on low/medium high-silicon steel grades, specially designed as base material.

For that purpose, two digital tools (JMatPro and Mucg83) were extensively validated using phase transformation data of commercial steels for gears manufacturing. Then alloying additions were modified to ensure large austempering windows based on Bs and Ms calculations in carbon carburising profiles, as well as good hardenability, needed to avoid soft phases at the core of the component. Moreover, chemical composition was adjusted to ensure nanoscale bainite formation at the surface in an austempering holding time below 10 hours.

Paper 2123 6 **Carburizability and transformation kinetics of new high silicon steel alloys for nanostructured bainitic surface layer in wind turbines applications**

Mr. Gabriel Ebner, Germany

Oral Presentation (20')

Abstract

Wind energy is a key enabler of the European Green Deal, offering the most effective means of reducing emissions in the electricity sector. In 2023, Europe set a record by installing 18.3 GW of new wind power capacity. However, this falls short of the pace required to achieve the 2030 climate and energy objectives. To stay on track, Europe must add 260 GW of new wind capacity between 2024 and 2030, requiring an annual installation rate of 33 GW on average.

Wind turbines are becoming progressively larger and taller, with power ratings reaching 5 -6 MW for onshore installations and 14-15 MW for offshore systems. As a result, gearbox design faces growing challenges, as larger gears push the limits of traditional case-hardened gear steels. Additionally, the need for lightweight designs is gaining importance to minimize static loads on the tower and nacelle.

Within the project framework of NanoWinTur new gear steels are to be developed for the demanding application in future gear boxes. The talk will address the overall carburisability of six different newly developed case hardening alloys containing high amounts of silicon to achieve carbide free bainite. The carburisability was investigated especially against the background of high silicon content reducing the carbon activity in steels and significantly hampering the carburization. Both gas carburizing and low pressure carburization were tested.

For certain carbon contents the transformation behaviour into martensite and austempering kinetics are investigated in dilatometer. The results of the analyses are presented and discussed.

Paper 890 **1** **Revealing the history of white etching layer formation by correlative multiphysical characterization**
Dr. Oleksandr Glushko, Austria
Highlight (Oral Presentation 20')

Abstract

The surface of a railway track is exposed to harsh conditions: compressive load, severe plastic deformation, frictional heat, and rapid cooling. Such a complex thermomechanical loading can lead to the formation of so-called white etching layers (WELs) – hard and brittle near-surface regions, that can induce surface damage or even rail failure. The exact mechanisms responsible for appearance of WELs is still a matter of debate since multiple kinetic phenomena are acting simultaneously, rapidly, and spatially localized. To take a closer look at the WEL formation mechanisms, we applied multiple characterization approaches in a correlative manner, covering different length scales and different measurement principles. A single WEL and its interface to the bulk was first characterized by nanoindentation mapping followed by electron microscopy, high-energy XRD as well as atom probe tomography to pinpoint the exact structural changes, which are responsible for the specific morphology and properties of the WEL. It is proved that austenitic transformation has occurred within the WEL, suggesting that its microstructure is, at least partially, martensitic. At the same time, the WEL is characterized by normally distributed circular grains with the average grain size of about 400 nm. Such microstructure is not typical for a martensite. Atom probe tomography reveals a very sharp transition between the WEL with fully dissolved cementite and deformed pearlite with fully undissolved (though mechanically fractured) cementite. This observation contradicts with the model of progressive WEL development over large number of cycles. Based on the correlative characterization data we formulate a model suggesting that WELs can be formed through a single event of substantial wheel slippage. In this scenario, high temperatures required for material austenitization are reached not only due to the frictional heat generated on the rail surface, but also due to the volumetric heat caused by severe plastic deformation with high strain rate. Although the developed model does not pretend to be the only mechanism of WEL formation, it is crucial to understand whether WELs appear as a results of multiple loading cycles or due to a single event as well as whether shear plastic deformation or frictional heat is a dominant factor responsible for WEL formation. The mitigation strategy should be then adjusted according to the active WEL formation mechanism, e.g. prevention of a fatigue-based effect requires different measures than prevention of single slip events.

Paper 536 2 **Role of cementite precipitation in lath martensite revealed by rapid tempering and conventional tempering treatments of medium-carbon steel**
Dr. Sujith Surendran Vijayamma, Italy
Oral Presentation (20')

Abstract

Rapid tempering offers an energy saving process similar to induction heating and generates wide opportunity for the achievement of desired mechanical properties in several fields, for example in the automotive sector. Since the introduction of the tempering parameter, it has been successfully applied to a variety of steel alloys across a wide range of time–temperature combinations. The present study reveals promising mechanical properties with rapid tempering (20 s) as compared to conventional tempering treatment (1 h) of as quenched C45E martensitic steel, for the same tempering parameters. FESEM reveals that nanometer sized finer cementite is more evenly distributed in rapid tempered samples as compared to the conventional tempering. Fracture mechanisms and percentage elongation stood compliment to the cementite precipitation occurred in the tempered martensite under various tempering regimes (from 250 °C to 700 °C).

Paper 996 3 **Microstructural optimization and mechanical behavior of SS-QP treated 30CrNiMo8 steel**
Mr. Marco Belfi, Italy
Oral Presentation (20')

Abstract

The quenching and partitioning (QP) process aims to achieve superior mechanical properties and enhanced toughness by developing a microstructure consisting of martensite and retained austenite. In this study, single-step QP treatments (SS-QP) were applied to the commercial 30CrNiMo8 steel, a material widely used in industrial high-strength applications but not specifically engineered for this process. Preliminary studies on the initial microstructure are performed through the application of different routes for intercritical treatments. Microstructure evolution was examined using XRD and SEM/EBSD, while tensile tests were conducted to evaluate the impact of the treatment on the final properties of the material. SS-QP treatments were successfully implemented, delivering high tensile strength and improved ductility. Strain hardening behavior was analyzed and compared with specimens treated using conventional quenching and tempering treatments. The results demonstrate the feasibility of applying the QP process to 30CrNiMo8 steel and highlight the importance of initial microstructural control and treatment design in achieving desired mechanical performance.

Paper 649 **4** **An in-situ analysis of the kinetics of κ -carbide precipitation in Fe-Mn-Al-C low density steels**

Mr. Juan Emilio Rey Castañeda, Spain

Oral Presentation (20')

Abstract

The reduction of energy consumption is together with improving safety standards paramount in modern transportation. In this regard, the development of strong, tough, and ductile steels for automotive applications is an essential part in steel research. Low density Fe-Mn-Al-C steels are promising candidates for structural forged parts owing to their capability to contribute in reducing the vehicle weight mainly achieved through alloying with aluminium (Al) (~1.3% density reduction per 1 wt.% Al). The alloying elements not only promote the formation of austenite but also of carbides such as κ . The κ -phase is particularly important for enhancing strength due to its hardening effect. However, to effectively manage the precipitation, namely the size and distribution of the κ -phase within these alloys, poses the challenge of understanding the phase transformation kinetics during quenching and subsequent aging.

In this study, time-resolved analysis of κ -phase precipitation is conducted during heat treatments using in-situ high-energy synchrotron X-ray diffraction (HEXRD), enabling for real-time observation of phase transformations. After solution treatment of the Fe-Mn-Al-C alloy, the kinetics of kappa are investigated as a function of the cooling rate and aging conditions. The obtained samples are then characterized using both optical and scanning electron microscopy (SEM), as well as hardness testing.

Results from in-situ HEXRD indicate that slow cooling (<1°C/s) promotes local κ -phase growth along austenitic grain boundaries, whereas rapid cooling (>21°C/s) leads to a dispersed formation of the κ -phase. The results are contrasted with the diffusion-controlled mechanisms of κ -phase precipitation.

The findings cannot be acquired through conventional post-mortem characterization and offer novel information for optimizing the thermal treatment conditions of low density steels.

Paper 562 **5** **Deformation-Induced Microstructural Evolution in a High-Nitrogen Stainless Steel: A Detailed EBSD Study**
Mrs. Marine Barrabé, France
Oral Presentation (20')

Abstract

Due to upcoming regulatory changes, the use of medical devices containing cobalt will be severely restricted. As a consequence, it is urgent to find alternatives to cobalt-chromium alloys, widely used to produce dental prosthetic structures. As a promising alternative, the BioDur 108® alloy, a nickel-free high-nitrogen austenitic stainless steel (HNSS) has been investigated in this work. In addition to its excellent biocompatibility and good corrosion resistance, it presents favorable mechanical properties which can even be further improved through cold-working for specific demanding applications. While already commercial for some specific applications, only limited information is available on the microstructure-property relationships. Therefore, in this work, an extensive microstructural investigation including the impact of prior deformation on its final mechanical properties has been completed. For this purpose, cold-rolling, as well as classic and SEM-EBSD in-situ tensile testing were conducted, allowing the monitoring of the evolution of mechanical properties and microstructure during deformation. The results showed that deformation is mainly based on dislocation glide, and mechanical twinning appears beyond a certain threshold. Furthermore, with increasing deformation, the twin boundaries interact with dislocations, improving the material's strength and causing the reorientation of thermal twins. It is worth noting that this alloy has a significant strain-hardening capacity while maintaining good ductility, and it does not form martensite even under high stress, thus remaining non-magnetic and MRI-compatible. These findings suggest that BioDur 108® is a highly promising candidate for replacing Co-Cr alloys.

THICKNESS-DEPENDENT INTERFACE AND SURFACE POLARITY IN INFINITE-LAYER NICKELATE FILMS AND SUPERLATTICES

Prof. Peter A. van Aken, Germany

Highlight (Oral Presentation 20')

Abstract

The interplay between polarity, atomic structure, and electronic properties at oxide heterointerfaces and surfaces is a fundamental factor governing emergent quantum phenomena in correlated oxides. In infinite-layer nickelates, polarity-driven reconstructions are hypothesized to play a pivotal role in shaping their unique electronic behavior, particularly in superconducting thin films. Here, we investigate the thickness-dependent interface polarity, oxygen distribution, and atomic-scale distortions in NdNiO₂/SrTiO₃ superlattices and Pr_{0.8}Sr_{0.2}NiO_{2+x} thin films through a comprehensive multi-modal characterization approach, combining four-dimensional scanning transmission electron microscopy (4D-STEM) and electron energy-loss spectroscopy (EELS).

In NdNiO₂/SrTiO₃ superlattices epitaxially grown on SrTiO₃ (001) substrates, we uncover a progressive modulation of the oxygen content across the nickelate layers, indicative of a polar-driven interfacial reconstruction. The extent of this reconstruction is found to be thickness-dependent, with cation displacements reaching ~0.025 nm in 8NdNiO₂/4SrTiO₃ superlattices—twice as large as those observed in their 4NdNiO₂/2SrTiO₃ counterparts. These pronounced structural distortions suggest a strong orbital polarization emerging post-reduction, corroborating theoretical predictions of two-dimensional electron gas formation at pristine NdNiO₂/SrTiO₃ interfaces. Such observations highlight the critical influence of interfacial polarity in dictating electronic properties within reduced nickelates.

Concurrently, in Pr_{0.8}Sr_{0.2}NiO_{2+x} thin films, we directly visualize a strong surface reconstruction characterized by polar distortions and octahedral rotations. Atomic-resolution EELS measurements reveal spatially varying Ni valence states, closely correlated with local atomic electric field mapping. These variations are attributed to oxygen vacancy formation induced by topochemical reduction, leading to significant electrostatic effects at the surface. The spatial extent of these surface distortions is confined to approximately three unit cells, underscoring the intrinsic role of polarity-driven structural modifications in tuning the electronic phase landscape of nickelates.

Our findings provide direct evidence of polarity-mediated structural reconstructions at both interfaces and surfaces in infinite-layer nickelate systems. By elucidating the correlation between oxygen content modulation, atomic-scale distortions, and electronic reconstructions, we offer critical insights into the fundamental mechanisms underpinning quantum phenomena in reduced nickelates. These results have profound implications for the design and optimization of nickelate-based quantum materials, particularly in the context of high-temperature superconductivity, where interfacial and surface polarity effects may serve as key tuning parameters for emergent electronic states.

Paper 1612 2

High sensitivity electron holography combined with in situ biasing for studying dielectric and ferroelectric nanocapacitors.

Dr. Leifeng Zhang, France

Oral Presentation (20')

Abstract

Dielectric and ferroelectric materials are ubiquitous in microelectronic devices because of their ability to polarize in response to an applied electric field. They spur much fundamental and applied research over the years: the ability to measure polarisation locally and charge trapping is essential to furthering understanding and to develop a new generation of devices. Whilst ferroelectric and dielectric properties can be readily measured macroscopically using electrical methods, the task is difficult at the nanoscale and for thin-film materials.

In this presentation, we will show how the internal electric fields can be quantitatively mapped at the nanoscale within different dielectric and ferroelectric nanodevices using in situ electrical biasing and off-axis electron holography. For this purpose, we have implemented the dynamic microscope automation associated to a dedicated instrumental chain. Using a real-time measurements of sample drifts and interference fringes, followed by feedback control of the microscope to compensate for instrumental instabilities, this automation allows holograms to be acquired with unlimited exposure times and the implementation of sophisticated phase reconstruction techniques. The signal-to-noise ratio has thus increased by more than an order of magnitude and it is now possible to measure phase variations of a few mrad with a spatial resolution of 1 nm (for an electrostatic potential, this corresponds to variations of a few mV). The instrumental chain ranges from source-meter control software to the various protection systems against electrostatic discharges on electrically connected nanostructures. For example, the capacity of a nanocapacitor prepared for electron transparency does not exceed 1 fF (10⁻¹⁵ F).

We studied twin trilayer nanocapacitors, HfO₂/Al₂O₃/HfO₂ and Al₂O₃/HfO₂/Al₂O₃ and also a ferroelectric Hf_{0.5}Zr_{0.5}O₂ (HZO) tunnel junction. Our results highlight the presence of trapped charges at the different dielectric/dielectric and ferroelectric/dielectric interfaces with a strong effect on the distribution of the internal electric field. The trapped charge densities depend on the stacking sequence (leading to different interfacial layers in terms of defects due to different processing) and the sign of the bias. In addition, we succeeded to map the polarisation switching of the HZO film as the voltage gradually increases to the coercive voltage, observing that switching occurs via the nucleation and lateral growth of domains.

This ability to determine the internal electric field in a large field of view and to quantify the trapped charge densities at each of the interfaces in the stack open avenues to engineering and optimize nanodevice performances.

Atomic resolution DPC-STEM imaging of magnetic signal in antiferromagnets

Dr. Jan Michalička, Czech Republic

Oral Presentation (20')

Abstract

Efficient manipulation of antiferromagnetic (AF) domains and domain walls has opened up new avenues of research towards ultrafast, high-density spintronic devices [1,2]. AF domain structures are known to be sensitive to magnetoelastic effects, but the microscopic interplay of crystalline defects, strain and magnetic ordering remained largely unknown. We have explored antiferromagnetic CuMnAs thin films in which imaging by X-ray photoemission electron microscopy (XPEEM) revealed that its AF domain structure is dominated by nanoscale crystalline defects [3]. The results emphasized the crucial role of these defects in determining the AF domains and domain walls, and provided a route to optimizing device performance in term of scaling limits for the data density in the bulk of the antiferromagnet. However, even smaller magnetic objects were indirectly observed in the material, but they remained below the detection limit of the established XPEEM methods.

Here, we achieved atomic resolution imaging of abrupt AF magnetic domain walls in CuMnAs epilayers by utilizing scanning transmission electron microscopy (STEM), differential phase contrast (DPC) and 4D-STEM techniques [4]. Identification of the magnetic domain DPC signal was based on the specific symmetry of the CuMnAs crystal, where the opposite magnetic Mn sublattices occupy crystallographically distinct noncentrosymmetric sites. With a focus on small field-of-view high-resolution imaging, we could associate the DPC-STEM signals with two types of abrupt Néel vector reversals: The first type occurs at a crystallographic antiphase boundary defect, while the second type forms in a part of the epilayer with no crystallographic perturbation detectable by STEM.

The DPC-STEM magnetic signal was reconstructed by calculating the shifts of the center of mass (COM) of Ronchigrams recorded by a pixelated detector. The signal intensities were plotted as a function of integrated [001] component of COM shifts corresponding to the direction of the Lorentz force due to sublattice magnetic Mn moments pointing in the (001) easy plane of antiferromagnetic CuMnAs. This qualitative assessment of the magnetic order in Mn sublattices was paradoxically possible in substantially thick TEM lamellae, above 50 nm, and with small collection angles, below 10 mrad, since dynamical diffraction effects can be of advantage for magnetic imaging, which was revealed by Pauli multislice STEM-DPC simulations [4].

Paper 1594 1 **Detection of magnetic circular dichroism from individual atomic planes in a scanning transmission electron microscope**

Dr. Hasan Ali, Sweden

Oral Presentation (20')

Abstract

In an analogy to XMCD[1], the discovery of electron magnetic circular dichroism (EMCD) in transmission electron microscope (TEM) in 2006 [2] opened the possibility of mapping the orbital and spin moments in magnetic materials with atomic resolution. In EMCD experiments, electron energy loss (EELS) spectra at specific conjugate scattering angles in the reciprocal space contain magnetic information and their difference, called EMCD signal, can be used to determine orbital to spin moments ratio by applying theoretical sum rules.

When conducting EMCD experiments in scanning TEM mode, the resolution of analysis is determined by the size of electron probe which, in modern probe-corrected STEMs, can easily reach atomic resolution. Yet, the detection of quantitative EMCD signals at atomic scales remains elusive due to challenges associated with convergent beam setups. The strength of EMCD signal generally goes down with increasing convergence angles. Most importantly, EMCD experiments need the acquisition of two or more momentum-resolved EELS spectra, which would require to scan the same region of the specimen multiple times in STEM-EMCD experiments. This poses additional challenges to ensure spatial registration with atomic precision among multiple datasets. In our previous works [3], we addressed this issue by performing single scan EMCD experiments using customized hardware apertures. Building on this approach, we now demonstrate quantitative EMCD detection at atomic-plane resolution in STEM-EMCD experiments for (110) atomic planes of an iron (Fe) crystal. We not only quantify EMCD signals extracted from individual atomic planes, but we also reveal variations in the orbital to spin moments ratio between adjacent atomic planes. This enables unprecedented sub-atomic resolution in STEM-EMCD experiments.

The atomic plane resolved STEM-EMCD experiments were conducted using a Thermofisher Titan G3 50-300 PICO fourth generation transmission electron microscope at Ernst-Ruska Center for Microscopy and Spectroscopy using Electrons (ERC), Forschungszentrum Jülich, Germany. This microscope is equipped with a Schottky-type high-brightness electron gun (FEI X-FEG), a monochromator, a CS probe corrector (CEOS DCOR), a CS-CC achro-aplanat image corrector (CEOS CCOR+), a post-column imaging energy filter (Gatan Quantum 966 ERS) and a Gatan K3 direct electron detector.

Paper 1149 2

Enhancing the photocatalytic performance of carbon nitrides through controlled local structure modification

Dr. Nadezda Tarakina, Germany

Oral Presentation (20')

Abstract

Carbon nitrides are the most efficient and intensively studied earth-abundant photocatalysts. Their direct application in industry is prevented by several factors, including high recombination rate, deficient charge transport, and the lack of absorption above 460 nm. Here we investigate how the photocatalytic performance of layered carbon nitrides can be enhanced through: (1) fine tuning of the local crystal structure, using poly(heptazine imides) (PHI) with various cations ($M = H^+, Na^+, K^+, Mg^{2+}$) as a model system; (2) creating a heterojunction between PHI and e.g. poly(triazine imide) (PTI). We combined X-ray powder diffraction, low-dose HR-TEM and ADF-STEM imaging, energy filtered electron radial distribution function (EF-eRDF) analysis obtained from rotational electron diffraction data, valence electron energy loss spectroscopy, ELNES and EXELFS analysis in order to obtain a detailed understanding of the local structure, chemistry and electronic properties of modified PHIs and correlate it with photocatalytic performance.

For M-PHIs with various cations ($M = H^+, Na^+, K^+, Mg^{2+}$) we showed that both the short-range order (due to the sizes and charges of the solvated metal cations) and the medium-range order (due to the formation of twist domains between carbon nitride layers) considerably influence the photocatalytic hydrogen evolution rate. Na-PHI displays the best performance among other PHIs with metal cations in oxidation state +1, as the size of the solvated Na^+ cation, together with the presence of the rotational defects, enables cations to occupy positions in the channels equidistantly from nitrogen in polyheptazine layers. The combination of twist defects and the even higher charge of Mg^{2+} promotes a faster interlayer charge transfer and a more efficient polarization of the heptazine backbone in Mg-PHI, leading to an unprecedented quantum efficiency of 7.14%. The formation of a PHI/K-PHI heterojunction was realized for the first time and showed an improved photocatalytic O_2 reduction performance compared to pure phases. We explain the latter by the specific structural alignment of the polymeric phases along the c-axis, which enabled an improved charge transfer between PTI and PHI. Based on an analysis of SE- and ADF-STEM images, ELNES and EXELF, and the general thermochemical behavior of precursors we proposed a possible mechanism for the heterojunction formation. We believe that at the early stages a thin PTI layer is formed; K-PHI starts to crystallize at the defect sites of PTI inside the gas pockets formed in the salt melt.

We gratefully acknowledge financial support by the Max Planck Society.

Accurate nanoscale temperature determination in in-situ TEM heating using PEET

Prof. Joerg Jinschek, Denmark

Oral Presentation (20')

Abstract

In-situ scanning/transmission electron microscopy (S/TEM) heating experiments are critical for understand thermally induced microstructure phenomena and dynamics in materials, such as phase transformations in alloys. Thereby accurate in-situ temperature measurements of the TEM specimen on the nanometer scale is essential to correlate the findings from in-situ heating experiments with other microstructure information, e.g. with predictions from phase-temperature and phase-time diagrams.

In this study, we utilized plasmon energy expansion thermometry (PEET) and use the dependence of the bulk plasmon peak in an energy electron loss spectrum (EELS) with temperature. Using COMSOL multiphysics modelling and in-situ STEM-EELS experiments, we tested PEET's validity and accuracy using a tungsten (W) test TEM sample. Tungsten serves as an ideal model material with its high melting temperature (above 3000 °C) and sharp plasmon resonance in EELS, which benefit PEET with a wide implementation temperature range and precise determination of the energy of the bulk plasmon peak. We evaluated the accuracy of PEET for mapping local temperatures in a tungsten TEM sample from room temperature to 700 °C. Linear regression of the shift in plasmon energy and corresponding temperature values yielded an achievable temperature resolution of ± 30 °C. Additionally, we investigated the impact of a varying, inhomogeneous sample thickness on PEET accuracy and found that uncertainties in temperature increased from 41 °C to 49 °C due to local stress effects during TEM sample preparation and a larger surface-to-volume ratio when the thickness varied between 30–40 nm and 60–70 nm. In case of tungsten, we have calibrated this thickness-dependent effect below a thickness of 60 nm and propose a method to correct for this deviation by taking into account the broadening of the bulk plasmon peak. Our findings demonstrate that PEET can provide quantitative temperature measurements on the nanometer scale when considering TEM sample thickness, thus improving the reliability of structure-property correlations in in-situ S/TEM heating experiments.

EDS and EELS of Lithium in a 0.5 to 30 keV Electron Microscope

Prof. Raynald Gauvin, Canada

Oral Presentation (20')

Abstract

This paper will present quantitative EDS and EELS maps of Lithium-based materials acquired from 0.5 to 30 KeV with a cryogenic specimen holder. State-of-the-art results acquired with the Hitachi SU-9000 dedicated STEM will be shown. This microscope has EELS capabilities that allow Li detection [1]. It is also equipped with the Extreme EDS system from Oxford Scientific that can detect the $K\alpha$ line of Lithium. Results on several Li compounds used in battery materials as well as Li-based minerals will be presented.

Correlation of feldspar crystalline phases with measurement artifacts in confocal Raman microscopy

Mr. Pablo Rabasco, Spain

Oral Presentation (20')

Abstract

Raman spectroscopy is nowadays increasingly being used in industry beyond the academic space. There are several reasons, including the use of portable Raman spectrometers which allows to perform analyses outside labs, the capacity of doing microscale/in-situ studies and also non-destructively analyses without special preparation of the samples. Among some applications, these advantages are particularly relevant in the study of mineral samples. One of the important point in Raman spectroscopy is the selection of the measurement laser wavelength. The use of 785 nm wavelength laser, practical for the study of highly fluorescence materials, is often avoided within this field due to the anomalous response usually observed in natural and synthetic minerals and in glass-ceramic specimens, that mask the structural Raman signal. To date, the cause of the phenomenology that gives rise to this type of response is not precisely known. The family of silica-based glass-ceramic materials exhibits an enhanced Raman signal in the region of 1000-2500 cm⁻¹ for this wavelength. The intensity and shape of the Raman signal seems to depend on the interaction between the glassy and crystalline parts of the microstructure and are usually associated with photoluminescence [1-5]. Therefore, the main objective of this work is to establish a correlation between the structural Raman response measured with a 532 nm laser with the artifact Raman response observed when using the 785 nm laser in feldspar crystalline phases such as anorthite and albite. For this purpose, different glass-ceramic materials were synthesized. The microstructures analyzed by confocal micro-Raman microscopy combines the use of two excitation wavelengths (532 and 785 nm) at selected regions, thus allowing to explain the role of each glassy and crystalline phase in the enhanced Raman response of the designed materials. In addition, different techniques such as X-ray diffraction (XRD) and scanning electron microscopy (SEM) were used to complement the microstructural characterization of the different glass-ceramic materials studied in this work.

New insights into luminance quantification via correlated photoluminescence and confocal Raman microscopy

Ph.D. María Fernández Álvarez, Spain

Oral Presentation (20')

Abstract

Spectroscopic techniques are fast, non-destructive and easy to apply, providing valuable structural and functional information for material analysis across different applications. However, a typical limitation is the difficulty of quantifying intensity (usually given in arbitrary units), as it depends on different factors like equipment, optical paths, illumination power and detector efficiency. These variations make it challenging to compare optical responses across different instruments. This work presents a novel methodology for correlating the arbitrary intensity units from a photoluminescence (PL) spectrometer and a high-resolution confocal Raman microscopy, with luminance values ($\mu\text{cd}/\text{mm}^2$), facilitating the quantitative analysis of luminescent materials.

To develop this methodology, reference composite samples were prepared by dispersing Eu_2O_3 particles (0.1–10 wt%) in an epoxy matrix to achieve a homogeneous distribution. These samples were characterized using photoluminescence spectroscopy, and their luminance was measured with a luminancemeter. The results demonstrated a clear correlation between the PL intensity (in arbitrary units) and the emitted luminance at a given excitation wavelength. Furthermore, since Eu_2O_3 exhibits photoluminescence emissions under certain excitation conditions, we extended this approach to confocal Raman microscopy.

The results demonstrate that the photoluminescence intensity (in arbitrary units) measured with a PL spectrometer and with a confocal Raman microscopy can be quantitatively related to luminance ($\mu\text{cd}/\text{mm}^2$) obtained from a luminancemeter. It was also found that the optical response of these Eu_2O_3 -epoxy composites does not follow a strictly linear relationship with concentration, highlighting the necessity of developing reference samples across a defined concentration range for accurate calibration. Therefore, constructing reliable calibration curves is essential for precise luminance quantification.

The proposed methodology was validated, demonstrating its applicability in anti-counterfeiting applications, specifically in the quantification of luminescence in cotton-type paper doped with Eu_2O_3 , similar to that used in security documents. Thus, it has been observed that this methodology allows the quantification of luminance at both macro and microscopic scales by confocal Raman microscopy, offering a simple and versatile tool to detect security markers in forensic applications.

Ultimately, this study enables luminance quantification in both photoluminescence and Raman spectrometers, with potential industrial and scientific applications. It also introduces a new approach to analyzing luminance at the microscopic scale, offering unprecedented luminescence correlation for various emerging applications.

In-situ insights into interfacial processes at reactive liquid-solid interface during magnesium corrosion using cryo-atom probe tomography

Dr. Tim M. Schwarz, Germany

Highlight (Oral Presentation 20')

Abstract

Interfacial reactions at liquid-solid interfaces especially corrosion has a critically impact on the infrastructure degradation and sustainability (1), failure of functional materials such as battery systems (2) and in medicine for biodegradable implants (3).

For the application of biodegradable metals, Magnesium (Mg) has a great potential however, Mg alloys corrode rapidly and uncontrollably, through mechanisms not fully understood. Consequently, there are still open questions regarding the influence of different alloying elements, their distribution and different electrolytes on the corrosion processes. Understanding the interfacial processes at the reactive liquid-solid interface that are responsible for the degradation mechanism requires analytical methods with high local and chemical analysis capability and ideally to measure these reactions in-situ, on an atomic length scale, which is currently lacking. Atom probe tomography (APT) provides analytical imaging in 3D with equal chemical sensitivity across the periodic table even for light elements such as nitrogen, carbon and hydrogen and with comparable spatial resolution and can therefore close the gap.

By correlating cryo-APT and transmission-electron microscopy, we observed outward growth of Mg hydroxide and inward growth of an intermediate corrosion layer of hydr/oxydes with different compositions during the corrosion of a MgCa alloy using deionized water. The high chemical sensitivity of APT revealed that instead of a MgO layer between the hydroxide and the surface of a Ca-containing Mg alloy, a Mg(OH) layer was formed, into which Ca partitions (4). The observation of a metastable defect phases at the reactive interface was possible, yet these early reaction products are highly reactive and must play a critical role in accelerating the corrosion.

We demonstrated a new approach where it is possible to quasi-"in-situ" analyse the reactive interfacial processes at the liquid-solid interface by APT and investigate the early corrosion mechanisms of a Mg alloy. However, a better understanding of these early stages of corrosion and their products is necessary to advance the understanding of corrosion processes and their modelling, and consequently for higher level of control over the biodegradation rate of future implant material.

This method could be applied to a wide range of systems to provide new insights into the interfacial processes responsible for the degradation of, for e.g., catalysts or battery materials.

Evaluating Techniques for Identifying Isotopically Spiked Non-Metallic Inclusions in Steel

Dr. Kathrin Thiele, Austria

Oral Presentation (20')

Abstract

Non-Metallic Inclusions (NMIs) are primarily microscopic particles, typically in the size range of a few micrometers, present in steel. These NMIs are inevitably formed during the steelmaking process and significantly influence both the chemical and physical properties of steel. Given their impact, it is crucial to study their formation and modification. By understanding the origin and behavior of NMIs during production, targeted countermeasures can be implemented to reduce the number of detrimental NMIs in specific steel grades. As a result, downtimes in the steelmaking process can be minimized and the product quality can be enhanced. The implementation of tracing techniques allows the identification of the origin of NMIs. One novel promising approach lies in stable isotope labelling. Due to the modification of the isotopic ratio of, for example, one component in the slag, it is possible to study the steel/slag/refractory system in more detail. In the present study, the MgO used in the slag was spiked using an enriched stable ²⁶Mg isotope. By measuring the isotopic ratio of slag, refractory and NMIs, it was possible to identify whether NMIs were modified or originated by slag or crucible. Sensitive measurement techniques are required to determine the isotopic composition of slag and refractory as well as to evaluate the origin of NMIs.

Within this study, three analytical approaches were compared in terms of their applicability to measure the isotopic ratio in NMIs. The first analytical method was Laser Ablation - Inductively Coupled Plasma-Mass Spectrometry (LA-ICP-MS), a fast analyzing technique with limited spatial resolution (1 – 50 µm). As the second technique, Time-of-Flight Secondary Ion Mass Spectrometry (ToF-SIMS) was applied. This method has a minimum spatial resolution of 35 nm and, hence, enables an investigation of the entire spectrum in single atomic layers. Due to the coupling of ToF-SIMS to Scanning Electron Microscopy with Energy-Dispersive X-ray Spectroscopy (SEM/EDS), it is possible to obtain elemental and isotopic information about the investigated NMI. The third method is atom probe tomography, which has the highest spatial resolution and allows measurements on the atomic level. Here, only small parts of an NMI can be investigated since the analyzable sample size is only a few hundred nanometers in size. All three techniques successfully detected the ²⁶Mg spike in the isotopically modified slag. Within this work, advantages as well as challenges of the applied analyzing methods are discussed.

4DSTEM-in-SEM in event driven mode to characterize metallic materials

Dr. Ujjval Bansal, Germany

Oral Presentation (20')

Abstract

Over a past decade, 4DSTEM has emerged as a powerful tool in TEM, enabling simultaneous acquisition of spatial and diffraction information [1]. Recent advancements in direct electron detector technology now allow the integration of 4DSTEM even into SEM, opening up new possibilities for in situ studies in a controlled environment [2]. So far characterization of 2D materials such as MoS₂ and graphene have been demonstrated [3-5]. Enabling this novel technique for bulk materials can offer valuable insights into real-world performances. This integration could also have potential for in situ studies because of the large chamber of SEM than in TEM. However, the slow data acquisition rate poses a challenge. In this talk, we highlight the integration of 4DSTEM in SEM focusing on a novel event-driven mode to accelerate data acquisition rate and its application to metallic materials. Also, we address the challenges posed by sample thickness and SEM parameters optimizations. Our experimental setup includes an in-house configuration utilizing the MiniPIX TPX3 camera from ADVACAM. The event-driven mode significantly reduces the data storage requirements compared to conventional frame-based method, which is a key challenge in high-throughput 4DSTEM. The acquired data is processed using python scripts and stored as 4D data set. Utilizing open-source platforms like LiberTEM and py4DSTEM, virtual bright and dark-field (BF and DF) images were generated. As an example we present a nanograin Pt thin film was deposited by DC magnetron sputtering directly on TEM grid. Using the MiniPIX detector, the 4D data set with 250 x 250 pixel in real space was acquired. A virtual DF images (using LiberTEM) and in-plane orientation map (derived from radial Fourier analysis) were developed revealing the nano grain size of thin film as one of its key characteristics. The in-plane orientation maps can be exemplified to determine the misorientations between phases providing valuable insights into materials structure. In conclusion, the successful integration of 4DSTEM-in-SEM offers significant advances in understanding material performance and establishing a foundation for ongoing breakthroughs in this field.

Towards Single-Pattern Absolute HR-EBSD without using Simulated Patterns as Reference

Dr. Tijmen Vermeij, Switzerland

Oral Presentation (20')

Abstract

Over the years, High Angular Resolution Electron Backscatter Diffraction (HR-EBSD) has become a reliable tool for measuring misorientations and relative stresses (elastic strains) in crystalline materials with high sensitivity. However, in the absence of stress-free intragranular reference points, absolute stress measurements are not yet routinely performed, despite their potential to provide new insights into the nano- and micromechanics of a wide range of (poly)crystalline materials. The extension from relative to absolute cross-correlation-based HR-EBSD, using a simulated EBSD pattern as a reference, remains an area of ongoing development. However, this approach is limited by factors such as inaccuracies in EBSD pattern simulations and uncertainties in the experimental EBSD geometry. Consequently, an absolute HR-EBSD approach that does not rely on simulated reference patterns or any experimentally obtained stress-free reference pattern would be of significant interest to the community.

Recently, global correlation frameworks have been proposed, demonstrating the potential for non-simulation-based absolute HR-EBSD by leveraging crystal symmetry, simultaneous correlation between multiple (intergranular) patterns, and co-correlation of the pattern center. However, experimental validation on polycrystalline samples has been challenging, and excess-deficiency features (band asymmetry) in the patterns are expected to introduce complications.

To address these challenges, we have further developed this framework to reduce complexity and to enable absolute, non-simulation-based HR-EBSD correlation using only a single EBSD pattern. Specifically, we correlate different regions within the same pattern using crystal symmetry operators. By applying all available symmetry operators, we perform multiple parallel correlations within a single pattern, treating absolute in-plane stress components, absolute orientation, and pattern center parameters as degrees of freedom.

In this presentation, we will first demonstrate how the framework operates and performs on idealized simulated patterns. Further validation on single experimental stress-free patterns, acquired using a direct electron EBSD camera, will highlight the impact of excess-deficiency features on experimental accuracy, as confirmed through comparisons with dynamically simulated patterns. To mitigate these effects, we introduce an integrated excess-deficiency correction approach, demonstrating that non-simulation-based absolute HR-EBSD is within reach.

Resolving Overlapping EBSD Patterns Using Iterative Dynamic Template Matching

Dr. Grzegorz Cios, Poland

Oral Presentation (20')

Abstract

Overlapping Kikuchi diffraction patterns often hinder accurate phase identification in Electron Backscatter Diffraction (EBSD). We present an iterative approach using dynamic template matching in AztecCrystal MapSweeper [1] of dynamically simulated patterns [2] and Gaussian-blurred pattern subtraction to resolve overlapping diffraction signals. Our method first identifies the best-fit simulated Kikuchi pattern using dynamic template matching. This pattern is then blurred to match the experimental image optimally and subsequently subtracted, revealing the underlying weaker signal. Reapplying dynamic template matching to the residual pattern ensures accurate detection of minor phases that would otherwise remain omitted. This method significantly improves phase discrimination in complex materials, addressing a key limitation of conventional EBSD analysis. This method doesn't require a known orientation relationship between two patterns [3] or close neighbor experimental patterns like previously published approaches [4]. During the talk several examples will be shown.

Development of a High-Throughput method for Microstructure Analysis of Aluminum HPDC components

Dr. Deepjyoti Mukherjee, Sweden

Oral Presentation (20')

Abstract

As the automotive industry transitions towards electrification, the demand for lightweight, high-performance materials grows rapidly. High-pressure die-casting (HPDC) aluminum (Al) alloys are widely used in electric vehicle (EV) applications due to their excellent strength-to-weight ratio, mass production capability, and cost-effectiveness. However, optimizing these alloys and processing parameters for improved mechanical properties and corrosion resistance of the casting components requires a detailed understanding of their microstructure and chemical composition. In traditional characterization methods for Al alloys in the scanning electron microscope (SEM), a single sample piece is often mounted, polished, and analyzed individually. The process is often time-consuming and labor-intensive, limiting the speed of product development in industrial settings. This study presents a high-throughput method to analyze HPDC Al components by using SEM, an addition to the standard optical microscopic analysis, incorporating automated imaging, energy-dispersive X-ray spectroscopy (EDS) analysis, and advanced data processing techniques. With the help of 3D printing, polymer-based sample holders were designed and produced to hold multiple samples, enabling efficient sample preparation and SEM analysis. Automatic SEM imaging, EDS mapping and data analysis enable comprehensive microstructure and chemical analysis for identification of key alloying elements, secondary phases such as intermetallic compounds, and defects such as porosity and oxide inclusions. The proposed high-throughput SEM methodology has significant implications for the automobile industry. By accelerating the sample preparation and microstructure characterization process, this approach facilitates rapid iteration in alloy and casting parameter design, ultimately supporting the development of next-generation lightweight materials and optimizing manufacture for EV applications. It can be integrated into industrial quality control workflows, enhancing process monitoring and defect mitigation strategies. Finally, this method can be readily adapted to general materials research.

Paper 1701 1 Metastable defect phase diagrams as roadmap to tailor chemically driven defect formation

Dr. Tilmann Hickel, Germany

Keynote (Oral Presentation 40')

Abstract

Thermodynamic bulk phase diagrams have become the roadmap used by researchers to identify alloy compositions and process conditions that result in novel materials with tailored properties. Recent experimental studies show that changes in the alloy composition can drive not only transitions in the bulk phases present in a material, but also in the concentration and type of defects they contain. Defect phase diagrams in combination with density functional theory provide a natural route to study these chemically driven defects. Our work reveals, however, that direct application of equilibrium bulk thermodynamics can fail to reproduce experimentally observed defect formation. Therefore, we extend the concept to metastable defect phase diagrams to account for kinetic limitations that prevent the system from reaching equilibrium. In this regard the exothermic formation of defect phases can be explained. We apply this concept to successfully (1) design suitable conditions for synthesis, which we subsequently realized experimentally, successfully validating the formation of the predicted defects in Mg-Al-Ca alloys. Finally, we (2) resolve the discrepancy between bulk phase diagrams and experimental observations regarding the formation of Mg-rich C14 and Al-rich C15 Laves phases in MgAlCa alloys at moderate temperatures and (3) clarify, the effect of the thermodynamic state of alloys on the competition between solute-rich hcp-like planar defects and stoichiometric basal stacking faults. The concept of metastable defect phase diagram offers new avenues for the design of materials performance by tailoring defect structures.

First-principles-based description of segregation in steel

Mr. Franco Moitzi, Austria

Oral Presentation (20')

Abstract

This study presents a first principles investigation of the paramagnetic α/γ interface in iron. The research is divided into two main parts. The first part focuses a methodology for interface calculations in Green's functions codes using coherent potential approximation. This methodology enables DFT calculations of α/γ interfaces in the paramagnetic state, leveraging the disordered local moment (DLM) approach. The methodology is used in a combination with VASP supercell calculations of interfaces in iron, which are also used to calculate the fundamental properties of a representative α/γ interface.

The second part addresses an evaluation of available first principles methods for solute segregation to grain boundaries in combination with recent machine-learning models and their potential for application to segregation calculations in paramagnetic and concentrated alloys. We present a methodology to evaluate the composition of interfaces in the dilute limit and necessary methodological steps for its extension towards concentrated alloys. This research work aims at providing insights into the segregation phenomena in steel, contributing to the development of advanced materials with optimized properties.

First principles modeling of short-range order in Fe-Si-Al alloys

Mr. Daniil Khodachenko, Austria

Oral Presentation (20')

Abstract

Unique electromagnetic properties of steels with silicon and aluminum make them a perfect choice for the production of transformers and electric motors. These so-called electrical steels have enhanced energy efficiency due to reduced core losses and enhanced magnetic permeability. However, increasing the concentration of silicon and aluminum beyond a critical amount leads to significantly worse ductility, which makes production very challenging.

The theoretical origin of these embrittlement effects is still not fully understood, as ab-initio modeling based on Density Functional Theory (DFT) are rather challenging, due to requiring large supercells and complex magnetic interactions. Such first principle simulations frequently use Special Quasirandom Structure (SQS) approaches to simplify the problem, as they are designed to describe a fully random distribution of the alloying elements. However, real systems are not perfectly random, due to atomic interactions, which result in short range ordering (SRO) of the atomic sites. We investigate atomic SRO phenomena using accurate, DFT based full potential methods, as well as the Generalized Perturbation Method (GPM) to account for the magnetic state dependence of the effective cluster interactions and study their hierarchy. We introduce thermal atomic displacements to investigate the effect of temperature on magnetic exchange interactions in selected electrical steels. We discuss how accurate modeling of thermodynamic properties of these materials close to the Curie temperature should take such thermal effects into account, and that a semiclassical approach using thermal displacements is a computationally efficient way of achieving this.

Ab-initio informed CALPHAD modelling of SIGMA7 grain boundary phases in the Mg-Ga system

Dr. Alexander Walnsch, Germany

Oral Presentation (20')

Abstract

The study of defect phases is of crucial importance when it comes to the design of nanostructured metals and alloys. Grain boundaries (GBs), a significant class of defects, influence key material properties such as deformability and strength. It has been demonstrated that alloying can induce GB phase transformations and thus alter mechanical performance. Employing defect phase diagrams facilitates the identification of phase transformations in the Mg-Ga system, e.g. from the SIGMA7-T to the SIGMA7-A structural type of the GB, alongside a systematic transition in segregation site preference. [1]

Consequently, Ab-initio simulations were conducted on various grain boundary structures to parametrize a CALPHAD model of the bulk phase and the grain boundary phases, SIGMA7-T and SIGMA7-A. The grain boundary phases are described using a virtual system component for defects. This enables the inclusion of grain size as an input parameter to a CALPHAD calculation and thus enables the quantitative treatment of partitioning of the elements at the grain boundary.

By integrating the bulk phase diagram with defect phase energetics, a defect phase diagrams with temperature, chemical potential, grain boundary energy, composition or grain size as axes can be drawn. These diagrams delineate the formation of distinct grain boundary structures as functions of temperature, composition, and grain size, under both stable and metastable conditions. The theoretical predictions align well with experimental microstructural investigations performed via transmission electron microscopy and atom probe tomography.

The integration of complementary thermodynamic modelling approaches engenders a holistic perspective on the prediction of grain boundary phases and segregation effects in defect structures. This methodology can be expanded to examine interactions among various structural imperfections. The results demonstrate a very good agreement with experimental observations, underscoring their broader implications for defect-engineering in metallic alloys.

¹Instituto Eduardo Torroja (IETcc), CSIC, C/Serrano Galvache 4, 28033 Madrid, Spain

²Universidad Carlos III de Madrid (UC3M), Madrid, Spain

Abstract

In this work, the feasibility of synthesizing materials with excellent pozzolanic properties has been studied. Different precursors with a composition like a type C fly ash, have been synthesized. More specifically, the reactivity of the precursors has been analyzed by studying the influence of the incorporation of several fluxing agents to the raw meals, as well as by changing the synthesis temperature (1000 and 1250°C). The precursors manufactured have been characterized by XRD and ²⁹Si and ²⁷Al MAS NMR. The reactivity of the different precursors has been checked according to the R3 test and the saturated lime dissolution test. Two precursors have been selected to produce hybrid alkaline cements (HAC), also known as Ultra-Low Clinker Cements (clinker < 30%). The mechanical strengths were determined. Characterization of the reaction products (by XRD, TG, NMR and BSEM) revealed the formation of a (N)-C-A-S-H gel responsible for the good mechanical behavior of the cements. Precipitation of portlandite, calcite and ettringite as secondary hydration products was observed.

Mechanism of Alkali-Activated Cements Retardation by Zinc Addition

Mrs. Alice Gava, France

Oral Presentation (20')

Abstract

The incorporation of zinc into cementitious materials has been explored both for heavy metal stabilization and its retardant properties on initial setting. However, its role in regulating rheological fresh properties and its compatibility with superplasticizers remain unclear. This study aims to review and investigate the mechanism by which Zn influences the properties of fresh alkali-activated cements. The control of its retardant effect in the presence of polymer-based admixtures will allow the monitoring of cement paste workability.

The composition and microstructure of zinc-doped cement paste, and the zinc mechanism of action during the hydration process remain subjects of ongoing debate. The hydration of cement paste during the induction period is a highly complex system involving interconnected reactions that are modified in presence of zinc. The specific impact varies depending on the chemical form of zinc, whether as ions (together with their counter-ions) or oxides. These effects have been predominantly reported for OPC-type materials(1). Several mechanisms of zinc action have been proposed in literature: 1- formation of a metastable coating that impedes ion transport, 2- inhibition of C-S-H nucleation through the precipitation of calcium-zinc hydrates on grain surfaces, 3- pH reduction caused by zinc precipitate formation, and 4- complexation of Zn^{2+} with silanol and aluminol groups on surfaces. For low-Ca-content materials, such as alkali-activated systems like blast furnace slags, the situation is less clear due to interplay of Zn with the activator(2).

This work focuses on the fate of zinc in the presence of other admixtures that also help control the initial rheological properties, such as superplasticizers. The behavior of zinc in activated solutions of various types and pH, both with and without the addition of polymers, has been studied. Various Zn-doped alkali-activated paste preparation protocols were examined, resulting in different zinc precipitate products and corresponding variations in the rheological behavior of fresh paste. These results contribute to a deeper understanding of the zinc action mechanism in alkali-activated materials, depending on the activated solution, as well as the interaction and potential competition between the retardant and superplasticizer effects to control the fresh cement properties.

Recycling of oil bleaching earths and mine tailings as a precursors in alkaline one-part cements activated with a sodium silicate based on spent diatomaceous earth residues.

Mrs. Lucila Alicia Menacho Rodriguez, Spain

Oral Presentation (20')

Abstract

The search for sustainable cementitious materials has driven the development of alkali-activated cements (AACs) using industrial by-products. This study explores the valorization potential of spent bleaching earth (SBE) from the oil refining industry as a precursor for one-part AACs. An alternative sodium silicate, derived from the thermal treatment of NaOH and spent diatomaceous earth (a by-product of the brewing industry), is employed as the activator.

The use of alternative sodium silicate derived from waste materials offers several advantages over commercial sodium silicate. Firstly, it significantly reduces the environmental impact associated with conventional sodium silicate production, which involves energy-intensive processes and the consumption of natural resources such as silica sand and sodium carbonate. Secondly, it promotes industrial waste valorization, fostering a circular economy and reducing landfill disposal. Moreover, by utilizing alternative feedstocks and less energy-intensive processes, this approach presents a more cost-effective and sustainable solution for AAC production.

The study first examines the influence of the Na₂O content in the alternative activator on the activation of SBE, assessing the technological properties of the resulting cements. Subsequently, the effect of partially substituting SBE with mine tailings is investigated to optimize the cementitious system's composition and enhance its mechanical performance.

Results indicate that the Na₂O content in the activator significantly influences the technological properties of AACs based on SBE. Furthermore, the partial incorporation of mine tailings enhances the mechanical properties of the final product. These findings provide a deeper understanding of the potential of these industrial by-products as raw materials for alternative cement production, contributing to waste valorization and the development of materials with a lower environmental footprint.

This research aligns with the principles of the circular economy and green transition by offering a viable and sustainable alternative to conventional cements, advancing the use of industrial by-products in the construction sector.

Paper 286 1 **Scalable Cement-Based Thermoelectric Systems for Sustainable Energy Harvesting in Outdoor Environments**
Mr. Mohamad Barzegar, Spain
Highlight (Oral Presentation 20')

Abstract

Thermoelectric (TE) materials offer a promising pathway for converting waste heat into sustainable energy. While conventional TE materials typically exhibit low Seebeck coefficients (< 1 mV/K), ionic TE materials achieve higher values but are limited by scalability and cost challenges. Cement-based TE materials emerge as a practical alternative, offering scalability, affordability, and durability. This study explores the potential of engineered cement composites for outdoor photo-thermoelectric energy harvesting. By leveraging cement types arranged to enhance light absorption and temperature gradients, a system of interconnected TE cells demonstrated a Seebeck coefficient exceeding 9 mV/K. Additionally, different strategies were employed to maximize the energy harvesting potential, achieving significant energy output. The intrinsic ability of the cement composite to absorb atmospheric humidity after drying further mitigated issues of evaporation common in ionic TE systems. These findings highlight the feasibility of cement-based TE systems as a scalable and sustainable solution for efficient energy conversion, paving the way for innovative approaches to renewable energy.

Simulation-Driven Optimization of Multifunctional Sandwich Panels for Energy-Efficient Buildings

Mr. Nicolás Escribano, Spain

Oral Presentation (20')

Abstract

In recent years, the building sector has made great progress in developing advanced materials and technologies that enable the practical adoption of near-zero, or even energy-positive, energy/emission buildings. These innovations aim to balance and reduce the energy costs of the building industry through innovative and more efficient materials and components that adapt to the environment [1]. Multifunctional composite sandwich panels have a layered design which has the advantage of being able to couple different materials with specific functions to offer advanced multifunctional features [2]. Moreover, the use of innovative materials, which have a specific thermal response, has been increasing. Among these innovations, Phase Change Materials (PCM) stand out due to their capacity to accumulate energy, and mortars combined with aerogel provides high thermal insulation performance. These advanced materials beyond SOA can be integrated into composite sandwich panels to help providing the desired thermal response.

Given the possibilities offered by multifunctional composite panels in terms of geometry and material design, computer simulation plays a key role in optimizing thicknesses and selecting materials to meet specific requirements. Thus, this work aims to develop and validate simulation models that reproduce the mechanical and thermal behaviour of sandwich panels, optimizing thicknesses based on the thermal and mechanical loads they are subjected to. To experimentally evaluate the performance of the sandwich panels mechanical (compression and 3-point bending) and thermal (static and dynamic) tests in heat flow meter apparatus were carried out. The experimental results were used to calibrate thermal and mechanical Finite Element (FE) models of the composite sandwich panels. Design of Experiments (DoE) approach was applied to generate simulations adopting such models, which were then used to generate metamodels capable of predicting thermal and mechanical responses of the panel under various load cases and thicknesses. Finally, a digital tool, based on these metamodels, was developed, providing a user-friendly application applicable to various façades types and environments. This methodology offers a powerful virtual engineering tool for predicting the behaviour of intelligent multifunctional composite panels.

This research has received funding from the European Union's Horizon 2020 research and innovation programme iclimabuilt, under Grant Agreement No 952886.

Innovative Geopolymer Composite for Buildings Thermoregulation

Dr. Mario Alberto Ávila Gutiérrez, Italy

Oral Presentation (20')

Abstract

The construction industry contributes 40 % of global greenhouse gas emissions (GHGE), of which 80 % is generated during energy consumption for the heating and cooling of buildings. To limit climate change and reduce CO₂ emissions from the construction and building sectors, numerous research teams have concentrated on creating highly energy-efficient and sustainable materials with minimal carbon footprints. Geopolymers have emerged as eco-friendly alternatives to conventional Portland cement, with the aim of reducing manufacturing expenses by repurposing industrial waste. In recent years, thermal energy storage materials (e.g., inorganic salts) have attracted increasing interest because of their ability to absorb and release energy at high and low temperatures. This research seeks to develop novel sustainable thermoregulator building materials using a zero-carbon-emission-composite-based geopolymer. Herein, we present a physicochemical analysis of the behaviour of an innovative geopolymer composite containing Calcium L-lactate (CaL), an organic salt hydrate that enhances the thermochemical energy-storage capacity of the material. CaL was incorporated into the geopolymer matrix at various weight percentages (wt. %), promising new thermochemical material exhibiting good thermal stability (150 °C) and complete hydration-dehydration reversibility cycles. Moreover, owing to the macroporous structure of the composite, which facilitates water vapor flow during the expansion and contraction of the organic salt, the heat storage and release capacities of the composite material were determined to be 301-441 kJ/kg of the composite material. This study provides valuable insights into the development of sustainable and energy-efficient building materials that can contribute to mitigating climate change within the construction sector.

Paper 1468 4 Integrating AI and Image Processing for Microstructural Analysis and Strength Forecasting in Cement-Based Materials

Ph.D. Vanessa Alvear, Spain

Oral Presentation (20')

Abstract

The development of high-performance cementitious materials relies on accurately predicting mechanical properties and understanding their microstructural composition. This study employs two distinct yet complementary approaches: Computer Vision (CV) to analyze cement microstructure from Scanning Electron Microscopy (SEM) images, and machine learning (ML) to predict compressive strength. In the ML framework, various predictive models, including polynomial regression, Support Vector Machines (SVM), random forests, and neural networks, are trained on a dataset where input features characterizing the material composition and elaboration conditions are used. Here, the target variable is the compressive strength. A comparative analysis of the model's output is done. In parallel, we explore several techniques of deep clustering to segment cement SEM images at different stages. A Convolutional Neural Network (CNN)-based approach is proposed to analyze these images, identifying and segmenting cement phases such as clinkers, hydrates and pores. This automated microstructural characterization enables a deeper understanding of phase distributions, which can further support material optimization. By integrating data-driven strength prediction with AI-powered microstructural analysis, this research provides a scalable, cost-effective framework for cement design and optimization. The results highlight the potential of machine learning and computer vision in accelerating material science research and enhancing the performance of cementitious materials. This study is conducted as part of the MatCHMaker project.

Paper 1677 5 Machine Learning and High-Throughput Experimentation in Sustainable Infrastructural Materials Research

Dr. Bilal Ul Amin, Ireland

Oral Presentation (20')

Abstract

Innovation in materials science has long been a catalyst for technological advancement. Historically, these advancements relied on costly and time-consuming trial-and-error experimentation. Depending on traditional development protocols and legacy laboratory technologies often introduces complexity and unpredictability, as these approaches often demand the screening of millions of candidates, incurring substantial costs and requiring extended timeframes. However, recent advances in computational screening, industrial automation, and artificial intelligence (AI) have transformed this landscape. By integrating machine learning (ML) and deep learning (DL) with high-throughput experimentation (HTE), AI-driven platforms are revolutionising polymer discovery—predicting properties, optimising formulations, and generating novel structures with unprecedented efficiency. This project aims to develop a novel, reduced-temperature mastic asphalt for infrastructural applications, addressing the energy-intensive and often toxic nature of traditional asphalt. By leveraging AI-informed data analytics, molecular dynamics (MD) simulations, density functional theory (DFT), and quantum chemistry models, researchers can accelerate the identification of sustainable materials in parallel with the optimisation of mechanical, electrical, and thermal properties. Previous efforts have shown progress in reducing application temperatures, but further innovation is needed to minimise the embodied energy of the installed technology. By combining AI-driven predictive modelling, object-based material synthesis, and real-time optimisation, this research seeks to redefine the future of mastic asphalt. The project not only advances sustainable infrastructure but also exemplifies how AI and advanced synthetics can transform materials science—reducing development time, costs, and environmental impact while pioneering next-generation polymer systems for the pavement industry.

Machine Learning to Predict the Thermomechanical Properties of Reinforced Polymeric Composites Manufactured with Thermoplastic or Thermosetting Matrices – A Review for Civil Construction Applications

Ph.D. Deesy Pinto, Portugal

Oral Presentation (20')

Abstract

This review explores the potential of using machine learning (ML) to predict the thermomechanical properties (TMP) of polymeric composites (RPC's), which are made with reinforced thermoplastic or thermosetting matrices for civil construction applications. The typical ML workflow includes several steps: Data Collection and Preprocessing: Gathering data on TMP of RPC's, covering composition, processing parameters, and environmental conditions. This step also involves preprocessing the data to handle missing values, outliers, and scaling; Feature Selection and Engineering: Identifying relevant features and creating new ones, if needed, to enhance model performance. This may require domain knowledge and statistical techniques to pinpoint key predictors for TMP; Model Selection: Choosing suitable ML models such as regression, neural networks, or decision trees for prediction tasks; Training and Evaluation: Splitting data into training and testing sets to train models and evaluate their performance using metrics like mean squared error, mean absolute error, or R-squared; Hyperparameter Tuning – Optimizing model hyperparameters through grid search or random search techniques; Cross-Validation – Evaluating model generalization and preventing overfitting; Model Interpretation – Analyzing feature importance and relationships between input variables and TMP to derive insights. To support this approach, the authors compiled recent scientific literature, including their own research, primarily focusing on RPC's TMP. It is well established that achieving optimal TMP depends on a proper combination of multiple material families—often two or even three in hybrid materials. These composites exhibit favorable performance under harsh environmental conditions (e.g., saline or corrosive atmospheres) and provide durability and permeability suited to specific applications. However, achieving the ideal material combination is rarely accomplished on the first attempt. Multiple experimental iterations are necessary to refine the formulation, ensuring optimal TMP without significantly compromising individual material properties. Any misalignment in composition adjustments can negatively impact the final desired TMP of the RPC's. In this context, ML serves as a valuable tool to fine-tune material compositions and predict desired TMP, ultimately reducing experimental costs while improving efficiency. By leveraging ML, researchers and manufacturers can streamline the material selection process, enhance performance predictions, and optimize RPC's formulations tailored for various structural applications. This topic is still under development and has emerged to meet the increasingly complex demands of the civil construction sector in the search for new construction materials capable of meeting a variety of applications.

Ceramic 3D printing of constructive systems of façades. Pros and Cons

Prof. María Del Mar Barbero-Barrera, Spain

Oral Presentation (20')

Abstract

Ceramic is a material with a large tradition in Spain due to the abundance of clay materials in most of the Peninsula. This circumstance together with the appropriateness of the material are some of the reasons for its proliferation. In addition, their inorganic nature, strength and chemical resistance made them suitable and justify its durability, in such a way that examples of centuries of history could be found in a perfect state of conservation.

Against their vision as a traditional and obsolescence material, ceramic industry has driven a complete renewal and change of perception in which 3D printing has arisen as an alternative for the implementation of a new image.

Indeed, in the last decades, 3D printing with ceramics had arisen because of its high potential in terms of the versatility in the design of complex shapes without a specific tool, but also, manufacturing 3D printing is aligned with the reduction of waste during the fabrication and the control processes to optimize them.

Taking advantage of this tool, there is still a huge field to research in terms of ceramic compositions, designs not only as a single piece but as part of a constructive systems, especially in façades. Indeed, ceramic printing has a huge potential in the development of constructive systems in new buildings but also for renovation purposes, in which the optimization of the design could be achieved attending to the final properties in terms of appearance but also to control lighting or shadowing, among others. On the contrary, the extrapolation of printing of single parts to the manufacturing of large quantities requires high throughput.

In this paper, a review of the literature regarding the use of this technology for 3D printing on constructive systems of façades is performed attending to their requirements, final performance and difficulties found in the application to large manufacturing processes.

This work has been supported by the project Project PROYEXCEL_00532 CERE3D funded by Junta de Andalucía (Consejería de Transformación Económica, Industria, Conocimiento y Universidades)

Paper 1323 1 Unveiling the Link: Correlation Between R3 Test Results and Compressive Strength in Five SCM Families

Prof. Angeles G. De La Torre, Spain

Oral Presentation (20')

Abstract

Incorporating locally available supplementary cementitious materials (SCMs) into cement blends is essential for reducing the building materials industry environmental footprint. The pozzolanic activity of SCMs is typically assessed using two standardized methods: ASTM C1897 (R³ test, which measures continuous heat release at 40°C) and ASTM C311 (Strength Activity Index, SAI, evaluated at 20°C after 28 days). However, previous studies have reported weak correlations between these two approaches. To address this inconsistency, this study examines the elemental composition, mineralogy, texture, and pozzolanic behavior of 22 different SCMs.

While the ASTM C1897 procedure was followed precisely, the ASTM C311 methodology was modified in two key ways: (1) maintaining a constant water-to-binder ratio and (2) introducing an additional mix alongside the conventional 80% Portland cement (PC) and 20% SCM blend. This new formulation—comprising 68% PC, 20% SCM, 10% limestone, and 2% gypsum—was designed to minimize filler effects and better reflect real-world applications.

Results aligned with known pozzolanic kinetics, revealing a general trend: kaolinite-rich calcined clays $\approx$ silica fume > smectite-rich calcined clays > natural pozzolans $\approx$ class-F fly ashes. In the standard 80/20 series, the SAI at 20°C after 28 days (SAI_{20°C_{28d}}) exhibited two distinct correlation patterns with heat release at 40°C after 12 hours (Heat_{40°C_{0.5d}}), separating kaolinitic calcined clays from other pozzolans. Conversely, in the 68/20/10/2 series, correlations were notably stronger, as the influence of filler materials was reduced. The SAI_{20°C_{28d}} demonstrated a robust relationship with Heat_{40°C_{3d}}, forming two well-defined clusters indicative of broader material behavior. These findings suggest that the modified mix design provides a more reliable basis for SAI evaluation. Furthermore, additional insights into pozzolanic kinetics and SCM performance contribute to a deeper understanding of their role in sustainable construction.

Paper 1303 2 **Mechanisms involved in the flow evolution in superplasticized limestone- blended cements**
Dr. Marta Palacios, Spain
Oral Presentation (20')

Abstract

Limestone is a globally accessible Supplementary Cementitious Material (SCM) widely used to replace clinker and decrease the carbon footprint of cement and concrete. However, clinker replacements above 10% leads to a reduction of the mechanical properties due to the almost “inert” nature of limestone. Superplasticizers play a crucial role to decrease the water demand in limestone-blended concrete to compensate the loss of strength. The rheology of admixed limestone blended cements is complex and controlled by different mechanisms that simultaneously occur. In particular, rheology depends on particle packing, polymer adsorption and cement hydration. The main focus of this research is to understand the flow loss in limestone blended cements (OPC-LS) containing polycarboxylate-ether superplasticizers (PCE) and its correlation with polymer adsorption and the new hydrates formed. The main outcomes have been compared with the flow loss in pure OPC systems.

Results concluded that at the same solid volume fraction, OPC pastes required higher dosages of PCE than OPC-LS pastes to reach a similar initial yield stress. This is related to the higher amount of ettringite initial formed in admixed OPC pastes, as measured by ²⁷Al MAS NMR, since ettringite has a high affinity to adsorb polymer. In general, a good correlation between the evolution of the yield stress and hydration kinetics have been observed. The onset of the flow loss occurs at the end of the induction period when the higher increase of the specific surface area due to precipitation of hydration products has been measured. An increase of the charge density of the PCEs leads to greater delays of the onset of the flow loss.

Comparing pastes with the same initial yield stress, a faster flow loss is observed in admixed OPC-LS pastes than in OPC pastes. This can be explained by the lower initial PCE dosages used in OPC-LS blends, leaving less free PCE to adsorb over time onto the new surfaces formed as concluded from the analysis of the organic carbon content of the pore solution.

When PCEs are added a few minutes after mixing the binder and water, lower dosages of polymer are required to reach a certain value of yield stress with respect to when PCE is added directly into the mixing water. This is explained by the adsorption of PCE on ettringite nuclei in direct addition. Furthermore, a faster flow loss is measured in pastes when PCE was added in delayed mode.

Paper 217 **3** **Impact of the interparticle forces in the rheology and particle size of binary blended cements.**
Mr. Sergio Real, Spain
Oral Presentation (20')

Abstract

The interest of the cement community towards limestone-calcined clay cements (LC³) has increased in recent times because of their lower carbon emissions and suitable hardened properties. However, they also have very high water demands that can be compensated by the use of superplasticizers. These chemical admixtures decrease the initial yield stress of LC³ cements although they still suffered a fast flow loss, whereby the mechanisms remain unknown. This study aims to gain a deeper understanding of the parameters controlling the rheology of LC³ cements. For this purpose, rheological properties, polymer adsorption and evolution of the particle size distribution of binary blends of the main components of LC³ cements, ordinary Portland cement (OPC), limestone (LS) and metakaolin (MK), were investigated. These results together with the zeta potential values of the individual components, in absence and presence of superplasticizers, were used to calculate the interparticle forces in binary blends by using the open access software Hamaker (<http://hamaker.epfl.ch/>).

In absence of superplasticizers, initial particle agglomeration was observed in all studied systems, pure OPC, limestone-blended cements with limestone contents up to 30% and in metakaolin-blended cements with metakaolin contents up to 50%. These results can be explained by the interparticle forces calculation (Hamaker simulation), where very high absolute values of the secondary potential minimum were calculated for all mixes which correlates with strong attractive forces and agglomeration. With time, particle size decreases due to both, particle deagglomeration and OPC dissolution.

When PCE superplasticizer is added to the systems, interparticle forces calculations show a strong repulsive potential barrier up to distances equal to the adsorbed layer thickness of the polymer, which leads to the particle deagglomeration experimentally observed. At initial hydration times, higher dosages of PCE are required to induce particle deagglomeration in OPC-MK systems, with respect to OPC-LS blends. This is attributed to the higher specific surface area of metakaolin particles and thus the higher dosages needed to reach a certain polymer surface coverage. Over time, particle agglomeration is observed which could be related to the formation of hydrates able to also adsorb polymer.

Effect of PCE superplasticizers on the control of the rheology of low clinker cements

Mrs. Jennifer Artiles Cupull, Cuba

Oral Presentation (20')

Abstract

Understanding the rheological properties of cementitious materials is essential to control their properties in the fresh state and to improve their practical applications. Clinker replacement by supplementary cementitious materials (SCMs) is currently the most feasible strategy to reduce cement and concrete carbon footprint. However, the SCMs availability and their slow reactivity have limited the level of clinker replacement in recent years. Limestone calcined clay cements (LC3) are cements with clinker contents even above 50% which contain widely available SCMs. In general, mortars and concrete prepared with LC3 have suitable hardened properties but rheological properties still need to be improved to facilitate its application onsite, while keeping low water/binder ratios. In this research, the effect of superplasticizers on the rheology of LC3 pastes and mortars have been investigated and compared to zeolite-blended cements. These rheological properties have been also correlated with the polymer adsorption on the cements and its impact on the cement hydration.

The obtained results concluded that, compared to zeolite-blended cement, LC3 cement pastes required a double dosage of superplasticizer to reach a similar initial yield stress, despite the similar clinker replacement of both blended cements (53% clinker substitution) and the similar specific surface area of the zeolite and calcined clay used. In particular, a dosage of 0.4% of PCE superplasticizer was needed to obtain LC3 pastes with an initial yield stress of around 5 Pa, while 0.2% of PCE was needed for zeolite-blended cements. This can be explained by the higher polymer adsorption of PCE measured for LC3 pastes. In contrast, a faster increase of the yield stress over time was observed for the admixed zeolite-containing cements.

Advancements and open challenges in sorption-based thermal energy storage for industrial and building applications: The LOBSTER project perspective

Prof. Matteo Fasano, Italy

Oral Presentation (20')

Abstract

Thermal energy storage (TES) is a pivotal technology for mitigating the temporal mismatch between renewable energy supply and energy demand across both building and industrial sectors. Building heating and cooling account for a significant portion of global energy consumption, while industrial processes similarly demand efficient thermal management. Among the various TES technologies, sorption-based systems offer promising advantages by utilizing adsorption or absorption processes to store and release latent heat effectively, enabling long-term thermal energy retention with minimal losses.

In this presentation, we will provide a comprehensive overview of the state-of-the-art in sorption-based TES, highlight the open challenges that impede its broader adoption, and outline the advancements achieved within the LOBSTER project. Although the project primarily focuses on enhancing energy performance in nearly zero energy buildings, its innovations have implications for industrial applications as well, particularly in processes requiring low-temperature heat recovery and loss-free long-duration storage.

The LOBSTER project is a multidisciplinary research initiative that bridges expertise in thermal engineering, multi-scale material simulations, building physics, and material science to develop advanced sorption-based TES solutions. Our work focuses on optimizing two principal TES configurations. Closed systems, which employ evacuated tanks and optimized heat exchangers, are designed to achieve high energy density with minimal external influence, offering stable performance independent of ambient conditions. In contrast, open systems present a more straightforward and scalable technological approach, but their effectiveness is inherently tied to ambient air properties such as humidity and temperature, necessitating optimized sorbent materials. A key aspect of the project is the development of multi-scale models and the systematic optimization of composite sorbents, enabling the selection of materials with tailored thermophysical properties for seasonal TES applications. Complementing this digital toolset, we have established innovative in-house synthesis protocols—including wet-impregnation of salt solutions into porous matrices and one-pot synthesis methods—to produce novel composite sorption materials. These materials are engineered to overcome existing limitations in storage capacity, cyclic stability, and degradation, while addressing key concerns such as cost, toxicity, and corrosiveness.

Beyond material and system development, the project integrates a techno-economic assessment to evaluate the scalability, market potential, and overall sustainability of these TES technologies. Thanks to the advanced material engineering and system-level optimization, LOBSTER contributes to the transition toward more efficient, renewable-based thermal energy solutions for both the building and industrial sectors.

Paper 1668 **2** **Kinetic feature in Calcium Chloride-Impregnated Mesoporous Silica Gel Composites for Thermochemical Energy Storage**
Dr. Matteo Ametta, Italy
Oral Presentation (20')

Abstract

The development of advanced materials for efficient energy storage is essential for supporting the transition to renewable energy sources. This study investigates the adsorption and desorption kinetics of composite materials made from mesoporous silica gel impregnated with calcium chloride (CaCl₂).

The first part of the study focused on determining the optimal salt content to balance storage capacity with the material's chemical-physical stability, specifically addressing issues related to swelling and deliquescence. Characterization tests, including TG/DSC analysis and thermogravimetric measurements, were conducted to assess the material's maximum water uptake and heat storage capacity. The results indicated that a 25 wt.% calcium chloride content provided the best compromise, improving the material's stability and performance. The maximum value of water uptake (41.60 wt.%) and heat flow (1199.10 ± 59.95 J/g) were evaluated in a range of temperature comprises between 120°C and 25°C with a scan rate of 5°C/min under a isobaric condition (17 mbar).

Then, the kinetic properties of the composite material were evaluated using a Large Temperature Jump (LTJ) apparatus during both adsorption and desorption processes under varying boundary conditions. LTJ experiments were conducted using a heat exchanger with dimensions of 120x80x22 mm and a fin pitch of 4.6 mm, filled with pure microporous silica gel, the composite sorbent, or a 50/50 in weight mixture of silica gel and composite sorbent. The boundary conditions tested were Pev/cond values of 12.3 mbar and 23.4 mbar, with an adsorption/desorption temperature set to 30°C. The high temperature source was fixed in the range between 50°C and 80°C.

The results showed that the composite material exhibited enhanced water adsorption performance compared to pure microporous silica gel, while the hybrid mixture displayed intermediate behaviour. Additionally, the heat exchanger filled with the composite/microporous silica gel mixture demonstrated slower adsorption/desorption kinetics compared to exchangers filled with single materials. This comparative approach allowed for a thorough analysis of how the composition of the sorption material affects kinetic parameters, such as the mechanisms governing adsorption/desorption and heat transfer between grains of the same or different sorbent materials.

In conclusion, the findings of this study will enable the optimization of composite materials for large-scale thermal energy storage systems, improving their efficiency and performance.

CaCl₂/MgCl₂/Silica Gel Sorbent Material for Thermal Energy Storage

Prof. Mauro Prestipino, Italy

Oral Presentation (20')

Abstract

This study assessed a novel CaCl₂/MgCl₂/silica gel composite sorbent for low-grade thermal energy storage (TES) application to reduce the scientific and technological gap for promoting sorption TES in building heating applications. Low-temperature dehydration/hydration salt hydrates are widely investigated for TES applications. Nevertheless, the use of pure salts as sorbents presents critical issues, such as deliquescence and agglomeration, which reduce their efficiency over cycling. Recently, CaCl₂ was encapsulated in silica gel to prevent salt spillage during its use caused by the deliquescence. However, the amount of salt that can be embedded in the matrix effectively reducing the deliquescence is still a limiting aspect. To this aim, a mix of CaCl₂/MgCl₂ was investigated in this study. Indeed, although MgCl₂ has a much lower heat storage and sorption capacity than CaCl₂ as a pure salt, it exhibits significantly less deliquescence, which is related to its higher deliquescence relative humidity (DRH%). Indeed, the DRH at 25 °C is 33% for MgCl₂ and 28.5% for CaCl₂. Hence, a synergic effect is expected from their mixture. The CaCl₂/MgCl₂ ratio was investigated between 1:1, 2:1 and 5:1. The salts mixture load into silica gel was fixed to 30% wt. The mixture was impregnated in mesoporous silica gel spheres and assessed structurally, morphologically, and thermochemically. Remarkably, the 1:1 CaCl₂/MgCl₂ mixture exhibited a significantly reduced deliquescence phenomenon without a sensible reduction in heat storage and sorption capacities. Furthermore, the TES potential of these composites was assessed under conditions relevant to residential buildings, and the sorption/desorption kinetic was investigated using the Thermal Large Temperature Jump (T-LTJ) method. This method measures the temperature difference at the inlet and outlet of the adsorber due to a sudden inlet temperature drop or jump, triggering the sorption or desorption step, respectively. The 1:1 CaCl₂/MgCl₂- silica gel composite was tested under the boundary conditions of real adsorption storage cycles. Specifically, two different evaporation temperatures were considered for the sorption, namely 10 and 15 °C. The investigated temperature drops are 85 → 35 °C, and 74 → 32 °C. The results highlight that the 1:1 CaCl₂/MgCl₂ mixture exhibits a high specific heat storage/release capacity (~850 kJ/kg) with fast sorption/desorption kinetics. To conclude, the approach of mixing two salts with different DRH effectively limits the deliquescence issues without sacrificing the heat storage capacity promoting its potential use in sorption-based thermal energy storage (TES) for building heating applications.

Cement-based sorption thermal energy storage materials for applications in the energy and construction sector

Mr. Alessio Mondello, Italy

Highlight (Oral Presentation 20')

Abstract

Thermal energy storage is crucial for exploiting sustainable and renewable energy sources by bridging the gap between supply and demand, particularly in the field of buildings, where local availability of low-temperature heat would reduce consumption of fossil resources. The fundamental operating principle of sorption-based thermal energy storage (STES) relies on reversible physical or chemical reactions, respectively absorption or adsorption, to store and release heat.

In literature, STES materials are classified into two main categories. Physically porous sorbents (e.g. zeolites) offer good stability but typically exhibit low energy densities. In contrast, salt hydrates provide higher energy densities but suffer from deliquescence, and bulking, which compromise stability and heat and mass transfer performance. Composite materials incorporate salt hydrates within a porous matrix, mitigating these issues while maintaining satisfactory energy densities.

This study uses an innovative approach to synthesise cost-effective composites by employing cement as a host matrix for various salt hydrates. Cement is chosen for its relatively low cost and wide availability and use in the construction sector. The composites were synthesised via the 'in situ' method by using Portland cement. A sequential learning algorithm is employed for material screening, evaluating 11 salt hydrates, saline solution concentration, water-to-cement ratio, and anti-settling agent concentration. Multiple objective functions are optimised during the screening targeting energy density and economic Key Performance Indicators (e.g. material cost divided by stored kWh).

Following the screening, the most promising composites are analysed in detail, including material characterisation (using SEM and optical imaging), and assessment of heat and mass transfer properties. Thermal conductivity was evaluated by Hot Disk® analysis, while adsorption properties, such as kinetics, energy density, isosteric heat of adsorption, and water uptake, were investigated using a water dynamic vapour sorption (DVS) analyser by proUmid.

The synthesised composites matured for 7 days in a glovebox at 100% relative humidity. After maturation, samples were pelletised, sieved (1 mm to 2 mm range), and dehydrated in an oven at 90 °C for 24 hours. Experimental water vapour adsorption isotherms were measured at 20 °C and 40 °C using the DVS analyser. Experimental data are thus fitted using the three-parameter BET equation to derive the isotherms. Finally, Polanyi's potential theory is applied to predict isotherms at additional temperatures, enabling the construction of isosteric curves on a Clapeyron chart, which are essential for defining the thermodynamic cycle and evaluating composites' performance in STES systems with promising applications in the building sector.

Paper	1499	5	Experimental analysis and optimization of sorption thermal energy storage systems Mr. Giorgio Tomaino, Italy Oral Presentation (20')
Abstract			Thermal energy storage (TES) systems based on sorption materials enable long-term energy storage, promoting the use of renewable energy for building air conditioning. This technology can therefore contribute to the decarbonization of the sector and the achievement of carbon neutrality by 2050. To widespread this technology, the sorption materials used must be low-cost, exhibit high adsorption capacity, and ensure safety and long-term stability. Research focuses on thermal energy storage systems based on innovative sorption materials, including cement-based and mesoporous silica gel impregnated with salts. Through a detailed experimental analysis supported by numerical simulations, the study highlights the advantages of the proposed technology and its potential applications in HVAC systems. In particular, system performance is experimentally analyzed under operating conditions representative of real use, and the results are used to assess the benefits at the building scale.

Alginate biopolymers for sorption technologies in building and industrial applications

Dr. Matteo Morciano, Italy

Oral Presentation (20')

Abstract

The water affinity of adsorbent materials can be exploited for many building and industrial applications: air humidification, water desalination, atmospheric water harvesting, industrial chilling, thermal storage (L. Lavagna et al, 2020). Recently, biopolymeric hydrogels have been studied as an option for such applications requiring adsorbent materials: compared to other common sorbents such as zeolites and silica gels, calcium-alginate (CaAlg) hydrogels show higher water uptake capacity and faster sorption kinetics, and their properties can be controlled by varying the material composition (V. Gentile et al, 2024). By properly adjusting the manufacturing process, CaAlg can be integrated within structural host matrixes, e.g. cements or plasters (V. Gentile et al, 2023), significantly increasing their moisture buffering value (MBV). This research aims at understanding whether CaAlg remains a suitable option when repetitively cycled in a real industrial sorption machine, at various temperatures and in more severe stressing conditions, such as under non-environmental pressure.

In this study, 700 grams of CaAlg are produced and tested in an industrial prototype for water desalination, to investigate the water uptake performance and stability of the material over time. The sorbent undergoes a cycle consisting of an adsorption followed by a desorption multiple times, while the desorbed water is condensed in a dedicated tank. After 0, 20, 30 and 40 cycles, a sample of material is removed from the machine and tested in a gravimetric machine to evaluate the uptake performance.

The first results show a significant amount of water processed per unit of time in the prototype. With an adsorption at 35°C for 45 minutes and a desorption at 70°C for 45 minutes, the prototype filled with CaAlg was able to condense ~126 mL/cycle (meaning a clean water production of 120 mL per hour and per kg of dry material), compared to the ~56 mL/cycle condensed under the same test conditions and with the same machine previously filled with 700 g of a common Silica Gel. The adsorption curves derived with the gravimetric machine on the material after 0, 20, 30 and 40 cycles do not show significant differences: the uptake capacity and kinetics after cycling the material are comparable to the ones of the non-cycled material.

Given the shown performance, integrating CaAlg in structural matrixes in place of other common sorbents may indeed be considered as an option: such a choice would reduce the size of an adsorption-based solution, decreasing production costs and design complexity.

Paper 1255 1 Smart polymer materials based on fiber spinning and additive manufacturing

Prof. Leonid Ionov, Germany

Keynote (Oral Presentation 40')

Abstract

Polymer fibers are a unique type of material that combines a high aspect ratio, large surface area, and a high degree of orientation of polymer chains, allowing them to be used in a wide variety of applications, the most well-known of which is reinforcement. However, the fibers are difficult to handle due to their length, making them difficult to combine with additive manufacturing. Various fiber spinning approaches, including electrospinning and electrowriting, have been used as an additive manufacturing method or in combination with additive manufacturing of smart structures. Despite the advantages of these fiber spinning methods, they have limitations. For example, programmable fiber deposition using electrospinning is challenging. Although electrospinning allows programmable fiber deposition, this method is slow, and the deposited fibers lack one of their main advantages, the orientation of the polymer chains, making them less effective for reinforcement. We have recently developed a fundamentally new fiber spinning method that allows for fast and programmed fiber deposition of fibers with oriented chains and can be easily combined with additive manufacturing. This and other fiber spinning methods combined with additive manufacturing open new perspectives for the fabrication of smart biomimetic structures, such as for tissue engineering.

Improving Fatigue Resistance in Organic-Inorganic PCL-Based Melt Electrowritten Scaffolds for Biomedical Applications

Dr. Irem Unalan, Germany

Oral Presentation (20')

Abstract

Biological structures such as coral, tree, enamel and fish bone demonstrate exceptional fatigue resistance, allowing them to withstand repetitive mechanical loading over prolonged periods without experiencing structural failure or degradation [1]. Understanding the fatigue behavior of engineered biomaterials is crucial to ensuring their durability and long-term functionality under dynamic mechanical forces inspired by these biological structures [2]. Consequently, anti-fatigue properties have become a significant focus in biomedical engineering, given their critical role in the design of implants, scaffolds, and prosthetics [2,3].

The objective of this study was to develop fatigue-resistant organic-inorganic structures using melt electrowriting (MEW) technology. MEW is a solvent-free additive manufacturing technique that employs electrohydrodynamics to fabricate micron-scale fiber struts with a highly ordered pore architecture and interconnected porous networks [4,5]. Initially, highly ordered MEW scaffolds were fabricated using polycaprolactone (PCL), a gold-standard thermoplastic polyester for MEW applications [6]. In the present study, the scaffolds were designed with varying fiber orientations, including 0-90°, 0-60°, 0-45°, and 0-30°, to evaluate the influence of architecture on mechanical and fatigue performance. On the other hand, to enhance the surface properties of the PCL-MEW scaffolds, an alkaline surface treatment was performed, followed by the coating of the scaffolds with gelatin (GEL) solutions loaded with mesoporous bioactive glass nanoparticles (MBGNs). Scanning electron microscopy (SEM) analysis revealed bead-free and uniformly deposited layers by layer PCL-MEW scaffolds, as well as the successful coating of GEL or MBGNs-loaded GEL on their surfaces. Additionally, Fourier transform infrared (FTIR) spectroscopy further confirmed the presence of PCL, GEL, and MBGNs in the coated scaffolds. Furthermore, preliminary quasi-static nanoindentation tests conducted on strips of the neat PCL-MEW scaffolds revealed a reduced elastic modulus of 1.1 GPa and a hardness of 70 MPa. These findings suggest that integrating organic and inorganic components into MEW scaffolds offers a promising strategy for enhancing fatigue resistance under various loading conditions. This approach highlights the potential of MEW technology in developing advanced biomaterials for biomedical applications.

3D in vitro skin model as broadly available and comprehensive platform for antibacterial therapies

Mrs. Simona Villata, Italy

Oral Presentation (20')

Abstract

Background:

The global rise of skin infections, exacerbated by antibiotic-resistant bacteria, is nowadays a great challenge to healthcare. Traditional treatments are increasingly losing their potential, leading to severe impacts on patient quality of life and survival rates. Consequently, many efforts are made to develop innovative antibacterial therapies. To test this new strategies, conventional methods, such as 2D cell culture and planktonic bacteria culture, often fail to replicate the complexity of infection environments, highlighting the potential of 3D in vitro skin models as a superior alternative.

Methods:

The initial focus of the study has been the development of a 3D in vitro skin model. The dermis compartment was biofabricated by embedding human fibroblasts in a gelatin methacryloyl matrix, with human keratinocytes seeded on top the dermis to form the epidermis. The models were cultured for 31 days in an air-liquid interface configuration. The model demonstrated robust barrier formation and extracellular matrix remodelling. A 3 mm biopsy puncher was used to simulate controlled wounding, followed by inoculation of *Staphylococcus aureus* (Gram-positive) or *Escherichia coli* (Gram-negative) to mimic infection. Antibiotic treatment was applied after 24 hours. The samples were subsequently analysed for bacterial survival and skin model responses.

Results:

Results were remarkable: differences between wounded and unwounded samples underlined the barrier effect: indeed, the bacterial proliferation was lower in unwounded samples, for both bacterial strains, meaning that the developed epidermis was able to partially stop the bacterial proliferation. Moreover, the 3D skin model was able to react to both wound and infection in a complete and complex way in terms of extracellular matrix deposition and remodeling, inflammatory response, antimicrobial peptides production and change in cellular behaviors, from epithelial to mesenchymal and from fibroblasts to myofibroblasts. Another important outcome was the change in skin response during infection, showing the ability of both bacteria, in different ways, to impair the model immune response. Also, the antibiotic interacted with the model, modulating some markers, giving some evidences of the release of endotoxins with *Escherichia coli* death.

Conclusions:

In conclusion the developed 3D in vitro skin model has the potential to become a future landmark as platform for infection investigation and novel therapies testing. Indeed, it demonstrated to be able to behave in a complex and complete way despite being easily producible and low cost. These properties put it in a prominent position for future standardization of platforms to test antibacterial therapies and strategies.

Macrophage Immune Response to a Skin-Mimicking Biocompatible Matrix: A Functional Insight

Ph.D. Veronica Vighetto, Italy

Highlight (Oral Presentation 20')

Abstract

3D biological models able to reproduce the physiology and the behavior of human tissues/organs are the focus of the newest groundbreaking research, enabling the scientific advancement of personalized medicine while simultaneously adhering to the principle of the 3Rs. Among the key features necessary to achieve a physiological and functional 3D model, there is the ability to replicate an immune response after stimuli. During the immune response, the immune system recognizes substances or microorganisms, for the purpose of defending against exogenous factors. The immune response, as the inflammation, implies the ability to recruit immune cells, as lymphocytes, granulocytes, monocytes, macrophages and others, in the damaged site of the skin, activating biological cascades of signals which matures the inflammatory response. Reproduce the complete and complex response to pathogens of in vitro immune system, considering both resident and circulating, is almost unexplored in literature for 3D skin model.

In this contest, a particular focus can be put on the behavior of monocytes and macrophages, which play a crucial role in the pro- and anti-inflammation processes, within the biological 3D skin model previously developed in our lab. This 3D model is composed by the epidermis and dermis layers, which are constituted respectively by human keratinocytes and human fibroblasts. Fibroblasts are embedded in gelatin methacryloyl (GelMA) to obtain a three-dimensional structure with cell-embedded. The ability to act as a barrier was verified.

The research here presented directs its attention to the differentiation and polarization processes of monocytes and macrophages. They were cultured within the gelatin methacryloyl matrix in different ratios and concentrations. The differentiation process, as well as signaling processes between cells of the same type and between monocytes and macrophages, were extensively analyzed by fluorescence microscopy, digital PCR, colorimetric analysis.

Further analysis was conducted to unveil details on the interaction between macrophages, monocytes and other immune cells, as healthy lymphocytes, when embedded in gelatin methacryloyl.

The incorporation of immune cells into the existing epidermis-dermis skin model creates a more advanced and physiologically relevant platform for drug and therapy screening. This innovation will greatly improve the model's functionality, providing a dynamic system for studying skin-related immune reactions. By closely mimicking the interactions between skin tissues and the immune system, this model will serve as a valuable tool for investigating disease mechanisms and therapeutic responses.

Paper 1364 3

3D constructs enhanced with nano(bio)materials for functional regeneration of both hard and soft tissues.

Prof. Sonia Fiorilli, Italy

Oral Presentation (20')

Abstract

Advanced clinical devices should not only serve as biocompatible support for tissue regeneration but also actively engage with host tissues to promote rapid and functional healing of both soft and hard tissues. Novel and personalized approaches are particularly needed when the intrinsic regenerative efficacy of tissue is impaired or delayed due to the patient's clinical context, the regenerative capability of the injured tissue, and/or the occurrence of concomitant complications.

To address this challenging perspective, advanced fabrication technologies like 3D printing and electrospinning have been extensively utilized in current literature to process both natural and synthetic functional polymers, creating biomimetic scaffolds for various clinical applications.

The potential and versatility of these constructs are further enhanced when combined with (bio)active and stimuli-responsive nanomaterials, enabling additional functionalities, such as the spatiotemporally controlled release of therapeutic agents and bio-specificity. This contribution aims to showcase recent studies, primarily conducted within collaborative EU-funded projects, focused on designing and validating novel solutions to prevent adverse remodeling in bone, skin, and cardiac tissues. Composite 3D scaffolds and flexible nanofibrous membranes have been fabricated using 3D printing and electrospinning, employing a variety of engineered formulations. These formulations include both naturally derived polymers (e.g., collagen, chitosan) and synthetic polymers (e.g., PCL, PVDF), combined with nanomaterials such as bioactive mesoporous glasses (MBGs), mesoporous silica nanoparticles (MSNs) loaded with drugs, nano-hydroxyapatites, and superparamagnetic iron oxide nanoparticles. Additionally, surface functionalization with biomolecules or coatings that respond to endogenous or exogenous stimuli can expand the range of functionalities and modulate the release properties according to the targeted clinical specifications.

Focusing specifically on bone tissue engineering, collagen-based formulations enriched with nano-hydroxyapatite or MBG, were optimized with special attention to rheological properties and the inorganic/organic ratio to enable 3D printability or electrospinning. The inclusion of superparamagnetic nanoparticles was also explored to create stimuli-responsive membranes that promote cell differentiation through mechanotransduction mechanisms.

In the field of cardiac tissue regeneration, the focus will be on recent achievements in designing an electrospun piezoelectric patch enriched with ultrasound-responsive MSNs for in situ, on-demand release of anti-inflammatory and anti-fibrotic agents after myocardial infarction (MI). To achieve this, MSNs were grafted with sodium alginate and cross-linked with CaCl₂ to exploit the reversibility of coordination bonds between Ca²⁺ and COO⁻ groups of SA.

Furthermore, the final constructs have undergone extensive physicochemical characterization and in vitro/in vivo assessments, providing essential data on biocompatibility and the efficacy of the proposed clinical solutions.

Advanced composite nano-structured bioactive scaffolds for bone tissue engineering

Prof. Djordje Veljovic, Serbia

Oral Presentation (20')

Abstract

The treatment of large bone defects is currently one of the major challenges in clinical orthopedics, as defects resulting from musculoskeletal tumors, infections, or trauma are unable to heal spontaneously, even with adequate medical care. The development of novel macro-porous bioactive composite nano-structured materials for treatment of large bone defects and human hard tissue regeneration is the main focus of this research, aiming to enable controlled volume, improve osseointegration and promote the formation of new bone tissue. In the first step multi-ion doped nano-structured meso-porous calcium hydroxyapatite (nHAp) was synthesized hydrothermally and multi-ion doped nano-structured meso-porous bioactive glasses (nBAG) was synthesized using micro-emulsion sol-gel method. In the second step, biodegradable scaffolds based on a poly(methacrylic acid)/gelatin interpenetrating network (IPN) were developed using 3D-printing and free radical polymerization. The effects of inorganic nano-particles on the microstructure, biodegradability, swelling behavior, mechanical properties, and biological performance of composite scaffolds were investigated. Magnesium, strontium, copper, and zinc therapeutic cations, used as dopants during the synthesis of rod-like nHAp and spherical nBAG particles, were successfully incorporated into the crystalline and amorphous structures, respectively. In both cases, biocompatible particles with the desired morphology and meso-porosity were obtained. The resulting composite hydrogels, based on poly(methacrylic acid) and gelatin IPN, exhibited a uniform microstructure and appropriate macro-porosity and biocompatibility. The biodegradability and porosity of the 3D-printed composite hydrogels were further controlled by the formation of a polymeric coating on the scaffold surface. The swelling behavior, biodegradability and mechanical properties in large quantities depend on the percentage of incorporated nHAp and nBAG bioactive particles. Both the 3D-printed and free radical polymerized scaffolds also showed potential for the controlled release of antibiotic and anticancer drugs. Due to their superior physic-chemical, mechanical, and biological properties, the obtained bioactive materials exhibited significant potential for applications in biomedicine, and bone tissue engineering.

Paper 514 **5** **Gelatin Methacryloyl as an effective alternative to conventional matrices for patient-derived 3D models of metastatic colorectal cancer (mCRC).**
Ph.D. Giulia Mesiano, Italy
Oral Presentation (20')

Abstract

Gelatin Methacryloyl (GelMA) is a biomaterial that has gained increasing attention in biomedical research in recent years due to its remarkable tunability and biocompatibility properties. As a semi-synthetic hydrogel derived from gelatin and functionalized with methacrylic anhydride, its features can be easily modified through variations in concentration and crosslinking degree, allowing for the creation of highly customizable matrices for 3D models¹.

Colorectal cancer is the third leading cause of cancer-related deaths worldwide and the 5-year relative overall survival for metastatic patients remains poor. This study introduces a tunable matrix based on GelMA for enhancing 3D models of patient-derived metastatic colorectal cancer (mCRC). Traditional 2D cell cultures inadequately replicate the complex tumor microenvironment, limiting the accuracy of preclinical drug testing and cancer research. The developed GelMA-based matrix aims to overcome these limitations by providing a more physiologically relevant scaffold that mimics the extracellular matrix of mCRC.

The study has been carried out with five patient-derived mCRC organoids from the XENTURION platform shared by Prof. L. Trusolino². All the organoids derived from liver metastatic, heavily mutated and resistant CRC tumor and showed the same transcriptional profile and sensibility to drugs of original tumor. The GelMA-based matrix was synthesized and optimized through in vitro 3D proliferation essays, for mechanical properties and biocompatibility, supporting realistic cell morphology, proliferation, and invasion behaviors. Two different types of GelMA sources (porcine type A and bovine type B) have been tested and three different concentrations for each one. Methacrylation level and GelMA concentration dictate pore size and matrix stiffness, impacting cell behavior. Different GelMA-based matrix morphology was analyzed via SEM, stiffness assessed through rheology, and methacrylation degree quantified using the Fluoraldehyde quantitative assay (OPA assay).

In vitro assays demonstrated that the GelMA A-based matrix is comparable to existing 3D culture systems in maintaining essential cellular functions and interactions. Two-week 3D cultures in the GelMA A-based matrix showed that patient-derived mCRC organoids proliferated and organized into typical tube-like structures, displaying good interactions and high viability upon confocal analysis and MTT assay.

The next steps will involve performing long-term 3D cultures in the GelMA matrix and subsequently confirming the tight similarity in the transcriptional profile and drug response of the patient-derived mCRC organoids. Ultimately, the aim is to propose our matrix as a valid alternative to conventional ones (Matrigel, BME), leveraging GelMA's superior tunability, mechanical stability, greater batch-to-batch consistency, biological versatility and low cost of self-lab-production^{3 4}.

Paper 1416 6 Novel biomaterial ink formulations and approaches for in situ bioprinting and regeneration of colorectal mucosa and submucosa

Prof. Chiara Vitale-Brovarone, Italy

Oral Presentation (20')

Abstract

Two million individuals in the European Union suffer from colorectal diseases, which account for several pathologies that affect the mucosa and submucosa layers of the anus, rectum, and colon. Among these pathologies, familial adenomatous polyposis (FAP) and ulcerative colitis (UC) could benefit from the removal of the intestinal mucosa and submucosa. Currently, when their removal is necessary, patients undergo a proctocolectomy (i.e., surgical removal of the rectum and all or part of the colon) with a subsequent ileal pouch that preserves the patient's continence but is often burdened by significant complications.

In this context, the EU project "TENTACLE" aims to develop a radically new strategy for the surgical treatment of UC and FAP by means of an innovative in situ 4D bioprinting suite to fabricate shape-morphing, layered bioconstructs directly inside the patient's rectum/colon. The unique formulation of the bioconstructs will promote the regeneration of colorectal mucosa and submucosa and will enable tissue regeneration also by delivering antibiotics and antifibrotics molecules. In addition, the mucosa layer will possess a shape-morphing capability, triggered by humidity, that will induce the creation of crypts on its surface, aiming to replicate the natural colorectal ones.

The TENTACLE in situ 4D bioprinting suite will include a novel colonoscopic bioprinter that will be mounted on commercial colonoscopes and will feature an extrusion-based bioprinting unit, a valvejet printhead, and a photocrosslinking apparatus.

Regarding the composite formulations used to print the layered bioconstructs, these will be based on two novel bioink formulations containing patients' cells and sharing a matrix based on photocrosslinkable gelatin and thiolated polysaccharides. These bioinks will be ad hoc enriched with engineered micro- and nano-carriers incorporating antibiotic and antifibrotic agents in the form of spray-dried micro- and nanoparticles and/or cyclodextrins.

The TENTACLE approach, in situ bioprinting suite, and composite bioink formulations will be validated ex vivo and in vivo in small rodents and swine models, thus paving the way for translating the approach, the bioprinting suite and the bioink formulations toward the clinics.

Overall, the TENTACLE project will introduce a minimally invasive alternative to proctocolectomy and is expected to positively impact the quality of life of patients affected by FAP and UC.

Paper 1208 7 Cell-Derived Extracellular Matrices for 3D in vitro Tumor Models for Breast Cancer Research

Mrs. GULSUN BAGCI, Spain

Oral Presentation (20')

Abstract

Decellularized Extracellular matrices are new scaffolds for bioengineering of 3D tumor-ECM in vitro models. The tunable composition, properties, and structure of Cell-derived Matrices (CDMs) make them versatile and easy to use by using desired cell types. Moreover, ECM composition can be modulated with the use of specific cells, or stimulants such as macromolecular crowding (MMC) or biomolecules. The aim of this work is to develop fibroblast CDMs from human dermal fibroblasts (hDFs) at 2D and from bone marrow human mesenchymal stem cells (BM-hMSCs)/Human Adipose-derived stem cells (hAMSCs) at 3D on PLA microparticles to assess their potential to bioprint cancer models for drug screening.

In this study, we generated CDMs from hDFs at 2D culture and CDMs from bone marrow human mesenchymal stem cells (BM-hMSCs)/Human Adipose-derived stem cells (hAMSCs) on Poly Lactic acid (PLA) derived microparticles (MPs) using several stimulants, and decellularized by chemical methods. MPs were generated by jet break-up method, and their size distribution was calculated by ImageJ whereas their porosity was imaged under SEM.

The ECM production before and after decellularization was evaluated by BCA, hydroxyproline, qRT-PCR, immunofluorescence and mass spectrometry. Then, CDM was methacrylated (CDM-MA) to prepare CDM Hydrogels. Hydrogels Young modulus were determined. Methacrylation of CDM was verified by ¹H-NMR and porous structure of them was determined by SEM. After hydrogels characterization, bioinks were prepared by mixing MCF7 cells with CDM-MA and GelMA, and tumoroids were bioprinted. Cell-laden hydrogels were cultured for 14 days. Cell viability and morphology was evaluated by confocal microscopy. Moreover, the doxorubicin resistance of the cell-laden hydrogels was determined by Alamar Blue. Based on our results, HDF are able to deposit a CDM that closely recreates the tumor ECM. MCF-7 cells formed spheroids in CDM hydrogels and they were alive after culturing 14 days with a high resistance to doxorubicin. Mixing GelMA with CDM increased young moduli of hydrogels to recreate the tumor stiffness and enables the bioprinting of cancer models. Altogether, these findings suggest that CDM-based bioinks and hydrogels could be a powerful biomaterial to develop more physiological relevant cancer models.

Advanced Hydrogel Bioinks composed of Natural Nanofibers and Polysaccharides for 3D Bioprinting applications

Dr. Maria Teixeira, Portugal

Highlight (Oral Presentation 20')

Abstract

The advent of 3D bioprinting has revolutionized fields such as tissue engineering and drug development, by enabling the biofabrication of 3D cell-laden constructs that mimic native tissues architecture. This innovative technology relies on the layer-by-layer deposition of 'bioinks' (cell-laden biomaterials) under computer-controlled conditions to create functional biological tissue analogues.

Polysaccharide-based hydrogels are widely employed as bioink matrices due to their favorable rheological properties, ease of crosslinking, structural similarity to the extracellular matrix, and inherent biocompatibility. However, achieving a precise control over their mechanical and rheological properties remains a challenge. One promising approach to address these limitations is the incorporation of nanostructured additives, which can enhance the performance of hydrogel-based bioinks.

In this communication, we explore the use of natural nanofibers, such as protein amyloid nanofibrils and nanofibrillated cellulose, into polysaccharide-based hydrogel bioinks composed of alginate [1], pectin [2], gellan gum [3], cellulose [4], FucoPol [5], and carrageenan. These biobased nanofibers, characterized by their high aspect ratio, mechanical robustness, thermal stability, and biocompatibility, demonstrate significant potential for the development of nanocomposite bioinks with enhanced rheological properties and printability. The incorporation of these nanofibers results in 3D bioprinted constructs with superior mechanical integrity and improved biological performance, paving the way for advanced biofabrication strategies in regenerative medicine and other biomedical applications.

Paper 1096 2

Polysaccharides chemical modification for biomedical additive manufacturing

Ph.D. Simona Braccini, Italy

Oral Presentation (20')

Abstract

Polysaccharides are carbohydrate-based biomaterials that are extensively used in the biomedical field. Their unique chemical structures are critical in determining their bioactivity exploited in a wide range of applications. However, some limitations may potentially hinder their use. In this context, many approaches have been studied to incorporate additional functional groups, cross-link the macromolecular structure, and vary the physico-chemical properties of the polysaccharides [1]. In this contribution, the application of computer-aided wet-spinning [2] was investigated to process different polysaccharide hydrogels into 3D scaffolds exploitable for tissue engineering: i) hyaluronic acid and chitosan polyelectrolyte complex scaffolds chemically cross-linked with poly(methyl vinyl ether-alt-maleic acid) (PMVEMA) [3] and ii) carboxymethyl chitosan scaffolds ionotropically crosslinked with Zn²⁺ and grafted with collagen [4]. The polyelectrolyte complex formation, cross-linking, and chemical functionalization were studied by infrared spectroscopy, nuclear magnetic resonance, thermogravimetric analysis, mass spectrometry, and differential scanning calorimetry. Furthermore, it was established that cross-linking processes were effective in improving the stability of hydrogels in physiological environment. Zn²⁺ crosslinking endowed the scaffolds with strong antimicrobial activity against E.coli and S.aureus. The in vitro cytocompatibility of both types of hydrogels was assessed using the Balb/3T3 clone A31 murine embryonic fibroblast cell line. The results indicated that the PMVEMA cross-linking and the collagen grafting enhanced cell biocompatibility and colonization within the scaffolds, as well as the wound healing process. This demonstrates that these hydrogels are suitable for long-term cell culture experiments and wound dressings for skin regeneration.

3D Bioprinted Cell-Laden Gel for Autologous Chondrocyte Implantation (ACI) Procedures

Mrs. Fatma Ozdemir, United Kingdom

Oral Presentation (20')

Abstract

Autologous chondrocyte implantation (ACI) is a surgical approach designed to repair cartilage defects in joints by using the patient's chondrocytes. These cells are harvested, cultured in vitro, and then implanted into the defect site, typically secured beneath a membrane to ensure they remain in place. For example, matrix-assisted chondrocyte implantation (MACI) involves encapsulating the chondrocytes within a membrane before implantation. This study explores the potential enhancement of MACI through the Reactive Jet Impingement (REJI) bioprinting technique. Utilizing the Chondro-Gide commercial product, the REJI bioprinting system was employed to print gels loaded with chondrocyte cells directly onto the surface of Chondro-Gide patches. This approach ensures that the bioprinted cell-laden gel features well-defined and consistent cell densities. Here we report on evaluating the use of ReJI bioprinting utilising an in vitro ACI model.

The REJI bioprinting technique was utilized to print chondrocytes derived from the Y201 stem cell line within a collagen-alginate-fibrinogen (CAF) hydrogel. The gels were printed onto the surface of Chondro-Gide patches at two distinct cell densities: 5 million cells per mL and 25 million cells per mL of gel. Over 14 days, the expression of functional genes, extracellular matrix (ECM) formation, and mechanical properties were monitored. Quantitative and qualitative analyses were conducted through assays to assess cell viability, DNA quantification, gene expression (ACAN, COL2A1, COL1A1, and SOX9), immunocytochemistry, and immunohistochemistry. The morphology of the CAF hydrogels was also examined using scanning electron microscopy (SEM).

The REJI system successfully printed CAF hydrogels with low and high cell densities onto Chondro-Gide patches. Immunocytochemistry, immunohistochemistry, and SEM results demonstrated an increase in the production of collagen type II, glycosaminoglycans (GAGs), and ECM-like matrix components over the culturing period, with higher production rates observed in high-density CAF gels compared to low-density ones. These findings suggest that the phenotype and cell-cell interactions were preserved. Live/Dead assays confirmed the cytocompatibility of the CAF gels from the early stages of culturing. DNA quantification indicated that high-density chondrocytes encapsulated in CAF gels remained viable for 14 days.

The REJI bioprinting system effectively prints and maintains Y201-derived chondrocytes, facilitating the production of matrix proteins when cultured in vitro. High-density CAF gels exhibited enhanced production of collagen type II and ECM-like matrix, suggesting that a high cell density in a biomimetic gel formulation on Chondro-Gide may offer an improved approach to MACI for regenerating articular cartilage tissue.

ADDITIVE MANUFACTURING OF BIOABSORBABLE CONTINUOUS WIRE-REINFORCED COMPOSITES FOR TISSUE ENGINEERING

Mrs. Ángela García de la Camacha Díaz, Spain

Oral Presentation (20')

Abstract

Additive Manufacturing (AM) has emerged as a transformative approach in biomedical research, offering significant advantages for addressing bone defects, where the fabrication of highly complex and patient-specific structures is essential. Bone tissue presents unique challenges for scaffold development due to its microstructural complexity and variation in mechanical properties. Effective 3D-printed scaffolds should replicate these characteristics while incorporating bioabsorbable materials to support bone healing. Unlike permanent implants, which remain in the body as foreign materials after and may require second surgeries for removal due to inflammatory responses, bioabsorbable implants gradually degrade and are absorbed in the human body. As a result, after degradation, only the natural tissue remains. On the other hand, composite materials are considered a promising option for bone scaffolds, as they combine the benefits of both polymers and metals. However, achieving polymer-based composites with mechanical properties that effectively mimic both cortical and trabecular bone remains a significant challenge, particularly for cortical bone, where higher mechanical demands must be met. Among AM techniques, Fused Filament Fabrication (FFF) is the most suitable for this purpose, as it allows the processing of a broader range of materials than other 3D printing methods, including continuous wire-reinforced composites. The integration of continuous wire reinforcement enables greater implant customisation by adjusting wire orientation in each layer to optimise the mechanical properties according to application and patient needs. This approach provides an optimal solution for enhancing the mechanical performance of polymer-based scaffolds used in bone regeneration. However, despite its potential, limited research has been conducted on the manufacturing of 3D-printed continuous wire-reinforced materials, with only a single study exploring biocompatible and bioabsorbable materials for tissue engineering.

The aim of this work is to manufacture and characterise bioabsorbable wire-reinforced polymers as a potential solution for the healing of bone defects. The first step involves a feasibility study in which polymer matrix composite laminates, reinforced with large diameter (300 μm) continuous metallic wires, will be manufactured using different wire orientations. For the first time, multidirectional wire-reinforced materials will be produced by FFF. Once the manufacturing method is validated, composite laminates of polylactic acid (PLA) and magnesium wires will be fabricated and analysed. Mechanical characterisation and degradation studies will be conducted to ensure that the laminate design accounts for progressive materials degradation without compromising structural integrity, thereby aligning with the regeneration time of native tissue. Finally, biological characterisation will be carried out through in vitro testing.

A Functional AM approach for Biofabricating Micro-Optofluidic Devices for Medical Non-invasive Diagnosis-related Bioapplications

Ph.D. Lorena Saitta, Italy

Oral Presentation (20')

Abstract

Micro-optofluidic (MoF) devices, integrating microfluidics and optical sensing, offer significant advantages for medical diagnostics (Achille et al. 2021, Basiri et al. 2021, Bahmaee et al. 2020). They enable real-time, label-free detection with high sensitivity while requiring minimal sample volumes (Fiorini et al. 2005, Wu et al. 2023). Their potential for portable applications makes them promising tools for non-invasive disease monitoring across various medical fields.

In this study, a MoF device was designed, fabricated, and characterized for potential medical non-invasive diagnostic applications. It was manufactured using a functional Additive Manufacturing (AM) approach to ensure suitable optical properties, surface chemistry, and biocompatibility. A biocompatible and transparent 3D-printable resin was selected, and the device was realized using the P-STL ultra-high-resolution 3D-printing technique.

The primary function of the MoF device is two-phase flow process monitoring through optical detection based on optical absorption phenomenon (Cairone et al. 2016). Its performance was evaluated by studying slug-flow and cell concentration monitoring. The investigated slug-flow process was composed by air and water. Slug-flow monitoring is essential in several physiological and pathological conditions, including respiratory, cardiovascular, renal, and neurological medicine (Selsby et al. 1990, Leerson et al. 2023, Mohsen et al. 2021). For instance, in respiratory medicine, slug-flow monitoring aid in assessing mucus clearance in chronic obstructive pulmonary disease. In cardiovascular care, it helps detect emboli in dialysis and extracorporeal membrane oxygenation, while in intravenous therapy, it ensures precise drug infusion. The device was also tested for cell concentration monitoring by analyzing a two-phase mixture of *Saccharomyces cerevisiae* cells suspended in PBS at different concentrations. Accurate cell concentration measurement is crucial for diagnosing various medical conditions (Laszlo et al. 2014, Hassan et al. 2015, Lehnert et al. 2024). In oncology, label-free MoF devices can detect circulating tumor cells (CTCs) in blood for early cancer detection. In hematology, they assist in determining red and white blood cell counts to diagnose anemia and infections. In nephrology they involve urine analysis to detect kidney diseases through cellular debris and infection markers.

An extensive experimental campaign was conducted under various conditions, testing different laser power levels $P \in \{1; 3; 5\}$ mW, flow rate $FR \in \{0.1; 0.2; 0.3\}$ mL/min, and cell concentrations $C \in \{0; 10^6; 10^7; 10^8\}$ in 10 mL of PBS. A Design of Experiments approach was used to determine optimal operating conditions for robust device performance. The results confirmed the MoF device's capability to effectively monitor slug-flow ($R^2 \in \{76.94\%; 98.27\%\}$) and differentiate between different cell concentrations ($R^2 = 98.74\%$), demonstrating its potential for future medical diagnostics.

Paper 1419 **6** **Bioprinting and electrophysiological evaluation of a 3D cardiomyocyte culture**
Dr. Wing Tai Tung, United Kingdom
Oral Presentation (20')

Abstract

Cardiotoxicity has been the major reason for drug withdrawal from clinical trials. New in vitro cardiac models which appropriately reflect human physiology are required. Contractile functions of in vitro cardiac models are essential measurement in assessing cardiac physiology and responses to pharmacological interventions. In our study, we use reactive jet impingement (ReJI) bioprinting to fabricate a 3D cardiac cell model and measure electrophysiology through a high-density multi-electrode array (HD-MEA) system.

ReJI bioprinting uses two different valves to jet out the gel precursor bioink composed of collagen, alginate and fibrinogen (CAF) to react in mid-air with the crosslinker bioink of thrombin, calcium chloride and HL-1 cells, depositing on the substrate as 3D cell-laden hydrogel construct with cell density of 5×10^6 cells/ml. This work assessed the cell viability, morphology, expression of cardiac-specific biomarkers (myosin and desmin) and gene expression (anti-natriuretic peptide and connexin43).

To assess the contractile functions of the 3D in vitro model, HL-1 cells were cultured in 2D MEA chips as controls, while the 3D gel carrying HL-1 cells was bioprinted directly onto the 3D MEA chips. Both chips have 4096 electrodes with a pitch of 60µm. The 3D chip has the electrodes on pillars while the 2D has the electrodes embedded on plane surface, with each electrode able to record the electrical signals generated from HL-1's spontaneous contraction as field potential. The field potential in 2D samples began from approximately 0.7 mV with regular waveform on day 1 to 1.4 mV on day 3 and declined to 0.8 mV with an inconsistent waveform on day 7. The 3D gel samples instead had a field potential of 0.7mV with consistent waveform from day 1 to increased field potential of 1.8mV and well-defined waveform on day 7. We further assessed the pharmacological responses by exposing the HL-1 cardiac cell to the β -adrenoceptor agonist isoproterenol and selective hERG potassium channel blocker E-4031 separately, demonstrated increased and reduced beat rate respectively, suggesting CAF gel encapsulated cells can responds to drug applied externally.

This provides an improved cardiac tissue in vitro model, and the processing techniques allow for the development of more complex in vitro models, involving co-culture of different cardiac cell types, to study tissue function, response to drugs, and the testing of new devices for tissue regeneration.

Advanced biofabrication technologies to design in vitro central nervous system models

Prof. Chiara Tonda-Turo, Italy

Highlight (Oral Presentation 20')

Abstract

Introduction/Objectives

The recovery of central nervous system functions after injuries remains an unmet clinical need as neurodegeneration involves a cascade of biological events leading to neuronal damage and loss of tissue functionality, whose full comprehension is still not achieved. Advancements in the creation of engineered 3D in vitro models of nervous tissue provide new opportunities in the understanding of these mechanisms, due to the ability of these models to mimic the neural microenvironment with greater physiological relevance than traditional 2D culture systems.

Here we combine additive manufacturing technologies and biomimetic bioinks to develop a 3D neural construct, intended for the in vitro modeling of nervous tissue in physiological and pathological conditions.

Methods

Gelatin Methacryloyl and Thiolated Hyaluronic Acid were mixed to produce bioinks for a motor neuron cell line (NSC-34) and a neural stem cell line (NE-4C) encapsulation. The cell-loaded hydrogels were printed on a polycaprolactone (PCL) oriented microfibrillar structure, fabricated by melt electrowriting technique. The obtained constructs were cultivated for up to 21 days to achieve cell maturation towards astrocytes and neurons. Then, a traumatic event was mimicked by mechanical and chemical insults to recreate a spinal cord injured model in vitro.

Results

The optimization of photo-crosslinkable Gelatin methacryloyl (GelMA) and Hyaluronic acid-based hydrogels was carried out to successfully bioprint neural stem cells (NSCs) without affecting cell viability and behavior. According to the results, the 3D bioprinted scaffold effectively supported the growth and proliferation of encapsulated NSCs, providing an ideal microenvironment for their differentiation into mature neurons and astrocytes. Moreover, the inclusion of an anisotropic pattern was shown to direct neuronal cell elongation according to a preferential orientation, thus enhancing the establishment of a mature and interconnected neural network. Lastly, the efficacy of this system in modeling neuronal injury was assessed by reproducing nervous tissue trauma in vitro.

Conclusions

Overall, it was demonstrated that the combined use of biomimetic hydrogels and organized 3D structures can significantly foster neural cell maturation in vitro, thus offering new opportunities for the creation of functional engineered tissue analogs.

Paper 1411 2

Biofabrication of a piezoelectric cardiac patch for the regeneration of the infarcted heart tissue

Prof. Chiara Vitale-Brovarone, Italy

Oral Presentation (20')

Abstract

Heart failure post-myocardial infarction (MI) is among the leading causes of mortality worldwide, primarily due to the limited regenerative capacity of myocardial tissue. The Horizon Europe REBORN project aims to develop an implantable multifunctional fibrous patch able to promote the regeneration of ischemic tissue and restore the physiological cardiac functionality. To this aim, a drug-loaded piezoelectric patch, biofabricated by electrospinning (ESP) was developed. The patch is designed to promote cardiomyocyte activity thanks to the aligned fibres, electromechanical coupling, and the release of anti-inflammatory and anti-fibrotic agents, as well as cardiomyocyte proliferative agents to control biological events after MI.

Polyvinylidene fluoride (PVDF) formulations for ESP were prepared using a safe solvent mixture combining acetone and dimethyl sulfoxide. Aligned nanofibers (diameter of 200-300 nm) were produced using a rotating collector, and ESP parameters optimized, up to a pilot scale using a system with 15 needles. The optimized process enabled the attainment of high PVDF crystallinity (about 48%) and maximized the piezoelectric β phase content (above 90%). Low-pressure oxygen plasma was used to modify the hydrophobicity of PVDF to a super hydrophilic-like behavior, improving biocompatibility and reducing inflammatory response, as observed in in vivo test on infarcted mice seven days after implantation. Drug loading in the fibrous patch was achieved by electrospinning hybrid formulations incorporating nanocarriers (e.g., mesoporous silica loaded with both anti-inflammatory and antifibrotic drugs), as well as by solubilizing the drug directly into these formulations. The patch also incorporates nanoparticles able to promote cardiomyocyte proliferation. The electrospun patch was characterized in terms of piezoelectrical and mechanical properties, obtaining good piezoelectric response due to the high amount of β phase ($d_{33} = -6.3$ pm/V) and suitable mechanical properties ($E = 65 \pm 12$ MPa; $\sigma_R = 11 \pm 2$ MPa). Cytotoxicity assays were performed using human cardiomyocytes and fibroblasts, and preliminary suturing in vivo tests were performed using mouse and pig models of MI. The patch can be easily handled and manipulated and was sutured to infarcted heart tissue in a pig model, withstanding pulling, stretching and needle passage without rupture. The patch delivery to the epicardium was proven using tools already available for transdiaphragmatic pericardial approach (e.g., integrated in electroanatomic mapping catheters). In summary, a low-toxicity ESP process was used to biofabricate a piezoelectric patch with suitable properties for being sutured on the infarcted heart tissue with low inflammatory response. The patch design was successfully optimized to enable the in situ release of anti-inflammatory, antifibrotic, and cardiomyocyte proliferative agents.

Coaxial Electrospinning of an Anisotropic Piezoelectric PVDF-based patch for Modulated Drug Delivery in Myocardial Infarction Therapy

Dr. Jacopo Barberi, Italy

Oral Presentation (20')

Abstract

Myocardial infarction (MI), among cardiovascular diseases, is currently one of the leading causes of mortality worldwide. After an ischemic event, incorrect remodelling of myocardium occurs, with the formation of a non-functional fibrotic tissue. Current therapeutic strategies, including reperfusion and pharmaceuticals, do not consent tissue regeneration, postponing the progression of the disease, possibly until heart failure. In this context, the Horizon Europe REBORN project aims to develop a drug loaded, nanofibrous patch which enables post-MI tissue regeneration by integrating piezoelectric activity for electro-mechanical coupling with the surrounding tissue, alongside with in situ modulated drug delivery of anti-inflammatory, antifibrotic and pro-regenerative molecules. Electrospinning (ESP) has been selected for its ability to manufacture aligned nanofibrous scaffolds that replicate the anisotropic microstructure of physiological myocardium, as well as for its versatility. In fact, when ESP is used in its coaxial configuration (coax_ESP), it is possible to modulate the drug loading within the fibres, along the radial distance, thereby impacting the diffusion-driven release mechanisms. In this research, coax_ESP in combination with a rotating drum collector was used to fabricate a piezoelectric polyvinylidene fluoride (PVDF) patch, enabling a modulated co-delivery of Ibuprofen (IBU) and Pirlfenidone (PIRF), and showing anisotropic mechanical features. PVDF is a fluoropolymer known for its excellent biocompatibility, mechanical durability, and piezoelectric features, which depend on its β -phase content. When PVDF is processed by ESP, it is possible to induce high β -phase recrystallization, thus increasing its piezoelectric activity. PVDF-based polymeric solutions were used for both the core and shell, to preserve ESP-induced piezoelectricity and mechanical features. IBU and PIRF at the concentration of 1% w/v were incorporated into the shell and core solutions respectively to enhance the anti-inflammatory release, while providing a slower and sustained release of the antifibrotic agent. The therapeutic windows of IBU and PIRF were defined by assessing drug concentrations' effects on inflammation and fibrosis markers in macrophages and cardiac fibroblasts. Computational analysis performed on SEM images confirmed the production of highly aligned nanofibers, with a dimension of approximately 300 nm. The characteristic β -phase behaviour along with the proper drugs incorporation were confirmed by XRD and FTIR. Additionally, DSC analysis showed an overall crystallinity of around 45%. Piezoelectricity of the patch was confirmed by piezoelectric coefficient calculation derived from butterfly-shaped hysteresis curve ($d_{33} \sim 10$ pm/V). The drug release kinetics, assessed by HPLC, highlighted the effectiveness of the coax-ESP in modulating the release of IBU and PIRF within their therapeutic windows.

Multiscale Perfusable Cardiac Tissue Model Using Electrospun PCL Fibres and a Bioprinted Cardiac Co-Culture

Dr. Vignesh Krishnamoorthi Kaliannagounder, United Kingdom

Oral Presentation (20')

Abstract

Developing physiologically relevant in vitro cardiac models is essential for improving drug testing and advancing regenerative medicine. Here, we present a novel approach for reconstructing functional cardiac tissue using a perfusion-based system integrating electrospun polycaprolactone (PCL) fibre scaffolds and bioprinted cardiac co-cultures. The engineered constructs incorporate a high-density cell-laden hydrogel composed of collagen, alginate, and fibrinogen (CAF) to support cardiac myocytes and fibroblasts, forming a biomimetic microenvironment.

Using the Reactive Jet Impingement (ReJI) bioprinting technique, human cardiac myocytes and fibroblasts (5 million cells/mL) were precisely deposited within CAF hydrogel onto PCL fibres, forming an integrated cardiac construct (5 mm diameter, 20 mm length). These constructs were maintained in a custom-designed 3D-printed perfusion system, where an optimized flow rate of 5 mL/min using a peristaltic pump was applied to induce physiological pulsatile flow. After an initial static culture period, samples were divided into static and perfusion culture groups and maintained for an additional seven days. The perfusion system was designed with controlled media exchange through inlet and outlet channels, along with a drainage system to prevent leakage.

Cell viability, proliferation, morphology, and functional marker expression were analysed at key time points for static culture and perfusion culture using fluorescence microscopy, proliferation assays, immunocytochemistry, and gene expression analysis. Results demonstrated that perfusion culture enhanced cellular organization, proliferation, and enhanced cardiomyogenic marker expression, suggesting improved maturation and function compared to static culture.

This study highlights the potential of multiscale scaffold integration with controlled perfusion for constructing physiologically relevant cardiac tissue. The approach offers a robust platform for preclinical drug testing, disease modelling, and cardiovascular tissue engineering applications, reducing reliance on animal models and enhancing the translational relevance of in vitro studies.

Paper 1035 5 **Fabrication and Optimization of GelMA Hydroxyapatite Scaffolds for 3D Printing via Digital Light Processing**
Mrs. Anastasiia Budaeva, Italy
Oral Presentation (20')

Abstract

Advancements in digital light processing (DLP) technology for 3D printing of polymer-ceramic photocurable resins are driving innovation in medicine and tissue engineering. This approach allows for the fabrication of highly precise, biocompatible scaffolds tailored for tissue regeneration. The development of sustainable photocurable resins derived from natural and biodegradable components offers a safer alternative to conventional epoxy and acrylate-based materials, reducing both toxicity and environmental impact. These next-generation materials enhance biocompatibility, optimize structural integrity, and contribute to more efficient and personalized solutions for bone and cartilage tissue repair.

In this study, a biocompatible photocurable polymer-ceramic composite was formulated using gelatin-methacrylate (GelMA) and hydroxyapatite (HA) nanoparticles (~300 nm average size). GelMA was synthesized in water at different pHs, and its degree of functionalization (DoF) was analyzed using nuclear magnetic resonance (NMR) spectroscopy. The photocurable resin was prepared by dissolving GelMA in water, followed by the addition of a photoinitiator and HA nanoparticles. To optimize the 3D printing process, curing depth experiments were conducted by adjusting LED power and exposure time. Rheological analysis was performed to evaluate viscosity and investigate how variations in GelMA/water ratio and HA content influence the resin's flow behavior during printing. FTIR analysis was conducted to evaluate the degree of conversion and the efficiency of photopolymerization. Additionally, FESEM analysis was performed to investigate the internal microstructure, including the dispersion of HA within the GelMA matrix, pore morphology, and overall homogeneity of the composite scaffolds. NMR analysis revealed that GelMA synthesized at pH 10 achieved the DoF, that is 92%. The enhanced DoF at pH 10 improved crosslinking efficiency during photopolymerization, as assessed with FTIR analysis, leading to stronger and more stable samples with superior mechanical properties and controlled degradation.

Printability tests indicated that a GelMA concentration of 30 w/v% provided the best printing performance. Compositions with HA content ranging from 15% to 55% were printed to evaluate the balance between printability and mechanical performance. After printing, samples were freeze-dried and their physical, mechanical and morphological properties were evaluated. FESEM micrographs revealed a not homogenous dispersion of the ceramic filler inside the matrix and new tests are ongoing to overcome this drawback. Moreover, HA addition affected samples porosity, leading to a more homogenous pores distribution with less interconnected pores. On the other side, as expected, density increased by increasing HA content. Finally, preliminary mechanical tests confirmed the benefits of HA addition on the GelMA/HA scaffolds compressive strength.

Paper 1263 6 **Reactive jet impingement bioprinting with fibre, metal and ceramic substrates for enhanced composite cell cultures**
Prof. Kenny Dalgarno, United Kingdom
Oral Presentation (20')

Abstract

Reactive jet impingement (ReJI) is a bioprinting technique developed at Newcastle University which allows cell filled hydrogels to be printed onto a wide range of biomaterial substrates.

The process works through the generation of two droplet streams, one a polymer solution, and the other a solution which initiates crosslinking of the polymer solution to create a hydrogel. The droplet streams are directed to collide in a "V" configuration at which point the crosslinking reaction occurs and a hydrogel droplet is created which falls to the substrate. If cells are suspended in either the polymer solution or the crosslinking solution or both, then the cells are ultimately encapsulated in the hydrogel droplets and cell filled gel droplets are produced. Through using microvalves with the capability to produce droplets at a high frequency and using hydrogel systems which provide for rapid cross-linking reactions a high throughput bioprinting system can be produced.

A valuable aspect of this approach to printing cells is that because the solutions are dispensed from the micro-valves when they are suspended in low viscosity solutions no significant shear stresses are generated in the flow. The reaction which creates the high viscosity gel happens after the solutions have been jetted, and this means that hydrogels can be created which contain a high concentration of cells without affecting viability. The high concentration has advantages in terms of the bioactivity seen within gels: cell-cell and cell-extracellular matrix interactions are closer to those seen in native tissues which means that the behaviour of the in vitro cultures is more representative of real tissues.

This presentation will show how the ReJI bioprinting process can be used with fibre, metal and ceramic substrates to create composite structures for regenerative medicine or in vitro modelling. Collagen, alginate and fibrin bio-inks have been used to print a range of cell types onto calcium-alginate and polycaprolactone fibre substrates to produce smart wound dressings and cardiac models, and onto metal and ceramic substrates to biologically enhance musculoskeletal implants immediately prior to implantation. The produced cell cultures have been evaluated for cell viability and function to demonstrate the value of the bioprinting approach in promoting the development of bioactive composites.

Paper 1549 1 **Towards material circularity and manufacturing sustainability in the automotive industry**

Prof. Alan Luo, United States

Keynote (Oral Presentation 40')

Abstract

Although materials and manufacturing are the backbone of the global economy, they also pose a significant climate liability. In 2023, 59 gigatons (Gt) of CO₂eq were emitted, with nearly 40% of industrial emissions coming from iron and steel, aluminum, and plastics. Decarbonizing these sectors by increasing circularity and reducing energy use is essential for achieving a carbon-neutral, circular economy. For example, steel production (1,700 Mt annually) uses only 45% scrap input, emits 3.7 Gt CO₂eq, and generates 425 Mt of scrap; aluminum production (94 Mt annually) relies on 30% scrap, emits 0.7 Gt CO₂eq, and produces nearly 40 Mt of scrap; while plastics account for 4.5% of global emissions with just 18% recycled, and their production is expected to rise as petroleum feedstocks shift to material applications. On the other hand, fossil fuels currently supply 84% of global energy and 90% of transportation energy, yet automotive OEMs worldwide are committing to carbon neutrality by 2035–2050. With California banning new gasoline-powered cars and Canada requiring all new vehicles to be zero-emission by 2035, the automotive industry in North America is shifting from internal combustion engines to electric and hydrogen fuel cell vehicles. This electrification presents major opportunities for achieving material circularity and sustainable manufacturing.

This paper reviews emerging technologies that promote material circularity and manufacturing sustainability in the automotive industry, using aluminum sustainability as a prime example. Although aluminum is increasingly employed for lightweighting in transportation to reduce energy consumption and carbon emissions, its primary production is highly energy-intensive and generates substantial CO₂ emissions. In contrast, re-melting aluminum scrap consumes only about 5% of the energy needed for primary production, markedly reducing emissions and ensuring a sustainable supply chain. Additionally, renewable materials such as “super wood”—densified natural wood with metal-like mechanical properties—offer further promise. Advances in energy-efficient large thin-wall die casting (mega/giga casting) support the sustainability of automotive manufacturing, especially as alternative energy vehicles adopt simplified body structures that enable the use of consolidated castings, thereby minimizing welding and assembly operations. Moreover, reclaiming high-value battery materials from electric vehicles remains challenging; however, a patented “Hydro-to-Cathode” direct precursor synthesis process effectively leaches impurities and retains valuable metals, streamlining recycling by eliminating multiple processing steps. Ultimately, the integration of recycled/renewable materials with energy-efficient manufacturing techniques is key to driving the automotive industry toward a circular and sustainable future.

Paper 1975 2 **Fe, Cu and Zn modification strategies in recycled AlSi10MnMg alloy: insights from high-pressure die casting (HPDC) and gravity casting processes.**
Dr. Dirk Lehmkus, Germany
Oral Presentation (20')

Abstract

The transition from internal combustion engines to electric vehicles has had a substantial impact on the automotive industry, particularly on foundries supplying high-volume products. There has been a decline in demand for traditional components such as engine blocks and gearboxes, which has led to a shift towards structural castings. Several of these castings are produced using Giga casting technology, which has been adopted by companies such as Tesla, Volvo, Nio, and XPeng. The fundamental idea behind this approach is to blow up the size of high pressure die casting (HPDC) equipment to levels that allow the production of large underbody parts or battery housings in a single operation. However, the increased use of aluminum alloys gives rise to concerns regarding their carbon footprint, with primary aluminum production emitting up to 20 kg CO₂eq per kg in China, compared to 8.6 kg in Europe. Recycled aluminum, such as AlSi10MnMg alloys, offers a lower carbon footprint but faces challenges due to impurities (e.g. Fe, Cu, Zn) in post-consumer scrap. The present study investigates the influence of such impurities on casting characteristics, microstructure and quasistatic mechanical properties with respect to an AlSi10MnMg base alloy. For this purpose, a DoE is developed covering, besides the reference alloy, stepwise compositional modifications with respect to the impurity content levels. A further comparison is made with two commercial alloys containing 58 and 89 wt.-% of secondary materials, respectively. The evaluation covers mold filling characteristics evaluated in gravity as well as high pressure die casting, metallographic studies based on light and scanning electron microscopy, and mechanical testing under bending and tensile loads. The aforementioned investigations are complemented by salt spray tests for evaluation of corrosion resistance. The results obtained are contrasted to corresponding data from the literature and recommendations are made with respect to the possibility of setting new compositional limits in order to facilitate the use of secondary aluminum casting alloys of the Al-Si-Mg type.

Paper 1830 1 **Multi-material Lightweight Design with Aluminum-Steel Hybrid-Casting: Process Parameters and Influencing Factors**
Mr. Florian Mielke, Germany
Oral Presentation (20')

Abstract Multi-material Lightweight Design with Aluminum-Steel Hybrid-Casting: Process Parameters and Influencing Factors

Introduction

Steel and aluminum remain key materials for lightweight design, especially in automotive applications. Both materials have different advantages in their mechanical and physical properties as well as their processing technologies. The presented aluminum-steel hybrid-casting process enables metallurgical bonding between aluminum cast components and steel sheets or profiles. It combines the specific advantages while eliminating the need for costly mechanical joining or adhesive bonding. The resulting hybrid structures are lightweight, space-efficient, and optimized for load conditions.

The metallurgical bonding is achieved by a unique Al-Si coating on steel inserts and optimized high-pressure die casting (HPDC) parameters. Casting simulations and experimental trials identified optimal process parameters, validated through mechanical tests.

Methodology

Steel inserts were coated with a 20-25 μm Al-Si layer by physical vapor deposition (PVD), forming a dual-layer structure. The first intermetallic sublayer ($\sim 2\text{-}3\text{ }\mu\text{m}$) contains Fe-Si-Al phases, while the thicker Al-Si layer on top ensures bonding with molten aluminum, inhibiting brittle phases.

Cold-forming and dual-phase steels were paired with an AlSi10MnMg aluminum cast alloy. Extensive casting trials were conducted using a HPDC machine. Key parameters varied were:

- Melt temperatures: 685–750 °C
- Gate velocities: 20–60 m/s
- Die temperatures: 180–280 °C
- Insert preheating: 20–500 °C

Numerical casting simulation supported parameter optimization. Mechanical testing on produced samples included tensile shear, pull-out, cross-tension, and fatigue experiments to evaluate joint strength.

Results

Die temperature and insert preheating significantly influenced bond strength, with higher values creating superior results. Higher gate velocities also improved bonding, whereas lower melt temperatures were favorable. Simulation data correlated well with fracture patterns and measurements.

Shear strength tests yielded an average of approximately 16 MPa, with low deviation ($< 1.2\text{ MPa}$). The ductility of the bond was evident from significant necking in the steel insert and heavily deformed honeycomb fracture surfaces in SEM images.

In pull-out tests, failure occurred in the steel component rather than at the joint. Similarly,

FEMS EUROMAT 2025 - SYMPOSIUM PROGRAM

15/09/2025

E1 – Automotive and surface transport

Z3 Room (Level -3)

fatigue tests under cyclic tensile loading showed crack propagation within the steel insert, without premature joint failure.

Conclusion and Outlook

This study establishes key process parameters for a reliable aluminum-steel hybrid-casting process, achieving a strong and ductile metallurgical bond. Future work aims to scale the technology from test samples to automotive components. Planned demonstrators include a hybrid aluminum-steel beam for torsion, bending, and crash testing, as well as a hybrid strut tower, pushing the technology towards industrial application.

Paper 1432 2

Advanced Laser welding processes for joining of High Pressure Die Casting (HPDC) components made from secondary aluminum alloys

Dr. Dirk Dittrich, Germany

Oral Presentation (20')

Abstract

The automotive industry is subject to the necessity of reducing the carbon footprint of their products. With the transition of from internal combustion engine to electric drive, the focus in this respect has moved from the use to the beginning-of-life, i.e. the production phase. At the same time, the production of rear and front underbodies as well as battery cases as single-piece castings (often termed Mega- or Gigacasting) has the potential of drastically increasing the amount of cast aluminum in automotive body structures. As a primary material, aluminum production carries the burden of a considerable energy input, and thus, depending on the energy source, a carbon footprint in a range from approx. 2 (hydro power, Norway) to 8.6 (Europe, average sourcing) and 20 kg (fossil fuels) CO₂eq./kg primary Al. The focus thus moves to the possibility of using secondary aluminum alloys. These are typically characterized by an accumulation of specific elements like Cu, Fe and Zn, which have an impact on structural characteristics, corrosion etc., plus a higher likelihood of other types of impurities. Several studies are currently addressing the issue of material characteristics, however, the question of joining techniques is of similar importance and has so far largely been neglected in terms of the impact of using secondary alloys.

The present study attempts to partially close this research gap by addressing the laser beam welding process. Since HPDC is mostly considered unsuitable for welding due to high hydrogen contents and trapped gases from the casting process an excellent welding process and the desired high quality cannot be guaranteed. By modifying conventional laser welding with the dynamic beam modulation approach, the welding process can be stabilized and the joint quality significantly improved. In experimental studies covering high pressure die cast AlSi10MnMg alloys with secondary material content levels ranging from 0 wt.-% to 89 wt.-%, castability and weldability were investigated and the structural and mechanical properties of the joint determined. The paper shows how the developed approach of dynamic beam modulation can be used to combine die casting with semi-finished products in order to achieve lightweight construction and produce a cost-effective car body. In combination with the use of secondary casting, this opens up the possibility of producing almost CO₂ neutral components.

Paper 1908 3 **Aluminium matrix composites with recycled alloys for lightweight automotive brake discs**
Ph.D. Lucia Lattanzi, Sweden
Oral Presentation (20')

Abstract

Aluminium-based metal matrix composites (MMCs) are promising materials for automotive brake discs, and aluminium provides an opportunity to use secondary alloys in the production of MMCs. Interest in the sustainability of composites is increasing steadily, and further investigation is needed when secondary aluminium alloys are included as the matrix. The drawback is that secondary aluminium alloys usually include several impurities and oxides that can harm the mechanical and thermophysical properties. Given the promising results of the preliminary studies, the present work focuses on the characterization of Al-Si-based MMCs reinforced with 20 wt. % of SiC particles. The brake discs are produced by squeeze casting using 0 %, 50 %, 70 %, and 100 % secondary AlSi9Mg alloy for the matrix.

The critical material properties for brake discs are good thermal conductivity, a suitable mechanical response at high temperatures, and a coefficient of friction that guarantees an acceptable braking performance. The microstructure of the MMC produced with the secondary alloy was comparable to that of the reference composite (0% recycled alloy), indicating good incorporation of SiC particles in the melt. The intermetallic phases present are linked to magnesium and iron, with Chinese script and lamellar morphologies, especially in MMCs containing recycled alloys. The presence of these phases had a limited effect on the thermal conductivities of the composites produced with secondary alloys. Similarly, the compression strength up to 470 °C is in line with that of the reference composites, indicating that the microstructural features related to the secondary alloy have a limited impact on the mechanical performance. The evolution of the microstructure with different strain rates and temperatures was investigated by SEM, EDS, and EBSD to describe the role of different microstructural features. The results of the present study confirm that these composite materials provide good mechanical performance and suitable thermophysical properties for automotive brake discs combined with a lightweight solution. The main challenge lies in the recyclability of the material at the end-of-life of the brake disc, which will be the focus of our future research.

4

Sustainable Recovery of Critical Raw Materials through Advanced Hydrometallurgical Recycling

Dr. Stylianos Spathariotis, Cyprus

Highlight (Oral Presentation 20')

Abstract

The emerging shift of the linear raw materials value chain to circular economy in the automotive sector entails the recycling of strategic and critical raw materials (CRMs) from End-of-Life (EoL) vehicle components and devices. Two innovative approaches have been developed focusing on recovering valuable materials from automotive catalysts, hydrogen fuel cells, permanent magnets, and lithium-ion batteries of electric vehicles (EVs), all essential for future mobility and sustainable transportation. The underlying research aims at closing the loop in the value chain of these EoL devices by utilizing two concepts; i) chlorine hydrometallurgy using HCl, and solvometallurgy using Deep Eutectic Solvents (DESS).

Both processes begin with pre-processing of the EoL device, followed by selective leaching and refining of CRMs, and is completed by reusing the recovered CRMs in new products. The hydrometallurgical leaching process has been developed and upscaled by MONOLITHOS in one-step, offering energy-efficiency and achieving very high CRM recovery rates from the aforementioned waste streams, i.e. 100% of Pt, 92% of Pd and over 61% of Rh from three-way catalytic converters (TWC) [1]. Characterized as environmentally friendly, the solvometallurgical leaching process developed by YS Cypriot Catalysts, utilizes biodegradable lixivants [2] to extract over 81% of Pt, 95% of Pd and 79% of Rh from EoL TWCs. Both processes can be tailored to meet the specific requirements of the different automotive waste streams, offering flexible and sustainable solutions for CRM recovery. The chlorine hydrometallurgy approach offers high efficiency in extracting metals from spent materials like autocatalysts but involves the use of acids, raising environmental concerns. In contrast, recycling using DESS is more environmentally friendly with low toxicity, but it has lower extraction rates and is presents challenges during upscaling for industrial operations. However, process optimization and parametrization through computational modeling can provide the potential for DES processing to achieve comparable metal extraction yields to chlorine hydrometallurgy. Thermodynamic modelling on DES systems can provide insights on the chemical interactions and process mechanism, towards resolving upscaling bottlenecks and the recycling of more EoL feeds beyond TWCs.

Aiming to reduce the EU dependency on virgin raw materials in the automotive sector, both recycling processes promote a sustainable, resilient and resource-efficient ecosystem aligned with the transition to “green mobility”.

Effects of different surface treatments on the fatigue behaviour of AlSi10Mg alloy produced by Powder Bed Fusion-Laser Beam: a comparison between machining, sandblasting and Ni-9%P+(a:c-H)DLC multilayer coating

Ph.D. Gianluca Di Egidio, Italy

Oral Presentation (20')

Abstract

The demand for sustainable mobility is growing and the use of innovative materials and processes is essential to support the ecological transition. The AlSi10Mg alloy produced by Powder Bed Fusion-Laser Beam (PBF-LB) is widely used in the production of lattice structures and thin-walled parts in electric and hybrid vehicles due to its high strength-to-weight ratio. However, poor surface finish and high defect density in the surface area of the as-built components can significantly reduce the fatigue performance of structural parts. In this perspective, surface treatments can be useful to improve the fatigue strength of PBF-LB-produced components, reducing the negative effects of process-induced defects and as-built surface.

In this work, rotating bending fatigue tests were carried out on the PBF-LB AlSi10Mg alloy subjected to two different heat treatments (direct aging (T5) and T6 solution treatment), used to maximize the mechanical properties, and in three different surface conditions: (i) machined, (ii) sand-blasted, (iii) Ni-9%P+(a:C-H)DLC coated. A detailed microstructural, mechanical and fractographic characterization was performed to evaluate the effect of heat treatments and surface treatments on the fatigue strength of the material.

The results showed significant and comparable improvement in fatigue strength achieved by both sandblasted and Ni-9%P+(a:C-H)DLC coated samples: approximately 55% for the T5 alloy and approximately 25% for the T6 alloy compared to the machined samples. The residual compressive stresses in the superficial and sub-superficial zone and the change in type and distance from the surface of the "killer" defects induced by sandblasting and multilayer coating deposition were identified as the main causes of the improved fatigue performance of the PBF-LB AlSi10Mg alloy. In addition, machining reduced the distance of killer defects from the surface by removing part of the contour zone, thus limiting the fatigue strength achievable by the material. The T5 alloy showed better response to surface treatments: (i) the ultrafine cellular microstructure was more susceptible to sandblast-induced work hardening than the T6 microstructure, resulting in higher and deeper surface compressive residual stresses, and (ii) the multilayer Ni-9% P+(a:C-H)DLC coating improved the defect tolerance of the T5 microstructure, increasing the distance from the surface of the possible crack initiation zone and the surface hardness.

This study demonstrated that sandblasting and Ni-9%P+(a:C-H)DLC multilayer coating can be good solutions to improve the fatigue performance of complex-shaped PBF-LB AlSi10Mg components for sustainable mobility, avoiding the need for mechanical processing to improve the surface finish and defect tolerance of PBF-LB-produced structural parts.

Paper 1476 1 Multiscale models combined with LCA design framework to conceive sustainable and circular energy storage systems

Dr. Matteo Alberghini, Italy

Highlight (Oral Presentation 20')

Abstract

The transition toward sustainable and circular energy storage solutions is a key challenge in the transport sector. In this work, we present a simulation-guided design framework for hybrid battery packs that integrate lithium-ion cells with high-energy-density supercapacitors. Developed within EU founded projects and validated on an e-scooter case study, our approach combines multiphysics and multiscale simulation with cradle-to-cradle life-cycle assessment (LCA) to support the entire value chain—from material development and process optimization to component design and upscaling. At the material level, atomistic models have been used to guide the fabrication of carbide-derived electrodes from recycled plastics. By bridging experimental observations (e.g., TEM characterization) with fundamental electrochemical behavior, these models can shed light on the complex interactions between key structural properties (i.e., pore size distribution) and interfacial interactions with electrolytes and ionic liquids, thereby reducing the need for costly trial-and-error investigations. At the mesoscale, microstructure models coupled with discrete and continuum simulations can capture the effects of electrochemical, thermal and mechanical processes on cell performance and selected ageing mechanisms, thereby linking the main operating and manufacturing parameters to performance metrics. At the system level, simplified models, such as equivalent circuit representations calibrated on synthetic data from continuum simulations, enable prediction of battery pack performance under realistic operating conditions. These models also support the development of control logic and monitoring strategies that account for ageing effects and ensure reliable operation in the field. The integration of this multiscale and multiphysics simulation chain with LCA analysis allows design decisions to be informed not only by performance targets but also by environmental impact and cost considerations. This is critical in electrochemical systems, where the use of critical raw materials or polluting techniques may jeopardize the goal of producing environmentally-conscious products. In summary, our work demonstrates that the combined use of atomistic, mesoscale, system-level simulations, and a systematic life-cycle assessment, can effectively guide the design and optimization of hybrid battery packs. This simulation toolchain provides a robust basis for accelerating material selection and process improvements while ensuring high performance, reduced charging times, steady power delivery, and extended driving range in sustainable transport applications.

Oral Presentation (20')

Abstract

The transition to green and sustainable mobility is accelerating as the automotive sector shifts toward electrification and hydrogen-powered technologies to reduce greenhouse gas emissions and dependence on fossil fuels. Fuel cells and electrolyzers are key components in this transition, enabling hydrogen-powered transport and energy storage solutions. However, these technologies rely on Platinum Group Metals (PGMs), which are both scarce and economically critical. Developing efficient End-of-Life strategies to recover PGMs from fuel cell and electrolyzer components is essential to ensuring resource security, cost efficiency, and environmental sustainability.

This study evaluates the sustainability, safety, and economic feasibility of a patented, eco-friendly, and industrial-scale hydrometallurgical process developed by MONOLITHOS Ltd. for the recovery of PGMs from End-of-Life Membrane Electrode Assemblies (MEAs), achieving high recovery efficiencies (Pt >99% and Ir >60%) [1,2]. The assessment integrates Life Cycle Assessment (LCA), safety risk analysis, and cost modeling to evaluate energy consumption, greenhouse gas emissions, human health impacts, and resource depletion.

Preliminary results indicate an 80% reduction in CO₂ emissions compared to traditional PGM extraction methods, demonstrating the process' environmental benefits. Additionally, an economic analysis highlights the cost advantage of the recovered materials, showing a 30% lower cost compared to commercial PGM components for hydrogen devices. Further optimization efforts aim to reduce the overall environmental impact by at least 15%, while maintaining high material purity and ensuring process scalability.

The LCA was conducted using SimaPro and the ecoinvent database, ensuring transparent process modeling and benchmarking against conventional end-of-life PGM recovery routes. Workplace safety risks—including chemical exposure, reagent handling, and waste management—are analyzed to support industrial-scale implementation.

This research contributes to sustainable hydrogen mobility and clean energy technologies, providing a scalable and environmentally responsible solution for PGM recovery in hydrogen fuel cells and electrolyzers. By integrating LCA, safety assessment, and cost modeling, this study aligns with the EU's circular economy objectives, supporting the transition to low-emission transport and energy systems.

This research has received funding from the European Union's Horizon programme and the Clean Hydrogen Partnership through the HERAQCLES project under grant agreement No 101111784.

Paper 1091 3

Environmental impact assessment of battery module lifecycle: a comparative evaluation of components replacement in the circular economy concept

Ph.D. Paniz Baradaran Kazemian, Italy

Oral Presentation (20')

Abstract

This study explores the environmental implications in the lifecycle management of batteries for electric vehicles, with a specific focus on a single module. The goal is to evaluate the possibilities of circular economy strategies to mitigate environmental challenge associated with batteries life cycle, focusing on reuse and repair strategies, as an alternative to complete disposal.

In order to analyze the life cycle stage of a single battery module, to be introduced to the second life application during the testing process, the gate-to-gate scope has been assigned by the Life Cycle Assessment (LCA) methodology. The Ecoinvent 3.8 database and the SimaPro software were used to measure various environmental impact categories, particularly climate change. Three different scenarios, according to the output of the module's technical and electronic test, have been identified. Defined scenarios measured the environmental impacts, driven by a single cell and electronic components, adopting a repair strategy, compared to the full module disposal scenario and to the production.

Obtained results highlighted that the complete discard highly effect on eutrophication in marine ecosystems and climate change, while adopting the inserted strategies reduce the effect notably in the considered categories, as well as material and resource use.

Performed studies highlighted several challenges, such as discrepancies between industrial and laboratory data, variations in recycling processes and methods, differences in battery chemistries, manufacturing technologies, and regional energy mixes. These data can affect results derived from the LCA methodology, confirming the need for a harmonized LCA methodologies to ensure consistent evaluations of environmental impacts.

Outcomes align with the three pillars of circular economy, showing that even partial reuse reduces the demand for new raw materials and mitigates the ecological consequences of critical material extraction. By maximizing the interval between manufacturing and recycling phases, industries can reduce environmental impacts, and promote a sustainable industry, along with the circular economy strategies, in the full battery life cycle manufacturing process. Several possible second life applications have been identified for the battery module under study, allowing to maximize the livability and reduce the need for critical material extraction for the new battery production.

KEY WORDS: Lithium-ion battery, Electric vehicle, Environmental impact, Life Cycle Assessment, Batteries second life application, Circular Economy.

3D-Printed integrated circuits for adhesive joints disassembly and locally thermal curing

Prof. Massimiliano Avalor, Italy

Oral Presentation (20')

Abstract

Various directives, including ELV, WEEE, Directive 2008/98/EC, and subsequent regulations regarding the prescribed recovery and re-use of various industrial waste products, have come into force through the European Parliament. In response to these new European sustainability directives emphasizing design for disassembly and waste reduction in manufacturing, the integration of printed electronics into structural components offers novel opportunities for localized heating applications. This study explores the development of 3D-printed integrated circuits within adhesive joints, enabling precise and efficient heating. By embedding conductive pathways directly into the printed structure, controlled heating can be achieved in the overlap region of adhesive bonds, enhancing adhesion performance and curing processes while aligning with circular economy principles.

Two experimental approaches demonstrate the feasibility of this technology, highlighting its dual functionality. First, printed circuits can be exploited for disassembly purposes: in thermoplastic-based adhesives, localized heating enables bond release through polymer softening, allowing for easy separation or even repair of joints without replacing the adhesive. In thermosetting adhesives, controlled thermal degradation facilitates separation without damaging the substrate. Second, these integrated circuits can be used to enhance joint strength by localized curing, reducing stress concentration effects. This targeted reinforcement allows for optimized material distribution, leading to lighter and more resource-efficient components without compromising structural integrity. Preliminary results demonstrate the effectiveness of these approaches. Heating circuits embedded within thermoplastic joints achieved adhesive softening and bond release at temperatures as low as 120 °C. Additionally, thermoplastic-based joints could be repaired up to five times while retaining more than 50% of their original strength. In thermosetting adhesives, controlled degradation at 180 °C enabled clean substrate separation. Furthermore, localized curing processes increased the maximum joint strength by up to 60%, reducing peak stress concentrations. These findings highlight the potential for integrating printed electronics into adhesive bonding processes, fostering sustainability and efficiency in industrial applications.

Beyond adhesive bonding, this approach can be extended to broader industrial applications, i.e. for automotive components like batteries, lights and electronics. The integration of modular, additive-manufactured circuits with enhanced recyclability can facilitate more sustainable production and disposal methods. By focusing on reparability, reusability, and material recovery, these technologies support circular economic principles while maintaining high performance. Furthermore, embedding heating circuits into structural components can contribute to innovative urban regeneration strategies, where sustainability, technological advancement, and design converge to optimize resource efficiency and promote environmentally conscious manufacturing practices.

Experimental investigation of tire-wear particle sizes

Mr. Alexander Schmiedhofer, Austria

Oral Presentation (20')

Abstract

The electrification of personal vehicles is a crucial step in combating climate change. One significant initiative driving this transformation is the implementation of the new EURO 7 emission standards. This regulation addresses exhaust emissions and targets non-exhaust sources, particularly tire wear, which is recognized as the largest contributor of microplastic particles to the environment.

While extensive research has focused on tire abrasion and determining abrasion rates, relatively little attention has been given to the distribution of particle sizes generated during this process. The size of microplastic particles plays a vital role in determining their environmental impact. Therefore, it is essential to understand how driving parameters—such as slip, velocity, and normal force—affect the size distribution of these particles.

This study utilized a mini traction machine to replicate tire abrasion under real-world conditions. In this scaled-down experiment, the tire was represented by a ball made from the same material, while the road surface was simulated with an asphalt disc composed of small-grain gravel and bitumen.

In this experimental setup, multiple tests were conducted with varying normal loads, slip ratios, and velocities. The generated particles were carefully collected with a brush and analyzed using microscopy to classify them by size, and EDX to determine their chemical composition.

This approach provides valuable insights into how driving parameters influence the size distribution of microplastic particles, contributing to a deeper understanding of their environmental implications.

Paper 1418 6 Additive manufactured complex cooling channels for High Pressure Die Cast (HPDC) electric power train components for automotive applications
Dr. Dirk Lehmkus, Germany
Oral Presentation (20')

Abstract

Several components of the electric powertrain require solutions for cooling or temperature control. These include electric engine as well as power electronics housings, or battery cases, which are typically realized as cast aluminum components, with HPDC as the production process of choice based on its high productivity. However, realization of cooling channels in HPDC is a difficult business, as many lost core techniques are not applicable to this process due to the high forces acting on the cores during the filling as well as the intensification phase. An alternative is the integration of aluminum hollow profiles. According to the state of the art, this is e.g. possible based on the CombiCore® or the ZLeak Tube® technology. However, both approaches require a filler which stabilizes the cooling channel during casting, and thus affords an additional process step, which is the removal of the filler. The alternative approach suggested by the BioniCast project is the use of additively manufactured cooling channels. The advantage of this concept is that cooling channel design can be optimized for stability, heat transfer and flow resistance, and varied along the length of the channel if necessary.

The present study outlines approaches to determine, by means of casting and finite element simulation, the stability of given cooling channels made via the Laser Powder Bed Fusion (LPBF) additive manufacturing process from AISi10Mg alloys in different heat treatment states, namely stress relieved for 2 hours at 350°C and warm aged for 6 hours at 170°. We use the MAGMASOFT® casting simulation package to extract the thermal loads acting on the cooling channels and transform them directly into a stability criterion based on a simplified equation for tube stability under external pressure. As the relevant moment in time, we identify the freezing of the gates, as we must assume that intensification pressure can only be transferred to the cavity until this moment in time. We add a finite element simulation assuming (a) homogeneous temperatures within the insert and (b) the temperature distribution derived from the casting simulation to compare this data with the aforementioned MAGMASOFT® user result as well as experimental data based on casting of actual test components. The prerequisite for all analyses is the detailed characterization of temperature-dependent properties of the additively manufactured AISi10Mg alloy in both heat treatment states, which has been done in a range from room temperature to 450°C using a Gleeble system.

Paper 205 **1** **Molecular simulations of nanoporous carbon-based electrocatalyst for H₂ production**

Prof. Roland Pellenq, France

Keynote (Oral Presentation 40')

Abstract

This work focusses on the modeling of H₂ production assisted with porous carbons in a supercapacitor device configuration using a realistic model of electrodes texture. Using reactive meta-dynamics simulations in the constant voltage (N, V, T, Velec) ensemble, we reveal the synergic charge coupling between the electric double layer (EDL) at the external electrode surface or that of mesopores in contact with the electrolyte and sub-nanopores that are able to dock bare ions and induce a global electric charge redistribution toward topological and chemical defects such as surface species. In turn, this surface over-charging (induced by in-nanopores ion docking) that is the consequence of the electrode voltage polarization) leads to an ionic strength increase of the surface electric double layer (EDL) that is nanometric in thickness. Surface EDL then becomes the location of global strong electrostatic field that is able to induce chemical reactions such as electrolysis and cathodic H₂ production and can be seen as nanoreactor. Hence, this “reinforced” EDL leads to a boosted the hydrogen evolution reaction (HER) efficiency, in line with experimental results. This study reveals the crucial catalytic impact of ion docking, elucidating the fundamental mechanisms governing carbon-based electrocatalysis that is due to a collective, global, reinforced surface-polarization EDL effect initiated from carbon nanopores.

Modeling of the hydrophobic treatment of Gas Diffusion Layers to predict PTFE distribution after the drying step

Mr. Pierluigi Arnelli, France

Oral Presentation (20')

Abstract

Proton Exchange Membrane Fuel Cell (PEMFC) is currently considered as a pollutant-free alternative to thermal engines, especially for Heavy Duty applications. The Gas Diffusion Layer (GDL) is a major component ensuring heat, mass (gas and liquid), and electrical transports thanks to its carbon porous structure [1]. GDL plays a crucial role on the performance of PEMFC and especially on the water management by ensuring a trade-off between drying (too low water vapor content) and flooding (too high liquid saturation). To reduce the flooding risk during PEMFC operation, a hydrophobic treatment is applied to the GDL. The pristine carbon material is dipped into a hydrophobic ink (colloidal dispersion of PTFE) then dried and sintered. Experience shows that the resulting PTFE distribution is not uniform, depends on the drying conditions [2], and impacts the PEMFC performance. Interestingly, an 'optimized' PTFE distribution is still an open question and progress on this matter will help improving GDL.

In the spirit of GDL improvement, the most advanced models consider 3D volumes representing the GDL microstructure, which are obtained from X-ray microtomography or randomly generated. However, PTFE is rarely taken into account correctly, as it is not visible in X-ray tomography, or it is numerically added by morphological opening [3] for which the 'deposition criteria' are questionable.

Our research aims at modeling the main manufacturing steps of the hydrophobic treatment to predict more accurately the PTFE 3D distribution and the resulting (single and two-phase) GDL transport properties, which are key for the GDL performance. Based on characterizations of the hydrophobic ink and on SEM observations to locate the PTFE, a model of drying of the GDL is discussed and developed to simulate the final PTFE distribution in the microstructure. Numerical results are compared to experimental ones and the impact of PTFE treatment process is discussed on GDL transport properties. This research is part of the project "DECODE" which has received funding from the European Union's Horizon Europe research and innovation program under grant agreement N° 101135537. Fraunhofer High Performance Center Green Materials for Hydrogen – GreenMat4H2

Prof. Emanuel Ionescu, Germany

Highlight (Oral Presentation 20')

Abstract

The Fraunhofer High-Performance Centers organise the close cooperation between university and non-university research and industry. Universities, universities of applied sciences, Fraunhofer Institutes and other non-university research institutions work together with companies and civil society players at a single location on specific topics in order to quickly put innovations into practice. High-performance centres stand for infrastructure, training concepts and expertise that can be used across organisations. They bring together suitable partners and support ideas as innovation pilots all the way to the market.

The GreenMat4H2 High-Performance Center was founded at the beginning of 2021 and is jointly managed by the Fraunhofer IWKS in Hanau and the Fraunhofer LBF in Darmstadt. The aim is to provide scientific and technological support for the development of a sustainable and reliable hydrogen economy in the federal state Hesse/Germany in order to make an important contribution to climate protection and ultimately strengthen Hesse as a high-tech federal state. Our aim is to consolidate a central contact point for the hydrogen economy in the Rhine-Main region and beyond. It promotes the application-orientated research and development of 'green' materials and technologies for the safe, sustainable and reliable production, storage, transport and use of hydrogen as well as for the conversion of existing structures to hydrogen applications. GreenMat4H2 focuses on the core competencies of the participating institutes Fraunhofer LBF and IWKS in the hydrogen sector.

This results in a coordinated, complementary portfolio of services in the four core areas of material development, reliability, sustainability and recyclability, particularly:

- Damage identification, damage development (degradation) on materials/components (e.g. cells)/systems (e.g. H2-tank) under mechanical and electrochemical stress
- Characterisation of the operational stability and system reliability of components and systems (e.g. fuel cell) exposed to hydrogen under realistic conditions
- Recoverability/recycling of functional materials from fuel cell systems or electrolyzers: catalyst (platinum, iridium, ...) and membrane materials (PFAS) or bipolar plates from stacks, C-fibres from hydrogen pressure tanks
- Potential applications of secondary materials in components

In this presentation, the set-up and development of the GreenMat4H2 Center as a role model to establish a strong network of the relevant players in the regional hydrogen landscape, identifying the need for application-oriented research and expertise, developing specific transfer measures and initiating targeted research collaborations with partners from industry and science is shared. Furthermore, approaches for international cooperation in applied research are proposed to create synergies.

Paper 2091 4 Compositional Complexity and Structural Disorder as Enablers for the Circular Economy

Prof. Emanuel Ionescu, Germany

Oral Presentation (20')

Abstract

Circular Economy (CE) represents a concept concerning the production and consumption of goods which basically should reduce the amount of waste to a minimum. There is an obvious contradiction between the need for a CE and the tremendously increasing amount and complexity of consumer goods, their planned obsolescence, and the massive amount of waste due to the take-make-waste peculiarity of their production/consumption.

CE has a powerful enemy, i.e. the second law of thermodynamics, which actually prevents that closing the production loops leads to full resource efficiency. Thus, minimizing residues and losses should be considered as important as and in addition to closing the material loops. The consequence is the stringent need to minimize the entropy increase across the various added value chains.

However, we will show in the present talk that entropy increase may not always be seen as acting against CE. Firstly, we will discuss the concept of structural and compositional disorder. Secondly, we will elaborate on the compositional complexity in materials as an effective way to consider highly heterogeneous waste streams as valuable secondary raw materials. And thirdly, we will perform a prospective discussion on preparative concepts and strategies to develop materials with maximized performance and high tolerancy for admixtures & impurities.

Strategic Needs, Market Opportunities and Technical Advancements in Large-Scale Manufacturing for Wind Turbine Components and Hydrogen Storage.

Dr. Evgenia Yakushina, United Kingdom

Oral Presentation (20')

Abstract

The global transition toward renewable energy has significantly increased the demand for large-scale manufacturing innovations in wind turbine components and hydrogen storage systems. Projections indicate that the global hydrogen market could reach approximately €1.3 trillion by 2050, while the global wind energy market is expected to attain €130 billion by 2030. Developing cost-effective, scalable, and high-performance manufacturing solutions has thus become a strategic imperative. This work explores how large-scale manufacturing capabilities, bolstered by academia-industry collaboration, can address the technical and economic challenges.

The National Manufacturing Institute Scotland (NMIS) has been instrumental in advancing next-generation manufacturing technologies for wind and hydrogen infrastructure. Through collaborative research and development, as well as technology transfer, NMIS has partnered with industry leaders to integrate digital manufacturing, AI-driven process optimization, and automated quality assurance into production workflows. These collaborations have resulted in enhanced efficiency, cost reductions, and improved material sustainability. Notably, NMIS has contributed to projects such as EnergyWorks, a €10.5 million energy incubator supporting advancements in offshore wind, hydrogen, and battery storage.

In the wind energy sector, large-scale manufacturing improvements are essential to achieving the global wind capacity target of 2,157 gigawatts by 2030.

Innovations in lightweight composite materials, turbine blade recyclability, and advanced forming techniques for substantial structural components are pivotal in enhancing efficiency and sustainability. Similarly, in hydrogen storage, advancements in high-pressure tank production, large-scale flow forming, and novel welding techniques are crucial for reducing storage costs, thereby making hydrogen a more viable alternative to fossil fuels.

The economic landscape is evolving, with over €1.1 trillion invested globally in renewable energy in 2023 alone, driven by favorable policy frameworks and industrial decarbonization incentives. This study also assesses the economic feasibility of manufacturing innovations, examining how cost-reduction strategies, supply chain readiness, and automation can enhance the competitiveness of wind and hydrogen technologies.

NMIS has established robust collaborations with industry leaders, including ScottishPower Renewables, BOC, and the European Marine Energy Centre (EMEC), fostering the development of Scotland's hydrogen economy. Additionally, NMIS's partnership with Ecomar Propulsion supports the transition to zero-emission shipbuilding, thereby extending the impact of large-scale manufacturing innovations.

Paper 913 1 2D materials-based nanostructured interfaces for advanced membranes and porous materials synthesis for application in energy and environment

Prof. Philippe Miele, France

Keynote (Oral Presentation 40')

Abstract

Porous ceramics are of great importance for various applications in energy, catalysis, filtration and refractory applications. Achieving rational design of polymer- derived ceramics (PDC) with hierarchical porosity has been made possible with the use of porogen agents, direct foaming or (nano)casting. However, these approaches often suffer from complexity and limited control over the desired porous architectures. Here, we describe an innovative method for fabricating porous ceramics monoliths by combining the preceramic polymer route and the Pickering emulsion method. The emulsions were prepared using a SiOC precursor and stabilized with modified graphene oxide (GO) nanosheets. The effects of formulation and the chemical parameters on the final properties of Pickering emulsions will be discussed. As a proof of concept, the monoliths have been used as electrode materials for electrochemical energy storage in Li-ion batteries (LIBs). Following a similar strategy, new process for the preparation of porous polymeric filtration membranes, of great interest in the context of green technologies development, has been developed. In that case, the formation of the porosity of the polymeric membranes results from Pickering emulsion templating involving hexagonal boron nitride (h-BN) nanosheets as stabilizer. In addition, Other examples Finally, some tailoring strategies susceptible of improving 2D materials membrane separation performances will be presented, including the development of laminar membranes prepared from 2D MoS₂ nanosheets for enhanced desalination performance. In a similar vein, another part will be dedicated to the use of 2D clay membranes for organic solvent nanofiltration (OSN) applications, by intercalating cations into the interlayer of the nanosheets, which significantly improves the stability and molecular sieving properties of the membranes.

Paper 293 2 **Ultrafast high-temperature sintering of B4C with Si aids**

Dr. Francisco Martinez-vazquez, Spain

Oral Presentation (20')

Abstract

Boron carbide ceramics are very attractive because of their combination of super-hardness and ultra-lightness. They are commonly sintered by techniques involving pressure and high temperatures, often by Spark Plasma Sintering. In this study, the ultrafast high-temperature of B4C with SiC aids was investigated. The effect of the proportion of Si aids, green body compaction, and sintering temperatures and times were studied, demonstrating that relative densities close to 90% can be achieved and therefore that UHS is preferable to pressureless-SPS. Implications of this work are discussed.

Paper 1981 1 **Achieving High-Temperature Stable Structural Color through Nanostructuring in Polymer-Derived Ceramics**

Prof. Kaline Pagnan Furlan, Germany

Highlight (Oral Presentation 20')

Abstract

Structural colors present many advantages over traditional pigment-based colors, which often contain scarce or toxic chemical compounds and are prone to UV degradation. To make use of these benefits in demanding environments, there's growing interest in creating structural colors out of ceramic materials. Polymer-derived ceramics (PDCs) are a great option because they combine ease of shaping in their polymeric form with excellent temperature resistance after being converted into ceramics. This study presents the fabrication development of non-iridescent structural colors by (nano)structuring a silicon oxycarbide (SiOC) PDC. The developed functionally graded material (FGM) with an inverse photonic glass 3D structure, takes advantage of SiOC's natural light-absorbing properties, producing a bright structural color that remains vivid even in white backgrounds with diffuse illumination conditions. The study explores the relationship between the process, structure, and properties of the resulting structural color by analyzing each layer of the functionally graded material (FGM) during the fabrication process. To show the flexibility of working with PDCs, the FGM design is also adapted to an additive manufacturing approach, where free-form structural colored shapes are printed by direct writing. Finally, the FGM-PhG structural colors were found to have an impressive thermal stability, maintaining their nano features, porous structure and properties at temperatures up to 1000 °C for 100 hours, enabling their use in demanding environments without degradation.

Straightforward design of 3D structured SiC objects via a granule-derived FDM technology of polycarbosilane-based formulations

Dr. Samuel Bernard, France

Oral Presentation (20')

Abstract

There is a trend toward more performant or competitive materials with the objective to improve the efficiency of actual systems and to repel technological boundaries. Silicon Carbide (SiC) attracts strong interests due to its properties targeted for future materials and technologies especially in aerospace. Inherent difficulties to the traditional techniques for manufacturing such dense materials with a complex geometry can be overcome by the development of new manufacturing approaches and the deployment of synthetic paths where chemistry of materials and ceramic science are combined rationally. The Polymer-Derived Ceramics (PDC) route offers great opportunities in material sciences when combined with 3D printing. Here, the aim of this talk is to introduce a straightforward design approach consisting in tailoring the extrusion ability of polycarbosilanes to fit with a granule-based fused deposition modeling process and form after a two-step heat-treatment process at a relatively low temperature 3D stoichiometric SiC and derived composites parts.

Paper 1439 3 From the properties of ceramic slurries to sintered elements - shaping through aqueous-based ceramic suspensions.

Mrs. Blanka Seredynska, Poland

Oral Presentation (20')

Abstract

The development of technology brings challenges to modern materials. They must not only have excellent mechanical and strength properties but also have complex geometries. In addition, waste emissions and pollutants accompanying production are being reduced. As a result, technologies that reduce machining, such as 3D printing and drop-casting, are being thrived. Both of the techniques above can be used to form specific shapes. 3D printing techniques allow easy modification of the complex geometry and the degree of filling of the parts. On the other hand, drop-casting makes it possible to obtain spherical elements. They can be both solid and porous. The porous effect is obtained by adding organic or inorganic compounds.

The ceramics industry is irreversibly linked to emissions of gases, such as carbon dioxide. This is related to the decomposition of carbonates and the removal of organic binders, among other things. Although complete zero-emission is impossible to achieve, it is necessary to minimize it. Replacing some organic binders with water is important in this regard. It is also crucial to control the selection of organic additives whose decomposition does not involve the emission of toxic compounds. For this reason, it is essential to perform thermal analysis coupled with a mass spectrometer to determine the products of thermal treatment. In addition, thermogravimetry will make it possible to determine whether the organics have been removed in their entirety, and differential thermal analysis will help select the debinding process parameters.

It is essential to take a comprehensive approach to shaping ceramics. The study considered the water-based Al_2O_3 and ZrO_2 ceramic slurries' rheological properties (dynamic viscosity and viscoelastic features). It also allowed the selection of organic components and their amounts, e.g. 2-carboxyethyl acrylate. The nature of the debinding process and its products were determined by STA/MS analysis. The shaping process, *inter alia* DIW, was carried out, and the basic mechanical properties (Vickers hardness, fracture toughness) of the sintered parts were studied, followed by their microstructure analysis.

The Warsaw University of Technology financed the research under the Excellence Initiative - Research University (IDUB) Program.

4

Development of ceramic photocurable slurries with metal precursors for the fabrication of functional materials by Digital Light Processing

Dr. Mario Borlaf, Spain

Oral Presentation (20')

Abstract

Since the early stages of additive manufacturing (AM), one of the key objectives was the fabrication of multimaterials. Using Digital Light Processing (DLP), when the material is the same but differs in characteristics (e.g., particle size), changing the slurry exhibit minimal difficulties. However, when printing with two different materials, a cleaning step should be incorporated to avoid cross-contaminations. Moreover, if a layered material is desired, the problems/limitations are much less than if a multimaterial is desired in each layer.

In the case of functional materials, other limitations may appear, such as light absorption. In many cases, it is not possible to print the materials (for example: black powders, TiO₂, etc.), and new alternatives are necessary to produce ceramic functional materials by 3D printing.

In this work, we propose the use of a photocurable slurry of a structural ceramic like SiO₂, with different metal precursors to fabricate functional materials. Slurries with different solids contents and metal precursor concentrations were prepared. The influence of the metal precursors nature on the stability of the slurries, printing parameters, and thermal treatments was studied. Finally, the obtained functional materials were characterised and evaluated.

Paper 927 **6** **Effect of precursors properties and mixing on the development and final properties of dense boron carbide and B-rich boron carbide**
Dr. Sébastien Lemonnier, France
Oral Presentation (20')

Abstract

Ceramic based armor is generally used to protect a vehicle or person against the impact of a small caliber projectile. This protection consists of a ceramic layer on the front, attached to a metal or composite support, called "backing". The purpose of the ceramic layer is to erode the projectile and distribute the force on the backing. Among the three well-known ceramics (Al_2O_3 , SiC and B_4C), boron carbide ceramic, known as B_4C , has the highest efficiency while being the lightest ($\rho = 2.52 \text{ g cm}^{-3}$) but its cost and loss of performance when subjected to large non-hydrostatic stresses (like the one caused by an impact of WC core threat), limits its use in the specific situations where the weight is the crucial parameter. However, in the B-C binary phase diagram, a solid solution of the boron carbide phases is defined from one side by the $\text{B}_{4,3}\text{C}$ crystalline phase, the common phase in the literature called B_4C , and on the other side by the boron-rich $\text{B}_{10,4}\text{C}$ crystalline phase [1]. These B-rich boron carbide ceramics are lighter than the conventional B_4C ceramic, with a density of 2.46 g/cm^3 against 2.52 g/cm^3 for the conventional B_4C [2] and an increase of the B/C ratio could reduce the brittleness and sensitivity of the ceramic as reported in the literature [3, 4]. These specificities make B-rich boron carbide ceramic a promising candidate for ceramic based armor thanks to the improved versatility and remarkable properties and lightness.

The objective of this work is to set up an approach to develop fully dense $\text{B}_{4,3}\text{C}$ and $\text{B}_{10,4}\text{C}$ ceramics starting from the same precursors and following the same protocol in order to compare their final microstructural and mechanical properties. The effects of elemental precursors properties and mixing method on the reactivity and Spark Plasma Sintering behavior is discussed. Complete microstructural and mechanical properties are presented and reveal that B-rich boron carbide ceramics can present Young's modulus and Knoop hardness very close to the values measured for $\text{B}_{4,3}\text{C}$ while being lighter.

This research activity is part of the EDA project B-PRJ- RT- 690 – CERAMBALL II.

WC based cermets with low additions of Ni

Mrs. Aida Martínez Barja, Spain

Oral Presentation (20')

Abstract

There is an increasing interest in substitute Co in the traditional WC-Co cermets compositions owing to its carcinogenicity and for being considering as a strategic material due to its limited supply. The most studied alternative metals were Fe and Ni or combinations of Co-Fe-Ni. Iron is abundant, non-toxic and low-cost raw material, but shows low wettability with the WC grains and a poor corrosion resistance. However, nickel has a better wettability with the WC grains, that is crucial to obtain a good joining and full densification during sintering, as well as a better corrosion resistance in use.

The metal to ceramic ratio in the composition is a compromise between the thermomechanical properties of the carbide and the sintering conditions. Low metal contents on the composite will provide low corrosion rate and a better response at high temperature. Colloidal processing of the starting powders allows a homogeneous distribution of low amounts of metallic particles with the WC powders, also if they have a variable quantity and very different sizes. The high distribution of the metallic particles promotes a uniform liquid state sintering, even with the low amount. As a result, the metal acts as a sinter-aid to achieve full densification, without being detrimental for the carbide properties.

Little research has been done about WC compositions with low Ni content sintered by conventional methods due to the difficulties in achieve full densification. Therefore, in this study, low amount of Ni was used as a sinter-aid in the WC cermet, thanks to the previous colloidal processing of the powders, achieving a high densification. First, samples were conventionally shaped and different conventional sintering conditions were studied. Density, microstructure and mechanical properties were compared to decide the best sintering condition. Furthermore, in view of use these compositions in additive manufacturing, microstructure and post-processes were optimized to improve densification after the de-binding and sintering stages.

Paper 2092 1 SiOC-Based Strain Gauge with Ultrahigh Piezoresistivity at High Temperatures

Prof. Emanuel Ionescu, Germany

Highlight (Oral Presentation 20')

Abstract

The nonlinear response of strain gauges at high temperatures has restricted their applications despite their high-precision and real-time measurement capability. This work addresses this limitation by utilizing the easy preparative access and versatility of silicon oxycarbide-based (SiOC) thin films as strain gauges offering outstanding high-temperature robustness and giant piezoresistive response. The sensitivity of the strain gauge is assessed with continuous cyclic loads, tensile and compressive, resulting in gauge factors of ca. 2000–5000. The linearity of the response is preserved up to 700 °C with a shift in the electrical response occurring at temperatures beyond 500 °C, switching the SiOC film from semiconducting to conducting behavior. This change causes a drop in the gauge factor of the SiOC-based thin films; nevertheless, it is still significantly higher than that of metallic and Si-based commercial strain gauges. Notably, the studied thin films can regulate the effect of temperature enabling them to be a highly sensitive device with good reversibility and replicability in high-temperature environments. Furthermore, the electrical shift at 460 °C broadens the application of the SiOC film as a current-limiting device and temperature sensor.

Paper 1157 2 Sol-gel derived SiOC(H) particles as inorganic components of hybrid bigels based on polyelectrolyte complexes for HIV prevention
Dr. Aitana Tamayo, Spain
Oral Presentation (20')

Abstract

Hybrid gels and bigels containing inorganic drug carriers embedded into a polymeric matrix emerge as suitable option with promising features for the prevention of the sexual transmission of HIV. We report on the preparation of freeze-dried polyelectrolyte bigels containing sol-gel derived mesoporous SiOC(H) particles for vaginal administration of drugs. The antiretroviral drug Tenofovir (TFV) and the poorly soluble Dapivirine (DPV) have been introduced into the hybrid. The aim of this work is the development of freeze-dried polyelectrolyte bigels for vaginal administration of drugs. The selection of the temperature of the treatment for the consecution of the SiOC(H) particles allowed loading two drugs with different physicochemical characteristics which are subsequently released to the releasing media (simulated vaginal fluid) because of the presence of the polyelectrolytic complexes in the polymeric matrix. Impedance spectroscopy characterization allows identifying the different wettability of the vaginal films in the presence of the mesoporous SiOC(H) particles as well as the penetration of the fluid to allow the drugs to be released.

Thermo-Mechanical and Tribological Analysis of WC/Ti(C,N)-FeNi Ceramic-Metallic Compositions Obtained By Colloidal Processing

Mrs. Sandra Tarancón Román, Spain

Oral Presentation (20')

Abstract

Cutting tools are mostly based on the WC-Co system due to its exceptional abrasive properties, including high hardness, toughness and wear resistance; these qualities make them ideal for heavy-duty applications. However, the production of essential materials for cemented carbide manufacturing, such as tungsten and cobalt, presents significant challenges due to the toxicity of Co and the political strategic nature of both metals in the European Union, which makes them susceptible to significant fluctuations in price and availability. Furthermore, although Co is the preferred binding material for WC, as it forms a solid solution, its toxicity, price, relatively low melting point and oxidation resistance are prompting the need for the search of alternative composites for faster processing speeds.

Therefore, other binder and ceramic materials have been investigated aiming the substitution of Co. Researchers are particularly focused on developing more cost-effective and environmentally friendly manufacturing routes. One promising strategy is the use of Fe-based metal phases in combination with colloidal processing techniques. By employing colloidal processing, stable suspensions are created in which the particles are effectively dispersed within an aqueous medium. This dispersion prevents oxidation, a common issue when working with metal-based powders.

This study examines the performance of a new class of cutting materials produced by varying the binder composition of standard cemented carbide composites. By replacing the cobalt binder with FeNi, two economical and more sustainable composites result: Ti (C,N)-FeNi and WC-FeNi, since powder precursors were obtained via colloidal processing. Properties such as hardness, flexural strength, fracture toughness and wear resistance have been evaluated, from room temperature up to 800 °C, to simulate service environmental conditions. The results of these evaluations were then compared with those of Co-based commercial cemented carbide systems. The results show a slight advantage for the alternative Fe-Ni binder tools as evidenced by a 10 % and 25 % increase respectively in both flexural strength and fracture toughness at low temperatures with WC in the hard phase; however, the effects of using Ti(C,N) are inconclusive. The study demonstrated that these new Fe-based materials exhibit promising properties and could potentially replace traditional cemented carbide materials in industrial applications that demand high performance under harsh operating conditions.

Smart Ultraporous 0D-Nanocarbon Containing Ceramic Composites for Environmental Remediation

Dr. Gabriela Mera, Germany

Oral Presentation (20')

Abstract

In a time of extreme and multiple crises, the synthesis and processing of advanced materials with multiple functionalities play a crucial role. Sustainable usage of our existing natural resources without further exploitation, combined with alternative technologies such as nanoremediation of the ecosystems, is one of the most significant worldwide challenges of our day.

The present era is represented by the use of “smart” and intelligent materials exhibiting tunable properties as function of different stimuli and their development is strongly needed in almost all spheres of life. As modern-age smart materials, 0D carbon-based ceramic composites show exceptional mechanical and optical properties, tunable surface structure, and ultrahigh specific surface area, just to mention few of their outstanding features which have attracted a lot of attention in the last years, these materials have found various applications in fields including sensing, optical computing, quantum computing, electrical energy storage, as well for wastewater treatment.

In this presentation, the development and processing of novel multifunctional quantum confined ultraporous 0D-nanocarbon-based polymer and ceramic composites with well-defined nanostructures, synthesized via sol-gel process and polymer derived ceramics route will be introduced, underlining the relationship between the processing / phase composition / nanostructure and the properties of the target ceramic nanocomposite materials consisting of 0D-nanocarbon-based phases (such as ultrasmall nanodiamond (UND), ultrasmall bucky nanodiamond (UBNDs) or ultrasmall onion-like carbon (UOLC)) finely dispersed or confined within a ceramic matrix (i.e., silica or Si₃N₄). Combining 0D-ultrasmall-nanocarbons with a ceramic material in a single functional nanostructure, it results in a novel smart approach to exploit the physicochemical properties of both materials concomitantly for applications in environmental remediation, more precisely here, for the dyes and heavy metals detection and adsorption from water.

Paper 1968 1 **Sandwich Structured SiCf/Si₃N₄ Composite with Discontinuous Absorption Attenuating Layer for Temperature-Insensitive and Broadband Microwave Absorption**

Mr. Yuchen Cao, China

Oral Presentation (20')

Abstract

Achieving temperature-insensitive microwave absorption (MA) over a wide temperature range is an immensely challenging task due to the inherent variations in electromagnetic response and energy conversion characteristics. Herein, we present a novel silicon carbide fiber-reinforced ceramic matrix MA composite (CMC) with a structural-functional-integrated design based on the absorption attenuation layer concept. Through a comprehensive exploration utilizing complementary experimental and computational techniques, we systematically analyze the relationship between key structural parameters of the absorption attenuation layer and microwave absorption characteristics. The results demonstrate that the sandwich-structured SiCf/Si₃N₄ exhibits exceptional broadband radar wave absorbing properties. Notably, the introduction of a discontinuous periodic structure in the absorption attenuation layer significantly enhances the absorbing capabilities. The experimental findings demonstrate that the discontinuous sandwich-structured SiCf/Si₃N₄ achieves an effective absorption bandwidth (EAB) of 11.4 GHz (6.6-18 GHz) at a thickness of 3.9 mm, corresponding to a reflection loss of ≤ -10 dB. Furthermore, due to the unique scattering and interference cancellation effects of the metastructure, the DSS-SiCf/Si₃N₄ exhibits temperature-insensitive electromagnetic performance under elevated temperatures. Importantly, the EAB and average reflection loss of the composite remain essentially unchanged even when the temperature is elevated to 600 °C. This work provides a significant advancement in the design of "thinner, wider, stronger, and temperature-insensitive" microwave absorption components with practical applications.

Paper 1969 2 **Interfacial Mechanics and Polarization Behavior of Structural-Functional-Integrated SiC/Si₃N₄ Composites in Different Fiber Preform**
Dr. Jie Liang, China
Oral Presentation (20')

Abstract

The demand for structure-functionally integrated materials for applications in high-temperature environments has increased significantly. SiC/Si₃N₄ is the most suitable material candidate due to its excellent exceptional temperature resistance, high-temperature stability, toughness and dielectric tunability. Currently, the design of ceramic matrix composites (CMC) for electromagnetic wave (EMW) absorption is mainly centered around microstructural design and macrostructural design, thus the design of fibers at mesoscopic scale is neglected. In this work, three SiC/Si₃N₄ composites were prepared by CVI process using two-dimensional half (2.5D), three-dimensional four-direction (3D4X) or three-dimensional five-direction (3D5X) braided structures as preforms. It is evident that altering the orientation of the fiber bundles will result in alterations to the mechanical and dielectric properties. Initially, it may be easily posited that elevated tensile strength and permittivity only come from elevated fiber content. However, it is imperative to acknowledge that the pore structure and matrix distribution of the composites are affected during matrix preparation due to the different fiber preform structure. According to our results, the 3D4X composites have the highest proportion of intra-bundle pores, indicating that the thermal residual stress at the interphase is relatively minimal (interphase zone is more effectively protected), so that the deviation between the tested and theoretically calculated values of its tensile strength is minimized. In addition, unexpectedly, following the destruction of the BN interphase of 2.5D and 3D5X composites, the formation of a SiC/Si₃N₄ interface occurs. This phenomenon leads to the enhancement of interfacial polarization and the high-temperature insensitivity of 3D5X composites. 3D5X composites exhibit effective absorbing properties within a broad temperature range of 25-900 °C.

Paper 1971 3 **Multiscale synergistic design of SiCf/SiBCN-based metamaterial for high-performance electromagnetic wave absorption in a wide temperature domain**
Mr. Bo Huang, China
Oral Presentation (20')

Abstract

Electromagnetic wave (EMW) absorption materials effectively synergize room temperature (RT) and high-temperature absorption are essential for harsh environments applications such as stealth aircraft and aerodynamically heated components of aero-engines. Herein, an ingenious multiscale design strategy is proposed by combining the SiCf/SiBCN composite with metastructure to achieve synergy RT and high-temperature absorption. Firstly, as the skeleton material, the microstructure, electromagnetic parameters, and high-temperature EMW absorption performance of the SiCf/SiBCN composite have been systematically investigated. After optimizing the metastructure and corresponding geometric parameters, the SiCf/SiBCN composite with a frustum pyramid structure has exhibited exceptional broadband and temperature-insensitive absorption characteristics. The effective absorption bandwidth (EAB) of optimized SiCf/SiBCN-based metamaterial reaches 34.8 GHz (5.2~40 GHz, covering 96.7% within the tested frequency band) at RT, while the EAB remaining 12.5 GHz (5.5~18 GHz, covering 89% within the tested frequency band) even at 1100 °C. Notably, it maintains stable absorption against oblique incidence (within 40°) under transverse electric polarization. The broadband absorption mechanism of the wide temperature domain and the oblique incidence are ascribed to optimized gradient impedance matching and multiple attenuation resulting from multiscale design. This study pioneered the fabrication of high-performance EMW absorption metamaterial that synergizes broadband, wide temperatures domain as well as oblique incidence insensitivity.

Novel multi-functional porous Si₃N₄-SiC composite for high-temperature applications

Mr. Siddharth Siddharth, India

Oral Presentation (20')

Abstract

Porous Si₃N₄-SiC composites are potentially very attractive in various applications such as chemical-gas industries, nuclear power plants, and automobile industries, and as heat-absorbing materials for solar thermal power plants and electromagnetic radiation shielding materials for commercial and military applications. The fabrication of these advanced composites generally requires expensive raw materials and very high temperatures necessitating advanced sintering techniques, thereby making these materials very expensive. In this work, a novel technique for fabricating these porous composites at a low temperature of 1200°C using phosphoric acid both as a binder and pore former has been proposed. Two different Si₃N₄-SiC composites with different SiC particle sizes and varying SiC content have been fabricated. The operating sintering mechanism in the work can be succinctly described as the reaction between H₃PO₄ and SiO₂ (present on the Si₃N₄ powders' surfaces), since H₃PO₄ does not react with Si₃N₄ and SiC. Two separate phenomena have been proposed to describe the sintering cycle. First, the volatilization of H₂O in H₃PO₄ producing pyro-phosphoric acid (H₄P₂O₇), and second, the reaction between H₃PO₄ and SiO₂ to form silicon pyro-phosphate (SiP₂O₇). SiP₂O₇ can form a strong, water-insoluble, acid-resistant phase, that can bond well to Si₃N₄ and SiC particles and provide strength to the compact. A detailed study of the influence of the composites' composition on their microstructure and mechanical properties has been carried out. The results show that both the SiC particle size and its content strongly influence the strength, stiffness, and elastic anisotropy of the fabricated composites. Despite the significantly lower fabrication temperature, the mechanical properties of the porous composites are comparable to the best reported values in the literature.

Paper 2150 5 **Electron Paramagnetic Resonance Spectroscopy of Fast and Ultrafast Sintered 3YSZ Ceramics**
Dr. Isacco Mazo, Switzerland
Oral Presentation (20')

Abstract The defect chemistry of 3 mol% Y_2O_3 -stabilized ZrO_2 (3YSZ) plays a crucial role in its optical and electronic properties, particularly in relation to oxygen vacancy formation and cation reduction processes. In this study, the impact of sintering and heating rates on the concentration and nature of defects in 3YSZ was investigated using Electron Paramagnetic Resonance (EPR) spectroscopy. To explore a wide range of heating rates, two advanced sintering techniques—Spark Plasma Sintering (SPS) and Ultrafast High-Temperature Sintering (UHS)—were employed to examine the formation of paramagnetic centers, such as Zr^{3+} ions, oxygen vacancies (F-centers), and defect clusters.

EPR analysis reveals a strong correlation between heating rate, defect concentration, and blackening, with distinct variations in defect populations as sintering conditions change. Beyond certain processing thresholds, a transition in defect behavior is observed, where shifts in EPR signal intensity and defect types suggest the emergence of alternative charge compensation mechanisms, defect clustering, or modified electronic states. Additionally, higher sintering rates influence both the onset temperature and intensity of these emerging defects, shifting their activation threshold and altering their relative concentrations. At higher sintering temperatures, an additional EPR-active defect species emerges, increasing in concentration up to a certain point, after which a reduction in primary defect concentration is observed, despite intensified optical blackening. This behavior suggests the formation of clustered defects, spin-pairing effects, or deep electronic states not detectable by EPR.

By elucidating the influence of sintering kinetics on defect structures, this study provides insights into the controlled engineering of oxygen vacancies, charge transport mechanisms, and optical properties, relevant to YSZ applications in solid oxide fuel cells (SOFCs), thermal barrier coatings, and electroceramics.

From the 1st order phase transition in cristobalite to a compact high-temperature stable chemically stabilized ceramic

Dr. Lars Ortmann, Germany

Oral Presentation (20')

Abstract

The limits of the applicability of fused silica in HT processes due to the material properties are well known. However, the use of fused silica at temperatures $> 1300^{\circ}\text{C}$ is limited by the deformation and crystallization of the material. In case of crystallization, cristobalite precipitates and during cooling a first-order phase transition, which runs parallel to a steep decrease in volume, appears. This phase transition leads to material failure. Reflecting on these properties and in connection with the good thermal shock resistance of cristobalite in the temperature range between $300\text{--}1600^{\circ}\text{C}$, the idea arose to develop a technology for the production of a material that combines the very good thermal shock resistance of fused silica with the good deformation resistance at high temperatures ($> 1300^{\circ}\text{C}$) of cristobalite by making use of the mechanism of chemical stabilization of the high-temperature phase of cristobalite (β -cristobalite) down to room temperature, which has already been mentioned many times in the literature. Based on previous work and evaluation of the relevant literature, this work describes the production of a chemically stabilized ceramic (CSC) via the glass-ceramic route based on surface and bulk crystallization of glasses with high SiO_2 concentrations. Furthermore, the mechanisms of stabilization depending on the crystallization conditions are presented and the resulting effects on the thermal and mechanical properties of the generated material are discussed. The ternary system $\text{SiO}_2 - \text{Al}_2\text{O}_3 - \text{CaO}$ was selected for screening experiments, where the effect of the dopant ratios, the raw material preparation and the aging temperature were investigated with respect to the crystallization behavior as well as the stabilization mechanism of the β -cristobalite phase. Thermal and mechanical properties were discussed based on dilatometry and X-ray diffraction (XRD). Furthermore, a technological route to produce materials with a strongly suppressed phase transition is presented. Material properties such as flexural strength, thermal shock resistance and deformation resistance are presented. In further work, investigations must be carried out to optimize the glass-ceramic manufacturing technology and the aging behavior. Synthesis conditions and compositions for the glass-ceramic route have to be identified, where a deformation-free (in the temperature range $\leq 1600^{\circ}\text{C}$) and compact material with high thermal shock resistance can be produced.

1 Circular materials characterisation with synchrotron X-rays: an update on the European project ReMade@ARI

Dr. Gary Admans, France

Highlight (Oral Presentation 20')

Abstract

ReMade@ARI is a European project that provides free and assisted access to fifty analytical research infrastructures across Europe. The project is supported by Europe, UK and Switzerland at a level of 15 million EUR and runs until August 2026. The aim of the project is to boost circular materials research through access to synchrotrons, neutron sources, lasers, electron microscopes, ion and positron beams, and high magnetic field facilities. ReMade@ARI offers services that goes beyond the usual level of support at ARIs. This includes consultation on project ideas, free access to the research facilities, experiment assistance and travel support. This opportunity is open to researchers from both academia and industry and is particularly beneficial to first time users or experienced users wishing to learn a new complementary technique. Three years into the ReMade@ARI project, we can now report on its success stories of circular materials characterisation. ReMade@ARI attracted 192 research proposals for standard access (transnational access, TNA) in the first four access rounds, of which 124 were accepted. In addition, there were 25 requests from industry of which 19 have already been accepted, and it is noteworthy that more than half were from small and medium enterprises (SMEs). These achievements underscore the project's success and its potential to support diverse research needs. Users still have the opportunity to apply for access through ReMade@ARI. The deadline for the final call for standard access is 08 October 2025, while tailored SME access is available through rolling applications until 15 April 2026. SME access can be confidential, without obligation to publish results, and includes specific assistance for data analysis. Our presentation will demonstrate how researchers and industry partners can access these opportunities and make the most of the support provided by ReMade@ARI. To inspire prospective applicants, we will also showcase highlights from the project's achievements, including examples of cutting-edge research carried out at the synchrotron facilities ESRF and ALBA. Whether you are new to these facilities or looking to expand your research toolkit, this session will offer practical advice and showcase the potential of ReMade@ARI.

Mapping Circularity, Responsibility and Sustainability in Power Electronics Research: A Bibliometric Analysis

Dr. Pearl Agyakwa, United Kingdom

Oral Presentation (20')

Abstract

The sustainability of power electronics is an increasingly pressing issue, given the criticality of materials like cobalt, rare earth elements and gallium, all vital to global energy and digital transitions. These materials are often sourced from geopolitically unstable regions, raising concerns over resource depletion, exploitative labour practices and the concentration of supply chains in the Global North. These challenges represent one facet of the broader sustainability issues in electronics manufacturing. Circular economy strategies, including recycling, remanufacturing and material recovery, are explored as solutions. However, the integration of social responsibility, particularly issues related to responsible manufacturing, supply chain justice and social life cycle assessment, into power electronics research aimed at supporting the global energy transition remains underexplored[1].

In this bibliometric analysis, VOSviewer software tool is employed to assess the co-occurrence of circularity and social responsibility and terms related to power electronics research including integration and design, mapping the prevalence and thematic focus of these issues in academic discourse. Web of Science serves as the exclusive data source, with a structured search strategy identifying relevant publications from 2010 to the present. A targeted set of keywords relating to power electronics, circular economy, ethics, sustainability justice and the global energy transition are applied using Boolean operators to ensure comprehensive retrieval. The dataset is refined through inclusion and exclusion criteria, filtering out irrelevant studies and duplicates. Bibliometric techniques, including co-occurrence analysis to identify dominant research clusters, co-citation analysis to pinpoint influential works and citation network analysis to map scholarly influence, are used. Visualisation of trends in VOSviewer identifies key intersections between the technical and social dimensions of circularity in power electronics. Temporal keyword analysis tracks the evolution of ethical concerns, highlighting priorities such as responsible manufacturing and supply chain justice within the global energy transition. Thematic analysis using NVivo explores how social considerations like social life cycle assessments and sustainable design are represented in power electronics research, offering a holistic view of how these issues are integrated into developments supporting the global energy transition. A manual/semi-automated approach is used to identify links to funding sources, policy documents and industry connections, providing an overview of the broader social and economic forces shaping the field. Potential biases in the Web of Science database, particularly the underrepresentation of research from the Global South, are acknowledged. The study also reflects on the systemic marginalisation of knowledge production from regions most affected by extractive practices.

From Waste to Value: Harnessing Green Technologies for Residue Valorization and Circular Textile Innovation

Dr. Ana Luísa Alves, Portugal

Oral Presentation (20')

Abstract

Forestry and agriculture industries generate tons of waste each year, driving a global quest for sustainable and circular waste management solutions. As circular economies gain traction, innovative strategies to maximize residue utility while minimizing ecological impact have gained importance. Upcycling byproducts through bioconversion and resource recovery offers potential for value creation and market expansion across various sectors. Several pollutant industries, like the textile, are putting great effort into the development of more sustainable processes and bio-based solutions empowering decarbonization and zero-waste.

In this sense, the be@t project - Bioeconomy at textiles - is transforming Portugal's textile and apparel sector with its approach: "From nature to people, in a circular and sustainable way". This initiative aims to overhaul the entire textile value chain by introducing innovative, sustainable solutions promoting circular bioeconomy.

One strategy involves valorizing forestry and agro-industrial residues by extracting bioactive compounds and pigments to mitigate the negative ecological impacts of synthetic dyes, while conferring health benefits to textiles. The project offers opportunities for value addition and market diversification. For that, greener extraction technologies (energy-efficient processes), have been employed, which offer advantages such as reduced solvent consumption, shorter extraction times, and higher yields.

This study explored biomass from eucalyptus and banana leaves to obtain bioactive compounds and pigments using ultrasound-assisted extraction combined with eco-friendly solvents. Extracts were characterized for bioactivity and incorporated into formulations for spray-coating (known for minimal material waste and reduced energy consumption) in different natural fibers like cotton and linen. Alongside this approach, micronized banana leaf residue, resulted from the extraction process, was also used as raw material for textile coating, envisioning a full circular process, conferring coloration and residual bioactivity. The spray-coated textiles were assessed for relevant properties for the sector (washing and light fastness) as well as the functional properties (antioxidant, antimicrobial and UV protection), demonstrating promising results as sustainable alternatives to conventional dyeing and functionalization products.

This work highlights the potential of forestry and agro-industrial residues as valuable resources within a circular bioeconomy framework. The results underscore the feasibility and the advantages of integrating greener technologies and bio-based solutions into industrial processes, such as textile manufacturing, to promote sustainability and reduce environmental impact, aligned with global decarbonization and zero-waste goals.

The authors acknowledge financial support from the integrated project be@t – Textile Bioeconomy (TC-C12-i01, Sustainable Bioeconomy No. 02/C12- i01.01/2022), promoted by the Recovery and Resilience Plan (RRP), Next Generation EU, for the period 2021-2026.

Paper 1711 1 **Replacing boric acid in industrial nickel electroplating: toward REACH compliant electrolytes**

Dr. Roberto Bernasconi, Italy

Keynote (Oral Presentation 40')

Abstract

Boric acid plays a crucial role in industrial nickel electroplating, acting as a buffering agent to stabilize pH and improve deposit quality. However, due to its classification as a substance of very high concern (SVHC) under the REACH regulation (EC No 1907/2006), industry faces increasing pressure to find suitable alternatives. Substituting boric acid is challenging, not only for its consolidated role in the plating industry but also for its intrinsic qualities: high bath stability, grain refinement, exceptional pH stabilization. Alternative buffering agents must therefore ensure equivalent pH control, without compromising bath stability, in front of comparable coating properties.

The substitution is crucial for well-established practices like bright nickel plating, but it also constitutes an important step toward the development of nickel-based composites. These are deposited by dispersing functional nanoparticles in an electrodeposited nickel matrix. Such particles can be either hard ceramic particles (B_4C , Al_2O_3 ...), suitable to improve the wear resistance of the layer, or solid lubricant particles (graphene, MoS_2 ...), which confer low friction coefficient and self-lubricating properties [1]. Hard composites, in particular, are promising for the replacement of hard chromium coatings. This action is vital for a wealth of industrial applications, as the hexavalent chromium species required for hard chromium plating are harmful for human health.

The ongoing research is focusing on boron-free buffers for the deposition of both pure nickel coatings and nano-composite layers, but industrial-scale implementation remains complex. The electroplating sector must balance regulatory requirements with technical feasibility to ensure sustainable and efficient nickel deposition. In this context, the MOZART European project aims at implementing electrolytes compliant to the REACH normative for the electrodeposition of nickel-based materials as alternatives to hard chromium.

The present work aims at discussing, in the framework of the MOZART project, the feasibility of boric acid replacement for the industrial electrodeposition of nickel. The laboratory practice is discussed in parallel with the industrial practice, considering the point of view of the partners of the project. The influence of some alternative buffers, mainly belonging to the class of carboxylic acids [2], on the properties of the coatings obtained is evaluated. Then, the impact of such alternative buffers on LCA is evaluated, with a particular focus on bath longevity and disposal procedures.

A Comparative Life Cycle Assessment of Catalytic Converters: Recycled vs. Conventionally Sourced Platinum Group Metals

Mrs. Derya Dilara Ataş, Turkey

Highlight (Oral Presentation 20')

Abstract

Automotive catalytic converters (catalysts), introduced in the 1970s, have undergone continuous evolution to meet increasingly stringent emission standards. Their primary function is to mitigate air pollution from incomplete fuel combustion by catalytically converting hazardous gases, such as carbon monoxide, hydrocarbons, and nitrogen oxides, into carbon dioxide and water vapor. These converters typically comprise a platinum group metal (PGM)-based monolith core housed within an outer steel shell. PGMs -including platinum, palladium, rhodium, ruthenium, iridium, and osmium- are highly valued for their unique properties. Their exceptional catalytic activity, chemical inertness, corrosion resistance, thermoelectric stability, and aesthetic appeal facilitate their widespread use across diverse industries. Applications range from catalytic converters and hydrogen fuel cells to biomedical implants, aerospace components, and jewellery. However, the limited natural abundance of PGMs (estimated at 66,000 tons globally) necessitates efficient recovery strategies for sustainable production. Currently, the predominant methods for recovering PGMs from end-of-life (EoL) products, such as spent catalysts, are hydrometallurgical and pyrometallurgical processes. Hydrometallurgical methods involve dissolving PGMs in acidic solutions, while pyrometallurgical techniques concentrate them through smelting or roasting. The EU funded PEACOC project presents an integrated approach to PGM recovery, incorporating innovative technologies such as microwave-assisted leaching (MWAL), gas-diffusion electro crystallization (GDEx), superconducting magnetic density separation (MDS), ultra-fast sensor-based sorting (UFS), and the NOVA process. This integrated system aims to provide an efficient and scalable solution for extracting PGMs from EoL resources, including automotive catalysts and electronic waste, with feasibility demonstrated at a pre-commercial pilot scale. A life cycle assessment (LCA) will evaluate the environmental impact of the entire PGM recovery process chain, from EoL product collection to final PGM valorisation. This study will specifically compare the environmental performance of catalytic converters manufactured using PGMs recovered via PEACOC's innovative solutions against those produced using conventional methods. Furthermore, it will identify opportunities to minimize the environmental footprint and ensure the new processes contribute to sustainable practices within the automotive sector.

Paper 1774 4

Development of a thermoplastic starch-based compound for extrusion of biodegradable foams

Mr. Carlos M. Correia, Portugal

Oral Presentation (20')

Abstract

Starch foams have gained attention due to growing concerns regarding their non-biodegradable counterparts. Since the early 90s, starch foams have been extensively used in niche applications, such as extruded foam peanuts, where they offer a positive balance between cost, cushioning performance, and ease of disposal through composting or water dissolution. However, poor processability, weak mechanical properties, and low water resistance have limited a wide utilization of starch foams as packaging solutions. To improve starch foams processability, researchers have explored their plasticization, chemical modification, and blending with other polymer or additives. These advances, coupled with stricter environmental regulations targeting expanded or extruded polystyrene (EPS and XPS), have contributed to a revived interest in starch-based foams. This study aims to develop a starch-based material suitable for extrusion foaming through the compounding of a modified thermoplastic starch (TPS) and an expandable grade of polylactic acid (PLA). The extrudability of the TPS/PLA blends with different TPS contents (0–100 wt.%) was evaluated by analyzing their thermal properties (DSC and TGA) and processing behavior (screw torque, melt viscosity, and melt flow index). Moreover, selected TPS/PLA blends foamability with a chemical blowing agent (CBA) was evaluated using a laboratory-scale twin-screw extruder. Apparent density, compression behavior, and foam morphology were monitored as a function of the TPS/PLA ratio of the blends. Furthermore, the effects of CBA concentration, screw speed, and die temperature on the starch foam structure and physicochemical properties were also analyzed. Interestingly, as TPS content increased, the melt transition temperature decreased, leading to higher flowability and lower screw torque under similar extrusion conditions. These results highlight the opportunity of leveraging the material composition and processing conditions to obtain starch foams with enhanced properties which can contribute to higher material circularity in the packaging industry.

From cheese-making waste to compostable cheese packaging films: physicochemical and environmental assessment

Prof. Koro De La Caba, Spain

Oral Presentation (20')

Abstract

Approximately 180 - 190 million tonnes of whey are produced every year worldwide. In particular, around 80 - 90% of the milk required for cheese manufacture becomes whey. In this work, whey protein extracted from cheese-making by-products was analysed as a potential alternative for both food waste valorisation and food packaging waste reduction. With this aim, a complete study of whey protein-based films, from the extraction of the protein to the biodegradation of the film, considering the film manufacture, was carried out in this work. The whey used in this study to extract whey protein was collected from a local farm in the Basque Country. This biowaste was selected for its accessibility and availability. To ensure the maximum protein recovery from whey, ultrafiltration processes were performed. Two fractions were obtained from the ultrafiltration process: a filtrated cheese whey with a content reduced in protein and a purified fraction mainly composed of protein, achieving a final protein content of 91.6 % wt, with the presence of some carbohydrates, such as lactose, as shown by Fourier transform infrared (FTIR) spectroscopy, X-ray diffraction (XRD) and scanning electron microscopy (SEM) analyses. This whey protein, extracted from local cheese whey, was used to produce food packaging films by compression, resulting in transparent and easy-to-handle films. Since the amino acid analysis showed that glutamic and aspartic acids were the major amino acids in whey protein, films were tested using ethanol as fatty food simulant. The solubility outcomes showed that films were suitable for fatty foods, such as cheese, following this way circular economy strategy. Furthermore, the films were found biodegradable under industrial composting conditions, highlighting the more sustainable character of these packaging films.

Paper 2127 4 Magnets in Resilient Supply Chains

Ph.D. Ane Jimenez, Spain

Highlight (Oral Presentation 20')

Abstract

The supply of magnets and critical materials, such as rare-earth elements (REEs), is of paramount importance for Europe, particularly in the context of the growing demand for electric vehicles and renewable energy technologies. Europe relies heavily on imports for these materials, making the region vulnerable to supply chain disruptions and geopolitical risks. Ensuring a stable and sustainable supply of REEs is crucial for the development of electric vehicle traction motors (EVTMs) and other green technologies, which are central to the European Union's transition towards a low-carbon economy. Consequently, the need for innovative approaches to secure and optimize the use of these critical materials has never been more urgent. This MAGELLAN project aims to address these challenges by developing a sustainable and cost-effective REE permanent magnet value chain, enhancing Europe's autonomy and resilience in the face of material shortages.

The main objectives include advanced recycling and manufacturing technologies, incorporating efficient material reuse through Powder Injection Moulding. Additionally, the work focuses on optimizing EVTm rotor design to improve motor assembly, performance, and facilitate End-of-Life dismantling. Another key goal is enhancing magnet recovery and recycling to minimize REE losses and promote standardized labelling for improved reuse.

The results of this project are expected to contribute to the reduction of pollutant emissions by incorporating a higher amount of recycled material in the production of new magnets, making the European magnet-related industry more resilient and competitive.

Paper 1442 5 Driving the Circularity of Materials with Digital Solutions: A Case Study on Integration with the CE-RISE Information System

Dr. Daria Kieczka, United Kingdom

Oral Presentation (20')

Abstract

Transitioning to a circular economy (CE) requires a robust information framework to enable transparency of material sourcing, use, and recovery. Digitalization can play a key role in improving transparency, traceability, and efficiency across industries. The CE-RISE (Circular Economy Resource Information System) project, funded by the European Union (EU) under Horizon Europe, is developing an advanced system to facilitate data sharing across the value chain. In July 2024, the Ecodesign for Sustainable Products Regulation (ESPR) came into effect, requiring Digital Product Passports (DPPs) full implementation expected by 2030. DPPs provide essential data on product composition and its environmental impact, amongst others. CE-RISE aims to implement an intelligent data system that integrates DPPs, RE-indicators (such as recyclability and repairability), lifecycle assessments, and socio-economic indicators. By enabling better traceability, predictive maintenance, and informed decision-making, this digital infrastructure will help increase product circularity and reduce waste.

This presentation explores how CE-RISE leverages digital tools to drive circularity. CE-RISE will provide detailed end-of-life options and information, empowering consumers, manufacturers, and repairers to make informed decisions. We examine how materials data management software can enhance the information system by providing more comprehensive information about materials' properties and processes among others. As part of this project, we focus on integrating Ansys Granta MI Enterprise with CE-RISE systems to support decision-makers in developing circular strategies based on materials in products. We propose a framework within the CE-RISE project, that links with DPP systems and a product Bill of Materials (BoM) to generate reports on restricted substances in materials, assessed against legislation. Additionally, the framework delivers sustainability data, including climate impact (CO₂-eq) and material attributes such as recyclability and biodegradability. This enables a deeper understanding of products' sustainability credentials.

Valorization of Construction and Demolition Waste in Ceramic Tile Industry: A Sustainable and Circular Economy Perspective

Mrs. Sonia Marín-Cortés, Spain

Keynote (Oral Presentation 40')

Abstract

Construction and demolition waste (CDW) accounts for one-third of the total solid waste generated annually. This waste typology has a low recycling rate due to several inherent characteristics, including its high heterogeneity and the absence of a unified management policy that enables these materials to be obtained in a form suitable for upcycling applications. The ceramic tile industry plays a significant role in the European economy, particularly in countries like Spain and Italy. For example, in Spain, this industry accounted for 15,000 direct jobs and €4.864 billion in revenue in 2023. However, it is also a sector with high energy and natural resource demands, being responsible for 143.823 tons of CO₂ emissions not covered by free allowances in 2023 [1].

Therefore, the transition of this industry towards a circular economy model and decarbonisation is essential for achieving a greener future.

This work explores strategies aimed at increasing the sustainability of the ceramic tile industry, with a special focus on the recovery of CDW and low-impact practices.

Firstly, it explores a system for quantifying construction materials based on chemometrics applied to Raman and SWIR spectroscopies. This methodology quantifies the brick and concrete content in real CDW samples, providing a tool for applications where material composition is critical, such as in recycled ceramic tiles. [2] Secondly, the easibility of manufacturing ceramic tiles with 55 wt% of real CDW at a high level of industrial readiness (TRL 7) is demonstrated. After various experimental assessments, industrial production of recycled ceramic tiles was achieved, containing 89% ceramic debris and 11% mixed CDW. These tiles exhibited flexural strength and water absorption values that classify them under BI and BIII typologies of ISO13006, respectively, confirming their industrial viability.

In addition, the development of a traceability tool based on a photoluminescent ink compatible with ceramic glaze is explored. For the first time, a photoluminescent pigment based on (Ca,Sr)(Na,K)AlSi₃O₈:Eu³⁺ was designed, characterised, and scaled industrially. Applied via inkjet printing, the pigment remains invisible under visible light but becomes visible under UV light, enabling smartphone-readable traceability. [3] Finally, cold sintering was explored as a sustainable manufacturing route. Compositions with up to 95% CDW showed flexural strength above required thresholds by the standard, which increased significantly after post-treatment at 1100 °C without compromising dimensional stability [4,5]. In this way, the study proposes a multi-strategy advancement in sustainability for the ceramic tile industry.

Green ironmaking at higher H₂ gas pressures: Reduction kinetics and microstructure evolution of hematite

Mrs. Özge Özgün Gülten, Germany

Oral Presentation (20')

Abstract

Steel production is a key factor in the global transition toward sustainability, however, it is the largest source of CO₂ emissions in the industrial sector, contributing 7–8% of global emissions. Hydrogen-based direct reduction (HyDR) has attracted immense attention as a promising solution for producing sustainable iron from iron ores without CO₂ emissions. This solid-gas reduction process with H₂ occurs in multiple sequential steps, converting hematite into magnetite, then wüstite, and finally metallic iron at temperatures above 570°C. While previous studies indicate that H₂ gas pressure influences the reduction kinetics and microstructural evolution of iron ore during HyDR, the fundamental reaction mechanisms governing each step remain poorly understood. Here, we perform in-situ synchrotron high-energy X-ray diffraction during HyDR to monitor real-time phase transformation kinetics of hematite at different H₂ gas pressures at 1, 10, 50, and 100 bar at 700 °C. The microstructure evolution of the reduced hematite specimens was characterized using scanning electron microscopy equipped with the electron backscatter diffraction (EBSD) technique. Furthermore, the influence of H₂ gas pressures on the three-dimensional pore structure of reduced iron was analyzed using X-ray nano-computed tomography. The results offer valuable insights into the pivotal role of H₂ gas pressures in HyDR, paving the way for improving the reduction efficiency of HyDR.

Recycled Inconel 718 Powder for sustainable metal additive manufacturing

Dr. Hossein Rajaeinajafabadi, Italy

Oral Presentation (20')

Abstract

Inconel 718 is widely used in additive manufacturing (AM) due to its exceptional corrosion resistance and superior mechanical strength. However, the reuse of powder in AM processes raises significant challenges, as alterations in powder properties can potentially compromise the performance of fabricated components. This study explores the feasibility of reusing Inconel 718 powder by evaluating a mixture composed of 50% cyclone-collected used powder and virgin powder, with virgin powder serving as the baseline for comparison. Comprehensive characterization of the powders was conducted, focusing on particle size distribution, flowability, and chemical composition. To determine the impact of powder reuse on part quality, defect analysis was performed on laser powder bed fusion (L-PBF) specimens using light microscopy to assess porosity and defect distribution. Mechanical properties were further evaluated through tensile and fatigue testing. The results revealed that pore distribution trends were consistent between the virgin and blended powders, with pore sizes consistently below approximately 70 microns. Tensile testing demonstrated negligible differences in yield and ultimate tensile strength between the two powder types. Interestingly, fatigue testing indicated enhanced performance in components produced from the blended powder. These findings suggest that incorporating partially recycled Inconel 718 powder in AM processes is not only feasible but also advantageous, offering a sustainable and cost-effective solution without sacrificing mechanical performance. This study underscores the potential for optimizing powder reuse in AM, contributing to both economic and environmental benefits in advanced manufacturing.

Paper 1885 1 Additive manufacturing of metallic bioresorbable stents

Prof. Joaquin Rams, Spain

Keynote (Oral Presentation 40')

Abstract

Customizable, bioresorbable cardiovascular stents utilizing additive manufacturing (AM) offer a transformative approach to heart health, directly addressing two of the most critical needs in modern medical devices: personalization and non-permanence within the body. Currently, only metallic materials can fully meet the stringent demands of cardiovascular stents, with strut size that minimizes its impact on the blood flow. Through 3D printing with metals, stents can be tailored to each patient's unique vascular anatomy, ensuring a customized fit that enhances effectiveness while having the required resistance.

Most current implants are permanent, and in some health problems, once the tissue or organ is healed, they become superfluous as happens to cardiovascular stents. Bioresorbable stents would gradually dissolve as the artery heals, reducing the long-term risks of permanent implants such as chronic inflammation and restenosis, while supporting the body's natural healing process. The most considered bioresorbable materials that can be additively manufactured are based on Mg and Fe, and they provide the mechanical strength required for arterial support while fully degradable over time. Laser Powder Bed Fusion (LPBF) technology is the metal AM technology that provides the best resolution and detail, and it has been used to manufacture stents and stent-like structures with Mg (WE43) and FeMn (Fe20Mn0.5C) alloys. The freedom of design that LPBF provides has been used to optimize the performance of the stents, and conventional and auxetic designs have been used.

Also, to meet the stringent roughness requirements of cardiovascular stents, the surface of the 3D printed stents has been modified to reduce the intrinsic roughness of the LPBF process and to modulate the degradation rate and its interaction with the biological environment. In the case of the Mg-based stents, a sol-gel silica coating has been deposited to assimilate their corrosion rate to the conventional healing times of cardiovascular arteries.

The microstructure and roughness of stents have been evaluated. Also, tensile and compression mechanical tests have been applied to stents and structures with a central part with a stent-like structure but with clamps compatible with standard universal testing machines. The results obtained match those obtained from mechanical simulations. Therefore, it has been proven that LPBF is a valuable tool for manufacturing bioresorbable stents and testing structures that cannot be fabricated with other techniques.

Towards partly degradable implants made from titanium and magnesium

Dr. Vasyl Haramus, Germany

Highlight (Oral Presentation 20')

Abstract

Medical implants consisting of a degradable and a permanent part offer the opportunity to develop novel therapies and improved implant functionality. In particular, the combination of permanent titanium (Ti) and degradable magnesium (Mg) alloys as hybrid implant materials could be beneficial. Ti is a well-known excellent implant material due to the high strength and biocompatibility, while Mg has mechanical properties similar to bone, degrades in the body and stimulates several biological functions, for example bone formation. Thus, the aim of this study is to get synergy in the interaction between these strongly different metals transforming Ti into tissue stimulative material and supports Mg by load bearing application.

There are some challenges of Ti-Mg implants to overcome: (i) because of metal physical reasons the connection between Mg and Ti as key point of hybrid implant production is not trivial, (ii) due to electrochemical interaction the connection with Ti can change the degradation behaviour of the Mg part and (iii) hydrogen formed during degradation can deteriorate the mechanical properties of the Ti part. However, preliminary studies to solve these obstacles showed that Mg and Ti can be joined by a powder metallurgical sintering approach, enabling also additive manufacturing. Hydrogen evolution experiments, chemical composition determination, electron microscopy, X-ray diffraction and mechanical tests were applied for the characterisation of the hybrid Ti-Mg implant system [1].

The results point out the demand for coating of the implant surface to decrease rapid degradation of Mg which can be achieved by plasma electrolyte oxidation coating [2]. Hydrogen released due to Mg degradation ingresses into the Ti part and could lead to embrittlement if not properly controlled. By well determined hydrogen adsorption, there are hints that the biocompatibility of Ti can even be improved.

In sum, the results of the presented investigations will be used for further development of hybrid Mg-Ti implants facilitating the simultaneous application of completely different properties. Furthermore, the possibility to change the shape of the implant during application could be additional aspect with new field of patients' treatment.

Paper 1798 1 **Hydrogen use in valorization of bauxite residue to extract iron and alumina**

Prof. Jafar Safarian, Norway

Keynote (Oral Presentation 40')

Abstract

Bauxite residue (de-watered red mud) has been a long-lasting environmental problem in the alumina production from bauxite ores via the commercial Bayer process. The current world stockpiled bauxite residue is estimated over 4 billion tones, with annual addition of over 175 million tons. It has high alkalinity and hence is harmful if it leaks to the nature, and several red mud catastrophes happened shows its risks. As bauxite residue is a hazardous waste, it must be safely stored, valorized via sustainable approaches, or its generation prevented. The continues growth of aluminum and alumina industry is accompanied with more bauxite residue production in future, and hence it is crucially important to solve this waste problem. Bauxite residue contains high amounts of metal oxides such iron oxides, alumina, silica, titanium oxides, and it contains rare earth elements such as Sc, Ga, etc. Regarding the chemical characteristics of the bauxite residue, it is a potential secondary source for the extraction of some metals such as Fe, Al, RREs. Obviously, the establishment of new methods to valorize bauxite residue must be with no or insignificant hazardous waste generation. In an approach in Harare EU project, sustainable methods for bauxite residue valorization using hydrogen gas as a reductant to reduce iron oxides is demonstrated in lab and pilot scales. In an approach, which is called Ca-route, bauxite residue is mixed with lime fine, pelletized via different techniques, and then reduced by hydrogen gas at elevated temperatures. The reduced material is then post-treated, and iron is separated from the coexisting non-metallic components. The pre-reduced pellets obtained by hydrogen reduction contain iron particles distributed in the non-metallic oxide matrix, which is mostly calcium-aluminate. Alumina is leached from the oxide matrix of the reduced pellets via alkaline leaching by sodium carbonate solutions. Applying advanced materials characterization techniques, the formation of suitable phases with proper physical characteristics were studied and the process conditions were optimized. The mechanisms of reduction reactions and the role of pellets components in formation of metallic iron and leachable calcium-aluminate phases were proposed. It was found that upscaling of hydrogen reduction from lab scale stationary bed reactor to a pilot rotary furnace yields better reduced product in term of iron particles sizes. Materials analysis and thermodynamics calculations, the mechanisms involved in iron particles formation and growth were proposed.

Paper 1820 2 Sustainable metal production via hydrogen- and ammonia-based direct reduction of metal oxides
Dr. Yan Ma, The Netherlands
Oral Presentation (20')

Abstract

Fossil-free metal production is critical for reducing the substantial CO₂ emissions from the metal industry, which accounts for approximately 10% of global emissions and is a major contributor to climate change. Hydrogen-based direct reduction of metal oxides, including the use of hydrogen carriers such as ammonia, represents one of the most promising strategies for mitigating these emissions. In this study, we investigate the reduction behavior of metal oxides (e.g., iron oxide and mixtures of iron and nickel oxides) using hydrogen and ammonia, with a particular focus on the spatial and temporal evolution of the microstructure during the multistep solid-gas reaction. Advanced characterization techniques were employed to analyze phase transformations, porosity, and local chemistry throughout the reduction process. The fundamental reaction mechanisms are discussed, providing new insights into the sustainable production of metals and alloys via hydrogen- and ammonia-based direct reduction, ultimately enabling a pathway to metal production with minimal CO₂ footprint.

Hydrogen-based direct reduction and decomposition of mill scale at 400°C-700°C

Mrs. Bénédicte Kuypers, Belgium

Oral Presentation (20')

Abstract

The transition towards a more sustainable society requires the urgent decarbonization of the steel industry. Indeed, this sector is responsible for around 5% of the CO₂ emissions in the European Union and 7% worldwide [1]. In 2016, 70% of the world steel production was done via Blast Furnace or Basic Oxygen Furnace [2], using carbon as a reducing agent. Hydrogen-based direct reduction (HyDR) is a promising alternative to produce metallic iron with a lower CO₂ impact [3].

However, the behavior of the various iron sources during direct reduction is not yet fully understood. In this work, we studied the HyDR kinetics of mill scale, an industrial iron-rich oxide waste produced during the thermo-mechanical processing of steel. Mill scale mainly consists of wüstite (about 80%) with small amounts of impurities (Mn-0.4, Al-0.05, Si-0.04, Cr-0.02, Cu-0.02, Ni-0.02 in wt%). The studied iron oxides fines have a particle size range between 45-106 µm.

Isothermal reduction kinetics were analyzed using a thermogravimetric analyzer. The influence of both deep pre-oxidation (using dry air at 700°C, 800°C or 900°C) and reduction temperatures (400°C, 450°C, 500°C and 700°C) on crushed mill scale powder was studied in pure hydrogen. The evolution of the impurities within the powder during its reduction was measured by ICP, SEM-EDS and STEM-EDS analyses.

Pre-oxidation consistently resulted in faster reduction rates, with the highest kinetics obtained with a pre-oxidation temperature of 800°C followed by a reduction at 500°C. Interrupted tests were carried out at 500°C, with and without pre-oxidation, to assess the reaction mechanisms of the intermediate steps during direct reduction. The eutectoid wüstite decomposition at 500°C was also quantified. This is done with microstructural analyses (SEM, EDX, EBSD, XRD) coupled with kinetic fittings. For each reaction mechanism, the rate constant and activation energy was calculated and compared with the HyDR behavior of other Fe sources.

Direct reduction of iron oxides by hydrogen: Elucidating microstructure effects in single crystal and polycrystalline hematite

Dr. Barak Ratzker, Germany

Oral Presentation (20')

Abstract

The aim of reducing CO₂ emissions in the metal industry necessitates developing more sustainable metallurgical processing pathways. One of the most promising approaches is the solid-state hydrogen-based direct reduction (HyDR) of metal oxides. Extensive work has been conducted to study the influence of reducing conditions (e.g., time, temperature, gas composition, etc.) and material properties (e.g., metal oxide composition, gangue elements, powder particle size, etc.) on the HyDR process. Gaining a fundamental understanding of microstructural factors affecting the reduction behavior assists in further optimizing the process and the reactor design. In the present study, we investigated the reduction kinetics of single crystal and dense polycrystalline hematite (without initial percolating pores) exposed to pure H₂ at 700 °C using thermogravimetric analysis. Furthermore, the microstructure of partially reduced specimens was thoroughly characterized by scanning electron microscopy and electron backscatter diffraction to elucidate the microstructure evolution during the reduction process. The critical steps of porosity development alongside the formation of reduced oxides and metallic iron were thoroughly examined. Studying single crystal samples enabled us to assess the microstructure development for different crystallographic plane facets and analyze the orientation relationships between the different oxide phases. In addition, the polycrystalline hematite samples with various grain sizes revealed the effect of grain boundaries on the reduction behavior. The microstructural insights shed light on the importance of the microstructure aspects for HyDR of metal oxides.

Modelling microstructure evolution during reduction of iron oxide pellets

Dr. Anna Lena Ravensburg, Germany

Oral Presentation (20')

Abstract

The urgent need to reduce greenhouse gas emissions in steel metallurgy, driven by the challenges of climate change, is catalyzing a paradigm shift and transforming long-established industrial processes. A transition towards a clean hydrogen-based direct reduction of iron, for example, requires a deep understanding of the interdependencies among all process parameters. Such insights can be achieved through robust, physically sound process modeling with high extrapolative power.

We present a one-dimensional micro-reaction model with explicit time stepping capable of predicting and optimizing the reduction process of industrial iron ore pellets exposed to various reducing gas streams. In addition to reduction kinetics and mass transport, our simulation incorporates thermodynamics and microstructure evolution, thereby providing a comprehensive understanding of the thermochemical and thermophysical phenomena involved. Compared to other micro-reaction models, our thermodynamics-based approach reduces the number of fitting parameters while still accounting for all relevant gas-solid, gas-gas, and partitioning reactions.

This method enables the reliable integration and optimization of key input parameters, such as kinetic parameters, iron oxide pellet properties, as well as pure and mixed reduction gas streams. Ultimately, it supports the integration of hydrogen into industrial processes, contributing to a reduced carbon footprint in steel metallurgy.

Evaluating sustainable steam shaft production strategies through Life Cycle Assessment

Mrs. Mary Osorio Baena, Germany

Oral Presentation (20')

Abstract

Historically, product development has been a source of waste in the forging industry. This is often due to failed attempts to manufacture new steel parts, either due to quality defects or critical failures along the manufacturing process. While there are always risks in producing new steel grades and parts, these can be greatly minimized by integrating computerized tools into the design phase. This enables engineers to select optimal parameters and eliminate problematic ones. Although simulation-based tools such as FE thermal modelling are currently well-established in forging companies, artificial intelligence has emerged as a natural progression to optimize product design. Reinosa Forgings & Castings (RFC) is currently exploring the potential of these analytical techniques in combination with traditional FE modelling to predict the creep properties of a novel steam shaft before it is put into service. In this way, the trial and error approach can be avoided by selecting the most appropriate manufacturing parameters route to achieve the desired properties in the final product. To understand the environmental impact of these innovations, an analysis of a non-optimized process is proposed as the basis of the study. The study includes a life cycle assessment (LCA) to assess the environmental footprint of manufacturing steam shafts from recycled steel, highlighting how existing residue streams at RFC are revalorized, contributing to the circular economy. The analysis initially follows a 'cradle-to-gate' approach, prioritizing processes such as EAF melting, refining, and casting, proposing scenarios to measure the impact of by-product revalorization. Primary data was collected directly from industrial operations, supplemented with secondary data from Ecoinvent v3.10, and modelled using Umberto 11.14.1. The assessment of environmental impacts was based on the production of one tonne of ingot as the functional unit. Initial results indicate that RFC's processes where residue streams are revalorized present a reduction on environmental impact of as much as 15% in comparison with processes performed elsewhere where these streams are disposed as waste. Finally, by utilizing the synergies of AI-tools and LCA, the present study aims to be able to extend the lifespan of critical industrial components where the core product is utilized, i.e. energy generation turbines, on a broader 'cradle-to-grave' approach.

One step alloy-making from oxides: From thermodynamic design maps to atomic-scale chemistry

Dr. Shaolou Wei, Germany

Highlight (Oral Presentation 20')

Abstract

Metallurgical production traditionally involves three steps: extracting metals from ores, mixing them into alloys by liquid processing and thermomechanical processing to achieve the desired microstructures. This sequential approach, practiced since the Bronze Age, reaches its limit today because of the urgent demand for a sustainable economy: almost 10% of all greenhouse gas emissions are because of the use of fossil reductants and high-temperature metallurgical processing. In this talk, we will discuss a H₂ redox-inspired alloy synthesis strategy, turning oxides into sustainable bulk alloys in one single solid-state process step. We ask three fundamental questions: (1) What are the thermodynamic processing guidelines? (2) What are the rate-limiting kinetic processes at play? (3) What are the chemical characteristics of the redox-alloying fronts? By taking Fe-Ni Invar alloy as a demonstrator case, we will address these questions in quantitative depth via theoretical calculations, in situ synchrotron X-ray experiments, and the cutting-edge correlative 4D scanning transmission electron microscopy (STEM)-atom probe tomography (APT) analyses. We will also discuss a hypothesis concerning tailored metal-oxide interface for improving oxide reducibility. Finally, we will outline an “one step metallurgy” concept conceived to further dissolve some of the classical borders between extractive and physical metallurgy.

Paper 281 **2** **Theoretical predictions and high-resolution experimental observations of lenticular hematite formations in partially oxidised magnetite powder**
Dr. Martina Ruffino, Germany
Oral Presentation (20')

Abstract

The reduction of iron oxides into pure iron is the most energy intensive and polluting process in steelmaking. Pre-oxidation of magnetite to hematite is an effective approach to increase its reducibility in ironmaking due to the associated microstructure refinements and defect formation during oxidation, thus creating an opportunity for optimisation of the process. In this study, we investigate the crystallographic orientation relationship between hematite and magnetite and their interfacial structures down to the atomic scale in order to elucidate the growth mechanism of hematite in magnetite during oxidation. We first build a theoretical model for the advancement of the hematite/magnetite interface by identifying disconnections (i. e., steps with dislocation character) suitable for the accomplishment of the phase transformation, according to the topological model of interfacial defects, and calculated their Burgers vectors and step heights. The role of the disconnections in partially compensating for the lattice misfit on the interface plane is also noted. We then investigate a magnetite powder oxidised in air at 700 °C for 30 min via electron microscopy. We observe lenticular hematite formations and confirm that their relationship with the magnetite matrix follows the Shoji-Nishiyama orientation relationship $((111)_{\text{mag}} \parallel (0001)_{\text{hem}}, [1-10]_{\text{mag}} \parallel [10-10]_{\text{hem}})$ using electron backscatter diffraction (EBSD). We analyse one of these hematite plates with a high-resolution transmission electron microscope (TEM), characterising the hematite/magnetite interface as a faceted interface containing steps through high-angle annular dark-field (HAADF) imaging. Coherent terraces of interface parallel to $(0001)_{\text{hem}}$ and $(111)_{\text{mag}}$ are seen to be separated by the steps. The dislocation content of the steps is found through Burgers circuit mapping to correspond to that of the transformation disconnections predicted by the theoretical model. We thus validate the proposed growth mechanism of hematite plates in magnetite mediated by interfacial disconnections.

Computational prediction of the effect of process parameters and pellet properties on the hydrogen direct reduction of iron oxide pellets

Mr. Ömer Büyükuslu, Germany

Oral Presentation (20')

Abstract

The urgent need to reduce greenhouse gas emissions in steel metallurgy, driven by the challenges of climate change, is catalyzing a paradigm shift and transforming long-established industrial processes. A transition towards a clean hydrogen-based direct reduction of iron, for example, requires a deep understanding of the interdependencies among all process parameters. Such insights can be achieved through robust, physically sound process modeling with high extrapolative power.

We demonstrate that our one-dimensional thermodynamics-based micro-reaction model can simulate the direct reduction of porous industrial iron ore pellets exposed to pure or mixed reducing gas atmosphere. With our novel approach we can predict how porosity and convergence degree are affected by process parameters - like temperature or the reduction gas composition - and materials properties - like the pellet porosity, composition and diameter. Model predictions are validated through comparison with experimental data from pellet reduction processes and microstructure analysis of reduced iron oxide pellets.

Our simulations offer detailed insights into the system's dynamic behavior, including chemical, thermophysical, and transport phenomena within the pellets. Ultimately, our predictions support the integration of hydrogen into industrial processes, contributing to a reduced carbon footprint in steel metallurgy.

Thermodynamic-guided sustainable alloy design via hydrogen-based direct reduction of metal oxide mixtures

Mr. Shiv Shankar, Germany

Oral Presentation (20')

Abstract

More than 2 billion tons of metals and alloys are produced annually to facilitate economic growth and meet the demands of rapid civilization. However, conventional alloy production routes, which use carbon-based reductants, emit CO₂ as a by-product and contribute approximately 40% of all industrial greenhouse gas emissions. The co-reduction of metal oxide mixtures using hydrogen as a reductant offers a one-step approach toward sustainable alloy production. In this study, we propose a thermodynamic model to predict the effect of temperature and composition on the reducibility of NiO+Cr₂O₃ and Fe₂O₃+Cr₂O₃ mixtures using CALPHAD approach. Based on the thermodynamic prediction, hydrogen-based direct reduction was performed to produce Fe-10Cr alloy by reducing the corresponding oxide mixtures at 900 and 1100 °C, as well as Fe-50Cr alloy at 1100 °C. The reduction kinetics of the binary oxide mixtures were quantitatively analyzed by thermogravimetry analysis, while the microstructure of the reduced samples was characterized by X-ray diffraction and scanning electron microscopy. The experimental results were consistent with the thermodynamic predictions. Furthermore, the findings demonstrated that mixing different oxides enables the reduction of highly stable oxides (here, Cr₂O₃, which in the pure oxide form cannot be reduced by pure hydrogen at 1100 °C), offering a potential pathway for sustainable alloy production.

Iron recovery from EAF slags through hydrogen-based reduction

Mrs. Raquel Sánchez San Juan, Spain

Oral Presentation (20')

Abstract

The steel production in the electric arc furnace (EAF) is continually growing as more steel is recycled. The iron content in EAF slags is significantly higher than conventional BF slags, which makes them attractive as potential Fe sources. It is estimated in 25 million tons the total iron content of the EAF slag produced in 2023. Therefore, the development of sustainable iron recovery methods from EAF slags will enhance the circularity of the steel industry. Our thermochemical calculations for the hydrogen-based reduction of molten slags show that recovering high-purity Fe is thermodynamically feasible and could offer advantages over carbon-based processes.

This study proposes the experimental framework for the design of hydrogen-based iron recovery processes from industrial EAF black slags. Firstly, the chemistry and mineralogy of different industrial EAF slags were characterized. Elemental analysis was conducted using X-ray fluorescence (XRF), crystalline and amorphous phases were determined through Rietveld refinement of X-ray diffraction (XRD) patterns, and the morpho-compositional study of the slags was performed by scanning electron microscopy (SEM) and energy dispersive X-ray (EDX) spectroscopy microanalysis. The iron is mainly distributed in the amorphous phase and the RO phase (Fe,Mn,Mg)O.

In order to design adequate reduction heat treatments, thermodynamic equilibrium calculations by FactSage 8.3 were combined with phenomenological models to predict the foaming index of the slags under a variety of hydrogen injection flow rates and temperatures. It has been verified that, for fixed H₂ injection conditions, the chemical composition of slags influences the optimum temperature range to get the proper fraction of solid phases coexisting with the liquid slag and, thereby, the slag foam height. Finally, experimental validation was carried out using an innovative laboratory-scale melting furnace, equipped with a mini-lance to bubble hydrogen-based gas mixtures into the molten slag and a micro-gas chromatograph for the off-gas semi-continuous analyses. To evaluate the iron recovery efficiency after reduction, slag samples were subjected to both slow and quenching cooling routines and their chemistry and mineralogy were characterized.

The results of this study enabled the identification of experimental optimal working ranges, as well as the first experimental validation of our theoretical hypothesis. This knowledge will allow us to develop hydrogen-based metallurgical processes for slags, either to use them as alternative iron sources or to reduce the CO₂ emissions in EAF steel production.

Paper 1531 6 Thermochemical aspects of the substitution of natural gas by hydrogen in blister copper deoxidation during fire refining

Ph.D. Alberto Rivera Romero, Spain

Oral Presentation (20')

Abstract

High-purity copper, valued for its excellent conductivity, is essential for the energy and digital transitions. During blister copper deoxidation, the oxygen concentration in the melt is reduced to below 0.15 wt.% by bubbling, typically, natural gas (methane). This deoxidation process generates water vapor and carbon dioxide (CO₂) and has an average efficiency of 30 %. Replacing natural gas with hydrogen presents a promising strategy to lower CO₂ emissions and to increase the reduction efficiency in copper production. In addition to process parameter optimization, the design of more efficient refining strategies requires a deep understanding of the thermodynamics of Cu-O-S systems, including the presence of multiple minor impurities (As, Ni, Pb, Ag, Sb, etc...).

This study comparatively evaluates key thermodynamic aspects of the deoxidation process of Cu-S-O melts by methane and pure hydrogen by using the FactSage 8.3 software. The deoxidation dependence on temperature, oxygen, and sulfur contents, as well as minor impurity levels, are analyzed. In addition, given that industrial furnaces operate with a methane burner, the analysis incorporates a thermodynamic comparison of the methane-oxygen and hydrogen-oxygen flame products and their interactions with the liquid copper surface.

The results indicate that, regarding gas bubbling into liquid copper, since methane requires to run first through an endothermic decomposition before reacting with dissolved oxygen, hydrogen exhibits a better deoxidation performance over a broader range of gas temperatures compared to methane. Additionally, the nature and content of impurities are identified as key parameters governing the efficiency of copper deoxidation through the oxygen activity in liquid copper and the final solid microstructure. In respect of burner operation, the oxygen-to-fuel ratio is identified as the primary factor influencing both the atmosphere temperature and the fraction of reductant species. A comparative analysis reveals a higher fraction of reductant species in oxygen-methane adiabatic flames with respect to oxygen-hydrogen flames, and a more reductant behavior on liquid surface.

The results of this study enhance our understanding of molten metals refining based on 100 % hydrogen bubbling and combustion, which will aid the development of more sustainable and efficient metallurgical processes.

Paper 1509 1 Sustainable production of iron and steel via electric steelmaking routes for mitigation of CO₂ emissions

Prof. Joohyun Park, South Korea

Highlight (Oral Presentation 20')

Abstract

It is known that 7-8% emissions of CO₂ arise from the steel industry sector. Hence, many steel companies are trying to develop the electric arc furnace (EAF) and/or electric smelting furnace (ESF) processes instead of blast furnace (BF) – basic oxygen furnace (BOF) integrated routes by employing high amounts of direct-reduced iron (DRI) and/or hot-briquetted iron (HBI) to reduce CO₂ emissions. The DRI/HBI as substitutes for virgin scrap in EAF has been used because DRI/HBI does not have tramp elements. Unfortunately, however, commercially available DRI contains relatively high levels of phosphorus and gangue oxides, which adversely affects not only the steel properties but also the operation efficiency. Alternatively, integrated steel mills have focused on the ESF process by keeping conventional BOF to produce high-end quality products. The H₂-reduced DRI are potentially charged in ESF in conjunction with fluxes and carbon sources, producing hot metal. In the present lecture, the challenging points should be carefully considered to achieve the improved and stable EAF or ESF technology on the way to green steel will be reviewed, and the recent experimental and modeling research will be discussed. The slag chemistry is one of key parameters affecting the operation efficiency in electric steelmaking processes in view of FeO reduction behavior.

Scope 3 emissions in secondary steelmaking: relevance and impact on CFP

Mr. Luca Testini, Italy

Oral Presentation (20')

Abstract

As international regulations and stakeholder expectations tighten, transparency and accuracy have become increasingly important for GHG assessment and reporting. Nevertheless, steelmaking companies struggle to incorporate Scope 3 emissions, caused by the industry value chain, in their reports due to the complexity of the supply chain and the lack of incentives or regulatory requirements pushing for more transparent reporting.

In particular, stainless-steel production is heavily impacted by Scope 3 emissions due to its high content of alloying elements (e.g. Cr, Ni and Mo), which leads to intense ferroalloy and raw materials consumption.

In this work a product carbon footprint (CFP) study for stainless-steel production via Electric Arc Furnace (EAF) was performed, incorporating both direct and indirect emissions along the value chain, adopting a cradle-to-gate boundary. Primary data for raw materials and energy consumption were gathered at facility level, while secondary data from ecoinvent 3.10 were used to characterize upstream processes such as raw materials extraction.

The steelworks under investigation featured three main areas—steel shop, forging line and rolling line. The steel shop direct CO₂ emissions were calculated via mass balance, considering carbon content in cast steel, raw materials, electrodes, EAF dust and EAF slag. Electric energy and methane consumption were directly measured for EAF and LF while other contributions were allocated based on the manufactured steel mass. Forging line and rolling line were subdivided into divisions, zones, and working centres. Emissions were allocated linking data on electricity and methane consumption to specific products through a combination of mass, processing time, and temperature-based allocation factors. Additional indirect emissions from transport, waste disposal and other auxiliary operations were evenly distributed across the product portfolio.

The results show that emissions distribution is heavily influenced by the product steel grade (i.e. chemical composition) as this parameter is the main driver for raw materials consumption (i.e. ferroalloys). In fact, Scope 3 emissions are always higher than 60% of total emissions for every analysed steel category (i.e. austenitic, ferritic, martensitic and duplex steel); in particular Ni, Cr and Mo are the most impactful elements. Finally, Scope 1 and Scope 2 emissions are driven by CH₄ and electricity consumption, which are both dependent on the steel grade (e.g. thermal treatments) and on the product format (i.e. product diameter and section). For example, an austenitic bar with diameter ranging from 110 to 160 mm features a CFP difference equal to 11.5% mainly due to the different diameter.

Heating and melting behavior of hot briquetted iron (HBI) under isothermal conditions for sustainable electric steelmaking

Mr. Minjoo Lee, South Korea

Oral Presentation (20')

Abstract

In the carbon-neutral era, the scarcity of high-quality scrap for electric arc furnace (EAF) steelmaking has led to an increased focus on direct reduced iron (DRI) and hot briquetted iron (HBI) as sustainable alternatives. While EAF processes traditionally rely on scrap, a transition to DRI/HBI-based operations introduces challenges due to difference in heating and melting behaviors of DRI/HBI. The current study investigates the melting behavior of industrial HBI under isothermal heating conditions to optimize its use in sustainable steel production.

Three types of industrial HBI – standard (ST), high-SiO₂ (HS), and high-carbon (HC) – were characterized at 1250oC, 1300oC, and 1350oC using a vertical furnace to investigate the effects of gangue oxide and carbon content in HBI on heating and melting behavior. The cross-sections of the HBI samples were examined using SEM-EDS.

The experimental results showed that gangue composition and intrinsic carbon content significantly influence melting behavior. ST-HBI forms CaO-SiO₂-based slag at 1300oC, whereas HS-HBI forms FeO-SiO₂-based slag at 1250oC. The presence of SiO₂ influences slag separation during heating and melting. However, MgO gangue oxide remained in all samples, indicating that MgO does not significantly influence melting behavior. In HC-HBI, the presence of Fe₃C accelerates melting, leading to the complete separation of liquid metal and slag at 1350oC. These findings highlight the need to optimize HBI composition for efficient melting and slag separation, thereby reducing energy consumption and improving melting efficiency in EAF process.

Effect of Tramp Elements on Hot Shortness in Steel Products

Mrs. Minseo Cho, South Korea

Oral Presentation (20')

Abstract

The introduction of the Carbon Border Adjustment Mechanism (CBAM) has significantly enhanced steel production via the Electric Arc Furnace (EAF) process, thereby improving the recycling rate of steel scrap. Steel scrap frequently contains tramp elements, such as copper (Cu) and tin (Sn), which conventional refining processes cannot eliminate, and which accumulate during the steel recycling process. Specifically, Cu exhibits greater oxidation resistance than iron (Fe), remaining unoxidized during heat treatment and hot-rolling processes, leading to its accumulation at the steel surface. When the concentration of Cu surpasses the solubility limit of the base steel matrix, it precipitates at the interface between the steel surface and the oxide scale, resulting in the formation of a Cu-rich liquid phase. During high-temperature processing, such as hot rolling, this copper-rich liquid phase penetrates along the grain boundaries of the steel, causing hot shortness, which significantly impairs the hot workability of the steel.

The phenomenon of Cu-induced hot shortness is influenced by several factors, including the chemical composition of the steel. Nickel (Ni), as a residual element, raises the melting point of the Cu-rich phase and enhances the solubility of Cu in the austenite steel matrix, facilitating the back-diffusion of Cu into the matrix. This phenomenon has been extensively studied to mitigate the Cu-rich liquid phase at the steel/scale interface. The critical Cu equivalent is regarded as a key parameter, quantifying the relative contributions of various elements to crack formation and indicating that surface cracks caused by the Cu-rich phase may arise when the value exceeds a defined critical upper limit. However, a definitive standard remains elusive due to the varying effects of each constituent element.

This study analyzed the chemical composition of steel produced in domestic EAF steelworks in Korea to assess the current levels of tramp elements. High-temperature oxidation experiments demonstrated the formation of the copper-rich liquid phase and its chemical composition, which aligns reasonably with thermodynamic calculation results. Further thermodynamic calculations were conducted to investigate the influence of tramp elements on the formation of the Cu-rich liquid phase during the high-temperature oxidation process. A novel Cu equivalent formula is proposed to evaluate hot shortness in steel products derived from the EAF process in Korea.

This study establishes that the experimental results can be theoretically reproduced through thermodynamic calculations, indicating that these calculations serve as a suitable tool for predicting the formation of the Cu-rich liquid phase and the consequent hot shortness.

Paper 1004 5 **Interplay of scrap introduced tramp elements and non-metallic inclusions in steels on wetting conditions and deformation behavior of inclusions**
Mr. Julian Cejka, Austria
Oral Presentation (20')

Abstract

Increasing steel scrap recycling rates is essential to achieve the ambitious climate targets set by the European Union. Low-quality scrap containing elevated levels of tramp elements such as copper, nickel, molybdenum, and tin, introduces these elements into the steel cycle. However, their complete separation in the melt by metallurgical processes is impossible. Due to various effects on steel properties, such as delayed phase transformation or hot-shortness, the tramp element content is restricted to low levels for many steel grades. Recent research therefore focuses on the development of more tramp element tolerant compositions. Furthermore, increased tramp element contents also lead to issue during processing of liquid steels, e.g., most dissolved elements lower the surface tension favoring the formation of non-metallic inclusions (NMIs).

During continuous casting, attachment of NMIs onto the submerged entry nozzle and resulting clogging may even lead to interruption of casting and, thus, increasing production costs. This behavior is favored by an agglomeration tendency of NMIs and a high wetting angle between steel and oxides. This is why one focus of this study is the wetting behavior of steel on various materials with chemical compositions matching those of refractories and NMIs. It is shown that most tramp elements decrease the wetting angle.

Since tramp elements affect phase transformations and can accumulate at NMIs, the influence on the surrounding steel matrix of NMIs is the second important point of this work. Thereby, the deformation behavior of NMIs in steels with and without tramp elements is evaluated using quenching and deformation dilatometry in combination with Scanning Electron Microscopy (SEM) to obtain the aspect ratio before and after deformation. While the influence of tramp elements on the deformation of hard NMIs was negligible, softer NMIs' deformation behavior was altered by the presence of certain tramp elements.

Paper 1836 6 **Effect of Surface and Thermal Reconditioning on the Re-Use Potential of Quenched and Tempered Martensitic Steel in a Circular Steel Economy**
Mr. Oguz Gulbay, Germany
Oral Presentation (20')

Abstract Sustainable engineering practices necessitate extending the lifespan of steel components, particularly in a circular steel economy, where re-use strategies can significantly reduce material consumption and carbon footprint. This study investigates the effect of surface (mechanical + electropolishing) and thermal reconditioning on the fatigue life extension of quenched and tempered martensitic steel subjected to cyclic loading.

To assess re-use potential, specimens are pre-loaded up to 75% of their fatigue life under controlled fatigue conditions. The damage state of these specimens is characterized using non-destructive testing (NDT), scanning electron microscopy (SEM), and plasma focused ion beam (PFIB) lamella extraction to analyze subsurface crack propagation and damage depth.

Following initial damage assessment, surface reconditioning (mechanical + electropolishing) and thermal reconditioning are performed to evaluate their impact on microstructural recovery, residual stress redistribution, and fatigue resistance. Additionally, the study examines the influence of frequency, geometry, and specimen size on fatigue performance to establish the most effective reconditioning strategies for steel component re-use.

The findings contribute to the development of a residual life assessment model for steel structures, providing insights into the reusability of pre-damaged components and advancing sustainable material utilization in engineering applications.

Abstract

EMMC is a community of stakeholders covering all types of materials models, computational methods and applications. Improved methods integration and digitalisation are of particular relevance to advancing and accelerating materials design in a way that takes multiple dimensions of properties, performance and circularity into account. To that end, EMMC has been facilitating workflow integration, data documentation and semantic interoperability. Multiple projects have been collaborating under the EMMC banner in the development of the EMMO ontology for applied sciences and manufacturing. EMMO provides a strong semantic framework for all the datasets generated by experimental, modelling and characterisation activities.

We give an overview of pertinent EMMO ontologies, including characterisation, manufacturing and their industrial applications. In more detail, we highlight the CoBRAIN project, demonstrating the impact of integrating computational and experimental data through semantic interoperability. It enables the development of intelligent tools that (a) propose novel materials from the class of high entropy alloy-based “hardmetals” for direct deposition by Thermal Spraying techniques, and (b) are capable to estimate their impact on the economy and the environment.

Development of new materials with high wear and good corrosion resistance is usually based on experimental trial-and-error and operational feedback. Combining data coming from modelling and experimental approaches provides an advancement but is limited by the fact that the final coating properties depend on too many materials and process factors. Hence obtaining reliable results from physical modelling as well as experimentation are in conflict with the response time and cost containment required for industrial innovation. Here, the application of modern AI techniques can speed up the innovation process when used as complementary tool to existing experimental, modelling and characterisation activities. It can also enhance decision systems integrating all aspects of the materials and production process, taking account of economic and environmental factors.

In order to facilitate such a system, all the CoBRAIN generated data are collected into a single end-point via a full conceptual model based on the EMMO ontology. Datasets from the various areas of expertise within the project have been integrated thanks to the interoperability provided by the EMMO framework and made available to the users through a triple store Knowledge Base. Besides dramatically improving the FAIR level of the project results, it facilitates the creation of meaningful and coherent dataset for AI training and verification.

Using Computer Vision and Microstructure Informatics to Characterize Dendrite Growth in Ni-base Single Crystal Superalloys

Prof. Gunther Eggeler, Germany

Oral Presentation (20')

Abstract

Microstructure informatics combines traditional quantitative metallography with computer vision, algorithmic geometry and data science. It uses automated procedures to retrieve statistically relevant information from micrographs. Its power is demonstrated in a case study which focusses on competitive dendrite growth during directional solidification of single crystal Ni-base superalloys (SXs). The method presented in this work relies on three basic components: (1) A deep learning object detection network for detecting dendrite core positions. (2) A 3D image reconstruction routine for tracing dendrite paths. (3) And an ontological database of relational geometric data, documenting relationships between individual dendrites. To develop this method one had to assess the performance of different deep learning classification architectures (AlexNet, GoogleNet and MobileNetV2) in combination with a subdetection network (YOLOv2). In parallel the network hyper parameters (anchor box sizes, confidence scores) needed to be optimized to achieve a detection better than 99%. And, most importantly, an ontological data base had to be designed.

Deep learning architectures were trained using manually annotated reference images. Detection performances were evaluated based on manually curated ground truth data. The best performing network consisted of the first 30 layers of a MobileNetV2 architecture combined with a YOLOv2 sub-detection network. Optimum results were obtained when combining this architecture with an anchor box size of 35 x 35 px using a confidence score (CS) of 0.4. A central element of the proposed procedure is a microstructure specific relational geometric ontology database (RGO) which provides a foundation for further quantitative evaluation. It represents a digital replica of all relevant morphological features of the 3D dendritic microstructure. A cylindrical SX bar with 12 mm diameter of the alloy CMSX4 was investigated. Optical wide field micrographs from 1 mm spaced cross sections were taken over a length of 76 mm. Each cross section contained close to 3000 dendrites. The method presented here allows to follow the growth paths of all dendrites in the test volume (16,631 objects). It moreover provides new quantitative insight into competitive growth with a focus on branching and extinction events and neighborhoods (156,735 relations). The method also provides specific results which account for crystal mosaicity, individual dendrite growth directions, competitive interactions between dendrites and groups of dendrites and interaction between dendrites and mould walls. The proposed methodology and especially the developed database scheme can be fully generalized. It can act as a foundation for digital infrastructures for microstructure characterization in the future.

Paper 25 2 **Artificial intelligence-enhanced atom probe microscopy: Local chemical ordering analysis**

Dr. Yue Li, Germany

Oral Presentation (20')

Abstract

In solids, chemical short-range order (CSRO) refers to the self-organisation of atoms of certain species occupying specific crystal sites. CSRO is increasingly being envisaged as a lever to tailor the mechanical and functional properties of materials. CSRO is typically characterized indirectly, using volume-averaged (e.g. X-ray/neutron scattering) or through projection microscopy techniques that fail to capture the complex, 3D atomistic architectures. Quantitative assessment of CSRO and concrete structure-property relationships have remained so far unachievable. Herein, we showcase how machine learning-enhanced atom probe tomography (APT) can mine the near-atomically resolved APT data and jointly exploit the technique's high elemental sensitivity to provide a 3D quantitative analysis of CSRO in a series of metallic materials, including Fe-Al, Fe-Ga, and CoCrNi medium-entropy alloys. We reveal multiple CSRO configurations, with their formation supported by state-of-the-art Monte-Carlo simulations. Quantitative analysis of these CSROs allows us to establish relationships between processing parameters and physical properties. The proposed strategy can be generally employed to investigate short/medium/long-range ordering phenomena in a vast array of materials and help design future high-performance materials.

AI-Driven Multimodal Analysis of Microstructure and Phase Composition in a 3rd Generation Medium Mn Steel Using 4D STEM and X-ray Diffraction

Dr. Seyedeh Leila Panahi, Spain

Oral Presentation (20')

Abstract

The complex microstructural characterization of Advanced High-Strength Steels (AHSS) demands innovative analytical approaches to fully understand their multiphase nature. We present a novel artificial intelligence framework for analyzing 4D Scanning Transmission Electron Microscopy (4D-STEM) data, where, in combination with the Automated Crystal Orientation Mapping (ACOM) procedure, enabling precise visualization of grain boundaries and texture variations. This development addresses a critical challenge in the automotive industry, where AHSS materials are increasingly utilized for lightweight, high-performance auto body components due to their exceptional combination of strength and ductility. The microstructure of AHSS, typically comprising phases such as austenite, ferrite and/or bainite, presents significant challenges for traditional characterization methods due to its complexity and fine-scale features.

In this study, we developed and implemented machine learning algorithms for the automated analysis of the microstructure and morphology of medium manganese steel (Mn1000), produced by Voestalpine. Our approach combines advanced data analysis from both X-ray diffraction (XRD) and 4D-STEM electron diffraction patterns. The AI-driven analysis pipeline integrates crystallographic information from both techniques, enabling rapid and detailed phase identification along with grain orientation and stress mapping. Additionally, Energy dispersive X-ray Spectroscopy (EDS) was employed to analyze the elemental composition across the depth of the bulk regions, providing complementary chemical information to validate our AI-based structural predictions.

These results demonstrate the power of combining advanced characterization techniques with artificial intelligence, providing not only valuable insights into the microstructure of medium manganese steels but also establishing a new model for automated materials characterization. This approach paves the way for improved manufacturing processes and enhanced performance in next-generation AHSS materials, while significantly reducing the time and expertise required for complex microstructural analysis

High-throughput analysis of loop dynamics in irradiated MPEAs using deep learning

Mr. Camilo Fernandes Salvador, France

Oral Presentation (20')

Abstract

With the modernization of in situ transmission electron microscopy (TEM) irradiation experiments [1], there is a latent need to establish high-throughput data segmentation of TEM micrographs. To address this necessity, we evaluate the performance of Mask-CNN [2] — a popular computer vision model that enables simultaneous object detection, classification, and pixel-level segmentation — to identify dislocation loops in TEM video frames.

The use of deep learning in materials science has grown in recent years. The work of Jacobs et al. [3] is a pioneer concerning the application of Mask R-CNN to identify defects in TEM images of irradiated BCC FeCrAl alloys. The authors showed that the model successfully categorizes $\langle 100 \rangle$ loops, $\langle 111 \rangle$ loops, and black dots. In 2024, T. Bilyk demonstrated that a similar strategy could convey insights into overlapping perfect, faulted, or on-edge loops in irradiated Multi-principal element alloys (MPEA) alloys [4].

In the present work, we focus on segmenting black dots in bright-field TEM images. Our model was trained on five annotated snapshots from a video with nearly 3600 unique features of the same class. Such video records an in situ ion irradiation experiment performed within the JANNuS Orsay facility [1] of austenitic stainless steel 316L with the following parameters: Fe⁺ irradiation at 2 MeV for 60 min at 550 °C; total flux of 10^{15} ions/cm². After training, the model helps interpret a second video concerning a similar experiment with the 16Cr-37Fe-13Mn-34Ni (at.%) MPEA alloy, with slightly different irradiation conditions.

The model performs well and segments images with a mean average precision (mAP) of around 80%. The digested data points to a rapid increase in dislocation loop density after 2 minutes, reaching values close to $8 \cdot 10^{14}$ 1/m², which is consistent with the expected behavior for this system. In conclusion, the proposed framework may help researchers extract critical data on the dislocation loop dynamics from in situ experiments, even in the case of low-magnification or low-resolution videos. The talk will also include the characterization of radiation defects formed in situ in high-purity FCC metals at low temperatures, providing insights into their energetics.

Microstructural characterization of stainless steels from distorted in-situ X-ray diffractograms by means of machine learning tools

Prof. Ernst Gamsjäger, Austria

Oral Presentation (20')

Abstract

The phase fractions and the dislocation densities during the heat treatment of stainless steels are determined by in-situ X-ray diffraction measurements. Due to comparatively fast cooling rates the diffractograms are frequently degenerated with a high signal to noise ratio. Asymmetric peaks caused by the slit system, peak broadening and peak overlapping further reduce the quality of the diffractograms. Then, these diffractograms are evaluated by using the Rietveld method including the fundamental parameter model with the Voigt profile, to estimate phase fractions and dislocation densities in martensite and austenite. Whereas classical least-squares optimizers frequently fail to find the peak positions, the Markov Chain Monte Carlo algorithm successfully overcomes the limitations of covariance matrix-based error estimation by providing robust uncertainty quantification. By means of L1 regularization methods the influence of the instrument on the diffractograms is deconvoluted. In addition, neural networks trained by synthetic diffractograms are used to calculate the initial values for the optimization problem. Thereby, the evolution of the microstructure during thermal processing can be elucidated from comparatively cost-effective X-ray measurements under industrial conditions.

Deep learning based strategies for noise reduction of synchrotron X-ray nano-tomography images of light alloys: investigation on experimental extensive dataset.

Mrs. Alba Pascual, Spain

Oral Presentation (20')

Abstract

This research aims to develop and optimize deep learning algorithms to enhance the temporal resolution of X-Ray nano-Tomography (nanoCT) at the ID16B beamline of the European Synchrotron Radiation Facility (ESRF). By incorporating advanced artificial intelligence techniques, this study seeks to enable rapid data acquisition while preserving the quality of the reconstructed images. These innovations are pivotal for reducing exposure times, thereby minimizing radiation-induced artifacts and extending the applicability of nano-CT to in situ experiments, where precise and reliable imaging is essential for the characterization of light alloys elaboration and processing.

The methodology employed in this study revolves around the adaptation and evaluation of the Noise2Inverse algorithm, an unsupervised deep learning technique developed by Hendriksen et al. (2020)¹ tailored for denoising X-Ray Computed Tomography (XCT) data.

Datasets were carefully selected to include aluminum alloys with varying compositional and microstructural complexities, allowing the exploration of the algorithm's performance limits. These extensive datasets consist in nano-CT acquisitions of the same samples under about 200 diverse experimental conditions, including variations in spatial resolution (from 25nm to 250nm), number of projections (from 100 to 2000) and exposure times (from 0.28ms/proj to 40ms/proj), being last one the only variable relevant for the denoising task. This diversity ensured a robust evaluation of the algorithm across a wide range of scenarios on real data.

The Noise2Inverse algorithm was systematically studied in different domains: projections, sinograms, and reconstructed images. Its architecture, specifically evaluated using U-Net and MSD-Net models, was assessed in multiple configurations, including 2D, 2.5D, and 3D implementations, to determine its effectiveness in preserving spatial fidelity across various data dimensions and domains.

Noise2Inverse treated volumes are compared with holotomography high quality volumes (long exposure time, high number of projections) to assess the quality of the results and to ensure the faithful representation of material features critical for advanced analysis. This work highlights the potential of deep learning techniques to significantly enhance nano-CT imaging by improving noise handling and facilitating faster data acquisition.

These advancements are critical for in situ experiments and broader multi-scale imaging applications in additive manufacturing and materials science. Future efforts will focus on integrating these algorithms into beamline operations for real-time use.

Advanced Correlation Analysis of Process-Microstructure-Property Relationships in LPBF AlSi10Mg: Beyond Traditional Metrics

Dr. Robin Kromer, France

Oral Presentation (20')

Abstract

Recent advances in Laser Powder Bed Fusion (LPBF) of AlSi10Mg have underscored the need for more comprehensive analyses that link processing parameters, microstructural features, and mechanical properties. In this study, we present an in-depth correlation analysis that clusters and quantifies interactions among key variables, including laser power, scan speed, porosity (Archimedes vs. XCT), sub-grain cell dimensions, and mechanical performance indicators such as ultimate tensile strength (UTS) and elongation at fracture.

Our results show that certain microstructural descriptors—particularly solidification cell size—are strongly correlated with mechanical response in near-dense parts (<0.5% porosity), suggesting that strength and ductility can be better predicted when both porosity metrics and cell structures are considered. Interestingly, the figure also reveals how large, irregular pores affect overall ductility more than finer round pores, reaffirming that defect morphology plays a major role in fracture initiation. Conversely, when samples remain below a critical porosity threshold, the effect of cell size can dominate, leading to both higher strength and a potential decrease in ductility.

Additionally, we confirm that laser energy density and hatch spacing do not act independently: certain parameter combinations drive either lack of fusion or keyhole porosity, which in turn governs overall mechanical performance. By visually clustering these parameters, it sheds new light on specific “safe zones” for optimal density and mechanical properties, beyond the simplified process windows typically reported.

In conclusion, our correlation-based approach identifies strategic pathways for parameter tuning to achieve targeted mechanical behavior. Future work will integrate these findings with advanced in situ monitoring and machine learning models to predict and control defect formation in real time, thereby pushing the envelope of performance in LPBF-manufactured AlSi10Mg.

D9_3 - Bayesian and Advanced Optimization for Materials

Chair: Romero, Ignacio

Paper 255 **1** **ACBICI: An Open-Source Python Library for Bayesian Calibration of Complex, Data-Scarce Models**

Dr. Christina Schenk, Spain

Highlight (Oral Presentation 20')

Abstract

Standard techniques for model calibration typically focus on minimizing the fitting error between model predictions and experimental data. While straightforward, this approach overlooks errors present in the available data and can lead to parameter estimations that are local error minimizers, heavily dependent on the given samples. This is especially problematic when data is scarce, and model testing is resource-intensive or expensive.

A powerful and well-established methodology that can overcome some of these limitations employs Bayesian inference to obtain probabilistic distributions for the model parameters while accounting for the scatter caused by experimental errors. These types of calibrations profit from preexisting knowledge about the parameter values -- whether from past experience or published data -- and can provide detailed information about the uncertainty of parameters. The latter can be exploited to ascertain the confidence of the calibration, for example, but also to guide experimental campaigns and optimize resource allocation.

In our group, we have developed a framework for the calibration of complex, data-scarce models based on Bayesian inference approaches, called ACBICI, following the pioneering work of Kennedy and O'Hagan [1]. This open-source Python library can be used in a variety of applications since it is designed for ease of use, and employs Gaussian process surrogates to simplify the calibration of extremely costly models.

In this talk, we will introduce the ACBICI library, highlighting its capabilities and demonstrating its utility in practical applications. As a specific example, we will showcase its use in calibrating a complex model for creep in steel. Through this example, we will illustrate how ACBICI can provide valuable information to modelers and material scientists.

Optimal Discovery of multi-dimensional Pareto Sets in High Entropy Alloys

Prof. Raymundo Arroyave, United States

Oral Presentation (20')

Abstract

Recent advancements in materials discovery have shifted from traditional, labor-intensive methods to data-driven, informatics-based approaches. High-throughput (HTP) experimentation and computation dominate current efforts but are constrained by practical limitations such as resource availability and human decision-making bottlenecks. To address these, framing materials discovery as an optimal experimental design problem has emerged as a promising paradigm. In this talk, I will explore the application of Bayesian Optimization (BO) in the targeted exploration of the CoCrFeNiAl FCC high-entropy alloy space. This integrated framework identifies Pareto-optimal solutions across performance metrics, including strength, hardness, and strain rate sensitivity, while leveraging advanced cyber-physical workflows. By utilizing only 0.15% of this vast design space, our iterative synthesis-characterization-testing loops achieved unprecedented acceleration in discovering optimal alloy compositions. The results highlight the efficiency of Bayesian-guided discovery in navigating complex, multi-objective spaces and the insights gained into the underlying chemical and microstructural drivers of alloy performance. I will also discuss current challenges, the impact of these findings on alloy optimization processes, and future opportunities for integrating AI/ML-assisted simulations with experimental workflows. This approach represents a significant step toward autonomous materials design and scalable multi-objective materials optimization.

From accelerated creep tests to performance parameters: Efficient dataset generation, creep curve representation, and performance prediction using machine learning and numerical simulations

Dr. Dirk Helm, Germany

Oral Presentation (20')

Abstract

Creep is an industrially significant material behavior that describes the time-dependent deformation of materials under constant stress, particularly at elevated temperatures. Understanding creep performance is crucial for the design and longevity of components in high-temperature applications, such as in power plants or aerospace applications. However, standard creep tests are traditionally time-consuming and cumbersome, posing significant challenges in the conduction of tests and slowing down materials and component design processes. In contrast, accelerated creep tests provide faster results; however, these tests do not allow for direct identification of creep performance parameters as is the case with standard creep tests. To address this gap, machine learning models can be employed to predict creep performance parameters from accelerated creep test data. This contribution focuses on the fundamentals and key challenges of developing such machine learning models using data from numerical simulations. Critical issues to be addressed include defining a suitable parameter space, efficient dataset generation, and representing creep curves in a lower-dimensional feature space. From this, we will derive and present concepts for mapping accelerated creep test data to creep performance parameters and discuss their applicability to experimental data. Ultimately, our aim is to accurately predict creep performance parameters from accelerated creep test data, enabling a faster evaluation of the creep performance of metallic materials.

Efficient Steel Creep Behavior Prediction with Bayesian-Calibrated Models

Mr. Yufei Liu, Spain

Oral Presentation (20')

Abstract

Steel production accounts for 20-25% of industrial CO₂ emissions[1], significantly contributing to global carbon emissions. Accurate and efficient prediction of steel creep behavior is essential for improving material performance and supporting sustainability goals. However, traditional predictive approaches face major challenges, including the high cost of experiments, computationally intensive models, and uncertainties in material properties and operating conditions. Overcoming these challenges is critical for advancing material science and reducing the environmental impact of steel production.

To tackle these challenges, we present a Bayesian calibration framework, following the original ideas of Kennedy and O'Hagan[2], which leverages Gaussian processes for robust uncertainty quantification. This method enables precise estimation of model parameters, hyperparameters, and system discrepancies. Using our open-source Python library, ACBICI (A Configurable Bayesian Calibration and Inference package), we calibrate and predict steel creep behavior based on experimental data and synthetic data generated through complex finite element simulations using the research code Lagamine[3].

Our application of this methodology demonstrates its effectiveness in predicting steel creep behavior under uncertain conditions. The Bayesian calibration framework provides probability distributions of the physical creep model parameters and hyperparameters consistent with experimental data and simulations. Hence, quantifying underlying uncertainties. These results highlight the practical advantages of combining Bayesian methods with advanced computational tools for material modeling. Beyond creep modelling, this approach illustrates new avenues for dealing with calibration and uncertainties across a wide range of engineering and scientific domains.

Paper 1583 6 Bayesian Active Learning for Physics-Informed, Multi-Constraint, Multi-Objective Alloy Design: A Probabilistic Approach
Mr. Brent Vela, United States
Oral Presentation (20')

Abstract

Given the diverse performance criteria in materials development, alloy design is better approached as a simultaneous optimization and constraint satisfaction problem rather than a straightforward optimization task. In this work, we introduce a Bayesian closed-loop framework that concurrently identifies feasible alloys—those meeting all predefined performance constraints—and alloys that are Pareto-optimal across multiple properties. Unlike traditional optimization approaches, our method assigns probabilistic scores to candidate alloys based on their likelihood of satisfying constraints and achieving Pareto optimality. Moreover, Bayesian principles are employed to update low-fidelity prior models with limited high-fidelity data, thereby expediting the active learning process. We demonstrate the efficacy of this framework through a multi-constraint, multi-objective high entropy alloy design case study.

Paper 1381 1 Real or Fake? Evaluating synthetic Electron Microscopy Data in Materials Science
Dr. Daria Tomecka, Belgium
Highlight (Oral Presentation 20')

Abstract

The growing adoption of AI in materials characterization demands increasingly large, unbiased datasets, yet acquiring comprehensive steel microstructure data through electron microscopy remains resource-intensive and often leads to sampling biases. While generative AI offers a promising solution through synthetic data creation, validating these artificial microstructures raises fundamental questions about authenticity and scientific utility. Using the Ultra High Carbon Steel Database (UHCSDB) as our foundation, we investigate the effectiveness of current validation approaches for synthetic metallographic images. Our study critically examines standard AI-based metrics in both real and Fourier space, questioning their ability to guarantee preservation of physical properties. By comparing these computational assessments with expert metallurgists' evaluations, we explore whether conventional similarity metrics align with domain expertise in distinguishing real from synthetic microstructures. This comprehensive analysis aims to establish whether current validation methods can ensure physically meaningful synthetic data, addressing the fundamental question posed in our title: can we reliably determine if a metallographic image is real or fake, and what criteria should guide this determination?

Can AI Clean Up Your Characterization Data? Modern Approaches to Historical Dataset Curation

Mrs. Sepideh Khalatabad, Belgium

Oral Presentation (20')

Abstract

Materials characterization datasets, both historical and modern, often suffer from inconsistent documentation, varied formats, and unclear metadata. This presentation introduces a systematic AI-driven approach to transform such datasets into well-organized, standardized resources for materials research. Using self-supervised learning and specialized clustering algorithms, we demonstrate how modern machine learning techniques can extract meaningful patterns and relationships from poorly documented data while preserving physical validity. Our case study focuses on a historical metallurgical dataset, showcasing how contrastive learning methods, guided by materials science domain knowledge, can automatically organize microstructures. The developed framework establishes best practices for both retroactive dataset curation and future data collection, enabling more efficient knowledge extraction from materials characterization archives.

Understanding microstructure-property correlation of pearlitic steel by machine learning-based modeling

Mrs. Ruomeng Chen, Germany

Oral Presentation (20')

Abstract

Understanding and predicting the structure–property relationship is a cornerstone of materials science, particularly for designing advanced materials with tailored properties. The mechanical behaviors of pearlitic steel, widely used in demanding applications, are often dominated by the lamellae spacing, the colony shape and grain size [1, 2] while several other aspects concerning its microstructure-related properties have not yet been studied in detail.

In this study, a novel data-driven framework was proposed to predict localized hardness in 100Cr6 steel based on the integration of advanced imaging techniques, nanoindentation measurement and machine learning-based modeling. The workflow begins with the acquisition of high-resolution Scanning Electron Microscopy (SEM) images and Electron Backscatter Diffraction (EBSD) data to capture the morphology of ferrite crystallite lattices and cementite lamellae. Convolutional Neural Networks (CNNs) are employed for automated image segmentation, enabling precise identification and quantification of microstructural features such as lamellae spacing and colony morphology. These segmented features are then integrated with corresponding nanoindentation hardness data to train predictive machine learning models. The results demonstrate that the morphology of ferrite and cementite phases significantly impacts localized hardness at the nanoscale. The developed model provides quick, cost-effective predictions of hardness, validated by detailed experimental measurements, and reveals new insights into the relationship between pearlite microstructure and mechanical properties.

Machine Learning-Driven Prediction of Mechanical Properties in Resorbable Magnesium Alloys for Biomedical Applications

Dr. Vicky Nandal, Czech Republic

Oral Presentation (20')

Abstract

Magnesium alloy wires exhibit significant potential for biodegradable medical applications, particularly in bone support, where they serve as cerclage and fixation wires [1,2]. This study establishes a quantitative relationship between the composition, processing history, heat treatment conditions, and mechanical properties of magnesium-based fine wires (diameter < 500 μm) by leveraging different machine learning (ML) techniques. A dataset comprising approximately 100 samples compiled from literature sources was utilized to develop predictive models, including support vector regression (SVR), linear regression (LR), polynomial regression (PR), decision tree regression (DT), random forest (RF), and CatBoost regression. These models were employed to predict key mechanical properties, namely ultimate tensile strength (UTS), yield strength (YS), and elongation (EL), with high accuracy. Notably, the CatBoost model demonstrated superior predictive performance, achieving coefficients of determination (R^2) exceeding 0.92 for UTS and 0.98 for YS on the testing dataset. The evaluation of various statistical metrics, including R^2 , mean squared error (MSE), root mean squared error (RMSE), and mean absolute error (MAE), confirms the reliability and robustness of the proposed models in predicting the mechanical properties of resorbable magnesium alloy for biomedical applications.

Leveraging AI and Genetic Algorithms for Self-Healing Alloy Design

Mr. Diego Wackerling, Chile

Oral Presentation (20')

Abstract

The well-studied 9–12% Cr steels are an economical and highly versatile material choice, making them suitable for power generation and other demanding industrial applications. However, prolonged exposure to high temperatures inevitably leads to creep damage. In this context, self-healing (SH) mechanisms have emerged as a promising approach to enhancing the steel's resistance and extending its service life under extreme conditions. While precipitation-based SH processes have been primarily identified in binary and ternary alloys, their underlying mechanisms in multicomponent systems remain unclear. To address this challenge, we propose a design strategy that leverages data science tools and genetic algorithms to optimize and predict self-healing behaviour in complex alloy systems.

Building on this premise, our strategy begins with a novel data extraction workflow designed to automatically collect key attributes from scientific journal articles, including material properties, chemical composition, heat treatments, and reinforcement particle size. Given the complexity and variability of scientific literature, traditional data mining approaches often struggle to extract structured data effectively. To overcome this limitation, we employ a large language model (LLM)-driven workflow, which offers superior adaptability in text classification and structuring. Notably, models such as GEMINI-AI, GPT, and DeepSeek were employed without pretraining or fine-tuning for the selected characteristics. The resulting dataset, which comprises information from approximately 15,000 scientific articles on 9–12% Cr steels accessed via the ELSEVIER API, was structured with achieved an average precision of 85% and systematically organized within an SQL database.

Genetic algorithms were chosen for their effectiveness in exploring large, high-dimensional search spaces and optimizing multi-objective problems, making them particularly well-suited for designing complex alloy systems with self-healing capabilities. The structured database enables advanced data mining analyses to uncover patterns that drive the optimization of genetic algorithm parameters, individual genes, and go/no-go criteria. Additionally, an existing fitness function was chosen to optimize precipitation and solid solution reinforcements, contributing to the self-healing capability of the alloys.

Paper 598 2 **How to involve students – and citizens - in strategic developments in materials science: the case study of a “court for the future generations”**

Dr. Lola Liliensten, France

Oral Presentation (20')

Abstract

The “court for the future generations” is an original format of event developed by the French media “Usbek & Rica”. In a scenarized way, real witnesses, or experts, testifying in the interest of the future generations, are questioned by a “fake” court composed of an attorney, a prosecutor and the president of the court. The jury, ultimately ruling, is picked by a lottery system in the audience. Tens of such events have already been organized in France, to explore topics of concern for current and future generations. For its relevance to communicate with a large audience (civil society, students, professionals), and the possibility to address, in a short time and in a light and humoristic manner, many facets of the addressed question, this format has been selected to organize an event around the future of materials science for scientists, students and civil society (40%, 40% and 20% of an audience of about 350 people, respectively). The question selected was “should we keep inventing materials?”.

Indeed, orientations in materials development, as in many other scientific fields, have been mostly following decisions and fundings decided by governmental institutions, industries, and of course researchers. However, they obey not only scientific and financial principles, but also, among others, ethical and ecological ones. Recently, materials are at the forefront of ecological concerns: although increased recycling and circularity is called for, research seems to remain focused on overcoming its own limits by continuously inventing always-more-complex materials for specific applications, consuming more energy, away from circularity. Is this race for high-tech materials a requirement to build tomorrow's society, or should we now focus on sobriety? Should we keep inventing materials? To answer this questions, 4 witnesses from the industry (head of SafranTech), academia (Professor at UC Louvain), and specialists in the history of materials science (Emeritus professor) and in its future (SciFi writer), were invited. Many topics, including the motivations behind materials developments, future trends, and suggestions for increased democracy in strategic choices were covered. The debate was carried on by two PhD students in the role of the attorney and the prosecutor.

In this presentation, the context and the format “court for the future generations” will be presented, before to discuss this specific event: the witnesses, the court, the arguments, including all the preparation steps. At last, the practical organization will be rationalized, to end with the dissemination and the future steps of this project.

Paper 1161 4

Embedding Responsible Research and Innovation in a doctoral training programme

Dr. Ilija Rašović, United Kingdom

Oral Presentation (20')

Abstract

Here we present the integration of Responsible Research and Innovation (RRI) training into a UK-based Centre for Doctoral Training, addressing the growing need for research and researchers that anticipate and respond to societal challenges. Exposure to a wider knowledge base complementing their technical skills encourages early career researchers to engage with broader dimensions of their work, incorporating communication, sustainability, legal, ethical, and other issues around equality, diversity and inclusion.

We show that, from the student perspective, there is no strong need for any previous explicit exposure to theories of interdisciplinarity. As such, we posit that effective RRI training in this vein can be adapted and embedded successfully in other related programmes. Access to quality RRI training across the UK and internationally is variable, and so this work addresses this gap.

The course design emphasises active learning and critical engagement across disciplines, providing students with the means to navigate complex research landscapes responsibly. It puts student agency and authentic learning front and centre, both of crucial importance when looking to engender a sense of responsibility in strongly society-linked subjects such as materials science and engineering.

This emphasis on student agency and authentic learning is demonstrated in the assessment portfolio, particularly in the inclusion of an innovative student-led citizens' assembly. The experience equips students with skills unachievable in traditional doctoral education.

This engagement of doctoral students with RRI training is having a broader impact on research practices across the university, demonstrating first- and second-order effects both on researchers of the future and the institutions within which they work.

All claims above are evidenced by results gathered in a student survey and via semi-structured interviews with students and staff involved with the wider Centre for Doctoral Training.

How to connect materials education with cutting-edge product development on the university level by enriching classroom knowledge with extracurricular engineering projects

Prof. Dirk Reith, Germany

Oral Presentation (20')

Abstract

International student competitions enable engineering students to improve their technical expertise significantly and to gain a lot of hands-on practise. By tackling such complex real-world problems students gain quasi-work experience and get to apply the theoretical knowledge they acquired in university courses. This is very important in materials education, because the physical test of the products design and its materials properties will exhibit problems and solutions that can hardly be taught in regular course modules.

One example of such a competition is the Formula Student, which was already established some decades ago. Participating teams design, construct, and fabricate single-seater formula-style race cars. They compete against teams from other universities around the world at international events. Aside from competing on the racetrack (dynamic disciplines), students also participate in so-called static disciplines that aim at evaluating the design process, their understanding of cost and manufacturing, and business skills. It is therefore a perfect interdisciplinary project to embed materials science into a high-performance product development.

In this contribution, we present a teaching approach that connects intracurricular and extracurricular elements to significantly enhance learning outcomes. We show how theoretical course knowledge can be augmented to reach the level of cutting-edge product development with the best choice of materials and manufacturing methods in a bottom-up student-driven learning environment. Key prerequisites to do so, such as the incorporation of companies, will be discussed as well as typical obstacles that occur in our teaching approach. Additionally, we use product examples to explain in detail which steps of the learning process are triggered and how (peer) docents can systematically guide student learners through it. These examples consist e.g. of 3D-printed weight-optimized and function-integrated uprights and gearbox parts that are subjected to high loads. In summary, we demonstrate how students can increase their materials skills significantly by taking part in extracurricular activities such as Formula Student and how this approach can be transferred to similar tasks in engineering education.

Paper 1556 6 **Bringing Cutting-Edge Research to the Lecture Room: Material Acceleration Platforms for Applied University Students**
Prof. Dorottya Kriechbaumer, Germany
Oral Presentation (20')

Abstract

This paper presents a practical example of how an introduction to Material Acceleration Platforms (MAPs) and other advanced, high-throughput, automated research tools can be effectively integrated into applied university education for master's students from diverse academic backgrounds. The concept will be demonstrated as a sub-module of a "Heterogeneous Catalysis" course, with a focus on the synthesis, characterization, and design of catalysts. The audience consists of an interdisciplinary group of students with backgrounds in chemical engineering, mechanical engineering, materials science, and computational modeling.

A detailed approach will be presented on how advanced materials research tools, such as MAPs and other automated solutions, are incorporated into a module traditionally focused on legacy lab tools. The goal is to combine both conventional methods and cutting-edge techniques within the same curriculum, ensuring that students are exposed to a broad spectrum of solutions, from foundational to advanced, providing a well-rounded education early in their academic careers. A proposed structure for a lecture series and laboratory practice will be outlined, allowing students to apply theoretical knowledge in real-world contexts and gain practical experience in accelerating catalyst synthesis, characterization, and design. These strategies are intended to foster interdisciplinary knowledge integration, preparing students for the multifaceted challenges of modern materials science and engineering.

Additionally, the presentation will introduce active teaching methods that align with the learning objectives, such as flipped classrooms, collaborative problem-solving sessions, and virtual lab simulations. Concrete example exercises and best practices will be shared, with a focus on engaging students and continuously monitoring their progress. Insights from the project "Time Efficiency: Implementing Flipped Learning to Activate Students" in the "Heterogeneous Catalysis" module will be presented.

The paper will also address the challenges and opportunities of integrating advanced tools into graduate education, particularly in an interdisciplinary context. Feedback from students participating in this interdisciplinary pilot program will be shared, along with suggestions for improvement and insights into how students from different academic fields engage with these methods. Practical recommendations for educators wishing to incorporate similar approaches into their courses will be provided, emphasizing the importance of adapting to the diverse learning needs of students from various disciplines.

Paper 1648 1 **Sherlock Holmes in the Laboratory: Material Properties to Solve a Mystery**

Mrs. Sandra Tarancón Román, Spain

Oral Presentation (20')

Abstract

In recent years, the gamification of laboratory practice has developed into a more dynamic approach using available technology. This method aims to make the educational process more appealing, motivating, and interactive by incorporating elements that break away from traditional teaching styles. Crucially, though, it never loses sight of the main objective: to apply the knowledge acquired in the classroom in a practical way.

One such application of gamification can be seen in a challenge presented to the students. The task is to uncover the identity of the most infamous assassin in Materials Land, a fictional world where every citizen is distinguished by a specific material. The students are given a clue, a piece of material discovered at the crime scene, known to belong to the murderer. From this clue, the students are required to extract as much information as possible about the material to identify it, which, in turn, leads them to unmask the villain.

The students, acting as Scotland Yard detectives, are tasked with solving the case. However, they are told that the key to uncovering the villain's identity lies in a tensile test, a laboratory procedure used to assess the strength of materials. To assist them in their investigation, they are granted access to the expertise of the world-renowned detective of Materials Land, Sherlock Holmes—Mike Ashby—who is equipped with an extensive database known as Granta-EduPack. This database allows the students to match the "criminal profile" of the material based on its specific properties, aiding them in identifying it.

Through analysing the test results, the students are able to identify the villain—the material—by comparing the data they collect to known profiles stored in the Granta-EduPack database. The success of the method lies in the fact that students apply their theoretical knowledge of materials science in a very practical context. Most students, by carefully examining their tensile test results and using the database to collate material characteristics, are able to successfully identify the material in question.

This approach encourages active student participation, making learning more interactive and enjoyable. As they engage with the challenge, students become more familiar with the use of laboratory equipment and develop a deeper understanding of how to analyse and interpret results. This method not only consolidates fundamental concepts of material properties but also does so in a way that is both fun and effective.

Innovative Learning in Materials Engineering: A Hands-on Approach to Material Design and Characterization

Dr. Jaime Orellana-Barrasa, Spain

Oral Presentation (20')

Abstract

This study presents a novel educational project for first-year Materials Engineering students, designed to enhance their understanding of material design and characterization through hands-on experience. Unlike traditional coursework, students were challenged to create a material from scratch, optimize its properties, and document the process scientifically.

The project included four key phases: (1) selecting and designing the material according to the desired properties, (2) synthesis and processing, (3) characterization using laboratory techniques, and (4) documentation in the format of a scientific journal submission. Additionally, the students presented their materials at a simulated investor fair, where they defended their innovations to the audience.

This experiential approach enhances critical thinking, teamwork, and problem-solving skills. Although this project-based learning process requires that both teachers and students assume a more active role and a greater shared commitment, evaluation of the coursework illustrated that students have indeed integrated the knowledge they already gained during the course in developing the project, showing improved understanding of the material-structure-property relationships. Feedback highlighted the value of bridging theory and practice, as well as the importance of communication in scientific and business contexts.

These results suggest that integrating project-based learning into early engineering education enhances technical and professional competencies, preparing students for research and industry challenges.

The Art of Overcoming: Challenge-Driven Learning

Dr. Marina Macias, Germany

Oral Presentation (20')

Abstract

An experimental concept for accelerated learning was subjected to a trial, adopting an interdisciplinary approach that integrates insights and methodologies from multiple domains to optimise the learning process. The block seminar, "High-Performance Materials for Fusion Technology," designed for engineering students, integrates insights from both engineering and physics through the combined expertise of a materials science researcher and a plasma physicist. Throughout the seminar, participants explore the challenges and innovations within fusion technology while gaining hands-on experience in problem solving, critical analysis, and effective communication. By employing an inverted classroom model, the program fuses intensive lectures with interactive workshops and project-based learning, fostering creative thinking and collaboration across disciplinary boundaries.

The curriculum emphasizes the synthesis of diverse perspectives to address the complex challenges inherent in fusion technology. Students explore the interplay between material performance and plasma interactions, engaging in case studies and hands-on exercises that illustrate real-world issues and innovative diagnostic techniques. A novel method is employed to activate creative thinking: students are first challenged to propose innovative solutions for new materials before being introduced to state-of-the-art approaches. This strategy has resulted in an enormous increase in the speed at which learning material is absorbed, stimulating deeper engagement and understanding. The seminar not only enhances technical knowledge but also develops essential professional skills, including teamwork, critical thinking, and effective communication. A key component of the course is the final project—a 20-minute PowerPoint presentation conducted in a professional setting that simulates collaborative work in committees and tech research communities. This format aims to further develop advanced presentation and discussion skills.

By bridging the gap between academic theory and industry needs, this seminar equips graduates with the versatile expertise necessary to drive technological innovation and meet the evolving demands of higher education and industry.

Innovative Teaching in Materials Science: Methods, Challenges, and Opportunities

Prof. Paloma Fernández Sánchez, Spain

Oral Presentation (20')

Abstract

Materials Science cannot be considered in isolation from its social context. Everything we use in daily life is made of “something,” and that “something” is, fundamentally, a material. As society evolves rapidly, so does the field of Materials Science, which plays a crucial role in technological advancements across multiple industries. Teaching and learning must adapt to these transformations, integrating the challenges and demands posed by an increasingly technology-driven world. However, traditional teaching methods often struggle to keep pace with the interdisciplinary and applied nature of the discipline.

This talk explores innovative approaches to modernizing Materials Science education, emphasizing active learning methodologies, digital tools, and industry collaboration. Problem-Based Learning (PBL) and flipped classroom strategies foster critical thinking and problem-solving skills by shifting the focus from passive knowledge reception to hands-on exploration of real-world material challenges. Additionally, virtual labs and simulation software enhance students' understanding of complex material behaviors, bridging the gap between theoretical concepts and practical applications. The integration of Artificial Intelligence and Big Data further transforms learning, enabling predictive modeling and computational material design—key competencies for the future of the field.

By aligning education with societal and industry needs, this approach better prepares students for their professional careers, ensuring they develop both technical expertise and essential problem-solving skills. Collaborations between academia and industry provide students with project-based experiences that enhance their adaptability and innovative mindset. Ultimately, modernizing the teaching of Materials Science ensures that graduates are not only proficient in fundamental principles but also equipped to thrive in an ever-changing technological landscape.

Transforming students into scholars: the approach of the Queen Mary Centre for Undergraduate Research

Dr. Giuseppe Viola, United Kingdom

Oral Presentation (20')

Abstract

Abstract

The present contribution traces the journey of the Queen Mary Centre for Undergraduate Research (QMCUR) and discusses the operational model and pedagogical strategies that are being used with the intention of transforming students into scholars. QMCUR was built by integrating well-established models of undergraduate research [1, 2] and addressing common challenges in promoting such initiatives [3, 4], by introducing innovative elements and tailored procedures to facilitate its foundation at Queen Mary. The centre's pedagogical framework combines co-creation and inquiry-driven approaches, through which students are integrated into research groups and expected to independently conduct hands-on research, contributing to knowledge creation and dissemination under structured mentorship programs with their respective hosts. The pedagogical strategies employed are grounded in the principles of progressive education, democracy in learning, and methods that promote heutagogy, self-efficacy, and student emancipation. The success of this educational framework is evidenced by the numerous awards, prizes, research opportunities, and paid internships and placements secured by students as a direct result of their involvement at QMCUR.

The achievements of QMCUR students demonstrate how early involvement in co-creation activities and engagement in meaningful research strengthens academic skills, builds confidence, accelerates professional development, and significantly broadens future opportunities.

Developing Interdisciplinary Professional Engineering Skills at University

Dr. Faith Nightingale, United Kingdom

Oral Presentation (20')

Abstract

Engineers are required to have a number of hard and soft skills in order to be considered competent in their profession (Engineering Council, 2020). It is however widely reported that engineers lack soft skills which costs businesses money (The Institute of Engineering and Technology 2021; Winterbotham, et al. 2018). Therefore, it is a university's responsibility to ensure students develop the skills needed during their studies (Department of Education, 2017). However, there is a lack of consistency when teaching and developing soft skills which are usually taught sporadically and generically. This talk will show how professional engineering skills are taught at Queen Mary Engineering School (QMES), Xi'an, China using a project-based, interdisciplinary approach. The talk will demonstrate activities that take place in all years in the Professional Engineering Skills modules to develop the skills that student engineers require such as through the Materials Library project, escape room challenges and the Engineering Logbook. By developing these activities that support students throughout their time at university, students develop professional skills that will support future academic or career applications. From research conducted, students recognise their development of these skills and acknowledge the importance of them. By completing these activities, not only do students develop graduate attributes which aligns with the aims of QMUL and TEF (Department of Education, 2017), but they also learn through engineering themed projects which enables them to see the interdisciplinary relationship between engineering and soft skills. Developing activities that contain real-world engineering problems helps students see the relatability of professional skills in the workplace. Additionally, soft skills align with AHEP objectives for accreditation of a programme which has been achieved in QMES through these professional skills modules. The aim of this talk is to show that supporting students to develop soft skills at university is not only worthwhile for the students but also supports inclusivity. These activities can be developed and embedded into any programme using a project-based pedagogic approach. It is beneficial for a university to also develop interdisciplinary education and skills modules to aid in accreditation and diversifying the curriculum.

Paper 1742 1 Integrating Materials AI: A New Scientific Process for the Lab-of-the-Future

Dr. Christoph Kreisbeck, Germany

Highlight (Oral Presentation 20')

Abstract

AI and digitalization are about to fundamentally disrupt chemistry and materials science, with the opportunity to accelerate innovation by up to 10 times. However, technology alone will not be enough. To realize AI's full impact, we need to integrate AI into everyday lab processes.

As a spin-off from the Karlsruhe Institute of Technology (KIT), we are advancing the adoption of AI in chemical research through our R&D management and AI platform. This platform empowers chemists to use AI without specialized data science or coding expertise—similar to Apps on an iPhone.

In this presentation, we demonstrate our adaptive optimization for the fabrication of Metal-Organic Frameworks (MOFs), a versatile materials class relevant for many applications, such as gas separation or storage, sensors, photodetectors, and catalysts. Using AI-powered closed-loop optimization, we precisely control film properties such as orientation and surface roughness, surpassing traditional methods like OFAT and expert-driven trial-and-error.

Key technologies that we bring from development to commercially ready, plug-and-play software tools include:

1. Automated data extraction and machine learning for optimal synthesis predictions.
2. Adaptive experimental planning for autonomous optimization.
3. Large language models to streamline data management and accelerate knowledge extraction.

Our platform, EDISON-4.0™, bridges the gap between AI innovation and practical lab application, fostering the widespread adoption of AI in materials research. With self-learning AI and adaptive optimization, labs can accelerate material development and boost productivity by up to 10 times.

OpenSemanticLab: Accelerating Materials Innovation through Semantic Integration and AI Workflows

Dr. Simon Stier, Germany

Oral Presentation (20')

Abstract

Materials research is inherently complex, involving intricate relationships between material properties, compositions, and processing methods. To expedite the journey from laboratory breakthroughs to market-ready solutions, there is a pressing need for integrated platforms that harness the power of materials informatics. We introduce OpenSemanticLab, an open-source platform designed to accelerate materials research by integrating semantic web technologies, linked-data schemas, and artificial intelligence (AI) workflows.

OpenSemanticLab serves as a comprehensive knowledge platform where shared resources are efficiently managed. Object-oriented linked-data schemas (OO-LD) are embedded to harmonize data across various domains, including Lab-Inventory Management Systems (LIMS) and Electronic Lab-Notebooks (ELN). This integration ensures that both unstructured and structured data are accessible and interoperable, fostering better collaboration among researchers and streamlining R&D processes. A standout feature of OpenSemanticLab is its incorporation of Large Language Models (LLMs) and deterministic agents orchestrated by AI workflows. By delegating time-consuming tasks—such as data entry, form completion, and data analysis—to AI agents, researchers can significantly reduce the time and effort required for routine activities. The platform employs retrieval-augmented-generation (RAG) using phrased Resource Description Framework (RDF) graphs and document embeddings to enhance data retrieval and analysis capabilities. In addition, a chat-based automatic tool selector allows users to find the forms they are looking for, access key information and speed up data analysis without the need for advanced programming skills. Through this AI-assisted approach, OpenSemanticLab allows scientists to produce and structure large amounts of validated and AI-accessible data.

In this regard the interoperable description of material properties is a key element in both material research and material related value chains, particular in the form of product passports. For example, various initiatives like BatteryPass and Catena-X have drafted machine readable schemas for battery characteristics. Despite modelling the same asset based on the same regulation different initiatives came to diverging results.

In addition we face various ontologies just for physical quantities and units while those for material properties and characteristics are still emerging (e.g. EMMO, PMDco, IOTMaterials). We therefor picked up the path and extend those initial collections to a growing catalog of interoperable data characteristics in order to ensure both FAIR research and compliance with industry requirements.

In this presentation, we will introduce the high-level architecture of OpenSemanticLab and illustrate how semantic technologies and AI workflows are seamlessly integrated to create a platform for linked-data. We will delve into case studies that demonstrate the platform's impact on research efficiency and collaboration.

Paper	1752	4	Transforming R&D Efficiency: The Role of Dataspace Management in Material Development Mr. Yoav Nahshon, Germany Oral Presentation (20')

Abstract	In the manufacturing industry, development cycles within R&D departments play a crucial role in the incremental improvement of products. However, these cycles are often lengthy and resource-intensive, hindering innovation and responsiveness to market demands. This contribution introduces the Dataspace Management System (DSMS), a comprehensive technology stack designed to power dataspaces and digital ecosystems, which addresses these challenges by improving the way materials and process data are handled. By connecting and harmonizing disparate data sources, DSMS facilitates a semantic-based overview of materials and process data as well as data-processing workflows, significantly enhancing development efficiency. Additionally, it allows for the seamless integration and management of custom applications for data analysis and post-processing. Through its user-friendly interface, DSMS simplifies the use of semantic technologies, making it accessible to various stakeholders along the development cycle (technicians, engineers, data scientists, R&D managers, ...), thereby facilitating collaboration among them. We demonstrate the applicability of the DSMS in case studies of materials engineering and manufacturing. Our findings illustrate how DSMS not only accelerates product development cycles but also enables a more agile and data-driven approach to materials innovation.

AI Explainability by Transparency for Surrogate Computation, Inference and Data Exploration in Material Informatics

Dr. Rodrigo Iza Teran, Germany

Oral Presentation (20')

Abstract

The use of data-based methods for predicting effective material properties and material design has been intensified recently with the availability of efficient approaches like Deep Learning. Even more the application of Large Language Models in many areas is transforming the way engineering tasks are performed. The development of this approaches is very dynamic, and it is advancing as we speak, nevertheless for effective use in material science and in general in engineering, there are a few challenges that must be addressed and overcome.

In this work we present a research framework that address those challenges. Starting with the development of a transparent method for surrogate modelling that, in contrast with deep learning, is not as data intensive. The methodology is transparent in the sense that computed features for learning are based on mathematical principles. This is coupled with the use of Large Language Models for the efficient surrogate evaluation, data exploration and documentation that is merely used as a convenient interface to specific predefined data analysis functionality, aiming at avoiding hallucinations, that interacts with the user.

The framework uses a graph database to have full flexibility for learning and adapting. It can also be used to represent, if available, specific ontologies. A python-based backend is implemented as well as a convenient React and python-based frontend. Applications of the framework are demonstrated for the computation of surrogate models in predictive effective material properties from given two-point microstructure statistics as well as for computing a surrogate for forming simulations by given input process parameters. For interfacing with the data analysis results, an open-source Large Language Model is implemented and demonstrated.

Keynote (Oral Presentation 40')

Abstract

The influence of hydrogen on the deformation behavior of structural materials is still a controversial topic largely due to the limited understanding of the role of hydrogen-induced effects on the collective behavior of plasticity. In austenitic steels, the influence of hydrogen on plasticity has been mainly associated with slip localization. This effect has been ascribed to the locking of dislocations by hydrogen atmospheres and the hydrogen-induced reduction of dislocation cross-slip. According to these processes, hydrogen tends to localize the emitted dislocations into a narrow slip band formed by unrelaxed pileups that, at interacting with GBs, result in the initiation of a microcrack via void nucleation at GBs (hydrogen embrittlement, HE). However, these hydrogen-related phenomena do not explain the small influence of hydrogen on the fracture behavior of austenitic steels (316L and 310S) and austenitic FeMnAlC low-density steels. In this presentation, we present unrevealed hydrogen-induced effects on plasticity that evidence the complex influence of hydrogen on the collective behavior of dislocation plasticity and their impact on strain-hardening in austenitic steels. The quantitative analysis of the hydrogen-related deformation structure by several electron microscopy techniques, such as electron channeling contrast imaging (ECCI), electron backscatter diffraction (EBSD), and scanning transmission electron microscopy (STEM), reveals novel dislocation-based processes associated with hydrogen-induced strain localization phenomena. These processes have a significant influence on the deformation and strain-hardening behaviors of the steels. Two cases will be presented. On the one hand, we will show experimental evidence of the hydrogen-induced promotion of dislocation structures associated with inhomogeneous plasticity (deformation bands) and strain localization (microbands) in an austenitic Fe30Mn6.5Al0.3C low-density steel with a solute hydrogen content of 101 mass ppm [1]. These hydrogen-induced mechanisms contribute to plastic accommodation by accommodating local lattice rotation gradients and relaxing the elastic field associated with dislocations, favoring the excellent HE resistance exhibited by the steel. On the other hand, we will show experimental evidence of hydrogen-induced effects on the GB-assisted nucleation of dislocations in an austenitic 310S stainless steel with a solute hydrogen content of 131 mass ppm. These processes modify the dislocation structure of slip bands, favoring slip localization. Upon straining, the propagation of hydrogen-induced coarse slip bands results in the localized shear of the primary dislocation structure. The grain orientation dependence of this process is evaluated, and its contribution to the deformation behavior is discussed.

Fracture Toughness of Hybrid Laser-MAG and MAG Welded API 5L X65 Steel in air and hydrogen: Influence of Nano-Chemistry Change

Dr. Mahdiah Safyari, Finland

Oral Presentation (20')

Abstract

This study examines the microstructural and mechanical properties of ferritic steel specimens welded using the metal active gas (MAG) and hybrid laser-MAG welding (HLAW) processes, focusing on their behavior in both air and hydrogen environments. Using atom probe tomography, we conduct a detailed atomic-scale analysis to investigate element distribution and oxide inclusion composition. The results show distinct nano chemistry differences, with HLAW specimens exhibiting layered oxide structures and Mn depletion zones around the inclusions that lead to the formation of the higher densities of acicular ferrite and high-angle grain boundaries (HAGBs). These microstructural features are linked to mechanical properties assessed using single edge notch tension testing. The results show that the higher density of HAGBs in HLAW enhances fracture toughness in air and resistance to hydrogen embrittlement. In contrast, the MAG specimens which show more uniform elemental distribution in oxide inclusions and lower HAGB density adopt a lower fracture toughness in air and high hydrogen embrittlement sensitivity. This study concludes that the HLAW process is better suited for applications like pipeline welding, where high strength, resistance to hydrogen-induced damage, higher speed, and lower cost are essential.

Boron segregation informed HE mitigation strategy in a two-phase lightweight steel

Dr. Xizhen Dong, Germany

Highlight (Oral Presentation 20')

Abstract

In response to stringent regulations and challenges regarding weight reduction for fuel economy as well as the enhancement of crashworthiness performance for passenger safety in vehicles, advanced Fe-Mn-Al-C lightweight steels with specific high strength have garnered significant attention in recent decades. However, these alloys are prone to hydrogen embrittlement (HE) which hinders their application. The understanding of the operating mechanisms of HE and the development of effective strategies to mitigate HE are inevitably important. Here we studied the HE mechanisms and the effect of boron-doping on hydrogen-tolerant capability in lightweight steels featuring an austenite plus ferrite two-phase microstructure. We found the embrittlement in these alloys is driven by hydrogen-induced intergranular cracking along austenite-ferrite phase boundaries and hydrogen-induced transgranular cracking inside the ferrite phase. The boron-doped material demonstrates an enhanced hydrogen-induced intergranular resistance albeit with a reduced resistance to hydrogen-induced cleavage cracking within the ferrite phase. These effects are further elucidated based on a detailed comparison of damage behavior, the segregation of boron via atom probe tomography and the ab initio calculations. Those findings shed light on boundary conditions of different HE mechanisms in multiphase alloys as well as the effective mitigation strategies for HE.

Hydrogen-defect interaction in nanostructured iron samples

Dr. Marlene Kapp, Austria

Oral Presentation (20')

Abstract

Understanding hydrogen embrittlement has been in the focus of metal research for many decades. Since the embrittling effect of hydrogen is most pronounced for high-strength grades (i.e., small structural sizes or multi-phase structures), the small (submicron) microstructural dimensions and their chemical and structural complexity (i.e., multiphase steels) makes a direct determination of the trapping sites and associated effects on the defect behavior challenging. This knowledge would however, be essential to understand failure mechanisms and derive effective design guidelines for hydrogen resistant materials. To reduce the chemical and microstructural complexity we therefore focus on hydrogen-defect interactions in nanostructured pure iron. This simple model material contains only grain boundaries and dislocations, but perfectly allows to reproduce the mechanical behavior of (nano) bainitic, pearlitic or martensitic steels. Deforming hydrogen charged nanostructured iron specimens thus allows for conclusions of a wide range of structural materials.

We will show by cyclic high-pressure torsion of pre-charged samples that hydrogen is homogeneously distributed in the specimen and does not favor strain localization nor enhances plasticity during cyclic loading. In fact, hydrogen seems to be located at grain boundaries and effectively pins them, stabilizing the nanostructure. For monotonic loading quite the opposite is observed. Deformation in the hydrogen charged samples becomes inhomogeneous and outstanding hardness (up to 11 GPa) and grain refinement (sub-10 nm grains) in these localized regions was observed. This implies that the effect of hydrogen on grain boundaries and dislocations depends not only on the material but also on the strain path applied.

Paper 1031 3

Simulation of hydrogen behavior at crystal defects in Fe-based alloys

Dr. Daria Smirnova, Germany

Oral Presentation (20')

Abstract

With atomistic simulations we consider hydrogen behavior in iron and its alloys (Fe-Cr, Fe-Ni). Simulations are based on a new interatomic potential developed by the authors [1]. Namely, we concentrate at cases of lattice distortions, such as crystal defects, alloying elements or deformation due to applied stresses. We characterize hydrogen segregation at typical defects: from vacancy to grain boundaries (GBs). Equilibrium distribution of H in the presence of crystal defects is discussed. A role of hydrogen in alternating vacancy diffusion is illustrated by results of finite-temperature diffusion simulations. We also report hydrogen diffusion coefficients at GBs, for fcc and bcc phases. The interplay of H with GBs depends on the phase structure. For fcc-Fe, GBs provide an accelerating path for hydrogen diffusion. As opposite, GBs in bcc-Fe may retard hydrogen mobility compared to bulk case. Calculated hydrogen concentration and diffusivity at GBs were used to interpret experiments on H permeation [2]. For bcc Fe we show that GBs of the considered type do not act as diffusion accelerating channels. Hence, we may assume that a picture of H permeation observed in situ came from a combination of fast H diffusion in bulk and strong segregation at GBs.

Hydrogen embrittlement of 316L stainless steel studied by synchrotron tomography.

Ph.D. Gianpaolo Pillon, France

Oral Presentation (20')

Abstract

Europe's decarbonization program aims to replace gas, petrol and coal with green energies such as green hydrogen, which is produced by renewable energy such as windmills. Green hydrogen needs to be transported and stored in pipelines or tanks. Hydrogen storage structures are often made from austenitic stainless steel, like 316L.

However, the materials used in this application may experience hydrogen embrittlement (HE). In storage or transport applications, gaseous hydrogen will diffuse into the bulk. Following the time exposure, different conditions can be observed: gaseous hydrogen is present as a gradient or is uniformly present inside the bulk.

The material used in this study is a sheet of 316L stainless steel sheet. To quantify HE phenomenon of this material, tensile tests are performed on sub-size tensile samples. Testing conditions are: (i) under air, (ii) under hydrogen gas at 240 bar and (iii) thermally H₂ precharged samples. Tests are conducted to fracture using strain rate of 10⁻⁴ s⁻¹ and 10⁻⁵ s⁻¹. Tests interrupted before fracture were also performed for subsequent nondestructive ex-situ synchrotron micro-tomography examination. In-situ tomography tests were carried out with thermally hydrogen precharged samples. Damage evolution is quantified through ex-situ and in-situ tomography measurements carried out at Soleil Synchrotron.

Each post-mortem sample is additionally analyzed by classical SEM fractography to quantify the ductile to brittle transition, but not only. Results witness a significant effect of hydrogen on 316L stainless steel: there is a significant decrease in ductility and a moderate reduction of ultimate tensile strength. Hydrogen-atmosphere tested samples exhibit flat surface cracks of 80 to 100 µm depth. There is a coalescence zone between the surface cracks which exhibits a mixture of brittle damage features, ductile dimples and ductile shear features that could originate from the HELP mechanism. In addition, there are aligned damage features surrounded by ductile dimples for a strain rate of 10⁻⁴ s⁻¹. Their sizes and spacing is consistent with the presence of delta ferrite revealed by metallography and EBSD. Moreover, the potential effect of martensitic transformation on hydrogen embrittlement is investigated. In addition, gage length observation reveals a significant amount of surface cracks. Fracture scenario seems to be the result of a competition between HE of the surface, internal ferrite-related cracks, martensite transformation and ductile shear damage. For a strain rate of 10⁻⁵ s⁻¹, deeper brittle surface cracks are seen. Ductile damage features are also present at the center of the sample.

Paper 1190 5 Hydrogen Distribution in FCC and BCC Alloys: Impact of Electrochemical Charging Conditions

Mr. Donát Horváth, Finland

Oral Presentation (20')

Abstract

Hydrogen charging into a material is typically achieved through either gaseous or electrochemical methods. Gaseous charging involves exposing the material to a high-pressure hydrogen gas environment at elevated temperatures, whereas electrochemical charging takes place in an electrolytic solution under either galvanostatic or potentiostatic conditions, usually at or near room temperature. Due to safety concerns associated with the use of pressurized hydrogen gas, electrochemical charging is sometimes employed as an alternative for hydrogen gas exposure when investigating hydrogen embrittlement susceptibility of a material. The severity of hydrogen embrittlement effects is highly dependent on the hydrogen charging conditions. Therefore, the optimization of the charging conditions is crucial for accurately assessing material behaviour. Thermal desorption spectroscopy (TDS) is a prevalent analytical method used in the study of hydrogen absorption behaviour and distribution in metals, which can lead to hydrogen embrittlement (HE). In our study, cathodic charging at different temperatures was conducted in sulfuric acid and neutral NaCl solutions using various steel samples with both face-centered cubic (FCC) and body-centered cubic (BCC) structures. The effect of the charging conditions on hydrogen uptake and distribution was studied via TDS, aiming to improve the accuracy and effectiveness of hydrogen charging, which is essential for assessing hydrogen embrittlement susceptibility in metallic materials.

Paper 125 **6** **Influence of hydrogen on the γ -matrix lattice parameters of a polycrystalline Ni-based superalloy – a synchrotron diffraction study**
Dr. Massimo Fritton-Fantini, Germany
Oral Presentation (20')

Abstract

To reduce reliance on fossil fuels and combat climate change, hydrogen has emerged as a versatile and sustainable alternative, offering a pathway to carbon neutrality. Its dual role as an energy carrier and industrial feedstock makes it an essential component in transitioning to cleaner energy systems while enabling decarbonization across sectors like transportation, power generation, and chemical production. However, hydrogen dissolved in alloys can drastically alter their deformation behavior, transitioning from ductile to brittle, a phenomenon known as hydrogen embrittlement (HE). Understanding this effect is critical, particularly, as hydrogen becomes increasingly important as a possible candidate for future mobility applications.

The objective of this study was to investigate the hydrogen uptake of Ni-based superalloy VDM® Alloy 780 through electrochemical charging via high-energy X-ray diffraction (HEXRD). The results demonstrate that hydrogen incorporation at interstitial sites of the fcc lattice causes a slight increase in lattice parameters compared to hydrogen-free samples. In-situ HEXRD measurements reveal that at elevated temperatures the lattice parameters of uncharged and charged specimens gradually converge. This suggests the reversibility of hydrogenation through diffusion and subsequent effusion of hydrogen. Hot gas extraction (HGE) measurements were conducted to quantify the hydrogen content, showing that prolonged electrochemical charging increases hydrogen uptake. Temperature-dependent quantification confirmed that hydrogen diffusion rates increase with temperature, as evidenced by higher measured hydrogen content at elevated temperatures.

To evaluate the mechanical impact of hydrogen, tensile tests were performed, supported by fractographic analysis via scanning electron microscopy (SEM). The hydrogen-charged specimens exhibited cleavage fractures near the surface, contrasting with the ductile fracture patterns observed throughout the entire reference sample. These findings provide valuable insights into the effects of hydrogen on superalloys, offering a foundation for further research on their performance in hydrogen-rich environments.

Tritium-based micro-fracture experiments for mechanistic understanding of hydrogen embrittlement

Presenting author email: johannes.reibenspies@kit.edu

Presentation in the symposium “B8 – Hydrogen embrittlement of structural materials”

Green hydrogen is considered a potential game changer in the transition to cleaner energy systems with lower CO₂ emissions. However, for safe storage and transportation of hydrogen, hydrogen embrittlement (HE) has remained a major concern. The ERC-funded project, TRITium based microMEchanics (TRITIME), aims to isolate, observe, and quantify the debated mechanisms responsible for HE, leveraging the unique properties of tritium.

In this talk, we will present the concept of using tritium (³H) charged single-crystal Fe-3wt-%Si samples for micro-fracture tests to elaborate the fracture behavior under the influence of hydrogen (tritium). The notched microcantilevers are prepared using a combination of a femto-second ablation laser and a focused ion beam, prior to the charging with a hydrogen-tritium gas mixture. The microcantilever fracture experiments are conducted inside an SEM using an in situ nanoindentation system. Post-deformation imaging of the hydrogen isotopes ¹H and ³H (tritium) across the relevant length scales is done applying various methods, including atom probe tomography (APT). This combination enables the quantitative correlation of the (fracture)-mechanical properties with the locally resolved hydrogen content. The results will be discussed in the framework of the Hydrogen Enhanced Decohesion (HEDE), Hydrogen Enhanced Localized Plasticity (HELP), and their interplay.

Hydrogen induced softening and deformation mechanisms in nanoparticle reinforced CoCrFeNi

Dr. Vivek Devulapalli, Switzerland

Oral Presentation (20')

Abstract

Hydrogen embrittlement poses a critical challenge for structural materials in energy infrastructure, particularly in emerging hydrogen-based technologies and storage systems, where material degradation can lead to catastrophic failures. This study investigates the influence of hydrogen charging on the mechanical behavior and deformation mechanisms of TiN and TiO₂ nanoparticle-reinforced CoCrFeNi medium entropy alloy (MEA) processed via laser powder bed fusion (LPBF). A characteristic LPBF microstructure consisting of alternating refined grain tracks and larger square grain pockets was obtained. Nanoindentation revealed that the as-processed composite exhibited minimal mechanical anisotropy, with hardness values of 3.55 ± 0.12 GPa in track regions and 3.51 ± 0.11 GPa in pocket regions, indicating homogeneous distribution of TiN reinforcement particles.

Electrolytic hydrogen charging was conducted under potentiostatic conditions (-1.2 V) for durations of 12 and 24 hours. Systematic nanoindentation mapping coupled with electron backscatter diffraction was performed on all the hydrogen charging conditions. Following 24-hour charging, thermal desorption spectroscopy detected 20 wt. ppm of hydrogen. The hydrogen-exposed surface showed a significant reduction in hardness to 3.05 ± 0.03 GPa, while the unexposed surface maintained 3.46 ± 0.19 GPa. High-resolution scanning transmission electron microscopy analysis combined with precession electron diffraction of subsurface deformation zones revealed distinct changes in deformation mechanisms. The uncharged state exhibited prevalent deformation twinning, whereas the hydrogen-charged condition displayed spatial heterogeneity in deformation features: well-defined subgrains with reduced dislocation content near the indent, and localized deformation twins in deeper regions.

These observations suggest a hydrogen-enhanced localized plasticity (HELP) mechanism, where hydrogen facilitates dislocation mobility and dynamic recovery processes. The spatial distribution of deformation features indicates complex interactions between competing mechanisms: enhanced dislocation mobility through HELP and increased propensity for twinning due to hydrogen-induced reduction in stacking fault energy. The presence of TiN nanoparticles appears to influence the distribution and evolution of these deformation mechanisms, potentially through their role as hydrogen trapping sites and stress concentrators. These findings provide new insights into hydrogen-microstructure interactions in nanoparticle-reinforced MEAs and demonstrate the potential of microstructural engineering for enhancing hydrogen embrittlement resistance in advanced structural materials.

Paper 1094 4

A comparative study of hydrogen trapping kinetics and embrittlement susceptibility of additively manufactured and wrought 316L austenitic stainless steel: influence of post-processing

Prof. Luis Borja Peral, Spain

Oral Presentation (20')

Abstract

Selective laser melting (SLM) is one of the common methods of additive manufacturing technology. SLM can be employed to customize mechanical components with complex geometry such as elbows and valves, which are expected to work in hydrogen atmospheres under high-pressure hydrogen gas. However, more studies are still needed to characterize the behavior of the printed mechanical components intended to work in contact with gaseous hydrogen. It is known that additively manufactured 316L boasts superior mechanical properties than those of conventional state. However, greater absorption of hydrogen can be induced in the SLMed 316L because of its higher density of dislocations, induced due to the rapid cooling rates during solidification. Accordingly, new production techniques, especially additive manufacturing, require re-evaluation of hydrogen susceptibility of austenitic stainless steels.

In this work, microstructural and mechanical behavior, in the presence of internal hydrogen, of the 316L wrought series and the as-built and post-heat-treated additively manufactured 316L samples, is studied.

Experimentally, thermal desorption analysis (TDA) and electrochemical hydrogen permeation (EP) experiments are both used to analyze hydrogen trapping and diffusion kinetics, in the different series. In this regard, the hydrogen concentration, the apparent hydrogen diffusion coefficient (D_{app}), the density of traps (NT) and hydrogen activation energies (E_a) attributed to the desorption of hydrogen from various microstructural singularities, are compared among the analyzed series. TDA analysis was carried out on hydrogen precharged samples at high temperature.

Besides, mechanical behavior is analyzed at room temperature by Slow Strain Rate Tests (SSRTs) on smooth tensile samples, precharged in a high-pressure hydrogen reactor at 195 and 300°C for 24h. Fracture mechanisms (HELP -Hydrogen Enhanced Localized Plasticity- and HEDE -Hydrogen Enhanced Decohesion-) and micromechanisms are deeply analyzed.

Hydrogen damage was especially noted in the 316L wrought series (i.e. hot-rolled and annealed grade), where fracture micromechanism changed from ductile in the absence of hydrogen to quasi-brittle in the presence of internal hydrogen. In this case, the presence of HELP (Hydrogen Enhanced Localized Plasticity) mechanism was also confirmed. On the other hand, HE resistance enhanced in the printed samples, especially in the post-heat-treated SLM 316L series, where the fracture micromechanism was ductile.

To explain the impact of the internal hydrogen on the mechanical properties of the studied series, the role of the strain-induced martensite, dislocation glide, deformation twinning, and cellular structures is discussed.

States of hydrogen and hydrogen embrittlement susceptibility of flake and spheroidal graphite cast irons

Mr. Ryo Umehara, Japan

Oral Presentation (20')

Abstract

It is essential to investigate the safety of cast iron used in hydrogen environments to apply cast iron to hydrogen-fueled internal combustion engines. However, there has been little research on hydrogen embrittlement of cast iron. The present study attempts to clarify factors causing hydrogen embrittlement based on the relationship between states of hydrogen present in cast iron and hydrogen embrittlement susceptibility. Flake graphite cast iron (FC) and spheroidal graphite cast iron (FCD) were employed. Specimens were electrochemically charged with hydrogen in a 0.1 N NaOH solution at a temperature of 30 °C at a current density of 30 A·m⁻². Charging times were 96 h and 192 h for FC and FCD, respectively. States of hydrogen were analyzed using thermal desorption analysis (TDA). The activation energy for hydrogen desorption (E_a) was calculated from the dependence of peak temperatures of hydrogen desorption on heating rates for TDA. Specimens with the parallel part were used in tensile testing. A crosshead speed of 0.01 mm·min⁻¹ with/without hydrogen charging was employed. TDA results showed that FC and FCD specimens had two and three peak temperatures of hydrogen desorption, respectively, which are labeled as Peak 1H, 2H, and 3H in order from the lower temperature. The E_a value of Peak 1H was calculated to be 28 kJ·mol⁻¹ for both FC and FCD specimens. The E_a value of Peak 2H was calculated to be 76 kJ·mol⁻¹ for both specimens. The E_a value of Peak 3H was calculated to be 103 kJ·mol⁻¹ only for FCD specimen. Based on the E_a values, Peak 1H presumably desorbs from dislocations, whereas Peak 2H presumably desorbs from interfaces and/or voids between graphite and matrix in addition to casting defects for FC and FCD specimens. Peak 3H only for FCD specimens probably desorbs from graphite. The results of tensile testing showed elongations of hydrogen-charged FC and FCD specimens decreased compared with those of non-charged specimens. However, the elongations of FC specimen only with Peak 2H and FCD specimen only with Peak 2H and 3H were the same as those of non-charged specimens. These findings indicated that Peak 1H, i.e. hydrogen present at dislocations directly causes embrittlement, while Peak 2H and 3H, i.e. hydrogen present on the interfaces between graphite and matrix, in casting defects, and in graphite are not related to hydrogen embrittlement at a room temperature.

Paper 750 6 **Tensile Properties of X70 Pipeline Steel Under In-Situ Electrochemical Hydrogen Charging**
Ph.D. Siddharth Suman, Finland
Oral Presentation (20')

Abstract This study investigates the influence of hydrogen embrittlement susceptibility of X70 pipeline steel through uniaxial tensile testing under electrochemical hydrogen charging. Specimens were strained at $1.25 \times 10^{-5} \text{ s}^{-1}$ and electrochemically charged with hydrogen in 0.1 mol/L NaCl containing 1 g/L Thiourea. Hydrogen absorption induced severe loss in ductility. Effects of stress concentrations as well as pre-strain are also investigated. Fractographic analysis revealed a transition from ductile dimple rupture in hydrogen-free specimens to a mixed-mode fracture of quasi-cleavage and intergranular fracture in hydrogen-charged samples, confirming the embrittling effect of hydrogen.

Paper 379 1 **Effects of Pressure and Frequency on Hydrogen-induced Fatigue in X65 Pipeline Steel**
Mr. Aswin Suresh, The Netherlands
Highlight (Oral Presentation 20')

Abstract Repurposing natural gas pipelines for hydrogen transport is crucial for sustainable energy transition, necessitating an understanding of hydrogen degradation mechanisms. While much research exists on hydrogen-induced failure, fatigue loading remains underexplored due to its complexity. This study examines the effects of hydrogen gas pressure and loading frequency on the fatigue crack growth behaviour of X65 pipeline steel. Constant force amplitude tests were conducted at hydrogen gas pressures of 0.2, 2, 5 and 10 MPa and loading frequencies of 0.01, 0.1 and 10 Hz. Paris regimes of base and weld metals were obtained in both nitrogen and hydrogen environments. The hydrogen-assisted crack growth rate increased with higher pressure and lower frequency. Moreover, the crack growth rate ratio in hydrogen to nitrogen was higher at lower ΔK . Constant ΔK experiments were performed at various pressures and frequencies, followed by electron backscattered diffraction to analyse deformation near the crack flanks. Postmortem fractographic analysis identified degradation mechanisms and weak links in the microstructure.

Integrating in-situ performance tests, advanced materials characterization, and computational modelling to understand hydrogen-material interactions

Prof. Elina Huttunen-saarivirta, Finland

Oral Presentation (20')

Abstract

To realise the promise of the hydrogen economy, the structural integrity and operational reliability of components, assets and infrastructures needs to be ensured all through the hydrogen value chain: production, storage and transfer, and utilization. Particularly in the storage and transport phase, materials are retained long times in interaction with gaseous hydrogen (H₂), that has the capacity to dissociate in the atomic form. Hydrogen as the smallest of atoms diffuses readily into and within materials, with diffusion characteristics relying strongly on the material microstructure and chemical composition. On the macroscale, hydrogen may contribute to the dramatic loss of plastic deformation capability and/or load bearing capacity of structural materials, a phenomenon called hydrogen embrittlement (HE). This may occur already at ppm levels of hydrogen in the material.

For components, assets and infrastructures to perform as planned, interactions between materials and hydrogen need to be understood well. This work gives an overview, how the combination of advanced tools in materials research: in-situ performance tests, advanced materials characterization methods, and multi-scale multi-physics computational modelling can deepen the understanding of material-hydrogen interactions. Selected example cases are demonstrated.

Comparison of hydrogen embrittlement susceptibility of tempered martensitic steels adding Mo and Mo-V

Mr. Kousuke Kagiya, Japan

Oral Presentation (20')

Abstract

Recent studies have reported that the precipitation of fine carbides with co-addition of molybdenum (Mo) and vanadium (V) in a matrix improved the resistance to hydrogen embrittlement of tempered martensitic steel due to the interfaces with high binding energy with hydrogen atoms under low hydrogen content. However, the effect of fine precipitation of co-added Mo and V carbides on reducing the susceptibility to hydrogen embrittlement of tempered martensitic steel under high hydrogen content has not been clarified. This study investigates the effect of finely precipitated Mo and V carbides on the susceptibility of hydrogen embrittlement of tempered martensitic steels with different Mo and V amounts evaluated by both slow strain rate testing (SSRT) and constant load testing (CLT) under low to high hydrogen charging conditions. Three kinds of steel (Base steel, 1%Mo steel, and 1%Mo-0.1%V steel) were compared. The specimens with a diameter of 5 mm and a gauge length of 30 mm were pre-charged with hydrogen in a 0.1 N NaOH solution with the addition of NH₄SCH of 5 g·L⁻¹ at current densities ranging from 1 to 50 A·m⁻² for SSRT and at a current density of 50 A·m⁻² for CLT at 30 °C for 192 h, respectively. SSRT was conducted at a crosshead speed of 0.02 mm·min⁻¹ while maintaining hydrogen charging under the same conditions. In CLT, hydrogen-charged specimens were loaded to an initial stress of 0.8σ_B (tensile strength: σ_B) under the same conditions of hydrogen pre-charging. When no fracture occurred after 48 h, the applied stress was incrementally increased by 0.05σ_B every 48 h. The critical stresses for delayed fracture were determined. Stress relaxation tests were also performed with an initial stress of 0.7σ_B to evaluate the degree of dislocation mobility. SSRT results show that the difference in fracture strength among the three kinds of steel was smaller at lower current densities, whereas that at higher current densities was larger. The order of fracture strength was Base steel < 1%Mo steel < 1%Mo-0.1%V steel. In CLT, the order of the critical stress for delayed fracture was the same as the fracture strength obtained by SSRT. Stress relaxation increases in the order of 1%Mo-0.1%V steel < 1%Mo steel < Base steel. These results indicate that the co-addition of Mo and V not only enhances hydrogen trapping but also reduces dislocation mobility, thereby reducing the susceptibility of hydrogen embrittlement even under higher hydrogen content.

Hydrogen Effects in Pre-Strained 316L Austenitic Stainless Steel Sheets

Mrs. Stavroula Maritsa, Greece

Oral Presentation (20')

Abstract

The maritime industry is actively investigating innovative technologies for the safe transportation and storage of liquid hydrogen (LH₂), playing a crucial role in the shift toward a sustainable green economy. Material selection of storage tanks is a critical factor, given the extreme conditions required for LH₂ containment (-253 °C, at atmospheric pressure). LH₂ tanks utilize corrugated austenitic stainless-steel sheets due to their outstanding mechanical performance at cryogenic temperatures, superior resistance to hydrogen diffusion, and excellent weldability. However, the corrugation process induces pre-deformation in the material, significantly increasing its susceptibility to hydrogen embrittlement (HE) due to strain-induced martensitic (SIM) transformation. Controlling and understanding this transformation is essential for ensuring long-term reliability. This study aims to shed light on the link between SIM and HE of AISI 316L stainless steel, as a promising candidate material for LH₂ applications. Specimens were subjected to uniaxial pre-strain at varying levels (10%, 20%, 30%, and 40%) to replicate the effects of corrugation process. Cathodic charging was employed to introduce hydrogen into the material efficiently, bypassing the prolonged exposure times required for natural diffusion. To analyze the phase transformations induced by pre-straining, metallographic techniques such as Electron Backscatter Diffraction (EBSD) and X-ray Diffraction (XRD) were employed. The influence of hydrogen was assessed through two key aspects: the amount of hydrogen absorbed by the material and its impact on mechanical properties. Thermal Desorption Spectroscopy (TDS) was used to quantify hydrogen absorption and correlate it to the fraction of SIM. Additionally, Slow Strain Rate Tests (SSRT) were conducted on cathodically H-charged specimens that contained a fraction of SIM from prior pre-straining. The insights gained from this research showed an increasing martensite fraction as pre-strain increased, despite the relative stability of 316L, which affected H absorption and ductility. These findings will contribute to the development of optimized materials and structural designs for LH₂ storage and transportation, ensuring greater safety and reliability in future marine applications.

Paper 538 6

Ab initio study of hydrogen trapping at coherent and semicoherent interfaces

Song Lu,

Oral Presentation (20')

Abstract

Small and dense carbide precipitates in steels increase the resistance to hydrogen embrittlement by providing deep trapping sites which reduce the concentration of mobile hydrogen content. The critical factors affect hydrogen trapping capacity of carbide precipitates remain unclear. The present study uses ab initio calculations to study the complicated interactions between hydrogen and metal carbides (e.g., VC, NbC, TiC) in steels aiming at revealing and quantifying the effects of interfacial properties, e.g., chemistry, coherency, local strain, and interfacial dislocations etc. on hydrogen trapping and distribution. We compare the calculated atomic site-specific trapping energies (energy spectrum) with the experimentally determined hydrogen de-trapping activation energies for interfaces from thermal desorption spectroscopy measurements.

Paper 1010 1 **Effect of the tempering on microstructure development and mechanical properties of bainite in a 42CrMo4 steel**
Ph.D. Denis Jorge-Badiola, Spain
Highlight (Oral Presentation 20')

Abstract

Medium- and large-sized forged steel components are usually subjected to additional Q&T (Quenching and Tempering) heat treatments to achieve the required final mechanical properties (MP). The tempering conditions are of special interest as MP can be accomplished by its fine control. Additionally, depending on the dimensions of the component, its chemical composition and quenching conditions, different microstructures are developed from the surface to the core, that behave differently with the tempering conditions. Traditionally, the tempering treatment aim to improve the outer martensitic layer mechanical performance in terms of toughness and to produce additional stress relief due to quenching. However, due to the volumetric character of the heat treatment, not only the hardened martensitic layer is affected, but also deeper regions in the forged parts. In the case of 42CrMo4 (4140) steel, widely used as a forging steel grade, the region just below hardened layer is chiefly made up of bainite. The effect of tempering on its microstructure evolution and MP has drawn less attention than in martensite. In the present work, two heat treatment strategies have been undertaken in a dilatometer to create bainitic microstructures: bainitic quenching (BQ) and anisothermal cooling paths, which simulates the thermal profile at several positions in a large-sized cylindrical specimen quenched in water. The BQ temperatures have been chosen in the region of bainite and some prior martensite formation, whereas tempering temperatures have been set at 480 °C and 640 °C for 1h. A thorough microstructure (optical, FEG-SEM and X-ray) and hardness characterizations have been performed. The experimental results have shown that bainite may lead to a wide range of mechanical properties and microstructures, which are controlled by the specific complete thermal cycle (Q&T). Specifically, tempering conditions have been proven to affect the microstructure development and hardness in different manner depending on the nature of the bainite formed on the previous quenching step.

Paper 1343 2 **Simulation of Steel Plate Response undergoing Differential Cooling with Air and Water Impinging Jets**

Dr. Pavel Romanov, Sweden

Oral Presentation (20')

Abstract

Differential cooling is widely used in the automotive industry to tailor the microstructure and the mechanical properties in thin-walled beams through tool or spray quenching. However, thicker steel plates, such as those used in soil-working agricultural tools, typically require high hardness and are conventionally quenched by immersion in water. While this ensures strength, it does not account for the spatial variation of mechanical loads that these tools experience in service. By implementing differential cooling, it is possible to engineer hardness gradients that optimize both wear resistance and structural integrity.

This study explores the use of Impinging Jet Quenching Technique (IJQT) to achieve differential cooling of 15 mm-thick carbon steel plates by employing different water and air jet flow rates. The cooling process was monitored using embedded thermocouples, generating spatial and temporal temperature evolution data, which was then utilized in finite element simulations to predict phase transformations and final hardness gradients. The simulation framework enables extrapolation to other steel grades, using their chemical composition as an input parameter to a machine learning tool for phase transformation data generation, making the methodology adaptable for various industrial applications.

The experimental trials produced a wide range of cooling rates (0–43 °C/s) along the steel plate, depending on the quenching strategy and cooling medium. The simulated phase transformations revealed distinct hardness distributions across three steel grades with different hardenability levels (0.26, 0.27, and 0.38 mass-% C). The results showed that higher-hardenability steels retained a greater proportion of martensite, whereas lower-hardenability steels exhibited increased bainite, ferrite, and pearlite fractions, particularly in the slower cooling regions. The results clearly show how different steels react on different cooling medium and flow rates in terms of hardness profile variations along a potential component. Furthermore, it was found that differential air cooling could, in some cases, replicate the effects of slower water quenching, providing an alternative method for controlled microstructure tailoring.

These findings highlight the potential of IJQT as a flexible and scalable approach for achieving site-specific material properties in thick steel components. The demonstrated simulative and experimental approach opens new possibilities for enhancing the durability of steel components exposed to variable mechanical loads, offering an efficient means to optimize hardness distributions through controlled cooling strategies.

Paper 1370 4

In situ DSC of homogenization in 6xxx aluminium alloys

Mr. Aurel Arnoldt, Austria

Oral Presentation (20')

Abstract

6xxx-series aluminum alloys are widely used in automotive and construction industries due to their low weight, recyclability, and excellent mechanical properties. The homogenization heat treatment plays a critical role in optimizing these alloys for subsequent hot forming (e.g., rolling or extrusion) by influencing dispersoid precipitation and the dissolution and re-precipitation of Mg-Si phases. However, common experimental methods for studying these phenomena are time- and labor-intensive. In this study, we employ in situ differential scanning calorimetry (DSC) to analyze the homogenization behaviour of three 6xxx aluminum alloys under varying soak temperatures and cooling rates. The resulting heating and cooling curves provide insights into phase transformations, dispersoid number density, and Mg-Si-phase evolution, supported by microstructural investigations using scanning electron microscopy (SEM) and transmission electron microscopy (TEM). Our findings show that soak temperature has the most significant impact on microstructural changes, while cooling rate variations within an industrially relevant range have a lesser effect. This study demonstrates that in situ DSC is a rapid, cost-effective tool for optimizing homogenization parameters, reducing the need for extensive furnace trials, and enhancing alloy performance in industrial applications.

Defect detection in composite materials with lab-based X-ray scattering

Prof. Peter Modregger, Germany

Oral Presentation (20')

Abstract

Glass fabric reinforced thermoplastics (GFRT) represent a promising class of composite materials ideal for automotive and similar applications due to their lightweight, ease of production, and favorable mechanical properties. Despite these advantages, defects can arise during the manufacturing process - particularly during the forming of prefabricated laminates - which can jeopardize the safety and longevity of the final components. Therefore, it is crucial to detect these defects and understand their formation for production monitoring and recycling. The latter is especially crucial as the safety of the to-be-recycled component necessitates information about fiber integrity and local distribution on the micrometer scale.

Various NDT techniques, such as ultrasonic imaging, X-ray computed tomography, and infrared thermography, have been investigated for the purpose of defect detection in GRFTs. Among these, laboratory-based X-ray scattering using the edge-illumination (EI) principle has shown promise for defect detection. The EI technique utilizes two line masks in the beam, one close to the sample and another close to the detector, in order to sense sub-pixel structural changes in the order of micrometers. The corresponding contrast is called scattering or dark-field contrast.

We have demonstrated the detection of local fiber shifts in GRFT samples with scattering EI in radiographic imaging, i.e. without the need for time consuming high resolution x-ray tomography [1]. Further, data analysis with EI is straight forward compared to potentially work intensive fiber segmentation in tomography. In addition, we will demonstrate the quantitative determination of projected fiber densities with EI. Both of these milestones have obvious applications in current composite materials research as well as in future production monitoring and recycling efforts. Finally, we demonstrate the high sensitivity of this approach by the ability to distinguish the protein networks in raw versus cooked egg yolk – for a bit of fun.

Development of curve smoothing systems for a more accurate and automated Ball-on-Disc test analysis

Mrs. Ester Villanueva Viteri, Spain

Oral Presentation (20')

Abstract

The Ball-on-disc (BoD) test is the most employed for the study of wear. Various factors influence the signal obtained during friction tests. In addition to material-related factors, sample alignment, equipment accuracy, sampling frequency, and transitions between wear mechanisms can introduce noise and fluctuations in the recorded coefficient of friction (CoF), complicating precise value determination, particularly during the steady-state phase but also in the early stages. In some cases, the average coefficient of friction during equilibrium may not be accurately defined, which is particularly relevant when comparing samples with very similar friction values. These variations can impact the interpretation of wear rates and other tribological phenomena and the evaluation of materials for final uses.

This study presents a smoothing method designed to improve result accuracy in the study of CoF curves. The selected method applies Nyquist's criterion for setting the correct sampling frequency to prevent aliasing, ensuring proper signal capture and processing. This technique is compared against ten other filtering techniques, including Gaussian, Butterworth, Savitzky-Golay, to evaluate the best balance between reducing noise and preserving essential signal features.

The results show that applying the moving average filter improves the precision of the friction coefficient values and reveals delicate but significant phenomena that may otherwise remain undetected. Also, some transient events such as delamination, adhesion, or microstructural changes during the wear become more apparent after applying appropriate smoothing. These phenomena are crucial for understanding wear mechanisms, especially in materials with complex microstructures or new alloy formulations.

Additionally, the comparative analysis demonstrates that different methods may be more suitable depending on the characteristics of the signal depending on tested materials. While the moving average method is effective in reducing high-frequency noise and providing clear trends, methods like Butterworth or Gaussian filtering may be optimal for preserving signal fidelity when necessary.

In conclusion, implementing a suitable smoothing method, enhances the reliability of friction test data, allowing for a more accurate interpretation of tribological behaviour. This approach not only improves the precision of coefficient of friction measurements but also enables a better understanding of key wear mechanisms that might otherwise remain undetected.

The study has been performed in a new patented multi-phase aluminium alloy and the AlSi9Cu3 cast alloy.

Correlated Analysis with a Nanomechanical Microscope

Dr. Ernest Fantner, Austria

Oral Presentation (20')

Abstract

Correlated Analysis with a Nanomechanical Microscope

When nano-indentation and AFM experiments are done at separate instruments, the spatial correlation of the data from the two methods is an inherent problem. We solved this problem by integrating a standard Alemnis nanoindenter, a new very compact dedicated AFM-scanner employing cantilever with integrated strain sensors [1] and an optical USB-microscope into the measurement head (200x200x200mm³). The distance between nanoindenter and AFM cantilever tip is 20mm. Their position relative to the sample is secured by a patented reference procedure.

This means that this new table-top instrument allows to switch between the 2 methods back and forth to investigate the area of interest by either of the two methods – real-time: The operator can decide on the sequence of indentation, scratch or imaging experiments at different point(s) of interest (PoI) on one sample: real interactive correlated analysis.

WE will report the data from the following experiments:

- Indents on thin Cu-, Al and Ni-films with Berkovich nanoindenters:
 - o Subsequent to higher force (<100mN) indents, indents with much lower forces (5mN) were made precisely into the contour ridge of the previous bigger indent. This was possible by the sub-micron positioning accuracy of various indents relative to each other combined with nm-resolution AFM topography. By comparing the force-distance curves from such small indents with indents of equal force in the surrounding film we determined the difference in hardness very accurately and concresolved strain hardening effects. .
- Investigation of hardness-effects on multilayer organic solar cells :
 - o A series of indents through the sandwich structure at certain positions and depths were performed - with subsequent AFM imaging @ nm resolution –
- Analysis of nano-crystals embedded in electro-chemically plated 300nm-thick Cu-films:
 - o Nanometer sized Copper-nuclei were located via AFM and subsequently directly probed by indents with different forces. Hence, direct probing of nanoparticles has been achieved by the 100nm-positioning accuracy and the nm-resolution of the AFM -topography image.

The extension of the AFM functionality with KPFM and c-AFM modes is in progress.

Paper 1314 1 **Effect of selective laser remelting on microstructure and tensile properties of 304L stainless steel processed by laser powder bed fusion**

Dr. Miroslav Smid, Czech Republic

Highlight (Oral Presentation 20')

Abstract

Laser powder bed fusion presents a processing technology for fabricating slender and complex components of variable sizes. Although the technology has great potential, multiple challenges and uncertainties lie in the consistency of the process. For instance, optimized processing parameters, usually verified on small test cubes, may be unsuitable for the fabrication of significantly larger bodies. Such process discrepancies can lead to lower overall build quality, for instance, extensive porosity. In this study, we investigated the effect of an additional laser scanning sequence, remelting, on microstructure character and tensile properties at ambient and decreased temperatures. The study demonstrates that remelting has a distinctively beneficial effect on inherited porosity without dramatic changes in other microstructural characteristics. Moreover, remelted microstructure exhibits more reliable mechanical properties. The results suggest a possible application of remelting during the LPBF process of complex-shaped components to maintain a nearly defect-free microstructure.

Paper 373 **2** **In-situ neutron microstructural and mechanical characterization of WL –DED 316L stainless steel**

Mr. Alexander Mejia Reinoso, France

Oral Presentation (20')

Abstract

Additive manufacturing (AM) of metals is generally more environmentally friendly than conventional casting-based manufacturing (CM), as it reduces material waste and produces complex, lightweight and repairable components. Among AM techniques, wire laser directed energy deposition (WL-DED) is increasingly utilized to fabricate large parts, especially with AISI 316L stainless steel, given its corrosion, creep, and oxidation resistance. However, the broader industrial uptake of AM faces challenges. Rapid thermal cycles during the process result in complex microstructures with coarse grains and epitaxial growth, which can compromise the predictability and safety of AM components in structural applications.

Characterizing these intricate microstructures requires analysis over representative sample volumes, which neutrons facilitate due to their ability to penetrate up to 6 cm into steel. The Institut Laue-Langevin (ILL) aims to support the implementation of AM in industry through neutron diffraction characterization, in this particular case of WL-DED 316L samples manufactured by the Technical University of Catalonia (UPC). These samples exhibit a two-phase, γ -austenite matrix and δ -ferrite, microstructure. The δ -ferrite is undesirable due to its chromium reaction, promoting the formation of brittle intermetallic FeCr (σ -phase) and reducing both corrosion resistance and mechanical properties. 3D Residual stress distribution was determined at SALSA, a strain analyzer for engineering applications. Three strain components (longitudinal, transverse, and normal) were measured in as-printed 15x150x15 mm³ prisms still attached to the baseplate. Initial results of the as-printed condition indicated areas with significant differences in stress concentration that could lead to material failure. A stress relief treatment at 700 °C for 2 hours was applied to study stress evolution and relaxation. High-temperature tensile tests conducted at SALSA and Engin-X provided diffraction elastic constants (E_{hkl}, v_{hkl}) to understand their influence on the mechanical properties of the material by analyzing the load partitioning under mechanical stress and its temperature dependence. To understand phase evolution with temperature, in-situ neutron diffraction using the XTREMED instrument was performed on 4x4x5 mm³ coupons. These were subjected to cycles at room temperature (RT), 300, 400, 600, 700, and 900 °C and RT again, producing full high-resolution diffraction patterns. Rietveld refinement revealed a thermal expansion coefficient of 1.89x10⁻⁵ °C⁻¹, as lattice parameters increased from 3.599 Å (RT) to 3.658 Å (900 °C). At RT, 4.36 vol.% δ -ferrite transitioned to 7.21 vol.% σ -phase after 7 hours at 800 °C and continued increasing at 900 °C.

3

Microstructural and mechanical characterization of PBF-LB 316L by neutron and synchrotron diffraction

Dr. Paula Rodriguez Gonzalez, France

Oral Presentation (20')

Abstract

Additive manufacturing (AM) technologies offer a great opportunity for spaceflight by saving materials, and lowering transport weight. In particular, Laser-based Powder Bed Fusion (PBF-LB) is one of the most versatile AM technologies due to its ability to produce complex geometries and its adaptability to a wide range of materials. In this work, a microgravity-compatible system using PBF-LB was designed to meet environmental requirements in space, such as resisting the dynamic loads and vibrations during rocket launch and stabilizing the powder in microgravity. This study focuses on the microstructural and mechanical properties of 316L parts produced in the printer-designed device. The printing strategy considered a single-pass cylindrical wall with an external diameter of 30 mm and a thickness of 1 mm. The region of interest lies in the initial layers, from the base plate to the printed material, due to the high RS expected there. Samples were printed with heights 3 and 10 mm to analyze the impact of RS distribution with time and build height. The microstructure was analyzed by x-ray diffraction during printing in the DiffAbs beamline at SOLEIL (Paris, France). The set-up considered a lateral resolution of 250 μm and an exposure time of 5 s/acquisition. Results disclosed the dynamic evolution of the lattice parameter of the γ matrix and precipitating phases such as ferrite (α). Regarding stress analyses, neutron diffraction was carried out on SALSA strain diffractometer at ILL (Grenoble, France). In this case, the lateral resolution is higher than 0.01 mm and acquisition required 3 c/s, proving enough to disclose RS gradients and enhance a full tensor analysis. Note that for the first time worldwide, the printer and SALSA set-ups allow in-situ monitoring in the BD direction of samples thanks to the tailored baseplate powder suction system. The evolution of γ matrix and in particular the Fe(311). Initial ex-situ tests were conducted for preparation of in-situ monitoring experiments: the first involved rotation of the baseplate to simulate the movement during printing meaning averaging one build height condition, and the second was static meaning just one single point acquisition in build height and radial positions. The results disclosed similar RS values between static and dynamic conditions (compare statistics/count times for both conditions). For the three strain components, the longitudinal and radial directions displayed a similar trend ($\sim 1000 \mu\epsilon$), while the hoop direction exhibited different behavior, from 1000 $\mu\epsilon$ on the surface to $-1000 \mu\epsilon$ in the cylinder.

As-built microstructure characterization of thin walled laser wire directed energy deposited (LW-DED) AISI 316L with different process parameters

Mr. Srinidhi Sampath, Sweden

Oral Presentation (20')

Abstract

Laser wire directed energy deposition (LW-DED) is a versatile manufacturing method for relatively large structures. The relation between process, microstructure and mechanical properties has been described in detail in recent publications. However, these studies are typically limited to rather thick specimens where the surfaces have been machined prior to testing, in some cases after post annealing. Hence, there is a gap in understanding the mechanical properties of as-deposited thin walled structures without further machining and/or heat treatment. In this work, stainless steel AISI 316L wire was deposited with two different process parameter sets on a carbon steel substrate with a nominal wall thickness of 2 mm using a co-axial laser. The parameter sets were chosen to maintain approximately constant energy densities while simulating slow and fast production scenarios. The layer height in the fast scenario was twice that of the slow scenario. Specimens near the substrate and at mid-height of the deposited walls were characterized using metallographic methods such as LOM, SEM/EDS, EBSD and microhardness. The parameter sets resulted in surprisingly different microstructures despite the same energy density. The low layer height sample had, comparably, larger fraction of large grains in the centre but finer recrystallized grains at the surfaces. We explore the reasons for this difference through comparison of the solidification rate and the residual stresses during cooling and its influence on recrystallization. Furthermore, the carbon steel/stainless interface microstructure showed very little mixing for both parameter sets with some pores originating from the infill design. Surface waviness of the low layer height sample was also lower and had smoother valleys, indicating more flow during solidification. These differences in microstructure and surface topography are expected to have significant impact on fatigue properties due to possible notch effects.

Paper 128 **5** **Microstructural and mechanical evolution of IN718 alloy produced by additive manufacturing after heat treatment optimization**
Mrs. Annalisa Ferrarotti, Italy
Oral Presentation (20')

Abstract

This research investigated the effects of different heat treatments on microstructure and mechanical properties of additively manufactured Inconel 718 (IN718) superalloy, produced using laser powder bed fusion technique. Samples included bulk materials and lattice structures, with three different geometries. In order to investigate the above-mentioned properties of the specimens, many experimental techniques have been used, such as optical microscopy, scanning electron microscopy, electron backscattered diffraction, differential scanning calorimetry, X-ray diffraction and Vickers hardness measurements.

After a full characterization of the as-built samples, they were heat treated, starting from the standard industrial treatment employed for IN718 alloy. It includes a solution annealing at 980 °C for 1h then air cooling, followed by a first ageing at 720 °C for 8h and a second ageing at 620 °C for 8h. The resulting microstructure shows some fine γ'/γ'' precipitates, dispersed inside the grains of the γ matrix. Along grain boundaries, coarser precipitates were continuously distributed, attributable to both δ and Laves brittle phases. The standard heat treatment is often optimized for traditionally manufactured products, such as samples produced via casting. In this case, the involved production technique is additive manufacturing, so an optimization of the heat treatment should be considered. In fact, the embrittlement observed on annealed samples suggested an optimization of the standard heat treatment, being the lattice structures employed for structural applications. The study has been then focused on the tunability of the heat treatment by varying both the annealing and the aging temperatures, to understand which step is the most critical for defining the final microstructure and mechanical properties. In order to reach this goal, some modifications have been successfully applied to the standard heat treatment, by firstly modifying the solution annealing temperature, which has been increased up to 1150 °C. The obtained samples showed different microstructural features, in terms of secondary phases, with a low amount of brittle phases. Then, being the ageing responsible of the hardness increment, the two steps of ageing have been investigated, in order to evaluate the impact of these steps on both microstructure and mechanical properties. Finally, all samples, both bulk and lattice structures, were heat treated with the optimized treatment, and better microstructural features have been observed, in terms of fraction of secondary brittle phases. Furthermore, mechanical properties have been also improved, being suitable for application purposes of selected structures.

Investigation of recrystallization in high strength Ti-10-2-3 forged alloys: impact of the stored mechanical energy on active mechanisms

Mr. Louis Mabon, France

Highlight (Oral Presentation 20')

Abstract

Due to its high strength Ti-10-2-3 titanium alloy is commonly used in the design of aircraft landing gear. It is well known that the final properties of the structural parts are closely linked to key microstructural parameters such as the size and orientation (texture) of the beta phase, as well as the volume fraction of the different phases present in the final bimodal microstructure.

As far as the beta phase is concerned, it is an important factor on the control of the recrystallization stages during the forging route. However, the underlying recrystallization mechanisms during the final thermomechanical treatment of the Ti-10-2-3 alloy remain poorly understood due to the simultaneous occurrence of multiple phenomena during the annealing above the beta transus temperature step. At this temperature, the dissolution of the alpha phase occurs. Concurrently, several mechanisms related to the release of stored energy take place, including strain-induced boundary migration, continuous and discontinuous recrystallization, grain coarsening, substructure misorientation evolution, and heteroepitaxial recrystallization.

The forging paths are highly complex, and among the important parameters influencing the beta phase are the temperature and deformation rate, as well as the amount of local deformation, which is directly responsible for the amount of stored mechanical energy. The latter is a key value as it constitutes the essential driving force behind the recrystallization phenomena. The use of forged double truncated cones is particularly advantageous for investigating local deformation and the activation of stored energy release mechanisms. This geometry provides access to a wide range of deformation levels due to its shape, while eliminating the influence of deformation temperature, strain-rate and chemical variation parameters—all of which impact as well the selection of mechanisms. Sampling specific areas on the forged double truncated cones allowed for precise determination of the deformation levels in the sampled materials.

Federico García Lorca Auditorium (Level 0)

EBSD mapping was performed to observe the morphological evolution as a function of local deformation levels and post-processing temperatures. Finally, the competition between the different recrystallization mechanisms is discussed as a function of the quantity of mechanical energy stored in the microstructure during the processing path.

Paper 1749 2

3D strain heterogeneity and fracture studied by absorption and diffraction contrast X-ray tomography and crystal plasticity in an aluminium alloy

Dr. Thilo F. Morgeneyer, France

Highlight (Oral Presentation 20')

Abstract

Strong correlations between measured strain fields and 3D crystal plasticity finite element (CPFE) predictions based on the real microstructure are found for a plane strain tensile specimen made of 6016 T4 aluminium alloy. This is achieved using multimodal X-ray lab tomography giving access to both the initial grain structure and the strain evolution. The real microstructure of the central region of interest (ROI) of the undeformed specimen is obtained non destructively using lab-based diffraction contrast tomography (DCT) and meshing. An in situ tensile test, using absorption contrast tomography (ACT) is then performed for twelve loading increments up to fracture. Taking advantage of the plane strain condition, the evolution of the internal strain field is measured by two-dimensional digital image correlation (DIC) in the material bulk using the natural speckle provided by intermetallic particles. Early strain heterogeneities in the form of slanted bands, that are spatially stable over time, are revealed and the fracture path – determined from the post mortem scan – is found to coincide with the bands exhibiting maximum strain. CP-FE simulations are performed on the meshed microstructure of the specimen acquired by DCT and are compared with image correlation measurements. The measured strain fields are well described by 3D CP-FE predictions, whilst it is shown that neither a macroscopic anisotropic plasticity model nor a CP-FE simulation with random grain orientations could reproduce the measurements.

Paper 878 **3** **Microstructure evolution of alloy 625 subjected to concentrated solar radiation at 600°C**

Dr. Maria Jesus Ariza Camacho, Spain

Oral Presentation (20')

Abstract

Solar thermal systems concentrate sunlight by directing it with adjustable mirrors towards a solar receiver. This receiver absorbs the intense solar radiation, transforms it in thermal energy and transfer it to the heat-transfer fluid (such as water/steam, molten salts, liquid sodium, or air) that flows through it, causing the fluid's temperature to rise. In central tower setups, the solar receivers, predominantly made of nickel-based superalloys with tubular shape, experience challenging working conditions due to solar radiation intensities exceeding 1MW/m² and operational temperatures nearing 1000°C. The receivers are not exposed to steady temperatures; rather, they face daily cycles of heating and cooling because of the inherent variability of solar radiation. These cycles become more frequent on cloudy days, as cloud cover can intermittently block the sunlight.

This study presents the initial results of a comparison of the aging processes in one of the most commonly used alloys for manufacturing tube-type high concentration solar receivers, i.e. alloy 625. A set of flat specimens, 20mm square and 0.8mm thick each, made of alloy 625, was aged at 600°C constant temperature in a muffle furnace during different times to study the effect of thermal radiation in the alloy microstructure evolution. Simultaneously, a second set of samples with an identical design was exposed to concentrated solar radiation in a solar furnace to compare the aging when this material is selected for solar thermal applications. The microstructure evolution was characterised by optical and electron microscopies after preparing the metallographic sections of the specimens. Vickers micro-hardness tests were also used to follow the possible evolution of the mechanical properties.

The results indicate that concentrated solar radiation (CSR) significantly impacts both the rate and nature of alloy 625 aging at 600°C. On the one hand, with only 13h of CSR treatment, an increase in hardness equivalent to 30 hours of isothermal treatment has been observed, which is equivalent to an aging rate of more than double when using this alloy with CSR. On the other hand, the shape and grain size of the phase producing this hardening is different, suggesting an onset of δ phase formation with RSC rather than the γ'' phase that forms in isotherm treatment. The abundance of intermetallic precipitates at the interface between grains and in the grains themselves suggests that RSC accelerates the aging of about 8 times with respect to the isothermal case.

Paper 1926 4 **Influence of the annealing parameters on the development of microstructure and porosity due to the Kirkendall effect in diffusion couples of Ni/Ni-based Superalloy CMSX-4**

Prof. Bettina Camin, Germany

Highlight (Oral Presentation 20')

Abstract

Turbine blades are critical components in aircraft engines and landbased gas turbines because they operate at high temperature and load. These turbine blades therefore consist of thermo-mechanically highly resistant nickel-based superalloys. If they are exposed to high temperatures over a longer period of time and are connected to a material of a different composition, interdiffusion occurs. The diffusion couple technique is applied for the experimental investigation of interdiffusion. A diffusion couple of high-purity Nickel and the Nickel-based superalloy CMSX-4 was used here, which was joined by diffusion welding. CMSX-4 is a two-phase material with a γ/γ' microstructure directionally solidified with a uniform orientation. At high temperatures elements fluxes accompanied with vacancies flux across the Ni/ CMSX-4 diffusion welding interface take place. While the alloying elements of the CMSX-4 diffuse to the pure-Ni side, a reverse flux of Ni and vacancies to the CMSX-4 side occurs. From this follows a nucleation and evolution of porosity induced by Kirkendall effect in the CMSX-4 part near the joints interface. The issues of diffusion mobility of alloying element atoms and pore formation are of practical importance. So, it is relevant for welded and brazed joints of gas turbine blades, as well as the interface "blade material - protective coating". In the worst case this leads to failure of the material joint by separating of the both materials or by cyclic mechanical loading. Forming and evolution of the Kirkendall porosity depends strongly on the composition of the joined materials, crystallographic structure, annealing temperature, and annealing duration. The microstructure of three different diffusion couples, Ni/ CMSX-4 [001], Ni/ CMSX-4 [001]-HIPed and Ni/ CMSX-4 [111], exposed to three different temperatures (1200 °C, 1250 °C, 1300 °C) and three different time durations each, was investigated by synchrotron X-Ray radiation 3D μ -tomography (3D-XCT), optical and electron microscopy and energy dispersive spectroscopy (EDS). This provides a more information regarding the underlying complicated mechanisms of the void formation and evolution and a deeper insight into the kinetics of Kirkendall porosity, microstructural changes due to forming of topologically close pack (TCP) phase and dissolution of the γ' -phase. The obtained experimental 3D-XCT and EDS data are accompanied by phase-field and continuum simulations.

Paper 1105 5 **Advanced Correlative Characterization of a Gas-Nitrided 42CrMo4 Steel: Insights into Gradient Microstructure and Mechanical Properties**
Dr. Sabine C. Bodner, Austria
Oral Presentation (20')

Abstract

Gas nitriding is a widely used thermo-chemical surface modification process to enhance the hardness, wear resistance and fatigue strength of steels. In this process, a gradual modification of the base material is created by nitrogen diffusion. Additionally, a ceramic compound layer can form at its surface, which consists of iron nitrides. While the formation and process parameter correlation of this layer had been intensively studied by research groups worldwide, there is still a lack of knowledge of its mechanical properties and residual stress distribution with high spatial resolution. These results are critical for increased simulation accuracy and industrial design efficiency.

In this study, a gas-nitrided 42CrMo4 steel was comprehensively analyzed using correlative techniques to elucidate gradients in phase composition, microstructure, mechanical properties, and residual stresses at micro- and nanoscales. Cross-sectional X-ray micro- and nanodiffraction (CSmicroXRD, CSnanoXRD) experiments were performed in transmission diffraction geometry at the High-Energy Materials Science beamline HEMS at PETRAIII in Hamburg and at the ESRF in Grenoble, respectively, the latter achieving spatial resolutions below 500 nm. The synchrotron results were correlated with optical and scanning electron microscopy, microhardness profiling, nanoindentation and micromechanical cantilever bending tests.

CSmicroXRD revealed a compressive residual stress profile with a peak of -192 MPa at 100 μm depth, which could be correlated with the depth of nitrogen diffusion in the martensitic base material. The diffusion induced broadening of the XRD peaks extending to 169 μm . This is consistent with results from energy dispersive X-ray spectroscopy and microhardness data. CSnanoXRD showed that tensile stresses within the porous ϵ -nitride Fe_{2-3}N layer (approximately 3 μm thick) relax at the γ' -nitride (Fe_4N) interface. In the γ' -nitride, comprising an additional 3 μm , maximal tensile stresses of 500 MPa were determined, which further relaxed into the martensitic base material.

Micro-cantilever bending tests of the γ' -nitride revealed a Young's modulus of 158 ± 18 GPa and a fracture toughness of 1.8 ± 0.2 MPa $\cdot\text{m}^{0.5}$. In addition, mechanical properties were also determined by nanoindentation. This method yielded Young's moduli of 201 ± 8 and 142 ± 6 GPa for the γ' -nitride and ϵ -nitride, respectively. The higher Young's moduli determined by nanoindentation experiments compared to micro-cantilever tests can be attributed to the different scales, measurement regions, and specific test conditions of each technique.

This study demonstrates the power of advanced correlative characterization to deepen the understanding of gradient materials and provides deeper insights for optimizing material performance in industrial applications.

Paper 1022 1 Functional All-Cellulose Composites for Innovative Sustainable Textiles

Prof. Carmen Freire, Portugal

Keynote (Oral Presentation 40')

Abstract

Cellulose is the most abundant natural polymer, known for its renewability, biocompatibility, biodegradability, high chemical stability, and good mechanical properties. These attributes have been widely used in the development of various bio-based cellulosic materials, particularly composites. In recent years, all-cellulose composites (ACCs) have garnered significant research interest. These class of polymer composites consist solely of cellulose (or its derivatives), where the matrix comprises regenerated (or modified) cellulose, and the reinforcement phase is made of high-strength cellulosic (nano)fibers. ACCs present inherent advantages of cellulose, while exhibiting superior mechanical, optical, and barrier properties compared to traditional cellulose-based materials. Their versatility offers a sustainable and innovative approach in several applications, including in sustainable textile. This work explores the fabrication and characterization of ACCs using different cellulosic substrates (bacterial nanocellulose and cellulose pulp fibers), and following different approaches, and their functionalization with biobased additives for potential application as functional textiles. The developed ACCs presented enhanced properties, namely mechanical performance and water sensitivity, and their renewable and biodegradable nature aligns with circular economy principles, reducing the environmental impact of textile production.

Advanced multifunctional hybrid carbon nanocomposites

Mrs. Priyanka Goyal, United Kingdom

Oral Presentation (20')

Abstract

This research presents the development of novel hybrid polymer nanocomposites with enhanced multifunctional properties, addressing the growing demand for advanced smart functional materials combined with other advantages of lightweight and easy processability. Hybrid nanocomposites could offer multifunctionality with improved mechanical and electrical properties. However, they have not been explored much. This study focuses on a blend matrix of thermoplastic polyurethane (TPU) and acrylonitrile butadiene styrene (ABS), strategically combining TPU's elasticity with ABS's rigidity to optimize shape memory characteristics and processability. The innovation lies in addressing common challenges in nanoparticle dispersion and agglomeration by the incorporation of both carbon nanotubes (CNTs) and graphene nanoplatelets (GNPs) by solution processing method to create a hybrid reinforcement system. This unique approach exploits the synergistic effects between 1D CNTs and 2D GNPs, resulting in an intercalated hierarchical network forming a co-supporting conductive pathway. The combination of polymer blending and mixed fillers significantly reduces the percolation threshold, thereby improving electrical properties as proved by enhanced conductivity. Our findings demonstrate efficient nanoparticle dispersion without agglomeration as observed by Scanning Electron Microscopy (SEM) imaging. Mechanical properties are also significantly enhanced, with a 50% increase in modulus and tensile strength observed with only 2wt% CNT reinforcement. These nanocomposites exhibit impressive multifunctionality, namely shape memory behaviour and piezoresistivity. Remarkable improvements have been observed in the shape memory properties, with at least 97% shape fixity and 92% shape recovery for only 2wt% GNP composite. Such behaviour is mainly due to increased crystallinity of the hybrid composites, which have been confirmed with X-ray Diffraction (XRD) analysis and Differential Scanning Calorimetry (DSC). The CNT reinforced composite shows good strain sensitivity with a gauge factor as high as 12 at 24% strain, indicating potential for integrated sensing capabilities. Mixed fillers form a more strain susceptible network and offer improved sensitivity. The multifunctional nature of these hybrid nanocomposites makes them ideal candidates for various smart material applications. In aerospace, they could serve as self-sensing, shape-morphing structures for adaptive wings or deployable space structures, or for structural health monitoring. This research represents a significant step forward in the field of smart functional materials, particularly in shape memory polymers. The synergistic effects observed in these hybrid systems not only improve individual properties but also create new possibilities for material responsiveness and adaptability, opening up exciting avenues for further research and development in smart materials.

A new synthetic route for the production of well-structured PEDOT-MXene hybrid nanoparticles

Ph.D. Valeria Guglielmotti, Italy

Oral Presentation (20')

Abstract

Conductive polymers (CP) are a category of conjugated organic polymers known for their unique features, such as ease of processing, lightweight nature, cost-effective production, and both electrical and ionic conductivity. Moreover, numerous studies have shown that their properties can be tailored and improved by incorporating appropriate organic or inorganic fillers. Among the various inorganic materials utilized as fillers, carbon-based materials like carbon nanotubes, diamond, and graphene are among the most widely used. However, recently, a new class of two-dimensional materials composed of carbides and carbonitrides, known as MXenes, has attracted significant scientific attention for their potential as fillers in CP-based composites. MXenes represent a class of two-dimensional materials with a generic formula of $M(n+1)X_nT_x$ where the symbol "M" indicates the transition metal (such as Sc, Ti, Zr, Hf, V, Nb, Ta, Cr, Mo, and so forth) and "X" denotes the carbon while "Tx" represents a generic terminal surface functional group as -O, -OH, -Cl, or -F. They are typically produced by exfoliation of the corresponding MAX precursor, where A indicates elements belonging to group IIIA or IVA. The unique physical and chemical characteristics of $Ti_3C_2T_x$, such as its hydrophilicity, biocompatibility, high electrical conductivity, large surface area, redox activity, and distinctive optical and electronic properties, make it an ideal material for diverse applications. These include biomedicine, energy storage device fabrication, sensors, and biosensors, as well as batteries and supercapacitors. To harness the established properties of conductive polymers alongside the remarkable characteristics of MXenes, this work presents the synthesis of a composite material composed of poly(3,4-ethylenedioxythiophene) (PEDOT) as the host matrix and MXene as the filler. The nanoparticles were synthesized using sodium dodecyl sulfate (SDS) as a micellar soft template, facilitating control over the shape and size of the PEDOT nanostructures while enhancing their dispersibility in aqueous environments. The morphology and structure of the synthesized nanoparticles were analyzed, along with functional characterizations, to evaluate the properties of the final composite material for potential applications in the optoelectronic sector.

Paper 1393 1 3D PRINTABLE IONIC CONDUCTIVE HYDROGELS AND ORGANOHYDROGELS FOR WEARABLE SENSOR APPLICATIONS

Prof. Stefano Stassi, Italy

Highlight (Oral Presentation 20')

Abstract

Smart sensors made from conductive hydrogels have demonstrated significant potential in bridging the gap between the flexible human world and rigid electronics, particularly in fields like wearable technology and soft robotics. However, their widespread use in sensors is hindered by water evaporation, which reduces their durability. In recent years, organohydrogels, hydrogels where part of the water is replaced with a high-boiling-point organic solvent, have emerged as a promising alternative due to their flexibility and long-term stability. Additionally, traditional manufacturing techniques like casting limit the range of achievable shapes, restricting their applications. To overcome these limitations, 3D printing has gained attention as a method for reducing material waste, enabling product customization, and creating complex geometries that enhance sensing performance. However, integrating this technology with hydrogels and organohydrogels remains a challenge.

This study presents a photocurable double-network hydrogel composed of poly(vinyl alcohol)/acrylic acid (PVA/AAC) doped with sodium chloride (NaCl) to enhance ionic conductivity. The resulting PVA/AAC/NaCl hydrogel demonstrated excellent stretchability, electrical responsiveness to strain and pressure, and compatibility with 3D printing. Using Digital Light Processing (DLP) 3D printing, intricate structures were fabricated to improve mechanical stress sensitivity. However, the hydrogel's properties degraded over time due to water evaporation. To address this, a solvent replacement strategy was implemented using a glycerol/water binary solution. The resulting PVA/AAC/NaCl organohydrogel maintained stretchability up to 350%, exhibited stable mechanical and sensing performance for up to three months, reduced hysteresis, and demonstrated high sensitivity to both small and large deformations. The sensor demonstrates an outstanding strain detection limit of 0.05% and a pressure detection limit of 1.5 Pa, enabling the evaluation of micrometric deformations across a wide temperature range, including below room temperature. Notably, its 3D printability remained intact, further enhancing sensing capabilities through structural design. Additionally, the presence of glycerol enabled sensitivity to temperature and humidity. With its versatility, 3D printability, flexibility, and durability, the PVA/AAC/NaCl organohydrogel is a strong candidate for soft sensor applications.

Paper 1424 2 **Influence of substrate temperature and annealing on the conductivity of ZnO thin films**

Prof. Paloma Fernández Sánchez, Spain

Oral Presentation (20')

Abstract

ZnO is highly valued in electronics and optoelectronics because of its wide bandgap, strong exciton binding energy, and natural n-type conductivity. However, controlling its electrical properties is challenging since factors like substrate effects and temperature must be considered. In this study, we explore how the substrate temperature during growth and the use of p-type silicon (p-Si) substrates affect the electrical properties of zinc oxide (ZnO) thin films. ZnO thin films were deposited using Pulsed Laser Deposition (PLD) in a 2×10^{-2} Torr oxygen atmosphere on p-Si substrates. The substrate temperature was adjusted to study its impact on film growth and electrical properties. After deposition, the films were annealed in air at 800°C for three hours to improve crystal quality and reduce defects.

The films were analyzed using X-ray diffraction (XRD), atomic force microscopy (AFM), ellipsometry, UV-VIS absorption and Hall effect measurements. ZnO films showed variable -type conductivity depending on the growth temperature. Our findings suggest the p-Si substrate itself play crucial roles in determining ZnO film conductivity. These results align with existing studies and show that growth conditions and substrate interactions can be used to fine-tune ZnO's electronic properties [1].

Halide Perovskite Thin Films for Neutron Detection

Ph.D. Leunam Fernandez-izquierdo, United States

Oral Presentation (20')

Abstract

The need for high-efficiency, wide-area coverage radiation detectors is essential in applications related to nuclear medicine, industrial imaging, environmental monitoring, spacecraft applications, and homeland security, among others. In all these applications, the detector material interacts with high-energy particles or photons while operating at high electric fields. The material should also show negligible leakage current, high resistivity, and be able to scale. Cesium lead bromide (CsPbBr_3) is an excellent candidate that needs most of these requirements. CsPbBr_3 has excellent electric, optical, and spectroscopic properties while stable under extreme operating conditions. These properties make CsPbBr_3 an ideal material for high-energy radiation detectors. However, the use of CsPbBr_3 for charged particle and photon sensing is normally limited to single crystals. This is primarily due to the lack of deposition techniques for CsPbBr_3 films, which is necessary for high-energy radiation sensing. To overcome this, thin films were deposited using the close space sublimation (CSS) process, which allows the deposition of stoichiometric and high-quality CsPbBr_3 films with reduced defects, large grains, and high deposition rates. Alpha particles and neutron sensing using a p-n diode are also presented.

Planar $\text{CsPbBr}_3/\text{Ga}_2\text{O}_3$ p-n junction diodes coupled with ^{10}B neutron conversion film have been demonstrated by showing a thermal neutron detection efficiency of 2.5% [1-2]. The theoretical neutron detection efficiency of planar detectors is limited to <4.5% due to the self-absorption of reaction products within the neutron conversion layer. Higher efficiencies (20 % – 35 %) have been demonstrated using micro-structured silicon diodes backfilled with a neutron conversion material [3]. Micro-structured detectors fabricated using thin-film semiconductors can be more easily scaled for large-area applications than detectors using single-crystal semiconductors. Neutron detection efficiency using micro-structured detectors has also been demonstrated recently [4-5].

Modifications of furan-based polyesters and copolyesters - a silver bullet for developing novel and sustainable materials

Prof. Sandra Paszkiewicz, Poland

Highlight (Oral Presentation 20')

Abstract

There is growing interest in preparing new chemicals and materials based on renewable resources, as biomass-derived fuel and chemicals are a promising alternative to fossil-based materials [1]. The 2,5-furan dicarboxylic acid (FDCA) in particular, has been selected as one of the most important building blocks or top value-added chemicals derived from biomass [2]. The promising developments in the FDCA synthesis have led to the lab-scale synthesis of several FDCA-based polyesters including poly(ethylene 2,5-furandicarboxylate) (PEF) and its copolymers and blends. Concerning modification of furan-based materials, the state-of-the-art reports composites based on furan polyesters and copolyesters with carbon nanofiller, mineral fillers, and fibers [1, 3]. In the present work, poly(ethylene 2,5-furandicarboxylate) (PEF)-based copolymers and blends with an elastomer of poly(tetramethylene oxide) (PTMO) or epoxidized natural rubber (epNR) have been studied. Moreover, composites based on PEF-b-PTMO containing plant modifiers such as fenugreek or gentian have been prepared and their impact on flame retardancy has been verified. The molecular structure of the synthesized copolymers has been analyzed by ¹H NMR and FTIR spectroscopies. In order to evaluate phase transition temperatures and the thermal effects in the synthesized series of copolymers and composites, DSC, DMTA, and TGA have been performed. The obtained copolymers and blends exhibited a good combination of mechanical and processing properties, which resulted from high values of limited viscosity number (LVN). The obtained copolymers and blends do not undergo crystallization during cooling from the melt. One confirmed that the addition of PTMO had a significant effect on thermal and thermo-oxidative stability and tensile and cyclic properties. Moreover, it has been clearly demonstrated that the introduction of an elastomeric part during polycondensation is a more effective form of polyester modification than reactive blending with epNR. An increase in hardness and Young's modulus values was demonstrated, with significantly reduced elongation at break values for the samples with the plant additives. Furthermore, flammability analysis revealed that the addition of gentian and fenugreek slightly reduced THR, suggesting the potential of these additives as flame retardants.

Funding

The study was carried out under the project "Development of a new approach to the production and compatibilization of polyester blends using hybrid organic-inorganic additives" No. OPUS-26 2023/51/B/ST8/00775 financed by the Polish National Science Centre

Paper 1916 2 **Synthesis of functionalized polyphosphazene-based materials for decontamination of anionic pollutants from wastewater**
Ph.D. Francesco Lanero, Italy
Oral Presentation (20')

Abstract

The increasing presence of emerging pollutants in water sources poses a significant environmental and public health challenge. This study presents the synthesis and application of novel anion-exchange polymers designed to efficiently remove anionic contaminants of concern from contaminated water.

In particular, anion exchange polyorganophosphazenes are proposed as materials for wastewater treatment. They were synthesized through a multi-step process, involving the functionalization of the polydichlorophosphazene backbone with quaternary ammonium groups, optimizing their ion-exchange capacity and thermal stability.

Polyorganophosphazenes were selected due to the easy and versatile chemical functionalization that allows the development of several structures. The polymer properties were modulated by selecting different molar ratios of side groups introduced by nucleophilic substitution of the chlorine atoms of polydichlorophosphazene, synthesized through cationic polymerization approach.

The material structures were characterized by ¹H, ¹⁹F, ³¹P NMR, 2D HSQC NMR and ATR-FTIR then the thermal and morphological properties were evaluated.

Finally, the ability to bind anionic molecules in solution was investigated through NMR experiments to evaluate the removal efficiency of the synthesized polymers for a range of common anionic pollutants. The results in terms of the sequestration of pharmaceutical and perfluorinated substances in anionic form and highlighting the potential of anion exchange polymers as an effective solution for water purification, offering an alternative to conventional ion-exchange resins.

Paper 442 3 Bio-Based Photocatalytic Nanocellulose-based Aerogels: A Sustainable Solution for Microplastic Capture and Degradation
Ph.D. Remedios Montenegro Elvira, Spain
Oral Presentation (20')

Abstract The utilization of photocatalytic nanoparticles in powder form is frequently linked to considerable additional costs, attributable to the downstream processes necessary for their recovery and reuse post-application, including filtration, sedimentation, or centrifugation. Immobilizing these nanoparticles within a matrix that serves as a structural support material offers a promising solution by significantly reducing the need for such processes, thereby streamlining operations and making particle management and recovery more cost-effective and efficient.

Among the diverse range of options for immobilization, biopolymers, particularly cellulose nanofibers, stand out as a particularly promising solution. These materials exhibit numerous advantageous properties, including biodegradability, renewable origin, non-toxicity, high specific surface area, wide availability, and potential for functionalization. These properties enable the fabrication of composite materials in the form of aerogels with highly porous microstructures, which showcase ease of handling and photoactive surfaces, making them highly suitable for environmental applications.

In this study, C,N-doped TiO₂ photocatalysts with enhanced visible light absorption were incorporated into nanocellulose obtained from agricultural waste using colloidal synthesis routes. The resulting C,N-TiO₂ aerogels offer a dual functionality: they can physically capture microplastics while simultaneously photodegrading them under visible light. This integrated approach offers a sustainable and efficient solution to address microplastic pollution, a critical emerging contaminant in water resources. These findings contribute to the development of environmentally friendly technologies for water purification by exploiting renewable materials and advanced photocatalytic properties.

3D-Printed Colorimetric Chemosensors Using Natural Dyes for Sustainable Environmental Monitoring

Dr. Chiara Olla, Italy

Oral Presentation (20')

Abstract

The growing interest in sustainable and eco-friendly materials has driven research into natural dyes as viable alternatives to synthetic pigments, which often pose environmental and health concerns. Natural colorants such as anthocyanin and phycocyanin are biodegradable, non-toxic, and renewable, making them promising candidates for applications beyond traditional dyeing. In particular, their intrinsic colorimetric response to environmental stimuli, including pH variations and pollutant exposure, enables their use as chemical sensors. This work explores the integration of anthocyanin and phycocyanin into photopolymerizable resins for Digital Light Processing (DLP) 3D printing to develop functional colorimetric chemosensors. Optimized resin formulations were investigated to ensure both high-resolution printability and reliable sensing performance. The printed materials were characterized through optical spectroscopy to assess their colorimetric response, while photorheology studies evaluated their suitability for 3D printing. Our findings demonstrate that these bio-based dyes enable the fabrication of 3D-printed objects capable of detecting environmental contaminants in both liquid and vapor phases via visible color changes, underscoring the potential of natural dye-based materials for sustainable sensing applications.

From local agrifood waste to advanced materials for sensing

Ph.D. Maria Vittoria Piras, Italy

Oral Presentation (20')

Abstract

Agri-food waste represents an environmental problem; hence it is important to get in the mindset of the circular economy, using waste in an efficient and sustainable way to reduce the problems related to its disposal.[1,2] In this frame, the aim of the project is to convert fractions of waste into a potential resource for innovative materials.

Herein, cellulose pulp was extracted from Sardinian Olive leaves.

Cellulose pulp has been dispersed with eutectic solvents (ES) [3]; the innovative composition of the ES, using acrylic acid and Zn salt, permits partial dispersion and solubilization, allowing the simultaneous grafting of acrylate functionalities onto the cellulose chain, enabling the production of a "ready-to-use" photocurable formulation in which cellulose acts as a crosslinker. The formulations are suitable as a resin in 3D printing, especially DLP, and present ionic conductivity making them good candidates to produce conformable strain sensors [4].

Some tests have been conducted using aloe vera and olive leaves, which have opened the doors to possible creation of the material using cellulose from various waste sources. Studies are still ongoing.

Development of a functional membrane for island and coastal desalination device

Dr. Noel Peter Tan, Philippines

Oral Presentation (20')

Abstract

Sustainable desalination methods geared towards geographically isolated and disadvantaged areas (GIDA) are gaining attention. One promising technology is the Passive Solar Driven Membrane (PSDM) desalination system, which possesses key advantages to delivering safe water in rural areas of an archipelagic location. Our research group explores the PSDM multi-stage system to determine the productivity, yield and salinity using simulated seawater, providing valuable insights regarding the system's performance under Philippine atmospheric conditions. Desalination of 3.5% salt solution was conducted on a rooftop setting with PSDM multi-stages. Results show the average productivity of the 1, 2, 4, 7, and 10 stages are 93.84, 328.57, 401.47, 203.701, and 258.15 g/kWh, respectively, showing a 94% - 96% reduction in the salinity of the distilled water at all stages.

Further development on the improvement of this type of desalination system involves modifying its membrane layers. The purpose of this modification is to enhance the productivity and salinity rejection of the desalination device. Such modification was carried out through Polyamide (PA) functionalization of its polyethersulfone (PES) membrane layer. These modified membranes were oven-cured and integrated into PSMDS configured in single, four, and seven-stage setups to evaluate changes in distillate productivity. The presence of polyamide on the surface of PES membrane is confirmed via Fourier Transform Infrared Spectroscopy. The modified PSMDS showed significant increased productivity of 797%, 153%, and 564% for the single, four, and seven-stage configurations, respectively. Water Contact Angle measurements of the PA-PES membranes exhibited an average water contact angle of 17.85° while Scanning Electron Microscopy revealed that the polyamide formed on the PES has corrugated nanostructures. These characteristics enhance the system's hydrophilicity, thereby increasing its productivity. However, only the four-stage configuration achieved 99.9% saline rejection. Such quality water can be used for irrigation for crops, livestock, household use, and potable water.

Paper 561 1 **Microalloying Strategy: How Small Additions of Alloying Elements Can Significantly Boost the Strength of Titanium Alloys**

Ph.D. Stéphanie Delannoy, France

Oral Presentation (20')

Abstract

Due to their low density, high corrosion resistance, and biocompatibility, titanium and titanium alloys are highly attractive for many industries, including notably aeronautics and biomedical fields. However, the mechanical strength of Ti-based materials can be too limited for certain applications at room temperature, and even more so at high temperatures. In an original approach, this study aims to investigate the impact of adding small amounts of alloying elements on the microstructure and mechanical properties of titanium. Among various beta-stabilizing elements, the effect of micro-alloying with rhenium is particularly investigated. The results obtained highlight that a limited addition, < 1 wt.% of Re, can more than double the mechanical strength while maintaining a high reserve of ductility. The associated microstructural analysis shows that the addition of Re induces the presence of nanometric beta-phase particles (both intra- and inter-granular) as well as a significant refinement of the grain size.

Exploring the Quenching and Partitioning Heat Treatment in a Fe-alloyed Titanium Alloy: An in-situ and ex-situ approach

Mr. Martin Klein, Austria

Oral Presentation (20')

Abstract

Titanium alloys and steels, although chemically rather different, share some similarities in their metallurgical behavior. For example, the interplay of martensitic structures within a ductile matrix phase, such as austenite in steels or the β -phase in titanium, leads to the overlapping applicability of some rules and treatments for both metals. These structural similarities motivate the exploration of the effects that quenching and partitioning (Q&P) heat treatments have in the realm of titanium alloys. The Q&P process was initially developed to enhance the mechanical properties of advanced high strength steels by stabilizing the retained austenite matrix through the redistribution of interstitially dissolved carbon from the martensite phase into the austenite. In comparison to conventional Quenching and Tempering treatments and dual phase steels, this results in an increase in strength with consistently high elongation or, conversely, an increase in elongation with consistently high strength. This achieves a balance between high strength and good ductility.

With this heat treatment being well established in steels, the question arises, if such a primary phase transformation would also be applicable to Ti-alloys. As it is equally conceivable to induce martensite upon solution heat treatment and subsequent quenching and decompose it in a partitioning step, where β -stabilizing elements redistribute into the softer β -matrix. Especially, additive manufacturing (AM) could benefit strongly from such a heat treatment, as many Ti-alloys face the issue of relying on thermo-mechanical treatments for a good strength-to-ductility balance. In the AM context this means that plastic deformation must be introduced already during manufacturing in every individual layer, which hence increases complexity and costs. The application of Q&P could finally balance out the tense relationship between high strength and good ductility in AM Ti-alloys without relying on traditional thermomechanical treatments. To investigate the feasibility and impact of Q&P treatments in titanium alloys, a series of experiments were conducted. These include synchrotron X-ray diffraction to track the phase transformations during the Q&P treatment and dilatometer compression tests on untreated and Q&P-treated material with microhardness measurements to evaluate its effects on the mechanical properties. Further, scanning electron microscopy was used to characterize the undeformed microstructures. The combination of these techniques provides detailed insights into the phase evolution and microstructure, clarifying the occurrence and exploitation potential of the Q&P effect in Ti-alloys.

A new approach on TWIP titanium alloys design: oxygen segregation through grain boundaries engineering

Mr. Thomas Belforti, France

Oral Presentation (20')

Abstract

In the context of global warming, titanium alloys play an increasingly crucial role in the transportation sector due to their lightness and unique properties. Among these, TWIP (Twinning Induced Plasticity) titanium alloys stand out. They offer an excellent combination of mechanical properties and strain-hardening ability, along with inherent titanium characteristics such as lightness and corrosion resistance.

However, titanium's sensitivity to interstitial elements like oxygen in solid solution makes these alloys vulnerable during the fabrication process, especially during heat treatments or when using lower-grade materials, such as recycled materials that contain more impurities than commercially pure elements.

Oxygen has two main effects on TWIP alloys. High oxygen levels prevent the formation of twins during deformation, favouring dislocation slip, which degrades mechanical properties (through embrittlement effect) [1]. Additionally, oxygen naturally segregates at grain boundaries [2].

The aim of this study is to optimize oxygen distribution in a β -metastable alloy through grain boundary engineering. This approach aims to maintain the TWIP mechanism, ensuring excellent mechanical properties, while developing strategies to mitigate the effects of impurities in these alloys. By optimizing microstructural control, impurities could even be leveraged to enhance the material's mechanical properties.

To achieve this goal, a Ti-15Mo-0.2O (wt%) alloy was investigated in different states. Following a simple fabrication process primarily based on heat treatments, a fully recrystallized microstructure was characterized and used as a reference state for comparison with the segregated state. EBSD mapping and in situ tensile tests were conducted to observe twin behaviour near grain boundaries and conditions of plasticity transfer. A quantitative analysis highlighted the impact of such impurities on mechanical properties, such as yield strength.

Novel Heterogeneous Structure Design and Performance Tailoring of Ultrahigh Strength-Toughness Titanium Alloy

Ph.D. Zhiqi Wang, China

Oral Presentation (20')

Abstract

To address the urgent demand for titanium alloys with superior strength-ductility synergy in aerospace structural lightweighting, this study innovatively proposes a heterogeneous lamellar structured titanium matrix composite (TMC) fabricated from high-strength β titanium alloy powder and Si powder via low-energy ball milling, reactive hot pressing sintering, and controlled hot extrusion. By dual regulation of reinforcement configuration and matrix structure, the TMC exhibits a 10% increase in tensile strength and an 8-fold enhancement in uniform elongation compared to extruded titanium alloys. The strengthening mechanism is mainly heterogeneous deformation induced (HDI) strengthening and multi-stage strengthening mechanisms are sequentially activated: heterogeneous deformation-induced work hardening at initial deformation, Si-enhanced cross-slip in the middle stage of deformation, stress-induced ω -phase transformation and dislocation pinning by submicron Ti_5Si_3 particles at intermediate stages. This hierarchical activation sustains high strain hardening rates even under large deformations. Based on the above research, a grain boundary-engineered aging treatment was developed to fabricate ultra-high strength hetero-cellular structured TMC. The optimized microstructure comprises $\sim 5 \mu\text{m}$ cellular grains formed by nano-scale Widmanstätten α -phase grain boundaries (αWGB), with cell interiors containing hierarchical nano-graded α -phase (αHS) and pyramidal α -phase ($\alpha\text{pyramid}$) near Ti_5Si_3 particles. The HCS Ti-Si composite achieves a yield strength of 1720 MPa, ultimate tensile strength of 1839 MPa, and ductility of 5.5%, demonstrating simultaneous improvements in strength and plasticity over aged titanium alloys. What's more, In-situ TEM heating revealed the dynamic phase evolution, while SEM-based digital image correlation (DIC) elucidated micro-deformation mechanisms, confirming the critical roles of hetero-interfaces and stress partitioning in enhancing mechanical performance.

Eco-friendly anodic colouring of titanium alloys

Mrs. Itziar Hidalgo-González, Spain

Oral Presentation (20')

Abstract

Titanium alloys are widely used in several sectors of the aerospace and biomedical industries due to their exceptional in-service properties. The anodization of titanium promotes the formation of a nanometric oxide titanium film (TiO_2), which provides an improved corrosion resistance in aggressive environments, facilitates the adsorption of lubricants and helps to prevent galling. Additionally, light interference of the passive film (<350 nm) is of great utility for colour-coding of biomedical devices and aesthetics in jewellery. The variation in the passive film thickness, and consequently the colour, is influenced by the applied voltage (ranging from 10 to 100 V) and surface pre-treatment. EN 2808 standard recommends surface pre-treatment in an aqueous mixture of HF and HNO_3 and anodizing in concentrated H_2SO_4 , which are extremely aggressive and present severe health-and-safety risks. In this study, a commercial alkaline surface pre-treatment (BONDERITE C-AK 4181 L AERO) and an alternative alkaline anodizing process at different voltages were assessed for Ti6Al4V alloy. The resulting colours were characterized using the CIELAB colour space and compared to those obtained in H_2SO_4 . Other characterization techniques included scanning electron microscopy (SEM), Rutherford backscattering spectrometry (RBS), contact angle measurements, and optical profilometry. Corrosion resistance was evaluated using electrochemical impedance spectroscopy (EIS) and potentiodynamic polarization (PDP) tests in Harrison's (acid rain) solution and Hanks' solution at 25°C and 37°C, respectively. Pitting and crevice corrosion resistance were examined in selected samples according to the ASTM F 746-87 standard. It may be concluded that for aerospace and biomedical applications, as well as for colour-coding systems, eco-friendly alkaline surface pre-treatment and anodizing are suitable alternatives to acidic industry-approved procedures.

Laser-ultrasonic characterization of additively manufactured TiNb alloys with low elastic moduli

Ph.D. Martin Koller, Czech Republic

Highlight (Oral Presentation 20')

Abstract

TiNb-based alloys are highly promising for biomedical applications, such as hip implants. Their key property is a low elastic modulus, which prevents stress shielding caused by a mismatch between the elastic moduli of bone and the implant. Metastable Ti alloys achieve the lowest elastic moduli while having complex multi-phase structures containing alpha, beta, and omega-Ti phases. Various alloying elements strongly influence the phase composition and the resulting elastic moduli, where even slight changes in the element combinations can lead to significant changes in material properties. Additive manufacturing is particularly advantageous in this context, as it enables the production of a diverse range of alloys from elemental powders. In this contribution, we used laser-ultrasonic techniques to study the elastic properties of additively manufactured TiNbZrO and TiNbSnFe alloys with varying compositions. By laser resonant ultrasound spectroscopy, we determined elastic moduli and the level of elastic anisotropy from resonant spectra of millimeter-sized samples. Besides that, scanning acoustic microscopy and transient grating spectroscopy were used to reveal the local variations in elastic properties. It was found that the lowest elastic moduli are achieved in the alloys with a low amount of the stiff omega phase, which simultaneously have a composition near the stability limit of the parent beta phase.

2

Multi-scale microstructure characterization of ultrafine Ti-Fe-based eutectics for additive manufacturing

Dr. JoAnn Ballor, Spain

Oral Presentation (20')

Abstract

Ti alloys are useful in applications that require a high strength-to-weight ratio, such as aerospace or structural applications. However, Ti parts are often costly and difficult to manufacture. Ti alloys can be particularly difficult to machine which increases their cost and limits their use outside of specialized applications. The development of additive manufacturing (AM) has provided an opportunity to manufacture Ti parts in near-net shapes, reducing the need for costly machining processes.

AM techniques like selective laser melting (SLM) use a laser to selectively melt metal powder in desired locations to build up a final shape layer by layer. This process involves melting and cooling the metal at timescales much faster than in traditional manufacturing. Investigators have taken advantage of this unique temperature environment to create alloys and microstructures that were not previously possible. For the first time eutectic and near-eutectic Ti-Fe alloys with ultrafine hierarchical eutectic microstructures were created using SLM techniques, and exhibited high strengths and enhanced compressive ductilities at room-to-intermediate temperatures. These alloys still pose challenges, though, as the extreme temperature gradients during melting and cooling induces significant thermal stress, causing the Ti-Fe alloys to crack during the printing process. High baseplate temperatures (approximately 790C) have been used to successfully prevent cracking during printing and solidification, but most commercial SLM systems are not equipped to reach such elevated temperatures which could limit the adoption of these alloys in industry.

Previous work has identified Ti-26Fe-4Sn-2.5Nb(wt%) as an alloy with potential to successfully print at temperatures below 790C [1]. In this study we investigated Ti-26Fe-4Sn-2.5Nb(wt%) using synchrotron x-ray imaging to determine how laser power, scan speed, and baseplate temperature affected the generation of defects such as cracks during the printing process. Laser power and scan speed affect the laser energy density, which is known to affect the formation of defects during SLM. Further multi-scale characterization was performed to determine the microstructure of the Ti-26Fe-4Sn-2.5Nb(wt%). Using the in-situ experiments along with the post-mortem characterization, the processing-microstructure relationships of Ti-26Fe-4Sn-2.5Nb(wt%) were explored.

The results from this work are expected to advance the knowledge of the fundamental mechanisms of SLM techniques in alloys sensitive to residual stresses and cracking during or after solidification. Using the in-situ experiments, we hope to help close the gap between information from process monitoring systems used in commercial AM machines and post-mortem characterization by standard laboratory techniques.

Paper 1636 4

Tailoring strength, ductility and directionality in laser powder bed fusion processed Ti-6Al-2Sn-4Zr-2Mo-Si and Ti-6Al-4V via post-process heat treatments

Mr. Benno Schönleber, Germany

Oral Presentation (20')

Abstract

Laser Powder Bed Fusion (LPBF) of the titanium alloys Ti-6Al-2Sn-4Zr-2Mo-Si (Ti-6242) and Ti-6Al-4V (Ti-64) results in an unfavorable as-built microstructure, necessitating post-process heat treatment to tailor mechanical properties for specific technological applications. For Ti-6242, which is designed for high-temperature applications up to 540 °C, research on suitable post-LPBF heat treatments remains limited. Furthermore, in additive manufacturing, variations in processing parameters and feedstock materials complicate the comparison of studies and literature, including a direct comparison of both alloys regarding their heat treatment response, is lacking.

At this point the present work picks up. This study aims to evaluate promising post-LPBF heat treatment strategies for each alloy and enable a direct comparison of their microstructural and mechanical response, particularly in terms of strength, ductility, and anisotropy. Therefore, various heat treatments were selected based on literature and applied to LPBF-processed samples. More precisely, the alloys were produced using alloy-specific processing parameters, and a selection of heat treatments following different approaches (stress relief, $\alpha+\beta$ annealing, α -globularization, subsequent ageing) were conducted in a vertical furnace flushed with argon gas. The as-built material as well as 14 heat treated material states were characterized. Microstructural characterization was performed using scanning electron microscopy (SEM) and high-energy X-ray diffraction (HEXRD). Mechanical properties were assessed through hardness and tensile testing, with tensile tests conducted in two loading directions to evaluate the directional dependence of mechanical properties.

The study revealed that heat treatments decomposed the initial fully martensitic microstructure, forming $\alpha+\beta$ microstructures. A broad spectrum of mechanical properties could be achieved through various heat treatments in both alloys. Coarser microstructures tended to be more ductile but less strong, following a general strength-ductility trade-off. Ti-6242 showed a greater variation of the uniform elongation and elongation at fracture for a given change in strength compared to Ti-64. Ti-6242 exhibited a highly elongated β -grain structure that persisted after all heat treatments. This resulted in a significant anisotropy of the ultimate tensile strength and yield strength. In contrast, Ti-64 did not show strong directionality.

Overall, the study enables a direct comparison of the heat treatment response of Ti-6242 and Ti-64, showing similar trends in both alloys. Specialized heat treatments enable the microstructure and mechanical properties to be tailored towards application specific requirements.

Paper 46 5 Titanium matrix composites produced by Electro-Sinter Forging

Mr. Gaëtan Denis, Switzerland

Oral Presentation (20')

Abstract

Electro-sinter-forging (ESF) is a novel ultrafast field-assisted sintering process developed by EPoS Technologies SA that combines the dual application of a mechanical pulse and an electromagnetical pulse to drive densification. This technology ensures a sintering at full density, in a sample obtained in a few seconds, and is highly suited for the production of unique metal matrix composite structures.

We explore in this work the production of titanium matrix composites using ESF process capabilities. This comprises the design and production of new materials, the in-depth study of their microstructural development, and their characterization for mechanical behaviour. General goals of the project are to design novel, high-performance titanium metal matrix composites for structural applications, and to contribute to our understanding of the links between composition and process parameters on one hand, and resulting microstructures and mechanical properties on the other hand, of metal matrix composite materials produced by the electro-sinter-forging process. This presentation will focus on in-situ Ti/TiC composites and their mechanical properties including their tensile behavior and elastic properties.

Paper 575 6 Effects of Creep in Titanium at Room Temperature during Tensile and Profilometry-based Indentation Plastometry Testing

Dr. James Miller, United Kingdom

Oral Presentation (20')

Abstract

Titanium alloys at room temperature are often observed to exhibit a dependence on strain rates within the 'quasi-static' regime. Three titanium alloys have been tested at a range of strain rates via conventional tensile testing and by Profilometry-based Indentation Plastometry (PIP) with a range of penetration velocities. In addition, they have been creep tested at fixed loads corresponding to nominal stresses in the vicinity of the yield stress. It is shown that the dependence of these materials on strain rate can be explained by simply considering the results of room temperature creep tests near the yield stress.

A numerical model has been developed, combining analytical equations for quasi-static plasticity and creep. Good overall consistency is observed and the procedures described here are thought to have wide potential for understanding and characterising titanium alloys which show a dependence on strain rate during tensile testing. These effects should have a large impact when designing protocols for materials testing certain alloys.

Grain size and texture effects on twinning in magnesium alloys

Ph.D. Filip Siska, Czech Republic

Highlight (Oral Presentation 20')

Abstract

Twinning is a significant plasticity mechanism in magnesium alloys, influencing their mechanical properties. Despite the long-term effort, it is still not fully understood. Analyzing twinning is challenging because it initiates a process on the atomic level but rapidly propagates to a grain size scale. The presented study analyses local stress-strain conditions inside the polycrystalline magnesium alloy and assesses the effects of grain size and crystallographic orientation on twin nucleation and propagation. The impact of existing twins on further twin evolution is particularly considered. The analysis is performed using the finite element method and crystal plasticity framework and compared with experimental observations. The results provide insight into the evolution of plasticity and twinning at the local scale.

Paper 1028 3 **Investigation on the interactions between nucleation, grain growth, and particle dispersion in magnesium-SiC nanowhiskers composites**

Mr. Syahwira Taqwa Triadi, United Kingdom

Oral Presentation (20')

Abstract

Magnesium and its alloys reinforced with SiC nanowhiskers are promising candidates for lightweight, high-strength metal matrix composites, particularly in structural applications within the aeronautics, aerospace, and lightweight vehicle industries. Despite their potential, achieving a uniform dispersion of reinforcing particles within the metal matrix and understanding the interphase between the components remains a significant challenge. Factors such as nanoparticle agglomeration, dispersion techniques, interfacial secondary phases, and nucleation and solidification dynamics all play critical roles. This research focuses on achieving well dispersed SiC nanowhiskers particle in Magnesium using melt stirring and die casting method. Since the as-received SiC nanowhiskers are heavily agglomerated, a particle loosening pre-treatment is essential. This optimised process can significantly reduce the agglomerate size, promoting much better dispersion during composite manufacture. Metallography and SEM-EDX analyses reveal that the particle loosening pre-treatment successfully minimise the nanoparticle agglomerates, breaking them down into individual particles and thereby improving their dispersion. With smaller particle sizes, there still has a tendency for those nanoparticles to be swept toward grain boundaries during the metal solidification, which is not desired in the composite microstructure design as the nanoparticles won't act as effective reinforcements at grain boundaries. A good understanding of the interaction between the nanoparticles and the metal melt solidification front is therefore needed to further guide the material microstructure design.

Synchrotron-based techniques, such as Diffraction Contrast Tomography (DCT) and Phase Contrast Tomography (PCT), are therefore employed in this study to observe particle distribution and position relative to grain and grain boundaries. These analyses indicated that particle distribution was predominantly concentrated at grain boundaries in both pure Mg and AZ91 alloys, which may be explained by the effect of Al element additional to the interface formation in the composites Furthermore, TEM analysis is also conducted to observe the atomic level of the interface between the SiC nanowhiskers with the metal matrix, both inside the grains and at the grain boundaries.

Paper 149 4 **Microstructure and Mechanical Properties of AZ91-MXene Composites Fabricated by Spark Plasma Sintering Near Solidus Temperature**
Dr. Radoslaw Chmielowski, France
Oral Presentation (20')

Abstract

MXenes, a novel class of two-dimensional (2D) metal carbides, are emerging as promising materials for reinforcing lightweight alloys due to their exceptional properties. In this study, we explore the mechanical properties and microstructure of composites composed of a magnesium alloy (AZ91) and varying concentrations of MXene, ranging from 0.1 to 10 wt%.

To achieve homogeneous distribution of MXene within the AZ91 matrix, we employed an optimized powder metallurgy process. Key steps included synthesizing the MAX phase, the precursor of MXene, followed by etching to obtain the desired 2D structure and subsequent integration into the composite matrix. Each stage of the process was carefully analyzed, with particular attention to parameters critical for achieving high-quality, dense MXene-AZ91 composites.

The synthesis was conducted near the solidus temperature of the AZ91 alloy not only to maximize densification during powder metallurgy but also to enhance interaction between MXene and AZ91. This approach enabled us to produce samples with near-full density, a crucial factor for ensuring mechanical reliability. The homogeneity and compactness of the composites were validated using advanced microstructural characterization techniques.

To evaluate the performance of these composites, we conducted friction and compressive tests, revealing significant insights into their mechanical behavior. The results suggest that MXene-AZ91 composites could be valuable in applications where a combination of lightweight properties and mechanical durability is essential, such as in aerospace and automotive industries.

Paper 1120 5 **Aging of ZA63 alloy containing stable quasicrystal phase**
Dr. Karel Tesař, Czech Republic
Oral Presentation (20')

Abstract

The stability of the quasicrystalline i-phase in the Mg-6Zn-3Al (wt%, ZA63) magnesium alloy presents an exciting opportunity to develop cost-effective quasicrystal-strengthened magnesium alloys. In this presentation, we highlight the growth behavior of the i-phase during aging and its effects, as revealed through various characterization techniques, including microhardness measurements, electron microscopy, small-angle X-ray scattering (SAXS), laser-based resonant ultrasound spectroscopy (RUS), and X-ray microscopy. Additionally, the fatigue crack growth rate and fracture toughness of this alloy are investigated, with crack propagation analyzed using scanning electron microscopy (SEM), X-ray microscopy, and electron backscatter diffraction (EBSD). Cracks resulting from the anisotropy of thermal expansion during quenching are also examined to identify potential weaknesses that may impact the industrial application of this alloy.

Corrosion Behaviour in NaCl and PBS Solutions of the Magnesium Alloy ZK60 after High Pressure Torsion Extrusion

Mrs. Stella Diederichs, Germany

Oral Presentation (20')

Abstract

Magnesium alloys are promising materials for implants. Not only because their mechanical properties are comparable to those of bones, which helps to prevent the stress shielding effect. Also, their high corrosion activity can be used to create bioresorbable implants – implants that degrade in the body over time to be replaced with the regrowing bone. Thus, making implant removal surgeries obsolete.

To be used for bioresorbable implants, the alloy should be non-toxic to the body, its mechanical strength should be adequate to support the healing bone, and the corrosion rate should be slow enough for the bone to be able to regrow. The main constituents of the magnesium alloy ZK60, Mg, Zn and Zr, are not toxic to the human body, making this alloy an interesting candidate for the manufacturing of implants. The corrosion rate can be modified, among other options, by refining the grain size. This can be straightforwardly done by Severe Plastic Deformation methods such as High Pressure Torsion Extrusion (HPTE).

In the present study, specimens of ZK60 are subjected to HPTE at two different temperatures. The resulting specimens, which show a significantly refined grain size, are subsequently tested for their corrosion activities in NaCl solution and Phosphate Buffered Saline (PBS) solution. The results are compared to the corrosion activity of the initial state before HPTE to determine whether the changes in the microstructure lead to different corrosion behaviours.

Paper 620 2 Characterization of the effect of copper addition on 316L Stainless Steel samples manufactured by Laser Powder Bed Fusion (LPBF)

Dottorato di ricerca Anna Maria Schiavone, Italy

Oral Presentation (20')

Abstract

Laser Powder Bed Fusion (LPBF) is one of the most attractive metal additive manufacturing technologies, receiving growing attention for fabricating parts without geometrical complexity restrictions linked to the layer manufacturing method. The production of the metal components by LPBF can result in mechanical properties comparable and sometimes superior to those of bulk materials, in terms of strength and ductility of the as-built parts. The AISI 316L austenitic stainless steel is one of the most widely used alloys in additive manufacturing, owing to its excellent properties such as corrosion resistance, high ductility and biocompatibility, making it very promising for structural and biomedical applications. Copper (Cu) addition generally enhances certain properties of stainless steel, such as antimicrobial activity and mechanical strength, while its impact on corrosion resistance can be complex and depends on its distribution within the base alloy, necessitating careful control of its distribution and concentration to optimize the desired properties. A Design of Experiment (DOE) approach was developed to assess the effect of variables such as laser power, scan speed, hatching distance, thickness and consequently the VED (Volumetric Energy Density) on the mechanical properties and microstructure of samples containing varying weight percentages of copper, produced using LPBF. Samples were subjected to conventional metallographic preparation, followed by electrochemical etching to highlight the microstructure. The samples were investigated using Scanning Electron Microscopy (SEM) and Energy Dispersive Spectroscopy (EDS) to assess the chemical composition and morphology. Optical Microscopy (OM) inspections were carried out to detect manufacturing defects, while X-ray Diffraction (XRD) was carried out to determine the distribution of the crystallographic phases in the samples. Vickers micro-hardness tests were conducted to investigate the mechanical properties on the XY plane and along the growth direction (YZ), aiming to assess potential variations between the central region and the edge areas, as well as between the bottom and top surfaces. Through detailed characterization and microhardness mechanical testing, the objective of this work is to identify the optimal process parameters and the appropriate amount of copper, in order to obtain the best compromise between microstructural properties and mechanical performance, while minimizing defects.

Oral Presentation (20')

Abstract

Alloy 718, a Ni-Fe-Cr-based superalloy, is extensively used in critical industries such as nuclear power, aerospace, and oil and gas, where high mechanical strength and resistance to corrosion are paramount. The alloy's exceptional performance under extreme environments makes it indispensable for components subjected to high stresses and corrosive conditions. With the increasing demand for efficient manufacturing and the need for substitutive parts, additive manufacturing (AM) offers a transformative alternative to conventional production methods. AM provides advantages such as reduced material waste, the ability to produce complex geometries, and shorter lead times, enabling the production of intricate components with tailored properties. This study investigates the influence of solution annealing and double ageing heat treatments on the mechanical and corrosion performance of additively manufactured Alloy 718. While optimising mechanical properties has been the traditional focus, the corrosion resistance of AM-produced parts is equally critical, particularly for applications in the nuclear industry where component reliability is vital. The primary aim is to evaluate the effect of varying solution annealing and double ageing temperatures to identify optimum conditions that ensure superior corrosion performance without compromising mechanical strength. By systematically analysing the microstructural evolution, hardness, tensile strength, and corrosion resistance, this research establishes guidelines for tailoring heat treatment protocols for AM Alloy 718. The findings will contribute to enhancing the service life and reliability of critical components, reinforcing the role of AM in modern manufacturing and its potential to replace conventional production methods for high-performance alloys in demanding applications.

Additive manufacturing of soft magnetic materials with Permalloy-80

Dr. Yasasween Hewavidana, United Kingdom

Oral Presentation (20')

Abstract

Abstract

Recent advances in the understanding and control of manufacturing techniques such as physical-property-targeted additive manufacturing (AM) technologies have made considerable advances in many industries. AM technology was developed not only for polymers, but also for ceramics, metals, composites, amongst other materials. Here the use of laser powder bed fusion additive manufacturing methods are demonstrated as a production technique relevant to manufacture of magnetic shielding materials with Permalloy-80 (80% Ni, 5% Mo and the remaining is Fe) called Mu-metal [1,2]. Powder characterisation experiments such as powder morphology determination with SEM imaging and EDX analysis were carried out with a Hitachi TM3000 microscope. Particle size distribution analysis and powder flowability with hall flow meter tests were conducted to measure powder quality properties prior to additive manufacturing processes. Samples were manufactured with an M2 Cusin laser machine, orientated 45° to the build platform. Initially, simple geometries were printed such as cubes, tubes, rings, tensile strips (ASTM E8), etc. Microstructural characterisation of materials provided significant detail to determine material behaviour. As a result, printed parts were characterised in terms of both macroscopic magnetic and microstructural scales. Currently, industry manufactures magnetic shielding assemblies with different thicknesses of Mu-metal sheets and bar stock using traditional manufacturing techniques such as rolling, bending, cutting, welding, etc. This research shows that the process of manufacturing magnetic shields additively with laser powder bed fusion can, in some circumstances, replace conventional manufacturing methods of magnetic shields. The economic feasibility of the manufacture of very complex on intricate shields is dependent on a large number of factors including cycle time, the number of disparate manufacturing operations required, geometric limitations, performance limitations, homogeneity limitations, mechanical integrity and robustness and material mass. The main objective of this research is to determine under which conditions it is appropriate to replace conventional manufacturing methods of soft magnetic structures with current additive manufacturing techniques and, more interestingly, identify utile geometries and structures which are currently unfeasible to manufacture using conventional techniques.

Laser powder bed fusion of AISI 4140 high strength low alloy steel: parameter optimization, microstructural and mechanical properties

Ms. Sarojini Sahu, India

Oral Presentation (20')

Abstract

Laser powder bed fusion is the predominant technique in metal additive manufacturing. It enables the production of intricate components with complex shapes by depositing metallic powders layer by layer, resulting in a nearly net-shaped final product. Experiments on single tracks were conducted to investigate the impacts of scan speed and laser power on the behavior of the tracks during laser powder bed fusion. For AISI 4140 steel, bead mode, the melt pool dimension, and the track stability were investigated. The laser power for the tracks was varied between 150 W and 400 W, while the laser scan speed ranged from 300 mm/s to 1400 mm/s. High porosity was seen at both high and low energy input densities. This was attributed to the presence of unmelted particles and keyhole pores, respectively. An increase in laser scanning speed results in the observation of discontinuities in the tracks. As the laser intensity increases, the depth of penetration of the bead also increases, indicating a shift in the bead morphology from conduction mode to transition mode or keyhole mode. This would lead to an increase in the occurrence of porosity flaws. The occurrence of balling can be elucidated by considering the Marangoni convection and the Rayleigh instability in relation to the flow of the molten material. Through the analysis of the track and bead morphology, a refined set of parameters was derived that can be utilized for printing specimens. A comparative study was conducted between additively manufactured and conventionally manufactured steel specimens. The examination of the additively manufactured specimens revealed the presence of martensite formation in the microstructure. Vickers hardness testing was performed in the vertical direction, starting from the bottom and moving towards the top. The hardness exhibited minimal variance, indicating a high degree of homogeneity. The mechanical properties and corrosion resistance of the additively manufactured specimens showed better and more promising results in comparison to the conventionally manufactured steel specimens.

Paper 899 **6** **Tungsten alloyed with varying carbon contents manufactured by Powder Bed Fusion – Laser Beam**
Dr. Jakob Braun, Austria
Oral Presentation (20')

Abstract

In this study, carbon-prealloyed tungsten powders were manufactured by powder bed fusion – laser beam (PBF-LB) in a substrate plate temperature range of 550 °C to 1000 °C. The carbon contents of the alloys investigated ranged from 0.02 wt.% to 0.21 wt.%. Characterization of the specimens was performed for defects by optical microscopy (OM) and scanning electron microscopy (SEM) of metallographic cross sections, for microstructure by electron backscatter diffraction imaging (EBSD), and for mechanical properties by three-point bending strength or tensile strength. In comparison to pure tungsten, the microstructure was refined and the epitaxial growth of grains was reduced. For lower carbon contents it was possible to reduce the amount of intergranular cracking and obtain samples without cracks in the inner regions, but surface cracks remained. By alloying with low amounts of carbon, the relative density as measured by optical density measurements increased to 99.9% with higher porosity at the surface areas where the cracks are located. For high carbon contents of 0.21 wt.% and small sample sizes 99.9% relative density and a crack-free microstructure was obtained. With increasing sample size, the thermal tensions and probability of lack-of-fusion defects increased, leading to 99.5% relative density and occurrence of cracking. The decrease in relative density can be attributed to the worsened powder spreading through increased adherence of the fine powder to the substrate plate at 1000 °C. The occurrence of cracks with increased sample size has a different origin than the cracks in pure tungsten or low carbon alloyed tungsten. While those are intergranular solidification cracks due to weakened grain boundaries, the cracks in tungsten alloys with high carbon contents are transgranular cold cracks due to thermal stresses and a lack of plasticity. The defect mechanisms of tungsten-carbon alloys manufactured by PBF-LB are discussed and mechanical properties presented. This study is a significant step towards the production of defect-free tungsten components with mechanical properties that meet market requirements using PBF - LB.

Additive Manufacturing of Hot Work Tool Steel Parts Using the L-PBF process

Prof. Piotr Bała, Poland

Oral Presentation (20')

Abstract

Additive manufacturing technologies are increasingly used in the metallurgical and machine industries. Due to the large possibilities of producing complex shapes without developing a series of manufacturing operations, they allow for additional optimization of production time and costs. In this work, the possibility of additive manufacturing of hot-work tool steels H11 (X37CrMoV5-1) and H13 (X40CrMoV5-1) as well as maraging steel MS1 (X3NiCoMoTi 18-9-5) was investigated using L-PBF technology with a laser in point-by-point mode. Based on the optimization, process parameters were selected to obtain acceptable quality prints from H13 and MS1 steel, introducing different amounts of energy into the material. Microscopic methods were used to characterize the produced materials, mechanical properties were examined, and the effect of heat treatment on the microstructure and properties of parts produced using the above technology was determined. In addition, the possibility of using a gas atmosphere and a laser beam for the controlled introduction of nitrogen into these steels was investigated. It was assumed that molecular nitrogen, present in a gas atmosphere, can be introduced into the pool of liquid metal by surface adsorption and subsequent decomposition into atomic nitrogen, which can form nitrides and carbonitrides during the solidification of steel. By controlling the time and size of the pool of liquid metal created using a laser beam, it was assumed that the amount of nitrogen introduced in this way could be controlled. The obtained research results show a new area of possibilities of additive manufacturing technology in the aspect of using gas atmospheres for local strengthening of 3D printed metals, which can open up new research directions for other materials.

Insights on Interface Features in 3D-Printed Multi-materials

Ph.D. Silvia Marola, Italy

Oral Presentation (20')

Abstract

Multi-material components, which integrate the properties of different materials within a single product, represent a major innovation in the industrial sector. This approach makes use of the unique characteristics of each material to enhance performance aspects such as mechanical strength, weight reduction, corrosion resistance, and thermal or electrical conductivity. However, integrating different metal alloys through additive manufacturing technologies remains challenging due to substantial differences in physical and metallurgical properties, which can compromise the quality and durability of multi-material interfaces. The study of interfaces in additively manufactured multi-material structures becomes thus crucial for understanding the mechanical, thermal, and chemical performance of the final component.

This research investigates the interfacial bonding mechanisms, defect formation, and property gradients that arise in additively manufactured multi-material samples obtained by coupling Ni-based, Fe-based, and Cu-based alloys. By using advanced characterization techniques (FEG-SEM, XRD, micro and nanoindentation) coupled with CALPHAD-based simulations, the microstructural and mechanical integrity of the interfacial regions were assessed. Results indicate that interface adhesion is influenced by printing parameters, material compatibility, and thermal history.

This study contributes to the development of high-performance multi-material AM components for applications ranging from automotive to aerospace, electronics, and medical devices.

Paper 1043 1 EFFECT OF PRINTING PARAMETERS ON THE MICROSTRUCTURE OF BLUE LASER DIRECTED ENERGY DEPOSITION OF A CuCrZr ALLOY

Mr. Claudio Madrid, Spain

Highlight (Oral Presentation 20')

Abstract

Copper-based alloys are extensively used in the nuclear, aerospace or injection molding industries due to their conductivity and corrosion resistance. Among them, the CuCrZr alloy, is a precipitation-hardened copper alloy which offers balanced properties such as relatively high strength, elevated softening temperature, and enhanced creep rupture strength. Directed Energy Deposition (DED) is a versatile additive manufacturing process capable of rapidly depositing high-performance materials. It enables efficient production of large parts, complex geometries, and component repairs, while offering precise control over material properties and supporting cost-effective, sustainable manufacturing through the repair and remanufacturing of components. Nevertheless, the manufacturing of copper alloys by laser DED remains challenging due to their high reflectivity to the conventional infrared laser (IR). IR radiation is reflected by copper at room temperature by up to 95%. Furthermore, the high thermal conductivity of copper alloys causes rapid heat dissipation during DED, resulting in anisotropic microstructures, and difficult control of residual stresses that may cause geometric distortions or promote cracking. Also, differences in heat dissipation along the building direction during DED manufacturing, result in heterogeneous properties and microstructures, which could limit the direct application of DED without costly post-processing heat treatments. Blue lasers sources provide an absorptivity of about 13 times higher than the IR in copper alloys. They offer greater manufacturing efficiency and flexibility, i.e., are gaining significant interest. This study investigates the effect of blue laser parameters used in laser wire DED and of the baseplate temperature on the microstructure formation of CuCrZr. Microscopy and synchrotron X-ray diffraction were used to analyze microstructural evolution along the building direction for developed printing strategies.

Paper 1068 2 **XCT image analysis for characterizing 3D printed thermomagnetic materials in energy harvesting applications**

Mrs. Savvina Maria Papaioannou, Germany

Oral Presentation (20')

Abstract

A critical amount of industrial energy input is lost as waste heat, and this amount peaks just above room temperature. The aim of this work, which is part of the ITN Heat4Energy project, is to develop a technology to convert this low-grade waste heat into electricity through a thermomagnetic generator based on Faraday's law of induction. To this end, water-flowable thermomagnetic elements will be developed both in the laboratory and by the industrial partner to be used as heat exchanger components in the demonstrator. The extrusion and post heat treatment process of the developed parts may introduce various defects that have an impact on their heat transfer efficiency, magnetic and mechanical properties.

Here, the non-destructive characterisation technique of X-ray computed tomography (XCT) is used to evaluate the morphology of the developed components and to identify trends that contribute to the improvement of material performance in the demonstrator. In specific, XCT image analysis enables the 3D visualisation of the developed 3D printed structures. Using DragonFly software, scalar quantities such as internal porosity, total surface area and void fraction are estimated for each sample. More specifically, image segmentation using the Otsu's thresholding method combined with morphological operations on multiple 2D XCT image slices, contributes to the estimation of the mean 2D void area of each slice and the distribution of the mean 2D void area as a function of z-coordinate along the printing direction.

Paper 1074 3 **Microstructure and Mechanical Properties of Laser Powder Bed Fusion Processed NiTi SMAs: A Comparative Study of Different Feedstock Powders**
Mrs. Mahima Rajak, India
Oral Presentation (20')

Abstract

NiTi shape memory alloys (SMAs) are known for their unique superelasticity (SE) and shape memory effect (SME) and are extensively used in aerospace, biomedical and actuator applications. Additive manufacturing (AM), particularly laser powder bed fusion (LPBF) process, has the ability to produce complex geometries with a high buy-to-fly ratio, and superior shape memory and mechanical properties compared to conventional routes. In this study, blended and pre-alloyed forms of NiTi powders with similar particle size distribution ($D_{50} = 39 - 40 \mu\text{m}$) were considered to compare the efficiency and performance of the respective printed parts. A noticeable difference in costs and availability of the two feedstocks are the main motivation behind the study. A one-on-one comparative study for LPBF process parameter optimization using the two forms of powders is the main objective of this work.

Firstly, both form of powders was characterized for morphology and shape memory properties before printing. The powders exhibit a spherical shape. Using LPBF, defect-free, high-density cubes were fabricated by varying laser power and scanning speed while keeping hatch spacing, layer thickness and scanning strategy printing parameters constant. The highest density achieved was 99.16% for pre-alloyed powder and 90.25% for blended powder. Differential scanning calorimetry (DSC) revealed single-step phase transformation in both printed parts with distinct transformation temperatures. X-ray diffraction (XRD) analysis confirmed different phase formations (B19 and B2) in the optimized cubes. Microstructural variations were observed along and perpendicular to the build direction for both printed parts. Hardness analysis showed that the optimized blended powder cube had higher hardness than the pre-alloyed cube. This difference is due to secondary phase formation, particularly Ni_2Ti phase in blended printed part, which degrades functional performance. However, pre-alloyed NiTi exhibits superior SME and SE properties. This study clearly identified the influence of powder type on LPBF processing, mechanical properties and functional behavior of NiTi SMAs. It is inferred that improving the density and powder characteristics of blended powder could enhance its printability using LPBF for various applications.

Paper 1106 4

Microstructural characterisation and thermophysical analysis of additively manufactured scrap aluminium alloys for circularity of material

Mrs. Nisha Singh, Germany

Oral Presentation (20')

Abstract

Aluminium alloys are exceedingly applicable engineering materials. Their very good mechanical and corrosive properties make them a highly sought-after material in automotive and aerospace industries. Accounting that, a huge amount of end-of-life aluminium alloy products is being recycled every year. Even though the energy required for the production of fresh aluminium is much higher (~95%) than that needed for its recycling, a considerable amount of high-grade engineering alloys still goes unrecycled every year. Thus, recycling of end-of-life scrap is necessary to meet the demand and to reduce energy consumption. In this research, we experimentally verify a computer-based rapid alloy development approach that predicts novel alloys purely based on mixing of automobile and aircraft aluminium waste fractions without refinement. The alloys 2024-T3 and Al-Si piston scraps were melted and cast in certain ratios to obtain three mixtures with varying content of silicon and other influencing elements. The ingots were cut into discs, ground to a thickness of 0.4 mm using 240P abrasive paper. A 3D-printer built at German Aerospace Centre (DLR) called MARS-M was used for laser re-melting by scanning straight lines on the discs. This treatment created melt pools which were investigated for their susceptibility to solidification cracking. Microstructural analysis with Scanning Electron Microscope (SEM) involved determining existence of strengthening and detrimental phases and precipitates, absence of solidification cracking or micro-cracks. Thermophysical analysis consisted of melting and solidification temperatures, enthalpy, specific heat and thermal diffusivity determination with Differential Scanning Calorimetry (DSC) and Laser Flash Analysis (LFA). After the analyses, a suitable mixture was powdered with ultrasonic atomiser and printed with MARS-M at DLR and SiMaP's 3D -printer at ESRF with different ranges of parameters. The results of two different printers were analysed for their microstructural characteristics involving elemental compositions and phases identification by SEM. Tomography results obtained at ESRF were analysed for porosity quantification and hot tearing in the printed material. Thermophysical properties, presence and formation of different phases were determined to understand the thermal behaviour of the material.

Paper 1119 5 Effect of long annealing heat treatment on the microstructure evolution and mechanical behaviour of LPBD Ti-6Al-4V alloy

Dr. Adrian Boccardo, Spain

Oral Presentation (20')

Abstract

The Ti-6Al-4V alloy is well known for its good mechanical properties, lightweight, and corrosion resistance. Laser Powder Bed Fusion (LPBD) additive manufacturing technique allows to produce complex geometry parts, as required in aeronautical, space, and medical industries. As built parts are very brittle because of its martensitic microstructure. To enhance the mechanical properties, such as ductility, post-built heat treatments are needed [1]. In this work, the effect of long isothermal heat treatments on the microstructure and resulting mechanical properties was studied. For this purpose, LPBD samples were fabricated. These samples were subsequently exposed to different thermal programs in the range of 750°C (14 hours) to 970°C (3 hours). Both, longitudinal and transversal crossed sections of the samples, have been analysed by scanning electron microscopy to study the microstructural changes in the sample series. Moreover, the hardness and elastic modulus of the samples were obtained by nanoindentation to investigate the mechanical properties evolution under the different thermal treatments. Besides that, dilatometry tests were performed on the samples, and the Avrami equation was fitted to represent the kinetics of the transformation (evolution of α and β fractions) at different temperatures. The main results are related to the microstructure coarsening (increment in the α phase particle thickness) with the temperature increment of the heat treatment.

Paper 1467 6

Heat treatments of 17-4PH stainless steel produced by binder jetting: tailored cooling rates for performance repeatability

Dr. Marco Mariani, Italy

Oral Presentation (20')

Abstract

Binder jetting has emerged as a key additive manufacturing technology, enabling the production of geometrically complex components from various metallic alloys. Nonetheless, the multistep nature of the process introduces a large variety of independent parameters which could affect the properties of the printed components, thus limiting the performance repeatability for the same material supplied by different producers.

This study explores the microstructural evolution and mechanical response of 3D printed 17-4PH martensitic stainless steel subject to tailored thermal treatments. The aim is to understand the interplay between processing and mechanical properties to design heat treatments capable of achieving repeatable performance regardless of the powder chemical composition, the binder jetting printing system and the sintering route (temperature/duration), thus facilitating the adoption and commercialization of printed components in the highly demanding biomedical sector.

A comprehensive description of the microstructure is obtained by SEM equipped with EDX and EBSD, aided by the detection of reverted austenite formation by XRD. Phase evolution description is clarified by CALPHAD modelling of equilibrium and precipitation phenomena. Hardness values are collected at the macro- and micro-scale through Rockwell C and Vickers indenters to determine the contribution of different phases. Tensile testing (ASTM E8/E8M) is performed on as-sintered and heat treated samples to evaluate the variation and strength and ductility at subsequent manufacturing stages.

For 17-4PH stainless steel, the as-sintered materials exhibited a continuous δ -ferrite network within a martensitic matrix, with Cu-rich phases localized within the ferritic regions, and solution annealing was found to redistribute alloying elements more homogeneously and reduce the continuity of the ferritic network. Different mechanical properties, especially tensile strength and hardness, can be achieved by aging at different temperatures and times, according to standardized procedures (e.g. H900 and H1150 from ASTM A564/A564M – 19a). The only available control parameter was the cooling rate: water quenching, air cooling and nitrogen-assisted cooling after solution annealing and aging were analyzed to understand whether specific combinations could produce constant and satisfactory mechanical performance regardless of the specimens production route.

This investigation highlights the critical role of thermal processing strategies in enhancing the microstructure and mechanical performance of binder jetted metallic alloys. The findings underscore the importance of solution annealing, which removes undesired secondary phases obtained during sintering, and fast cooling rates preventing the uncontrolled precipitation of copper after solution annealing, thus allowing an optimal tuning of the mechanical strength by aging.

Paper 1136 1 **Probing the Influence of HfC Nanoparticles on the Crack-Free Fabrication of CMSX-486 Nickel-Based Superalloy via Laser Powder Bed Fusion**
Mr. Abdulrahman Alqarni, United Kingdom
Oral Presentation (20')

Abstract

The CMSX-4 single-crystal Nickel-based superalloy is widely employed in the aerospace industry due to its exceptional oxidation resistance and mechanical properties at high temperatures. The use of Additive Manufacturing (AM), particularly Laser Powder Bed Fusion (L-PBF), presents significant challenges in fabricating this alloy due to the poor weldability and high susceptibility to cracking. To address this, the present work explores a novel in-situ incorporation of Hafnium Carbide (HfC) nanoparticles as a strategy to enable a successful LPBF processing of CMSX486. The findings reveal that adding 2 wt.% HfC nanoparticles improved weldability and enabled the fabrication of a fully dense nanocomposite, at an optimal laser energy density of 83.33 J/mm³. By combining HfC nanoparticles incorporation with heat input control, this approach fully suppressed both solidification and solid-state cracking, reducing the cracking density from 9.2 mm/mm² to an almost negligible 0.15 mm/mm². Synchrotron X-Ray Diffraction (S-XRD) confirmed that HfC remained stable within the microstructure, acting as a reinforcing secondary phase without altering the γ/γ' lattice structure. The dislocation entanglement near HfC particles was analysed using Bright Field (BF-TEM) to indicate their role in pinning the grains/cells boundaries. The Dark Field (DF-TEM) imaging revealed that the γ/γ' eutectic phases are formed along the cell's boundaries in CMSX-486. Energy Dispersive X-ray Spectroscopy (EDX-TEM) identified the modification in elemental segregation and depletion at the cell's boundaries. These nanoparticles particles also induced a 50% refinement of the solidification cell's structure, further suppressing the elemental segregation and the embrittlement caused by gamma prime contents. Additionally, the impact of post-processing treatments, including jet-cooling Hot Isostatic Pressing (HIP) and Double Ageing (DA) on the gamma prime evolution and defects mitigation was investigated. These findings establish a groundbreaking framework for extending AM capabilities to single-crystal Ni-based superalloys, thereby unlocking pathways for their integration into high-performance aerospace applications.

Paper 1155 2 Strategies for enhancing TiNbTa alloys via laser powder bed fusion processing: Effects of layer thickness, scanning speed, and remelting
Dr. Rodolfo Teixeira, Brazil
Oral Presentation (20')

Abstract

This study investigates the optimization of laser powder bed fusion (L-PBF) parameters for manufacturing Ti-Nb-Ta alloys, aiming to improve production speed, material properties, and reduce porosity. The focus was on achieving columnar grains with a {001} crystallographic texture while analyzing the effect of varying printing parameters across different sample sizes. Two compositions of pre-alloyed Ti-Nb-Ta powders were utilized: Ti-20Nb-6Ta and Ti-35Nb-6Ta (wt.%), both processed under controlled conditions to assess their microstructural and mechanical responses. Characterization included scanning electron microscopy, uniaxial tensile testing, hardness testing, and X-ray fluorescence. Initial experiments used a 30 µm layer thickness, 80 µm hatch space, and varying scanning speeds (400, 700, 1000 mm/s) and laser powers (100, 200, 300 W) to assess melt pool behavior. A 67° rotation between layers promoted directional effects with melt pools around 200 µm in size and the greatest depth at the edges. Based on this, the layer thickness was increased to 150 µm for full fusion. To mitigate these issues, additional strategies were implemented, including reducing the scanning speed to 400 mm/s and applying a remelting step. While remelting effectively reduced porosity and enhanced fusion, it nearly doubled the production time, making it unsuitable for high-throughput manufacturing. Therefore, the optimal parameter set – 400 W laser power, 400 mm/s scanning speed, 80 µm hatch spacing, 150 µm layer thickness, and 1 mm stripe, without remelting – provided a balance between material quality and production efficiency. This configuration resulted in low porosity levels (<0.1%) and acceptable fusion quality. The Ti-20Nb-6Ta and Ti-35Nb-6Ta alloys exhibited yield strengths of around 840 MPa and 600 MPa, respectively, exceeding those in existing literature. Hardness values were 281 HV for Ti-20Nb-6Ta and 218 HV for Ti-35Nb-6Ta. The study emphasizes the importance of optimizing L-PBF parameters to balance material performance and production efficiency.

Paper 1159 3

In-Situ Lamination during 3D Printing of High Silicon Steel

Prof. Soran Biroasca, United Kingdom

Oral Presentation (20')

Abstract

Theorists, experimentalists, and industrialists have all acknowledged that further improvements of electrical steel (ES) magnetic properties with the current chemical composition and manufacturing routes is extremely challenging. However, to enable the prevailing vehicle and aircraft electrifications revolution, further developments in materials and electrical machine design are required. Today, additive manufacturing (AM) unlocks opportunities for novel machine designs and production of higher Si steels than previously available via standard manufacturing routes. However, challenges around their inferior magnetic properties remain to be overcome. Here, the in-situ lamination during 3D printing of 6.5%Si steel is demonstrated. The in-situ steel lamination via “Coating and Fusion” was conducted through a combination of powder coating and printing strategies that enabled a production of a near net shape laminated high Si steel. The Ar atomised 6.5 wt% Si steel powder was coated with Fe-(Mn,Zn) ferrite by sol-gel auto-combustion method and with SiO₂ by sol-gel method for comparison purposes. Various Ferrite/ES and SiO₂/ES ratios were explored to determine the desired coating thickness. The coated powder was fused in the ProX300 Laser Powder Bed Fusion to build successive and insulated layer by layer of high Si steel. The study highlights the need for extensive optimisation of coating compositions, thicknesses, and scanning strategies to refine the process. While in-situ lamination was successfully achieved, the coating layers were non-uniform and discontinuous. Preliminary results suggest that coating 6.5% Si electrical steel with (Mn_{0.8}Zn_{0.2}) Fe₂O₄ improved its magnetic properties compared to conventionally printed 6.5% Si steel.

Paper 1421 **5** **Effect of Surface Finish and Heat Treatments on the Mechanical Behaviour of WE43 Alloy Lattice Structures Fabricated by Laser Powder Bed Fusion**
Mr. Jorge De La Pezuela, Spain
Oral Presentation (20')

Abstract

Laser Powder Bed Fusion (LPBF) is an advanced additive manufacturing technique that uses a laser to selectively melt metallic powder particles layer by layer, enabling high customisation in 3D component production. It allows for intricate geometries unattainable by traditional methods like casting or machining, optimising structures by reducing weight and material waste.

Magnesium alloys have significant potential in industries such as biomedical and transportation. They are the lightest structural material, with a density of 1.8 g/cm³, which gives them high specific properties. In the case of the WE43 alloy, the presence of rare earth elements in its composition allows it to be heat-treatable, enabling modifications to its mechanical and electrochemical properties.

In this study, compression specimens of WE43 alloy were fabricated using Laser Powder Bed Fusion (LPBF), and two heat treatments, T5 and T6, were applied. To compare the effect of these treatments on mechanical behaviour, the microstructures (as-built, T5, and T6), microhardness, and surface finish of the samples will be analysed.

The as-built alloy has a hardness value of 83 HV, which is 23% higher than that of the sample fabricated by non-additive processes. The T5 treatment results in a 20% increase in hardness compared to the as-built samples, while the T6 treatment yields values equivalent to the as-built ones. This phenomenon is related to a change in the proportion of β' precipitates and is accompanied by a decrease in ductility.

The microstructure has been analysed using optical microscopy, scanning electron microscopy (SEM), and transmission electron microscopy (TEM), as well as an EDS compositional analysis to evaluate the evolution of precipitates, the composition of different phases, and changes in grain size.

Regarding compression behaviour, taking the as-built sample as a reference, the T5 treatment shows higher strength. This effect is due to the precipitation of phases as a result of aging. In the case of the T6 treatment, greater ductility is observed compared to the previous cases, as the solution treatment eliminates secondary phases and precipitates formed during fabrication.

Paper 1486 **6** **Solar reactive sintering applied in Additive Manufacturing and Powder Metallurgy to process multi-material components**
Ph.D. Abraham Sánchez Romero, Spain
Oral Presentation (20')

Abstract

Multimaterials are becoming increasingly relevant in sectors such as the energy and aerospace industries due to their ability to combine advanced thermal, chemical, and mechanical properties into a single component, enhancing performance, durability, and operational safety. Among them, copper aluminides stand out for their applicability in heat dissipators, tribological components, and aircraft engine parts. This study analyzes the synthesis and processing of multimaterials based on intermetallic compounds through powder metallurgy and additive manufacturing. In the powder metallurgy method, laminated metallic materials are processed from mixtures of elemental copper and aluminum powders, activated using concentrated solar energy. Three experimental configurations have been designed: multilayer Cu/Al/Cu systems, multilayer systems with a reactive intermediate layer (Cu with 15-30-50 wt.% Al), and Cu-Al powder mixtures with 15, 30, and 50 wt.% Al. Prior to solar treatment, the samples, in the form of 16 mm diameter disks, were compacted at 200 MPa. On the other hand, multimaterials are obtained via additive manufacturing, using filaments composed of metallic powder (Cu and Al alloy) and PLA as a polymeric binder, which undergo a debinding cycle followed by sustainable solar sintering. In both processes, a Fresnel lens is used as a solar concentrator, capable of multiplying the incident solar radiation up to 2644 times, reaching a power density of $\sim 260 \text{ W/cm}^2$ in a 16 mm diameter focal point.

The processed multimaterials are characterized using X-ray diffraction (XRD), optical microscopy, and scanning electron microscopy with EDX analysis (SEM-EDX), and Vickers hardness testing. The powder metallurgy results reveal the synthesis of copper aluminides with different stoichiometries, low porosity, good metallurgical bonding between layers and minimal dimensional distortion after cooling. Similarly, 3D-printed parts exhibit excellent adhesion between layers during printing, proper binder removal, and high densification after solar processing. In both methods, solar reactive sintering activates highly exothermic reactions between Cu and Al, promoting the formation of intermetallic compounds through SHS (Self-propagating High-Temperature Synthesis) processes.

Paper 411 **6** **Fatigue behavior of 316L stainless steel and polylactic acid joints fabricated exclusively via additive manufacturing**
Prof. Nikolaos Michailidis, Greece
Oral Presentation (20')

Abstract

With the continuous advancement of multi-material additive manufacturing, the integration of dissimilar materials has gained increasing significance in both technological and industrial applications. This study investigates the adhesive-free joining of materials fabricated using distinct additive manufacturing techniques. Specifically, it focuses on the integration of 316L stainless steel, produced via Laser Powder Bed Fusion (LPBF), and polylactic acid (PLA), manufactured through Fused Filament Fabrication (FFF). The research emphasizes the design of tailored interface geometries and process optimization to enhance the bonding mechanism between these materials. The joining of 316L stainless steel and PLA presents substantial challenges due to their considerable differences in melting points, thermal expansion coefficients, and shrinkage behavior. A critical issue in this process is ensuring adequate filling of the interface geometries while mitigating polymer shrinkage during solidification which required meticulous fabrication planning. To address these challenges, various interface geometries were proposed, incorporating different cavity shapes and surface roughness characteristics to improve adhesion. The study systematically evaluates the influence of surface roughness, interface geometry, polymer integration within the metallic interface, and residual stresses through experimental tensile testing under both static and dynamic loading conditions. Tensile and fatigue specimens were designed and manufactured with a hybrid structure, consisting of half-metal (316L) and half-polymer (PLA) components along their length. Additionally, finite element analysis (FEA) was employed to develop a multi-physics thermomechanical transient model, enabling an assessment of thermal stress evolution at the 316L–PLA interface and its impact on principal stresses under tensile loading. By optimizing metallic component heating strategies, selecting suitable cavity geometries, refining interface roughness, and employing effective filling techniques, this study demonstrates the feasibility of achieving strong and durable joints exclusively through additive manufacturing, without the use of adhesives.

Towards printed zinc-lignin batteries

Prof. Reverant Crispin, Sweden

Keynote (Oral Presentation 40')

Abstract

Printed electronics involves using printing technologies as a mass production tool to integrate electronic circuits, sensors, and wireless communication on a flexible label, making any kind of object interactively connected to the internet. This is the "Internet of Everything," which is expected to connect billions of electronic labels to the internet. Powering these devices with conventional batteries presents a sustainability challenge in terms of material recycling and expensive maintenance. Today, bulky batteries are increasingly being replaced by low-power energy harvesters (e.g., thermoelectrics, solar cells, piezoelectrics) that charge thin batteries without the need for maintenance. The technical specifications for these types of thin batteries include high cyclability, high power, green materials, low cost, and compatibility with printed technologies, rather than the high energy density required in other sectors such as mobile phones. The greenest materials come from biomass. Lignin is of particular interest because it is an aromatic biopolymer that carries catechol groups capable of storing charges through electrochemical reactions. First, we explore the design of lignin electrodes by compositing with carbon or conducting polymers [1-3]. Second, a new class of electrolyte operating in the "water-in-polymer salt electrolyte" regime is considered to enable aqueous organic batteries with low self-discharge behavior [4-6]. Finally, we integrate these materials into a robust and promising zinc-lignin battery [7-8].

Paper 1914 2 COMPOSITE ANODES OF Si/SnS₂ FOR LI-ION BATTERIES: PHASE RELATIONS AND CRYSTAL STRUCTURE INVESTIGATIONS OF THE QUATERNARY SYSTEM

Mrs. Thangamalar Bhaskaran, Austria

Oral Presentation (20')

Abstract

Li-ion batteries have emerged as a critical technology in energy storage, powering devices from portable electronics to electric vehicles and renewable energy load level systems. This requires the development of novel anode materials, such as silicon and Sn which have high theoretical capacities, in enhancing battery performance and addressing challenges like capacity fading and thermal instability. Silicon (Si) has a very high specific capacity of 3579 mAh g⁻¹ which is about 10 times that of graphite, low cost, and high availability. Recent research shows that Tin (Sn) based materials can be used to increase the reversible capacity of anode by 20% in comparison to the traditional Graphite anodes. The full lithiation of Sn results in the formation of Li₁₇Sn₄ at a theoretical specific capacity of 994 mAh g⁻¹. Although Si and Sn- based materials exhibit high specific capacities, they undergo large volumes of expansion during lithiation. To counter this, we use SnS₂ instead of pure Sn. After intercalation of Li and conversion forming Li₂S and Sn the alloying reaction starts, only the latter is reversible. In a SnS₂/Si composite anode due to the presence of inert Li₂S heterojunction interfaces will be generated to buffer the volume expansions of the Si and Sn nanoparticles, which also inhibit further agglomeration during lithiation. To study and model this process, the main aim is to clarify phase relations and thermodynamics of the quaternary Li-Si-Sn-S system. Samples have been prepared via solid state synthesis in constituent ternary system and analysed using pXRD. Furthermore, some of the known ternary compounds were synthesized phase pure under our scope of work. Thermal analysis and calorimetry were performed to obtain thermochemical information, which will be subsequently used to optimize the Gibbs free energy descriptions of the systems in study. After successful evaluation of the ternaries, the data will be extrapolated into the quaternary, which will subsequently be used for the development of Si/SnS₂ nanocomposite anode materials.

High-temperature creep behavior in 8YSZ and 8YSZ-1wt%rGO composites

Dr. Felipe Gutierrez - Mora, Spain

Oral Presentation (20')

Abstract

8 mol% yttria-stabilized cubic zirconia (8YSZ) is widely used as electrolyte in solid oxide fuel cells (SOFCs) which function at temperatures between 800 and 1000 °C. This ceramic is chosen due to its optimal combination of affordability, high ionic conductivity, and chemical and mechanical stability across a wide temperature range and in various atmospheres. Also, 8YSZ/graphene composites have been suggested as novel materials for interconnects in SOFC since they fit several requirements to be used in these components, such as high electrical conductivity, chemical, structural and phase stability at operating temperature of 800-1000°C, gas tightness for both oxygen and hydrogen, matching coefficients of thermal expansion (CTE) with 8YSZ-based electrodes and electrolyte for minimizing the thermal stresses during initiation and close-down of SOFC device, as well as moderate mechanical strength combined with outstanding resistance to creep. Studies on creep behavior of polycrystalline 8YSZ are very scarce, besides, the influence of the incorporation of 2D nanomaterials on its creep behavior is completely unexplored until date.

In this work, the high temperature mechanical behavior of 8YSZ and composites of 8YSZ with 1wt% rGO (reduced graphene oxide) were investigated in creep tests between 1200 °C – 1300 °C ($T \sim 0.5 T_m$, absolute melting temperature) at different stress levels using air and Ar atmospheres. The mechanical data were analyzed, considering the microstructural changes observed during testing. These changes were investigated using scanning and transmission electron microscopy. The possibility that the presence of graphene nanosheets at grain boundaries inhibits diffusion processes increasing its creep resistance is investigated.

Advanced SiOx anodes for Li-ion batteries produced by metallothermic reduction of microalgae exoskeletons

Prof. Valeria Blanco, Spain

Oral Presentation (20')

Abstract

The development of advanced anode materials for lithium-ion (Li-ion) batteries is essential to meet the growing demand for high-capacity, long-lasting energy storage systems. Understoichiometric silicon oxide (SiOx) anodes have emerged as a promising alternative to conventional graphite-based anodes due to their higher theoretical capacity and excellent cycling stability. SiOx anodes are particularly attractive because they exhibit a combination of high capacity, good safety characteristics, and relatively low cost, while maintaining a balance between silicon's volume expansion during cycling and structural integrity. This study explores the synthesis and application of SiOx anodes produced via metallothermic reduction of silica (SiO₂) sourced from industrially cultured diatoms.

In this work, we utilized the exoskeletons of single-species diatoms, cultured on a large scale in industrial settings, as a sustainable and cost-effective source of SiO₂. Two metallothermic reduction processes, aluminothermic and magnesiothermic reduction reactions, were employed to convert the diatom-derived SiO₂ into SiOx. These methods were chosen for their efficiency and ability to control the stoichiometry of the silicon oxide phase, yielding a material with enhanced electrochemical properties suitable for Li-ion battery anodes.

The synthesized SiOx was then incorporated into the negative electrode (anode) materials of Li-ion batteries. A comparative analysis of the electrochemical performance of the SiOx-based anodes was performed against traditional graphite and pure silicon anodes. The results demonstrated that the SiOx anodes, derived from diatom-derived SiO₂, exhibited superior cycle stability and high capacity retention. In particular, the SiOx anodes showed excellent performance in terms of specific capacity, long-cycle life, and rate capability, outperforming pure silicon anodes while avoiding the severe volume expansion issues typically associated with pure silicon. This investigation highlights the promising role of diatom-derived SiOx as a sustainable and high-performance material for the next generation of Li-ion battery anodes.

The use of industrially cultured diatoms not only provides an environmentally friendly and renewable source of SiO₂ but also underscores the potential of bio-derived materials in advanced energy storage technologies. This study sets the stage for further exploration of metallothermic reduction methods in the production of silicon-based anode materials and opens avenues for more sustainable, high-performance energy storage solutions.

Paper 921 **5** **High-performance lithium-ion battery electrodes based on ion-implanted germanium thin films**
Mrs. Valentina Diolaiti, Italy
Oral Presentation (20')

Abstract

Germanium (Ge) has emerged as a promising anode material for lithium-ion batteries (LIBs) due to its high theoretical capacity and superior lithium-ion diffusivity compared to conventional graphite. However, its significant volume expansion during cycling remains a major challenge, leading to mechanical degradation and capacity fading. Nanostructurization appears an interesting solution to enhance structural stability and electrochemical performance. In this study, we explored ion-implanted Ge thin films as negative electrodes. The Ge films were fabricated using plasma-enhanced chemical vapour deposition (PECVD) followed by ion implantation to modify their microstructure morphology. The implantation process introduced controlled defects and altered the the Ge films, aiming to improve their mechanical resilience and lithium storage capability. The morphological and structural characteristics of the implanted films were analysed using scanning electron microscopy (SEM). This technique provided insights into surface morphology, film uniformity, and the evolution of the electrode structure after cycling. Additionally, X-ray diffraction (XRD) and Raman spectroscopy were employed to assess changes in crystallinity and phase transformations induced by ion implantation. Focused ion beam (FIB) cross-section analysis was also conducted to evaluate film integrity after the nano structuring process.

Electrochemical characterisation was carried out through galvanostatic charge-discharge cycling and cyclic voltammetry, measurements which allow the evaluation of capacity retention, rate performance, and reaction mechanisms of the ion-implanted Ge electrodes. The results demonstrated that the ion-implanted Ge films exhibited improved cycle life and higher stability compared to pristine Ge electrodes. Specifically, the modified Ge electrodes retained a higher capacity over prolonged cycling, with reduced initial capacity loss and enhanced coulombic efficiency. At a current density of 1C, the ion -implanted Ge films maintained a reversible capacity significantly higher than conventional graphite electrodes. These findings indicate that ion implantation is a viable strategy for tuning the structural and electrochemical properties of Ge-based anodes, mitigating volume expansion, and enhancing battery performance.

Paper 1533 6 **Reversible interfacial Li-oxide formation on germanium and silicon anodes revealed by time-resolved microgravimetry**
Dr. Yug Joshi, Germany
Oral Presentation (20')

Abstract

Germanium has recently garnered attention as a promising candidate for the next generation of Li-ion anodes due to its high capacity, higher conductivity, and faster lithium-ion diffusivity compared to silicon. However, uncertainty regarding the Li-storage mechanism and the formation of a solid electrolyte interface (SEI) has hindered its further development. In this study, operando microgravimetry was conducted on the Ge electrode to determine the SEI mass (irreversibly deposited) and to distinguish it from the reversibly cycled species, and their individual contributions to the total capacity. The time-resolved mass spectra, obtained by correlating gravimetry and charge flux, revealed that Li₂O along with Li is identified as a reversibly cycled species, contributing significantly to the electrochemical capacity. The amount of cycled Li₂O depends on both the cycling rate and the thickness of the anode. Interestingly, the amount of Li₂O decreases if pronounced anode cracking occurs. A direct comparison between Si and Ge indicates that the amount of the reversible Li₂O is predominantly controlled by the diffusivity of lithium into the electrodes. This study provides a general mechanism for balancing the interfacial and bulk storage of Li in the form of an oxide or by alloying, respectively.

Lignin-Derived Ionic Conducting Membranes for solid-state energy storage devices

Dr. Amjid Rafique, Portugal

Oral Presentation (20')

Abstract

Electrochemical devices, including energy storages and modulators, are expected to play key roles in creating a sustainable future. However, to realize the technological breakthrough in electrochemical technologies, the development of solid electrolytes applicable in various electrochemical devices seems crucial. The electrolyte being an integral part of the energy storage devices (i.e., Li-ion batteries) has been researched extensively, but properties of organic liquid electrolytes such as leakage, instability at elevated temperatures, and inclination to react with active materials seriously limit the development of Li-ion batteries [1,2]. Therefore, solid-state electrolytes are needed as an alternative to commercial liquid electrolytes owing to attributes such as high ionic conductivity, dendrite suppression, and compatibility with high-voltage electrodes in all-solid-state lithium-ion batteries (ASSLIBs) [3]. Here, we developed a polyvinyl alcohol (PVA)-lignin-based composite solid electrolyte, doped with lithium hydroxide (LiOH) salt, for solid-state lithium-ion batteries. The composite membrane exhibits an impressive ionic conductivity of 1.1×10^{-3} S/cm, demonstrating its potential for efficient ion transport. The effect of concentrations of Lignin and lithium salt on ionic conductivity has also been investigated. The obtained all-solid-state polymer electrolyte possessed a wide potential window of 6 V (vs. Li⁺/Li). The ionic conductivity and thermal stability of the membrane were investigated from 25 to 80 °C, and the membrane demonstrated excellent thermal stability and ionic conductivity. The membrane was also tested in devices with hard carbon and hard carbon composites with MoS₂ to investigate its applications in battery and supercapacitor configurations. The device has demonstrated excellent device stability for 5000 cycles and above 95% capacity retentions. The integration of lignin, a renewable and sustainable biomaterial, with PVA creates an eco-friendly and high-performance composite electrolyte for advancing solid-state lithium-ion battery technology while promoting sustainability in energy storage solutions.

Paper 1281 1 Scalable Hybrid Organic-Inorganic Solid-Solid Phase Change Materials for Thermal Management in Lithium-Ion Batteries

Dr. Gregory Largiller, France

Keynote (Oral Presentation 40')

Abstract

As the demand for safer and more efficient lithium-ion (Li-ion) batteries intensifies across diverse sectors, innovative solutions for thermal management are critical to addressing challenges in performance, safety, and lifespan. This study presents groundbreaking advancements in hybrid organic-inorganic solid-solid phase change materials (SS-PCMs), focusing on their synthesis, scalability, and application in passive thermal management for Li-ion batteries.

Hybrid SS-PCMs, including both perovskite and non-perovskite types with the general formula $(C_nH_{2n+1}NH_3)_2MIIIX_4$ ($M = Cu, Zn; X = Cl$), were synthesized at a 20-liter scale, demonstrating industrial viability. These materials feature tunable phase change temperatures ($54^\circ C - 95^\circ C$) tailored through organic structural modifications, validated via advanced characterization techniques such as synchrotron X-ray diffraction, ensuring compatibility with energy storage systems. Notably, these SS-PCMs remain solid during phase transitions, eliminating risks associated with liquid-phase leakage. Remarkably, despite their solid-state behavior, we successfully shaped these materials using compression and injection molding, enabling their integration into various battery configurations.

Thermal characterization revealed enthalpy changes of 72–85 J/g and thermal stability up to $180^\circ C$, ensuring effective heat management and reduced degradation risks. Mechanical testing demonstrated a rigidity of 1 GPa, further highlighting their robustness. These features make them ideal for addressing the thermal challenges of energy storage systems. Herein, we present for the first time, copper-based SS-PCMs integrated into a 7-cell Li-ion battery module, achieving superior passive thermal management, optimized temperature regulation, and enhanced performance under high thermal loads.

This work highlights the very promising role of SS-PCMs in advancing the thermal management of energy materials, demonstrating their scalability, versatility, and impact on next-generation energy storage technologies.

Optimizing Composite Phase Change Material Thermal Performance via Nanoparticle-Enhanced PCM Properties

Dr. Argyrios Anagnostopoulos, Poland

Oral Presentation (20')

Abstract

Thermal Energy Storage (TES) systems, particularly latent heat TES (LHTES), offer a highly effective solution for waste heat recovery, enabling energy conservation and efficiency improvements across industrial and renewable energy applications. Among TES media, phase change materials (PCMs) stand out due to their high energy storage density and nearly isothermal operation. However, their practical implementation is hindered by limitations such as low thermal conductivity, significant volume expansion during phase transitions, and structural instability. To address these challenges, composite phase change materials (CPCMs) have been developed by encapsulating PCMs within porous matrices, which enhance mechanical stability and heat transfer efficiency. Despite these benefits, CPCMs often suffer from complex or costly fabrication processes and a restricted PCM content, typically limited to around 60%, which constrains their energy storage potential.

This study explores the strategic use of SiO₂ nanoparticles (NPs) to enhance CPCMs, achieving an unprecedented PCM content of over 72% through a straightforward mix-sintering approach. Unlike conventional CPCMs, which require intricate processing techniques, our method significantly simplifies fabrication while maintaining high thermal and structural performance. The incorporation of SiO₂ nanoparticles plays a dual role: (1) enhancing the cohesion between PCM and the matrix, thereby improving structural integrity, and (2) modifying the physicochemical properties of the PCM itself, resulting in reduced thermal expansion and increased thermal conductivity.

Experimental results demonstrate that a CPCM containing 72% NaNO₃ exhibits structural stability, surpassing the conventional 60% threshold typically observed in oxide-based matrices. The nano-enhanced CPCM retains 86% of the energy storage density (ESD) of pure NaNO₃ while exhibiting a 28% increase in thermal conductivity. Additionally, the coefficient of thermal expansion (CTE) is significantly lower compared to pure NaNO₃, reducing mechanical stress during thermal cycling. These enhancements are particularly valuable for high-temperature applications where thermal stability and longevity are critical.

By leveraging SiO₂ nanoparticle modifications, this study presents a scalable, cost-effective approach to CPCM fabrication that overcomes long-standing material limitations in LHTES. The findings highlight the potential of nanoparticle-doped CPCMs to enable higher PCM content without compromising stability, opening new pathways for efficient and sustainable thermal energy storage solutions. Further research should focus on optimizing nanoparticle dispersion and exploring alternative high-conductivity matrices to further enhance CPCM performance and industrial applicability.

Flexible OPC-Polymer Composites for thermal management

Dr. Mikel Duran, Spain

Oral Presentation (20')

Abstract

Thermal management has become a key factor for a wide range of industrial areas, from buildings and renewable energy to automotive and electronics. Moreover, the increasing miniaturization and higher power density of the new generations of electronic devices require more efficient solutions for thermal management in ever smaller spaces. In addition, the emergence of flexible devices, such as wearables and foldable displays, introduces new challenges requiring materials that combine thermal efficiency, flexibility and shape adaptability.

In this context, phase change materials (PCMs) are considered outstanding tools for thermal management due to their ability to absorb or release large amounts of energy during their phase transitions. However, solid-liquid PCMs present safety-related limitations, such as the risk of leakage, which complicate their integration into advanced devices.

A promising alternative is the use of solid-solid PCMs, which eliminate these problems due to their shape stability during phase changes. Within this category, organic plastic crystals (OPCs) are promising materials with highly energetic phase transitions and the possibility to tune their working temperature over a wide temperature range, spanning 40 to 180 °C. These characteristics make them ideal candidates for specific thermal applications. However, the lack of flexibility and limited shape adaptability of OPCs restrict their use in flexible thermal management systems, posing a significant challenge for their implementation in practical applications.

In this sense, the aim of this work is to fabricate new flexible solid-solid PCMs based on OPCs in a simple way. For this purpose, Neopentyl glycol (NPG) powder is mixed and processed with PTFE particles in a mortar. During the processing step, these particles undergo spontaneous fibrillation, which leads to the formation of a nanofiber network that traps the NPG powder, resulting in a shape-stable material. The materials obtained by this method show good flexibility and shape adaptability, being able to be kneaded, folded and implemented on a variety of surfaces, as well as being shaped into films or pellets.

DSC and TGA analysis show that the melting temperature, enthalpy and degradation temperature of NPG are not affected by the addition of PTFE. Furthermore, it is observed that the subcooling of NPG is reduced by 30% when combined with 5% PTFE. Finally, the hydrophobic properties of NPG are also improved, drastically increasing the contact angle with water. Overall, the results show that this strategy gives rise to materials with potential for being implemented in complex device thermal management systems.

EFFECT OF THE SINTERING TEMPERATURE ON THE WEATHER RESISTANCE OF ANTI-SOILING COATINGS FOR SOLAR APPLICATIONS

Mrs. Naia Barandica, Spain

Oral Presentation (20')

Abstract

Anti-soiling (AS) coatings are critical for improving the performance of concentrated solar thermal (CST) systems by reducing surface soiling and maintaining high transmittance in glass covers. These coatings are particularly valuable as they help reduce the frequency and amount of water needed for cleaning, contributing to the sustainability and cost-effectiveness of CST operations. The coatings were prepared by dip-coating from sol-gel precursor solutions. Two fluorinated compounds with different chain lengths (F1 and F2) were used to provide hydrophobic character to the coatings. In addition, two sol-gel processes: one involving reflux and another without reflux (NR) were studied. In this work, the effect of sintering temperature on the properties of hydrophobic AS coatings was evaluated.

Three sintering temperatures were studied: 200 °C, 400 °C, and 500 °C. At higher sintering temperatures, an increase in transmittance was observed, which is attributed to the removal of organic components, resulting in more transparent coatings. However, the static water contact angle (WCA) decreased as the sintering temperature increased. Abrasion resistance was assessed over 500 cycles, and the results showed differences based on the fluorinated compound and the sol-gel process used.

The coatings abrasion resistance was studied by using a Taber linear abraser. The coatings prepared with the longer fluorinated chain (F2) exhibited better resistance to abrasion, as demonstrated by the lower increase in surface roughness (Ra) over 500 cycles and the higher retention of normalized transmittance compared to those prepared with F1. This behavior indicates that the longer fluorinated chain enhances the mechanical durability and optical stability of the coatings under abrasive conditions. Notably, the difference between F1 and F2 was more pronounced at higher sintering temperatures, where F2 coatings consistently maintained lower roughness and higher transmittance. Similarly, coatings obtained through the reflux method displayed superior abrasion resistance compared to the NR variants. This advantage is evident in the slower degradation of normalized transmittance and the more stable roughness values for the reflux coatings, regardless of the fluorinated compound used.

The results indicate that sintering temperature, fluorinated compound, and sol-gel process all influence the mechanical behavior of AS coatings. In addition to the abrasion tests, results from accelerated aging and further environmental durability studies will also be presented, providing a comprehensive evaluation of the performance of these coatings under real conditions.

Paper 314 **5** **Phase Changing Materials for efficiency improvement of Luminescent Solar Concentrators smart windows**

Mr. Leonardo Sollazzo, Italy

Oral Presentation (20')

Abstract

Commercial and residential buildings are the source of almost 40% of global CO₂ emissions and energy consumption. Building Integrated Photovoltaics (BIPV) and Phase Change Materials (PCMs) are promising technologies for reducing the carbon footprint of buildings.

PCMs can store large amounts of energy through their phase transition while maintaining constant temperature, releasing that stored energy with a significant time delay.

Luminescent Solar Concentrators (LSCs) are photovoltaic devices perfect for BIPV applications thanks to their transparency. They are made of a waveguiding material encapsulating a film functionalized with a fluorophore that partially absorbs solar radiation and emits fluorescence light that is waveguided to PV cells optically coupled to the edges. However, the Power Conversion Efficiency (PCE) of LSCs is limited by three main factors: amount of light absorbed, emitted and waveguided to the cell, efficiency of PV cells and efficiency derating of cells caused by high operational temperature. The first two factors are hard to modify in BIPV applications because of implementation costs and light management for indoor visual comfort. Thermal management of the Nominal Operating Cell Temperature (NOCT) via PCMs is an effective and low-cost solution to achieve higher PCEs without changing the other conditions. Above 25°C NOCT, a silicon PV cell can experience a PCE derating of 0.4-0.65%/°C.

This work consists of thermal simulations performed via "COMSOL Multiphysics" of LSCs solar windows combined with PCMs to evaluate the impact of PCMs on the NOCT of PV cells coupled to the LSCs. The simulations employ the Finite Element Method (FEM) and were performed based on weather data from different geographic locations. The 1m*1.4m simulated windows in both single- and double-glazed structures are framed in a PVC structure modeled to be full of air in one case and full of PCMs in the other.

Preliminary results show that the integration of a PCM with a melting point of 36°C and latent heat capacity of 240 kJ/kg can significantly reduce the NOCT of PV cells, up to 6°C in the considered locations. The temperature decrease leads to a +2.95% PCE per each cell, meaning +11.80% for the entire LSC. Performances can be further optimized by considering the coupling of several PCMs with different melting points. The effects of the PCMs are not only seen around the melting point but also at lower temperatures as their lower thermal diffusivity compared to air strongly attenuates the temperature increase inside the frame.

All-day Passive Radiative Cooling Performance of Porous Materials

Dr. Cristina Vicente Manzano, Spain

Keynote (Oral Presentation 40')

Abstract

Nowadays, a third of the total energy demand is destined for cooling due to the consequence of the global warming, which results in higher temperatures and heatwaves. All-day passive daytime radiative coolers (PRC) offer a promising solution for energy-free cooling of buildings and devices. At the same time, it is important to develop low-cost, easy-scalable to industry materials. In this talk, I will present 1D and 3D - anodic aluminium oxide (AAO) nanostructures on Al as a passive daytime radiative cooler. I will analyse how all the morphological properties and chemical structure of porous alumina nanostructures on Al influence on their optical properties and their radiative cooler properties. A maximum cooling temperature of 10.2 °C was reached under direct sunlight in a summer day in Spain for 3D-AAO. This cooling performance results of AAO nanostructures are higher than over previous studies, demonstrating the potential of AAO nanostructures to be used in thermal management applications. Moreover, I will present the use of various cellulose-derivative networks (porous materials) to achieve optimal and stable cooling performance. Our results showed that nitrocellulose network showed the highest cooling temperature, with a significant reduction of 14 °C from the ambient temperature and a power of 124 W/m² during the daytime and at night of 7.7 °C and 72.8 W/m². This study also analysed the dampness's effect on the cooling performance of cellulose-derivative networks. We observed that the cooling performance of nitrocellulose network drops ~3 °C (from 14 to 11.3 °C) when the humidity exceeds ~30%. Our findings indicate that the capacity of a material to absorb water from the surrounding air significantly influences its performance as a passive cooler, primarily due to changes in its optical properties. This is an important insight, as it highlights the need to consider environmental factors like humidity and sample hydrophobicity for PRC systems.

PHASE CHANGE MATERIALS IN INSULATING ELEMENTS TO INCREASE BUILDING ENERGY EFFICIENCY AND THERMAL CONFORT

Dr. Stefano Fasolin, Italy

Oral Presentation (20')

Abstract

The increasing demand for energy-efficient solutions in buildings has brought significant attention to advanced materials with synergistic thermal properties. The integration of phase change materials (PCMs) into polyurethane or geopolymer foams presents a promising way to improve the thermal comfort in buildings. PCMs are particularly appealing due to their high latent heat storage capacity that could confer higher apparent thermal capacity to insulating materials in defined temperature ranges, with effect of shaving and shifting temperature peaks. This approach combines the thermal insulation ability of porous lightweight materials with high thermal mass, thus increasing energy efficiency and thermal comfort.

In this work, composite materials with polyisocyanurate or geopolymeric foams incorporating organic PCMs at concentrations of up to 20 wt% were developed, while preserving the inherent thermal insulation properties of the pristine foams. In case of polyisocyanurate foams the process involved emulsifying a PCM formulation into the polyol component, while in case of geopolymers an emulsion of micro-encapsulated PCMs was used in the formulation. The selected PCMs were commercial materials with nominal melting point of 28 or 31 °C. The use of a nucleating agent to mitigate subcooling effect was also investigated.

The thermal performances of developed materials in static and dynamic conditions were analysed through Differential Scanning Calorimetry (DSC), Hot Disk Thermal Diffusivity measurements, Hot plate device and Infrared Thermography. These analyses provided insights into the thermal conductivity and demonstrated the impact of PCM latent heat on thermal peak shaving and shifting. The results indicate that increasing PCM concentrations lead to progressively larger time shifts in thermal oscillations as they propagate through the material.

Paper 458 **3** **Passive Radiative Cooling Performance of Nanostructured Poly(vinylidene fluoride) (PVDF) inside Aluminium Anodic Oxide (AAO)/Al**
Mrs. Amaia Iglesias-Elcano, Spain
Oral Presentation (20')

Abstract

The last few decades have seen a significant increase in energy consumption associated with conventional refrigeration, which aggravates environmental problems related to pollution and global warming. In this context, new technologies that do not rely on external energy supply, like Passive Daytime Radiative Coolers, are being developed. For a material to have potential as a 24-hour radiative cooler, it must have a high reflectance in the solar spectrum and a high emittance in the infrared, in particular, in the atmospheric transmission window between 8-13 μm .

Among the materials used for this application are polymers, like Poly(vinylidene fluoride) (PVDF). This material has a high infrared emissivity associated with the vibrational modes of the functional groups that compose them. Furthermore, studies have shown that their nanostructuration enhances their solar reflectance. One way to achieve this is through their infiltration inside one- and three-dimensional Aluminium Anodic Oxide (AAO) templates. Their morphological properties such as inter-channel distance or pore diameter can be tuned to obtain the highest reflectance values possible.

In this work, 1D- and 3D- PVDF metamaterials have been obtained by their infiltration inside AAO templates, with the optimization conditions carried out from the beginning. As well as that, three different cooling rates have been applied to study the polymer's different phases: natural cooling, fast cooling with a cold heat dissipator and ultrafast cooling with liquid nitrogen.

Moreover, the morphological, chemical characterization, and the crystallographic structure of the nanostructures were analysed conducted under different infiltration conditions. Additionally, the optical characterization of the polymeric (PVDF) metamaterials was performed by measuring the reflectance in the solar spectra, in the wavelength range from 300 nm to 1200 nm, and the emittance in the IR, from 2.5 μm to 17 μm . From these values the theoretical cooling power and cooling temperature of the material under direct sunlight and at night was calculated. The maximum cooling power and temperature were found to be -135 W/m² and 10 °C, respectively, for the case of 3D -PVDF without AAO / Al and fast cooling.

Towards nearly zero energy buildings (nZEBs) with smart optical materials

Dr. Amador Menéndez-Velázquez, Spain

Oral Presentation (20')

Abstract

The transition towards nearly zero energy buildings (nZEBs) requires innovative approaches to enhance energy efficiency and integrate renewable energy sources. In this context, smart optical materials emerge as key enablers of sustainability, as they interact dynamically with their surroundings, providing adaptive responses to environmental demands. This work explores two classes of smart materials and applications: luminescent materials for luminescent solar concentrators (LSCs) [1] and photochromic materials for smart windows [2].

LSCs can be integrated into windows, transforming them into energy-generating elements by capturing and directing solar radiation to photovoltaic cells, thus enhancing energy harvesting and electricity generation in urban environments. Meanwhile, photochromic smart windows dynamically adjust their transparency in response to solar irradiation, reducing heating and cooling demands, improving indoor comfort, and contributing to overall energy savings.

This work explores strategies to enhance LSC performance, including molecular alignment techniques [3] and spectral conversion approaches [1,4]. Furthermore, the potential of hybridizing LSCs with photochromic molecular systems will be discussed. This integration enables the development of multifunctional smart windows that not only regulate light transmission to reduce energy consumption but also generate electricity, creating an innovative solution that simultaneously enhances energy efficiency and sustainability. The incorporation of these advanced optical materials and devices represents a significant step toward sustainable building design, paving the way for energy-efficient, self-sufficient, and adaptive architectural solutions.

Paper 2153 1 Stress evolution during thin film growth: in situ studies of interface reactivity and structure formation at the nanoscale

Prof. Gregory Abadias, France

Keynote (Oral Presentation 40')

Abstract

The issue of stress in thin films and functional coatings is a persistent problem in materials science and technology that has congregated many efforts, both from experimental and fundamental points of view, to get a better understanding on how to deal with, how to tailor, and how to manage stress in many areas of applications.

In this talk, I will present the recent advances in our understanding of stress evolution during polycrystalline metal film growth, based on in situ and real-time diagnostics. These include simultaneous measurements of stress, structure and morphology of the growing layer using a combination of wafer curvature and X-ray scattering (XRD and XRR/GISAXS). In particular I will show the importance of interface reactivity on the intrinsic stress of nanoscale systems used in micro- and opto-electronics applications.

Two different systems will be showcased: the growth of ultrathin Ag layers on weakly interacting substrate (SiO_2) and the growth of silicide (germanide) compounds that spontaneously form at the interface during growth of Mo, W or Pd on amorphous Si (or Ge). For the former case, the impact of reactive plasma ($\text{Ar}+\text{N}_2$) on the nucleation and coalescence stages of Ag islands will be discussed. The presence of N species adsorbed on the substrate surface not only improves the wetting of Ag but also leads to incomplete coalescence, and as a result to the formation of a continuous Ag layer at lower nominal thickness. By selective deployment of N_2 we could tailor the Ag growth morphology without compromising the optical and electrical properties, which is key for the design of ultrathin Ag layer as transparent conductive electrodes. For silicide layers, our findings uncover a thickness-dependent crystallization process during growth associated with the development of tensile stress. In the case of W-Si alloys, a wide range of stress state (compressive or tensile) is observed depending on the phase and texture formation.

Overall, our real-time and in situ methodology makes it possible to disentangle different origins of stress build-up (interface formation, phase formation, grain growth, and texture) on the nanoscale.

Growing TiN/TiB superlattice thin films via multi-cathode DC magnetron sputtering

Mr. Thomas Pinter, Austria

Oral Presentation (20')

Abstract

Transition metal borides like TiB_2 are known to exhibit excellent hardness and strength as well as extremely high thermal stability. Like other ceramics, fracture toughness and brittleness in general are considered weak points that limit their use in certain applications. While hexagonal TiB_2 is the thermodynamically stable version of Ti-borides, ab-initio calculations indicate the existence of a metastable face-centered-cubic TiB with supposedly low stacking fault energy, potentially supporting the enhancement of plasticity through the formation of mechanical twins upon deformation.

We report the deposition of TiN/TiB superlattice thin films via physical vapor deposition (PVD), with TiN acting as a stabilizer for the formation of the metastable TiB phase. Cross-sectional transmission electron microscopy (TEM) reveals well-defined multilayer structures with coherent interfaces, while X-ray diffraction (XRD) highlights the superlattice effect contributing to the films' mechanical strength. We give a comprehensive overview of the material design, fabrication techniques, and the interplay between structure and properties, highlighting not only the possibility of using the template effect to stabilize otherwise unstable phases but also showcasing a superior combination of strength and ductility through nanotwinning effects.

Paper 874 **3** **Nanostructure engineering and properties enhancement of Cu-based films by Zr and Ta alloying**
Ph.D. Mariia Zhadko, Czech Republic
Oral Presentation (20')

Abstract

Nanocrystalline Cu films exhibit unique mechanical properties due to the increased surface area of grain boundaries. However, this structural state creates excess free energy leading to low thermal stability. Our study addresses this challenge through targeted alloying of magnetron sputtered Cu films with low content of Zr and Ta. The mutual immiscibility and large atomic size mismatch between Cu and Zr or Ta have the potential to influence grain boundary chemistry and structure implying grain boundary engineering approach. Magnetron sputter deposition, in turn, represents a non-equilibrium technique widely used for reproducible preparation of thin films with a variety of structural states, including both thermodynamically stable and metastable structures.

Nanocrystalline Cu-rich Cu-Zr and Cu-Ta films were deposited from two separate targets of the base metal (Cu) and alloying element (Zr or Ta) under identical technological conditions with a fine composition variation. The effects of Zr and Ta alloying on the structure, surface, mechanical, and electrical properties were investigated using X-ray diffraction, electron microscopy, atomic force microscopy, indentation, and the four-point probe method. Additionally, non-equilibrium atomic-scale growth simulations of Cu-rich Cu-Zr and Cu-Ta films were conducted to provide information not achievable experimentally.

The results show that alloying with Zr and Ta significantly influences the microstructure and anisotropy of the films, which leads to a notable structural refinement and a reduction of the average grain size from 220 nm in unalloyed Cu to below 100 nm with Zr or Ta alloying. A systematic investigation shows that during film deposition, a redistribution of alloying atoms occurs between the grain interior and grain boundaries resulting in the formation of a complex microstructure. As a result, the alloyed films exhibit hardness values between 3.2 and 4.2 GPa, exceeding the 2.5 GPa measured for the unalloyed Cu film. The electrical resistivity increases with increasing content of the alloying elements, primarily due to electron scattering by solute atoms and additional scattering at the grain boundaries. However, the as-deposited alloyed Cu films exhibit a favorable combination of hardness and electrical conductivity that is comparable to or better than reported values in literature.

Our findings demonstrate that precise alloying with Zr and Ta, combined with non-equilibrium conditions of magnetron sputter deposition, is an effective approach for modifying the structural state of the Cu films, optimizing their mechanical, electrical, and surface properties, and offer insights that can be applied to other comparable binary systems in the development of nanocrystalline metallic films.

Paper 2117 4

Study of ceramic materials by magnetron sputtering for barrier properties in paper-based food packaging

Dr. Mariana Marques, Portugal

Oral Presentation (20')

Abstract

The growing worldwide challenge with plastic waste management requires an urgent investigation into sustainable packaging alternatives. The use of paper with bio-barrier properties in food barrier packaging solutions, namely flexible packaging, cups, lids, straws, and capsules, emerges as a solution to tackle this problem. Furthermore, this transformation is essential to accomplishing the objectives of the Green Deal, guaranteeing an efficient transition to a climate-neutral and eco-friendly economy. By acknowledging this, the present work proposes and explores the integration of ceramic thin films through magnetron sputtering (PVD technology) onto paper substrates to improve their barrier properties against oxygen, water vapour, and oil. PVD coatings can be deposited as a first layer on the paper (monolayer), with additional coatings applied by other technologies like spray-coating, screen-printing, knife-coating, layer-by-layer, extrusion coating, and other solutions (multilayer). Hybrid multilayers, combining multiple coating technologies, represent a significant innovation and provide the capability to integrate diverse functionalities to enhance the overall paper-product performance.

To assess the effectiveness of these hybrid multilayers, tests for grease resistance, oxygen transmission rate (OTR), and water vapor transmission rate (WVTR) were performed. Additionally, a study to evaluate how the thickness of the ceramic thin film affects the barrier qualities is undergoing. In fact, the film thickness achieved with PVD deposition is rather low and may not be enough to completely cover the porosity of the paper, which impacts the barrier effect. Thus, this comprehensive study is fundamental to understanding the effect of the PVD films in both the monolayer approach and within the overall multilayer system.

The current study was developed within the scope of the Agenda "From Fossil to Forest-Sustainable Packaging and Products to Replace Fossil Plastic" [C644920945-00000036] Project nr. 8], financed by the RRP-Recovery and Resilience Plan under the Next Generation EU from the European Union.

Paper 699 **5** **Impact on the B/Ti-ratio on microstructure and mechanical properties of DCMS and HiPIMS TiB₂±z thin films**
Mr. Ludwig Enzlberger, Austria
Oral Presentation (20')

Abstract

Titanium diboride is widely known as a superhard material achieving an indentation hardness of 40 GPa and beyond. Coatings of TiB₂ produced by DC magnetron sputtering are typically in the superstoichiometric regime regarding the B/Ti-ratio in a range of TiB_{2.4} to TiB_{3.5}. This surplus in Boron is attributed to a different radial distribution of Boron and Titanium during the deposition process and forms a B-rich tissue phase which is highly relevant for the material's mechanical properties.

A reduction of Boron content in the coating would thus mean a reduction of tissue phase formed and consequently a clear change in e.g., hardness or fracture toughness. Earlier works have already shown an increase in fracture toughness (measured by microcantilever bending) of DC-sputtered TiB₂ when reducing the B/Ti-ratio from 4.4 to 2.1. There have also been reports of even higher fracture toughness in understoichiometric TiB_{1.43} produced through HiPIMS and measured by cube corner indentation, although films grown by DC showed a decrease in KC with decreasing B-content.

In the current work, we aim to show how the mechanical properties of TiB₂ change when crossing the stoichiometric point by DC and HiPIMS sputter deposition. The stoichiometry of DC-grown films is controlled by placing pieces of pure Ti along the race track of the target, while in HiPIMS mode it is controlled by varying the pulse on-time as well as adding pieces of Ti. The films are analysed through XRD and SAED for structural information, ICP-OES to determine the B/Ti-ratio as well as SEM and TEM for microstructure. Hardness and Young's Modulus are measured by nanoindentation while KIC values are determined by cube corner indentation and microcantilever bending to investigate the influence of stresses.

Innovative plasma nitriding process of a biomedical grade CoCrMo alloy by High Power Impulse Magnetron Sputtering

Dr. Valentina Zin, Italy

Oral Presentation (20')

Abstract

Medical implants are requested to meet stringent requirements to ensure their safety and reliability over long periods within the human body. Cobalt-Chromium-Molybdenum (CoCrMo) alloys are widely used in this field due to their excellent mechanical properties, corrosion resistance and biocompatibility. However, concerns about ion release and wear debris from implants [1], especially in Metal-on-Metal (MoM) applications, highlight the need for improved surface treatments to mitigate tribocorrosion effects and enhance implants durability. Surface engineering such as the application of protective coatings or nitriding treatments can reduce the effects of wear and corrosion as well as material release, addressing challenges like adhesion failure and wear debris generation in service. Surface conversion treatments, as nitriding and carburizing, are effective alternatives to coatings for improving tribocorrosion resistance of biomedical implants, enhancing mechanical strength, wear, and corrosion resistance, and can be tailored to meet specific implant requirements. Plasma nitriding, a recent and versatile technique, offers energy and cost efficiency, shorter treatment duration, and improved nitrogen uptake compared to traditional methods. Among plasma treatments, those based on magnetron sputtering technology appear particularly attractive, such as HiPIMS-based (High Power Impulse Magnetron Sputtering) low-pressure nitriding [2], which promotes superior nitrogen diffusion at lower temperatures, reduces oxygen interference and allows duplex treatments with the following application of protective coatings. The present study uses the HiPIMS discharge in an innovative way to perform a plasmachemical surface treatment on a CoCrMo alloy, modifying the target materials exploited to sustain the plasma, to affect nitrided layer properties. Among the target materials, i.e. Cr, Ti, Mo and Ta, molybdenum demonstrates the best overall performance, facilitating the formation of the desired γ N phase without the presence of secondary phases, enhancing mechanical properties and chemical stability. The nitriding process results in an increase in hardness, up to 18 GPa, which is significantly higher than that of the untreated CoCrMo alloy (~6 GPa). Moreover, the nitriding environment has been investigated, by changing the H₂/N₂ flow ratio in the chamber during the HiPIMS process. It has been demonstrated that all nitrided samples exhibit a positive shift in corrosion potential values in Ringer's solution, indicating improved corrosion resistance, reduced wear rate and smoother wear scars, compared to pristine samples, thus balancing wear and corrosion resistance effectively. These results highlight the potential of tailored plasma processes for biomedical applications. [1] N. Espallargas et al, Wear 332–333 (2015) 669–678 [2] P. Paper 413 1 **Amorphous Al₂O₃ Thin Films: The Influence of Alloying Elements on Dielectric Properties at High Temperatures**

Mrs. Norma Salvadores, Austria

Highlight (Oral Presentation 20')

Abstract

Aluminium oxide (Al₂O₃) is a widely recognized insulating material used as a thin film in various applications. This material obtains several polymorphs and features also an amorphous state, providing high oxidation resistance and excellent thermal stability. One significant advantage of amorphous-grown PVD films is typically their lack of pinholes and fewer diffusion paths for charge carriers. Research into the use of insulating Al₂O₃ thin films is ongoing in multiple fields, including as a dielectric substance in electronics, semiconductor applications, and energy storage. Therefore, exploring economically and sustainably viable deposition techniques for growing insulating Al₂O₃ thin films is essential.

The study examines how alloying Al₂O₃ thin films with silicon and yttrium-zirconium (YZr) affects the thermal stability of the amorphous state, aiming to prevent any phase transitions up to 1200 °C. To achieve this, Si and YZr were incorporated into the used target materials. Amorphous Al₂O₃ thin films have been synthesized using a reactive Modulated Pulse Power (MPP) process carried out in mixed Ar/O₂ atmospheres on a custom-developed sputter system (equipped with 3-inch targets). The formation and evolution of the amorphous state have been studied using in-situ X-ray diffraction (XRD) over a temperature range from room temperature to 1200 °C. Scanning and transmission electron microscopy (SEM) has been employed to assess the deposition rate and morphology of the coatings. Additionally, in-situ impedance spectroscopy has been used to investigate changes in electrical properties across various temperatures. For this procedure, photolithography has been utilized to deposit titanium/platinum (Ti/Pt) electrode pads for electrical characterization. The chemical composition of the films was determined using X-ray photoelectron spectroscopy (XPS), which also helped to examine the bonding nature of the elements present in the films.

Paper 1196 2 Helium-assisted deposition of Cu-doped TiO₂ for Conductometric Hydrogen Sensing via DC Magnetron Sputtering
Mr. Akash Kumar, Czech Republic
Oral Presentation (20')

Abstract

This study presents a novel helium-assisted sputter deposition method for Cu-doped TiO₂ conductometric sensors, intending to enhance the active surface area through microstructure modification, thereby improving sensing capabilities. This is achieved by careful optimization of discharge parameters, while the working gas consists of a mixture of argon, helium and oxygen. Partial replacement of argon with helium leads to the formation of structured porous films. The influence on the sensing response and the possible explanation of the effect in helium-rich working gas are discussed.

Cu-doped TiO₂ films were fabricated using conventional DC magnetron sputtering, utilizing a circular titanium target with an adjacent copper strip in carefully controlled working gas mixtures of argon, helium, and oxygen, maintaining a total pressure of approximately 520 mPa. Helium was introduced as a replacement for part of argon in the working gas mixture of argon and oxygen. After deposition, samples were annealed at 400 °C in ambient air to crystallise and stabilize the films for hydrogen sensing. A series of different helium concentrations was prepared, varying the helium content from 0% to 95% in the working gas. The glancing angle deposition (GLAD) technique was applied to enhance the films' active surface area. The copper doping was chosen to make the films more conductive since the undoped titania films are nearly insulating.

X-ray diffraction patterns revealed the effect of helium on film microstructure: Films deposited under helium exhibit both anatase and rutile phases, whereas films deposited without helium show only the anatase phase. Scanning electron microscope observation reveals a grain size reduction with increasing plasma helium content. Nevertheless, the most pronounced effect was the distinct change in the structure, which appears highly porous for the films prepared with helium. Conductometric sensing was carried out using a four-point probe, demonstrating that helium usage leads to a 600% increase in sensor response for Cu-doped TiO₂ films (maximum He vs 0% Helium).

This paper further discusses the He-induced effects leading to microstructure modification. The discharge with He-rich working gas specifics is also mentioned. The effect of the GLAD is also presented.

Paper 1316 3

Assessing hydrogen diffusion in ceramic PVD coating materials

Prof. Helmut Riedl, Austria

Oral Presentation (20')

Abstract

The introduction of hydrogen-based energy production, storage, and conversion technologies requires materials that can withstand hydrogen's unique and reactive properties. A key concern is the durability of structural components, particularly issues like hydrogen embrittlement and corrosion in fuel cell and electrolyzer technologies. These factors are crucial as we transition to green and sustainable energy sources. Specifically, the interaction of hydrogen with the uppermost micrometers and the microstructural features of materials will significantly influence their performance. Thus, employing physical vapor deposition (PVD) coating materials to protect and enhance material surfaces will be essential for a wide range of future applications. Degradation mechanisms related to hydrogen occur at multiple length scales, involving different strategies for exposure or treatments. These strategies are typically divided into the two hydrogen-related material research worlds: (i) electrochemical degradation setups and (ii) and non-electrochemical treatments as a collective term for pressure/gas-related setups. Nevertheless, the broad field of hydrogen-related applications is increasingly merging. Consequently, the different degradation strategies primarily focus on electrochemical test setups as they are highly versatile. Therefore, in this study, the interaction of hydrogen with well-known protective coating materials such as TiN, CrN, ZrN, or TiAlN and AlCrN is described by an electrochemical Devanathan-Stachurski permeation setup. Different sets of these ceramic coating materials have been deposited on ferritic steel sheets through sputter and arc-evaporation technologies with varying deposition parameters. Subsequently, the coatings have been electrochemically loaded, and parameters such as diffusion coefficients, permeability, or permeation reduction factors are estimated. These results are correlated with the coatings' microstructural appearance before and after hydrogen testing using a set of diverse high-resolution techniques such as SEM, TEM, XRD, and micro-mechanical testing methods.

Paper 300 4 **Effect of Sputtering Conditions and Post-Deposition Treatment on Structure and Properties of CrZrNbN Thin Films**
Dr. Sayedalireza Ataie, Czech Republic
Oral Presentation (20')

Abstract

Protective coatings are increasingly valued for their exceptional resistance to corrosion, oxidation, and wear. Chromium-based thin films have emerged as a primary choice due to their commendable properties since their development in the 1990s. However, the demand for enhanced performance under more challenging conditions necessitates improvements in wear and oxidation resistance. Thus, CrN and CrAlN thin films require further enhancement through innovative approaches. This study investigates the effect of sputtering parameters, such as nitrogen flow rate, discharge power and substrate temperature, on the structure, mechanical properties and oxidation behavior of CrZrNbN thin films. These films were produced via reactive high-power impulse magnetron sputtering of a single CrZrNb (40:30:30) target in argon-nitrogen mixtures. Analysis using energy-dispersive X-ray spectroscopy, X-ray diffraction, X-ray photoelectron spectroscopy, and Raman spectroscopy demonstrates that precise controlling the sputtering parameters, as well as variations in the oxygen content (ranging from trace amounts to significant levels), can significantly alter the phase compositions (from solid solutions to novel crystalline phases). In addition, microscopy analysis (scanning electron microscopy and atomic force microscopy) revealed a significant influence of these parameters also on the morphology of thin films. The resulting phase changes, combined with a multilayer oxygen-induced design, can enhance the hardness, tribological properties, oxidation resistance, and self-healing capabilities of CrZrNbN thin films. The findings of this study may serve as a foundation for the development of smart surfaces featuring multifunctional thin films.

Paper 877 **5** **Study on Microstructure and Mechanical Properties of Nanoparticle-Coated Maraging 300 for Iron-Based MMCs**

Mr. Jongtae Kim, South Korea

Oral Presentation (20')

Abstract

Metal matrix composites (MMCs) are promising materials due to their high specific strength, hardness, wear resistance, and relatively low density, making them widely used in civil engineering, aerospace, electronics, and automotive industries. Although Ti- and Al-based MMCs have excellent performance, their high cost and limited availability restrict their use in general industrial applications. In contrast, iron-based MMCs have attracted attention due to their lower cost, good mechanical properties, high thermal stability, and wide applicability. In particular, particle-reinforced iron-based MMCs with additives such as Al_2O_3 , Y_2O_3 , and TiC have shown great potential for high-performance materials by providing uniform microstructures and improved mechanical strength. However, conventional casting and powder metallurgy methods for fabricating particle-reinforced MMCs often face challenges in achieving uniform dispersion of nanoscale reinforcement. Strong van der Waals forces between nanoparticles cause agglomeration, leading to non-uniform distribution in the matrix, which can reduce mechanical performance. Additionally, traditional mixing and sintering processes may result in particle growth and microstructural segregation, limiting the full benefits of reinforcement. To overcome these challenges, this study applied powder metallurgy techniques by coating Maraging 300 powder with nanoscale ceramic particles to produce an iron-based MMC. The microstructure and mechanical properties of the composite were analyzed using X-ray diffraction (XRD), scanning electron microscopy (SEM), energy-dispersive spectroscopy (EDS), electron backscatter diffraction (EBSD), microhardness testing, and compression testing. This research provides insights into the effects of nanoparticle dispersion and reinforcement mechanisms in iron-based MMCs.

Operational properties of Mn_{1.9}CuFe_{0.1}O₄ protective coatings deposited on ferritic stainless steels of different Cr content for SOC application

Dr. Agnieszka Zurawska, Poland

Oral Presentation (20')

Abstract

The technology of solid oxide electrochemical cells (SOC) is attracting a huge scientific interest because it is seen as the most efficient green technology for generating hydrogen or electricity, with a high commercialization potential. Therefore it requires further material development to prolong the failure-proof operation time and to reduce its cost. One of the key components of a SOC stack is the interconnect, that has a role to conduct electrical current between adjacent cells and serve as a separator for the air and fuel zones. It is exposed to high temperatures (~700°C) and corrosive factors (oxygen, hydrogen, steam), which dictate the choice of material: ferritic stainless steel (FSS). This generates challenges such as the growth of oxide scale and the evaporation of chromium compounds that poison the air electrode. To mitigate it, protective coatings made of spinel-structured oxides are used. The state-of-art coating materials rely on critical raw materials, specifically Co. The presented approach is using Cu-based coatings, which seems promising concerning price, conductivity, and sustainability. Moreover, the common usage of specially designed steel Crofer 22APU for small scale studies is hampering the up-scaling. Since only a single producer offers this material, its price is high, and its availability is limited.

The aim of the study was to investigate Co-free coatings deposited on four generic types of FSS differed in Cr content (15-18 wt%) for their potential application as interconnect. Steel samples were subjected to different pre-oxidation procedures and coated with a 15-30 µm layer of Mn_{1.9}CuFe_{0.1}O₄ powder by colloidal processing. The sintering procedure was adjusted to technical aspects of possible implementation for full scale interconnects and allowed to obtain layers of 20% porosity. Obtained samples were then subjected to ASR measurements in temperature range 620-750°C, with 200h hold at 700°C. SEM/EDS was used to analyse the surface of oxide scales, the surface and cross-section of the protective coatings before and after the sintering, as well as post-test. Special focus was given to the intermediate layers formed at the interface between the steel and the coating. The results indicate that K41 steel is the most perspective for applied studies and that Mn_{1.9}CuFe_{0.1}O₄ powder can offer desired properties of the coating.

Paper 1295 2 Plasma etching-controlled microstructure and optical properties of ZrN Coatings on ABS for automotive applications
Dr. Zohra Benzarti, Portugal
Oral Presentation (20')

Abstract

Zirconium nitride (ZrN) coatings of 750 nm thickness were deposited on plasma-etched acrylonitrile butadiene styrene (ABS) substrates using low-temperature direct current reactive magnetron sputtering. Argon plasma etching time and pressure were varied from 2 to 8 minutes and 0.4 to 1.5 Pa, respectively, under a -70 V bias. Plasma etching modified the substrate's surface reactivity, roughness, and hydrophilicity, leading to an increase of the total surface free energy (up to 50.2 mN/m). X-ray diffraction analysis showed that etching parameters influenced the coating's texture, with a predominant [111] orientation and a [200] texture emerging at 5 minutes of etching under 1.5 Pa pressure. Optimal etching (5 min at 0.4 Pa) resulted in ZrN coatings with a smooth surface, golden hue, high lightness ($L^* \approx 74\%$), and 62% total reflectance. Higher etching pressures (1.5 Pa) produced glossier coatings with fewer pinholes but introduced minor reflectance loss due to stress-induced cracking. Peel tests confirmed strong adhesion across all samples. These findings underscore the importance of plasma etching in optimizing both the functional and aesthetic properties of ZrN coatings, highlighting their potential for decorative automotive applications.

Paper 564 **3** **Nanocomposites based on transition metal borides and silver in view of mechanical and antibacterial properties**
Mrs. Katarzyna Zielińska, Poland
Oral Presentation (20')

Abstract

Transition metal borides are becoming increasingly popular due to their unique properties. They are outstanding not only for their very high hardness and fracture resistance, but also for their considerable chemical and thermal stability. Silver, on the other hand, is valued as an antibacterial material due to its unique biological properties. The combination of these two materials may enable the development of an innovative super-hard composite with antibacterial properties.

In this study, it was decided to create Ag/WB2.5, Ag/W0.84Ti0.16B2.5 nanocomposites and compare their properties to the individual composite components. The silver coating was produced by pulsed laser deposition (PLD), while the WB2.5 and W0.84Ti0.16B2.5 coatings were produced by high-power pulsed magnetron sputtering (HiPIMS). Subsequently were carried out a series of necessary tests for the realisation of the work's topic. The microstructure and surface morphology were characterised using a scanning electron microscope (SEM) with chemical composition analysis (EDS) and an optical profilometer. The observations revealed that the silver particles are uniformly covered by a coating of tungsten borides. This contributed to a reduction in the roughness of the composite compared to a layer composed of pure silver (Ra of about 100 nm).

In order to determine the mechanical properties, hardness tests, adhesion of the coatings by scratch-test and wear resistance by abrasion in reciprocating motion were tested. As a result of the presence of the silver film, the wear resistance increased compared to the coating composed of W0.84Ti0.16B2.5.

The biological properties of the materials were assessed by a test in a liquid suspension of Staphylococcus Aureus bacteria (Gram-positive bacterium). The samples were incubated in a greenhouse at 37°C for a specified time and then analysed for changes in the number of bacterial colonies.

Sintering Response of Columnar Thermal Barrier Coatings Deposited by Solution Precursor Plasma Spray (SPPS) Technique

Dr. Isha Gupta, United Kingdom

Highlight (Oral Presentation 20')

Abstract

Yttria-Stabilized Zirconia (YSZ) Thermal Barrier Coatings (TBCs) are widely used to protect gas turbine components from high-temperature oxidation and creep degradation. However, prolonged thermal exposure can lead to sintering, phase transformations, and cracking in the TBC, degrading its mechanical integrity by altering the elastic modulus and fracture toughness. Sintering is particularly critical for columnar coatings, which are engineered for high in-plane strain tolerance to mitigate the risk of delamination under thermal cycling. Recent studies on Axial Feed Solution Precursor Plasma Spray (SPPS) have shown promise for producing such columnar YSZ coatings while addressing the sedimentation issues of Suspension Plasma Spray (SPS) and the high costs of Electron Beam Physical Vapor Deposition (EB-PVD). In EB-PVD YSZ coatings, high-temperatures sinter the columns together, drastically reducing the strain tolerance. Since columnar SPPS-YSZ coatings have only been reported recently, their sintering response has not been widely investigated yet.

In this talk, we will provide a systematic assessment of the microstructure and mechanical property evolution of columnar SPPS-YSZ TBCs upon thermal exposure. Hastelloy disk specimens coated with SPPS-YSZ are subjected to 1150°C in air for 50-200 hours. Microscopy is used to quantify key microstructural changes that influence mechanical properties, including column density, vertical crack density, porosity, and thermally grown oxide (TGO) formation at the TBC/Hastelloy interface. Additionally, Rietveld refinement of X-ray diffraction (XRD) data is performed to analyze TBC degradation through phase transformations from stabilized tetragonal zirconia to the monoclinic or cubic phases. The second part of the talk will focus on the mechanical property evolution with increasing thermal exposure duration. The elastic modulus and hardness is measured at two length scales, using a nanoindenter and an instrumented-microindenter, while the toughness is assessed using the Palmqvist method. The observed behaviors are compared with those in SPS and EB-PVD columnar coatings reported in the literature. Our findings provide key insights into the microstructure-property correlations in SPPS-YSZ TBCs and their post-sintering delamination resistance.

Paper 1587 6 **Functionally graded laser deposition to overcome fabrication challenges in Tribaloy™ T800 hardfacing on stainless steel**

Mr. Shubhra Kamal Nandi, United Kingdom

Oral Presentation (20')

Abstract

Laser additive manufacturing by directed energy deposition (DED) of hard and brittle materials presents significant challenges. Tribaloy™ T800 (Co-17.5Cr, 28.5-Mo, 3.6Si in wt.%), a cobalt-based alloy, exhibit exceptional wear and corrosion resistance, however, its laser deposition to produce hardfacing coatings poses difficulties due to its limited ductility. The rapid cooling rates inherent to additive manufacturing, gives rise to significant thermal contraction strain which can lead to fabrication cracking and delamination in part due to high volume fraction of brittle Laves phase (~60 vol%) and low fracture toughness ($20 \text{ MNm}^{3/2}$) of the material. To address these challenges, a functionally graded T800 (FG-T800) is developed via in-situ alloying by blending the Tribaloy powder with stainless steel 316L (SS316L) powder. Alloying T800 with Fe and Ni reduces the proportion of the primary Laves phase and enhances the Laves-Co-solid solution eutectic aggregate, improving the toughness of the alloy at the expense of hardness. This understanding is leveraged to fabricate a four-layer 2mm thick clad, comprising a T800 top layer with successive layers of pre-blended T800-SS316L powders in ratios of 9:1, 3:1, and 3:2. This graded structure achieves a spatial variation in composition, microstructure, and mechanical properties along the build depth. The FG-T800 clad retained superior surface hardness (903 HV5) and wear resistance ($1.4 \times 10^{-5} \text{ mm}^3 \text{N}^{-1} \text{m}^{-1}$), comparable to monolithic T800 deposit, while exhibiting significantly improved toughness in the interior regions. Serial sectioning along the build direction revealed a progressive reduction in fabrication cracks while approaching the clad-substrate interface. This improvement is attributed to the gradual incorporation of SS316L, which modifies the Laves phase morphology and distribution, reducing brittleness while preserving the tribological advantages of T800 at the surface. The study demonstrates the potential of functionally graded laser cladding to mitigate cracking in hard and brittle materials, enabling the fabrication of robust, high-performance coatings for demanding applications.

Paper 1182 1 **Insights into the Origins of Friction in Hard Materials from Two-Axis Nanoindentation**

Prof. George Pharr, United States

Keynote (Oral Presentation 40')

Abstract

Friction is commonly thought to be controlled by processes in small asperities between two sliding surfaces. The asperities hold a large fraction of the mating surfaces apart and thereby dramatically increase the local contact stresses. In this study, a special two-axis nanoindentation system was used to examine the mechanics of deformation of micron-scale asperity contacts by sliding a spherical diamond indenter with a radius of $\sim 2 \mu\text{m}$ over a flat plate of fused silica under a combination of normal and transverse loading. The nanoindentation system is comprised of two independently controlled nanoindentation actuators oriented transverse to each other in such a way that the forces and displacements of each can be independently controlled and monitored. The two actuators can also be operated in continuous stiffness mode (CSM) to measure both the normal and transverse contact stiffnesses and the degree of energy dissipation during sliding through the phase shift of the CSM load and displacement oscillations. Tests were conducted by holding the normal force on the spherical indenter constant and ramping the lateral force at a constant rate. The extent of plasticity during sliding was varied by controlling the magnitude of the normal load so as to produce either a perfectly elastic contact or a combination of elastic and plastic deformation. Atomic force microscopy (AFM) was used to image the scratch tracks, and finite element simulations were used to confirm and explain some of the observations from the nanoindentation data. Results are presented and discussed in terms of prevailing ideas on the mechanistic processes that control friction in single asperity contacts, with special emphasis on differences between purely elastic contact and contact that involves both elastic and plastic deformation.

Dynamic Nanoindentation – A Key to Advanced Materials Understanding Under Extreme Conditions

Prof. Verena Maier-Kiener, Austria

Oral Presentation (20')

Abstract

The demand for materials capable of withstanding extreme environments—such as high and cryogenic temperatures, aggressive electrochemical conditions, and high strain rates—has driven the evolution of nanoindentation techniques. Dynamic nanoindentation, particularly continuous stiffness measurement (CSM), has emerged as a powerful tool for characterizing mechanical properties beyond conventional quasi-static methods. By enabling real-time analysis of hardness, modulus, and time-dependent deformation behavior, dynamic nanoindentation provides critical insights into material performance under application-relevant conditions.

Recent advancements have extended these methods to extreme testing environments, including in-situ electrochemical charging, high-temperature oxidation-resistant coatings, and cryogenic material studies down to liquid helium temperatures. A further enticing proposition for materials scientists is to characterize the flow behavior of materials with minimal experimental effort while ensuring highly reliable results. Although it is established as a standard method for extracting hardness and Young's modulus, the technique has not been fully exploited for determining localized flow curves. This gap exists due to the inherent challenges in understanding the correlations between mechanical properties obtained from spherical indentation experiments and uniaxial data. To address this issue and accurately account for tip imperfections, a calibration procedure based on fundamental geometrical considerations is applied. This procedure lays the groundwork for strain-rate-controlled experiments, enabling the depth, thus strain dependent evaluation of the constraint factor while considering mechanical properties and induced strain.

These protocols are applicable under both ambient and non-ambient conditions, including electrochemical scenarios, by employing a novel in-situ electrochemical charging approach known as the side-charging cell. It is evident that electrochemical charging not only increases hardness and flow stress but also results in a reduced constraint factor. This reduction provides further insights, indicating a significant influence on the deformation behavior under electrochemical charging.

This contribution highlights the latest developments in dynamic nanoindentation and demonstrates its crucial role in accelerating high-throughput materials design for next-generation engineering applications. By bridging the gap between laboratory precision and real-world conditions, dynamic nanoindentation paves the way for a deeper understanding of materials under extreme conditions.

Strain rate dependence of slip vs. twinning in c-axis compression of α -titanium

Mrs. Kamila Hamulka, Switzerland

Oral Presentation (20')

Abstract

Deformation twinning plays a crucial role in governing the plastic behavior of hexagonal close-packed (HCP) metals, primarily due to the limited availability of easily activated slip systems. Twinning is often associated with reduced ductility and the generation of high residual stresses, which can contribute to material failure through cracking. Understanding the nucleation and propagation of twinning in HCP metals is essential for optimizing their mechanical properties and enhancing their performance in various engineering applications. In this study, we explore the strain rate sensitivity of deformation twinning and non-basal slip systems.

In-situ uniaxial compression tests of micro-pillars in single crystal pure α -titanium at different strain rates ($\dot{\epsilon}$), ranging from 10^{-3} to 45^3 s^{-1} . All experiments were conducted with the [0001] crystal orientation aligned with the loading axis. The crystallographic orientation, active slip systems as well as the distribution of the geometrically necessary dislocation (GND) within the deformed volume of the material were analyzed using post-mortem cross-sectional transmission Kikuchi diffraction (TKD) of the deformed pillars. Additionally, post-mortem transmission electron microscopy (TEM) is used to characterize the activated dislocations and twin plane features under different deformation conditions. A transition from slip-dominated to twin-dominated deformation is observed as the strain rate increased. At low strain rates ($\dot{\epsilon} < 10^2 \text{ s}^{-1}$), plasticity was primarily governed by dislocation slip, with twinning remaining inactive. In contrast, at high strain rates ($\dot{\epsilon} > 10^2 \text{ s}^{-1}$), plasticity was predominantly accommodated by {1T22} {1T23} deformation twinning. By combination of post mortem TKD and TEM techniques, our work adds new pieces towards the fundamental comprehension of deformation twinning in HCP metals at the micron scale and at high strain rates.

Paper 347 **4** **High Strain Rate Mechanical Behavior of Structurally Graded Materials Processed by Surface Mechanical Attrition Treatment (SMAT)**
Mrs. Mona Stoll, Germany
Oral Presentation (20')

Abstract

The service lifetime of structural components is often limited by surface-initiated failure. Surface hardening treatments aim at preventing crack initiation while preserving the properties of the bulk material. The so-called Surface Mechanical Attrition Treatment (SMAT) induces severe plastic deformation through repeated multidirectional impacts of ultrasonically accelerated spherical shots. This creates a gradient microstructure that transitions from nanocrystalline just beneath the treated surface to coarse-grained deeper within the sample. While significant hardening has been evidenced at conventional testing velocities, the behavior of this microstructurally graded layer at high strain rates - typical in collision scenarios and a common cause of component failures - remains less understood.

Nanoindentation tests at medium to high strain rates (0.1/s, 1/s, 10/s, 100/s) were conducted on cross sections of SMAT processed austenitic 316L steel, pure copper, and Inconel 718 to investigate their hardness and strain rate sensitivity. The hardness was evaluated using the Merle-Higgins-Pharr method for high strain rate nanoindentation testing. The measurements reveal a distinct hardness gradient within the SMAT layer, and show that the overall strain rate sensitivity of the SMAT treated material increases at high strain rates.

Toward High Strain Rate Nanoindentation Testing

Dr. Mohammed Tahir Abba, Germany

Oral Presentation (20')

Abstract

Knowledge about the local mechanical behavior at high deformation rates is crucial to increase the safety of components that involve impact loadings such as bird impacts in the aviation industry, automobile crashes and many others. In the past few years, the scope of nanoindentation has increasingly expanded toward high strain rates. However, the new developments are hindered by the equipment electronics, test methodologies and inertial effects at very high strain rates.

This talk will focus on both the technical implementation of high constant strain rate nanoindentation and the development of custom methods to analyze the high-speed data [1]. It will showcase a displacement-controlled instrument, which was designed around piezoelectric transducers and fast signal processing electronics allowing sampling rates of up to 1 MHz. Experimental measurements at strain rates of up to 10^5 s^{-1} will be demonstrated, along with a discussion of the current bottlenecks in high constant strain rate indentation.

Acknowledgement

Micromechanical Assessment of Electrodeposited Zinc Coatings: A Comparative Study of Spherical Nanoindentation and Micropillar Compression

Ph.D. Maria Watroba, Switzerland

Highlight (Oral Presentation 20')

Abstract

Zinc and its alloys have gained significant attention in biomedical applications due to their biocompatibility and controlled biodegradation properties. However, their widespread adoption for implants is limited by relatively low strength and brittleness in as-cast form. Due to Zn's low melting temperature (419.5°C, 0.43T_m), it exhibits unusual mechanical behavior at room temperature, including dynamic recovery, recrystallization, and enhanced grain boundary mobility. These thermally-activated processes, combined with limited work hardening and inverse Hall-Petch behavior below 25 µm grain size, make conventional strengthening strategies ineffective while making Zn an intriguing material for fundamental mechanical studies.

This research investigates the correlation between microstructure and mechanical behavior in electrodeposited (ED) Zn coatings, focusing on validating spherical nanoindentation (NI) methodology against established micropillar compression techniques for evaluating local plastic deformation in anisotropic HCP materials. Four distinct pure Zn coatings were synthesized under varying ED parameters, resulting in different grain sizes, morphology and crystallographic textures. EBSD analysis revealed that in all coatings, the c-axis <0001> direction was oriented perpendicular to the deposition direction and parallel to the surface, with a predominant {10-10} texture component whose {11-20} contribution increased with grain refinement and transition from columnar to equiaxed grains. The mechanical properties were evaluated using both spherical NI and micropillar compression techniques. Spherical NI was performed on both top surfaces and cross-sections to assess the influence of grain orientation on mechanical properties. The micropillar compression tests revealed yield strengths ranging from 100 to 800 MPa, with spherical NI showing similar trends but consistently lower values. Hardness and Young's modulus extracted from spherical NI tests in continuous stiffness mode were comparable to conventional Berkovich NI measurements. Detailed microstructural characterization and post-mortem analysis revealed that the discrepancy between NI and micropillar compression results was more pronounced in columnar microstructures but became negligible in ultrafine-grained equiaxed microstructures. This difference can be attributed to uniaxial loading in micropillar compression versus complex stress states in spherical NI, particularly significant in highly textured materials.

This study demonstrates that spherical NI can serve as a reliable alternative to micropillar compression for mechanical characterization of HCP materials, especially for ultrafine-grained microstructures. Moreover, unlike micropillar testing, spherical NI does not require FIB preparation, thus avoiding potential artifacts from ion damage. The comprehensive approach involved in this work provided valuable insights into the relationship between ED processing parameters, microstructure, and mechanical properties of Zn coatings.

Paper 1299 1 **How experimental micromechanics can help in the design of High Temperature Superconducting magnets**

Prof. Guillaume Kermouche, France

Highlight (Oral Presentation 20')

Abstract

The need for strong steady magnetic fields, above 40 T, raises several new challenges in the design of superconducting magnets. As a start, the field requested exceeds the limitations of the consolidated LTS technologies, leading us to the use of HTS technology. Besides the difficulty of making HTS magnets, the challenges at ultra-high field are found in the structural mechanics, driven by electromagnetic forces, and quench protection, due to the high stored energy density. ReBCO, the leading candidate for ultra-high field magnets, is produced in the form of thin tapes, consisting of multiple layers of different materials with very diverse nature and properties. Understanding the elastic and plastic behavior of these materials is crucial for both the magnet design process and advancing technological development to meet end-product requirements. However, the small size of HTS makes it impractical to employ macroscopic mechanical tests for characterizing the required mechanical properties at the right scale. In this paper we show how nanomechanical testing can help to address this issue. More specifically, elasticity, plasticity and toughness of REBCO materials are measured at the scale of the tape's constituents at room temperature and at cryogenic temperature (120 K). The paper concludes by highlighting the main results of our initial test and the forthcoming developments in the field of nanomechanical testing to aid in the design of HTS superconductors.

Indentation stress relaxation tests for studying transient plasticity in metals

Prof. Gaurav Mohanty, Finland

Oral Presentation (20')

Abstract

Nanomechanical tests are moving beyond regular hardness and modulus measurements to encompass host of different mechanical properties like strain rate sensitivity, creep, and fracture toughness. Developing the capability to measure stress relaxation behavior of materials will be useful to not only extend the gamut of properties studied at the micro/nanoscale, but also to study fundamental time-dependent deformation behavior of materials.

This talk will discuss the development of a novel indentation-based stress relaxation test that can reliably extract the activation parameters for deformation at micrometer length scales. The developed testing methodology, data analysis framework and the validation results will be presented. Nanocrystalline metals were selected for validation tests because they do not show size effects in indentation since hundreds of nanometer sized grains are interrogated in the indentation zone. Therefore, the micromechanical response can be considered to be “bulk” even in case of these small-scale tests. The indentation results were systematically compared with compression tests on micrometer sized pillars which have previously been shown to exhibit “bulk” scale behavior. A good match was found between both indentation and micropillar compression tests validating the developed testing methodology. Further, stress relaxation results on single crystal metals will be presented to study the operative deformation mechanisms. This opens the possibility to perform transient stress-relaxation tests on thin films and individual grains in future to systematically study the deformation mechanism(s) in a wide range of materials.

Separation of humidity, strain rate and temperature effect on the orientation dependent micromechanical properties of cortical ovine bone

Dr. Christian Minnert, Switzerland

Oral Presentation (20')

Abstract

Metabolic bone diseases such as osteoporosis have a significant impact on the bone quality and its properties. One out of three women and one out of five men at above the age of 50 are affected by osteoporosis [1]. However, only about 75% of the age-related increase in fracture risk can be attributed to a decrease in bone mass, bone density or changes in skeletal architecture [2]. To better understand the age- and disease-related increase in fracture risk, a closer look at the hierarchical structure of bone and its most important building blocks is required. The basic building blocks are type I collagen, hydroxyapatite and water. Water has a major influence on load transfer by facilitating interface sliding. The water content of healthy cortical bone is in the range of 10-20 vol.% but can drop to around 5 vol.% by the age of 60 [2].

In total 419 micropillars were tested in the axial and transverse fibril orientation under 56 different experimental conditions to study the effects of water content, temperature, and strain rate on the properties of ovine cortical bone. Quasi-physiological conditions and fracture relevant conditions were mimicked by varying the bone water content (3.1 wt.% - 8.3 wt.%), the temperature (25°C -60°C), and the strain rate (0.1-100 s⁻¹).

Micropillars were fabricated by femto-second laser ablation. Additional finite-element simulations were carried out to correct for the taper of the ablated micropillars. Polarized Raman spectroscopy was applied to determine the mineral-to-matrix ratio, the collagen quality and the orientation of the mineralized collagen fibrils. The analysis of the data with the paired t-test did not indicate any significant change in the amide I sub-band ratio, which suggests that the temperature and humidity applied did not degrade the collagen in the tested samples. The effect of temperature and water on the mechanical properties could finally be separated by applying a linear modeling approach. This results in a temperature related softening of 1.2 MPa/K and 33-111 MPa/wt.% water. Moreover, the activation parameters provide an indication about the rehydration process of bone. The results highlight the effect of hydration on the mechanical behavior of bone and are valuable for future multiscale simulations of fracture risk in patients, as the age- and disease-related decrease in the moisture content of bone can be taken into account.

Paper 1848 4 **Plasticity of olivine at high strain rates: an experimental micromechanics study on meteorite impact dynamics**
Dr. Szilvia Kalacska, France
Oral Presentation (20')

Abstract Olivine plasticity at ambient temperature governs the strength of a terrestrial planet's lithosphere during crustal divergence, convergence, and subduction. It also plays a crucial role in planetary collisions, influencing the formation of microstructures that accommodate impact-induced deformation. Such naturally occurring deformation processes bridge over a large strain rate regime, that is typically difficult to achieve under laboratory conditions using a single test piece. Small scale mechanical investigations allow us to focus on a few microstructural features in a well-controlled manner, using a scanning electron microscope.

Plastic deformation of olivine samples could be accommodated by dislocation generation and motion, but local stress-induced amorphisation and cracking can also happen during external loading. This work focuses on single crystal olivine pillars machined by FIB, that were compressed at various strain rates (from 0.001/s up to 1000/s). The micromechanical setup was coupled with acoustic emission detection to monitor the elastic waves emitted during the compression testing. High (angular) resolution EBSD is applied to study the dislocation structure before and after deformation. Differences in the deformation processes observed on the pillar surface morphologies and also in the collected data will be presented.

Paper 2122 5

A High-Throughput Framework For Pile-Up Correction In High-Speed Nanoindentation Maps

Dr. Daniele Duranti, Italy

Oral Presentation (20')

Abstract

Pile-up is a common issue in nanoindentation that occurs when material plastically deforms and accumulates around the indent, leading to an overestimation of mechanical properties such as hardness and elastic modulus. While the traditional method involves the use of AFM, which is accurate but time-consuming, this work presents a high-throughput approach leveraging optical profilometry to assess roughness variations induced by nanoindentation and correlate them with pile-up height, providing a fast and scalable correction method [1-2].

The framework was validated on bulk metals (Cu, Ti, Al, BMG) and thin coatings of 1µm thickness (Au, Cu, Ti). All materials were characterized using four high-speed nanoindentation maps at depths of 300 nm, 500 nm, 600 nm, and 1000 nm. A systematic methodology was developed to establish a linear correlation between surface roughness changes (Sa) measured by optical profilometry and pile-up height obtained via AFM. Finite Element Modeling (FEM) was employed to support the experimental findings and validate the calibration functions derived. The method was further applied to a cobalt-based alloy (Stellite 6B), a heterogeneous material with distinct mechanical phases, where machine learning-based clustering was utilized to selectively correct pile-up in the softer cobalt matrix while preserving the mechanical integrity of harder carbide phases. The implementation of this correction significantly reduced errors in hardness and modulus estimation, achieving an improvement of up to 7% in accuracy.

The results demonstrate that the developed method provides a reliable and efficient alternative to traditional pile-up correction techniques, making high-speed nanoindentation mapping more accurate and applicable to a wider range of materials. The identification of two distinct linear calibration functions, one for bulk materials and another for coatings, enables the framework's broad applicability. By integrating machine learning and high-throughput optical profilometry, this approach advances the precision of phase-specific mechanical property mapping, bridging a crucial gap in nanoindentation methodologies.

Lattice strain distribution in BCC polycrystals - How does the local grain neighbourhood influence microstructural strain level

Mr. Konrad Prikoszovich, Germany

Oral Presentation (20')

Abstract

Strain and stress heterogeneities determine the lifetime and failure of structural materials. Understanding the relationship between macroscopic and microscopic strains is essential for a quantitative assessment of the micromechanical behaviour of polycrystalline materials. In this work, we combine Diffraction Contrast Tomography (DCT), Far-field 3DXRD (FF-3DXRD), and Phase Contrast Tomography (PCT) measurements at beamline ID11 of the European Synchrotron Radiation Facility (ESRF) to capture the shape, arrangement, orientation, and average elastic strain tensor of a representative ensemble of grains during mechanical loading. The finalized dataset encompasses the relevant information for each grain within the investigated volume throughout the entire loading sequence.

Our analysis follows two distinct approaches: (1) a statistical analysis of strain tensor distribution evolution during loading across all grains, correlating mechanical grain behaviour with microstructural properties such as size, orientation and neighbourhood; and (2) a focused investigation of individual grains and their local neighbourhood and how the local properties affect the strain level in individual grains. By investigating grains with higher strain levels, we reveal microstructural factors relevant for strain localization and subsequent damage initiation.

In the talk, our latest findings on strain heterogeneities in bcc-iron as a model material are presented. We investigated more than 5000 grains representing the gauge section of a micro tensile samples during tensile deformation. Different annealing protocols have been utilized prior to the experiments to vary the eigenstrains of our samples in order to investigate how different initial eigenstrains affect the evolution of the strain distributions during loading. The deformation sequence predominantly focused on the elastic regime, with only the final two steps exceeding the yield strength. This experimental design allowed us to follow the transition from elastic to plastic deformation on the microstructural level for a large number of grains, providing relevant insights into micromechanical deformation behaviour.

Our approach presents a significant step forward in understanding the evolution of strain heterogeneities and microplasticity in polycrystalline materials during tensile deformation, with the potential to be also applied to multiphase materials and offering valuable insights for optimizing material design and processing strategies for more damage tolerant materials in structural applications and metal forming.

Paper 1326 1 **High-Speed nanoindentation mapping for a deeper understanding of microstructures**

Ph.D. Edoardo Rossi, Italy

Highlight (Oral Presentation 20')

Abstract

High-speed nanoindentation mapping (HSNM) has evolved into a scanning-probe-like technique, enabling large-area, high-resolution characterization of microstructures. By directly imaging variations in mechanical properties, phase boundaries, and deformation mechanisms, it provides critical insights into heterogeneous materials. However, key challenges remain, primarily in extracting phase-specific mechanical properties from large datasets, a task that requires statistical, machine learning and deep learning approaches allowing also to retrieve second-order information such as pop-ins, phase transformations, and strain localization events. Integrating HSNM with electron backscatter diffraction (EBSD) and energy-dispersive X-ray spectroscopy (EDX) further demands precise dataset alignment and registration algorithms to ensure accurate phase-property correlations.

In this work, phase identification in HSNM datasets is demonstrated using statistical machine learning techniques such as k-means++, k-medoids, Gaussian mixture models (GMM), and skew-normal deconvolution. Correlation with EBSD is performed through map registration and consensus algorithms, ensuring robust phase differentiation. A case study on advanced high-strength steels (AHSS) demonstrates the effectiveness of this approach in resolving mechanically distinct phases that are otherwise challenging to differentiate due to crystallographic similarities.

Pile-up effects pose an additional challenge in nanoindentation, leading to overestimation of hardness and modulus, particularly in compliant phases. Traditional correction methods rely on atomic force microscopy (AFM), limiting throughput and applicability to HSNM. Here, a high-throughput correction framework is introduced, leveraging HSNM-induced surface roughness changes quantified via optical profilometry and calibrated through machine learning. By selectively applying correction only to piling-up phases, universal calibration functions are derived, validated through finite element modeling, and demonstrated on WC-based hard metals, effectively eliminating AFM dependency.

Extracting phase-specific stress-strain behavior is another advancement. The interaction volume of spherical indenters is not only material-dependent but also poorly constrained, limiting phase resolution. Axisymmetric indenters provide a confined interaction volume, and when combined with HSNM-driven phase deconvolution, enable accurate phase-specific property extraction. Indenters of varying geometries introduce controlled stress states, distinguishing elasto-plastic responses at the nano-scale.

Paper 1154 2 **Evaluation of Strain Rate Sensitivity in a Superplastic Zn-1Cu Alloy: A Comparative Study of Nanoindentation Instrumental Effect**
Ph.D. Wiktor Bednarczyk, Poland
Oral Presentation (20')

Abstract

Strain rate sensitivity (SRS) measurements are widely employed to assess creep-related deformation at high temperatures or to determine the strain rate sensitivity parameter and activation volume of ultrafine-grained metallic materials at room temperature. The recently developed nanoindentation strain rate jump (SRJ) test has significantly accelerated SRS parameter evaluation in small samples and thin films. The introduction of constant strain rate loading has enhanced the reliability of this technique by minimizing depth-related effects. However, the repeatability of SRJ measurements across different testing devices and bulk samples remains largely unexplored.

In this study, the SRS of a room-temperature superplastic Zn-1Cu alloy processed via equal channel angular pressing (ECAP) and cold rolling was investigated. This material was chosen to exaggerate the SRS effect while minimizing challenges associated with high-temperature measurements. Bulk compression ($\varnothing 3 \times 4.5$ mm) and tension ($1 \times 2 \times 5$ mm) samples were fabricated using wire electro-discharge machining, while nanoindentation measurements were performed on polished surfaces perpendicular to the deformation direction. SRJ tests were conducted at three constant strain rates using KLA G200, Alemnis ASA, and Femtotools FT-NMT04 nanoindenters, as well as an Instron 5966 universal testing machine.

The results reveal significant discrepancies between different testing devices. Hardness SRJ curves from displacement-controlled nanoindenters exhibit abrupt changes in hardness values upon strain rate transitions, whereas the load-controlled KLA G200 shows a more gradual response with smaller variations between strain rate steps. Despite a relatively good correlation between nanoindentation and bulk behavior, notable discrepancies were observed. These findings underscore the need for further standardization and cross-validation of nanoindentation-based SRS measurements to ensure reliable comparisons across different testing platforms.

Paper 1716 3 Deformation twinning induced mechanical properties of layered twin-matrix FCC metallic materials

Prof. Maciej Szczerba, Poland

Oral Presentation (20')

Abstract

Deformation twinning effect on the properties of slip and twin systems of face-centered cubic structure and the critical resolved shear stresses will be shown. The plastic shear modes of the deformed matrix structure – single glide oriented Cu-8at.%Al alloy crystals deformed by room temperature tension up to the onset of deformation twinning - and the plastic shear modes of bimodal twin/matrix layered structure – subsequently twinned Cu-8at.%Al crystals – were examined. It was found that all twin and slip systems of the matrix structure may operate independently and their critical resolved shear stresses are dispersed by about fifteen percent around the mean value. However, not all of the accessible slip and twin systems of the twin/matrix structure may operate independently and their critical stresses may differ by a factor of well over four. Also, inverse temperature dependences of the detwinning stress of face-centered cubic deformation twins will be shown studying the effect of temperature on plastic deformation properties of the FCC twin/matrix structure. The critical resolved shear stress of detwinning was found to increase with temperature when plastic deformation occurred by the π detwinning mode. However, when the alternative $\pi/3$ mode of detwinning was activated, a decrease of the shear stress with an increase of temperature was observed. Thus, the twin/matrix structure behaved in two opposite ways, showing anneal hardening (the π mode) or anneal softening (the $\pi/3$ mode) with increasing temperature.

Paper 350 4 **Enhanced mechanical and tribological properties of nitrogen-doped PVD MoS₂ coatings in rolling-sliding contact**
Mr. Tizian Arold, Germany
Oral Presentation (20')

Abstract

Friction causes energy dissipation and wear in mechanical parts. The exorbitant cost that this could incur across the world is usually mitigated by the use of lubricants. Liquid lubricants are most common due to their ease of handling. However, under certain extreme environments, their use may not be feasible. That holds particularly for vacuum applications, for which molybdenum disulfide (MoS₂) is a very sought-after dry lubricant alternative. MoS₂ exhibits low friction values and high chemical stability across a broad range of temperatures and pressures.

Nitrogen doping has recently gained traction as a possible pathway toward further improving the mechanical properties and the tribological performance of transition metal dichalcogenides coatings, such as WS₂ [1]. To assess the impact of nitrogen-doping to PVD MoS₂ coatings, specimens were deposited by magnetron sputtering in a reactive nitrogen environment, using different gas flows. The resulting MoS₂ coatings were characterized for surface morphology and roughness, coating thickness and density, chemical composition, as well as mechanical properties. To evaluate the influence of nitrogen incorporation on wear and tribological behavior, all characterizations were performed both before and after rolling-sliding tests. Results demonstrate a beneficial effect of nitrogen doping on wear behavior without altering the friction coefficient under higher loads.

Paper 18 **5** **Influence of the interfacial strength on wear resistance in Ni-SiC composite**

Mr. Piotr Jencyk, Poland

Oral Presentation (20')

Abstract

Wear resistance is one of the most important properties for materials. Increasing its value is of interest for both scientists and industry. One of the typical approaches is to apply anti-wear coatings on mechanically poor materials instead of the use of high-end materials, usually expensive, in bulk.

Anti-wear coatings can be prepared by means of electrodeposition. However, the tribo-mechanical performance of deposited metal may not be reliable enough. To increase anti-wear properties even further, one can use co-electrodeposition in order to produce metal -matrix composite coating, such as Ni-matrix with SiC particles as reinforcement.

Properties of composites are derivatives of not only matrix and reinforcement, but also their interface. If the connection is weak, it may lead to premature fracture and poor performance. Macroscopically conventional methods to measure interfacial strength are tensile and bending tests. However, one has to take into account geometry of the interface. Especially for micro-sized samples, where interface cannot be considered flat anymore. In this work, we combined experimental and numerical methods to study interfacial strength in Ni-SiC composites and its influence on wear resistance.

New experimental procedure includes FIB-milling of micro-beams with matrix-reinforcement interface, beam bending with nanoindenter until fracture and AFM scanning of fracture surface. Then, numerical approach was employed. FEM model was built based on experimental geometry of each studied micro-beam. Interfacial strength was computed.

Also, macroscopic wear was measured in typical ball-on-flat geometry. The results were analyzed based on interfacial strength results.

Both interfacial strength and wear resistance depend on fabrication process and method was proved useful for small-scale testing of experimental interfaces.

Stress-strain Relationship of Metals by Indentation Tests

Dr. Ude Hangen, Germany

Oral Presentation (20')

Abstract

The relationship between stress and strain in materials characterizes their deformation behavior, ranging from elastic loading at low stresses to yielding, work hardening, and eventual failure at higher stresses and strains. This relationship is typically determined through tensile tests using macroscopic samples. In the realm of 3D interconnects, the small volumes of material make traditional tensile tests impractical. Copper (Cu) interconnect structures can be evaluated using nanoindentation hardness and reduced modulus measurements, spherical indentation tests, and compression experiments on pillar structures. This paper explores the transition from elastic to plastic deformation in spherical indentation and highlights the significance of the constraint factor, which plays a crucial role in the relationship between hardness and yield strength and is material dependent. A comparison between the spherical nanoindentation stress-strain method and microscale pillar compression tests will be presented for Cu and Fe-Si. The indentation and compression experiments are performed on a new TI990 TriboIndenter platform with improved noise levels and sensitivity.

Paper 1221 1 Optimization methods for advancing thermoelectric materials into practical applications

Prof. Yaniv Gelbstein, Israel

Keynote (Oral Presentation 40')

Abstract

Thermoelectrics is an emerging technology for effective recovery of waste heat and its conversion into useful electricity without moving parts, noise or the release of harmful chemicals. Therefore, such converters exhibit a high potential to contribute to the global efforts to reduce CO₂ emissions from fossil fuels and towards a cleaner and sustainable environment. Currently available converters can only work in a limited temperature range, resulting in limited efficiencies of only up to several percent, and exhibit insufficient mechanical properties.

In this talk the potential of both n- and p- type novel and highly efficient materials including the TiNiSn- based half-Heusler, HH, compounds, as well as Mg₂Si- and GeTe- based alloys will be described via understanding the role and controlling of meso-scale defects, such as grain-boundaries, separated phases, dislocations/twinning and chemical impurities on the thermoelectric properties. Such materials, containing available constituents, can be optimized for better mechanical endurance and are capable at different temperature ranges of operation up to 700°C, and therefore expected to enhance the Carnot efficiency with all of the other associated advantages. The efforts of maximizing the potential of such materials by both electronic and phonon effects will be described in detail in the talk and the routes approaching practical energy conversion devices will be addressed.

Site determination and refinement in nanocrystalline thermoelectrics by electron channeling

Dr. Andreas Delimitis, Greece

Oral Presentation (20')

Abstract

Electron microscopy-based spectroscopic techniques, such as energy dispersive X-ray analysis (EDX/EDS), or Electron Energy Loss Spectroscopy (EELS) have been widely exploited for structure determination and refinement since the 1960's. These methods take advantage of the electron channeling effect, where the yield of element characteristic X-ray emission, or electron energy loss is modified, dependent upon the direction of the incident electron beam with respect to the crystal structure and the kind of ions in the lattice. These channeling effects are powerful in determining atomic site locations; hence, techniques such as ALCHEMI (Atom Location by CHanneling Enhanced Microanalysis) have been developed and widely applied since then.

Structural analyses are particularly focused in materials for renewable technologies and energy harvesting, such as mixed magnesium silicides ($\text{Mg}_{2.38}\text{Si}_{0.38}\text{Sn}_{0.62}\text{Bi}_{0.02}$) or n-type ($\text{Ti}_{0.4}\text{Zr}_{0.6}\text{O}_{0.7}\text{Hf}_{0.3}\text{NiSn}_{0.98}\text{Sb}_{0.02}$ half-Heusler (HH) thermoelectrics (TE), for medium to high temperature range applications. Synthesis of nanocrystalline TEs often comes along with a complexity of phases, so that host or dopant site kind and location remain controversial. Application, therefore, of electron channeling is highly desirable in order to accurately determine and refine their structural characteristics. Planar electron channeling experiments were performed using the {111} rows of reflections, as this enables to distinguish among different lattice sites in the unit cell. EDS spectra were acquired after small tilting increments of the sample, so the incident electron beam forms small angles with the {111}-types of planes.

The variations of the normalized X-ray emission revealed a strong channeling effect for both mixed Mg silicides and HH nanomaterials. In general, the X-ray intensities' profiles are asymmetrical, demonstrating a modification of their nominal structures. Furthermore, Mg or Ni normalized counts are always distinct and complementary with all other ones, which confirms that Mg or Ni ions predominately occupy the tetrahedral T sites in silicides or HH, respectively. Variations in the X-ray intensities' profiles, as well as the specific ion kind for tetrahedral or octahedral positions will be further analyzed and discussed.

Investigation of Structure and Electrical Properties Modifications in Layered Oxyhalide Nanoplates Induced by Anion Exchange and UV Irradiation

Dr. Adrian Radoń, Poland

Oral Presentation (20')

Abstract

Layered oxyhalides from the Sillén family form a diverse group of materials with potential applications as photocatalysts, photocathodes, and photodetectors, as well as alternatives to lead-halide perovskites [1-4]. This wide range of applications stems from their unique structure, where positively charged $[\text{Bi}_2\text{O}_2]^{2+}$ layers and halide ions are stacked along the [001] direction through van der Waals forces. As a result, these anions are mobile, and their selective replacement can significantly influence the electrical properties of nanoplates. Additionally, surface modifications in layered nanoplates can impact their characteristics, such as catalytic activity. Notably, these surface changes can be induced directly through UV light irradiation, leading to the formation of oxygen vacancies and alterations in the oxidation state of bismuth ions [3].

In this study, two approaches were used to modify the properties of bismuth oxychloride (BiOCl) nanoplates: anion exchange and oxygen vacancy formation. The effects of these modifications were analyzed using dielectric spectroscopy, which enabled real-time monitoring of changes in the electrical properties of nanoplates under UV irradiation. Structural changes were further examined through X-ray diffractometry, transmission electron microscopy, UV-Vis spectroscopy, and X-ray photoelectron spectroscopy.

The findings demonstrate how layered oxyhalides' dielectric and optical properties can be tuned for specific applications. The anion exchange approach provided insight into how different ions affect the dielectric properties of these materials while minimizing morphological effects. Meanwhile, UV-induced modifications on the nanoplates' surface revealed how charge carrier type and concentration variations influence their high-frequency properties.

Design and Engineering of Carbon Defects in TiO₂ Nanoparticle Architectures

Mr. Guillem Vives Ollé, Austria

Highlight (Oral Presentation 20')

Abstract

The photoconversion of CO₂ into valuable molecules using solar radiation offers a promising approach to recycle the vast amounts of CO₂ emitted by modern society. Titanium dioxide (TiO₂) particle-based systems are useful for this purpose, as they are efficient photocatalysts with high performance under UV irradiation. However, their practical applications remain constrained due to the low lifetime of electron-hole pairs and unidentified trapping sites.¹ In this context, defect engineering constitutes a powerful strategy to enhance charge generation and separation in photocatalysts.² Despite its potential, systematic investigations on how the design of nanoparticle architectures (NPAs) and carbon dopants influence defect states and charge carrier dynamics are limited. In this work, we present strategies to engineer carbon impurity-based trapping sites, termed Carbonecks, in different NPAs. These Carboneck defects function as electron traps, promoting charge redistribution under UV irradiation.

We investigate four different TiO₂ architectures: (NPA1) unsupported TiO₂ nanoparticles synthesized via Chemical Vapour Synthesis (CVS), (NPA2) unsupported cast TiO₂ nanoparticles, (NPA3) silicon-supported cast TiO₂ nanoparticles, and (NPA4) silicon-supported TiO₂ heterostructured films, prepared by combining a cast TiO₂ nanoparticle film on a sputtered TiO₂ film. Excess electrons are generated upon oxygen removal from the TiO₂ lattice at 973 K under high vacuum conditions. Electron Paramagnetic Resonance (EPR) spectroscopy is used to characterize (EPR-active) electron traps. In addition to superoxide radicals (O₂⁻), all slurry-derived NPAs (i.e. NPA2-4) exhibit an isotropic signal at $g = 2.0042$, which is attributed to carbon impurities inside the contact area between aggregated nanoparticles.³ For silicon-supported cast TiO₂ nanoparticles (NPA3), an additional isotropic signal at $g = 2.0020$ is observed, which we assign to paramagnetic carbon impurities at the silicon/TiO₂ interface. The organic constituents of the nanoparticle slurry are identified as the main source of these carbon trapping sites. However, when a TiO₂ sputtered film is deposited on the silicon substrate before the casting process (NPA4), it acts as a protective layer, preventing the Carboneck formation. UV excitation of the NPAs leads to charge redistribution involving the Carboneck signals.

This contribution will discuss the implications of these findings for converting particle powders into functional materials like photocatalytic layers and electrodes.

Synthesis and Characterization of Titanium Niobium Oxides for Advanced Photocatalytic Applications

Mr. Aarón Calvo-villoslada, Spain

Oral Presentation (20')

Abstract

Titanium niobium oxides (TNOs) have gained significant attention as electrode materials in lithium-ion batteries due to their stability, high energy storage capabilities, and tunable electronic properties [1,2]. However, these same characteristics—unique electronic structures, adjustable band gaps, and excellent stability—also make TNOs promising candidates for photocatalysis [3,4]. Photocatalysts are widely used in environmental applications, including hydrogen production via water splitting, CO₂ reduction, and the degradation of organic pollutants. Despite their potential, the photocatalytic properties of TNOs remain relatively unexplored, with only a few studies investigating their capabilities. One of the key advantages of TNOs is their ability to modify their electronic band structure when titanium is incorporated into niobium oxide Wadsley-Roth lattices. This modification extends light absorption into the visible spectrum, improves charge carrier mobility, and reduces recombination losses, enhancing overall photocatalytic efficiency. Given their established role in the energy storage industry, TNOs present an exciting opportunity as scalable, multifunctional materials that can bridge the gap between energy storage and photocatalysis.

In this study, we synthesized TNOs with the most common stoichiometries—TiNb₂O₇ and Ti₂Nb₁₀O₂₉—using three different synthesis methods: solid-state, hydrothermal, and solvothermal routes. Among these synthesis methods, the hydrothermal and solvothermal routes are the most efficient for photocatalytic applications. This is related to the smaller particle size obtained through these routes, along with optimized morphology, and crystallinity, leading to improved light absorption and charge separation properties.

Through extensive characterization, we gain deeper insights into the photocatalytic performance of TNOs and their potential to drive sustainable chemical transformations. By further exploring these materials, we hope to contribute to the development of next-generation photocatalysts with enhanced efficiency and stability for environmental and energy-related applications.

Unveiling Surface Dynamics: In Situ Oxidation of Defective WS₂

Dr. Daria Kieczka, United Kingdom

Oral Presentation (20')

Abstract

Defects on transition metal dichalcogenides (TMDs) surfaces influence their surface reactivity, stability, and performance in electronic and catalytic applications. In this work, we investigated the oxidation dynamics of defective WS₂ using in situ X-ray photoelectron spectroscopy (XPS) and density functional theory (DFT) simulations. Sulfur vacancies are introduced via grazing incidence Ar⁺ sputtering, leading to the emergence of a shoulder in W 4f core-level spectra at low binding energy, indicative of reduced tungsten states. Upon controlled O₂ exposure, oxidation proceeds in a pressure-dependent manner: at low pressures (<10⁻⁴ mbar), oxidation is minimal, while at higher pressures (>10⁻² mbar), rapid conversion to W⁶⁺ occurs, signifying WO₃ formation. XPS analysis shows the disappearance of defect-related features as vacancies become passivated. DFT calculations reveal that vacancy clusters reduce the effective charge on tungsten atoms, lowering the activation barrier for O₂ dissociation (<0.3 eV). Electron transfer from the surface to the O₂ molecule facilitates oxygen incorporation into the lattice, driving oxidation. Understanding these oxidation pathways is crucial for tuning WS₂ stability in applications such as catalysis and gas sensing, where surface reactivity plays a key role. By controlling defect densities and oxidation conditions, WS₂ can be engineered for sustainable energy applications, including hydrogen evolution reaction (HER) catalysts and chemical sensors for environmental monitoring. These insights provide a pathway for optimizing TMD-based materials for long-term stability and functionality in green technology and device applications.

High performance supported Fe nanoparticles as CO₂ activation catalysts that can self-heat by magnetic induction

Prof. Maricruz Sánchez, Austria

Oral Presentation (20')

Abstract

Introduction.

We investigated Fe-based catalysts for CO₂ utilisation via RWGS. Fe nanoparticles are ferromagnetic and can be inductively heated to the reaction temperature by a relatively small, alternating magnetic field with intensities in the order of 10-2 T. The approach of using Fe nanoparticles both for catalysis and inductive heating is expected to bring advantages such as the elimination of heat transfer limitations, fast response and the possibility of directly using electricity from renewable sources [1]. This work studies the magnetic and catalytic properties of Fe and Fe-Co supported nanoparticles and their stability as catalysts and inductive heaters under RWGS reaction conditions.

Methodology.

Supported Fe and FeCo nanoparticles were prepared by wet impregnation on γ -Al₂O₃ and CeO₂ supports. Structure and redox properties of the catalysts were studied by in-situ XRD, H₂ temperature-programmed reduction and operando XAS. The catalysts were tested in a lab scale 9 mm ID fixed bed reactor, equipped with a coil generating an alternating magnetic field (B_{app}= 47 mT, f= 323 kHz) and online GC analysis. Catalysts were activated in a conventional oven at 550oC for 1h in 10% H₂ in Ar.

Results and discussion.

Our materials containing supported Fe and Fe(Co) nanoparticles on Ce-based supports inductively self-heat up to 500-600oC and under CO₂/H₂/Ar gas flow (100 mL/min 1:1:2) and, under such conditions, they catalyse the RWGS reaction with 100% selectivity towards CO. It was determined that only materials with average nanoparticle size > 11 nm are able to heat sufficiently. Operando XAS combined with XRD revealed that about 50% of metal Fe forms Fe₃C under reaction conditions. This translates into a lower induction temperature due to its lower Curie temperature. Conversely, the addition of small amounts of Co leads to an alloy, which stabilises the metal particles against carbide formation, ensuring stable induction heating at 600oC for at least 2h. Alternatively, a pretreatment in CO₂ at 550 °C generates Fe₃O₄ phase that can be inductively heated up to 500°C and was found to perform stably as RWGS catalyst. Combining operando XRD-XAS with the characterisation of spent catalysts after induction shows the unique effects of induction heating of nanoparticles embedded in a non-magnetic support. Investigation of temperature nanogradients and their effects on catalytic activity and stability is on-going.

Acknowledgments.

The authors thank ALBA Synchrotron for the beamtime at NOTOS beamline (experiment 2023097875).

Paper 2021 1 The use of artificial intelligence to rapidly optimize nanomaterials production

Prof. Edward Lester, United Kingdom

Keynote (Oral Presentation 40')

Abstract

Hydrothermal synthesis is a key route to the sustainable manufacture of nanomaterials and is used in laboratories around the world. Some researchers prefer to use batch systems, whilst others use exclusively use continuous flow reactors, with a few laboratories using both approaches. Whilst continuous flow systems are inherently more scalable, they also have drawbacks, particularly around understanding the relationship between operating variables with product characteristics. There are more than 10 variables (e.g. temperature, precursor type, concentration, flow rate, flow ratio), that can operate across a wide range of conditions. Essentially this creates an infinite number of experiments that could be attempted when seeking to make a nanomaterial for the first time.

Design of Experiments is one approach which seeks to correlate variables with outcomes, whilst minimizing the amount of test work. This is still time consuming and generally still separates production from characterization from correlation.

Artificial Intelligence methods are perfectly suited to continuous hydrothermal flow systems because they can monitor products (in real time) and use self-optimizing algorithms to directly control process variables in order to quickly find out how to make materials that match target characteristics (size, shape, crystal structure etc).

This approach can reduce the development cycle for a new material and can also contribute to a more sustainable route to manufacture with more favourable sustainability metrics.

Examples of different types of AI algorithm and self optimization experiments will be given during the developments of functional nanomaterials such as MOFs (metal organic frameworks) and metal oxides (Fe₂O₃, ZrO₂, ZnO).

Paper 1869 2 **Wind turbine blade erosion monitoring and predictive maintenance: combining microstructural and machine learning approaches**

Mr. Waqar Ali, Norway

Highlight (Oral Presentation 20')

Abstract

Achieving 2000 gigawatts of offshore wind power by 2050, on a global scale, has significantly boosted the development of wind energy sector. Wind turbine blades are crucial components, and their structural integrity is essential for uninterrupted operation and downtime minimization. Blade erosion forms one of the main failure modes that lead to high production losses and maintenance expenses. Several studies have used time-domain and frequency-domain features alongside machine learning techniques to predict faults in wind turbine blades, such as erosion and cracks. However, a key gap remains in integrating these methods into a unified framework for fault prediction, which could offer a more comprehensive solution for diagnosing faults.

In this study, a combination of fault classification in wind turbine blades by leveraging well-known signals and analysis with machine learning techniques, along with microstructural investigations of faulty/eroded blade sections is presented. The methodology involves a detailed feature engineering process that extracts and analyzes features from the time and frequency domains. The time- and frequency-domain features were extracted and analyzed using various machine learning algorithms. It was found that erosion and crack faults have unique time- and frequency-domain features. The crack fault introduces an amplitude modulation in the vibration time wave, which produces sidebands around the fundamental frequency in the frequency domain. However, erosion fault introduces asymmetry and flatness to the vibration time wave, which produces harmonics in the frequency-domain plot. The results also highlighted that utilizing both time- and frequency-fault features enhances the performance of the machine learning algorithms. As a complementarity approach, microstructural analysis, predominately using optical and electron microscopy techniques in various scales has been performed in order to assess the effect of fault and erosion in the blades and for a direct comparison with the machine learning data. These findings provide valuable insights into optimizing predictive maintenance strategies and advancing renewable energy reliability.

Inkjet printing of hard magnetic iron-platinum layers

Dr. Roberto Bernasconi, Italy

Oral Presentation (20')

Abstract

In recent years, hard magnetic thin films have attracted considerable attention due to their wide applicability in the field of advanced electronics. Their capability to retain some degree of permanent magnetization proved essential for magnetic recording systems, telecommunication devices, magnetic sensors or spintronic applications [1]. The equimolar alloy formed by iron and platinum, in particular, is of major interest due to its exceptional coercivity and remanence, coupled with superior corrosion and wear resistance.

FePt thin films can be deposited using physical evaporation techniques like sputtering [2] or wet deposition techniques like electrodeposition [3]. In both cases, coercivities of many kOe can be easily obtained. Beside these well-established techniques, one of the most promising approaches to deposit the thin FePt layers required for advanced magnetic applications is inkjet printing (IJP). This process, still largely unexplored for the deposition of hard magnetic thin layers, relies on the controlled jetting of an ink, containing the material in the form of solubilized compounds or suspended nanoparticles (NPs), through a nozzle and towards a suitable substrate. The jetting of small amounts of ink, corresponding to single droplets, allows for optimal material usage. This aspect, together with the dimensional precision and the scalability typical of this technique, make IJP highly promising for the controlled patterning of FePt layers.

In this context, the aim of the present work is to deposit, for the first time, thin layers of FePt using IJP. The alloy is synthesized, in the form of NPs, operating the reduction of simple inorganic precursors. The resulting NPs are dispersed, without the aid of surfactants, in an environmentally friendly solvent and subsequently inkjet printed. The FePt thin layers obtained are annealed in a H₂/Ar atmosphere to sinter the NPs and promote the formation of the highly ordered, hard magnetic, L10 phase. Finally, they are characterized from the morphological, microstructural and magnetic point of view. In particular, the coatings obtained evidence good hard magnetic properties, with a remanence in the order of 34 emu/g and a coercivity in excess of 7 kOe.

Extraction of Reactive Dyes from Wastewaters with Metal-Organic Framework MIL-101(Fe)

Mrs. Anastasia Silina, France

Oral Presentation (20')

Abstract

Each year, textile wastewater grows richer with dyes, as sustainable practices like clothes recycling unintentionally amplify the issue by extracting dyes that end up in nature. These persistent or decomposed dyes infiltrate the water cycle, making their way into drinking water and posing significant risks to human health.

To address this pressing concern, researchers have explored numerous wastewater treatment methods. Among them, adsorption has stood out as a particularly cost-effective and efficient approach. One class of materials gaining attention for their adsorption capabilities is metal-organic frameworks (MOFs). Renowned for their exceptionally high surface area, customizable pore size, and structural versatility, MOFs have shown promise in removing dyes.

Most studies on MOF applications for dye removal focus on ionic dyes, such as methylene blue or methyl orange, which often have comparatively small molecule sizes and charge. At the same time, the processes of reactive dyes removal remain underexplored. Nevertheless, reactive dyes are particularly problematic due to their widespread use in dyeing natural fibers like cotton and linen. In this research we focus on solvothermal synthesis of iron-based MIL-101 for the application for removal of Reactive Blue 4 (RB4) dye.

A series of MIL-101(Fe) was synthesized with different $\text{FeCl}_3 \cdot \text{H}_2\text{O} : \text{H}_2\text{BDC}$ (terephthalic acid) molar ratios from 0.5 to 3.5 (MIL-101(Fe)-0.5 to MIL-101(Fe)-3.5). The SEM analysis of synthesized powders reveals that MIL-101(Fe)-0.5 has homogeneous particles size, whereas at higher precursors ratios, particles sizes are heterogeneous, and side compounds are produced. The FTIR analysis suggests that the structures of MOF with different ratios are similar, and that at a higher precursor ratio, the peak corresponding to Fe—O bond at 555 cm^{-1} is more pronounced because an iron-based side compound is produced due to the higher initial concentration of ferric chloride in the synthesis. This has its effect on RB4 dye adsorption. Removal of RB4 was two times greater in the case of MIL-101(Fe)-0.5 compared to MIL-101(Fe)-3.5. That is apparently due to the homogeneity of particles and their smaller size, exposing a higher surface area, which is one of the most important characteristics of an effective adsorbent.

Paper 1472 **5** **Clinoptilolite functionalization with antimicrobial nanoparticles using a green in situ reduction process**
Prof. Marta Miola, Italy
Oral Presentation (20')

Abstract

Natural zeolites are extensively investigated due to their impressive ability to adsorb toxic substances, reduce airborne pathogens, and promote cleaner air. Among them, clinoptilolite has attracted significant attention in air purification and wastewater treatment. Furthermore, the introduction of antimicrobial nanoparticles on their surface can enhance their pathogen removal efficiency.

In this study, clinoptilolite powders were functionalized with silver and copper nanoparticles (NPs) to provide antimicrobial properties, using an environmentally friendly approach. The process concerned the in situ reduction of antimicrobial NPs on the surface of zeolites with tannic acid (TA) as a green reducing agent. The multi-step functionalization process was investigated from a morphological-compositional and structural point of view using Fourier-transform infrared (FTIR) spectroscopy, field emission scanning-transmission electron microscopy (FESEM, STEM, TEM) equipped with energy dispersive X-ray spectroscopy (EDS), and X-ray diffraction (XRD). The absorption properties were evaluated through BET analysis, while the antibacterial effect was assessed via the zone of inhibition and bioaerosol contamination tests.

FTIR analysis confirmed the successful functionalization of clinoptilolite powders with tannic acid. Morphological and compositional analyses showed the presence of antimicrobial NPs on the zeolite surface, and XRD confirmed the presence of metallic silver and copper or copper oxide NPs. The functionalized clinoptilolite exhibited antibacterial activity against both Gram-positive and Gram-negative bacterial strains. In conclusion, the environmentally friendly process of functionalization of clinoptilolite with NPs with antimicrobial effect proved to be a promising strategy to develop natural materials capable of adsorbing toxic compounds and effectively inhibiting the growth of pathogens.

Paper 2119 1 **Physics-based simulations and machine learning for nano-materials and nano-devices**

Prof. Alejandro Strachan, United States

Keynote (Oral Presentation 40')

Abstract

This presentation will highlight recent work in our group on combining machine learning (ML) and physics-based simulations to explore nano-materials. The first example uses density functional theory (DFT) to explore 2D materials as building blocks for layered ceramics for high-temperature applications. High-throughput DFT calculations predict the stability of the structures and their elastic constants; this is followed by ML models that use these properties to predict melting temperature, a property that is very computationally intensive to calculate directly. We discovered 67 new hexagonal, layered materials with thermal stability comparable to or better than previously observed zeta phases. A second example focuses on phase change materials, leading candidates for future non-volatile memory storage devices. We use ML interatomic potentials to perform molecular dynamics simulations of the operation of these devices. Simulations of amorphization and recrystallization of carbon-doped Ge₂Sb₂Te₅ with temporal and spatial scales matching those of current devices reveal the role of C atoms in the nucleation and growth processes.

Paper 776 2 **Theoretical probe into the kinetics of phase transitions and magnetization reversal in magnetite nanoparticles**
Prof. Roman Gröger, Czech Republic
Oral Presentation (20')

Abstract

We examine the phase transition kinetics in 23 nm nanocubes using time-resolved X-ray diffraction (XRD), with phase fractions determined through Rietveld refinement. The process is modeled using three coupled reaction - diffusion master equations that describe the concentrations of oxygen, wüstite, and magnetite, incorporating thermally activated oxygen diffusion and its reaction with wüstite. Model parameters were optimized to match XRD data at 298 K and 353 K, while its predictive accuracy was evaluated by comparing predictions to experimental data at 403 K. Understanding how magnetic moments in single-domain magnetite nanoparticles reorient is essential for optimizing these nanoparticles for biomedical applications, such as magnetic particle imaging and magnetic hyperthermia. To explore this, we employ the geodesic nudged elastic band method to determine the atomic-level minimum energy path for field-free magnetization reversal in bulk magnetite and single-domain cuboidal magnetite nanoparticles with {100} surface termination. Our results reveal that this reversal occurs through three successive elementary rotations of magnetic moments within distinct {110} planes. For iron-rich surface terminations, the energy barrier for this process is influenced by surface spin anisotropy, particularly in nanoparticles with a high surface-to-volume ratio, while no such dependence is observed in oxygen-rich terminations. This effect weakens as the particle size increases.

Paper 1441 3

Acoustically-driven Hybrid Nanocrystals for In Vivo Pancreatic Cancer Treatment

Ph.D. Marzia Conte, Italy

Oral Presentation (20')

Abstract

Background

Pancreatic ductal adenocarcinoma (PDAC) is one of the deadliest tumors, projected to become the second leading cause of cancer-related death in the United States by 2030. PDAC is marked by hypoxia, intrinsic chemoresistance, a “cold” tumor microenvironment and dense desmoplastic stroma, which hinders drugs penetration. In the continuous effort to develop alternative treatments, this study proposes a multimodal therapy leveraging a nanomedicine-based approach.

Methods

A nanoconstruct based on iron-doped zinc oxide nanoparticles (NPs) was developed, and a tailored lipidic formulation - inspired by those employed in COVID-19 vaccines - was implemented to shield the NPs while enhancing their stability in biological media. It was hypothesized that NP administration, followed by local ultrasound stimulation, could elicit a tumor response through the generation of reactive oxygen species (ROS) via a process called inertial cavitation. This effect was enhanced by incorporating a lipophilic molecular sonosensitizer (IR780) into the lipidic shell. After in vitro validation on KPC cells, the approach was translated in vivo using mouse models bearing subcutaneous KPC pancreatic tumors.

Results

The resulting nanoconstructs were thoroughly characterized from a physico-chemical perspective. The in vitro results showed that the combined therapy triggered significant ROS production and the death of KPC cells. In vivo, the antitumor efficacy was particularly pronounced when both the sonosensitizer and the ultrasound stimulation were employed. In fact, the experimental group receiving lipid-coated NPs incorporating the sonosensitizer (lipid-coated-IR780 NPs) and subjected to ultrasound stimulation showed a clear reduction in tumor size. Moreover, increased immune cell infiltration, enhanced cancer cell apoptosis and prolonged survival of treated animals were achieved.

Conclusions

These results underscore the potential of a combined therapeutic strategy that integrates lipid-coated, sonosensitizer-loaded nanoparticles with ultrasound stimulation, offering a potent treatment option for PDAC and in situ monitoring. Most importantly, these results were achieved by combining two safe-by-design treatments and employing an FDA/EMD -approved ultrasound transducer, paving the way for future clinically translatable therapies suitable for deep-seated tumors such as PDAC.

Paper 1026 4

Full-Stokes analyzer using near-field dielectric metasurfaces

Mrs. Angela Soria-Garcia, Spain

Oral Presentation (20')

Abstract

The polarization state of a light beam, that describes the path along with its electric field oscillates, is a relevant parameter in almost every area of science like astrophysics, medicine or biology, among others. Dielectric metasurfaces are ultrathin optical structures that modulate locally the phase or polarization of a light beam by modifying the field in the subwavelength scale. A phase change is introduced by a phase discontinuity under the general Snell's law rather than by optical path accumulations as the traditional optical components.

In this work, we propose an algorithm for designing metasurfaces that modulate the phase or polarization in the near field, along with their manufacturing process by electron beam lithography. The design method is based on the polar decomposition of a Jones matrix, which claims that any Jones matrix can be expressed as the product of a retarder (lossless) and a diattenuator (lossy). Given a desired polarization distribution in the image plane, we determine the Jones matrix of the metasurface, which corresponds to a pure retarder matrix as we aim to avoid any diattenuation. Since we are working in the near-field range, we apply the Vector Rayleigh-Sommerfeld (VRS) propagation method to iterate between the image and object planes and determine the final metasurface Jones matrix. Then, using Comsol software we relate the phase shifts given by the Jones matrix to the dimensions of the pillars for further fabrication. We have developed a full-Stokes analyzer that forms six light spots at the focal plane with 0°, 90°, 45°, 135° linear polarization states, right and left circular polarization states. By measuring the intensity of these focuses, we reconstruct the polarization state of the input light. We manufactured the device by electron beam lithography technique. In particular, we have patterned our metasurface design on a 1.2 μm GaN layer over a sapphire substrate. In this way, we developed a full-Stokes analyzer with which we are able to modulate the polarization at the nanometric scale.

Paper 2154 5 **A bottom-up approach for multifunctionality optimization in nanoreinforced polymers**
Prof. Fahmi Bedoui, France
Highlight (Oral Presentation 20')

Abstract

A novel fabrication methodology for nanocomposites with precise size control and optimal dispersion of spherical nanoparticles will be presented. In contrast to conventional methods of mixing nanoparticles with polymeric materials, we propose to circumvent the traditional approach by synthesizing the nanoparticles in situ within the polymer matrix. Nanoparticles are synthesized in a mixture of solvent and polymer. In addition to the established parameters (standard synthesis) that govern the morphology and size of the nanoparticles, the polymer composition and macromolecular architecture are hypothesized to play a significant role in determining the resultant nanoparticle size and dispersion within the surrounding matrix. This latter approach considered the polymer macromolecular chains as a critical parameter to control both the size and three-dimensional organization of nanoparticles within a polymeric matrix. By exerting control over both crucial parameters (size and distribution), the obtained properties (NP size distribution and dispersion in the polymeric matrix, induced magnetic and strengthening effects of the composite material that exceeded expectations. These results constitute a precious data base to validate modeling approach, from the atomistics to finite element crossing by micromechanics. During this seminar, an overview on previous challenges and the opportunities given by our new results will be presented in details.

Paper 323 1 **Deformation mechanisms in Refractory High Entropy Alloys comprising two-phase B2/bcc microstructures**

Prof. Hamish Fraser, United States

Keynote (Oral Presentation 40')

Abstract

The deformation mechanisms in refractory high entropy alloys has been characterized using the alloy AlMo_{0.5}NbTa_{0.5}TiZr as an example. Specifically, the modes of plasticity active in the B2 matrix and the precipitate bcc phase have been determined using nano-indentation. For the B2 phase, a combination of weak-beam dark-field and superlattice imaging revealed dissociation of $\langle 111 \rangle$ superdislocations into two superpartial dislocations, bounding an anti-phase boundary (APB), following the reaction: $a\langle 111 \rangle = a/2\langle 111 \rangle + APB + a/2\langle 111 \rangle$. The dislocations in the B2 phase exhibited long, relatively straight screw segments and short edge segments, such that the mobility of the edge dislocations appears to be higher than that of the screw segments. Evidence of a B2 to bcc slip transmission process has been observed through use of stereo-pair imaging and anaglyph construction. This process involves the transmission of slip from the B2 matrix, followed by the decorrelated motion of the two $a/2\langle 111 \rangle$ dislocations in the bcc precipitate, demonstrated by the increased separation of the dislocations within the bcc phase. The relative lack of ductility exhibited by this alloy has been attributed to the deformation behavior in an alloyed version of the phase Al₄Zr₅ found at grain and subgrain boundaries, which was explored also by use of nano-indentation. Regarding the deformation of the Al₄Zr₅ intermetallic phase, it was found that indentation of this phase resulted in no evidence of dislocation generation and motion, and cracking at the edges of the given indent. It has been concluded that the lack of plasticity of this phase is the cause of the room temperature brittle nature of this alloy.

Paper 1579 2 **Chemical short-range order and local lattice distortions in High-Entropy Alloys: state of the art**

Dr. Andrea Fantin, Germany

Highlight (Oral Presentation 20')

Abstract

Understanding the complex atomic-scale structures of High-Entropy Alloys (HEAs) is crucial for tailoring their properties to diverse applications. The present contribution aims to provide an overview of the state-of-the-art experimental techniques employed in probing local lattice distortions and chemical short-range order in HEA solid solutions: from synchrotron/neutron-based techniques such as X-ray absorption spectroscopy and X-ray / neutron total scattering to novel and less known techniques such as single-crystal diffuse scattering and atomic-resolution holography. A key challenge in analyzing multi-component alloys lie in the inherent low scattering contrast among the five or more alloying elements, which are often neighbors in the periodic table. Additionally, HEAs generally exhibit simple crystal structures with few or even one single Wyckoff site further complicating the extraction of local structural information. These characteristics pose significant challenges for data interpretation, including in transmission electron microscopy.

At the laboratory level, the more accessible thermo-physical methods such as differential scanning calorimetry and electrical resistivity have proven valuable in the corroboration and quantitative estimation of ordering within HEAs.

It becomes evident that rather than relying solely on individual techniques, it is the combination of several experimental approaches, ideally complemented by simulations, that can effectively assign the contribution of each element to the alloy structure and, ideally, to the overall alloy performance.

However, it is important to recognize that each experimental method has its own strengths and weaknesses, which will also be shortly addressed within this contribution.

Chromium effect on the behavior of NbTiZr refractory medium entropy alloys

Ph.D. Loïc Perriere, France

Oral Presentation (20')

Abstract

The objective of this study is to examine the effect of chromium addition on the microstructure, mechanical behavior and environmental properties of a refractory medium entropy alloy (RMEA).

The alloy that has been selected for this study is an equimolar NbTiZr alloy, which has been comprehensively researched in the literature and features a microstructure composed of a single-centered cubic solid solution. The addition of chromium to this system results in the emergence of brittle Laves phases in relatively limited quantities. Utilizing thermodynamic calculations employing the Calphad method (Thermocalc), a series of alloys with chromium contents of up to 8% at. were developed and subsequently exposed to temperatures at the dissolution temperature of the Laves phases, with the objective of establishing the solubility limit of chromium in the solid solution. The microstructure was then prepared to a size close to 100 μm by a cold rolling step and heat treatment at 1100°C.

Structural analyses were conducted by X-ray diffraction, while microstructural analyses were performed using scanning electron microscopy (SEM), including EBSD orientation mapping. The alloy composition was verified by ICP-OES, and the mechanical behavior was measured by micro-indentation tests, tensile tests and relaxation tests. The environmental resistance of the alloys was studied by thermogravimetric analysis (TGA). Observations demonstrate that Laves phases emerge at grain boundaries as soon as 4.5% at. chromium is incorporated, despite thermodynamic calculations indicating the presence of a single solid solution for contents of up to 6% at. Vickers microhardness and tensile yield strength increase with chromium content, reaching a plateau at 4.5% at. These results therefore suggest that the solubility limit of chromium is approximately this level. However, Rietveld refinement of the diffractograms demonstrates that the cell parameter of the solid solution continues to evolve above 4.5% at.

It is shown that chromium, even when added in small quantities, exerts a significant effect on the behavior of the NbTiZr alloy. The results of this study indicate that up to 3% at. chromium can cause significant solid solution hardening, although this content is insufficient to form a protective oxide layer and protect the alloy against oxidation.

- Paper 1617 5** **Investigation of phase content of TiZrAlNbMo high entropy alloys with compositional gradient**
Ph.D. Josef Stráský, Czech Republic
Oral Presentation (20')
- Abstract** Elemental powder mixtures were sintered by SPS to produce samples with intentional chemical variations to study the effect of chemical composition on the phase content of the TiZrAlNbMo based high entropy alloys (HEA). Annealing and quenching from 1200°C produce material with phase content associated with the thermodynamic equilibrium at 1200 °C. The microstructural characterization was conducted by means of scanning electron microscopy, including EDS and by x-ray diffraction. It was revealed that major phase is the bcc-matrix, depending on composition, AlZr based intermetallic particles were also present. The threshold of Nb and Mo content for stabilization of single-phase bcc matrix was revealed. The experimental results were complemented by Thermocalc calculations using TCHEA4 database. It was revealed that qualitative predictions and trends are correct, while explicit quantitative determination is not fully consistent with experimental data. We consider high-throughput experimental determination of phase content and microstructure irreplaceable for HEA development and tailoring. Manufacturing and characterization of gradient samples allows efficient analysis of the effect of individual elements on microstructure and phase content in HEA.
- Paper 667 6** **Microstructure evolution and excellent mechanical properties of TiVNbHf refractory High Entropy Alloy fabricated by powder metallurgy**
Mr. Naonao Gao, China
Oral Presentation (20')
- Abstract** This study introduces a powder metallurgy (PM) approach combining mechanical alloying (MA) and hot press sintering (HPS) to fabricate high-performance TiVNbHf refractory high entropy alloys (RHEAs), which consist of BCC and V-Hf-rich phases. The ball milling process and HPS sintering temperatures were optimized to enhance the alloy's properties. Notably, the average grain size of the TiVNbHf RHEAs was only 1 µm, two orders of magnitude smaller than that of as-cast TiVNbHf alloys. This fine microstructure resulted in a low density (8.12 g/cm³) and significantly improved mechanical properties, with yield strength, fracture strength, and fracture strain reaching 1880 MPa, 2227 MPa, and 24.4%, respectively, at room temperature—approximately 500 MPa higher than those of as-cast TiVNbHf alloys. Furthermore, reducing the V and Hf content led to the complete elimination of the V-Hf-rich phases, contributing to further improvements in density (7.49 g/cm³). In addition, the yield strength, fracture strength, and fracture strain reached 1630 MPa, 2198 MPa, and 34.4%, respectively, at room temperature—approximately 41% higher in strain than that of the TiVNbHf alloys. Notably, at 800 °C, the yield strength was 859 MPa. Consequently, the specific strengths of these TiVNbHf RHEAs significantly surpass those of publicly reported Ni-based superalloys, especially above 800 °C, indicating potential for partial substitution of conventional Ni-based superalloys in aerospace applications, where both weight reduction and performance improvement are critical. Finally, the microstructural evolution and the underlying strengthening-toughening mechanisms of the PM TiVNbHf RHEAs are discussed.

Laser metal deposition of NbTaTiV Refractory High Entropy Alloy

Mr. Eric Barth, France

Oral Presentation (20')

Abstract

Mechanical resistance at high temperature is a critical challenge for the aerospace and aeronautical industry. A new category of alloys, refractory high entropy alloys (RHEA), made of refractory elements in close to equimolar proportions, shows very promising high temperature resistance. However, they encounter multiple manufacturability issues, and are still held back by cost and density issues, and by the number of possible alloy composition.

In parallel, additive manufacturing is an ever-growing technology, allowing the production of highly complex parts. This could lead to simpler and lighter structures, and to more efficient material usage. Moreover, the Laser Metal Deposition (LMD) technique can be used as a high throughput scanning tool to identify new RHEA compositions. However, this process comes with its own set of problems.

This study therefore offers to analyze the manufacturability of NbTaTiV by LMD process.
Procedure

The samples are manufactured on commercial BeAM Mobile and Modulo400 LMD machines.

A mixture of pure elemental powders was used to manufacture single-beads, 5-layer walls and bulk samples, using various deposition parameter. A second laser exposure without powder addition was tested to homogenize the deposited microstructure. All samples were produced under argon atmosphere. The samples were observed with an optical and a scanning electron beam microscope. The composition of the samples was analyzed by EDS. The microhardnesses of the deposits were also measured, and tensile samples were extracted from the bulk samples and tested.

Combined CFD+DEM simulations were conducted to help with the composition control of the powders.

Upon analyzing the samples, it appears that their composition strongly deviates from the expected equimolar one. The ratio between the obtained concentrations and expected ones was 0.78, 0.57, 0.94 and 2.01 for Ti, V, Nb and Ta, respectively. Ta powders therefore have a better deposition efficiency. DEM+CFD simulations showed that this discrepancy was mostly due to variations in term of powder impact velocity.

Upon performing an EDS mapping of the samples' cross-section, large quantities of Ta and Nb powder (elements with the highest melting point) can be observed. The 2nd laser exposure allowed to homogenize the microstructure and reduce the number of Ta and Nb particle.

The tensile tests returned an average yield strength of 832MPa and an average maximal elongation of 5.55%

The next step in the study is the high-scale, high-temperature testing of the alloy, and the application of a thermal treatment to further homogenize them.

Paper 169 1 **Strong and tough high-entropy materials with excellent multifunctionality**

Prof. Zhiming Li, China

Highlight (Oral Presentation 20')

Abstract

Multicomponent high-entropy materials (HEMs) composed of multiple principal elements have attracted great interest owing to their considerable potentials for achieving unprecedented properties in their practically infinite compositional space. Apart from exceptional mechanical properties such as high strength and good ductility, it has been shown that excellent magnetic, electrical and thermal properties can also be involved in HEMs via compositional and microstructural design. In this talk, we will present the unique combinations of multiple functions and even mutually exclusive properties that we have successfully achieved in recently developed multicomponent HEMs. The multiple functions include high strength, good ductility, electrical resistivity, soft magnetism, low thermal expansion (Invar), resistance to corrosion and hydrogen embrittlement. The associated design strategies will be clarified and some potential directions for further developing multifunctional HEMs will also be briefly discussed.

Paper 40 **2** **Hydrogen trap characterization in 200 and 1,000 bar charged CoCrNi medium entropy alloy compared to steel AISI 316L**

Dr. Michael Rhode, Germany

Oral Presentation (20')

Abstract

Multiple principal element alloys (MPEAs) represent a new class of metallic materials. MPEAs, such as the CoCrNi medium entropy alloy (MEA), have attracted considerable research attention as potential materials to replace, for example, austenitic steels in high-pressure hydrogen environments. Due to the relatively new alloy concept, studies on the specific hydrogen diffusion and trapping behavior of high-pressure hydrogen-charged CoCrNi MEAs are rare so far. For this reason, a CoCrNi-MEA was investigated and compared to an austenitic stainless steel, AISI 316L. Both materials were subjected to high pressure hydrogen loading for two different pressures: 200 bar and 1,000 bar. After charging, thermal desorption analysis (TDA) was used with three heating rates from 0.125 K/s to 0.500 K/s to clarify the specific hydrogen desorption and trapping behavior. To the best of our knowledge, this study is the first to characterize hydrogen diffusion and trapping in 1,000 bar high-pressure charged CoCrNi. For this purpose, the underlying TDA spectra were analyzed in terms of peak deconvolution into a metallurgically justifiable number of defined peaks. The individual peak temperatures and activation energies "EA" were calculated. The following conclusions can be drawn from the results obtained: (1) Exposure to 200 bar or 1,000 bar leads to an increase in hydrogen absorption, regardless of the material investigated, expressed by a significantly increased desorption rate at 1,000 bar. However, the effusion peaks typically occur only at high temperatures. The (2) TDA showed that a four-peak deconvolution scenario was sufficient to describe the trapping behavior and the "EA" indicated the dominance of irreversible traps. In addition, the average trapping energy is higher than in the 316L. The (3) charge pressure related hydrogen solubility was in the order of: CoCrNi-MEA < 316L for both pressures and (4) charging at 1000 bar results in an average concentration of 49 wt.ppm (CoCrNi-MEA) and > 75 wt.ppm (316L). In summary, the CoCrNi-MEA was characterized by a reduced solubility, but very deep entrapment compared to the 316L. For this reason, further application potentials of the MEA may arise.

Paper 541 **3** **Empowering high-entropy alloys with unique nanostructure for exceptional oxygen evolution performance through self-replenishment**
Prof. Xiongjun Liu, China
Oral Presentation (20')

Abstract

Oxygen evolution reaction (OER) catalysts suffer from degradation under harsh oxygen evolution conditions, especially at large current densities, which is a longstanding challenge when developing OER catalysts for industrial applications. In this talk, we will report ultra-stable high-entropy catalysts with outstanding OER performance, created by forming two-layered nanostructures in noble metal-free high-entropy superlattice alloys, which boost activity and stability simultaneously through a counterintuitive parallel-mechanism strategy. The outer high-entropy amorphous oxide layer endows compelling OER activity (235 mV at 10 mA cm⁻²), while the underneath layer affords dynamic self-healing capability for sustainable performance (working stably for 1600 h at 500 mA cm⁻²) in alkaline electrolytes. More appealing is that the catalyst can be easily revitalized, significantly extending its service durability and reducing its cost. This finding can be applied to developing other cost-efficient catalysts with considerable potential for industrial applications, but also offers a design paradigm to break the activity-stability trade-off of electrocatalysts.

TiVCr-based High Entropy Alloys for solid-state hydrogen storage

Dr. Aude Bailly, France

Oral Presentation (20')

Abstract

High-entropy alloys (HEAs) emerged as promising materials having a significant potential for solid-state hydrogen storage due to their very good sorption properties. The high mixing entropy, resulting from their multi-elemental composition, favors the formation of solid solution phases with simple crystallographic structures (bcc, fcc or hcp). The wide range of relevant chemical elements and adjustable compositions offers a favorable playground for optimizing HEAs with excellent hydrogen sorption properties and equilibrium pressures above 1 bar at 25°C in order to target industrial applications. Our work focused on TiVCr-based HEAs with a small percentage (4 to 8 at. %) of Mn, Fe or Mn and Fe, synthesized by induction melting. Structural analysis was performed by X-ray and neutron diffraction. The as-cast alloys contain a predominant bcc phase and a minority hexagonal C14 Laves phase, of which amount seems to depend on the Mn-Fe proportion. The co-existence of these two phases is supported by CALPHAD thermodynamic calculations. Upon hydrogenation, two distinct hydride phases are observed: a β -bcc monohydride which forms at the lowest hydrogen pressures and a γ -fcc dihydride at higher pressures. Microstructural and chemical analyses were carried out using scanning electron microscopy, coupled with energy-dispersive X-ray spectroscopy. They revealed some degree of elemental segregation at grain boundaries, correlated to the wide range of melting points and an uncontrolled cooling process. These local spatial inhomogeneities, together with the variable bcc/C14 proportion, play a crucial role in the overall hydrogen sorption properties. These latter were assessed by pressure-composition isotherms, using the Sievert's volumetric method. The alloys demonstrated fair hydrogen storage capacities (1.5 to 3.6 wt. %) with fast kinetics (< 3 min) and equilibrium pressures exceeding 1.5 bar at 25°C, making them potential candidates for industrial hydrogen storage applications.

The complementarity of the experimental techniques we used sheds light on the subtle structural and chemical variations existing at the micrometric scale and promotes a better understanding of the parameters that could influence the hydrogen sorption properties. These promising results motivate in situ diffraction studies during hydrogen absorption and desorption to better understand the structural transitions occurring during hydrogenation.

Interstitial solid solution high-entropy thin films

Ph.D. Konstantin Werner, France

Highlight (Oral Presentation 20')

Abstract

Face-centered-cubic (fcc) high-entropy alloys (HEAs) have attracted significant research interest over the past two decades mostly due to their exceptional mechanical properties, which are attributed to their low stacking fault energy and the resulting activation of deformation twinning and/or martensite formation [1,2]. However, their respective room temperature yield strength is low. Common methods to enhance yield strength, such as partial recrystallization or grain refinement, often lead to a significant reduction in ductility at least when a significant increase in yield strength is targeted [3]. Interstitial elements, like carbon and nitrogen, are the most effective solid-solution strengtheners. Nevertheless, the interstitial content in HEAs is typically kept low to prevent the formation of carbides and/or nitrides, which are known to degrade mechanical properties, particularly ductility, and corrosion resistance. This limitation restricts the degree of solid-solution strengthening achievable through interstitial elements. To incorporate significant interstitial content into HEAs, nitrogen must be introduced at high temperatures where nitride formation is thermodynamically unstable, followed by rapid quenching to suppress precipitation during cooling. Reactive DC magnetron sputtering provides a viable pathway to produce interstitial-rich thin films due to its ability to achieve very high cooling rates. However, research on nitrogen-containing HEA thin films often focuses on the formation of high-entropy nitrides, with relatively few studies investigating high-interstitial solid solutions.

This study explores the effect of nitrogen flow rate on the microstructure and mechanical properties of Co-free Cr_{0.5}FeMnNi(100-x)N_x HEA thin films using a combination of nanoindentation, transmission electron microscopy (TEM), and X-ray photoelectron spectroscopy (XPS). The findings demonstrate that HEA thin films significantly supersaturated with nitrogen with a significant increase in mechanical properties can be successfully synthesized via reactive DC magnetron sputtering.

Paper 1109 2

Development of layered Cu-Mo composites with tailored thermal properties

Mr. Filip Kapuscinski, Poland

Oral Presentation (20')

Abstract

Keywords: Cu-Mo-Cu composites, thermal management, ARB, diffusion bonding, interfacial bonding.

Nowadays, the demand for materials with tailored thermal and mechanical properties is growing rapidly, particularly in the electronics and aerospace industries, where thermal expansion mismatches pose significant challenges. Copper-molybdenum (Cu-Mo) composites are promising candidates due to their exceptional thermal stability, high thermal conductivity, and adjustable coefficients of thermal expansion (CTE).

In this work, attempts have been made to produce and characterize Cu-Mo composites with layered structures and optimized properties for advanced thermal management applications. Two distinct manufacturing approaches were applied to achieve unique microstructures and performance characteristics, i.e. accumulative roll bonding (ARB) supported with diffusion bonding and electroplating for submicron laminates.

The ARB process, combined with diffusion bonding, was employed to produce Cu-Mo laminates with submicron layers thickness. This method ensures strong interfacial bonding between the Cu and Mo layers, which is crucial for thermal and mechanical properties. Electroplating was integrated into the process to enhance the active surface and refine layer uniformity at submicron scales prior to the diffusion bonding step. This approach provided a cost-effective pathway for scaling up production while maintaining precise control over composite properties.

Comprehensive characterization of the composites was conducted, including microstructural analysis using SEM and TEM, thermal conductivity and mechanical strength measurements, along with CTE evaluation. The investigated method allowed us to obtain promising materials and outline guidelines for the design and fabrication of novel layered composites with tailorable thermal and mechanical properties.

Acknowledgment

Processing of Biphasic High-Entropy Alloys by Laser Powder Bed Fusion and Optimization of Heat Treatments: Enhancing Strength at High Temperatures via Precipitates Strengthening.

Ph.D. Alberto Meza, Spain

Oral Presentation (20')

Abstract

High-entropy alloys (HEAs) have attracted significant attention in recent years due to their unique microstructures and exceptional mechanical properties. Among these, biphasic HEAs (FCC+BCC phases) offer a promising balance of strength and ductility, especially when their phases are precisely tailored. In this study, Laser Powder Bed Fusion (LPBF) is employed to fabricate two novel Al-containing biphasic HEAs based on the Cantor alloy from commodity powders. Using these powders, rather than elemental ones, helps to reduce the overall cost of developing HEAs. These commodity powders contain the essential alloying elements required for fabricating the alloys, offering a more affordable and sustainable option by allowing the recycling of metal scraps from these commodity alloys. Besides, the alloys will receive post-processing based on heat treatments involving solution treatment and aging. These treatments are designed to finely disperse the BCC phase as precipitates within the FCC matrix, thereby enhancing mechanical strength and hardness at room and high working temperatures (600-750 °C). Microstructural characterization was performed by SEM, EDS, EBSD, and TEM explorations, while the mechanical performance was assessed by hardness measurements, profilometry-based indentation plastometry (PIP), and micro-compression tests at room and high temperatures. Correlating the microstructural features with the final mechanical performance will be a key step in demonstrating the effectiveness of the dispersed BCC precipitates in the FCC matrix. This research represents a novel integration of advanced additive manufacturing and precise thermal processing to optimize biphasic HEAs. By optimizing the post-printing heat treatments, it is possible to obtain tailored strength-to-ductility ratios for specific applications by dispersing differently the BCC precipitates in the FCC matrix. Furthermore, their development through LPBF offers the consecution of complex geometries, increasing their overall added value. Finally, evaluating their mechanical properties at room and high temperatures showcases the alloys' potential for high-performance applications in critical engineering sectors.

Martensitic islands in the AlCoNiV multicomponent alloy

Dr. Raymond Kwesi Nutor, Germany

Oral Presentation (20')

Abstract

Multicomponent alloys including medium- and high-entropy alloys (M/HEAs) are an emerging alloy class comprising multi-principal elements with exceptional mechanical properties. Among various equiatomic single-phase face-centered cubic (FCC) MHEAs, the equiatomic CoNiV MEA has displayed impressive mechanical properties by maximizing lattice distortion. Al-addition to the CoNiV MEA further improves strength by forming Al-rich body-centered cubic (BCC) related precipitates. Like in conventional alloys, martensitic transformation is viable in these M/HEAs during rapid cooling or mechanical deformation. We observe for the first time, a martensitic transformation localized only in the BCC regions surrounded by the FCC matrix in the AlCoNiV MEA. The formation of these martensitic islands is due to the heterogeneous cooling between the FCC and BCC phases of the alloy. The martensitic islands provide significant strength enhancement due to their high hardness while the surrounding ductile FCC matrix prevents premature fracture. These findings provide valuable insights into the design of novel high-performance alloys.

B1_5 - Processing and Microstructural Design of Advanced High-Strength Steels

Chair: Franceschi, Ph.D. Mattia

Paper 856 1 Advanced High-Strength Steels: Fundamental Insights and Industrial Applications

Prof. Ilana Timokhina, Sweden

Keynote (Oral Presentation 40')

Abstract

Martensitic PHS 1500 steel has been the dominant choice in the automotive industry for over two decades, offering a tensile strength of 1.5 GPa and an elongation of 6–8%. To achieve an optimal balance between strength and ductility, a sustainable approach combining press hardening with subsequent bake hardening is employed. Enhancing the steel's properties requires a thorough fundamental understanding and precise control of its microstructure after these processes. To understand microstructural changes at the atomic scale during press hardening and bake hardening, a micro-alloyed, fully bainitic steel with low dislocation density than martensite was selected as a laboratory alloy. The mechanical properties of PHS 1500 steel were evaluated through tensile, bending, and fracture toughness tests. The samples exhibited excellent tensile properties, with an ultimate tensile strength of 1542 ± 7 MPa, a yield strength of 1147 ± 3 MPa, and a total elongation of $8.86 \pm 0.16\%$. While bake hardening led to an increase in yield strength, it had no significant effect on bending properties. Fracture surface analysis revealed ductile dimpling, indicating high fracture toughness.

The laboratory alloy after deformation simulating press hardening condition and aging simulation bake-hardening treatment was studied using transmission electron microscopy and atom probe tomography and tensile testing. The microstructure consisted of fine bainitic structures with a lower dislocation density than martensite, enabling atomic-scale characterization. Notably, the yield strength of laboratory alloy increased significantly under different strain aging conditions, reaching up to 790 MPa, compared to 630 MPa after initial processing. The experimental results showed the formation of carbon Cottrell atmospheres around dislocations and the formation of carbon clusters/fine carbides in the bainite during aging. It is proposed that this is associated with the high dislocation density of bainite (martensite in industrial steel) with formation of a complex dislocation substructure after deformation and its high average carbon content. The segregation of carbon and substitutional elements such as Mn to the bainitic lath boundaries was observed by atom probe tomography.

2

Impact of Steelmaking Route and Rolling Strategy on Nb Solubility in Reinforcement Bars Production

Ph.D. Unai Mayo Ijurra, Spain

Highlight (Oral Presentation 20')

Abstract

Traditionally, the use of Nb microalloying has been related to the production of flat products. However, recent innovations have introduced low Nb additions in reinforcing bars production to enhance steel strength and toughness by refining the austenitic structure. Additionally, Nb is being utilized to improve cost efficiency and as an alternative to QST (Quenching and Self-Tempering) processes that do not comply with earthquake safety regulations.

In flat products, Nb is commonly used in low-carbon steels processed through Thermomechanical Controlled Processing (TMCP), where the modification of the austenite structure via strain-induced precipitation enhances mechanical properties. However, in high-carbon long products (>0.20 wt.% C), the role of Nb is less established due to its limited solubility in austenite. In these grades, Nb—whether in solid solution or as precipitates—can help inhibit grain growth during hot rolling, leading to a refined austenitic structure. In this context, understanding the amount of Nb in solid solution at the onset of hot rolling is critical. This is typically estimated through thermodynamic calculations, such as solubility products or commercial software. However, these methods assume equilibrium conditions, whereas industrial reheating processes often deviate from this assumption.

This study proposes an experimental indirect method to evaluate the amount of Nb in solution prior to hot deformation. Nb solubility is analyzed in rebar products coming from different steelmaking routes (BOF and EAF), and various rolling technologies (cold and direct charging), comparing the results with TEM-based precipitation analysis and thermodynamic predictions. The findings suggest that this approach serves as a valuable complementary tool for assessing Nb in solid solution under specific industrial conditions.

Multi-Objective Optimization of the Thermo-Mechanical Control Process in HSLA Plate Steels

Dr. Maria Ioanna Tzini, United States

Oral Presentation (20')

Abstract

The design of the Thermomechanical Control Process (TMCP) of HSLA steels and the identification of the optimum processing parameters constitute a challenging problem in the industrial pipeline applications, especially for heavy plate rolling. The TMCP of an X70 HSLA plate steel consists of a two stage multipass hot rolling in austenite region (roughing and finishing), followed by controlled accelerated cooling during the austenite to ferrite phase transformation. A multi-objective optimization approach is presented for the process design of an X70 HSLA steel using a physically-based mean field (PBMF) model. The PBMF model incorporates an integrated precipitation and recrystallization model to describe the microstructural evolution due to the interaction of strain-induced precipitation of niobium and titanium carbonitrides and static recrystallization of austenite. An integer multi-objective optimization problem is formulated, and the non-dominated sorting genetic algorithm (NSGA-II) is applied on the PBMF model to determine a set of optimal processing routes that meet process design criteria. Aiming to increase the strength of the HSLA plate, a trade-off between the microstructural objectives is obtained, i.e. average ferrite grain size, the niobium content in solution, and the residual strains at the end of the finishing stage. A single processing route was selected, and the microstructural evolution during TMCP was investigated by multi-phase field calculations in conjunction with the PBMF model. Experimental data on the optimized steel via SEM and STEM revealed good agreement with model predictions. The proposed approach can contribute to the process design of HSLA and microalloyed steels.

Exploring G91 Steel in Laser Powder Bed Fusion: Powder, Parameters and Microstructure

Mr. Erick E. Alvarado, Spain

Oral Presentation (20')

Abstract

G91 grade is a ferritic-martensitic steel extensively used in the manufacturing of components for high temperature applications within the energy sector due to its excellent mechanical and thermal properties, as well as its affordability. Consequently, it is employed for the production of structural components in power plants. However, traditional manufacturing methods commonly employed to produce these components hold back the creation of complex geometries. Laser Powder Bed Fusion (LPBF), an Additive Manufacturing (AM) technique, has been brought in to fabricate components in various alloys. Nevertheless, the feasibility of producing G91 steel components using LPBF is still being investigated.

This study focuses on the fabrication of G91 steel samples using Laser Powder Bed Fusion (LPBF). A

comprehensive characterization of the G91 steel powders ($D_{50} = 44.4 \mu\text{m}$), produced via gas-argon atomization, was performed. The chemical composition of the G91 steel was confirmed using ICP-OES and XRF, while the initial crystallographic phase in the powder was identified as $\alpha\text{-Fe}$ through XRD analysis. Additionally, microstructural observations were carried out using both Light Optical Microscopy (LOM) and Scanning Electron Microscopy (SEM), revealing the absence of oxides and impurities. Moreover, the presence of minimal porosity and homogeneous spherical particles was observed, which correlates with the excellent flowability behavior demonstrated in the rheological tests.

Following an extensive optimization process aimed at reducing porosity to values between 0.035% and 0.2%, the optimal printing parameters were determined: 150-200 W, 750-1000 mm/s, a hatch distance of 0.05 mm, and a layer thickness of 0.03 mm. The resulting microstructures were examined in both as-built and normalized conditions. XRD analysis revealed the formation of retained $\gamma\text{-Fe}$, coexisting with $\alpha\text{-Fe}$. Consequently, detailed metallographic observations were conducted using LOM and SEM. The results displayed a complex mix of morphologies, dependent on the printing conditions. However, no evidence of microsegregation was found, in line with the results from EPMA analysis. Finally, the mechanical properties were assessed through Small Punch and compression tests.

5

On the mechanism of nucleation of static recrystallization in austenite: a combined experimental and modelling approach

Mr. Pablo Garcia-Chao, The Netherlands

Oral Presentation (20')

Abstract

In the hot rolling mill, steels undergo static recrystallization (SRX) in the austenite phase. The properties of the new phases formed in the subsequent cooling largely depend on the grain size resulting from this SRX. Consequently, its accurate prediction is key to predicting the final properties of the steel. The grain size after SRX is determined by the density of new grains produced by the SRX. In turn, the nucleation of SRX in hot-deformed austenite is widely known to take place at the boundaries of the deformed grains. SRX nucleation at deformed grain boundaries is directly associated by current models with the event of strain-induced boundary migration (SIBM), or bulging. However, whether SRX nucleation at those sites effectively occurs by SIBM is yet to be experimentally proved. In this view, the present study analyzes in detail the factors determining the nucleation of SRX in a Ni-30%Fe alloy deformed at high temperature, via electron backscatter diffraction (EBSD). Ni-30%Fe has the same stacking fault energy as the austenite in carbon steels, but remains in austenite phase after cooling to room temperature. This makes it possible to access the substructure imparted by the high-temperature deformation. Results show that the number of bulges (SIBM) developed in the deformed microstructure is at least four times larger than the number of SRX grains. Results also demonstrate that significant growth of potential SRX nuclei occurs only when they are fully surrounded by high-angle boundaries (HABs). Therefore, the nucleation of SRX is not determined by SIBM, but by the transformation of their low-angle boundaries into HABs (LAB-HAB transformation). The conclusions of the experimental study are encompassed in a novel physics-based model and criterion for the nucleation of SRX at deformed grain boundaries. This model is based on the migration of dislocations into pre-existing subgrain boundaries, which gradually increases their misorientations. Nucleation then happens whenever the misorientation of a subgrain boundary reaches the HAB misorientation threshold. Finally, the model has been implemented into a 3D-cellular automaton (3D-CA), together with an extensive characterization of the subgrain misorientations in the deformed microstructure of Ni-30%Fe. Predictions of the model display good agreement with experimental results in terms of all nucleation density, SRX kinetics, and SRX grain size. All in all, this study paves the way for a new description of SRX nucleation at deformed grain boundaries, which can give robust predictions of the resultant grain size via models incorporating microstructural topology.

Experimental and simulation study of the mechanical behaviour of high-strength steel processed by friction stir welding

Mr. Jorge Velasco, Spain

Oral Presentation (20')

Abstract

The welding of high performance materials such as high strength steel is recognised as a challenge for the development of new structural components within the European production industry. Maximising material performance and hence material efficiency requires improved joining technologies to overcome the limitations of conventional welding methods applied to high strength steels. In this scenario, the friction stir welding process (FSW) arises as a candidate solution. FSW is a solid-state joining process in which the materials are joined without reaching their respective melting temperature. Hence, most of the quality issues (e.g voids) associated to conventional welding methods are avoided. For its introduction in load-bearing applications, it is required to control the weld seam properties and orientation, as they have a critical influence on the material properties, and on any subsequent forming operation that takes place. In this work, FSW-joints performed on high strength structural steels (Docol S700MC and Docol S960MC) provided by the Swedish steel manufacturer SSAB in 6 mm thick sheet format are tested at coupon scale under quasi-static tensile and bending loads, as well as impact toughness testing, following relevant standards (ISO 4136, ISO 5173, ISO 6892). Different positions of the weld's root are considered to assess its impact on the bending behaviour. Metallographic analysis and microhardness measurements are carried out as a means of linking the microstructure of the weld seam with the macroscopic behaviour of the material. Besides, microstructural evaluation allows identifying the main regions of the weld (Weld Nugger, Thermo-Mechanical Affected, Heat Affected Zone), as well as detecting the presence of any kind of defect that may influence the performance at the macroscale. The data obtained during the tests are used to feed a Finite Element model of the material in its base and welded conditions, including the Heat Affected Zone. This model is then employed to carry out a parametric study of the influence of the weld seam positioning and properties on the forming behaviour of the welded steel joints. Finally, the potential application of this solution in strategically placed reinforcement plates of a loader crane is explored, as a lighter and customizable substitute of conventional plate-on-plate construction methods.

Paper 948 1 **Impurities in Recycling Steels - Challenge and Potential for the Fatigue Resistance of Steels**

Prof. Ulrich Krupp, Germany

Keynote (Oral Presentation 40')

Abstract

Representing more than 20% of the industrial CO₂ emissions, the steel value chain provides a powerful lever to substantially contribute to the goal of eliminating the net CO₂ emissions by 2050. The transformation towards direct reduced iron (DRI) that can be gradually mixed with scrap and melted in the electric arc furnace (EAF) allows climate-neutral production of steel grades. However, the change in metallurgical refinement by the DRI route and contamination of post-consumer scrap, lead to variations and gradual accumulation of detrimental impurities, like Cu, Sn or N. Accordingly, the respective recycling steel grades are not sufficient to fulfil the demanding specifications of modern steel grades. During hot forming, selective oxidation of Fe leads to a near-surface enrichment in Cu that may segregate at the prior austenite grain boundaries, eventually leading to the problem of hot shortness, i.e., massive embrittlement of hot-formed steel products. Increasing nitrogen contents lead to the risk of coarse TiN inclusions, acting as fatigue crack initiation sites in high strength steels. In the present study, various low- and medium-C lab-scale steel grades were enriched with 0.5 to 2 wt.% Cu and tested with respect to hot shortness susceptibility and fatigue behaviour in the solution-annealed and aged state. In the case of aged Cu-containing steel grades, an improvement of the fatigue strength and damage tolerance is associated with the precipitation of nano-sized, semi coherent Cu precipitates that were identified by high resolution transmission electron microscopy (TEM) and atom probe tomography (APT). The results are discussed in terms of future recycling steel grades with higher degrees of impurities and inclusions but nevertheless, having fatigue-resistant microstructures for successful application in a circular economy.

Atom probe tomography investigation of the impact of tramp elements from steel scrap recycling on the embrittlement of 51CrV4 quenched and tempered steel

Mr. Nikolaus Kostwein, Austria

Oral Presentation (20')

Abstract

To mitigate CO₂ emissions, the steel industry increasingly relies on recycling steel scrap using the electric arc furnace. However, this practice introduces increased amounts of tramp elements such as Ni, Cr, Mo, Cu, Sn, Sb, and As into steels, some of which, unless already used as alloying elements, can significantly degrade mechanical properties. Sn, Sb, and As are particularly detrimental among the tramp elements, potentially causing severe embrittlement.

This study investigates the effects of tramp elements on an industrial 51CrV4 steel subjected to quenching and tempering. Small-scale laboratory alloys were produced with controlled additions of Sn, Sb, Cu, and Ni to simulate increased levels that may occur due to recycling in the future, ranging from 0.01 – 0.2 wt.%. Hardening at 840 °C and tempering at 450 °C, 550 °C, and 650 °C with subsequent furnace cooling was applied to assess the susceptibility to reversible temper embrittlement. Mechanical properties were evaluated using tensile and Charpy V-notch impact tests, while multiple microstructural characterisation methods were employed to identify the cause of the embrittlement. The results revealed no significant change in tensile strength or elongation, consistent with the absence of detectable microstructural changes in scanning electron microscopy and electron backscatter diffraction analyses. However, impact toughness decreased by half with increasing amounts of Sn, Sb, and Cu. In combination with advanced site-specific sample preparation methods using femtosecond laser ablation and focused ion beam techniques, atom probe tomography (APT) was used to identify nanostructural changes. APT revealed nm-sized Cu clusters and precipitates along grain boundaries and significant segregation of Sn and Sb to high-angle grain boundaries. Furthermore, the difference in segregation to various types of high-angle grain boundaries, specifically martensitic and prior austenitic grain boundaries, is discussed. These findings suggest that embrittlement is primarily driven by the segregation of Sn and Sb and nanoscale precipitation of Cu at high-angle grain boundaries rather than bulk microstructural changes.

This work highlights the critical role of tramp elements, particularly Cu, Sn, and Sb, in the embrittlement of 51CrV4 steel during tempering. It underscores the importance of advanced characterisation techniques, such as APT, for uncovering the nanoscale mechanisms behind mechanical property degradation.

Making High Mn Steel by Sustainable Ferromanganese Pre-alloy for Cryogenic Applications

Dr. Shao-Lun Lu, Germany

Oral Presentation (20')

Abstract

Driving toward net-zero CO₂ emissions in steel industry, a more sustainable approach should be adopted in both iron-making and steel-making processes. While the sustainability of iron making is supported by the prospering hydrogen-based direct reduction technology [1], research on the sustainability of alloying ingredients used in steel making has been limited.

In this study, we utilized three Mn alloying ingredients to produce three high Mn steels with similar composition. The first one is electrolytic Mn (hereafter referred to as "EMn"), which is a high purity form of metallic Mn; the second one is a conventional medium carbon ferromanganese pre-alloy (FeMn), which has been used in the steel making industry; and the third one is a "green" FeMn pre-alloy produced by a novel "HAIMan" process, which ensures lower energy consumption during the production of FeMn pre-alloy [2]. These three steels were named as EMn steel, MCFEMn steel and HAIMan steel. The chemical composition is designed with the aid of thermodynamic calculation, aiming for cryogenic applications of high Mn steel.

All three steels are produced by a lab-scale vacuum induction melting furnace, and underwent identical thermomechanical processing. Comparability between these steels were demonstrated by a thorough microstructure characterization, and mechanical testing at either room temperature or cryogenic temperature. From the testing results, all three steels exhibited similar microstructure, similar grade of tensile properties and impact toughness, which demonstrated the feasibility of making high Mn steel by the HAIMan "green" FeMn pre-alloy.

In summary, the HAIMan steel showcases similar grade of high Mn steel performance as EMn steel and MCFEMn steel while utilizing a more sustainable alloying ingredient. This research effort aims to reduce the overall energy consumption of steel making without compromising steel performance, contributing to a more sustainable future in the steel industry.

Paper 64 **4** **Alteration of phase transformation behavior due to elevated tramp element concentrations in a hypoeutectoid steel**

Mr. Lukas Hatzenbichler, Austria

Oral Presentation (20')

Abstract

In order to reduce CO₂ emissions, steel industry shifts their production towards the usage of higher scrap amounts. This transformation leads to an elevation of tramp element concentrations, which could alter the steel's behavior during heat treatments. In this work, the phase transformation behavior of a hypoeutectoid steel grade was studied in detail. A reference alloy from the blast furnace route is compared to trial alloys with intentionally increased tramp element concentrations.

Dilatometry experiments were conducted to determine phase transformation temperatures and construct continuous cooling transformation diagrams. Additionally, a detailed exploration of the microstructure was done with hardness measurements, light optical- as well as scanning electron microscopy including electron backscatter diffraction. Moreover, in-situ high-energy X-ray diffraction measurements were done to follow the microstructural evolution during a heat treatment and to give a detailed overview of the evolved phases after cooling. Finally, the prior austenite grain size has been measured with a high-temperature laser scanning confocal microscope and correlated to the results of the phase transformation behaviors.

The results show that tramp elements not only shift the phase fields in the continuous cooling transformation diagrams to longer times, but also decrease the phase transformation temperatures. As a consequence, the evolution of displacive phases, such as martensite and bainite accompanied by retained austenite, is facilitated during cooling. Furthermore, it has been observed that tramp elements impede the growth of prior austenite grains by segregating to the grain boundaries at high temperatures, thereby inducing a solute drag effect, which could influence subsequent phase transformations as well.

Paper 180 **5** **Fundamental study on grain boundary segregation in Fe-Zn system using in-situ heating transmission electron microscopy**
Dr. Yuki Ikeda, Germany
Oral Presentation (20')

Abstract

The strong need for high-performing materials drives the continuous development of new structural materials. One such example is the next generation galvanized advanced high-strength steels (GI-AHSSs) that excellently combine strength and ductility with a high corrosion resistance. Despite its outstanding performance, this new material class often suffers from ductility degradation due to so-called liquid-metal embrittlement (LME) by Zinc (Zn) during metallurgical joining processes. Under such conditions, the GI coating may melt, allowing Zn to diffuse along grain boundaries (GBs), thereby initiating embrittlement of the matrix. Based on our recent findings using 4D-STEM and thermodynamic calculations, the occurrence of an interfacial decomposition and the subsequent formation of Fe-Zn compounds along high-angle GBs (HAGBs) are sought to be the root cause of LME (Mat. Today Adv. 13 (2022) 100196; Acta Mater. 259 (2023) 119243; Scripta Mater. 238 (2024) 115758). Here we now aim at directly tracking this proposed GB-mechanisms during in-situ TEM experiments. To this end, we capture the microstructural dynamics of Zn-bearing HAGBs. In this talk, we will report the first results of our in-situ heating TEM observation in the temperature regime from 150 °C to 500 °C, which yielded significant alternation of the GB structure due to the presence of Zn upon isothermal heating. The outcome will be discussed in the context of GB segregation and interfacial decomposition in connection to LME of GI-AHSS.

Paper 1052 1 **Effect of Mo and Cu on hot deformation behavior, recrystallization kinetics and thermomechanical processing of QP-treated medium-Mn steels**

Prof. Adam Grajcar, Poland

Highlight (Oral Presentation 20')

Abstract

The evolution of Quenching and Partitioning (QP) steels was from 0.2C-1.5Mn-1.5Si to higher strength levels using increased C and/or Mn contents. Especially promising results were achieved in lean medium-Mn sheet steels like: 0.2C-(3-5)Mn alloyed with different Si and/or Al additions. Microalloying was also applied, although it should be noted that the effects of Nb and Ti (sometimes V) are different than that known in HSLA steels. Finally, recycling induced impurity elements (like Cu, Cr, Mo, Ni) need to be consider for new steel designs.

The high hardenability of Mn and its effective use makes sense in high-thickness products like plates for structural applications or forgings for automotive or machine industries. The hot deformability of three 4Mn steels alloyed with silicon and aluminum were investigated in the present study. Mo alone (0.3wt.%) or together with Cu (1wt.%) were added to investigate the effects of the elements on hot deformability compared to the 0.17C-4Mn-0.5Si-0.8Al reference steel. The continuous compression tests were performed at 900, 1000 and 1100°C at different strain rates of 0.05, 0.5 and 5 s⁻¹ in the Gleeble 3800 simulator. The registered compression curves allowed to assess values of flow stress and to determine the activation energy of plastic deformation, which was above 420 kJ/mol. Double-hit compression tests were applied to determine the kinetics of austenite recrystallization. Finally, the steels were subjected to different quenching and partitioning treatments following the deformation to identify the effect of the QP parameters on microstructure, retained austenite amount and sub-sized mechanical properties.

Characterization of high-strength medium manganese zinc-coated steels for the automotive industry

Ph.D. Mattia Franceschi, Spain

Oral Presentation (20')

Abstract

Advanced high-strength steels (AHSS) continue to evolve in response to the automotive industry's stringent requirements for enhanced environmental sustainability and passenger safety. Within this evolution, medium manganese steels (MMnS), representative of the third generation AHSS, have emerged as exceptional candidates. These steels are characterized by a distinctive compositional range of 3-12 wt.% manganese, up to 0.4 wt.% carbon, complemented by strategic additions of Si, Al, Cr, and microalloying elements (Nb, Ti, and V). Their complex microstructure, comprising ferrite/martensite and retained austenite (>10%), can yield an exceptional combination of high ultimate tensile strength (UTS ~ 1.2-1.6 GPa) and substantial total elongation (TE ~ 15-20%), rendering them particularly suitable for automotive anti-intrusion components and high-energy absorption applications. Moreover, their elevated manganese content facilitates reduced forming temperatures during warm stamping processes while maintaining compatibility with zinc-based corrosion protection coatings, thus addressing historical challenges of liquid metal embrittlement with Zn-coating and associated cracking.

This research focused on developing novel medium manganese steels specifically engineered to meet demanding requirements for high-energy absorption (Total Elongation $\geq 18\%$, Ultimate Tensile Strength ≥ 1200 MPa) and anti-intrusion (TE $\geq 10\%$, UTS ≥ 1500 MPa) components. The alloy design methodology incorporated comprehensive thermodynamic calculations to determine critical transformation temperatures (Ac1, Ac3, Ms) and phase evolution characteristics (volume fraction and chemical composition), using 22MnB5 steel as a benchmark. Based on these calculations, nine distinct steel compositions were formulated varying C, Mn, Al, Cr and B contents, and subsequently produced as 50 kg ingots and processed through sequential hot and cold rolling. The specimens underwent systematic industrial process simulation, encompassing intercritical annealing (700-760°C), hot-dip galvanizing (470°C), hot stamping (700-750°C), and paint baking treatments (170°C, 20 minutes). Through micro-tensile testing, two optimal compositions were identified and subjected to a comprehensive characterization utilizing high-resolution dilatometry, scanning electron microscopy, X-ray diffraction analysis, and hardness measurements. The resultant microstructure consisted of a mixture of ferrite, martensite, and carbon-enriched retained austenite (7-30%), and sometime carbides. The developed materials demonstrated superior mechanical properties, with hardness values ranging from 400 to 500 HV, ultimate tensile strength of 1200-1700 MPa, and total elongation of 10-22%.

Funding received for this work from the European Research Executive Agency (REA) under the Grant Agreement No. 101112425 is gratefully acknowledged.

3

Design of QP heat treatments for plastically-deformed and undeformed austenite in medium-Mn steels alloyed with Mo and Cu

Dr. Aleksandra Kozłowska, Poland

Oral Presentation (20')

Abstract

High strength steels (yield strength >700 MPa and tensile strength >900 MPa) are widely used for automotive forgings, which should withstand high stresses under different load conditions. The 42CrMo4 steel meets the requirements concerning a combination of high strength and fracture resistance; however, due to the increased chromium content and the need for applying high-temperature energy-consuming heat treatment after the forging process, the use of this type of steel associated with a high environmental impact. A promising alternative to 42CrMo4 steel are medium manganese steels containing 3-5 wt.% of Mn. This type of steel has a multiphase microstructure composed of ferritic/bainitic or martensitic matrix providing high strength and 10-15% of ductile retained austenite (RA) preventing the formation of microcracks.

Ultra-high strength (yield strength >900 MPa and tensile strength >1300 MPa) Quenching and Partitioning QP steels have been originally developed for hot/cold rolled automotive sheets. Such beneficial mechanical properties can be achieved for medium-Mn QP steels mainly through proper designing of martensite-austenite (a quenching step) ratio and a tailored stability of RA (a partitioning step). The adaptation of QP treatment for products with increased thickness requires different approaches for designing their thermal processing routes. The challenge is to ensure a uniform microstructure throughout the entire cross-section of the forging.

The aim of this study is to characterize the phase transformation kinetics of plastically-deformed and undeformed austenite during the isothermal holding step and to design optimal time-temperature parameters of QP treatment of medium-Mn steels (4 wt.% of Mn) containing Cu and/or Mo additions with a potential application for automotive forgings. The critical temperatures as well as phase transition phenomena during isothermal holding were theoretically determined using Thermo-Calc and JMatPro softwares. The experimental time-temperature-transformation (TTT) and deformation-time-temperature-transformation (DTTT) diagrams were determined in dilatometric investigations, which were the basis for designing quenching and partitioning parameters of the QP treatment. Due to the increased Mn addition, only the formation of martensite and bainite were recorded during the isothermal holding step, while the formation of undesired ferrite and pearlite was eliminated both in the plastically-deformed and undeformed states. The quenching temperatures in a range of 270-290°C were applied to determine the optimal martensite-austenite ratio. The partitioning step was carried out at temperatures from 400 to 450°C and times from 120 to 900s to obtain lath-type microstructures composed of carbide-free martensite and about 10-15% of RA with a tailored stability.

Atom-scale insights on the influence of B in preventing liquid metal embrittlement (LME) of third-generation advanced high-strength steels (AHSS)

Dr. Kiranbabu Srikakulapu, Austria

Oral Presentation (20')

Abstract

The 3rd generation advanced high strength steels (AHSS) are developed to optimize strength and ductility combinations majorly for automotive structural application. Examples of such steels include enhanced dual-phase (DP) steels, modified transformation induced plasticity (TRIP) steels, medium-Mn TRIP steels, ultrafine bainitic steels and, quenching and partitioning (Q&P) steels. Some AHSS grades are alloyed with high Si to prevent detrimental cementite precipitation. Moreover, the automobile AHSS parts undergo sacrificial Zn or Zn-Fe coating to prevent corrosion. However, The presence of Si enhances Zn-assisted liquid metal embrittlement (LME) behavior during resistance spot welding, a common welding process for automobile parts. The LME is an embrittlement phenomenon that occurs because of molten Zn diffusion into steel prior austenite grain boundaries (PAGBs) during welding. The diffused Zn reduces PAGBs cohesive strength and thus causes intergranular cracking in the presence of tensile stresses. The mitigation of LME is possible through 10-50 wt.ppm B addition to the steel's chemistry. The significant reduction of crack lengths was conclusively verified using an LME-specific resistance spot welding test. The theory is that B segregates to PAGBs, mitigates Zn diffusion, and thus regulates LME cracking by decreasing grain boundary energy. Recent investigations through hot-tensile tests also displayed B effectiveness except for the tests performed at 900 °C. Here, the ductility loss of the boron steel appears higher, which suggests a shift in the state of B and its behavior regarding LME. In the current work, we use site-specific atom-probe tomography (APT) investigations to unravel the mechanisms causing ductility loss in a B-added AHSS heat-treated at 900 °C. The APT results show that all the B is confined in grain boundary nano-carbides network along PAGBs instead of segregating at PAGBs. Thus, B is no longer playing the role in decreasing the grain boundary energy through segregation. Moreover, the generated precipitate-matrix interfaces are supposedly weaker than PAGBs. This further resulted in adverse performance at 900 °C than in no-B condition.

Paper 502 5 Mechanical performance of Al-alloyed medium-Mn steels following IA and QP treatments in the continuous annealing regime

Dr. Adam Skowronek, Poland

Oral Presentation (20')

Abstract

The final mechanical properties of construction elements in the automotive industry are often determined in sheet steel stage during heat treatment. For storage, transportation, and technological purposes, steel sheets are often rolled into coils. The heat treatment process of steel coils may be performed using either batch or continuous annealing. A significant drawback of batch annealing is the long processing time and the non-uniform mechanical properties along the coiled steel. In continuous annealing, a single sheet thickness is heat-treated at a time, which shortens production time and enables the use of advanced thermal cycles, leading to multi-phase or two-phase structures. Recent advancements in automotive steels (AHSS) have led to the development of medium-Mn steels, which may represent an evolutionary step in the automotive steel industry. In this study, a systematic heat treatment optimization process was performed for IA and QP cycles on steel with a composition of 0.17% C, 4.7% Mn, 1.6% Al, 0.2% Si, and 0.2% Mo to achieve the highest possible strength and plasticity product. A wide range of parameters was analyzed, allowing for additional identification of conditions that ensure either maximum strength or plasticity. The heating and cooling rates, along with the energy-saving annealing time of maximum 120 s (intercritical soaking in IA and partitioning in QP), were selected to enable the heat treatment process using industrially available continuous annealing production lines. The research began with a dilatometric analysis of the material and an investigation of the influence of heat treatment parameters on the thermal stability of austenite (M_s temperature). For a promising range of process parameters, heat treatment was performed on subsized tensile samples using a dilatometer. In the IA process, the maximum UTS $\times$ TEI of 38 GPa% was obtained for a sample with a total elongation (TEI) of 38%. In the QP process, the maximum value was 29 GPa% for samples with a yield strength (YS) of 850 MPa.

Paper 1093 6 **Ultra-Rapid Heating and Phase Transformations in Low- and Medium-Alloy Steels: A Dilatometric Study**
Ph.D. Rafał Dziurka, Poland
Oral Presentation (20')

Abstract

The heat treatment of structural steels encompasses a wide range of technological processes, among which techniques utilizing ultra-rapid heating exceeding 100 °C/s hold a special place. Such dynamic temperature changes enable the development of unique material properties, which can be crucial for engineering applications in automotive, aerospace, and energy industries. In industrial and research practices, induction heating technology is commonly used for ultra-rapid heating processes, allowing for extremely high heating rates while maintaining precise temperature control. Applying appropriate analytical methods is essential to accurately track phase transformations for the physical modeling of such processes. One of the most effective tools for this purpose is dilatometry, which enables the recording of dimensional changes in the material as a function of temperature and time, providing valuable insights into the kinetics and extent of phase transformations. This study presents dilatometric investigations of cyclic ultra-rapid heating processes conducted using the Linseise L78 RITA dilatometer. This device utilizes inductive heating, allowing precise control of the sample heating rate up to 500 °C/s, simultaneously measuring length changes at a resolution of 0.01 µm. Such measurement capabilities enable a detailed analysis of the influence of ultra-rapid heating on the kinetics of phase transformations and the microstructure formed during rapid cooling. The experimental studies were conducted on low-alloy steels with varying carbon content and on medium-alloy steels enriched with chromium, manganese, molybdenum, and vanadium. Special attention was given to analyzing the differences in the phase transformation behavior between non-alloyed and alloyed steels. These studies provide new insights into the effects of ultra-rapid heating on steel microstructure and final properties, contributing to the optimization of modern heat treatment processes. Additionally, cyclic heating with ultra-rapid austenitization enables controlled microstructural refinement, particularly influencing the prior austenite grain size. In some cases of alloyed steels, this process allows a significant grain size reduction, decreasing the average grain diameter from 30 µm to 5 µm. This effect is associated with shifting the recrystallization temperature into the austenite formation range, which limits grain growth by overlapping recrystallization and phase transformation processes. As a result, precise control over the material's microstructure is achieved, critical for enhancing its mechanical properties, such as strength, ductility, and fracture toughness.

Paper 132 1 Machine Learning and Kinetic Monte Carlo Models of Transport in Concentrated Alloys

Ph.D. Anjana Talapatra, United States

Highlight (Oral Presentation 20')

Abstract

With the increasing interest in so-called high entropy, multi-principal component, or compositionally complex alloys, there is a greater need to understand how transport is affected by the complex chemistry of these materials. As compared to a simple elemental solid, in which every lattice site is identical and transport can be described by a handful of saddle points, these materials exhibit a very rugged potential energy surface in which every site has a unique chemical environment. This means that every site exhibits a different defect formation energy and corresponding migration barriers for motion to neighboring sites. As the number of elements in these systems increases, it becomes increasingly challenging, and soon impossible, to enumerate the energetics of every site in the system. Alternative approaches are necessary. Machine learning has become a popular choice to describe the chemistry-dependent properties of defects in these alloys. By training on atomistic data, machine learning models can predict the energetics of defects in unseen environments and be subsequently used in kinetic Monte Carlo simulations of defect transport. However, for the transport simulations to be thermodynamically valid, the underlying machine learning model must obey detailed balance. Here, we describe various ways that detailed balance can be enforced in a machine learning model of defect formation and migration energies. Specifically, we consider a brute force model, a “soft constraint” model in which penalty associated with detailed balance is added to the loss function, and two “hard constraint” models in which detailed balance is explicitly included in the architecture of the model. We find that these physically-constrained models exhibit superior performance in maintaining detailed balance. This is demonstrated by determining the error in the energy of the system as defects traverse closed loops. We conclude that detailed balance must be considered to obtain valid trajectories. We implement this approach to investigate various materials science problems with inherent constraints.

Oral Presentation (20')

Abstract

Machine learning based potentials represent a new powerful tool for accurate modelling of complex interatomic interactions in materials. In our work, we apply the high-dimensional neural network (HDNNP) methodology using the atom-centred symmetry function descriptors for the shape memory alloy NiTi in the martensitic phase [1].

NiTi is a system that poses significant challenges for both experimental and theoretical modelling, and an accurate atomistic scale model is required to fully understand all of its mechanical properties. Recent experimental results from thermomechanical testing and microstructural analysis of polycrystalline NiTi shape memory alloys have provided a qualitatively new picture of the plastic deformation mechanisms of this most common shape memory material. In particular, they challenge the widely accepted paradigm that austenite is a phase more susceptible to dislocation slip and plastic deformation in NiTi than B19' martensite, despite the fact that only a single [100](001)M dislocation slip system is observed in martensite. The simultaneous activation of [100](001)M plastic slip and reorientation of martensite between two variants sharing the (010)M plane results in kink banding and twinning, forming the so-called "kwink" bands [2].

We show that our newly developed interatomic potential is suitable for simulating the evolution of the martensitic microstructure, is close in accuracy to density functional theory, preserves the strong plastic slip anisotropy of NiTi in the martensitic phase, and has all the prerequisites to simulate the new kwink mechanism.

Decoupling chemical and vibrational contributions to vacancy formation at high temperatures in MoTaNbWV high-entropy alloys

Mr. Xiang Xu, Germany

Oral Presentation (20')

Abstract

We calculate the temperature-dependent vacancy formation energies in the refractory high-entropy alloy (HEA) MoTaNbWV and its unary, binary, and quaternary subsystems using machine-learning-based interatomic potentials. This study systematically examines the chemical, configurational, and vibrational contributions to vacancy formation over a broad temperature range of up to 3000 K. The results show that while temperature strongly influences vacancy formation energies, vibrational contributions remain largely independent of the local chemical environment, even at high temperatures. This finding reveals a decoupling between chemical and vibrational contributions. Leveraging this insight, we develop a general phenomenological model that treats these entropic contributions separately, enabling accurate predictions of vacancy formation energies across all investigated subsystems and the MoTaNbWV HEA. These findings provide a foundation for improving diffusion models and optimizing the design of multicomponent alloys.

Paper 1444 5

Ab initio machine-learning unveils strong anharmonicity in non-Arrhenius self-diffusion of tungsten

Dr. Jiahui Zhang, Finland

Oral Presentation (20')

Abstract

Understanding diffusion mechanisms in materials is essential for predicting their high-temperature behavior and stability, yet accurately capturing the underlying physics, particularly thermal effects, remains a challenge. In particular, the experimentally observed non-Arrhenius diffusion behavior has long been difficult to explain due to the lack of effective computational approaches. Here, we introduce an efficient ab initio framework for computing the Gibbs energy of the transition state in vacancy-mediated diffusion, incorporating relevant thermal excitations at the density-functional-theory level. Leveraging a tailored machine-learning interatomic potential, we demonstrate that the temperature-dependent vacancy formation and migration Gibbs energies in body-centered cubic (BCC) tungsten are significantly influenced by anharmonic effects. This insight provides a fundamental explanation for the non-Arrhenius self-diffusion behavior observed in experiments. Our results exhibit remarkable agreement with experimental self-diffusivity data, accurately capturing both the temperature dependence and its curvature. Furthermore, the robustness and versatility of the framework are highlighted through preliminary applications to a hexagonal close-packed (HCP) multicomponent high-entropy alloy. These findings establish a reliable path toward an accurate ab initio diffusion database, enabling predictive modeling across diverse material systems.

Foundation Models For Aluminium Alloys

Dr. Daniel Marchand, Norway

Oral Presentation (20')

Abstract

Foundation models have proven very popular in recent years, with new record-breaking models coming out every month. But how accurate are they, and can they replace "bespoke" potentials? In this talk I will present the state of the art in both categories.

First, I will show that using the GRACE2L-OAM foundation model we can achieve very high accuracy across a broad range of metallurgically-relevant benchmarks "out of the box" with no further modification or fine-tuning. Overall these models are able to produce results that are almost as accurate as a collection of custom BP-NNPs for aluminium developed over the course of several years by hand.

I will then show how the ACE model can be used to create a class of very powerful next-generation custom potentials. Some techniques, such as ladder learning, and training on individual elements first will be discussed. A performance evaluation showing how while foundation models can produce very impressive results, for the greatest accuracy and speed one should still use 'bespoke models'.

This talk will include the challenges in computing material properties: elastic constants, lattice constants, surface energies, generalized stacking fault energies and dilute solute interactions. I will also cover how to select and evaluate foundation models and reasons why any of the most popular datasets (at time of writing) are insufficient for aluminium metallurgy. Computational considerations, such as how to design effective 'unit tests' for interatomic potentials, and computational performance issues regarding the ASE python interface vs directly computing with LAMMPS.

While the focus will be on aluminium alloys, the author will also mention the use of foundation potentials in the context of designing new batteries and magnetic materials.

First-principles and machine learning-accelerated molecular dynamics for complex disordered materials in energy applications

Dr. Guido Ori, France

Highlight (Oral Presentation 20')

Abstract

The accurate modeling of disordered materials is essential for understanding their potential impact and applications in energy applications. This work leverages first-principles molecular dynamics (FPMD) and machine learning interatomic potentials (MLIP) to bridge the accuracy of quantum mechanical methods with the efficiency of large/long-scales simulations. These advances enable us to accurately describe highly complex disordered systems—such as chalcogenides, transition metal-containing oxides, and antiperovskites—that have so far been approximated only by classical interatomic potentials.

We apply this approach to sodium vanadium phosphate (NVP) glasses and glass-ceramics, promising electrode materials for sodium-ion batteries; amorphous Na_3OCl , an emerging solid-state electrolyte; and disordered chalcogenides (GexSy, GeSe_y, GexSbyTez) for multifunctional applications, including thermal management in PCM devices. A crucial requirement for optimizing these materials is a detailed, quantitative description of their intricate structure and bonding, which in turn enables the accurate prediction of key functional properties such as ion dynamics, thermal conductivity, and electronic/magnetic behavior.

For NVP glasses and glass-ceramics, FPMD reveals the intricate interplay between V coordination, phosphate network polymerization, and Na-ion mobility, while MLIP simulations extend time and length scales, capturing percolation pathways critical for ion conduction [1-3]. Similarly, in Na_3OCl , our simulations establish the structural characteristics of the amorphous phase, validating MLIP models against FPMD-derived structure factors, structural features, and ion transport mechanisms [4-6]. The ability of MLIP-driven simulations to achieve near FPMD accuracy while reducing computational cost by orders of magnitude makes them indispensable for designing next-generation functional materials.

Additionally, we highlight advances in data-driven approaches for improving MLIP performance. Multikernel similarity-based clustering methods provide an optimized database construction framework, enhancing the representativity and transferability of MLIP for complex amorphous chalcogenides and enabling accurate predictions of their thermal properties at the nanoscale [7-10]. By integrating these advancements, our study establishes a powerful and efficient methodology for modeling disordered materials, paving the way for predictive materials design in energy applications.

Paper 1150 1 Machine learning and Bayesian calibration of multiphysics simulations of crystal growth

Prof. Lorenz Romaner, Austria

Highlight (Oral Presentation 20')

Abstract

Material development and optimization inherit the need to understand and control processing-structure-property relationships. Of particular interest is SiC, which is utilized in power electronic devices due to its exceptional properties such as a wide bandgap, high breakdown voltage, and high thermal conductivity. The most common method to produce SiC single crystals is through physical vapor transport (PVT) where the SiC boules are grown within a closed reactor. Process temperatures around 2000 °C as well as pressure close to 5 mbar make it not only challenging to acquire experimental data but also complicate the quantification of physical material properties of the system. In order to improve process knowledge and reduce the need for expensive experimental trials, multiphysics FEM-based crystal growth simulations are frequently utilized. Reliable models not only facilitate the production of high-quality crystals as well as high output and resource-saving processes, but they can also aid in optimizing growth conditions or scaling the process appropriately. However, models must consider complex coupled physics phenomena, accurately representing the key aspects of the growth environment within reasonable computational efforts. A further challenge arises from uncertainty in the materials parameters of the furnace which need to be calibrated precisely to achieve reliable simulation results. Novel techniques from machine learning (ML) offer great opportunities in this respect.

We present an approach providing a computational and time-efficient active learning algorithm, that sequentially builds an ML model that can replace the COMSOL multiphysics calculation to access relevant quantities in the reactor. Training data are generated by sequential design of experiment combined with Gaussian Process Regression. Based on real PVT furnace data, ML models in combination with Bayesian inference, particularly with Markov Chain Monte Carlo, are used to calibrate the unknown physical material parameters. With this, our approach addresses several challenges simultaneously, i) improvement of execution speed of multi-physics FEM simulations ii) calibration of the FEM simulations to experiments iii) in-service determination of materials properties, and iv) material degradation monitoring. The adapted methodology is quite general and shows great potential to be used also for other calibration tasks and for different downstream tasks, like sensitivity and uncertainty analyses.

Phase-field simulations of grain and dendritic-scale microstructures under additive manufacturing solidification conditions

Mr. Saurabh Tiwari, India

Oral Presentation (20')

Abstract

Investigations of directionally solidifying melt pools during metal additive manufacturing (AM) reveal that the resulting subgrain cellular structures often grow along crystalline orientations different from the temperature gradient direction, some of which are not even along preferred crystallographic directions. It is well-known that dendrite orientation results from the growth competition between the heat flow direction and preferred crystallographic orientation. Specifically, the competition between interfacial anisotropy and process anisotropy (thermal gradient and interface velocity) during directional solidification leads to rich morphological diversity of the resulting dendritic structures, including columnar dendrites, tilted dendrites, and seaweed patterns. The orientation selection mechanisms of such patterns remain unexplored at high velocity in the frame of AM. We study the tilted growth of cellular-dendritic arrays as a function of the misorientation angle between the thermal gradient and crystal lattice directions and other relevant control parameters. First, we explore dendritic-scale microstructure evolution during high-velocity binary alloy solidification using two-dimensional phase-field simulations. We find marked effects of thermal gradient, growth velocity, alloy composition, and anisotropy parameters on the possible growth directions and the primary arm spacing, constitutional undercooling, microsegregation, and secondary phases that arise during dendritic-scale melt-pool solidification. Then, growth competition among favorably- and unfavorably-oriented dendrites was simulated as a function of misorientation within a bicrystal setup. Finally, we perform simulations of grain-scale solidification within a full-melt pool to shed light on the formation of cellular microstructures, stray grains, and competitive grain growth, among others. The results reasonably agree with analytical and experimental measurements. Our findings should have qualitative relevance for controlling the subgrain structure, chemical segregation, and texture randomization in various commercial dendrite materials relevant to AM.

Paper 1241 4 **A Phase-Field Study on the Effect of Nanoparticle Size, Concentration and Type on Columnar Growth during Electrodeposition**
Dr. Javier Fernández Troncoso, Spain
Oral Presentation (20')

Abstract Electrodeposition is a complex process in which a metal or alloy accumulates onto the surface of another material via reduction and oxidation reactions in the presence of an electric current. However, the properties of the resulting coating depend strongly on the final surface texture and solidification dynamics. In this presentation, we introduce how the incorporation of nanoparticles into a polycrystalline matrix during electrodeposition significantly influences the solidification process, affecting both columnar growth and surface texture, and study the effect of nanoparticle size, shape and type via Phase-Field modelling. We observed that relatively large concentrations of spherical metal oxide nanoparticles like MgO or Al₂O₃, which enhance interface wettability, and 2D nanomaterials like MoS₂ or graphene, thanks to their capability to reduce drag and promote smooth interface movement, show up as perfect candidates to control columnar growth during electrodeposition.

Paper 1165 5 **A multi-phase-field model for simulation of solid-state sintering**
Dr. Sandeep Sugathan, South Korea
Oral Presentation (20')

Abstract Particle sintering is a well-established and widely utilized powder-processing technique for manufacturing metal and ceramic components. Sintering induces morphological changes in the green compact, reducing surface area and increasing density. Understanding the mechanisms behind the densification and microstructural evolution during the sintering process is of immense importance because of its broad industrial applications. A model is developed based on the multi-phase-field approach to describe the microstructural evolution during solid-state sintering. This model integrates the multiphase Allen-Cahn equations to describe the evolution of different particle phases and the multiphase Cahn-Hilliard equations to characterise the behaviour of the vapour phase. The multiphase Cahn-Hilliard formulation enforces volume conservation of the sintering compact, ensuring physically realistic simulations. The model considers different diffusion mechanisms including volume diffusion, surface diffusion, and grain boundary diffusion together with grain boundary migration. To enhance computational efficiency, the model is implemented using parallel GPU-based computing, allowing for the simulation of multiple interacting particles. We validate the model by matching two-particle sintering simulations with the analytic solutions. We also investigate the relation between the dihedral angles and energy ratios of the sintered powder particles. Beyond two-particle interactions, we extend our investigation to large-scale sintering simulations involving multiple particles. The results of these large-scale sintering simulations of multiple particles are compared with an existing analytic model.

A phase-field model of CALPHAD stoichiometric phases of Aluminum alloys

Dr. Dong-Uk Kim, South Korea

Oral Presentation (20')

Abstract

The phase-field method is widely recognized as one of the most effective tools for simulating meso-scale material phenomena due to its robust interface tracking capabilities. It allows for the modeling of complex interfacial dynamics, including arbitrary interface shapes, with minimal computational effort. By incorporating the equal diffusion potential condition and anti-trapping currents, the method significantly reduces numerical artifacts associated with diffusive interfaces. However, challenges remain, particularly in accurately modeling stoichiometric phases. A key difficulty arises from the use of point-wise free energy expressed in terms of composition, which often lacks the necessary composition dependencies. This limitation forces the introduction of artificial composition variations to apply the equal diffusion potential condition. In this study, we address these challenges by developing a phase-field model that is both computationally efficient and easy to formulate for stoichiometric phases and phases with limited solubility. Our approach builds upon the existing relaxation-based equal diffusion potential condition, which has proven effective for simple soluble phases. We extend this framework to more complex systems, including general stoichiometric compounds and phases with restricted solubility ranges. By refining the model in this way, we aim to improve the accuracy and efficiency of phase-field simulations for a broader range of material systems, ultimately enabling better predictions of meso-scale material behaviors in diverse contexts. This work represents a step forward in the development of practical, versatile phase-field methods for complex material phenomena.

On Neural Networks for Grain Boundary Segregation

Prof. Fadi Abdeljawad, United States

Highlight (Oral Presentation 20')

Abstract

Most structural and functional materials are polycrystals; they are composed of crystalline grains that are joined at grain boundaries (GBs). Such interfaces play a critical role in controlling many engineering and functional properties. Understanding GB physics is, therefore, a key aspect of materials discovery and design efforts. Owing to their local atomic environments, GBs provide preferential sites for alloying elements to occupy. Indeed, the direct manipulation of GB chemical states has been found to influence a host of materials properties and processes, such as cohesion, electrochemical response, and electrical conductivity. Of particular interest is the impact of GB solute segregation on boundary dynamics, as it influences microstructure formation and evolution pathways during processing treatments or under operating environments. For example, GB segregation has been used to mitigate grain coarsening and thermally stabilize nanograined structures. While GB solute segregation has been the subject of active research, most existing studies focus on the thermodynamics of GB segregation and the kinetic role (i.e., dynamic solute drag) remains unexplored. GB solute drag results when segregated alloying elements exert a resistive force on migrating GBs hindering their motion. The challenge here is that solute drag depends on several properties, such as alloy thermodynamics, and dynamic processes including solute diffusion and boundary migration; solute drag is a hypersurface. In this talk, we unravel GB dynamic solute drag through theoretical analysis, mesoscale modeling, and machine learning studies. We establish design maps relating drag effects to relevant bulk alloy and GB properties. We find that solute drag is dominant in immiscible alloys with far-from-dilute compositions in agreement with experimental observations of GB segregation in metallic alloys. Further, asymmetric GB segregation is found to greatly influence solute drag values. On the whole, our work provides future avenues to employ GB segregation to control GB dynamical processes.

Extending Grain Boundary Phase Diagrams to Multi-Phase Boundary Diagrams

Dr. Jegatheesan Murugan, Germany

Oral Presentation (20')

Abstract

Phase diagrams serve as fundamental blueprints for comprehending material behaviour and guiding material design. However, the phase diagrams are largely available only for the bulk phases. The thermodynamic properties and phase behaviour of defects, such as grain boundaries (GBs) and phase boundaries (PBs), are equally important for the safe design of materials. Recently, we developed CALPHAD-integrated density-based phase field model (DPF) to calculate the thermodynamic data of GBs. In the model, the GB was represented by a continuous relative atomic density field with reference to a single bulk density and a Gibbs free energy functional was derived. In this work, we extend the DPF model by re-deriving the Gibbs free energy functional for PBs lying between heterogeneous bulk phases of different atomic densities. Here, we use phase-specific atomic densities to normalize the phase properties on either side of the PB such that the relative density fields are continuous across the interface. Using the model, the multi-phase interfacial thermodynamic data are obtained and related phase boundary diagrams are constructed. We study binary and ternary Fe-Mn-X alloy systems. In the Fe-Mn multi-phase boundary diagram, a shrinkage in the α -ferrite region is observed. Integrated with CALPHAD databases, the developed model may be used to calculate the segregation of solute to the PBs, paving way to manipulate segregation behaviour for microstructure design.

Data-Driven Prediction of Thermal and Mechanical Properties in Composite Materials Using Machine Learning and Computational Simulations

Mrs. Mozhdeh Fathidoost, Germany

Oral Presentation (20')

Abstract

The effective design of composite materials with tailored thermal and mechanical properties requires a fundamental understanding of the underlying structure-property relationships (SPR). However, establishing accurate SPR models is challenging due to the complexity of microstructural features and the high cost of experimental characterization. To address these challenges, this study employs data-driven methods, combining machine learning (ML), computational homogenization, and finite element simulations to predict thermal and viscoelastic behaviors of composite materials. For thermal conductivity prediction, an ML-based approach is developed using microstructural features extracted from scanning electron microscopy (SEM) images. The microstructure is reconstructed using a diffuse interface method, facilitating accurate interpolation of phase and interface properties. Principal Component Analysis (PCA) is utilized to condense two-point statistics, which serve as input descriptors for the ML model. A dataset of 1440 synthetic microstructures is generated to train the model, with effective thermal conductivity values obtained from simulations. In parallel, a deep learning-based framework is proposed for predicting the viscoelastic behavior of composites. A recurrent neural network (RNN) is leveraged to capture the time-dependent stress-strain response under varying loading conditions. This approach integrates microstructural descriptors with applied loading histories, enabling the prediction of viscoelastic behavior beyond traditional constitutive models. The ML-based surrogate model efficiently maps complex structure-property relationships in ceramic composites and provides a computationally efficient alternative to direct finite element simulations. This study highlights the potential of ML-driven approaches in accelerating the design of advanced composites by reducing reliance on expensive experiments and computationally intensive

Modelling exploration of contact area and stress in the deposition of a pathogen in an antimicrobial MIRIA nanocoated surface

Mr. Israel Bellanato, Spain

Oral Presentation (20')

Abstract

Innovative biocidal nanocoatings constitute a relevant option for preventing the spread of infectious diseases. Understanding their interaction with the pathogens they aim to eliminate is, therefore, essential for enhancing their efficacy and design. The model works with an elastic triangular mesh acting as the pathogen and immersed in a computational Lattice-Boltzmann fluid. The coated substrate is also modelled as a triangular mesh, and the interaction between both objects is introduced through a Lennard-Jones potential. The simulations performed cover the deposition of the pathogen on the nanocoated substrate, revealing the stress endured by the pathogen upon deposition and measuring the contact area between the pathogen and substrate. Additionally, simulations are performed for variations in the substrate roughness and dispersion of the surface at hand, introduced by scaling the surface in the z-direction, or in the (x,y)-plane. This enables an analysis of how these surface properties could affect the antipathogenicity of the substrate.

It is expected that for large dispersion values, as we initially consider, a higher roughness would lead to a higher contact area and, in theory, to lower stress, as the forces on the pathogen should be more distributed. Similarly, for static roughness, lower dispersion should lead to a lower contact area, presumably implying higher stress. This thesis is put to the test in the study, and the obtained results are presented, establishing the relationship between stress endured by the pathogen, contact area, surface roughness and dispersion. The main conclusion of the study is that there is a direct correlation between contact area and stress.

Mesoscale Modelling of Phase Transformations via Cellular Automata: The Role of Artificial and Physical Anisotropy in Ferrite Growth Kinetics

Dr. Jarosław Opara, Poland

Oral Presentation (20')

Abstract

This contribution presents a mesoscale modeling approach for the austenite-to-ferrite transformation in Fe–C–Mn steels, highlighting how both artificial and physical anisotropy can influence ferrite growth kinetics. The mesoscale model employs a Cellular Automata (CA) method to simulate phase growth, coupled with a finite difference (FD) method to model the diffusion of solute elements. Thermodynamic data are incorporated through the CALPHAD methodology, ensuring a robust calculation of the local driving force for phase transformation across heterogeneous compositions.

Artificial anisotropy stems from the microstructure discretisation using a regular CA grid, where a nominally isotropic interface migration velocity can generate non-spherical growth morphologies. On the other hand, physical anisotropy arises from a range of factors, including grain boundary curvature, crystallographic orientation, preferred boundary diffusion pathways, spatial variations in local chemical composition, and anisotropic diffusion coefficients sensitive to changes in carbon content. These phenomena collectively alter the local growth rate of ferrite, underlining the necessity of carefully accounting for microstructural heterogeneities and their thermodynamic implications.

By focusing on relatively simple Fe–C–Mn alloy compositions, the model effectively isolates and elucidates the impact of the aforementioned anisotropic effects. This approach not only provides more accurate predictions of ferrite kinetics but also paves the way for higher-fidelity simulations in modern steel-processing routes.

Paper 403 **1** **Investigating the micro-structure of calcium carbonate precipitated during bio-cementation of sand**

Dr. Marilyn Sarkis, France

Highlight (Oral Presentation 20')

Abstract

Bio-cementation of sand is a new, environmentally friendly process gaining traction for soil reinforcement, material fabrication, and for the preservation of buildings and monuments. This process uses bacterial activity to precipitate calcite (calcium carbonate, CaCO_3) crystals in the sand (quartz, SiO_2) matrix. This calcite acts as a binder between the sand particles. This process can be used as an alternative to other, hazardous materials that are commonly used in construction, such as cement. However, there is still a lack of information on the microstructure of these crystals and how it changes under mechanical load. Understanding this could be crucial for optimizing the process and improving the material's strength.

In this study, two samples were studied using x-ray tomography (CT), 3D X-ray Diffraction (3DXRD) and Dark Field X-ray Microscopy (DFXM) on ID03 at the ESRF. One sample was a single grain covered with calcite crystals. The other was a pair of sand grains bonded by the calcite crystals. For both samples, the orientation maps obtained with 3DXRD for the calcite phase showed a visible texture, indicating a preferential growth orientation of the crystals. Some crystals visible in CT appear as stacks of multiple grains, each with different orientations, resulting in polycrystalline structures. The 3DXRD strain tensor revealed mostly undeformed crystals, with the presence of some hydrostatic strain due to impurities. Using DFXM to 'zoom-in' on Bragg reflections in two different lattice planes, we were able to observe the local misorientation and strain in one individual calcite crystal. The computed mosaicity maps show distinct sub-domains. In particular zones of the grain, the elastic strain was coupled with misorientation, which also shows that the crystals indeed grow in a certain preferential orientation. A comparison of DFXM measurements showed that calcite crystals bridging two sand grains had a relatively 'pristine' microstructure, whereas calcite crystals attached to only one sand grain showed significant strain, indicating that they might have undergone fracture. Furthermore, applying mechanical load was found to significantly alter the calcite microstructure, leading to increased elastic strain in the grains.

In conclusion, we employed a multimodal approach to investigate the microstructure of bio-precipitated calcite in sand, providing insights critical for optimizing bio-cementation processes. Future work will explore calcite growth mechanisms during cementation cycles and the behavior of the calcite grains under shear loading, aiming to enhance material performance for sustainable construction and soil reinforcement.

Exploring Different Replacement Rates of Recycled Construction and Demolition Waste in Building Applications

Dr. Luca Lavagna, Italy

Oral Presentation (20')

Abstract

The construction industry faces an urgent need to address the depletion of natural resources and the environmental impact of material extraction. In this context, Construction and Demolition Waste (CDW) emerges as a promising resource, accounting for nearly 40% of the total waste produced annually in Europe. While traditional recycling practices have leveraged CDW for applications such as road base materials, these strategies only address a small fraction of the waste generated, emphasizing the necessity for more comprehensive solutions. Recent studies explored CDW as an aggregate and cement substitute in structural mortars, have shown promising results. In this work, virgin aggregates were replaced with processed CDW in varying proportions (25%, 50%, 75%, and 100%) and using fine CDW powder as a partial Portland cement substitute (5%, 10%, 15%, and 20%). This dual substitution approach not only enhances CDW valorization but also aligns with circular economy principles, reducing dependency on virgin materials and promoting sustainable construction practices. Such innovations are essential for advancing the construction sector's sustainability and reducing its environmental footprint.

After 7 and 28 days, all specimens were tested following the UNI-EN 196-1 standard. The specimens generally exhibited similar or slightly lower performance compared to the control mixture. The improvement in mechanical properties of mortars made with Construction and Demolition Waste (CdW) can be attributed to the porous nature of CdW aggregates, which absorb free water in the mixture, reducing the effective water-to-cement ratio and enhancing mechanical performance. At 28 days, the compressive strength of the CdW mortars was approximately 6% higher than the control mixture. The fine fraction obtained during the sieving process was used as a partial replacement for Portland Cement at 5%, 10%, 15%, and 20% (CdWF). Flexural strength decreased as the fine fraction increased, with a notable 30% reduction at 10% substitution compared to OPC. However, compressive strength remained promising up to a 10% substitution, after which it declined from 50 MPa to around 43 MPa. This loss of more than 10% in compressive strength is expected, as the reduction in cement content directly affects the binding capacity of the mixture, with cement acting as the primary binder.

Recycling of gypsum based binding materials

Dr. Christian Pritzel, Germany

Oral Presentation (20')

Abstract

Gypsum is one of the most used building materials. Because of the energy transition a large raw material source, FGD-Gypsum, will be lost. Gypsum is $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$, but to use it as a binding material the better soluble Hemihydrate $\text{CaSO}_4 \cdot 0.5\text{H}_2\text{O}$ or Anhydrite CaSO_4 is produced by heating or in an autoclave process. This subhydrate will react back with water to gypsum. This process is predestined for recycling. It is well known from other recycling processes, like glass, paper or polymers, that the quality may change during the recycling process. The normal raw material for gypsum recycling at the moment is plaster board. That plaster board is not pure gypsum, it contains cardboard, fibres and several organic additives like retarders, super plasticizers, surfactants and some more. The fibres and the cardboard are collected nowadays very accurately, but there is a lack in research for the organic additives.

During the research presented in this paper a stepwise project was done. During the first step, larger self-grown gypsum crystals were recycled by heating up to 140°C to produce hemihydrate and followed by rehydration with water. This process was done for several cycles. As the next step gypsum crystals, produced in presence of single additives, were cycled. This part is more academic to understand the basics. The obvious upcoming step was to use technical gypsum for the recycling process with and without additives. To do that, hemihydrate was hydrated with or without additives and then cycled also at 140°C . During any recycling step several analyses were done. The morphology of the gypsum was investigated by scanning electron microscopy, the heat of hydration was measured by heat flow calorimetry and the phase composition was examined by simultaneous thermal analysis and x-ray powder diffraction.

It is shown, that during the recycling process the particle size of the gypsum particles change. The gypsum crystals become smaller till a limit is reached, hence influencing also the product properties. The other challenge is the remaining of the additives during the cycling, because those additives are changing the morphology of the gypsum crystals and the properties, too. Most of the additives stay inside of the recycling material and can cause side effects in the later use of the recycling materials. As particle size shrinks in recycling, the effect of the additives lowers to a certain extent. Gypsum recycling is possible, but may be tricky.

Carbon-negative concrete by using biochar

Dr. Luca Lavagna, Italy

Oral Presentation (20')

Abstract

Biochar is a carbon-containing material obtained as the solid residuum of the pyrolysis of vegetable feedstocks. Its current main interest resides in the fact that it fixes carbon coming from the atmosphere in solid form. Thus biochar can help to compensate the carbon emitted during the cement and concrete production and transport. Biochar is typically obtained by pyrolysis between 200 and 1000 °C, and the main vegetal sources are wood, food, and agricultural wastes, with a particular interest in silica-rich ones (i.e. from rice). Biochar contains mainly carbon, and present high specific surface area. If carbonization is not complete, oxygen, nitrogen, and hydrogen are still found in biochar, together with Ca, Mg, Si, Al, Fe, Na, K, depending on the vegetal feedstock. In this work we report the preparation of mortar and concrete containing biochar, where the amount of biochar was selected in order to reach first zero-carbon and then carbon negative conditions. In literature it is known that the addition of biochar can lower the mechanical strength of mortar and concrete, save in the case of silica-rich biochar. In this work, however, by conveniently choosing the vegetal feedstock and thus the properties of biochar, and by suitably selecting the biochar grain size distribution, the mechanical properties were not reduced, even at rather high biochar content. Thus, we could prepare carbon neutral or carbon negative mortar and concrete, with the same or higher compression strength than reference samples. The addition of biochar, however, caused the worsening of the workability of the mortar/concrete paste, so that a superplasticizer additive was added. The lower workability was due to the adsorption of water by the biochar, as shown by water adsorption isotherms. Biochar seemed also to retard the mortar setting. The main parameters influencing mortar strength were deemed to be porosity, water absorption, chemical composition, and powder size distribution of the biochar. Porosity measurement performed on mortar samples containing biochar helped to elucidate the mechanism governing the development of significant mechanical properties, notwithstanding the biochar insertion inside the mortar/concrete. The calculated emissions of standard concrete were 0.33 tCO₂/m³. With 10%wt substitution of cement and 5%wt substitution of aggregate it was possible to obtain a carbon neutral concrete (-0.08 tCO₂/m³) with slightly improved compressive strength with respect to the reference, while with 10%wt substitution of both cement and aggregate the concrete was carbon negative (-0.35 tCO₂/m³), with comparable strength.

Sustainable Concretes Containing Red Mud And Slag: Mechanical Characterisation, Radioactivity and Heavy Metal Leaching

Mr. Andrés Caño Blanes, Spain

Oral Presentation (20')

Abstract

The cement manufacturing for the concrete production accounts for a high percentage of the global CO₂ emissions (6-8%), and therefore in the current climate change scenario it is imperative to enforce mitigation measures to reduce the environmental impact in the construction industry. One of these measures is the partial or total replacement of cement with supplementary cementitious materials (SCM's), such as copper slag (S) and red mud (RM), an industrial by-product of copper manufacturing and an unexplored waste derived from bauxite processing for alumina and aluminium production, respectively. However, these materials are known to have high concentrations of heavy metals, as well as being classified as Naturally Occurring Radioactive Materials (NORM), and as a result of this, their use might represent health and environmental risks. Other materials typically used in the construction sector are granites, which, although they do not have high concentrations of heavy metals, are considered also as NORM due to its high concentration of natural radionuclides. For this reason, research studies besides evaluating the mechanical properties of the produced concretes, should also assess their suitability from a radiological protection point of view and the potential leaching of heavy metals when exposed to different operating conditions.

With that purpose, in this work different concrete mixtures were designed, according to the composition of the cementitious fraction: i) concrete made with 100% of an ordinary Portland Cement (OPC), ii) blended concrete with 70% OPC and 30% RM and, iii) alkaline activated concrete with 70% S and 30% RM. The mixes were prepared in duplicate, using in each case 100% siliceous aggregate (SA) or 100% granitic aggregate (GA). Specimens with dimensions of 15 cm x 7.5 cm were prepared and their compressive strength was characterised at ages of 2 and 28 days, in addition to the radionuclide activity concentration by gamma spectrometry. Finally, leaching tests were performed on concrete samples by varying the following parameters: 1) the samples geometry (bulk and powdered) and 2) the leaching environment (water and acid water). Preliminary results revealed optimum compressive strengths at 28 days ages and a radionuclide content suitable from a radiological protection point of view. The heavy metals concentration released into the environment was compared to the limit values established by the European regulation for inert wastes, showing that the leaching values can be controlled by proper mix design.

Paper 1130 8 FUNCTIONALIZED CARBON MATERIALS IN CEMENT BASED COMPOSITES, A MULTIVARIATE APPROACH

Dr. Carlo Amata, Italy

Oral Presentation (20')

Abstract

This study focuses on optimizing mechanical performance in cement-based composites reinforced with functionalized carbon allotropes: carbon nanotubes (CNTs), graphene nanoplatelets (GNPs), and carbon fibers (CFs). Functionalization was achieved via acid treatment to introduce carboxylic (-COOH) and hydroxyl (-OH) groups, enhancing dispersion and matrix interaction. A face-centered central composite design (FCCD) was employed to vary the amounts of CNTs, GNPs, and CFs, ensuring the total content did not exceed 0.2% by cement weight. The study aimed to determine how these variables influence flexural strength, fracture energy, and compressive strength. Response surface methodology (RSM) was used to analyze the data, identify optimal conditions, and maximize mechanical responses. RSM revealed that fracture energy increased with higher carbon allotrope concentrations, while compressive strength showed more complex behavior. This multivariate approach identified optimal amounts of carbon allotropes for maximizing the responses within the chosen domain. The optimized composite achieved a 27% increase in compressive strength and a 690% increase in fracture energy compared to the reference.

Harnessing magnetoelectric coupling at the nanoscale for advanced spintronics

Dr. Florin Ciubotaru, Belgium

Keynote (Oral Presentation 40')

Abstract

Spintronic computation could potentially offer significant advantages over CMOS technology, including area and power reduction, and the ability to perform complex logic functions with non-volatile magnetic materials. However, a complete magnetic/spintronic computing system does not yet exist, necessitating a hybrid spintronic-CMOS system. A major challenge in developing such a hybrid system is the lack of scalable and energy-efficient transducers to couple electric and magnetic domains effectively.

Magnetoelectric composite materials, which combine piezoelectric and magnetostrictive films, are promising for controlling magnetization with electric fields. The magnetoelectric coupling occurs via strain: an electric field generates strain in the piezoelectric layer, which transfers to the magnetostrictive layer, creating an effective magnetic field that can rotate magnetization or generate spin waves. An inverse effect also exists, linking changes in magnetization to strain and electric fields.

For microelectronic applications, these heterostructures must be miniaturized to the nanoscale. However, at these scales, strain is non-uniform, leading to complex magnetic behavior. Most studies have focused on in-plane switching of nanomagnets under high voltages.

This study demonstrates significant magnetoelectric coupling in sub-micron Ni stripes on a piezoelectric PZT layer using anisotropic magnetoresistance (AMR). Applying voltage generates strain and a magnetoelastic (ME) field in the Ni, which can be measured using AMR. The study finds a ME field in Ni as large as tens of Oe/V, consistent with simulations. Further miniaturization and material optimization could enhance this effect. The study shows a magnetization rotation of over 60° by applying voltage, with potential for further optimization.

COMSOL Multiphysics and MuMax software were used to study the mechanical and magnetic behavior of these devices. Generating charges or electric fields in thin film devices via the direct ME effect remains challenging, especially at small scales. This is crucial for spintronic applications, where conventional readout methods face limitations. The study also investigates the direct ME effect in thin film composites of PVDF-TrFE on Ni foil. Measurements of charge accumulation on dot capacitors show that rotating Ni magnetization generates significant voltage differentials. Simulations validate these results and demonstrate scalability, with minimal variation in output voltages across different dimensions. Optimized structures and materials could achieve even higher voltage differentials, surpassing conventional detection schemes and meeting CMOS compatibility standards.

Paper 280 3 Multiscale strategies for modelling the working mechanisms of triboelectric nanogenerators for drop energy harvesting

Dr. Jorge Alejandro Budagosky Marcilla, Spain

Oral Presentation (20')

Abstract

The harvesting of energy from low-frequency liquid flows is a relatively recent concept compared to the already established solar and wind energy sources, and it currently represents one of the major areas of interest in the quest to harness the potential of water as a clean and renewable energy source. In this context, triboelectric nanogenerators (TENGs) have emerged as very promising players in this field. However, despite extensive research efforts, the power output of droplet energy harvesters remains limited, primarily due to constraints in identifying materials with ideal triboelectric and wetting properties, as well as suboptimal device architectures that hinder the efficient conversion of the full kinetic energy of the incident droplets. In search for optimal solutions to this problem, the simulation of all the stages of the energy collection process is necessary, as each stage provides essential elements for the collection of energy stored in the droplets. As part of an effort involving the full development of a TENG designed to extract electrical energy from high-density droplets in a single step, in this work we have proposed a simplified model. This model is based on the conductivity of the droplet and the instantaneous electrical capacitance, which results from the high-speed contact between the droplets and the active area of the device's electrodes. This model has been implemented in finite element simulations using the COMSOL Multiphysics package. The results provide valuable information about the behavior of liquid-solid triboelectric nanogenerators and the role of the triboelectric surface pre-charging effect in shaping the temporal characteristics of the conversion event.

Paper 1919 4

Adamantane plasma polymers as versatile vacuum processable triboelectric thin films for mechanical and droplet energy harvesting

Mrs. Gloria Moreno Martínez, Spain

Oral Presentation (20')

Abstract

Current battery technology will not be able to sustain the expected demand for small, light, and even wearable portable devices. Portable nanogenerators can harvest environmental micro-energy at the point of need, powering up low-power wireless devices. This emerging technology holds significant promise for developing disruptive, self-powered electronic systems.

Triboelectric Nanogenerators (TENG) are among the most widely adopted solutions for efficiently converting low-amplitude and low-frequency mechanical/kinetic stimuli, such as human movements, into electricity. TENGs will revolutionize on-site power for smart devices, enabling self-powered sensors. Their high versatility in device architecture and triboelectric surfaces, without requiring specific crystalline phases or stoichiometries, places them at the forefront of microscale energy harvesting. The field currently relies on fluorinated polymers over 10 μm thick mostly made via solvent-phase synthesis.

In this context, we have developed adamantane thin films as a high-performance triboelectric organic material by Remote Plasma Assisted Vacuum Deposition (RPAVD) [2-3]. Adamantane plasma polymers are advanced dielectric films developed as protective coatings for perovskite solar cells and strain-engineering of 2D nanomaterials [4-5]. In this work, we study those layers as triboelectric surfaces, capable of exhibiting both, tribopositive and tribonegative character, through simple modification of the synthesis conditions and film structure without additives or functionalisation. The ADA plasma layers—from several nanometers to several microns thickness range—are hydrophobic, non-soluble, and transparent in the UV-VIS-NIR range. RPAVD ADA films devices present voltage and current outputs as high as 88 V/cm² and 1.05 μA for a 2800 nm (tribonegative) vs. 400 nm (tribopositive) combination and maximum power density as high as 2.0 $\mu\text{W/cm}^2$. Additional examples of using RPAVD ADA films as active components in micropatterned solid-solid and top-bottom drop-TENGs will also be presented.

RPAVD provides broad control over the surface composition, topography, and crosslinking degree. The proposed synthetic method is industrially scalable and straightforwardly compatible with photolithography and surface functionalization approaches. It is also environmentally friendly, making it a reliable and competitive solution to fluorinated-free thin film triboelectric material.

Keywords: Triboelectric Nanogenerator (TENG); energy harvesting; plasma deposition; plasma polymer.

Mechano-Responsive Bio-Piezoelectric Nanofibers for intelligent drug delivery

Dr. Fatemeh Mokhtari, Belgium

Oral Presentation (20')

Abstract

Control over biodistribution and pharmacokinetics is critical for enhancing the efficacy and minimizing the side effects (vomiting, immune system suppression, organ toxicity,...) of therapeutic agents. Therefore, there is a need for on-demand drug delivery systems that precisely control release time and dosage. The electromechanical conversion characteristics of piezoelectric platforms enable them to convert external stimuli into electrical energy. However, the most common piezoelectric polymer, PVDF (poly (vinylidene fluoride)), has limitations related to non-biodegradability and fluorinated contamination. To address this need, we explored the development of active biomaterials based on poly(3-hydroxybutyric acid-co-3-hydroxyvaleric acid) (PHBV), a biodegradable and biocompatible piezoelectric polymer, for drug delivery applications by tailoring its morphology, and crystallinity. Electrospun nanofibers of PHBV were fabricated using the electrospinning technique, and different concentrations of barium titanate (BT) were added as piezoelectric ceramics to enhance piezoelectric and mechanical performance. The electrospun web was remotely activated by external mechanical source of ultrasound waves to produce electrical charges in situ and control drug release locally. The developed PHBV/BT smart nanofiber web is applicable in future biomedical fields, as well as in electronic sensors and actuators.

Paper 2059 1 PLLA-based piezoelectric and magnetoelectric composites for flexible energy harvesting devices

Dr. Harvey Amorín, Spain

Highlight (Oral Presentation 20')

Abstract

Multifunctional hybrid composites are called to be the core elements of wearable electronics, electronic skin and bio-implanted devices for medical diagnosis and therapeutics, to only stand out three out of a range of application fields. They are also expected to realize autonomous sensing nodes for wireless sensor networks (WSNs). Node powering by energy harvesting from multiple sources, like mechanical vibrations or stray magnetic fields by using piezoelectric or magnetoelectric materials, is reckoned essential to avoid the cyclic replacement or recharging of batteries. A main line of research is the development of flexible polymer-matrix composites including embedded piezoelectric and magnetostrictive inorganic phases. Most works resorted to PVDF-TrFE as matrix, a fuel-based, non-biodegradable polymer with serious associated environmental concerns. Among alternatives, poly-L-lactic (PLLA) stands out because of its biobased and biodegradable character, as well as its biocompatibility.

In this context, we are investigating the suitability of bio-based thermo-polymers, like Poly-L-Lactic Acids (PLLA) and odd-numbered Polyamides (PA), as piezoelectric matrices, along with particulate BCZT piezoelectric perovskite and MZFO magnetostrictive spinel, non-toxic metal oxides, and the use of innovative approaches towards 3D-printing technologies. The control of the 3D-printing parameters is key to obtain high molecular chain orientation and crystallinity, thus allowing piezoelectric response of the matrix to be tailored. Surface functionalization of the most promising cases has been accomplished with silanes, which improved compatibility between the composite components and allowed high quality composites to be obtained. An in-depth characterization of the electrical, piezoelectric, magnetic and magnetostrictive properties is here presented, and used to discuss the piezoelectric and magnetoelectric responses. Results suggest a great potential of biobased polymeric composites for sustainable energy harvesting.

Local vs. macroscopic dielectric and ferro/piezoelectric responses in porous BaTiO₃ ceramics determined on the basis of 3D reconstructed ceramic microstructures

Dr. Leontin Padurariu, Romania

Oral Presentation (20')

Abstract

Porous BaTiO₃ ferroelectric ceramics with variable porosity level (i.e. with relative density between 74%-96%) are investigated by an experimental-numerical approach in order to optimise their piezoelectric harvesting response. The porous ceramics present anisotropy as derived from the deformation of sacrificial soft polymeric additives (PMMA spheres) during the pressing step [1]. 3D micro X-ray computed tomography experimental data with specific numerical procedures have been firstly used to reconstruct the ceramic 3D microstructures and to extract sample geometrical information as: pore size distribution, shape and tortuosity. These 3D microstructures have been employed as input in FEM-based models, in order to determine the local electric field and potential distributions inside the ceramic body [2]. The final aim is to evaluate the low field effective permittivity and high field ferroelectric switching P(E), tunability and piezoelectric responses as a function of porosity and applied field direction. The effective permittivity is estimated by computing the total electrostatic energy of the discretized system. The polarisation-field response is calculated by using a Preisach model for describing the switching properties of the dense ceramic component under the specific local field of each element and the tunability response is computed by using a Johnson approach to describe the nonlinear dielectric response of the dense ceramic component. The resulted dielectric and ferroelectric properties derived by using this procedure are discussed in comparison with the experimentally determined ones. Piezoelectric calculations for porous ceramics are more complicated for real 3D microstructures due to the tensorial nature of this phenomenon and involve higher computational resources [3]. New approaches are currently developed for this task. The present study demonstrates the usefulness of analyses and simulations of properties at different lengthscales based on real 3D microstructures for completing the understanding of the complex relationship between composition – microstructure – local/macroscopic properties and pave the way of development of new tools for material design of porous or composite multi-materials for energy storage and harvesting.

Paper 1236 3 **Material design and development of Pb-free ceramics with improved piezoelectric Figure of Merits for energy harvesting applications**
Dr. Cristina-Elena Ciomaga, Romania
Oral Presentation (20')

Abstract

This study examines the influence of porosity volume fraction and morphology on the dielectric permittivity, polarization-electric field, and piezoelectric response of Pb-free ferroelectric materials by combining experimental results with a modeling approach using the Finite Element Method. The experimental investigation focused on the effects of porosity on the structural and functional (dielectric, ferroelectric, nonlinear, and piezoelectric) properties of Ba_{0.85}Ca_{0.15}Ti_{0.90}Zr_{0.10}O₃ ceramics. Microporosity levels ranging from 3% to 31 vol.% were achieved using poly(methyl methacrylate) microspheres as sacrificial templates.

Structural analysis indicated phase coexistence at room temperature, as expected for this composition. The maximum permittivity decreased with increasing porosity, from approximately 7000 (at 3 vol.% porosity) to 3500 (at 31 vol.% porosity), while the Curie temperature shifted from 47°C to 67°C with increased porosity. These changes are likely due to porosity-induced structural and internal stress modifications. An enhanced piezoelectric response was observed in Ba_{0.85}Ca_{0.15}Ti_{0.90}Zr_{0.10}O₃ ceramics with an intermediate porosity of around 18 vol.%, achieving the highest piezoelectric response of 470 pC/N and a figure of merit of 7.3 pm²/N and enhanced pyroelectric response for 15% of porosity. The optimal piezoelectric properties at this intermediate porosity level are attributed to microstructural changes (pore shape and connectivity) and possible field-induced structural modifications.

The piezoelectric energy harvesting measurements indicate the potential for using Pb-free porous ferroelectric materials in energy harvesting devices.

Preparation of flexible PVDF-BT piezoelectric composite films for energy harvesting

Ph.D. Marco Fortunato, Italy

Oral Presentation (20')

Abstract

Energy-autonomous systems that utilize smart materials have the potential to significantly reduce fossil fuel consumption. Among these materials, those with piezoelectric properties are especially promising for integration into energy harvesting and conversion devices. Polymer-based composites with functional ceramic fillers, in particular, are attracting considerable attention due to their ability to combine the inherent flexibility and high breakdown strength (BDS) of polymers with the functional properties of embedded inorganic particles. Building on encouraging previous findings, this study presents a comparative analysis of piezoelectric materials, focusing on the mechanical, thermal, chemical, and electrical properties of flexible PVDF/BaTiO₃ composite films prepared using different techniques. We explored the impact of processing on particle dispersion and filler-matrix interactions, particularly regarding agglomeration phenomena and selective formation of PVDF polymorphs. Finally we examined how these factors influence the dielectric and piezoelectric response of the ensuing composites.

Paper 1548 5 Computational analysis of inverse opal photonic crystals using the RCWA method for photocatalysis applications

Dr. Omayma Habli, Belgium

Oral Presentation (20')

Abstract

The development of efficient photocatalytic materials is crucial for addressing global challenges in renewable energy and environmental remediation.

One promising approach to improve the efficiency of photocatalytic materials involves the use of inverse opal (IO) photonic crystals made from these materials. Indeed, inverse opals, i.e., three-dimensional periodic porous structures, exhibit unique optical properties such as photonic band gaps and slow photon effects, which can enhance light harvesting and improve photocatalytic performance by increasing the interaction time between light and photocatalyst.

In this work, we numerically investigated the optical response (reflectance and absorptance) of inverse opal photonic crystals to incident solar light radiation using the rigorous coupled wave analysis (RCWA) method. We analyzed the influence of key structural and optical parameters (pore size, refractive index), as well as simulation parameters, including the number of computational layers, the number of plane waves, and the incidence polar and azimuth angles.

Our results show that a well-designed shift in the reflectance spectrum near the material's electronic absorption edge leads to considerable enhancement of the absorptance compared to a planar slab of the equivalent material volume. This enhancement, due to the slow photon effect, highlights the potential of the studied IO structure for applications requiring efficient solar light harvesting, such as photocatalysis.

Paper 627 **6** **Energy Harvesting from Post-Consumer Plastic Waste: A Sustainable Approach to Electricity Generation**
Prof. Berenika Hausnerova, Czech Republic
Oral Presentation (20')

Abstract

The growing accumulation of post-consumer plastic waste presents significant environmental challenges. This study explores the feasibility of using unsorted plastic waste, composed of common packaging materials such as high-density polyethylene (HDPE), polypropylene (PP), polystyrene (PS), and polyethylene terephthalate (PET), for energy harvesting applications through mechano-electric conversion. Without the need for complex re-processing or even material separation, these plastic waste compounds were directly utilized as functional layers in nanogenerators, demonstrating the ability to convert mechanical (triboelectric) and thermal (pyroelectric) stimuli into electrical energy. In triboelectric applications, combinations of PET films with heterogeneous plastic waste compounds composed of HDPE/PP/PS/PET exhibited significant energy conversion efficiency, with peak output voltages exceeding 130 V, short-circuit current densities of 50 $\mu\text{A}/\text{cm}^2$, and charge densities of 390 nC/cm^2 . The so-called rejected recyclable plastic waste, a fraction typically sent to landfill due to its complex composition, also demonstrated promising energy conversion capabilities, achieving output voltages above 60 V in triboelectric configurations when paired with PET films. Pyroelectric measurements showed that waste plastics were capable of generating measurable voltage responses under temperature gradients, albeit at lower magnitudes compared to triboelectric effects.

As a secondary focus, the study investigated the integration of these plastic waste materials with polyvinylidene fluoride (PVDF), a polymer known for its excellent piezoelectric and triboelectric properties. The combination of immiscible plastic waste blends with PVDF resulted in a remarkable enhancement of energy conversion efficiency, achieving output voltages of up to 800 V and short-circuit current densities of 260 $\mu\text{A}/\text{cm}^2$. This hybrid approach leverages the inherent immiscibility of plastic waste to create physical domains within the polymer matrix, enhancing charge separation and energy output.

The findings of this study highlight the potential of post-consumer plastic waste as an alternative energy source and emphasize its practical applications in sustainable and cost-effective self-powered devices, such as sensors and low-power electronics. The results also provide a new perspective on the utilization of immiscible plastic waste blends, turning a recycling challenge into an opportunity for green energy solutions.

Paper 2096 1 **Cancer Diagnostics Reimagined: Applying Novel Biosensing Techniques in Clinical Research**

Dr. Carlo Francesco Morasso, Italy

Keynote (Oral Presentation 40')

Abstract

Advancements in biosensing technologies have the potential to revolutionize cancer diagnostics and patient monitoring by surpassing the limitations of conventional analytical methods. However, many of these innovations remain confined to research laboratories and fail to translate into clinical practice. This gap often arises from a lack of coordination between technical and clinical research, leading to the development of tools that do not fully address clinical needs.

Embedding the development of new biosensing tools within a hospital setting provides a unique opportunity to align technological innovation with real-world medical applications. Direct collaboration with clinicians, clinical laboratories, and patients facilitates the iterative refinement of these technologies, ensuring their relevance and usability in patient care.

This presentation will explore efforts at the Laboratory of Nanomedicine at Istituti Clinici Scientifici Maugeri, a research hospital in Italy, to adapt two advanced biosensing approaches—Single Molecule Array (SiMoA) and Raman spectroscopy—for clinical oncology applications. SiMoA's ultra-sensitive detection capabilities enable the profiling of cancer-derived extracellular vesicles directly from the blood of breast cancer patients, offering novel insights into disease progression. Raman spectroscopy, meanwhile, is emerging as a powerful tool for cancer diagnostics, with applications in both tissue analysis for surgical margin detection and liquid biopsy for profiling circulating tumor cells.

Thanks to the close collaboration between researchers and medical professionals, we focus on the adaptation of the novel sensing strategies to move beyond theoretical breakthroughs. This talk will thus highlight our ongoing journey to bridge the gap between material science and clinical application, ultimately pursuing how to enhance diagnostic precision and informing therapeutic decision-making in oncology.

Paper 1928 2 **SERS-on-a-chip as an excellent tool for the One Health approach of AMR monitoring**
Ph.D. Laura Rodriguez-Lorenzo, Portugal
Highlight (Oral Presentation 20')

Abstract

One Health approach in the EU Commission recognizes that the health of humans, animals, and the wider environment are inherently linked and interdependent. It is particularly essential for antimicrobial resistance (AMR) because resistant organisms can spread quickly through healthcare facilities, animals, food and the environment, making treating certain infections more challenging, and increasing the risk of disease spread, severe illness and death. Expanded monitoring of antibiotics and pathogens, adopting the One Health approach, can help better understand the effectiveness of actions to reduce antibiotic use and take a more holistic and systemic course of action to control AMR. Surface-enhanced Raman scattering (SERS) in combination with microfluidic technology, provides very sensitive detection of molecular species even in the single-molecule regime. On the one hand, SERS measurements can now be carried out in nanoliter volume in an automatic and reproducible manner; on the other hand, SERS offers to microfluidic devices an ultra-fast detection in small volumes. Implementing SERS-on-a-chip in environmental and biosciences is becoming very popular as it provides significant information about the studied system even directly from complex environments such as seawater, biological fluids, living tissues, and cells. This talk will focus on demonstrating SERS-on-a-chip configuration's ability to monitor antibiotics and pathogens.

Paper 1737 3 **SERS-based platform for mutation analysis in acute myeloid leukemia**
Ph.D. Alexandra Teixeira, Portugal
Oral Presentation (20')

Abstract

Acute myeloid leukemia (AML) is the most common form of acute leukemia in adults and is frequently associated with poor outcomes to conventional therapies in the most affected population [1]. After treatment with chemotherapy, even patients that clinically achieve complete remission can relapse through the persistence of minimal residual disease (MRD). Current diagnostic tools are not enough for early detection of MRD [2]. An accurate and early diagnosis of MRD would allow the application of appropriate therapy, improving the prognosis of patients. Surface-enhanced Raman scattering (SERS) spectroscopy has remarkably flourished in the recent years and demonstrated to be powerful tool for detection of specific markers, and for diagnosis [3,4]. The main goal of this work is to create a non-invasive diagnostic tool for the early detection of specific mutations in AML disease. For this purpose we designed, fabricated, tested and optimised a SERS sensor for efficient and fast detection of AML mutations, without any pre-amplification. Thus, some substrates were developed using an innovative strategy where gold nanostars were grown in situ. Afterwards, immobilisation of molecular beacons was performed and the performance of the substrates was tested using synthetic targets. This will promote a multiplex and quantitative detection of specific AML mutations in blasts isolated from patient samples, enabling the application of personalised therapy and consequently improving the prognosis of patients.

Paper 2025 4 Electrically Controlled Molecular Motions Tracked by Graphene-Enhanced Fluorescence Lifetime Microscopy

Prof. Pedro Alpuim, Portugal

Highlight (Oral Presentation 20')

Abstract

Graphene's near-field effects, when combined with fluorescence measurements, offer a powerful approach for observing molecular-scale distances in aqueous environments [Gaudreau 2013; Adao 2019]. Here, we demonstrate the application of this technique to track on-demand molecular motions induced by the electric gating of a graphene-based device. Using 3D origami DNA architectures tethered to graphene via molecular linkers, we applied a back gate voltage through gold contacts, enabling operation in two distinct voltage regimes [Azevedo 2024]. The resulting molecular responses were tracked with high precision using fluorescence lifetime measurements.

We successfully observed molecular motions linked to the flexibility of the molecular binding unit, transitioning between open and compact conformations. Furthermore, leveraging recent advancements in fluorescence wide-field TIRF microscopy, which allows for simultaneous tracking of multiple molecular emitters with millisecond-range temporal resolution [Soares 2024], we created molecular machines with a highly sensitive fluorescence-based readout system. In particular, we used fluorophore-labeled DNA hairpins to detect their unfolding kinetics during the hybridization reaction with fully and partially complementary DNA sequences containing a 10-mismatch nucleotide region located at the 5', 3' ends and in the middle of the DNA single strand. The average unfolding times were estimated to be between 0.21 and 0.29 seconds for the fully complementary, top, and bottom mismatch strands and notably longer for the middle mismatch strand in a range between 0.42 and 0.51 seconds. Moreover, based on fluorescence lifetime measurements, the axial nanometer-scale distances of the attached dyes reveal significant differences. The dye was 10 nm above the graphene surface in the middle mismatch DNA strand, while the fully complementary, top, and bottom mismatch strands showed distances of around 12 nm. Our approach paves the way for future applications in nanotechnology and molecular sensing.

Paper 1344 5 **SERS based biosensing: leveraging the ex-vivo potential of a plasmonic sensor for the classification and prediction of cancer patterns**
Mrs. Maria Relvas, Portugal
Oral Presentation (20')

Abstract

Surface-enhanced Raman scattering (SERS) spectroscopy is a technique that allows to enhance the intrinsic, though weak but also extremely precise, fingerprint Raman signal obtained from molecules of interest. SERS has shown increased potential for the detection of analytes in unusual small concentrations, down to the single-molecule range [1] being, at the same time, characterized by an extremely high multiplexing ability surpassing the conventional and widely applied fluorescence techniques [2]. SERS extensively demonstrated its application at the proof-of-concept level in cancer, however it still lacks clinical demonstration because of reproducibility and stability. In this work a plasmonic nanosensor composed by gold nanostars (GNS; plasmonic material) embedded in a porous hydrogel (biocompatible matrix) is proposed to detect and differentiate the specific SERS signals associated to the biological fingerprint carried within the plasma from prostate cancer (PCa) and benign hyperplasia (BPH) patients, as well as healthy donors (n=120). Prior to the trial of the sensor, an optimization of the biosensor was performed in clinically relevant conditions. GNS sterilization was optimized for their safe contact with biological specimens. The hybrid material was optically and morphologically characterized with UV-Vis-NIR spectrometry, scanning and transmission electron microscopy (SEM and TEM), and Raman spectroscopy. To evaluate the SERS efficiency of the sensor different Raman reporters, biological surrogate's samples and viability/ degradation tests were performed. To test the suitability of the sensor on clinically relevant settings, the latter will be incubated within the plasma from patient's cohort already mentioned. The classification of the clinical samples based on their SERS profiles will be accomplished by using machine learning (ML) algorithms. A comparison between ML applied to SERS profiles coming only from the plasma or from the plasma in contact with the sensor was performed to understand the plasmonic sensor's relevance in the performance of this nouvelle approach as a less invasive, more sensitive, and standardized cancer diagnosis tool. Discrimination results in mice plasma showed promising performance, rated up to 92% on Area Under the Curve (AUC) values, and also showed the sensor's relevance by the values of AUC up to 94% obtained for cell supernatants measured in contact with the sensor against AUC up to 61% for cell supernatants alone.

Innovative PLA Nanocomposites with MWCNTs and MWCNTs-COOH for Printed Electronics (PE)

Mr. Nikos Bikiaris, Greece

Oral Presentation (20')**Abstract**

Printed electronics (PE) have a wide range of potential applications in sensors. Currently, the substrates used for PE are typically made from fossil-based materials, with poly (ethylene terephthalate) (PET) being a common example. PLA, known for its eco-friendly nature, is gaining attention in the electronics industry due to its unique characteristics, such as high tensile strength, Young's modulus, non-toxic properties, and its recyclability and compostability. PLA offers a more sustainable alternative to traditional polymers, requiring 68% fewer greenhouse gases and 65% less energy to produce compared to fossil-based polymers. The primary objective of this work is to develop PLA-based nanocomposites as alternative substrates to replace PET in printed electronics. However, PLA has some limitations, including brittleness and a low crystallization rate. To address these issues, our team has proposed PLA nanocomposites incorporating MWCNTs and MWCNTs-COOH, which offer improved mechanical and physicochemical properties. The functionalized nanomaterial enhances compatibility with the polymer matrix, leading to better mechanical performance. Additionally, a series of plasticized samples were prepared to improve the elongation of the nanocomposite substrates, and the electrical conductivity of the samples was also evaluated.

In this study, PLA nanocomposites with varying amounts of MWCNTs and MWCNTs-COOH were prepared using a solvent casting method to create masterbatches, followed by melt mixing with a Haake-Buchler twin-screw co-rotating melt mixer. Compression-molded PLA-based nanocomposite samples were then created to assess the impact of the nanomaterials on their physicochemical and mechanical properties. The addition of the fillers did not alter the melting or glass transition temperatures of PLA, but it significantly improved the crystallization temperature from the melt. The incorporation of nanomaterials enhanced both the tensile strength and Young's modulus, while the elongation was increased in the plasticized samples. To further analyze the surface properties, adhesion tests were performed using different inks on both the PLA-based substrates and the commercial PET substrate commonly used in printed electronics.

Paper 1853 1 High-Sensitivity Graphene Liquid-Gate Transistors for Next-Generation Biosensing Applications

Prof. Francisco Gamiz, Spain

Highlight (Oral Presentation 20')

Abstract

The escalating global threat of antimicrobial resistance (AMR) demands innovative solutions for rapid and precise diagnostics. Current detection techniques are often slow, costly, and impractical for real-time applications, exacerbating the misuse of antibiotics and accelerating the emergence of drug-resistant pathogens. In this context, graphene field-effect transistors (GFETs) have emerged as promising biosensing platforms due to their extraordinary sensitivity, high carrier mobility, intrinsic low-noise properties, ease of use, and low cost.

This work presents a systematic optimization of graphene liquid-gate transistors tailored for biosensing applications, enabling the detection of proteins, glucose, viral particles (e.g., SARS-CoV-2, HPV), and cancer biomarkers (melanoma, colorectal cancer). The proposed fabrication process includes graphene transfer onto SiO₂/Si substrates, microelectronic-based fabrication, passivation strategies, and biofunctionalization with linker molecules and antibodies, ensuring selective and reliable analyte detection. The biosensing mechanism is based on the modulation of the GFET's electrical output characteristics, which shift proportionally to the charge and concentration of target biomolecules. Experimental validation demonstrates a clear and linear response for low-to-medium analyte concentrations, confirming the potential of GFETs as highly sensitive diagnostic tools. However, challenges related to device variability and signal reproducibility remain, necessitating deeper insights into the role of surface functionalization.

To address these limitations, we leverage nanometric structural characterization and TCAD simulations to explain the experimentally observed behavior of liquid-gated GFET biosensors. The simulation results, which model liquid-gated GFET biosensors while accounting for antibody distribution effects, reveal a quantifiable shift in the sensor's I-V characteristics, demonstrating strong agreement with experimental findings. However, non-uniform antibody adsorption introduces variability in the measured current, underscoring the need for precise surface engineering strategies.

Our findings underscore the transformative potential of graphene-based biosensors in next-generation point-of-care diagnostics, offering a fast, cost-effective, and scalable solution for real-time disease detection. Future work will focus on enhancing reproducibility through advanced biofunctionalization techniques and integrating microfluidic architectures to further refine sensor performance.

ENHANCING THE SENSITIVITY AND REPRODUCIBILITY OF GRAPHENE FIELD-EFFECT TRANSISTOR BIOSENSORS FOR PRECISE LABEL-FREE SARS-COV-2 DETECTION THROUGH OPTIMIZED SURFACE BIOFUNCTIONALIZATION

Mrs. Laura Lozano Chamizo, Spain

Oral Presentation (20')

Abstract

Since the COVID-19 pandemic, the necessity for a widespread, rapid and highly sensitive diagnostic tool has become a reality in the society. The incorporation of new detection devices, such as biosensors, that overcome the general drawbacks of the gold standard technologies is a necessity. At this point, the employment of two-dimensional nanomaterials, especially graphene, into point-of-care biomedical devices stands as a pioneering approach poised to transform diagnostic landscape. Despite the improvements in development of these type of biosensors, the relation between their surface functionalization and sensing response remains ambiguous. Owing to this statement, we have performed deep research combining a careful sensor design and fabrication and a precise surface modification of these biosensors to demonstrate how this could be crucial in enhancing their sensing performance. Particularly, we have biofunctionalized graphene field-effect transistor (GFET) sensors by surface modification with different biochemical reactions to promote either random/heterogeneous or oriented/homogeneous immobilization of anti-SARS-CoV-2 spike protein antibody. Both approaches were thoroughly analysed by in-silico simulations, physicochemical and biochemical techniques and electrical characterization. Then, sensing capacity of SARS-CoV-2 virus simulated clinical samples was further evaluated. Remarkably, the oriented GFET modification approach exhibited significantly reproducibility and responsiveness, surpassing the detection sensitivity of conventional non-oriented GFET by over twofold, without the need for sample preparation and providing rapid results. Beyond the immediate application of this advancement in COVID-19 diagnostics and future pandemic awareness, these results address unexplored mechanistic aspects of 2D nanomaterial-based biosensors, emphasizing the crucial role of biofunctionalization in improving diagnostic performance.

Wearable Heart Rate Sensors Based on Laser-Induced Graphene on Alginate and Novel Polyurethanes

Dr. Teodora Vicentic, Serbia

Oral Presentation (20')

Abstract

The rapid expansion of wearable sensor technology has raised concerns about electronic waste and environmental sustainability. Traditional wearable sensors are often made from non-degradable materials, contributing to long-term pollution and disposal challenges. As the demand for wearable health monitoring devices grows, it is essential to develop biodegradable alternatives that maintain high performance while minimizing environmental impact. In this study, we present two biodegradable substrates for wearable sensors: a naturally derived cross-linked sodium alginate (CL-SA) film and a novel synthetic polyurethane based on α,ω -dihydroxy-poly(ϵ -caprolactone)-b-poly(dimethylsiloxane)-b-poly(ϵ -caprolactone) (PCL-b-PDMS-b-PCL).

The alginate film was synthesized by dissolving sodium alginate in distilled water, followed by crosslinking with Ca^{2+} ions. Laser-induced graphene (LIG) was produced on CL-SA substrates via direct laser induction. For the polyurethane-based substrate, we synthesized a polymer network using PCL-b-PDMS-b-PCL, 4,4'-methylenediphenyl diisocyanate, and hydroxy-functional hyperbranched polyester through a two-step polymerization. Polyurethanes with soft segment contents of 40, 50, and 60 wt% were prepared for subsequent integration with LIG.

To assess the potential of both materials for wearable sensor applications, we performed an extensive physicochemical analysis of synthesized substrates and LIG samples on each substrate. Raman spectroscopy, scanning electron microscopy with energy-dispersive X-ray spectroscopy, X-ray diffraction, transmission electron microscopy, and Fourier-transform infrared spectroscopy were used to examine the structure and composition of the prepared materials. The analysis revealed that while CL-SA provides a biodegradable platform, the polyurethane-based network offers superior flexibility, making it more suitable for wearable applications. Given its enhanced flexibility, we selected the polyurethane-based LIG sensors for real-time heart rate monitoring. Utilizing the piezoresistive properties of LIG, we recorded heartbeat signals by connecting the sensors to a pulse simulator and a measuring device. Voltage changes were measured over time in constant current mode, demonstrating the sensor's ability to detect subtle physiological signals with high sensitivity.

These results highlight the potential of integrating LIG with biocompatible and biodegradable substrates for sustainable, high-performance wearable sensors. By combining biocompatibility, flexibility, and precise physiological detection, this work paves the way for eco-friendly, next-generation health monitoring technologies.

This research was supported by the University of Belgrade - Institute of Chemistry, Technology and Metallurgy through the "Seed Research Grant for Young Scientists" (G-PULSE), financed by Serbia Accelerating Innovation and Entrepreneurship Project (SAIGE). Paper 1525 5 Optimization of Liquid-Gate Graphene Field-Effect Transistors for Enhanced Sensing Reliability and Portable Characterization
Ph.D. Elsa de la Fuente Zapico, Spain
Oral Presentation (20')

Abstract

Graphene has attracted considerable attention across a wide range of applications due to its exceptional properties, which include high electrical conductivity, mechanical strength, chemical stability, sensitivity, and a large surface-to-volume ratio. These characteristics make graphene particularly useful in the development of novel electronic and sensor devices. Graphene field-effect transistors (GFETs), especially when integrated with a liquid gate, offer a versatile platform for detecting various molecules and ions in biological samples, making them highly promising for biosensing applications. However, the liquid gate and the formation of the electric double layer, both of which are essential for the sensing mechanism, introduce significant variability in the detection process. This variability can impact the accuracy and reproducibility of measurements, making it crucial to address these challenges for more reliable performance in practical applications.

This study focuses on optimizing the fabrication and lithography processes of liquid-gate devices to minimize variability and enhance device reliability. To achieve this, we employ a wafer-scale process with planar devices, eliminating the need for external gate probes. By using this approach, we ensure more consistent results across large-scale device arrays. Additionally, we enhance the standard lithographic process by incorporating a sacrificial layer to protect the graphene during fabrication, preventing damage and improving the overall quality of the devices.

Hundreds of devices have been characterized both morphologically and electrically to assess and refine the layout design and lithographic techniques, leading to a reduction in device variability. Characterization efforts include extensive morphological imaging (SEM, AFM, XPS and Raman) and electrical performance analysis, as well as detailed low-frequency noise measurements and interface state density determination, which provide critical insights into device behavior. Moreover, we introduce a printed circuit board (PCB) as a key innovation to facilitate electrical characterization outside of laboratory environments. The PCB enables the measurement of device performance in real-world, portable settings, offering greater flexibility and practical applicability in biosensing scenarios.

Looking ahead, the next phase of this research will focus on the functionalization of graphene to enable the detection of specific biological molecules. This step will involve tailoring the surface properties of graphene to enhance its selectivity and sensitivity for target analytes, making it a more effective tool for biosensing applications.

Engineering Fluorescence Resonant Energy Transfer (FRET) via plasmonic systems for ultra-sensitive biosensing

Ph.D. Olga Favale, Italy

Oral Presentation (20')

Abstract

Fluorescence Resonant Energy Transfer in the Förster regime is a widely studied photodynamic process based on a non-radiative dipole-dipole interaction between an excited donor molecule and a ground-state acceptor molecule [1]. Due to its strong dependence on the distance and relative orientation of the interacting dipoles, as well as the electromagnetic properties of the surrounding environment, FRET has emerged as a powerful tool for biosensing applications. While FRET inhibition can be achieved by increasing the donor-acceptor distance, its enhancement can be realized through interaction with resonant photonic environments, such as plasmonic structures or optical cavities [2].

This project explores the electromagnetic interaction between multi-resonant plasmonic systems and a biological FRET platform. By tailoring plasmonic resonances to match the absorption and/or emission spectra of the donor-acceptor pair (DAP), we aim to selectively modulate the acceptor fluorescence, enabling precise control over FRET efficiency [3]. Beyond fundamental insights into energy transfer mechanisms, this approach holds great potential for developing highly sensitive biosensors. Compared to conventional sensing platforms, plasmon-assisted FRET offers superior specificity, rapid response, and the ability to detect biomarkers at ultralow concentrations, making it a promising candidate for next-generation diagnostic tools. In this initial phase, we focused on a model biological system consisting of an engineered *E. coli* strain expressing a fusion protein composed of a cyan fluorescent donor (eCFP) and a yellow fluorescent acceptor (eYFP), connected by an amino acid linker of variable length (CLY#, Cyan-Linked-Yellow, where # indicates the linker distance). Furthermore, this work investigates the electromagnetic interaction between a biological FRET system and simple plasmonic structures, such as gold nanoparticles with a diameter of 50 nm. This well-defined system provides an ideal testbed for investigating and optimizing the interplay between FRET and plasmonic nanostructures, paving the way for advanced biosensing strategies with enhanced performance.

Paper 1237 3 **Novel nano- and submicron carriers with controlled high enzyme loading for electrochemical sensing**

Mr. Pavel Milkin, Germany

Oral Presentation (20')

Abstract

Enzymes are widely used in biosensing due to their high specificity for target molecule detection. Enzyme-based electrochemical biosensors offer several advantages, including high selectivity, rapid response, ease of use, compatibility with opaque solutions, and potential for miniaturization, making them suitable for portable and cost-effective devices. However, conventional enzyme-based sensors face several challenges, such as low immobilization density, difficulties in quantifying and controlling enzyme loading, reduced activity on electrode surfaces, and the risk of denaturation or deactivation during storage and use.

Here, we present a novel solution by fabricating a high-sensitivity enzymatic electrochemical biosensor using solid particles functionalized with grafted polymer brushes and a precisely quantified amount of immobilized enzyme. The enzymes were immobilized via physical absorption into polyelectrolyte brushes grafted from carriers. This pre-immobilization approach enables precise control over enzyme quantity and activity before deposition onto the electrode. The immobilized enzymes exhibited high loading density and activity and demonstrated long-term stability with minimal activity loss during storage.

As a proof of concept, we tested this system using laccase as the enzyme and hydroquinone as the substrate. The results showed a remarkable enhancement in enzymatic activity—at least 75 times higher than that of enzymes stored in buffer under optimal conditions. The sensor achieved the highest sensitivity reported in the literature for this enzyme-substrate pair, with a maximum response of 0.8 A·M⁻¹ for a 4 mm in diameter electrode. The lowest detection limit, determined via chronoamperometry, was 0.28 μM.

Additionally, we elucidate the mechanism of enzyme-polymer interactions, and the electrode kinetics involved in the redox processes. This work provides a reliable and efficient platform for enzymatic biosensing, offering enhanced sensitivity, stability, and precise enzyme control, which are critical for real-world biosensor applications.

Paper 1569 4 Microbial production of silver nanoparticles: characterization and applications

Alessia Di Fraia,

Oral Presentation (20')

Abstract

Silver nanoparticles (AgNPs) are highly valued for their distinctive physical and chemical properties, enabling applications in diverse fields such as antimicrobial coatings for medical devices, water purification systems, and biosensors for electronics and bioimaging. Conventional physical and chemical synthesis methods often pose environmental concerns, generating significant amounts of byproducts. This has driven a growing interest in sustainable alternatives, particularly microbial-based approaches. In this context, bacteria from extreme environments have shown great promise, as their adaptability to harsh conditions allows nanoparticle synthesis under a broad range of parameters.

In this study, AgNPs were biosynthesized using the cell-free secretomes of various thermophilic microorganisms from our collection. The synthesis process was monitored via UV-Vis spectrophotometry, while the nanoparticles were characterized using transmission electron microscopy, Fourier transform infrared spectroscopy, and dynamic light scattering with zeta potential analysis. Additionally, their catalytic and conductive properties were evaluated demonstrating their potential for several applications. These results highlight extremophilic microorganisms as valuable biological resources for the sustainable production of nanomaterials, reinforcing their role in advancing eco-friendly biotechnological processes.

Paper 1403 6 Tuning the chiroptical response of discrete gold nanoparticles

Dr. Sergio Gómez-graña, Spain

Oral Presentation (20')

Abstract

Chirality is a molecule or structure property that is present in our daily life, and it can be from nano (conformation of small molecules) to macro (our hands or the shape of galaxies). Generally, enantiomers show similar physical properties, however, normally they have opposite optical properties, depending on how they are rotating the plane of polarization of an incident beam light.

When an electromagnetic beam interacts with plasmonic nanoparticles, this generates a localized surface plasmon resonance (LSPR) with highly intense electromagnetic field at nanoparticles surface. Coupling the LSPR of achiral structures with chiral molecules, it is possible to increase and modify the chiroptical response of the hybrid nanomaterial. Chiral plasmonic nanostructures have been developed by assembly achiral plasmonic nanoparticles into chiral configurations by using chiral templates or chiral molecules [1]. Recently, plasmonic nanoparticles with an intrinsic chirality have been achieved [2,3]. In this context, we have developed one step synthesis of chiral-plasmonic nanoparticles by using achiral gold nanorods as seeds. We have studied the chirality evolution by HR-TEM as well as the chiral efficiency. Likewise, depending on the seed used, we are able to control and tune the CD response of the new chiral nanoparticles. Thanks to the layer by layer technique we have deposited on a glass substrate different layers of chiral nanoparticles and the chiroptical response have been evaluated. Moreover, taking advantage of the CD better efficiency than the LSPR, we have used the chiral substrates to develop a more efficient system to measure the refractive index sensitivity.

Paper 1219 1 Catalysts of Change: Advanced Ceramic Materials Steering Energy Transition

Prof. Sanjay Mathur, Germany

Keynote (Oral Presentation 40')

Abstract

Advanced materials are driving innovation across all fields of technology, ranging from construction and mechanical engineering, automotive and electromobility, to medical technology, energy storage and conversion technologies, and microelectronics. Given their technological impact, functional materials represent an essential segment of industrial technologies with significant value creation potential for both established markets and emerging technologies. Especially in the context of sustainable production techniques, substitution of critical raw materials, and energy- and resource-efficient manufacturing, tailored surfaces and interfaces are gaining increasing importance in the future. In this context, chemical processing of nanostructured ceramics in tuning the functional and interfacial properties for better charge transport, higher corrosion protection and enhanced performance. The examples will include the role of functionalized inorganic surfaces in electrolyzers for hydrogen production, and advances in photon-harvesting technologies for perovskite-based photovoltaics. This talk will emphasize the power of chemical synthesis in designing new materials for energy transition.

Highlight (Oral Presentation 20')

Abstract

Hydrogen (H₂) is considered as a promising energy carrier to assure the needs of humanity. Its combustion in a fuel cell (FC) emits only water and does not involve any noise pollution. However, in order to be used inside a FC, H₂ needs to be at a very high level of purity, which can be achieved by using the water electrolysis process. This clean reaction only represents 4% of the actual method of H₂ production around the world. The recent development of anion exchange membrane materials has led to the emergence of the anion exchange membrane electrolyzers allowing the use of non-noble transition metals in the composition of catalysts for hydrogen (HER) and oxygen (OER) evolution reactions in alkaline media. However, their nanoscale synthesis is highly challenging to limit the overpotential, particularly at the anode (OER). The PDC (Polymer Derived Ceramics) route is a non-conventional way of designing ceramics by using preceramic polymers as precursors. The coordination (or direct reaction) of these precursors with metal complexes via the functional groups and/or ligands of the polymer makes it possible to trap transition metal nanoparticles in a micro-/mesoporous PDC matrix upon pyrolysis at low temperature. By considering the fact that preceramic polymers display an intrinsic ability to in-situ form and maintain a porosity at different length scales at low temperature pyrolysis, these metal nanoparticles become accessible while overcoming their stability issue during the catalysis process. Besides, the activity and selectivity can be simultaneously enhanced by taking advantage of the synergy between the metal nanoparticles and the encapsulating materials. This will be the content of this presentation that will introduce our very recent works on this topic.

Metal-oxide ALD-coated electrospun nanofibers for fluorine-free and freestanding bipolar membranes

Mr. Arnaud Demore, France

Oral Presentation (20')

Abstract

As the demand for green hydrogen production grows, processes such as water electrolysis are among the most promising technologies. However, several limitations remain unresolved yet, Proton Exchange Membrane Water Electrolysis (PEMWE) relies on noble metal (IrO₂ for OER in acidic conditions) and Anion Exchange Membrane Water Electrolysis (AEMWE) can use earth-abundant metals for the OER in alkaline conditions, but HER is limited by the lack of available protons at the cathode. In this context, simultaneously achieving a high-pH OER and a low-pH HER is desirable and this is precisely one of the opportunities offered by bipolar membranes (BPM). When operated in reverse bias, BPMs can maintain a pH gradient across the electrochemical cell by dissociating water into protons and hydroxide ions. This allows for optimized reaction conditions at both anode and cathode, reducing catalyst costs. A BPM consists of two ion exchange layers of opposite polarity, separated by a catalytic layer. Water dissociation (WD) occurs at the interface of those two ion exchange layers known as bipolar junction. Water dissociation efficiency directly impacts energy consumption and overall cell performance. Additionally, while some catalysts have shown the ability to dissociate water effectively, the current deposition processes often produce a thick catalytic layer that can lead to delamination, catalyst leakage, further affecting long-term stability and performance. Therefore, our objective is to implement an efficient catalytic layer for WD, as thin as possible, in order to minimize catalyst usage while maintaining a strong bond to the polymer. A combination of Atomic layer deposition (ALD) and Electrospinning (ES) methods appears well suited to achieve this goal. ALD is a low temperature process that allows a precise control of thickness, conformity and uniformity of deposited layer, providing a chemically strong bonded layer even on polymer surfaces. ES is a cost effective method for producing high-surface-area, tunable, fluorine-free polymer nanofibers. By using quaternized poly(2,6-dimethyl-1,4-phenylene oxide) (Q-PPO) and sulfonated polyether ether ketone (S-PEEK), two ion exchange polymers of opposite polarity, TiO₂ ALD-coated nanofibers were produced and further processed to obtain a fully dense bipolar membrane. Bipolar membranes are tested in a two compartment H-cell, with a four probe electrode set-up and WD is studied through Current-Voltage (j-V) measurements. The nature, thickness and distribution of the catalyst will be studied to obtain optimal WD performances in the BPM as well as to ensure long-term stability and strong catalyst bonding in a BPMWE cell.

Composite electrodes and membranes for energy storage and conversion devices

Ph.D. Luca Pasquini, France

Oral Presentation (20')

Abstract

Composite materials are at the forefront of the modern conception and optimization of high technology storage and conversion devices, including anion exchange membrane fuel cells.

Complex multimaterials and their interfaces are important to increase the performances of catalysts at the triple phase boundary and ion conducting membranes (optimization of water uptake, ion conductivity, mechanical and degradation stability).

We intend to present here our work on electrodes and polymer electrolyte membrane development.

For electrodes, the combination of N-[1] or B-N co-doped[2] carbon quantum dots (CQD) with various anion exchange ionomers (AEI) is explored: AEI are based on hydrophilic polysulfone (PSU), hydrophobic poly(alkylene biphenyl) and intermediate poly(2,6-dimethyl-1,4-phenylene oxide) (PPO), quaternized with trimethylammonium (TMA) moieties grafted on long (LC) or short (SC) side chains. The complementary properties of these materials for the oxygen reduction reaction (ORR) in alkaline solution are studied. The direct functionalization of metal organic frameworks (Zr-MOF and Fe-MOF) with PSU-TMA moieties is also investigated to increase the processability of the electrodes and the integration of the ionomer with the catalyst, avoiding interface and delamination problems.

For membranes, the integration of Layered Double Hydroxides (LDH) with Zn/Al (containing also an Ionic Liquid)[3] or Mg/Al [4] or exfoliated LDH[5] dispersed as a filler in composite anion exchange membrane (AEM) based on PSU or PPO grafted with TMA or DABCO is investigated to increase the conductivity, chemical and hydrolytic stability in alkaline conditions. The integration of electrospun nanofibers of poly phenyl sulfone in proton conducting membranes based on sulfonated poly(ether ether ketone) (SPEEK) or sulfonated poly (phenyl sulfone) (SPPSU)[6] is explored to reduce the dimensional swelling and thus improve the hydrolytic stability of membranes.

The adopted strategies give great advantages in term of stability, catalytic activity and ion conduction by combining and increasing the synergy between materials with tuned properties.

PRODUCTION AND CHARACTERIZATION OF NEW MEMBRANES FOR HYDROGEN PURIFICATION BASED ON THE Nb-V-Pd SYSTEM

Ph.D. Luca Pezzato, Italy

Oral Presentation (20')

Abstract

Hydrogen is a universal, clean and efficient energy carrier, with a high calorific value (120MJ/kg), which can be used for storage and transportation of energy and converted into electricity via high-efficiency, emission-free fuel cells. Several processes, including biological-based ones, can be employed for hydrogen production but often these processes provide gas mixtures with high content of by-products (CO, CO₂, H₂S etc.). For this reason, a purification phase is necessary. Among the various separation technologies, membranes are a promising technology for hydrogen purification due to their operational simplicity, low energy consumption and the ability to work continuously. Dense metallic membranes, in particular, show a high selectivity for hydrogen. The palladium-based membranes are widely considered the best for this purpose, due to their ability to dissociate and dissolve hydrogen into their bulk. However, besides its cost, Palladium has been identified as strategic critical raw material by the Critical raw material act of European Union in 2024. More recently, transition metals have been investigated, in particular V and Vb group elements, as alternative to Palladium-based alloys. In this work, the possible production of alternative membranes based on Nb-V-Pd system was studied to reduce the Palladium amount and so the total cost of the membrane, with acceptable overall performances.

High Power Impulse Magnetron Sputtering (HiPIMS) technique was employed as deposition method of a hydrogen-selective membrane film. In detail, multilayer films based on the Nb-V-Pd system were deposited by a combined HiPIMS/Direct Current (DC) magnetron sputtering process onto porous alumina.

The obtained membranes were characterized both on the surface and cross section through SEM-EDS analysis and phase composition was evaluated through XRD analysis. Membrane permeability measurements were carried out by means of a custom-built test station, to investigate hydrogen permeance, selectivity and resistance to hydrogen embrittlement.

The results were very promising, showing formation of a compact and uniform film, characterized by permeances higher than $1 \times 10^{-6} \text{ mol m}^{-2} \text{ s}^{-1} \text{ Pa}^{-1}$ at 450°C and good stability to hydrogen embrittlement.

Effect of Different Dynamic Operating Conditions on the Materials of a PEM Electrolyzer

Dr. Javier Nuñez, Chile

Oral Presentation (20')

Abstract

Decarbonizing the energy matrix is a global goal driving the development of clean and sustainable energy solutions. In this context, hydrogen has emerged as a key energy carrier to support this transition. Among the available methods for hydrogen production, water electrolysis stands out as the most environmentally friendly, capable of producing hydrogen with a purity of up to 99.99%. Proton exchange membrane (PEM) electrolyzers are particularly notable due to their compact design, high current density (above 2 A/cm²), and low ohmic losses, achieving efficiencies between 50% and 80%. Their rapid response, operation at high pressures, and low temperatures further enhance their appeal as a promising technology.

However, PEM systems face challenges related to stability and durability under various operating conditions. The scientific community debates the optimal strategies for operation: some advocate for continuous operation to avoid performance fluctuations, while others recommend complete disconnection during intermittent periods. A third approach suggests operating at minimal currents, ranging from 10% to 25% of the nominal capacity, during these idle periods.

This study investigates the impact of different operating conditions on PEM cells: continuous operation, on/off cycles, and intermittent cycles with minimal current. Simulations were performed to represent one year of operation (365 cycles), and the cells were evaluated using polarization curves and Electrochemical Impedance Spectroscopy (EIS). Subsequently, the cells were disassembled to examine the degradation of their components at the microstructural level, employing techniques such as Scanning Electron Microscopy (SEM) and X-Ray Diffraction (XRD).

The results reveal that current interruption during idle periods mitigates degradation mechanisms, potentially extending the lifespan of PEM electrolyzers. The main contribution of this work lies in its comprehensive approach, integrating electrical, chemical, and microstructural analyses to provide a holistic understanding of the internal phenomena in PEM electrolyzers. Furthermore, this study highlights the importance of interdisciplinary collaboration between experts in electrical engineering and materials science, underscoring the value of joint efforts to improve the performance and sustainability of these technologies.

Study of RF Co-Sputtered $\text{ZnS}_{1-x}\text{Se}_x$ Alloys for Potential Photoelectrochemical Cell Applications

Mrs. Fernanda Itzel Gonzalez-Moreno, Mexico

Oral Presentation (20')

Abstract

Photoelectrochemical cells (PECs) are promising energy conversion devices that produce hydrogen (H_2) directly from solar energy using semiconductor materials. For efficient hydrogen production, semiconductors must have a band gap between 2–3 eV, with a conduction band minimum (CBM) more negative than 0 V vs. SHE and a valence band maximum (VBM) lower than -1.26 V vs. SHE. While ZnS has suitable CBM and VBM positions but an overly wide band gap (3.6 eV), ZnSe has a narrower band gap (2.7 eV) and compatible CBM and VBM positions. The potential of $\text{ZnS}_{1-x}\text{Se}_x$ pseudobinary alloys for PECs remains unexplored. In this study, $\text{ZnS}_{1-x}\text{Se}_x$ alloys were deposited by RF magnetron co-sputtering with varying ZnSe/ZnS ratios, followed by a post-annealing in Ar-H_2 at 300 °C. Morphological, structural, electrical, optical, and electrochemical properties were evaluated. AFM showed homogeneous film surfaces, and XRD revealed shifts in the (111) peak correlating with composition. XPS identified Zn interstitials and Se antisites, confirmed by Raman analysis of S-Se bonds. UV-Vis spectroscopy indicated tunable band gaps (2.74–3.57 eV), and photoluminescence revealed donor states. The alloys demonstrated favorable electronic properties for hydrogen production but also showed susceptibility to water oxidation, highlighting their potential for PEC applications.

Paper 1348 1 **Exploring a smart catalysts platform for the electroreduction of nitrogen species into ammonia: materials/performance correlation**

Dr. Noemi Pirrone, Italy

Highlight (Oral Presentation 20')

Abstract

The increasing demand for ammonia (NH_3) as a fertilizer precursor and alternative fuel has raised concerns about the sustainability of the primary production process, which relies on the well-established Haber-Bosch (HB) method. The HB process heavily depends on hydrogen (H_2) produced through methane (CH_4) steam reforming and uses reactors operating at high temperatures and pressures to facilitate nitrogen (N_2) triple-bond cleavage. Additionally, significant environmental impacts are associated with the transportation of the final product from centralized plants to end users. In recent years, various alternative approaches have been evaluated to reduce NH_3 production dependence on fossil fuels. The electrochemical nitrogen reduction reaction (E-NRR) in water-based electrolytes could potentially be carried out under milder temperature and pressure conditions. Despite its theoretical promise, several challenges - such as low selectivity at high current densities due to the unavoidable hydrogen evolution reaction (HER) - hinder its scalability. An alternative approach involves the electrochemical conversion of nitrate (NO_3^-) and/or nitrite (NO_2^-) present in polluted waters (e.g., groundwater, industrial, and nuclear wastewater) into NH_3 . This reaction is thermodynamically favoured compared to E-NRR, and the $\text{NO}_3^-/\text{NO}_2^-$ hydrogenation reaction has a lower energy barrier than N_2 activation.

In this context, our research focuses on identifying electrocatalysts that are active for NO_3^- - reduction in low-concentration aqueous streams, with the dual goal of denitrifying wastewater and producing a value-added product (NH_3). Specifically, we evaluate the activity of catalysts such as molybdenum disulfide (MoS_2), copper (Cu), and tin (Sn) in a flow cell reactor with a 10 cm^2 geometrical active area. Various parameters, including potential, catalyst loading, ions in solution, type of support for catalyst immobilization, and liquid flow rate, are varied to optimize the system performance with different materials. The process performance is assessed through Faradaic efficiency (FE) and NH_3 production over time. The ultimate goal of this investigation is to identify a catalyst and operational parameters that ensure high FE and production rates, even at high current densities, where the HER may dominate the process.

This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No. 948769, project title: SuN_2rise).

Fe/Mo bimetallic phases supported on TiO₂ for N₂ reduction into NH₃ by photo-processes

Mrs. Caroline Mary, France

Oral Presentation (20')

Abstract

As climate change and global warming are among the biggest challenges in the coming years, the main objective is to develop and use renewable energy sources like wind, solar and sea water to mitigate their impact. In our modern society, ammonia is considered as an unavoidable commodity chemicals, as well as an ideal H₂ storage and transportable material due to its green and high energy release capacity. This work consists in the use of solar power to catalytically produce NH₃ with low carbon emission, as the widespread conventional Haber-Bosch process requires so far high temperature and pressure conditions (typically 400°C and 100-200 atm), which is responsible of 300 million tons of CO₂ emission annually. Thereby the low-temperature photocatalytic N₂ fixation/reduction has become a hot topic in the recent years by allowing a green and environmentally-friendly way of production for ammonia using N₂ as cheap abundant reactants and photons as immaterial reactant under far milder and more sustainable conditions than the Haber-Bosch process.

In nature, the nitrogenase enzyme can convert N₂ to NH₃ at ambient conditions. The nitrogenase contains two key proteins, an Fe-based protein and a MoFe-based protein, working in tandem to convert N₂ to NH₃. The Fe-based protein hydrolyses the adenosine triphosphate (ATP) to adenosine diphosphate (ADP), hereby generating electrons that are subsequently transferred to the MoFe-based protein where N₂ is reduced to NH₃. As a consequence, our work is inspired from the natural enzymatic process based on the nitrogenase with MoFe active cluster sites for the development of novel photocatalytic systems for N₂ fixation/reduction to synthesis NH₃ under mild conditions.

This study deals with the assessment of both gas-phase photocatalytic and photo-thermal N₂ reduction using either H₂O or H₂ as H provider. Two different complementary methods were used to monitor the NH₃ production, respectively (1) a classical approach using indirect colorimetric tests (indophenol method) after accumulation in liquid phase and (2) a less common method based on direct measurement of gas-phase NH₃ production.

The present presentation will be focused on the elaboration, characterization and photocatalytic evaluation of Fe/Mo bi-metallic TiO₂-supported systems for both photocatalytic and photo-thermal NH₃ production from N₂ reduction. Structure/activity correlation will be discussed tuning the total metal (Fe+Mo) content, the Fe-Mo proportion and the Mo and Fe surface oxidation states.

Modified cryptomelane catalysts for OER

Ph.D. Paola Rosa, Spain

Oral Presentation (20')

Abstract

Environmental pollution and climate change have intensified the urgency of developing "green" alternatives to reduce the global carbon footprint. One of the most actively explored research areas is the production of green hydrogen via water electrolysis powered by renewable energy sources such as wind, solar, and hydroelectric power. A major bottleneck in this process is the oxygen evolution reaction (OER), which has driven significant interest in the development of efficient catalysts for this half-reaction. Currently, commercial OER catalysts are primarily based on noble metals such as Pt, Ru, and Ir, which, despite their high catalytic efficiency, are associated with high costs due to their scarcity. Consequently, extensive research efforts are focused on developing cost-effective catalysts with catalytic activity comparable to noble metal-based systems. Among the most widely studied alternatives are transition metal-based catalysts, particularly those containing Mn, Co, Ni, and Cu, as these elements are more abundant in nature and therefore more economically viable.

In this study, we report preliminary results on the synthesis, characterization, and catalytic evaluation of Mn-containing catalysts. Specifically, we investigated the catalytic behavior of pure cryptomelane and cryptomelane doped with different concentrations of Co, Ni, and Cu, all calcinated at 500 °C.

The catalytic activity in the OER was assessed using electrochemical techniques. Thus, the catalytic activity has been determined through the measurement of the overpotential (η), measured at a current density of 10 mA·cm⁻², where lower η values indicate higher catalytic activity. The results show that pure cryptomelane exhibits an overpotential of 490 mV at 10 mA·cm⁻², while Ni- and Cu-doped cryptomelane catalysts display higher overpotentials. In contrast, cryptomelane catalysts doped with 5% Co, 10% Co, and 25% Co exhibit overpotentials of 430, 420, and 440 mV, respectively. These findings suggest that Co doping enhances the OER catalytic activity of cryptomelane, with the 10% Co-doped catalyst showing the best performance.

BiOCl microsphere-based photoanodes and the effect on DSSC performance

Mr. Luis Pizarro, Chile

Oral Presentation (20')

Abstract

DSSCs stand out thanks to their ease and low cost of manufacture and ability to operate in low light conditions. These cells, generally manufactured with TiO₂, have limited efficiency, mainly due to the recombination processes that occur within the cell's photoanode. Among the strategies to reduce these processes is the doping of the semiconductor and the study of new materials; however, to date, these challenges have not been overcome.

Among the various semiconductors that could be used in DSSCs is BiOCl. This material presents a wide indirect band gap (close to 3.5 eV), low recombination rate, high electronic mobility, and non-toxicity, in addition to its ability to adsorb molecules of various dyes used in this device.

Despite its properties, few works are reporting the use of BiOCl in DSSC, so it is necessary to establish conditions for obtaining the semiconductor films to optimize the dye adsorption and its impact on the reduction of recombination processes and the overall efficiency of these devices. In this work, BiOCl powders were synthesized by coprecipitation, and films with hierarchical morphologies were obtained for the first time by screen printing. In addition, the impact on dye adsorption and efficiency of the cells fabricated with these BiOCl microsphere-based photoanodes was studied.

Optimisation and scale-up of solid oxide fuel cells employing aqueous-based tape casting of anodes and spray pyrolysed active layers

Dr. Domingo Pérez-Coll, Spain

Oral Presentation (20')

Abstract

In the current climate crisis, in which renewable energy must provide a larger share of the energy mix, green hydrogen is a promising solution for storing chemical energy for conversion to electricity, thus promoting the transition to a sustainable energy system. Solid oxide fuel cells (SOFCs), which work in the range 500-1000 °C, achieve this conversion efficiently, generating heat and power simultaneously, closing the energy cycle and promoting the circular economy. Even though performance at intermediate temperature (500-700 °C) is advantageous for long-term SOFC use and lower price, this reduces their efficiency considerably, mainly due to the higher polarisation resistance of the air electrode. In this sense, we have recently demonstrated that the addition of thin active layers of mixed-conducting materials between the electrolyte and the air electrode significantly improves the electrochemical performance at intermediate temperatures. This concept is based on the extension of the electrochemically active area through the adjustment of the ionic-electronic transport properties of the intermediate layers.

The present work demonstrates the scale-up of anode-supported SOFCs based on Ni-Ce_{0.9}Gd_{0.1}O_{2-δ} (CGO) and Ni-Zr_{0.84}Y_{0.16}O_{2-δ} (YSZ) cermets prepared by tape casting, with subsequent deposition of YSZ and CGO electrolytes, intermediate active layers and strontium ferrite-based cathodes by spray pyrolysis and screen printing. The preparation of water-based Ni-CGO and Ni-YSZ tapes and their thermal treatment have been optimised to achieve sintered anodic supports with suitable porosity and mechanical resistance. The thin electrolyte layers were deposited on the porous supports with the appropriate thermal treatment to obtain dense electrolytes with good adhesion to the anode. Scale-up of single cells of practical application with dimensions 5 cm x 5 cm involved the control of sintering to produce homogeneous, crack-free and delamination-free assemblies. The full single cells were analysed for electrochemical performance in a suitable test system for i-V characteristics and stability assessment.

SAN and ABS polymers as binders for metal hydride pellets for hydrogen storage at the solid state

Sig.ra. Valentina Fiume, Italy

Oral Presentation (20')

Abstract

Intermetallic compounds represent promising candidates for hydrogen storage applications under ambient conditions; however, their activation remains challenging.[1] The utilization of loose powder in metal hydride reactors often results in poor thermal conductivity and can cause the plastic deformation of tubes due to the volume changes during hydrogen charging and discharging cycles.[2] These issues can be alleviated by embedding the metal powder with a polymer to form pellets. The polymer should be homogeneously blended with the powder, be impermeable to oxygen but permeable to hydrogen, demonstrate elasticity to accommodate volume changes during hydrogen absorption/desorption cycles, and enhance thermal conductivity of the powder alone.[3] This study examines styrene acrylonitrile (SAN) and acrylonitrile-butadiene-styrene (ABS) polymers, supplied by Versalis s.r.l., as binders for metal alloy pellets intended for hydrogen storage. Pellets were prepared by mixing polymers and metal powder with a general La_{1-x}Ce_xNi₅ composition via ball milling and pressing. The pellets were characterized using X-ray diffraction (XRD), scanning electron microscopy with energy-dispersive spectroscopy (SEM-EDS), differential scanning calorimetry (DSC), and Fourier-transform infrared spectroscopy with attenuated total reflectance (FTIR-ATR). Hydrogen storage performance was evaluated using a Sievert-type apparatus. Both polymers yielded stable pellets with up to 95:5 weight ratio of metal powder and polymers at various pressures. XRD analysis confirmed that the crystalline structure of the metal powder remained unaltered, while FTIR-ATR spectra indicated no structural changes in the polymers. DSC analysis demonstrated no variations in the polymer glass transition temperature, suggesting thermal stability during pellet fabrication. Gas sorption tests enabled to assessment of the polymer's impact on the hydrogen storage properties of the metal powder, providing valuable insights into the compatibility and potential applications of these composite materials.

Role of Co, Cu, Cr, and Al in Recycled TiFe Alloys for Hydrogen Storage

Mrs. Francesca Garelli, Italy

Oral Presentation (20')

Abstract

Hydrogen has emerged as a promising solution to address environmental challenges posed by fossil fuels and to store excess renewable energy. Together with gas compression and liquefaction, the storage of hydrogen in suitable carriers is considered. TiFe-based alloys are particularly attractive for hydrogen storage, due to their storage capacity, although challenges remain regarding activation and plateau pressure stability. This study offers insights into the design of TiFe-X alloys for hydrogen storage, focusing on the use of commonly available elements found in scrap yards, and highlighting the potential of recycled materials to enhance sustainability. In this respect, this study is compliant with the innovation principles expressed by the Safe and Sustainable by Design approach for a responsible and sustainable production of chemicals and materials. TiFe-X alloys were synthesized via arc melting of high-purity raw materials under vacuum, followed by suitable annealing. Obtained samples have been characterized by X-ray diffraction, scanning electron microscopy, and energy-dispersive X-ray spectroscopy. The hydrogenation properties of the alloys were assessed through Pressure-Composition-Temperature analysis and high-pressure differential scanning calorimetry. The addition of Al and Cr was found to be particularly beneficial for the activation of the alloy. Al promotes compositional heterogeneity in the alloy, enhancing the number of fast hydrogen diffusion channels and improving the activation characteristics, while Cr forms secondary phases, that facilitate hydrogen absorption. Cr addition exhibited superior hydrogen uptake compared to other alloying elements, making it the best choice for maximizing storage capacity. In contrast, the inclusion of Co and Cu does not significantly improve either the activation or storage capacity of the TiFe alloy. From an environmental perspective, the Life Cycle Impact Assessment of the arc melting production and annealing revealed that Co is the most impactful among selected elements, while Al is the most environmentally friendly, due to the lowest environmental impact during production. Although Cr introduces higher environmental costs compared to Al, it offers a balanced solution due to its superior hydrogen storage performance. Thus, Cr can be regarded as an ideal compromise between hydrogen storage capacity (1.6 wt% of hydrogen compared to 1.1 wt% for the Al-substituted alloy) and environmental impact, positioning it as a promising alloying element for TiFe-based hydrogen storage systems. Future work will involve an analysis of scaling up the production of these alloys from recycled metal sources and evaluating their performance in industrial-scale hydrogen storage systems. Funds from Horizon Europe research, grant agreement No 101192503.

Paper 1426 **5** **Parametric investigation of the operation of an SO₂ depolarised electrolyser for hydrogen production**
Mr. Georgios Arvanitakis, Germany
Oral Presentation (20')

Abstract

Hydrogen is gaining momentum as a promising green energy carrier and different production routes are being intensely investigated. The hybrid sulphur cycle (HyS), or Westinghouse process, was developed as an alternative for the production of sustainable hydrogen. It consists of two main steps: a thermochemical (sulphuric acid decomposition to sulphur dioxide, water and oxygen in high temperatures, ~850-950°C) and an electrochemical (sulphur dioxide depolarized electrolysis - SDE). This electrochemical process, includes the oxidation of SO₂ to H₂SO₄ in the anode and the hydrogen evolution reaction in the cathode. The theoretical potential of the overall electrochemical reaction is 0.158 V, significantly lower than the one needed for direct electrolysis (1.23 V). This difference makes this hybrid approach an attractive alternative to conventional water electrolysis, as the same amount of hydrogen can be produced with lower electricity consumption, consequently lowering the operational costs. So far, research on SDE investigated the use of different catalyst materials and operating conditions, with most common catalysts being, platinum, palladium and gold-based. This work aims to experimentally investigate the performance of SDE in the lab-scale under different operational conditions, using commercial components designed for PEM electrolysers, in order to produce valuable insights and describe dependencies, useful for the process scale-up and the establishment of a baseline. This baseline will serve as a reference for comparison to the performance of SDE with custom modified components in future tests. The experiments utilize graphite monopolar plates and catalyst coated membranes, featuring a platinum loaded catalytic layer with a loading of 0.6 mg Pt/cm² at the anode side and 0.3 mg/cm² at the cathode, dispersed in carbon black. The pressure chosen for the long-term operation tests is close to ambient. The applied potential, operating temperature, concentrations and flowrates of the electrolytes are parameters of investigation. Results are extracted in a single cell setups of 5 cm², 10cm² and 25 cm² active surface area up to a stack with 100 cm² active surface area respectively. SO₂ consumption and H₂ production are evaluated in correlation with the electricity consumed, with specific energy consumption being used as a metric, while SO₂ cross-over from anolyte to catholyte and the parasitic actions in which it results, namely its reduction to H₂S and elemental sulphur is also assessed.

Paper 1217 6 **Advanced Transition Metal Vanadate Catalysts for Efficient Aqueous Electrochemical NRR**
Mrs. Naina Goyal, Germany
Oral Presentation (20')

Abstract

The Haber-Bosch process is a widely recognized methodology for the industrial production of ammonia, accounting for approximately 2% of global annual energy consumption and serving as a significant source of greenhouse gas emissions. To address these environmental concerns, electrochemical nitrogen reduction reaction (e-NRR) offers a promising alternative, utilizing nitrogen gas and aqueous electrolytes under ambient conditions for ammonia synthesis. Motivated by this, we investigate first-row transition metal-based vanadium oxide electrocatalysts for ammonia production. Zinc vanadate, synthesized via the sol-gel pyrochlore method, demonstrates vanadium as a highly active catalytic site, corroborated by density functional theory (DFT) calculations. Further efforts to incorporate lithium into the zinc vanadate framework aim to promote the formation of LixNy intermediates during the e-NRR process. This modification results in a composite of lithium vanadate and lithium zinc vanadate, which exhibits enhanced ammonia production activity compared to the individual phases. Our experiments explore the impact of transition metal incorporation into the vanadate matrix on ammonia synthesis in a basic aqueous electrolyte. The ammonia yield is quantified using the indophenol blue method and nuclear magnetic resonance (NMR) spectroscopy. This study highlights the potential of sol-gel-synthesized bimetallic oxide electrocatalysts for facilitating complex electrochemical reaction mechanisms and advancing sustainable ammonia production technologies.

Paper 265 1 **Ion-matter interactions for material modification and functionalization: insights from atomistic modeling**

Dr. Eva Zarkadoula, United States

Keynote (Oral Presentation 40')

Abstract

Ion beams are a very useful tool in multiple fields and applications, from material characterization and material synthesis to material modification and introduction of specific functionalities. Achieving exceptional material properties through material modification with the use of ions requires fundamental understanding of the multiscale processes that take place in ion-matter interactions. In this talk, I will discuss atomistic modeling approaches for understanding the underlying mechanisms in ion-matter interactions in 2D materials for controlled functionalization and efficient synthesis, where minimization of the induced damage and controlling the material's response are key challenges. I will present insights from modeling and compare with experimental observations, highlighting the importance of combining the two for the development of predictive capabilities.

Paper 616 2 **From solution to surface: applying supramolecular chemistry principles for device manufacturing through molecular self-assembly**
Dr. Imad Arfaoui, France
Highlight (Oral Presentation 20')

Abstract

The application of supramolecular chemistry principles to the assembly of active layers for devices is challenging because molecule-substrate interactions are added to the molecule-molecule interactions present in solution. In this talk I shall illustrate what this implies for building an ordered array of fluorescent molecules at a specific distance from each other, while preserving their functionality by decoupling them from the surface. The approach was to make use of pedestals to which the fluorophore was attached by metal-ligand coordination. Zinc phthalocyanine or zinc diphenylporphyrin were chosen as pedestal, perylene as the functional unit, and a pyridyl group as linker. The successful assembly of the three building blocks on a graphene surface was verified with the help of scanning tunneling microscopy and X-ray photoelectron spectroscopy, while near-edge X-ray absorption fine structure spectroscopy was used to determine the precise orientation of the fluorescent unit with respect to the pedestal, and hence the surface. We demonstrate that supramolecular chemistry principles can indeed be applied to build ordered 3D arrays of functional molecules on surfaces and show that it is even possible to exploit the molecule-surface interaction to achieve an arrangement that is not necessarily favoured in solution.

Paper 1134 3

Multifunctional metal-graphene composites for tribological applications

Dr. Anna M. Andersson, Sweden

Oral Presentation (20')

Abstract

Sliding metal-to-metal contacts frequently occur in switching devices (e.g. circuit breakers, contactors, disconnectors, and switches), used for electrical power distribution grid protection. These sliding mechanisms can both be electric-load carrying (e.g. Ag-to-Ag and Ag-to-Cu electric contacts) or be purely mechanical as part of the drive train (e.g. steel-to-steel contacts), and they are typically grease- or oil-lubricated to facilitate the switching actuation and to reduce friction and wear. However, lubricant aging and depletion constitute significant issues in these devices. In addition, metal oxidation is always a problem, especially in tough ambient conditions. Therefore, the development of robust and resilient metal contacts preferably providing solid-state lubrication to replace “wet” lubrication is of great interest for a broad range of applications.

Graphene (including bi-layer and few-layer graphene, and graphene nanoplatelets (GNP)) has in recent years been highlighted as an efficient solid-state lubricant. Adding a small amount of graphene (typically 0.05-0.5wt%) into a metal matrix can provide self-lubricating properties while maintaining favorable metal properties. Benefits of using graphene compared to other lubricating additives, e.g. graphite, MoS₂, and WS₂, include high electric and thermal conductivity, insensitivity to ambient conditions, and oxidation resistance.

This paper summarizes an extensive work conducted on silver-graphene- and copper-graphene composite systems optimized for use in electro-mechanical or mechanical sliding contact systems in electrical switches. Both metallurgical (sintering) and coating (electroplating) synthesis routes have been explored. By material design and optimized processing, composite systems with a combination of valuable electrical, tribological, mechanical, and anti-oxidation properties have been obtained, taking full advantage of the multifunctional properties of graphene. The choice of graphene, extent of dispersion, and graphene/matrix morphology are shown to be critical factors for beneficial tribological effects. For well-performing, optimized systems, a carbon-rich, low friction ($\mu < 0.2$) tribofilm is formed in the wear track. During long-term operation, the film will continuously regenerate from the reservoir of graphene within the composite. A well-dispersed system can also enable nano-effects like dispersion-hardening of the composite, improving wear resistance and durability. For electrical applications, the choice of graphene is a critical factor for providing a low and stable contact resistance over time, as graphene may offer conductive pathways through the contact area even as surface oxides of the metal (especially copper) grow over time.

An overview of the work and the main findings and achievements, including product demonstration, will be presented. The commercial applicability and sustainability of the processing methods will also be discussed and highlighted.

Increasing the functionality of graphene-based materials: pathways to carboxyl enrichment of Graphene Oxide

Dr. Leonardo Giaccari, Italy

Oral Presentation (20')**Abstract**

In the last two decades, the interest in graphene oxide (GO) has grown significantly due to the discovery of the wet chemical route to graphene. GO is a non-stoichiometric, 2D, carbon-based nanomaterials with outstanding properties and quivering chemistry. It is usually produced via the Hummers method, a wet chemical synthesis from bulk graphite [1]. GO can be described as a graphene layer decorated with islands of various oxygen-based functional groups (OFGs) such as: hydroxyls and epoxides in the basal plane and carbonyls, carboxyls, and phenols on the edges and defects [2]. Since the coexistence of these two domains, graphene oxide can be functionalized either covalently or non-covalently through a plethora of different reactions. Additionally, GO and functionalized GO can be reduced to partially restore the π -aromatic network and obtain properties similar to graphene. These unique assets make GO the perfect starting point for the synthesis of new functional materials [3].

Due to the very low abundance of carboxyl groups in graphene oxide, various attempts have been made in order to increase their quantity. In this work, two different functionalization reactions to obtain carboxyl-rich graphene oxide are presented. The first reaction is an O-acylation reaction with succinic anhydride in N,N-dimethylformamide (DMF) which involves alcohol and phenols-like groups [4]. An alternative approach is a nucleophilic substitution on the epoxide rings with γ -aminobutyric acid (GABA) in water. All the nanomaterials submitted have been fully characterized via various spectroscopic techniques such as: x-ray photoelectron spectroscopy (XPS), Raman spectroscopy, UV-Vis spectroscopy, solid-state nuclear magnetic resonance (SS-NMR), and cyclic voltammetry (CV). The obtainment of a carboxyl-rich GO points to fostering the implementation of graphene-based materials in various fields such as: proton exchange membranes (PEM) in low-temperature fuel cells (LTFCs), removal of heavy metal ions from wastewaters, and amide-coupling with various amine-rich nanomaterials [4].

Atomic-level insight into graphene-enhanced anticorrosive coatings deposited on aluminum alloy surfaces

Prof. Marcela Trybula, Poland

Oral Presentation (20')

Abstract

Metal corrosion causes heavy losses on human life and economy [1]. Anti-corrosion polymer coatings undergo self-decomposition under exposure to harsh conditions, which leads to their short-term loss of functionality [2]. Excellent chemical inertness, thermal stability and diffusion barrier properties of graphene have attracted growing interests in designing graphene-based composite (GC) coatings for anticorrosion purposes. The size of graphene flakes, structure, chemical composition, and roughness are important for obtaining adhesive, tightly covering layer of GC coating on metal surfaces with improved anticorrosion properties [3].

In line with recent literature data, herein we provide an atom-level picture of structure and properties of functionalized graphene oxide (fGO) coatings deposited on aluminum alloy surfaces exposed to corrosive media. Atomistic calculations, DFT and reactive molecular dynamics methods, are combined with experimental studies. fGO flakes varying in size and oxidation degree on metal surfaces were considered and discussed in view of the experimental knowledge of different properties of graphene materials[4]. Structural, morphological, chemical, and topological aspects of fGO deposited on Al-based alloy surfaces are discussed. The oxidation state of fGO on an Al alloy surface was characterized using Raman spectroscopy and X-ray photoelectron spectroscopy (XPS). Roughness and surface topography of fGO layer on Al alloy surfaces were determined experimentally and computationally. Electrochemical performance of fGO-covered Al alloy surfaces were established and discussed with available literature data.

An Effective Strategy for the Valorization of Industrial Waste Graphite Fines through the Preparation of Graphene Oxide-based Nanohybrids

Dr. Mohammed Subrati, Greece

Oral Presentation (20')

Abstract

Graphite is classified as a “strategic and critical mineral” by the US and EU, with a market value that is expected to reach \$28.33 billion by 2026. The growth of the graphite market is predicted to be primarily driven by the increasing demand for Li-ion grade graphite from the electric vehicle industry. Graphite is mainly produced in two forms: natural, which is obtained through mining; and synthetic, which is obtained by thermal annealing of highly pure graphitizable carbon materials at ultra-high temperatures (up to 3000 °C). In either form, graphite flakes need to undergo the micronization and spheroidization processes in order to be applicable as an anode material for Li-ion batteries. Consequently, these processes result in significant losses of the graphitic material of up to 70% in the form of ‘graphite fines’, which are regarded industrially as waste material or undesirable byproduct.

Herein, we report for the first time an effective strategy to utilize industrial waste graphite fines through the development of graphene oxide-based nanohybrids as non-toxic and efficient antibacterial agents. To achieve this, graphene oxide (GO) was initially synthesized using industrial waste graphite fines as a graphitic precursor. Subsequently, hyperbranched polyethyleneimine (PEI), or either of its guanidinylated (GPEI) and N-sulfopropylated (SPEI) derivatives were successfully and homogeneously attached onto GO, as confirmed by various characterization techniques, yielding GO-PEI, and novel GO-GPEI and GO-SPEI nanohybrids. The antibacterial activity of these nanohybrids was assessed against Gram (–) *Escherichia coli* and Gram (+) *Staphylococcus aureus* bacteria. Both GO-GPEI and GO-SPEI were found to exhibit higher antibacterial activity, specifically against *E. coli* bacteria, compared to the pristine GO and GO-PEI nanohybrid, with GO-SPEI being more active than GO-GPEI. Moreover, GO-GPEI and GO-SPEI were found to exhibit low cytotoxicity against mammalian cells, signifying that they can be used as potential antibacterial agents in various applications, including those in the disinfection industry.

Paper 1906 2 **High-Performance MoSe₂xTe_{2-2x} Alloy for Hydrogen Gas Sensing**

Dr. Gema Tabares Jiménez, Spain

Oral Presentation (20')

Abstract

This study provides one of the first comprehensive investigations into the out-of-plane growth of two-dimensional MoSe₂xTe_{2-2x} for three different Se:Te compositions, resulting in the samples MoSe_{0.46}Te_{1.55}, MoSe_{0.55}Te_{1.45}, and MoSe_{0.64}Te_{1.35}. Scanning electron microscopy (SEM) captures the morphological evolution, displaying nanoflakes primarily grown in a random out-of-plane orientation. Raman spectroscopy confirms the crystal structure of the MoSe₂xTe_{2-2x} samples, with no detectable MoO₃ or MoO₂ precursor residues. Characteristic peaks validate the presence of MoSe₂xTe_{2-2x}, and spectral shifts indicate compositional variations. Conductive Atomic Force Microscopy (C-AFM) was employed to measure the current flow between a diamond-doped AFM tip and the sample. Furthermore, the resistances of MoSe_{0.46}Te_{1.55}, MoSe_{0.55}Te_{1.45}, and MoSe_{0.64}Te_{1.35} compositions were characterized, yielding median resistance values of 108.0 Ω, 25.4 kΩ, and 240.0 kΩ, respectively. These values highlight the diverse electrical properties linked to Se content. Notably, the sample with the highest Se content shows increased resistivity, which aligns with the XRD spectra results. Finally, evaluation of the H₂ gas sensor revealed a decrease in electrical resistance of the samples upon exposure to hydrogen, particularly pronounced at higher temperatures. However, a complex relationship between sensor response and Se content was observed, with higher Se content samples exhibiting relatively lower response despite their potentially higher hydrogen absorption capability based on the morphology of the flakes.

Pulsed electrochemical exfoliation for an HF-free sustainable MXene Synthesis

Mr. Marko Piljević, Austria

Oral Presentation (20')

Abstract

MXenes are a two-dimensional materials (2DM) class with high industrialisation potential, owing to their superb properties and compositional variety which brought to their vast application in different fields ranging from energy conversion and storage to medicine and diagnostics, sensing and tribology. One of the big questions in MXenes is how to produce them in high amount and without involving hazardous chemicals. We have recently demonstrated a novel method to produce high quality MXenes in a sustainable manner, using pulsed voltammetry electrochemical synthesis. In a nutshell, we precisely control the potential applied on the anodic working electrode (MAX phase) at the Al etching potential and apply reverse cathodic pulses to foster surface reactivation and improve intercalant diffusion. This novel protocol led to a final product (EC-MXenes) with great physical and chemical properties and a production yield to 60% with no byproducts counted and out of a single exfoliation cycle.

In the talk I will present the details of the methodology and how synthesis of MXenes is related to the formation and control of electrochemically formed bubbles at the cathode's interface. Moreover, I will detail the extensive surface analysis performed on our product, which includes SEM, EDX, LEIS, Raman, AFM, TEM, XRD, and XPS.

Finally, I will present the follow up steps we are currently investigating, which include for instance the tribological application of this material and surface termination's post modification (e.g., amino acid) for high tuning of final physical/chemical properties.

To conclude, the work is setting the bases for a facile synthesis of MXenes in any labs and industries, where no specific infrastructure (for management of HF) is required.

Mrs. Andrea Carolina Villalvazo-Hidalgo, Mexico
Oral Presentation (20')

Abstract

In this study, molybdenum disulfide (MoS₂) was synthesized via a hydrothermal method. The structural impact and morphological properties of MoS₂ were tested by adding different reactive volumes and two rates of addition. The final structures were systematically investigated by X-ray diffraction (XRD), Energy Dispersive Spectroscopy (EDS), Scanning electron microscopy (SEM), and transmission electron microscopy (TEM). Experimental results demonstrate that variations in reactive volumes and addition rates significantly influence the reaction development. A smaller reactive volume leads to MoS₂ formation. On the other hand, a large volume forms sulfur. Effects on the synthesized MoS₂ morphology were also observed. By adding a lower reactive volume, it was possible to get MoS₂-2H. By featuring a larger volume, a heterojunction between MoS₂-3R and Sulfur is formed. In contrast, undesirable byproduct formation is generated due to lower addition velocities. The study contributes to the fundamental MoS₂ hydrothermal synthesis understanding and it provides valuable insights for tailoring the key properties of MoS₂-based applications such as catalysis, energy storage, biosensors and electronic devices.

CE-RISE (Circular Economy Resource Information System): A Digital Infrastructure for sharing information and connecting stakeholders along the circular supply chain

Dr. Joana Francisco Morgado, Switzerland

Keynote (Oral Presentation 40')

Abstract

The European Green Deal, through its Circular Economy Action Plan, introduced transformative measures to enable circular economy in the manufacturing sector. Policies like Ecodesign for Sustainable Products Regulation and Critical Raw Materials Act set clear targets for products and materials to optimize resource use and efficiency across the supply chain. To support this, a key objective of the CE-RISE project is to develop indicators based on product composition, material criticality, and safety concerns. This will allow first assessing and later communicating a product's potential for circular economy applications through a dedicated digital infrastructure, building on tools such as the Digital Product Passport (DPP). Therefore, CE-RISE will allow informed decision-making throughout a product's or material's life cycle.

The CE-RISE digital infrastructure uses data stored in DPPs, and user-supplied data, to perform key calculation routines for monitoring and assessing circularity, accessible through an online platform. The platform incorporates indicators to measure a product's potential for effective circular economy implementation and quantifies actual contributions through circularity ratios, such as the proportion of secondary raw materials used. These indicators, together with a socio-economic and environmental impact assessment, provide insights into both the feasibility of circular economy practices and their broader implications. By connecting these metrics, the framework ensures transparent evaluation of a product's circularity, assessing its alignment with circular economy principles and its impact on material efficiency and environmental/social sustainability.

The infrastructure adds value to actors along the whole value chain, such as original equipment manufacturers or post-use operators, as well as consumers. The combined set of indicators, circularity ratios, and socio-economic and environmental assessment, help guide and inform them in different ways. In the presentation we will show how manufacturers benefit using the platform to meet regulatory requirements, such as incorporating recycled or remanufactured materials, and efficiently reporting compliance in a quantified manner. Consumers benefit from precise and easily accessible indicator scores, enabling them to make well-informed purchasing decisions. Finally, post-use operators rely on the platform to access reliable data and tools to support material/product recovery and reintegration into the supply chain.

We will present the CE-RISE conceptual framework with the developed indicators to assess the extent to which end-of-life products and materials can contribute to enhancing

Cost-Effective Approach to Maraging Steel Development Using Mixes of Commodity Alloys

Mrs. Sama Safarloo, Spain

Oral Presentation (20')

Abstract

Currently, to achieve high-performance steels like the maraging family with improved strength-to-ductility ratios, alloying elements are required, which are considered critical due to their scarcity, cost, or carbon footprint. Elements like Ni or Co are among these and are crucial to achieving the desired microstructures in advanced maraging steels. Hence, instead of using these elements separately in the production of maraging compositions, an alternative would be the employment of other alloys already containing these elements. As these “commodity” alloys are also manufactured on a large scale, their cost is diminished, and they enable circularity by being recycled. Therefore, the development of high-performance maraging steels using commodity alloys containing essential alloying elements was investigated in this work. Arc melting and additive manufacturing (AM) processes, specifically laser powder bed fusion (LPBF), were employed to produce compositions as close as possible to existing maraging steel grades, including 18Ni-300, MAR-50 Co-free, and MAR-60 steels. Both arc melting and LPBF were used to create the alloys under different conditions, enabling a comparative analysis of the resulting properties and the evaluation of the two production techniques. Furthermore, the study focused on analyzing the structural and microstructural features of the produced alloys, as well as evaluating their mechanical properties. Microstructural characterization consisted mainly of SEM, EDS, XRD, EBSD, and TEM explorations. Besides, hardness measurements were employed together with Profilometry-based Indentation Plastometry (PIP) to assess their mechanical performance. As these steels’ properties heavily depend on their thermal history to ensure their peak performance by precipitation strengthening, heat treatments were applied to optimize the microstructure and enhance the steels’ properties. This approach offers a sustainable and cost-effective method for developing high-performance steels using available scrap from commodity alloys, reducing reliance on rare and expensive critical alloying elements in pure form.

Keywords: Maraging steels, Commodity alloys, Arc melting, Additive manufacturing (AM), Laser powder bed fusion (LPBF).

Bridging Material Science and Life Cycle Assessment: Integrating OpenSemanticLab with openLCA for Comprehensive Early-Stage Sustainability Optimization

Dr. Simon Stier, Germany

Oral Presentation (20')

Abstract

Safety and sustainability by design (SSbD) are increasingly critical in material science, especially in the pursuit of a circular economy. However, these considerations are often absent in the early stages of material development, where key decisions determine the direction and impact of research. This gap arises from a disconnect between material scientists and sustainability experts, which is amplified by diverging data structures and a lack of a common language between both domains. To address this challenge, we present an innovative approach that integrates OpenSemanticLab with openLCA, effectively building a digital bridge between material science and Life Cycle Assessment (LCA). Our methodology involves the creation of linked data schema for an electronic lab notebook (ELN) compatible with the openLCA data schema. By utilizing JSON-LD, shaped with JSON-SCHEMAS, we generate a user-friendly web interface through the OpenSemanticLab software stack. This interface empowers material scientists to input data on processes and materials directly from the lab using only a web browser, without requiring any knowledge of JSON-LD or openLCA. This accessibility ensures that sustainability considerations are seamlessly integrated into everyday laboratory practices. Beyond capturing general material and process properties, our system also incorporates economic and technical performance indicators, as well as Quantitative Structure-Activity Relationship (QSAR) toxicity metrics. This comprehensive data collection enables global multi-target optimization, allowing researchers to simultaneously consider safety, sustainability, performance, and cost factors in material development. By integrating these diverse metrics early in the research process, we facilitate more informed decision-making aligned with SSbD principles.

Building a system that enables the creation of a knowledge graph of experimental setups that can be automatically converted into openLCA workflows and processes was made possible by integrating OSL with openLCA via a Python plugin application. This tool queries and selects process entities, automatically assigns them to the appropriate format and generates an openLCA ZIP archive for import. LCA experts can then perform semi-automated or fully automated predefined assessments, evaluate various scenarios and provide immediate, valuable feedback to material researchers. By incorporating economic and technical performance indicators alongside QSAR toxicity metrics, the platform enables a holistic assessment of materials fostering early-stage innovation that aligns with circular economy principles.

We demonstrate this approach with a case study on paper-based electronics showcasing the potential of coupling materials and sustainability research from the outset. The integration not only facilitates the incorporation of SSbD principles but also enhances collaboration between disciplines contributing to resource optimization and waste reduction.

Circularity for Metal Additive Manufacturing: a review

Dr. Salomé Sanchez, The Netherlands

Oral Presentation (20')

Abstract

Material production contributes to 25% of global CO₂ emissions, highlighting an urgent need to transition towards a more circular economy. Metal Additive Manufacturing (AM) offers the potential to revolutionise industrial production by enabling complex geometries and improving material efficiency. However, sustainability challenges persist, particularly concerning metal feedstock. The use of recycled feedstock in AM remains underexplored, necessitating further investigation. This research explores circularity in metal AM feedstock. This research will be undertaken through a systematic literature review and meta-analysis. The study will encompass Powder Bed Fusion (PBF) and Directed Energy Deposition (DED) processes, focusing on metals that have been previously investigated for recycling. First, feedstock minimum quality requirements will be examined. Then, various metal waste streams both inside and outside the AM chain (e.g. machining scrap, end-of-life components, and residual material from AM processes), will be identified. The selection and pre-processing stages (e.g., cleaning, shredding) required to prepare these materials for reuse will also be explored. Next, conversion methods (e.g. powder atomization, ball milling and wire drawing) will be researched to determine their suitability for transforming pre-processed metal waste into viable PBF and DED feedstock. The study will also investigate the impact of using recycled materials on feedstock quality, processability, and on the resulting microstructure and mechanical properties. A comparative analysis will be conducted between parts fabricated using recycled versus virgin feedstock, evaluating differences in the presence, quantity and morphology of various phases, precipitates and defects. These microstructural variations will be correlated with the mechanical performance of the parts. Integrating recycled materials into AM aligns with sustainability objectives of reducing raw material extraction, minimising waste generation, and lowering environmental impact. The findings will contribute to the broader effort of advancing circular economy principles in AM, paving the way for more resource-efficient and sustainable manufacturing practices.

- Paper 1997 5** **Safe and Sustainable by Design Framework: An Exploratory Case Study in Additive Manufacturing with a Focus on Surface Functionalization of Parts with Complex Geometry**
Mrs. Khadija Sarquah, Germany
Highlight (Oral Presentation 20')

Abstract

The growing environmental challenges for materials exploration and production have necessitated a global adoption of sustainable practices to minimise resource depletion, waste and global warming. Additive manufacturing (AM) is a potential technology for increasing resource economy and environmental performance in manufacturing systems. Recent research, however, has demonstrated that the design and functionalisation of complex manufactured parts affects the sustainability of AM. The EU Safe and Sustainable by Design Framework as an iterative guideline aims to minimise environmental and social impacts throughout a product's life cycle while enhancing overall functionality and economic value. This study explores the application of SSbD to the design of complex shaped parts via additive manufacturing and surface functionality based on laser technologies. Four use cases were studied in different fields of application: biomedical (femoral component of a knee implant), aerospace (clamp band), and aviation (pivot bracket and lever). The study involved a life cycle mapping of the use case supply chain followed by a Material Energy Toxins (MET) analysis that expanded to include Criticality, Environment (land), and Social elements, referred to as C-MET-ES. Qualitative and quantitative data were analysed for C-MET-ES matrix, hotspot analysis using ranking, weighting, and expert group evaluation. A chemical hazards risk and gender dimensions assessment identified specific concerns related to post-processing. The results provide recommendations towards material changes and improvement of resource efficiency in target use cases via additive manufacturing, laser post-processing, and in-line monitoring. The outcome of this study contributes to a well-defined eco design checklist and optimisation potentials in the AM and laser processing of parts with complex geometry.

RECOVERY AND VALORIZATION OF SILICA FROM FLUORO-DERIVATIVES INDUSTRY WASTE FOR ADVANCED TECHNOLOGICAL APPLICATIONS

Prof. Roberto Scotti, Italy

Oral Presentation (20')

Abstract

In recent years, the recovery of silica from waste or end-of-life products has become a challenging issue as an effective waste management strategy and a sustainable circular economy model. In this context, the aim of the present work is the valorisation and reuse of silica as by-product of the recovery process to obtain CaF_2 as secondary raw material from hexafluoro silicic acid H_2SiF_6 (FSA), which is a hazardous by-product of phosphate and fluoride industry.

The main objective is to set the large-scale recovery process, based on the NH_4OH reaction with FSA, to directly provide silica particles with specific structural and morphological characteristics, aimed at reusing silica for highest value applications such as reinforcing filler for elastomeric nanocomposites with high mechanical properties for tyre industry. The conditions of process and post-process treatments were modulated to obtain FSA-derived silica with high surface area and controlled size, shape, aggregation and textural features by varying process temperature (3-20°C), pH (7.8-10), silica powder washing solution (acid/basic) and drying method (oven/fluid bed/spry drying) conditions. FSA-derived silica was morphologically and structurally characterized by SEM and TEM microscopy, XRD, TGA and nitrogen physisorption BET. Composition and purity were assessed by XRF, solid state NMR and XPS spectroscopy for the elemental surface analysis of silica particles.

FSA-derived silica was tested as reinforcing filler for elastomer nanocomposites upon incorporation in Isoprene (IR) and Styrene Butadiene (SBR) matrix. The reinforcement properties of the filler was analysed by studying the vulcanization curves (at 170°C for 15 min.) of the rubber nanocomposites, showing comparability with those of rubber nanocomposites prepared with commercial silica filler commonly used in the rubber industry. The mechanical behaviour at low deformation of nanocomposites prepared with FSA-derived silica, acquired by determining the strain dependence of the shear modulus G , confirms the good properties of the material prepared by reusing the silica from waste, comparable with of that obtained using the commercial reference.

The results indicates that FSA-derived silica has demonstrated interesting features alongside comparable performances to those of commercial silica as reinforcing filler for rubber composites with high mechanical properties, allowing to consider it as valuable and convenient alternative from a waste recovery process to conventional silica filler in large scale tyre manufactures.

Porous glass-derived products using vitrified ashes from municipal solid waste incinerators

Mrs. Mariacristina Martorino, Italy

Oral Presentation (20')

Abstract

Implementing circular economy approaches in materials processing and technologies is an important goal from environmental and socio-economical viewpoints because of the decrease in global resources and the constant increase of solid wastes. In this context, we used vitrified bottom ashes from municipal solid waste incinerators as a starting material to produce glass-ceramic foams for possible use in the thermal insulation of buildings. Sinter-crystallization of the material will be studied by thermal analyses (hot stage microscopy and differential scanning calorimetry). The morphological characteristics and chemical composition of the ashes, vitrified material and final porous products will be assessed by scanning electron microscopy and energy dispersive spectroscopy, respectively. The porous architecture will be investigated by combining micro-computed tomography analysis and permeability assessment. Specifically, permeability will be determined by using an acoustic method that involves measuring the pressure drop generated by an alternating airflow through the sample, using an oscillating piston (which creates the flow) and a low-frequency microphone detecting the drop. The advantage of this method is its relative ease of execution, speed and accuracy, especially for highly porous samples without causing any damage to them. The mechanical behaviour of the foams will be investigated by compressive tests and the release of heavy metal ions will be evaluated by leaching tests according to the current standards in order to confirm the suitability and safety of the product.

Paper 2000 8 **Technoeconomic and Performance Assessment of Refuse Derived Fuel (RDF) Production: A Response Surface Methodology (RSM) Approach**
Mrs. Khadija Sarquah, Germany
Oral Presentation (20')

Abstract

Utilising alternative fuel from waste as a substitute fuel contributes to energy diversity, economic value addition, and environmental benefits of sustainable waste management. For the coprocessing of alternative fuels such as refuse-derived fuel (RDF), it is essential to assess feasibility and investment viability. Response surface methodology (RSM) - Design of experiments (DoE) is a statistical approach that designs and analyses complex relationships between multiple variables, resulting in reliable and objective outcomes. This study aims to assess the economic viability of the refuse derived fuel production from municipal solid waste as a substitute fuel and process optimisation potentials in a case study. The economic analysis includes the net present value (NPV), profitability index (PI) and simple payback (SPB) for the feasibility check. Operating variables were optimised with the desirability approach of RSM to assess the optimum output using Minitab software. Input variables of production capacity, discount rate, life span and response or output variables of net present value, profitability index and simple payback were considered. The results estimate the predominant economic parameter on the response functions of the financial indicators. The sensitivity analysis predicts the effects of lifetime and interest ratios on the output variables. RSM-DoE application presented sensitivity analysis of the most significant parameters affecting the viability of the proposed energy recovery from MSW. Thus, process optimization with technoeconomic analysis is helpful in decisions for integrated waste management systems.

Bioprinted bioactive complex constructs under mechanical stimulation promote vascularized bone formation

Prof. Maria Chatzinikolaïdou, Greece

Oral Presentation (20')

Abstract

Background

Osteogenesis and angiogenesis are coupled in a spatiotemporal and inter-dependent manner during bone regeneration. A complex 3D bioprinted model was biofabricated as a holistic vascularized bone model, comprising (i) an outer zone from a photocrosslinkable hydrogel with electrically conductive properties aiming to enhance osteogenesis under dynamic conditions, and (ii) an inner zone including a vascular-like tubular structure from a biofunctional nanocomposite hydrogel to induce angiogenesis. The objective is to bioengineer a complex 3D bioprinted vascularized bone model and evaluate the synergistic interactions of the functional bioinks in dynamic cell cultures.

Methods

The angiogenic matrix was prepared by dispersing gellan gum in a laponite suspension. Wharton's jelly mesenchymal stem cells (WJ-MSCs) were incorporated in the nanocomposite forming a bioink functionalized with platelet-rich plasma (PRP). The osteogenic matrix was prepared from a blend of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS), polyvinyl alcohol, gelatin and polyethylene glycol diacrylate combined with bone marrow mesenchymal stem cells (BM-MSCs). Biofabrication of vascularized bone model was achieved through 3D bioprinting. For dynamic cultures, mechanical stimulation (1 Hz, 10% strain, 1 h) was applied daily for 28 days. Biocompatibility study included Live/Dead assay and evaluation of ECM formation. Angiogenic and osteogenic differentiation were examined through immunofluorescent staining, determination of VEGF/BMP-2 secretion by ELISA, gene expression via quantitative polymerase chain reaction (qPCR), ALP staining, calcium and collagen quantification. Subcutaneous implantation of the constructs was performed for two weeks.

Results

Bioinks maintained over 90% cell viability from day 1 to day 9, and were positive for all ECM markers. At day 28, qPCR analysis demonstrated that in dynamic conditions the complex model exhibited significantly increased expression of TIE1, Ang1, VEGFA, and VEGFR2, indicating an elevated angiogenic potential. Moreover, a significant increase in key osteogenic markers, including BGLAP, SPARC, OPG, and RUNX2 was observed, highlighting the enhanced osteogenic potential of the biofabricated constructs under dynamic culture conditions. Quantification by ELISA demonstrated that the complex model in dynamic conditions consistently yielded higher VEGF concentrations (313 pg/ml). Similarly, BMP-2 release in composite dynamic setups peaked at 28 ng highlighting the pronounced impact of dynamic culturing on enhancing BMP-2 release. Immunostaining at 2 and 4 weeks confirmed positive osteogenesis in biofabricated constructs from day 14, with dynamic conditions, notably with PEDOT:PSS, showing enhanced effects, suggesting the activation of mechanotransduction pathway.

2

Protein adsorption on biomaterials for tissue integration: a predictive way and a surface modification strategy

Prof. Silvia Spriano, Italy

Oral Presentation (20')

Abstract

Protein adsorption is the first step in the integration of an implanted biomaterial with tissues. It sequentially leads to clot formation, the inflammatory cascade, the osseointegration process, and/or soft tissue adhesion. Biofilm formation is also influenced by the protein layer adsorbed on the implant surface.

Surface characteristics, such as topography and morphology (at the micro- and nanoscale) or surface chemistry (exposure of functional groups, wettability, and charge), can affect the overall amount of adsorbed proteins and the surface selectivity for specific proteins. Therefore, a detailed study of protein adsorption is an interesting approach to predicting the outcome of an implantable biomaterial and guiding its design. Protein pre-adsorption can also be used as a surface modification strategy to direct the biological response of a surface toward a specific target.

Nevertheless, the study of protein adsorption has, so far, been underestimated in biomaterial characterization protocols. This is partly due to the complexity of this type of characterization, which, however, can be addressed through the use of more recently developed techniques.

The development of a detailed characterization protocol for protein adsorption is also relevant for minimizing the use of animals in experimentation.

A characterization protocol will be presented to provide insights into a surface's potential selectivity for proteins, the surface coverage by the protein adsorbed layer, the chemical interaction between the surface and proteins, and possible changes in the tertiary structure of the adsorbed proteins. As an example, modified titanium surfaces will be analyzed.

It will be demonstrated how certain surfaces can selectively promote the adsorption of fibrinogen over albumin or fibronectin, or how they can adsorb these proteins in different configurations. Additionally, correlations between this behavior and specific surface properties will be presented.

Self-Healing polysaccharide-based hydrogel as three-dimensional carrier for tissue repair

Mr. Jesús García Gutiérrez, Spain

Oral Presentation (20')

Abstract

Self-healing hydrogels are a crucial tool in tissue engineering, offering the advantage of autonomous repair (i.e. self-repair), which minimizes the need for extensive intervention and makes them ideal for developing functional implants with minimal disruption to surrounding tissues [1]. The biocompatibility of these materials is essential, making the use of natural polysaccharides, abundant in the extracellular matrix, highly beneficial. These hydrogels are typically synthesized using dynamic covalent bonds, enabling them to self-heal under physiological conditions. Additionally, the incorporation of inorganic components, such as magnetic particles, allows for external control over the material's behavior [2].

A key advantage of using these hydrogels as cell carriers is their ability to prevent cell loss during injection, as they shield cells from the shearing forces encountered in the injection process [3]. This property makes them particularly suitable for applications in cell-based therapies and tissue regeneration.

This study focuses on the development of biomimetic self-healing hydrogels synthesized via dynamic imine cross-links formed through a Schiff reaction between amino and aldehyde groups of functionalized polysaccharides. The resulting hydrogel exhibits self-repair capabilities, restoring its structural integrity after being injected through needles under physiological conditions. To study the mechanical properties of these hydrogels before and after the extrusion, rheological characterization is conducted using a torsional rheometer under various conditions, assessing viscoelastic behaviour, self-healing efficiency, and mechanical tunability. Additionally, the incorporation of carbonyl iron microparticles is explored to evaluate the impact of external magnetic fields on hydrogel structure and mechanical performance. Furthermore, cellular behaviour is analyzed through morphological characterization and biocompatibility assays to assess the hydrogel's interaction with cultured cells.

The results highlight the versatility of self-healing hydrogels as biomaterials for tissue engineering, offering a tunable mechanical response, adaptability, responsiveness to dynamic environmental stimuli, and significant potential as cell carriers.

Agarose as a tissue mimic for porcine kidney at the macro and micro-length scale

Dr. Aadarsh Mishra, United Kingdom

Oral Presentation (20')

Abstract

Agarose exhibits mechanical properties that are adjustable and have been widely used in tissue engineering [1-6]. Agarose is a linear polysaccharide that is extracted from marine red algae, containing D-galactose and 3,6-anhydro-L-galactose [5,6]. This study aimed to find an appropriate agarose concentration that matches the mechanical characteristics of pig kidney at the micro length scale and compare these to macro-scale properties. For all agarose samples and porcine kidneys, the shear storage modulus and loss modulus were measured at the micro-length scale using nanoindentation measurements with a 100 μm diameter probe, ranging from 10 Hz to 110 Hz. Measurements at the macro-length scale were carried out with a rheometer from 0.1 Hz to a maximum of 9.5 Hz at a shear strain amplitude of 0.1% and fit to a fractional derivative mechanical model. The storage modulus at the micro-length scale was higher by factor of 1.2 to 70 than the storage modulus at macro-length scale in kidney samples and agarose (depending on agarose concentration), which is linked to gel and tissue microstructure. An agarose concentration of 1.2% best fitted the kidney tissue properties at the macro and micro-length scales.

Paper 1373 1 **Upcycling bio-based side streams for 3D printing of sustainable bioplastic filaments**
Dr. Idalina Gonçalves, Portugal
Keynote (Oral Presentation 40')

Abstract

The valorisation of industrial side streams into high-performance biomaterials represents a key strategy for advancing circular economy principles in materials science. In this study, bio-based byproducts were investigated as sustainable feedstocks for the development of 3D-printable thermoplastic bioplastics, targeting applications in fused filament fabrication (FFF). Non-purified starch recovered from potato washing slurries was processed into a hydrophilic and flexible thermoplastic material, which could be extruded as a filament but exhibited excessive moisture sensitivity and lacked structural integrity for direct FFF processing. To enhance its printability, leather-rich byproducts derived from footwear industry, underutilized tomato wastes, and coffee byproducts (coffee silverskin and spent coffee grounds) were used, allowing to tune the physicochemical and mechanical performance, and FFF capacity of thermoplastic starch-based filaments. The results demonstrated the feasibility of upcycling bio-based side streams into engineered bioplastic filaments with potential for sustainable manufacturing. This approach contributed to waste valorisation in the agrifood and footwear industries, while offering a viable route for the eco-friendly production of customized 3D-printed biopolymeric structures, promoting innovation at the intersection of biopolymers, additive manufacturing, and green materials design. Hybrid nanomaterials from biowastes for sustainable agriculture

Prof. Giuseppina Luciani, Italy

Highlight (Oral Presentation 20')

Abstract

The use of nano-fertilizers can heavily support transition towards a more sustainable farming system, by exploring eco compatible materials able to enhance nutritional efficiency, biotic and abiotic stress tolerance, and/or crop quality. At the same time, the huge amount of waste generated, 338 million tonnes per year worldwide, with biowaste (BW) being the widest component, has caused economic and technological challenges to reduce and mitigate its environmental impacts due to improper management [2]. Indeed, BWs are emerging as a cheap and abundant source of chemical and biological richness, in view of their multiple properties including metal ion chelating, as well as intrinsic red-ox behaviour involving antioxidant and antimicrobial activity. Among BWs, lignin and humic acids exhibit great efficacy in improving plant growth and nutrition [3]. Furthermore, molecular combination of BWs with an inorganic nanostructured phase can address the issues related to high heterogeneity, provide stability and boost intrinsic bioactive features [4]. In this context, hydroxyapatite (HA), is an ideal component for forming hybrids with lignin (L), expanding its applications. Moreover, encapsulation of hybrid nanostructures into electrospun fibers can provide with 2D and 3D constructs mimicking soil structure. Herein, it is highlighted the bio-stimulant potential of hybrid nanomaterials derived from BW valorization according to a biomimetic approach. Notably, hybrid BW-apatite nanostructures have been designed and encapsulated into electrospun polylactic acid (PLA) fibers. On one hand, obtained nanostructured materials exhibit marked antioxidant activity as well as widespread potent biocide action towards phytopathogenic bacteria and fungi. On the other hand, they promote proliferation of microorganisms beneficial to the soil microbiome. Following a holistic approach to sustainability, this study provides with organo-mineral systems with multifunctional activity and boosted efficacy.

Solid-State Upcycling Of Aluminium Alloy Machining Residues

Mr. Fahad Zafar, Portugal

Oral Presentation (20')

Abstract

The conventional subtractive manufacturing processes generate a considerable amount of machining residues in the form of machining chips which are generally regarded as low-value scrap.

This study investigates the feasibility of using a mechanical milling technique for converting scrap machining chips into aluminum alloy powder suitable for additive manufacturing (AM), particularly laser powder bed fusion (LPBF) and laser direct energy deposition (DED). Mechanical shearing combined with ball milling is employed to convert the scrap material into a powder form that can be utilized in AM. Considering the requirements of these processes, the particle size distribution, particle shape, flowability, and spreadability of the resulting powder are analyzed and compared to a similar-grade commercial alloy to assess its suitability for purpose. Additionally, the evolution of the microstructure from the starting material to the ball-milled product is observed and discussed. The results of this study provide insights into the potential of upcycling the scrap machining chips into useful feedstock for AM processes. The findings of this research contribute to the development of an energy-efficient and environmentally friendly method for producing aluminum alloy powders suitable for AM applications.

Enhancing the Wear Properties of CoCrMo Alloy for Orthopedic Application by High-Power Impulse Magnetron Sputtering Nitriding Treatment: Life Cycle Assessment and Critical Raw Material Analysis

Ph.D. Stefania Fiameni, Italy

Oral Presentation (20')

Abstract

Technological developments in orthopaedic prostheses are mainly focused on improving the biocompatibility and tribocorrosion behavior of used materials in biological environment. CoCrMo alloys are widely applied in medical implants due to efficient biocompatibility and high mechanical characteristics. Previous studies demonstrated the possibility of further increasing their wear and corrosion resistance to overcome concerns about ions and wear debris release in service. Literature works reported different techniques mainly based on thermal treatment or coating approach with the aim to improve the functional characteristics of CoCrMo alloys. Recently, the use of high-power impulse magnetron sputtering (HiPIMS) nitriding treatments has proven effective in enhancing the surface properties of selected alloys. HiPIMS nitriding is advantageous in terms of reducing raw material use and processing time (Ehiasarian & Hovsepien, 2024; Zin et al., 2025). Due to the novelty of tribological improving approach together with the encouraging results, a Life Cycle Assessment (LCA) of the HiPIMS nitriding process at the lab-scale for CoCrMo alloys is presented. The environmental hot-spots have been analysed for two different nitriding treatments, using Mo and Ta targets. The results showed that the electrical consumption was the main impacting driver. The environmental assessment was useful to evaluate possible technological arrangements to decrease the total environmental impact of the treatment. A complementary study was performed on the criticality analysis of the raw materials used as targets during nitriding. The Critical Raw Material (CRM) assessment was performed using the European Commission methods, based on Supply risk and Economic importance indicators (Blengini et al., 2017). LCA at the laboratory scale coupled with CRM evaluation is crucial for identifying the environmental hot-spots at the early stage of development of novel technologies to provide insights for their sustainable development at industrial scale. For this reason, starting from these preliminary environmental results, LCA analysis could be an important approach in the next step of development of nitriding treatment by means of HiPIMS technique in ICMATE laboratories.

Maximising value and positive impact in campus-based circular economies of coffee

Dr. Ilija Rašović, United Kingdom

Oral Presentation (20')

Abstract

Our project, Circular Action for People and Planet: Using Coffee and Creativity in Innovative Networks and Operations (CAPPUCCINO), explores the creation of circular economy models of coffee based on university campuses by upcycling spent coffee grounds (SCGs) from on-campus coffee shops as a multi-product feedstock. SCGs are an abundant waste material on university campuses and current practices around their disposal leave a lot to be desired: key issues we have identified include human behaviour (e.g. café staff and community attitudes to disposal units, leading to significant contamination), patchy collection schedules, non-local non-sustainable transportation, and conversion into a carbon-emitting fuel pellet final product.

Herein, we present our vision and current work towards tackling this problem, in collaboration with partners in the United States of America and Brazil, in order to sustainably extract maximum material and chemical value from SCGs whilst simultaneously using the initiative for enhanced community engagement.

The model—which, crucially, can be adapted and optimised to different campuses—is segmented into three parts: Collection, Processing, and Product Creation. In Collection, we present strategies for mitigating the possibility of SCG contamination and discuss the opportunity for student engagement with the project. In Processing, we present a multi-step extraction of chemicals and materials. In Product Creation, we discuss the multitude of final products that can then be used either by research groups based within the university or by consumers. This final part of the model also offers fertile ground for the development of educational initiatives within the university and public engagement and outreach initiatives with local communities, as well as enterprise opportunities for the creation of sustainable ventures and a bottom-up approach to decentralised circular economies.

CAPPUCCINO presents a new, decentralised approach of integrating research, innovation, education and engagement on university campuses. In so doing, we hope to instigate a positive shift regarding the role of universities in the creation of sustainable value, broadly writ, highlighting the critical role of materials circularity in this endeavour.

SUSTAINABLE USE OF ELECTRIC ARC AND LADLE FURNACE SLAGS AS CONVENTIONAL FILLER REPLACEMENT FOR NITRILE BUTADIENE RUBBER

Ph.D. Anna Gobetti, Italy

Oral Presentation (20')

Abstract

The increasing demand for sustainable materials and the urgent need to reduce industrial waste have driven the exploration of innovative reuse applications for steel slag. This study investigates the potential of electric arc furnace (EAF) slag and ladle furnace (LF) slag as alternative fillers in nitrile-butadiene rubber (NBR) composites, replacing conventional fillers such as calcium carbonate.

The primary objective of this study is to evaluate the mechanical properties, processability, and environmental impact of NBR composites incorporating EAF and LF slag in comparison to those containing conventional calcium carbonate at equal filler volume fraction of 10%. This research aims to promote industrial symbiosis by converting steel industry waste into valuable raw materials for the rubber sector.

The study includes a detailed characterization of EAF and LF slag, focusing on their chemical composition, particle size distribution, and morphology. NBR composites were prepared with varying volume fractions of slag and calcium carbonate. Mechanical properties, including hardness, tensile strength, compression strength, and permanent set, were assessed. Additionally, a life cycle assessment (LCA) was conducted to compare the environmental impacts of using EAF slag versus calcium carbonate.

The results demonstrate that both EAF and LF slag exhibit morphological and chemical characteristics comparable to calcium carbonate. Rheometric analysis indicates that slag-filled NBR compounds have similar processability to those filled with calcium carbonate. Mechanical testing reveals that slag-filled NBR composites achieve comparable hardness, compression strength, and elastic modulus to calcium carbonate-filled composites. Notably, slag-filled NBR shows a higher tensile strain at break. The LCA highlights significant environmental benefits, showing reductions of at least 89% in all assessed impact categories when using slag as a filler.

This study provides compelling evidence for the feasibility and environmental advantages of using EAF and LF slag as sustainable fillers in NBR composites. The findings support industrial symbiosis, reducing waste disposal costs and promoting a circular economy. This research sets a foundation for further exploration and implementation of steel slag in rubber applications, contributing to sustainable materials management and environmental impact reduction.

Paper 573 1 **Adjustable degradation rates for additively manufactured implants made of Zn and Mg**

Dr. Ute Bergmann, Germany

Highlight (Oral Presentation 20')

Abstract

The potential of degradable implants lies in the health promise of avoiding revision surgeries. Initially, implants are intended to replace the supporting function of lost bone substance and initially should dissolve very slowly, after which they can dissolve quickly and as complete as possible. In recent years, laser powder bed fusion has become increasingly established as an additive manufacturing process for the production of targeted structures and porosities and porous metallic scaffold structures as well as smooth and continuous surfaces, which can promote cell proliferation [Hein21]. Further and more detailed structural features were created using electrochemical processes. This method shows their potential particularly in the case of complicatedly shaped surfaces, similarly. Moreover, these structures have aroused great research interest for biomaterial applications, as they allow continuous grading of their geometry [Rein20]. And so, biomorphic geometries with excellent mechanical properties and suitable load distributions are expected. Although, they should also have a controllable dissolution rate, which could be adapted to the mechanical requirements of the implant site. In this presentation, the degradation behaviour of differently produced magnesium and zinc samples is presented. The samples have been produced either by laser powder bed fusion or rolling technology and in some cases have been provided with an artificial oxide layer. Using spectroscopic and gravimetric methods, the degradation rates are determined and the relationship between morphology, microstructure and degradation behaviour is presented. Electrochemical impedance spectroscopy is used to discuss the degradation activities in front of the interface over time. Dependencies and correlations between degradation rate and morphology, microstructure and alloy composition controlled by additive manufacturing and electrochemical methods are mapped and discussed.

Overall, these initial degradation studies of bulk and trace elements should help to enable targeted control of the degradation behaviour of additively manufactured, porous structures made of pure zinc or magnesium in the future. The work should lead to a deeper understanding of the corrosive degradation behaviour of these materials. Initial experiments are also presented below, in which important mechanical properties were correlated with different functionally graded structures.

Corrosion behavior of Zn-1Mg and Zn-1Mg-1Ag (wt. %) alloys in simulated physiological environments

Mrs. Marlene Aydee Gonzalez Garcia, Poland

Oral Presentation (20')

Abstract

Zinc (Zn) is a biodegradable metal with controlled degradation, unlike iron (Fe) which degrades slowly with long-term retention of its corrosion products and unlike magnesium (Mg) which corrodes rapidly, producing harmful hydrogen gas. Zn is known as an essential nutrient for physiological functions in the human body with intermediate potential vs SHE (-0.76 V) comparing to Fe (-0.44 V) and Mg (-2.73 V). These factors make Zn a promising biocompatible material for biomedical applications that can extend to diverse domains such as in cardiovascular stents, orthopedic scaffolds and wound closure devices [1], [2].

The main goal of this work was to analyze the corrosive behavior of cast Zn alloys: Zn-1Mg and Zn-1Mg-1Ag (wt. %) and describe the role of silver (Ag) addition on the degradation performance. To approach this, immersion tests were performed using various solutions simulating physiological conditions such as: hanks' balanced salt solution (HBSS), Dulbecco's modified eagle medium (DMEM) and Dulbecco's modified eagle medium with the addition of 10% fetal bovine serum (FBS) during 7 days under cell culture conditions according to ASTM G1-03 [3]. During immersion, pH, osmolality and corrosion rate were analyzed. Surface degradation was examined using scanning electron microscopy (SEM) and optical profilometry. As per results of this work, both, Zn-1Mg and Zn-1Mg-1Ag provided stable pH and osmolality values, also its corrosion rate and surface damage match the biomedical applications requirements. The addition of Ag produced an earlier but uniform surface damage maintaining acceptable pH, osmolality and corrosion rate values.

- Paper 308** **3** **Resorbable Mg-0.4Zn strands for bone fixation: pilot in vivo tests on minipigs**
Dr. Karel Tesař, Czech Republic
Oral Presentation (20')
- Abstract** Magnesium alloys are a promising material for resorbable bone support implants, particularly in cases where biodegradable fixation can eliminate the need for secondary surgeries. Among Mg-based implants, thin wires and strands show potential for applications such as sternal fixation and reconstructive hand surgeries. However, several challenges remain, including excessive hydrogen generation, concerns about the long-term safety of certain alloying elements, localized corrosion, and defects such as MgO particles in thin wires, which can lead to premature and unpredictable failures. This presentation focuses on polymer-coated extruded Mg-0.4Zn wires with a diameter of 300 µm and the strands produced from them, their surface modifications, and key findings from a pilot in vivo study using a minipig model. The study evaluates the in vitro degradation and mechanical property changes of these strands, the in vivo tissue responses to the implants, and hydrogen production near the sternum, partially fixed with Mg-0.4Zn strands.
- Paper 478** **4** **Enhancing Magnesium Alloy Biocorrosion Resistance with Additivated Geopolymer Coatings**
Dr. Alfredo Rondinella, Italy
Oral Presentation (20')
- Abstract** Magnesium-based bioresorbable materials have emerged as promising candidates for bone regeneration applications due to their bone-like elastic modulus and osseointegrative capabilities. However, their bioresorption rate is closely linked to their corrosion behavior, which, if excessive, can negatively impact surrounding biological tissues. The presence of chlorides—prevalent in bodily fluids—can induce severe corrosion, leading to a rapid loss of mechanical integrity before the bone tissue has fully regenerated. Additionally, the fast dissolution of magnesium and its alloys can produce byproducts, such as hydroxides and hydrogen bubbles, which may accumulate in tissues. This study explores the development of coatings composed of a geopolymer matrix with biocompatible fillers such as glucomannan, sodium alginate, or hydroxyapatite nanoparticles to regulate the corrosion rate of magnesium in simulated biological environments. The microporous nature of these coatings allows controlled electrolyte penetration, preventing a complete barrier effect while maintaining corrosion rates within acceptable limits.
- The coatings were applied using a dip-coating technique and characterized through SEM/EDXS analysis to examine their morphology and chemical composition. To evaluate their performance, coated samples were immersed in saline, phosphate-buffered saline (PBS), and Hanks' Balanced Salt Solution (HBSS), closely resembling biological conditions. Corrosion behavior was assessed by electrochemical analyses—including open-circuit potential measurements, potentiodynamic polarization tests, and electrochemical impedance spectroscopy (EIS)—to compare the response of coated and uncoated samples in the tested solutions.

Additive manufacturing and post-processing of a beta-type Ti-Nb alloy with tailored mechanical biofunctionality for load-bearing bone implants

Dr. Annett Gebert, Germany

Highlight (Oral Presentation 20')

Abstract

Current requirements for load-bearing bone implants are patient-specific designs and new materials for improved mechanical functionality and biological compatibility. Additive manufacturing technologies such as Laser Powder Bed Fusion (LPBF) facilitate the near-net shape production of metallic bone implants. As a non-equilibrium technique, LPBF can also generate defined microstructural states, thereby yielding unique mechanical performances. This is specifically promising for metastable alloys such as beta-type Ti alloys which combine the benefits of low elastic moduli and composition of biocompatible constituents. On the example of the metastable Ti-42Nb alloy we demonstrate how LPBF processing and post heat treatments can lead to required low stiffness in combination with high hardness and strengths. For beta-phase Ti-42Nb, the control of LPBF parameters can lead to a strong anisotropy in the stiffness of bulk specimens. By using a non-standard top hat laser source, a unique microstructure with strong $\langle 001 \rangle$ texture parallel to the building direction (BD) was generated. Tensile tests along selected loading directions revealed a strong mechanical anisotropy with the lowest Young's modulus of 44 GPa parallel to BD. Suitable post heat treatment strategies for LPBF-produced Ti-42Nb cause substantial materials strengthening effects. Heat treatments within the $\alpha + \beta$ phase range at 723 K for different durations led to increasing fractions of the metastable orthorhombic α'' phase, acting as an intermediate to the stable α phase. The β grain boundaries are primary sites for early α'' precipitation. Micromechanical analysis by means of nanoindentation (at a constant strain rate) was used for assessing the impact of time-dependent microstructural changes on the evolution of reduced modulus (E_{red}) and hardness (H) values. Tensile tests demonstrated significant strength enhancements through treatments up to 108 ks compared to the as-built state, i.e. a yield strength of up to 1060 MPa and ultimate tensile strength of up to 1125 MPa, thereby reaching the performance level of clinical benchmark materials such as Ti-6Al-4V. Further, LPBF is a powerful technology for the fabrication of metallic scaffolds with low structural stiffness. On the example of Ti-42Nb scaffolds, designed as triply periodic minimal surfaces (TPMS), the successful transfer of those post heat treatment strategies for microstructure modification leading to scaffold strengthening will be shown. Funding is acknowledged by the German Research Foundation DFG, project no 419952351 and by the European Commission, H2020-MSCA grant no. 861046 (BIOREMIA-ITN).

Corrosion and tribocorrosion behaviour of β -type Ti-Nb alloy produced by laser powder bed fusion & isothermal aging for implant applications

Mr. Adnan Akman, Germany

Oral Presentation (20')

Abstract

Laser powder bed fusion (LPBF) has become a key technology in medical engineering for creating patient-specific titanium-based implants with tailored microstructures and optimized mechanical properties. LPBF-produced β -type Ti-Nb alloys outperform their conventionally manufactured counterparts due to their unique microstructures and localized control over mechanical properties, enabling customization for specific bone load requirements. However, load-bearing implants remain susceptible to tribocorrosion caused by motion in body fluids.

This study addresses the corrosion and tribocorrosion behavior of LPBF-produced and subsequently age-hardened β -type Ti-42Nb alloys, comparing them to conventional Ti-6Al-4V ELI. Tribocorrosion performance was evaluated under open-circuit potential (OCP) and anodic polarization (0.6 V vs. Ag|AgCl) in phosphate-buffered saline (PBS) using a pin-on-disk tribometer. Results revealed no significant differences in the corrosion behavior of LPBF Ti-42Nb alloy states in PBS, suggesting that strong passivation characteristics outweigh microstructural variations. Age-hardened alloys produced by LPBF exhibited lower wear resistance compared to the reference alloy under both OCP and anodic polarization conditions (0.6 V vs. Ag|AgCl). Despite their high hardness, the age-hardened alloys experienced greater total volume loss and wear depth. This difference is attributed to the presence of hard and brittle precipitates. The rapid detachment of ω precipitates in Ti-42Nb (LPBF-300 °C, 30 h) and α'' precipitates in Ti-42Nb (LPBF-450 °C, 30 h) results in a non-uniform hardness distribution, ultimately reducing tribocorrosion performance.

Dealloying as a facile process to improve cytocompatibility and antibacterial activity of biocompatible Ti-based amorphous alloys

Prof. Paola Rizzi, Italy

Oral Presentation (20')

Abstract

Implant infections and related biofilm formation are a major concern whenever implantable medical devices are considered. Since there is currently no standard treatment for implant-associated infections and antibiotic treatments are ineffective for biofilms, the best approach is to focus on the inhibition of both bacterial adhesion and biofilm formation by acting on the implant material itself. If metals are considered, Ti-based amorphous alloys are gaining importance as biocompatible materials due to the possibility i) to adapt the composition with the exclusive use of biocompatible elements and ii) to reduce the mismatch in Young's modulus between the bone and the implant material. Moreover, their biocompatibility and antibacterial activity can be improved by exploiting the dealloying process that is related to the dissolution of less noble elements from an amorphous phase enabling the surface diffusion of the noble adatoms that reorganise on the surface by forming ligaments and pores. Dealloying is an effective and simple process adapt to change both composition and morphology of the surface of the Ti-based amorphous alloys, so hindering the bacterial adhesion and the consequent biofilm formation.

In this work, two Ti-based amorphous alloys (Ti₄₇Cu₃₈Fe_{2.5}Zr_{7.5}Sn₂Si₁Ag₂; Ti₄₀Cu₄₀Zr₁₁Fe₃Sn₃Ag₃) were considered and different dealloying strategies were adopted to design the surface composition and morphology: both electrochemical and chemical dealloying was performed and different electrolyte (basic and acid) were considered. In general, mixed Ti/Zr oxides were formed with thickness ranging from tens up to hundreds of nanometres with variable morphologies. The oxide layers were studied by means of different techniques: field emission scanning electron microscopy (FESEM), X-ray diffraction (XRD), atomic force microscopy (AFM), X-ray photoelectron spectroscopy (XPS). Moreover, wettability, cytocompatibility and bacterial adhesion studies demonstrated the effectiveness of the dealloying process with the improve of the cytocompatibility and antibacterial activity.

A key point in the design of Ti based alloys are the modified surfaces to which an optimised biocompatibility is associated. Therefore, the dealloying mechanism was studied in detail in order to enable a connection between morphology and composition of the dealloyed layer and dealloying parameters used to antibacterial activity. The early stage of the dealloying process was evaluated by the calculated vacancy formation energy that described the tendency of one element to be easier released from the surface against another. Moreover, ab initio calculations evaluate characteristic XPS energy shifts between metals and oxides enlighten the role of surfaces and oxidation while the valence electron density reveals bonding features.

Paper 192 **8** **Developing antibacterial surfaces on Titanium based biocompatible alloys using low voltage Plasma Electrolytic Oxidation**
Mrs. Maria Evanthia Nousia, Italy
Oral Presentation (20')

Abstract

Modifying titanium implants' surfaces to introduce nano- and micro-scale patterning is a promising way to hinder bacterial adhesion and, thus minimize the biofilm formation and implant-related infections. β -Titanium alloys are well known for their inherent biocompatibility but there is still necessity to enhance their antibacterial properties, as most of the research that is being carried out is focused on cp-Ti or Ti6Al4V [1]. In this work we focus on two β -Ti-based alloys, Ti-24Nb-4Zr-8Sn (%wt) and Ti-45Nb (%wt), which are both free from any cytotoxic elements. The alloys were prepared by arc-melting under argon atmosphere followed by a heat treatment at 1000°C for 24 hours to ensure homogenization of the alloy composition and phases. Micro-porous and nano-textured surfaces were created through low voltage Plasma Electrolytic Oxidation (PEO), with a maximum voltage of 308V, a value relatively low when compared with the current literature [2]. The electrolyte used for the PEO treatment contained calcium acetate hydrate ($\text{Ca}(\text{CH}_3\text{COO})_2 \times \text{H}_2\text{O}$), sodium dihydrogen phosphate anhydrate (NaH_2PO_4) and potassium hydroxide (KOH), aiming to form hydroxyapatite (Hap) on the coatings. The antibacterial properties of the Hap-containing coatings were improved by incorporating Ga, Zn and Ag ions within the coatings and by soaking the samples in Iodine baths as a second treatment. The surfaces were characterized by Scanning Electron Microscopy (SEM), revealing in all cases a homogeneous oxide layer that is well adhering to the substrates, and Grazing Incidence X-Ray Diffraction (GIXRD) confirmed the presence of anatase, rutile and Hap on the surfaces. Their corrosion behaviours were assessed by performing Potentiodynamic Polarization tests (PDP) and Electrochemical Impedance Spectroscopy tests (EIS) using Simulated Body Fluid (SBF) as the electrolyte, at 37°C. In addition, Hemolysis Assays (HA) and Radical Oxygen Species (ROS) measurements were carried out to evaluate the hemo- and biocompatibility of the surfaces. These results are promising for creating orthopaedic implant surfaces that simultaneously promote cell adhesion and prevent bacteria adhesion on the surface.

Paper 1193 1 **Exploring the deformation mechanisms and degradation in Mg10Gd using acoustic emission and in situ SRμCT**

Mrs. Birte Hindenlang, Germany

Highlight (Oral Presentation 20')

Abstract

The research of biodegradable bone implant materials based on Mg has been increasing in recent years. In comparison to traditional implant materials, Mg has the advantage of being biodegradable, eliminating the need of an implant removal. Additionally, it has comparable mechanical properties to bone, providing support to the healing bone. Nevertheless, the degradation is complex and not yet fully understood since many factors influence the process. Next to commonly investigated factors like the chemical environment, also mechanical loads play a role in the degradation process. Since the mechanical deformation of a material is influenced by its microstructure, the internally occurring deformation mechanisms in as-cast and T4 heat-treated Mg10Gd were investigated using standard tensile tests with simultaneously recording the acoustic emission signal. The results show an increase in twin formation for the as-cast material which has only a negligible effect on the overall deformation. However, varying the strain rate showed an opposite effect for heat-treated and as-cast materials, indicating a major influence of the microstructure on the deformation process. Using these information, additional experiments were conducted to include the degradation process in the analysis. Here, in situ synchrotron radiation based micro computed tomography (SRμCT) was used to combine imaging techniques and acoustic emission to quantify the degradation process while simultaneously following the damage evolution in the material. In the experiment, heat-treated and extruded Mg10Gd was deformed in a tensile test while being immersed in simulated body fluid (SBF) having similar ionic concentrations to human blood to model near-physiological conditions. By applying in situ SRμCT, the degradation and deformation can be investigated during the deformation until the specimen failure. This investigation showed that under degradation conditions the mechanical failure is drastically faster. Additionally, the deformation showed significant differences between experiments in air and SBF, indicating differences in the deformation mechanisms. One reason for this is the occurrence of stress-corrosion cracking at low strain rates. The results clearly indicate that the interplay between degradation and deformation needs to be investigated further to enhance the understanding of degradation processes in future biodegradable bone implant materials.

Paper 1901 3 **Optimizing the mechanical properties of Ti-6Al-4V alloy produced by selective laser melting for biomedical use**
Mrs. Marketa Strakova, Czech Republic
Oral Presentation (20')

Abstract

This study investigates the potential of a Selective Laser Melting (SLM) Ti-6Al-4V alloy, specifically in relation to orthopedic implants. SLM is an additive manufacturing process that offers several benefits for creating customized medical devices. These structures help reduce the alloy's elastic modules, reduction of stress shielding that can occur in conventional implant materials. To improve the mechanical properties and microstructure of the Ti-6Al-4V alloy produced by SLM, the effects of a hot isostatic pressing (HIP) treatment at temperatures ranging from 850 °C to 950 °C are examined. HIP is known to reduce internal porosity and promote phase transformation in titanium alloys, affecting overall performance. Key findings from the research include:

1. Phase transformation: HIP treatment results in transformation of α' martensite to a more stable α (Ti) and β (Ti) two-phase microstructure.
2. Reduction in internal porosity: Using HIP significantly reduces internal porosities in SLM-produced samples, improving their structural integrity.
3. Mechanical properties: While HIP increases ductility, it also reduces tensile strength. This compromise is typical of many materials that undergo post-treatment, in which improved formability is achieved at a cost of strength.
4. Potential for biomedical applications: Overall, the combination of SLM and HIP

post-treatment results in Ti-6Al-4V alloys that are more suitable for use in biomedical applications, especially orthopedic implants, due to their improved mechanical properties and reduced internal defects.

This research highlights the promising potential of SLM and HIP post-processed Ti-6Al-4V alloys for use in medical devices, offering a tailor-made, bio-inert solution with optimized mechanical properties for orthopedic applications.

Paper 2063 4 Mg-Fe nanocomposites overcome the strength-corrosion dilemma of Mg-based materials

Dr. Oliver Renk, Austria

Highlight (Oral Presentation 20')

Abstract

The low strength and poor corrosion resistance of magnesium (Mg) has prevented its use for load-bearing bone fracture fixations. Core of this limitation is Mg's low solubility for most elements combined with its low electrochemical potential. This favors precipitation of secondary phases (i.e., micro-galvanic elements) but also excludes Mg-based composites (highly active galvanic couples), both of which would allow to improve strength significantly. Alternative concepts for high-strength yet slowly degrading Mg-based materials thus need to be developed. Here, we present promising results, indicating that the detrimental effects of galvanic corrosion might be overcome by manipulating the composite architecture at the nanoscale. Using nanostructured Mg-Fe composites – so far thought an incompatible materials combination – we find that a reduction of the phase spacing significantly slows down Mg-corrosion rates, achieving even the ultra-low corrosion rates of ultra-high purity Mg. However, in contrast to UHP Mg, the nanoscale composite spacing allows for strength levels from 500 MPa up to 1 GPa. We discuss possible mechanisms enabling this advanced material performance and outline indications for future applications based on the enormous extension of the property space for Mg-based materials.

Paper 509 **1** **Surface functionalization of titanium foams for controlled tetracycline release using a hydrogel-based delivery system**

Mrs. Hanaa Mehdi Sefiani, Spain

Highlight (Oral Presentation 20')

Abstract

Titanium is widely used for bone tissue replacement due to its ability to mimic the properties of natural bone, including biocompatibility, corrosion resistance, and a favorable elastic modulus. Despite these advantages, its bioinert nature can hinder rapid osseointegration and increase the risk of implant failure. Moreover, titanium implants are often recognised as foreign materials and for this reason after surgical intervention, pharmacological treatment is required to mitigate inflammation and prevent local infections that could lead to implant rejection. Unfortunately, conventional drug administration methods are often efficient, leading to undesired side effects, such as toxicity or suboptimal delivery.

To address these challenges, this study presents a novel approach using type A gelatin-based hydrogel as a long-acting drug delivery system which is infiltrated into the porous structure of the surface-modified titanium foams to provide a sustained and local drug release, improving the success of the bone replacement and patient compliance.

Specifically, titanium foams with a nominal porosity of 60 vol.% were developed using the space-holder technique and consequently modified through conventional thermal oxidation in static air and acid etching using sulfuric acid to modulate the drug release kinetics. The results shown that the acid-etched surface reduced the release rate of the drug (tetracycline) due to the increased surface roughness, whereas the hydrophilic rutile TiO₂ layer formed by thermal oxidation accelerated the tetracycline release.

This research highlights the potential of combining hydrogel systems with surface-modified titanium foams for controlled drug release, offering an innovative solution for localized treatment in bone tissue replacement surgeries.

Future studies are also being focused on optimizing the control of drug release by modifying hydrogel to enhance its thermal stability and mechanical properties as well as further surface functionalization of titanium foams using techniques such as pore surface anodization to tailor the drug release kinetic according to the therapeutic needs.

PM Ti- 5 vol.% TiB₂ COMPOSITES PREPARED VIA GREEN AND COST EFFECTIVE TECHNOLOGIES FOR DENTAL IMPLANTS

Dr. Jaroslav Kováčik, Slovakia

Oral Presentation (20')

Abstract

Titanium is also one of the most biocompatible metals with medical applications in prostheses, orthopaedic and dental implants, and surgical instruments. Ti belongs onto the EU list of critical raw materials and its products are significantly more expensive than steels. In aerospace industry typically 82% of the titanium became scrap metal before final goods are produced. To reduce titanium production and manufacturing costs, powder metallurgy as a near-net-shape manufacturing technology is developing for more than four decades.

After Russia's invasion of Ukraine, REPowerEU Plan is implemented to phase out Russian fossil fuel imports. Titanium production requires very high energy inputs/has large CO₂ footprint in comparison with the most used materials. Therefore, in this study, Ti - 5 vol.% TiB₂ composites were prepared from the mixture of Ti and TiB₂ powders using spark plasma sintering (SPS) technology at IMN, Gliwice, Poland and pressure less solar sintering at PSA, Almeria, Spain.

The SEM and XRD analyses indicate that TiB₂ is unstable at 950 – 1300°C and transforms onto TiB whiskers: In the case of microstructures after SPS, the TiB whiskers are very difficult to observe - Kroll's etching was necessary to observe them. They are significantly thinner and smaller in comparison to solar sintered TiB whiskers. Porosity of prepared composite is in the range of 6 – 16 % for solar sintered samples. SPS samples possesses porosity below 0.1 %. Vickers hardness of prepared composite is in the range of 200-327 MHV0.5 for solar sintered samples and 358 ± 28 MHV0.5 for SPS samples. Pin-on disk measurements were performed on SPS sample against alumina. Measured coefficient of friction was 0.5378 ± 0.0246 against alumina and observed wear of 0.0436 g.

Research works on laser surface treatment and evaluation of suitability of prepared composites for dental implants are currently undergoing.

This research was mainly financed by VEGA project: Laser surface modification of Ti –TiB₂ biocomposites prepared by powder metallurgy process in order to increase their osseointegration (2/0054/23). Partial financial support by of the SFERA-III project (Grant Agreement No 823802) is also acknowledged.

Laser powder bed fusion of nitinol for medical applications: Superelasticity under tensile stress

Dr. Simon Bonk, Germany

Oral Presentation (20')

Abstract

By developing laser powder bed fusion (LPBF) of nitinol, new design freedoms and enhanced functionality of future implants can be unlocked. However, challenges associated with LPBF, such as residual stresses, porosity, and microstructural variations, must be addressed to ensure the production of high-quality and reliable medical devices. Further, vaporization of nickel [1] and oxidation of titanium [2] are two important phenomena during the LPBF-process, which influence locally and globally the Ni-Ti ratio and thus significantly impact the thermomechanical properties.

This study investigates the influence of key SLM process parameters (e.g. laser power, scan speed, hatch spacing) on the microstructure and mechanical properties of LPBF-processed nitinol after specific heat treatments. A comprehensive approach along the process chain is employed, encompassing powder characterization, process monitoring and analysis at multiple steps along the post-processing chain. The latter comprises carrier gas hot extraction for oxygen content, micrographs for qualitative and quantitative evaluation of porosity, differential scanning calorimetry to determine phase transition temperatures and tensile tests at body temperature to characterize the superelasticity.

Key findings include the identification of a process window for achieving nearly full dense, crack-free parts. The phase transition temperatures can be adjusted within a temperature interval of 20 °C in the solution annealed state by means of LPBF parameter variation. Subsequent heat treatments allow to set the austenite finish temperature to the desired temperatures up to 40 °C. The heat-treated material shows superelasticity under tensile load, recovering deformations up to 6 % with a residual elongation below 0.2 % for the first cycle. Plateau stresses differ depending on LPBF process parameters and post processing but can be tuned towards 400 MPa to 500 MPa, typical values for conventionally produced semi-finished NiTi products.

These findings provide valuable insights into the optimization of the LPBF process to produce high-quality, reliable nitinol implants with fine-tuned performance. The results of this study will guide the development of additively manufactured nitinol components with superelastic properties and contribute to robust process control strategies. This will enable the utilization of the unique functional properties of nitinol in new medical applications.

Combinatorial Development of Mo-Ag Thin Films for Antibacterial Coatings: High-Throughput Synthesis, Characterization, and Performance Evaluation

Ph.D. Maria Watroba, Switzerland

Oral Presentation (20')

Abstract

High-throughput methodologies, particularly thin film combinatorial approaches, are transforming materials discovery by enabling rapid and systematic exploration of vast compositional spaces. Among these, physical vapor deposition (PVD) magnetron co-sputtering has emerged as a powerful tool, allowing precise control over compositional gradients and microstructures. This study focuses on the development of molybdenum-silver (Mo-Ag) alloys as antibacterial coatings for biomedical applications. Silver (Ag) is widely recognized for its antibacterial properties, but its uncontrolled ion release can lead to cytotoxic effects. Molybdenum (Mo), in contrast, provides high mechanical stability and controlled degradation. By combining these elements, we aim to develop coatings that balance antibacterial efficacy, biocompatibility, and structural stability, with a regulated ion release profile to minimize toxicity.

Mo-Ag thin films were synthesized using PVD magnetron co-sputtering, followed by heat treatment to relieve residual stresses and modify phase composition. Chemical and phase analysis confirmed the incorporation of Ag within the Mo matrix, while microstructural characterization using scanning electron microscopy (SEM) and transmission electron microscopy (TEM) provided insights into grain structure and morphology. Nanoindentation tests assessed the mechanical properties, particularly hardness and elastic modulus.

To evaluate degradation behavior, corrosion testing was conducted in Hank's solution, simulating physiological conditions. The results showed that Mo-Ag coatings exhibit a controlled corrosion rate, which was further analyzed through ion release measurements to establish a correlation between degradation kinetics and elemental dissolution. The cytocompatibility of these coatings was evaluated using both direct and indirect in vitro assays, confirming an acceptable level of biocompatibility. Additionally, antibacterial activity was assessed through in vitro tests, demonstrating bacterial suppression.

This study demonstrates that Mo-Ag is a promising system for antibacterial implant coatings. The developed high-throughput synthesis and characterization workflow proved to be an efficient approach for discovering new materials for biomedical applications. Future integration with CALPHAD modeling and machine learning-based predictions would further enhance the efficiency of materials discovery by guiding experimental efforts toward optimized compositions.

Paper 1117 6 The influence of the surface pre-treatments on the chitosan/bioglass coatings deposited on the titanium substrate

Mrs. Agnieszka Kowalczyk, Poland

Oral Presentation (20')

Abstract

In biomedicine, the surface of implants plays an important role in osteointegration processes as it is a place of first contact with the human body. It can influence the acceptance of the implant and the occurrence of inflammations. Due to that, studies on the surface of biomaterials have great importance nowadays. One of the methods to improve biocompatibility is the deposition of different coatings on the substrate material. Among them are the electrophoretically deposited chitosan/bioactive glass coatings. Due to their beneficial properties as: high corrosion resistance, bioactivity, and biocompatibility, they show great potential in biomedical applications. The limitation of these coatings is their relatively low adhesion to the substrate. It can be improved through the change of parameters of the deposition process or on the way of surface pre-treatments. However, the additional modifications can influence the topography of the coating, which can also impact the biological response. In this study, we investigate the morphology and topography of the chitosan/bioglass coating electrophoretically deposited on the pre-treated titanium substrate, as well as the influence of the conducted processes on the adhesion of the coatings.

Paper 1337 1 Materials Design and High-throughput Screening of Multicomponent High-temperature Coatings Accelerated by Artificial Intelligence

Dr. Kai Xu, China

Oral Presentation (20')

Abstract

The MCrAlY systems (where M represents Ni, Co, Fe, or their mixtures), along with nitride and diamond-like carbon (DLC) coatings, are widely employed in high-temperature, heavy-duty surface protection applications due to their exceptional resistance to thermal corrosion, high strength and hardness, superior wear and friction resistance, and versatile selectivity. These coatings effectively mitigate challenges such as high-temperature oxidation and impact failures in harsh environments, including extreme temperatures and high-speed conditions. Guided by the concept of data-driven intelligent material design, this study employs machine learning, CALPHAD phase diagram calculations, and first-principles simulations across different computational scales to predict the structure and performance of coatings. The study provides insight into the effects of various alloying elements on the oxidation resistance, phase structure, and friction and wear behavior of the coatings.

For the MCrAlY multicomponent coating system, high-throughput experimental preparation and performance testing were carried out on the selected MCrAlY compositions using physical vapor deposition (PVD) techniques. The results reveal that temperature, exposure time, and alloying elements (such as W, Ti, Nb, Co) are strongly correlated with the high-temperature oxidation rate. The addition of Si enhances the coating's resistance to marine environments, while its synergistic interaction with Ta improves the mechanical properties and optimizes oxidation and corrosion resistance. Based on these findings, a novel NiCrAlYSiTa multicomponent alloy coating was designed, demonstrating exceptional oxidation resistance and mechanical properties. Furthermore, a dual-migration machine learning strategy was employed to extract elemental and phase transition features related to the evolution of metastable nitride phase structures. This approach achieved an impressive prediction accuracy of 0.95 for the phase transition interfaces of typical ternary nitride metastable phases. Additionally, machine learning was integrated with large-scale molecular dynamics simulations (involving thousands of atoms on the nanosecond scale) to maintain the accuracy of density functional theory (DFT) calculations. The resulting deep potential model exhibited an error margin of approximately 10 meV, which was then used to simulate the surface structure evolution of DLC coatings under friction. A quantum effect correction method was also applied to calculate thermodynamic quantities, and when combined with the deep potential model, it provided a more generalized friction model capable of accurately predicting friction force changes over a range of temperatures and speeds. In conclusion, this study demonstrates that data-driven material design and screening approaches can significantly accelerate material development, reducing iteration cycles

Multiscale mean-field framework for process-structure-property prediction in large-scale component manufacturing: A case study of turbine shaft forging

Dr. Dirk Helm, Germany

Highlight (Oral Presentation 20')

Abstract

The manufacturing of large-scale components for energy applications presents significant challenges in terms of material efficiency, energy consumption, and sustainable use of critical raw materials. In response to these challenges, we present a comprehensive mean-field material model for predicting microstructure evolution during the hot forging of large turbine shafts, developed and utilized within the framework of the Horizon Europe project AID4GREENEST.
