Acknowledgements

The seventh edition of the Global Environment Outlook (GEO-7) assessment report is a product of the generous dedication and extraordinary investment of numerous individuals, whose knowledge, expertise and insight helped shape this important body of work. The United Nations Environment Programme acknowledges the contributions made by many governments, individuals, and institutions to the preparation and publication of this report. A more complete list of names of individuals and institutions involved in the assessment process is included following the annexes of this publication. Special thanks are extended to:

Assessment Co-chairs

Edgar E. Gutiérrez-Espeleta, Nyovani Madise, Ying Wang, Robert Watson

Intergovernmental and Multi-stakeholder Advisory Group (IMAG)

Arthur Eijs (Co-chair), Anna Mampye (Co-chair), Rolenas Baereleo (Vice-chair), Miroslav Havránek (Vice-chair), Ana Julieta Calvo - Obando (Rapporteur), Mohamed Abdelraouf, Zahra Abu Taha, Thuraya Said Al Sariri, Silvio Albuquerque e Silva, Djatougbe Aziaka, Leila Bendifallah, Thomas Chali, Merylene Chitharai, Ingrid Coetzee, Lisa Eriksson (Alternate), Toghrul Feyziyev, Marek Haliniak, Meri Harutyunyan, Neyra Herrera, Keri Holland (Alternate), Yi Huang, Claudia Kabel, Christina Komorski, Maha Maayta, Takashi Otsuka, Toral Patel - Weynand, Dušica Pešević, Salla Rantala, Kenset Amaury Rosales Riveiro, Modibo Sacko, Jerome Lugumira Sebadduka, Ruth Viola Spencer, Gillian Stanislaus, Jan - Gustav Strandenaes, Prem Singh Tharu, Alexandra Gurgel Valente da Costa (Alternate), Carlos Cordero Vega (Alternate), Fabian Wagner, Dominic Kailash Nath Waughray

Multidisciplinary Expert Scientific Advisory Group (MESAG)

Nicholas King (Co - chair), Maria del Mar Viana Rodriguez (Co-chair), Ervin Balázs (Vice-chair), Rosemarie Casimiro (Vice-chair), Gian Carlo Delgado-Ramos (Rapporteur), Ousséni Arouna, Dolors Armenteras Pascual, Alberto Santos Capra, Lorenzo Ciccarese, Sandra Bibiana Correa, Eric Davidson, Nagwa El Karawy, Tambe Honourine Enow, James D. Ford, Catherine Ganzleben, Razieh Ghayoumi, Joyeeta Gupta, Tatiana Kuznetsova, Yonglong Lu, Mónica Moraes R., Amal Moufarreh, Janez Potocnik, Nijavalli Ravindranath, Majid Shafie pour Motlagh, Belay Simane, Asha Singh, Inna Stecenko, Shau Hwai Aileen Tan, Alban Thomas

Coordinating Lead Authors (CLAs)

Tamiru A. Abiye, Ana Paula Aguiar, Peter Alexander, Barbara Amon, Apoorva Arya, Ghassem Asrar, Lindsay Beevers, Medani Bhandari, Meena Bohara, Gillian Bowser, David Broadstock, Monday Businge, Donovan Campbell, Kateřina Černý Pixová, Lynette Cheah, Leila Dagher, Vassilis Daioglou, Jonathan Davies, Mark Elder, Parfait M. Eloundou-Enyegue, Pierre Failler, Pedro Fidelman, Shinichiro Fujimori, Erica Brown Gaddis, Keisha Garcia, Sarah Green, Andres Guhl, Gladys Cecilia Hernandez-Pedraza, Susie Ho, Min Hu, Madhav Bahadur Karki, Monica Kerretts-Makau, Mizanur Khan, Andrei Kirilenko, Kyung Ah Koo, Joanna Kulczycka, Debora Ley, Jianguo Liu, Paul Lucas, Clever Mafuta, Sarah-Lan Mathez-Stiefel, Karina Miglioranza, Ruben Mnatsakanian, Rachid Mrabet, Kevin Nnanye Nwaigwe, Alice Odingo, S. Nadia Ouedraogo, Jacob Park, Jan Plesnik, Riya Rahiman, Adina Manuela Relicovschi, Henri Rueff, Aibek Samakov, Tek Sapkota, Heinz Schandl, Patrick Schröder, Jeff Seadon, Binaya Raj Shivakoti, George Florin Staicu, Paul Sutton, Gail Taylor, Catalina Turcu, Bruno Turnheim, Detlef van Vuuren, Sotiris Vardoulakis, Karen Helen Wiltshire, Xiyan Xu, Fang Yu, Pandi Zdruli, Eric Zusman

Lead Authors

Fagr Abdel-Gawad, Adolf Acquaye, Susana Beatriz Adamo, Kofi Akamani, Adenike Akinsemolu, Alaa Al Khourdajie, Aliyu Aliyu, Maryam Alkharusi, Farshad Amiraslani, Steve Arquitt, Quosay Awad Ahmed, Janelle Baker, Aistė Balžekienė, Aliyu Salisu Barau, Ricardo O. Barra, Claudio Belis, Lorenzo Benini, Hester Biemans, Fiffy Hanisdah Binti Saikim, Elliot Boateng, Souhila Bouilouta,

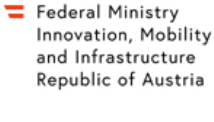
Edward Byers, Shaneel Chandra, Kalpana Chaudhari, Joanne Clarke, Salud Deudero Company, Jan Cools, Hancheng Dai, Loïc De Weerdt, Danielle Mendes Thame Denny, Sybil Derrible, Leila Devia, Jagath Premakumara Dickella Gamaralalage, Jonathan Doelman, Peter Edwards, Sibel Eker, Isa Olalekan Elegbede, Eduardo Erazo Acosta, Jessica Fanzo, Vinicius F. Farjalla, Dulce Flores-Renteria, Michele Fontefrancesco, Panagiotis Fragkos, Bonmwa Fwangkwal, Elisabeth Gilmore, Alex Godoy-Faundez, Mariana Guttieres-Paz, Taylor Hanna, Stephan Harrison, Maryna Henrysson, Rozana Himaz, Beata Houšková, Saleemul Huq, Ekhtekharul Islam, Efitre Jackson, Nandakumar Janardhanan, Kejun Jiang, Modupe O. Jimoh, Mulako Kabisa, Miho Kamei, Joanna Kámiche Zegarra, Govind Kelkar, Peter King, Mahdi Kolahi, Vojtech Kotecky, Lydie-Stella Koutika, Jyotsna Krishnakumar, Pankaj Kumar, Sigrid Kusch-Brandt, Juliana Subtil Lacerda, Annamaria Lammel, Tao Lin, Jinlong Liu, Melisa Ljusa, David Lopez-Carr, Yolanda López-Maldonado, Christian Löwe, , Simone Lucatello, Patricia Maccagno, Nomanesi Madikizela-Madiya, William Armand Mala, Aynur Mammadova, Olena Maslyukivska, , Alma Mendoza-Ponce, Juliana Merçon, Jonathan D. Moyer, Indu K Murthy, Veronica Mwangi, Ravendra Naidu, Didacus Namanya, Valerie Nelson, Thang Nguyen Trung, Jaee Nikam, Karachepone Ninan, Judit Oláh, Simon Høiberg Olsen, Jean Pierre Ometto, Evans Osabuohien, Nkechi Owoo, Leonidas Paroussos, Leisa Perch, Laura Pereira, Ramon Pichs-Madruga, József Popp, Joana Portugal Pereira, Svetlana Radionova, Graciela Raga, Kamal Kumar Rai, Stefan Reis, Chao Ren, Kamaljit K Sangha, Sanchit Saran Agarwal, Pallavi Saxena, Ronaldo Seroa Da Motta, Kalim Shah, Fangxia Shen, Fred Steward, Roopesh Kevin Sungkur, Elias Symeonakis, Natalia Tarasova, Audrone Telesiene, Thomas Thornton, Maria Cristina Tirado-von der Pahlen, Sandra Torrusio, Stella Tsani, Chiara Varazzani, Maria Virginia Vilariño, Samanta Villegas, Ken Webster, Jianhua Xu, Le Yu, Carol Zavaleta-Cortijo, Xianlai Zeng

Contributing Authors

Adedoyin Adeleke, Rob Alkemade, Michel Bakkenes, Sofia Belardinelli, Arthur Beusen, Suruchi Bhadwal, Bhabananda Biswas, Tanya Brodie Rudolph, Tatenda Dalu, Kenel Delusca, Catia Motta Domingues, Alan Feest, Steven Fletcher, Rose Foster, Dimitris Fragiadakis, Dimistris Fragkiadakis, Jessica Fuller, Sabine Fuss, Sandya Gunasekara, Henry Häkkinen, Julia Hammann, Britta Denise Hardesty, Tomoko Hasegawa, Chenmin He, Olga Illarionova, Mengxing Li, Yingying Lu, Stephen Maycock, Troy McGee, Estee Miltz, Amy Molotoks, Jiayi Ng, Yuki Ochi, Ken Oshiro, Paul Overduin, Daniel Alejandro Pacheco Rojas, Ruben Prutz, Hareenanden Ramasawmy, Lucia Reisch, Savio Rousseau Rozario, Arthur Silva, Helen Spence-Jones, Kazuaki Tsuchiya, Kaj-Ivar van der Wijst, Laszlo Vreedenburgh, Michaela Werning, Leila Zamani, Shaneica Lester

Fellows

Aseel Ibrahim Mohammed Abo-Taleb, Ayodeji Stephen Adekanbi, Tarik Alkharusi, Raphael Villela Almeida, Nadege Amizero, Alison Amoussou, Francis Boafo Asamoah, Zoe Barr, Marianna Baslandze, Sofia Belardinelli, Acasia Broomes, Ruijun Chen, Victoria Del Pilar Chicmana Zapata, Maryam Eqan, Tegan Evans, Laura Fanciulli, Rose Foster, Emmanuelle Freitas, Slobodan Gnjato, Zhuang Han, Qian Jia, Christina Karakizi, Gabriela Kreutzberger, Shaneica Lester, Astride Messaga Maffo, Jan Matuštík, Claude Mbarga Ella, Estee Miltz, Fanni Moilanen, Amy Molotoks, Botho Bahumi Motlhanka, Katie Noble, Iryna Ponedelnik, Jimena Reyeros Sanchez, Martina Rotolo, Michael Ruggeri, Arthur Silva, Eleni Sofik, Helen Spence-Jones, Sénankpon Stephane Marcel Tcheton, Ekaterina Terenteva, Pushp Raj Tiwari, Kelo Uchendu, Soham Vaidya



Review Editors

Ahmed Abdelrehim (Lead Review Editor), Bettina Hedden-Dunkhorst (Lead Review Editor), Kofi Akamani, Ramia Al Bakain, Chandani Appadoo, Amanullah Bahriuloom, William Balée, Suruchi Bhadwal, Miranda Boettcher, Ashok Das, Naa Dodua Dodoo, Oswaldo dos Santos Lucon, Timothy Dube, Paul Dumble, Samia Elfitouri Grimida, Miguel Equihua, Gabriela Fernandez, Elsa Galarza, Nadezhda Gaponenko, Konstantin Gongalsky, Wame Lucretia Hambira, Shan Hu, Arnulf Jaeger-Waldau, Rumiana Jeleva, Injy Johnstone, Joni Jupesta, Lian Pin Koh, Anil Markandya, David McCollum, Nibedita Mukherjee, Adetoun Mustapha, Alick Bulala Muvundika, Leonard Nurse, Eni Oko, Robert Onyeneke, Jiesper Pedersen, Dimitris Poursanidis, Kálmán László Rajkai, Kilaparti Ramakrishna, Abdulkarim Rashed, Ariana Rossen, Mayar Sabet, Georg Schiller, Faizi Shahul Hameed, Diogo Silva, Tannecia Stephenson, Saritha Sudharmma Vishwanathan, Miguel Angel Taboada, Ram Devi Tachamo Shah, Goran Trbic, Oksana Volosko-Demkiv, Fei Wang, Sarah Whitmee, Lucia Helena Xavier, Xinzhu Zheng, Malgorzata Zimniewska

Donors and partners

Producing an assessment of this scale requires many generous contributions. The following Member States and organizations provided funding directly or indirectly to the seventh edition of Global Environment Outlook: The European Union, Governments of Austria, Canada, China, Germany, Italy, Jordan, Norway, Republic of Korea, Netherlands (Kingdom of the), Sweden, and United Kingdom of Great Britain and Northern Ireland, and Asia Indigenous Peoples Pact, Korea Environment Institute, Society of Entrepreneurs and Ecology Foundation, Tongji University. Together with UNEP's Environment Fund and Regular Budget, these contributions allowed the production of GEO-7 and its accompanying Executive Summary, as well as subsequent outreach activities.

Technical Partners

GEO-7 also benefited from the generous contributions of several technical partners, including: Brazilian National Institute for Space Research, Center for Environment and Development for the Arab Region and Europe (CEDARE), Chenjiang Laboratory, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Energy and Resources Institute, the Environmental Pulse Institute, European Commission Joint Research Centre, E3 Modelling, Frederick S. Pardee Institute for International Futures, GRID-Arendal, Institute for Global Environmental Strategies (IGES), International Institute for Applied Systems Analysis (IIASA), International Research Center of Big Data for Sustainable Development Goals, Kyoto University, Laboratory of Energy & Environmental Economics and Policy (LEEEP), Millennium Institute, National Autonomous University of Mexico, PBL Netherlands Environmental Assessment Agency, SENDAS Association Civil, Tyndall Centre for Climate Change Research, and Wageningen University & Research.

GEO-7 Secretariat

Ignacio Sánchez Díaz (Acting Head GEO Unit), Maarten Kappelle (Acting Head GEO Secretariat), Pierre Boileau (Former GEO Head), Hilary Allison, Atina Aliyeva, Sunny Beyene, Matthew Billot, Yunting Duan, Muthoni Kangethe, Caroline Kaimuru, Paula Kawka, Rachel Kosse, Allan Lelei, Ruoxi Li, Caroline Mureithi, Birgita Ohanga, Franklin Odhiambo, Grace Odhiambo, Adele Roccato, Pinya Sarasas, Martha Stokes, Ying Wang, Edoardo Zandri

UNEP Chapter Coordinators

Hilary Allison, Atina Aliyeva, Sunny Beyene, Pierre Boileau, Kilian Christ, Yunting Duan, Melchior Elsler, Valentin Foltescu, Francesco Gaetani, Sophia Groll, Muthoni Kangethe, Caroline Kaimuru, Rachel Kosse, Allan Lelei, James Lomax, Ruoxi Li, Cheikh Tidjane N'dongo, Nada Matta, Llorenç Milà i Canals, Grace Odhiambo, Adele Roccato, Julia Rugo, Ignacio Sánchez Díaz, Romanas Savickas, Sudhir Sharma, Martha Stokes, Feng Wang, Ying Wang, Jinhua Zhang

Peer-review System

Mina Elnagar (CEDARE), Mayar Sabet (CEDARE), Samir Sayed (CEDARE)

GEO-7 Workspace

Stian Grønning (Egde), Andy Harrison (Egde), Christian Knarvik (Crayon), Oddmar Lid (Egde), Miles Macmillan-Lawler (GRID-Arendal), Clever Mafuta (GRID-Arendal), Marco Vinaccia (GRID-Arendal), Pål Andre Ropstad (Crayon), Håvard Setra Sørvik (Crayon), Martin Størkson (Egde)

Editorial Team

Alexandra Horton (Editor), Catherine P. McMullen (Science Editor), Nora Mžavanadze (Glossary Editor), Ekaterina Bessonova (Editor), Lene Søjberg (Project management, Phoenix Aid Design), GRID-Arendal

Maps and Graphics

blossom.it, Fang Chen (CBAS/Chenjiang Laboratory), Jane Muriithi (UNEP), Carlos Reyes (Reyes Work Studio), Audrey Ringler (UNEP), Lei Wang (CBAS), Liang Xiao (Chenjiang Laboratory), Bo Yu (CBAS), Haiying Zhang (CBAS)

Design and Layout

blossom.it**, Virginia Njoroge (UNEP), Reagan Sirengo (UNEP)**

Media and Launch Support

Daniel Cooney, Nicolien Delange, Carlota Estalella Alba, Iman Fasla, Florian Fussstetter, Miranda Grant, Nancy Groves, Anastasia Isyuk, Gabrielle Lipton, Michael Logan, Beverly McDonald, Gregory Mwara, Virginia Njoroge, Michael Onyiego, Moses Osani, Andrew Raven, Keishamaza Rukikaire, Amina Said, Mila Shopova, Reagan Sirengo, Nandita Surendan, Yahan You, Ahmed Yusuf

Special thanks are also extended to

Jordan Harold (Tyndall Centre for Climate Change Research), Andrea Hinwood (UNEP), Florence Kahiro (UNEP), Gladys Karanja (UNEP), Raees Khan (UNEP), Tito Kimathi (UNEP), Jian Liu (UNEP), Irene Lorenzoni (Tyndall Centre for Climate Change Research), Peter Muriithi (UNEP), Kelly West (UNEP).

Table of contents

Acknowledgements ..... **iv**
Foreword ..... **xxix**
Preface by GEO-7 Co-Chairs ..... **xxx**

Part A: Overview and Context **2**
Indigenous Knowledge and Local Knowledge Chapeau A **4**

1 Introduction **9**
1.1 Acting now for a healthy planet: initiating transformative change 10
1.2 A solution-focused approach for sustainability transformations 12
1.3 Realizing transformative change: solution pathways and driving the transformation 15
1.4 Structure of GEO-7 17
Appendix 1.1 Key findings from previous global environmental assessments since 2019 21
Reference 25

2 Historical, current, and projected drivers and pressures of environmental change **29**
Chapter Summary 30
2.1 Introduction 34
2.2 Drivers of Change 34
2.3 Pressures that Affect the Global Environment 56
2.4 Drivers, Pressures, and the Global Environmental Crises: Connecting the Dots 69
References 73

Part B: State and Trends of the Environment **84**
Global Environment Crises Chapeau **86**
Indigenous Knowledge and Local Knowledge Chapeau B **108**

3 Air **113**
Chapter summary 114
3.1 Introduction 117
3.2 State and trends of atmospheric composition 119
3.3 Connections between the atmosphere and biodiversity loss and land degradation 126
3.4 Impacts on human systems 131
3.5 Progress towards the goals of global agreements 141
References 146

4 Land and Soils **159**
Chapter summary 160
4.1 Introduction 163
4.2 Pressures on land and soils 164
4.3 State and trends of the land 167
4.4 Impacts of natural ecosystems on human well-being and human systems 190
4.5 Progress towards internationally agreed environmental goals 192
4.6 Indigenous as well as Local Knowledge in land and soil management 196
References 199

5 Oceans and Coasts 213
Chapter summary 214
5.1 Introduction 217
5.2 State and trends 218
5.3 Human systems 238
5.4 Progress towards internationally agreed goals 242
References 250

6 Freshwater 261
Chapter Summary 262
6.1 Introduction 265
6.2 Pressures on freshwater systems 265
6.3 Water resources 271
6.4 Water quality 275
6.5 Freshwater biodiversity 278
6.6 Impacts of freshwater system changes on human well-being and human systems 283
6.7 Progress towards meeting internationally agreed-upon freshwater goals 291
References 293

7 Implication of Environmental Crises on the Socioeconomic Dimensions of the Sustainable Development Goals 305
Chapter Summary 306
7.1 Introduction 309
7.2 Implications of the global environmental crises on the socioeconomic dimensions of individual SDGs 310
7.3 Common Themes 332
7.4 Conclusion 334
References 337

8 Interlinkages Across Environmental Changes, Scales and Geographic Regions and Subregions 349
Chapter Summary 350
8.1 Introduction 354
8.2 Africa and subregions 356
8.3 Asia and the Pacific and subregions 369
8.4 Eastern Europe and subregions 378
8.5 Latin America and the Caribbean and subregions 391
8.6 Western Europe and Others Group and subregions 407
8.7 Telecoupling 424
References 430

Part C: System Transformations and Outlooks 458
Indigenous Knowledge and Local Knowledge Chapeau C 460

9 Scenario Methodology: Current Trends and Transformation Pathways 465
Chapter Summary 466
9.1 Introduction 468
9.2 Explorative and target-seeking scenarios 468
9.3 Internationally agreed goals used in the scenario analysis 471
9.4 Process of building the narratives for the target-seeking scenarios 473
9.5 Models used to quantify the scenarios 475
9.6 Challenges and limitations of the scenario approach 477
9.7 Presentation of results 478

Appendix 9.1: Models used in global analysis (Chapters 10 and 11) 479
References 498

10 Continuation of current trends – global implications 501
Chapter Summary 502
10.1 Introduction 505
10.2 Drivers of environmental change under current trends 505
10.3 Systems development under current trends 507
10.4 Environmental implications under current trends 511
10.5 Tipping points and non-linearities 521
10.6 Socioeconomic implications under current trends 525
10.7 The need to break with current trends 533
References 534

11 Transformation pathways towards achieving global goals – global implications 543
Chapter Summary 544
11.1 Introduction 547
11.2 Two narratives of transformation 548
11.3 Systems transformations 552
11.4 Environmental implications 561
11.5 Socioeconomic implications 570
11.6 Synergies in the transformation 579
11.7 Challenges and opportunities 584
Appendix 11.1 Narratives quantification and mapping to solution pathways 587
References 591

Part D: Solution Pathways towards Transformation 596
Solution Pathways Chapeau 598
Indigenous Knowledge and Local Knowledge Chapeau D 604

12 Transforming systems – principles and levers in action 611
Chapter Summary 612
12.1 Introduction 615
12.2 Science-policy rationales for system transformation 616
12.3 Scientific perspectives for system transformations 618
12.4 Six fundamental principles for system transformations 628
12.5 From principles to requirements for intentional action within and beyond existing governance structures 636
12.6 Lessons from experiences of intentional transformative action principles acting on levers 641
12.7 New policy design for our times 650
Appendix 12.1 Definitions of system transformation and transformative change in global environmental assessment reports 654
References 655

13 Methodology for developing solution pathways towards system transformations 663
Chapter Summary 664
13.1 Introduction 667
13.2 Background 668
13.3 Evaluation of theories of development and environmental change and embracing complexity 670
13.4 Incorporation of Indigenous Knowledge and Local Knowledge 670
13.5 Policy effectiveness, coherence and decision-making 672
13.6 Presenting the 7-step methodology 673

13.7 Presenting the X-curve 675
13.8 Step-by-step description of the 7 steps 677
13.9 Monitoring and evaluation 684
13.10 Concluding thoughts 685
Appendix 13.1 Guidelines for the evaluation process in the GSL Framework 687
References 689

14 Solution pathways for the transformation of economic and financial systems 695
Chapter Summary 696
14.1 Introduction 700
14.2 Solution Pathways to achieve transformative change 707
14.3 Solution Pathway 1: Internalizing the externalities – correcting pricing 711
14.4 Solution Pathway 2: Making sustainability core in economic governance 717
14.5 Solution Pathway 3: Enhancing financial sector resilience and contribution to sustainability 722
14.6 Solution Pathway 4: Fostering non-pricing approaches towards greening behaviours 732
14.7 Combining solutions to achieve the goals 736
14.8 Synergies 737
Appendix 14.1 Additional detail on examples of payment for ecosystem services implementation in selected countries 739
References 744

15 Solution pathways for transformation towards circularity 751
Chapter Summary 752
15.1 Introduction 756
15.2 Potential solutions to achieve transformative change – immediate policy actions and strategic long-term planning 767
15.3 Solutions case studies 793
15.4 Synergies and trade-off interactions with other systems 795
References 797

16 Energy System Transformation Pathways 809
Chapter Summary 810
16.1 Introduction 813
16.2 Solution pathways for energy system transformation 814
16.3 Combination of solutions to achieve the desired goals 836
16.4 Case studies 840
16.5 Implication of the solution pathways on the other systems 842
16.6 Conclusions 845
References 847

17 Food Systems Transformation Pathways 855
Chapter Summary 856
17.1 Introduction 860
17.2 Solution pathways for food system transformation 868
17.3 Combination of solutions to achieve the desired goals 888
17.4 Implications of the solution pathways on the other systems 894
References 896

18 Solution pathways enabling a sustainable and resilient environment for systems transformation 909
Chapter Summary 910
18.1 Introduction 915

18.2 Solution pathways for a resilient and sustainable environment system 919
18.3 Implication of the solution pathways for a resilient sustainable environment on other systems 947
References 949

19 Implications for Different Economic Development Contexts 963
Chapter Summary 964
19.1 Introduction 967
19.2 Country groupings 967
19.3 Transformation of economic Systems 969
19.4 Transformation towards circularity and sustainable materials management 972
19.5 Transformation of energy systems 975
19.6 Transformation of food systems 981
19.7 Transformation of environmental Systems 988
19.8 Implications for the three economic groups 995
19.9 Summary and conclusions 995
Appendix 19.1 Country Data 997
Appendix 19.2 Renewable energy use by region 1007
Appendix 19.3 Disaggregation of model data by country grouping 1008
References 1009

20 Regional Dimensions of the Transformative Solutions for the Global Environmental Crises 1015
Chapter Summary 1016
20.1 Introduction 1024
20.2 Approach 1024
20.3 The GEO-7 Current Trends Scenario is not a Future Option 1025
20.4 Africa Region 1026
20.5 Asia and the Pacific Region 1041
20.6 Eastern European Region 1055
20.7 Latin America and the Caribbean Region 1069
20.8 Western Europe and Other Groups 1088
20.9 Changing Interrelationships Across Regions 1103
20.10 Conclusion 1107
Appendix 20.1 Eastern Europe Key Trends Across the 2030-2040-2050 Milestones 1108
References 1111

21 Driving the transformations 1123
Chapter Summary 1124
21.1 Introduction 1128
21.2 Co-producing transformations across systems and regions 1128
21.3 Overcoming barriers and breaking lock-ins 1131
21.4 Leveraging motivation 1136
21.5 Accelerating a sustainable transformation 1149
21.6 Concluding thoughts 1153

As the Global Environment Outlook 7 reminds us: now is the time for courage and creativity

António Guterres

Secretary-General of the United Nations

Foreword

Life is all about choices. Some are of little consequence. Some are life-altering. Humanity now faces perhaps the biggest choice it will ever make: continue down the road to a future devastated by climate change, dwindling nature, degraded land, and polluted air, land and water, or change direction to secure a healthy planet, healthy people and prosperity for all.

The Global Environment Outlook, Seventh Edition: A Future We Choose, the product of 287 multi-disciplinary scientists from 82 countries, tells us what we stand to gain by choosing the latter path – a path that tackles the interconnected crises of climate change, biodiversity loss and land degradation, and pollution and waste as one.

By investing in a global transformation of systems from energy to food, we can avoid nine million premature deaths by 2050 – many of them from decreased air pollution. We can lift 200 million people out of undernourishment and 150 million people out of extreme poverty by 2050. We can give 300 million more people access to safely managed water sources by 2050. And so much more. Yes, this will involve up-front costs, but there is long-term return on investment: the global macroeconomic benefits of this path appear in 2050, grow to US$20 trillion per year by 2070 and boom thereafter.

If we choose to stay on the current path – powering our economies with fossil fuels, extracting virgin resources, destroying nature, polluting the environment – the damages would stack up. Climate change would cut four per cent off annual global GDP by 2050, claim many lives and increase forced migration. Amazon forest dieback and ice-sheet collapse would become more likely. Hundreds of millions more hectares of natural lands would be lost. Vital species such as pollinators would be decimated. Food availability would fall. Urban air pollution would continue, with fine particulate matter alone causing around four million premature deaths annually. Solid waste, currently over two billion tonnes per year, would almost double, turning our world into a toxic garbage dump.

Sometimes a choice is no real choice at all.

To take the first path, we need interlinked, whole-of-society and whole-of-government approaches to reshape economy and finance, materials and waste, energy, food and, of course, the environment. This new journey begins with moving beyond GDP as a measure of economic well-being – instead using inclusive indicators that also track the health of human and natural capital, so that economic and business decisions are made from a position of full knowledge. It continues with a transition to circular economy models that reduce material footprints; a rapid decarbonization of the energy system; a shift towards sustainable diets, reduced waste and improved agricultural practices; and expanding protected areas and restoring degraded ecosystems – all backed by behavioural, social and cultural shifts that include respect for Indigenous Knowledge and Local Knowledge.

Change is always difficult, more so when it is on such a massive scale. But change we must. There are two futures ahead of humanity. Let us choose the right one.

Inger Andersen
Executive Director
United Nations Environment Programme

Preface by GEO-7 Co-Chairs

A Planet in Peril, A Call for Action

The fifth session of the United Nations Environment Assembly (UNEA-5) adopted, in March 2022, Resolution 5/3 on the Future of Global Environment Outlook (GEO). In this resolution, Member States established the objectives, core function and next steps in developing the GEO process and the seventh edition of the GEO - UNEP's flagship report. This was informed by two preceding years of analysis and consultations undertaken by UNEP under the auspices of the intergovernmental Steering Committee on the Future of the GEO. The latter was established pursuant to Resolution 4/23 adopted at the fourth session of UNEA.

The seventh edition of the Global Environment Outlook (GEO-7) continues UNEP's tradition of delivering comprehensive, science-based information and knowledge, critical to guiding policy and action towards environmental sustainability. This is done with the aim of addressing the multiple, complex environmental challenges humanity faces today. It provides a set of integrated and actionable solution pathways which are tailored to the needs of Member States and other stakeholders to support the necessary global transition to a sustainable, equitable, and resilient future for all.

A scientific assessment of the global environment demands collaboration across a vast array of scientific disciplines. Over 280 scientists– representing every geographic region and balanced in terms of gender distribution – contributed their specific expertise to writing this landmark assessment: the Global Environment Outlook (GEO-7). Hundreds more reviewed the chapters of the report and provided constructive peer-review comments.

This seventh edition of GEO examines two overarching themes:

1. The historic, current and projected status of the interconnected global environmental crises of climate change, biodiversity loss, land degradation and desertification, and pollution and waste, what causes them, and what are their impacts on human well-being.

2. Potential Solution Pathways necessary to address these crises successfully through the simultaneous and systemic transformation of the interconnected human systems of (i) economics/finance, (ii) materials/waste, (iii) energy and (iv) food, as well as through (v) improved environmental management.

This GEO-7 main report, released at the Seventh UN Environment Assembly (UNEA-7) in December 2025, situates environmental challenges within broader socio-economic and political landscapes, while translating complex systemic data, information and knowledge into clear, actionable insights needed by national and subnational governments, Multilateral Environmental Agreements (MEAs), and other stakeholders, to tackle adequately the afore-mentioned global environmental crises. The report's findings are poised to shape the agenda and deliberations of Member States and Stakeholders at UNEA-7.

At the country level, GEO-7's conclusions will guide the integration of environmental sustainability into national development agendas, strategies and policies, ensuring alignment with the universally agreed Sustainable Development Goals (SDGs) and related Internationally Agreed Environmental Goals.

Building on prior assessments by IPCC, IPBES, and earlier GEO reports, GEO-7 casts the widest net yet, encompassing the interconnected global environmental crises. It draws on diverse knowledge systems—from natural, social, cultural and behavioral sciences to scenario modelling, economics, and Indigenous Knowledge and Local Knowledge—to present a truly holistic view of the world's environment.

Decades of global assessments—both led by the UN and independent ones—have painted a stark picture:

the degradation of the global environment is continuous and accelerating every time. These assessment reports reveal how human systems, energy, food, materials/waste and prevailing economic models, drive cumulative environmental harm, and in turn are adversely affected by environmental degradation. While international treaties, like the Multilateral Environmental Agreements, often state what must be achieved by 2050, they seldom recommend how we can get there—leaving critical gaps in policy, governance, technology, and behavioral pathways across varied contexts.

UNEP's previous global environmental assessment, the GEO-6 report launched in 2019, as well as numerous other major reports confirmed that the world missed the Aichi Biodiversity Targets and is off track to meet the SDGs and the Paris Agreement's climate goals. Without swift, transformative action, humanity risks a 3 °C rise in global temperatures, rampant pollution, and catastrophic biodiversity loss. Governments have recognized these threats and have called for immediate, sustained responses, but the pace and scale of the interventions needed has been inadequate to date.

In direct response, GEO-7 focuses on solutions to complement the diagnosis. It equips policymakers with practical guidance on designing, implementing, and governing transformative policies, addressing timing socio-economic co-benefits and trade-offs, and unintended consequences. Acknowledging political and economic constraints, financing shortfalls, misaligned policies, vested interests, educational gaps, and fragmented governance, the GEO-7 assessment report provides concrete solution pathways to overcome these barriers.

The report opens with a rigorous review of the status of Earth's air, land, oceans, and freshwater natural systems—alongside the crises of climate change, biodiversity loss and land degradation, and pollution and waste. This analysis integrates robust scientific evidence with Indigenous Knowledge and Local Knowledge. For instance, Arctic communities' sea-ice monitoring deepens our understanding of climate anomalies, while Indigenous Peoples' fire-stewardship practices demonstrate nature-based approaches to wildfire mitigation and biodiversity conservation.

The GEO-7 report introduces two target-seeking scenarios that align with global goals through transformative solutions across all human systems. It then presents a new transformation framework based on six core principles and operationalized through seven actionable steps—designed to generate multiple solution pathways for each system.

The report explores how these systems' transformations can be addressed simultaneously, accelerated and effectively governed to meet the targets of internationally agreed environmental goals, while realizing socio-economic benefits. It continues by weaving together scenario insights and policy responses, clarifying the roles of governments, communities, the private sector, and civil society in driving systemic change.

Finally, the report outlines how transformation strategies can be adapted to suit regional contexts and the specific needs of various socio-economic country groupings, While many actions are similar from one country to another, and from one region to another, GEO-7 identifies some specific regional challenges and opportunities for action.

Looking Ahead

- Governments can pilot GEO-7's transformational framework in subnational contexts—cities, provinces, or watershed basins—to test its seven actionable steps in real-world settings.

- National ministries and other government entities could align their climate strategies, land use planning, and biodiversity action plans with the GEO's target-seeking scenarios, accelerating their 2030 and 2050 national commitments and targets.

- Academia and civil society should collaborate on monitoring progress towards targets, applying Indigenous Knowledge and Local Knowledge to refine policy interventions.

- Private-sector stakeholders should collaborate in resource-mobilization partnerships that channel finance towards nature-based

- solutions, green infrastructure, and circulareconomy initiatives.

This preface sets the stage for an evidence-driven, action-oriented journey towards a healthier, safer, and more equitable planet for all. The pages that follow will guide the reader through both the sobering challenges and the transformative opportunities that lie ahead.

The GEO-7 emphasizes not just what needs to be done, but how actions that address the issues and challenges can be implemented in a socially and economically acceptable manner. If we are to avoid a catastrophe for humanity, actions need to be taken now – the next five years are critical.

Grounded in our shared responsibility for sustainable development, we urge all Member States and stakeholders to act decisively. Time is running out. This report shows that the cost of action is far less than the cost of inaction – the health of the planet deserves no less. To neglect this moment is to betray the promise we owe to tomorrow's citizens.

The Indigenous Knowledge and Local Knowledge (IK & LK) Authors worked on all of the five IK & LK chapeaux in the GEO-7 report.

Indigenous Knowledge and Local Knowledge Chapeau A

Indigenous Peoples perspectives on environmental change and its causes can inform understanding of the global environmental crises of climate change, biodiversity loss, land degradation and desertification, and pollution and waste. Indigenous scholars, leaders and elders, as well as non-Indigenous researchers have identified capitalism, globalization, imperialism, colonialism and patriarchy as underlying causes of these global environmental crises (Whyte 2017; McGregor, Whitaker and Sritharan 2020; Smith 2021). Imposed natural resource extraction and conservation have become synonymous with the displacement of [Indigenous] peoples and animals, the denial of access to or destruction of lands and natural resources, and the elimination of traditional livelihoods and ways of life (United Nations 2021). Extractive and industrial activities, such as oil and gas extraction, unsustainable agriculture, uncontrolled lumbering, unrestricted overfishing, mining, and dams have resulted in severe environmental injustices with Indigenous Peoples disproportionately affected (Owen et al. 2023). False solutions to environmental challenges include conservation and climate mitigation policies that redesignate Indigenous lands, again disproportionately affecting Indigenous Peoples (A/HRC/54/31; United Nations 2021; IK & LK Dialogues 2025). Enforcing respect for Indigenous Peoples human rights, ensuring representation in decision-making, and promoting shifts in values towards care for all life are essential principles for sustainability and for future generations (United Nations 2021; IPBES 2022).

There is a rich diversity of Indigenous languages, values, traditions, practices and worldviews while they share affinities with lands, peoples, and cultures, however, Indigenous Peoples also share experiences and legacies of colonialism (IK & LK Dialogues 2025). These ways of knowing and doing build on reciprocal connections with the land and nature and with divine presence (Philippine Indigenous Peoples and Biodiversity Coalition 2024. Indigenous Peoples biocultural knowledge is generated relationally, shaped by values and through practice (IK & LK Dialogues 2025).

Indigenous Peoples ways of knowing and being persist and have significant potential for sustainability transformations (Ford et al. 2020; Arora and Stirling 2023; IPBES 2024). Indigenous Peoples do not conceive of nature as external to humans, nor as comprising mechanistic systems, or as a passive entity available primarily for exploitation and management (Polheim et al. 2024). Indigenous sciences do not position

Credit: NaturesCharm/Envato

humans as exceptional or as having authority, superiority, or ownership over other beings. Instead, many Indigenous sciences position humans as part of (entangled with) the world. (Ahenakew 2016; Stein et al. 2024). Two-Eyed Seeing or Indigenous-led Etuaptmumk in Mi'kmaw, is a methodology that effectively draws upon and gives value to both Indigenous Knowledge and positivist science (Bartlett, Marshall, and Marshall, 2012). Increased support for Indigenous-led research based on the application of Two-Eyed Seeing is needed (Smith 2017).

Centring Indigenous biocultural perspectives, governance, and science that value all life represents an important avenue for future sustainability (Gallegos 2015; Merçon et al. 2019; Burke et al. 2023; Datta et al. 2025). Indigenous Peoples ways of knowing and being assign spiritual and sacred value to all life. Practices such as eating or fishing are constituted relationally, often with species treated as kin and guided by reciprocity (Salmon 2000; Topa and Narvaez 2022). Respect for life cycles and their continuity is a sacred example of the Agdal systems of the Amazigh of North Africa (IK & LK Dialogues 2025). Lands and water are living places, perceived as inhabited by ancestral humans and non-humans who demonstrate how to live well together on a shared, finite planet (Bakawa Country et al. 2016; Stewart-Harawira 2020; McGregor, Whitaker and Sritharan 2020; Luque-Lora 2023; Chakraborty 2025). Multiple Indigenous concepts for convivial and sacred co-dwelling exist, as set out by Andean *Sumak Kawsay* and Southern African *Ubuntu* (IPBES 2022; IK & LK Dialogues 2025).

1.1 Acting now for a healthy planet: initiating transformative change

All life on Earth, including humanity, is facing an unprecedented threat, represented by the convergence of human-induced global environmental crises: the crisis of climate change, the crisis of biodiversity loss, land degradation and desertification, and the crisis of pollution and waste. These crises are interlinked and mutually reinforcing, pushing planetary systems towards uncharted territory where there is a growing likelihood that several tipping points may soon be irreversibly crossed. Despite numerous political commitments and repeated calls for action, the world is still not on track to meet internationally agreed objectives for responding to these crises.

Previous reports, including key findings from the Sixth Global Environment Outlook (GEO-6) report, explicitly show that global environmental crises are continuing at an accelerating rate, are worsening, and the costs of inaction are rapidly increasing. Meanwhile, the window for effective and timely action is closing (Dinerstein et al. 2019; Evans 2021; Muluneh 2021; Visseren-Hamakers et al. 2021; Leadley et al. 2022; Persson et al. 2022; Wilkinson et al. 2022; Chaplin-Kramer et al. 2023). These calls for immediate action are prioritized by the United Nations 2030 Agenda for Sustainable Development and its 17 SDGs and by several Multilateral Environment Agreements, including the Convention on Biological Diversity's Kunming-Montréal Global Biodiversity Framework (United Nations 2015; United Nations Environment Programme [UNEP] 2019a; Secretariat of the Convention on Biological Diversity 2022a; Secretariat of the Convention on Biological Diversity 2022b).

Transformative change is necessary to safeguard planetary and human health and well-being, as well as to address deepening inequalities caused by the unbalanced consequences of global environmental crises, which primarily affect the world's most vulnerable populations. Achieving the environmental, social and economic goals that can ensure a sustainable and just future for all will require a transformation of the interconnected systems of economics and finance, energy, food, material resources, and the environment.

The Seventh Global Environment Outlook (GEO-7) outlines an actionable roadmap for enabling such transformations. The report provides a comprehensive assessment of the latest information on the current state of the global environment and expected future trends. The report informs decision makers and all citizens worldwide that achieving sustainability and transformative change in a timely and equitable manner is both necessary and feasible.

The report calls on all actors, governments, non-governmental and multilateral organizations, the public, including Indigenous Peoples, civil society, academia and professional organizations, as well as the private sector to acknowledge the urgency of the global environmental crises and to collaborate in the co-design and implementation of integrated policies, strategies and actions. Such coordinated actions can initiate a process of change that transforms socio-ecological systems. Equitable and just transformations fundamentally require a shift away from the concentration of power and wealth, away from short-term decisions prioritizing individual and material gains, and away from the disconnection from and domination over nature. This shift involves values moving away from extractivism and unsustainable patterns of consumption towards regenerative socio-ecological systems based on reciprocity and care (O'Brien et al. 2024).

Indigenous Peoples' care for peoples, lands and nature demonstrates the latter. GEO-7 has sought to address Indigenous Knowledge, providing dedicated space as well as attention to it throughout the text and going beyond integration into scientific framings. This attention recognizes that Indigenous Peoples' ways of knowing and being have significant value. Approaches such as Two-Eyed Seeing, Etuaptmumk in Mi'kmaw, are practical Indigenous methodologies for bringing Indigenous Knowledge and science into balanced participation. Based on long-term observations and relations with the land, as well as scientific knowledge, these approaches weave together new knowledge while recognizing the inherent value of each. Indigenous Peoples' values and ways of being, such as Sumak Kawsay from Ecuador or Ubuntu from Southern Africa, prioritize collective well-being for all life, challenging dominant formations of resource extraction and appropriation. These ways of knowing, being and relating are thus highly valuable when considering the nature of sustainability transformations and how to achieve them.

Credit: Sun-Shock/Envato

Led by an Indigenous Knowledge and Local Knowledge Task Force and drawing from the findings of three dialogues held as part of this process, GEO-7 provides space for the articulation of Indigenous and local knowledge in five stand-alone chapeaus or sections. These provide Indigenous perspectives on the global environmental crises and solution pathways responses, as well as being included within many of the other chapters in the assessment.

Recognizing the need for more far-reaching change, the report outlines the key guiding principles, long-term thinking and planning, pluralism, participation and inclusion required for governing the transformation that can inform new policy designs for current times. It also outlines the levers, or domains of intentional action, for implementing these principles. The identified levers are Economic and financial, Individual and collective action, Knowledge and innovation, Governance, and Capabilities. Acting within these areas and following transformation principles can overcome barriers and generate options for transformative actions.

To illustrate the feasibility of transformative change to achieve globally agreed environmental goals, GEO-7 has also developed two contrasting target-seeking scenarios, which model possible alternative trajectories of systems transformations and explore the scale and effort required to achieve the goals. GEO-7 Behaviour-focused Transformation Pathway Scenario envisions a profound transformation in society´s values, beliefs, and norms, accompanied by a significant decrease in consumption, particularly in affluent countries. GEO-7 Technology-focused Transformation Pathway Scenario envisions massive investments in technology and development, aiming at efficiency and clean-technology gains in an economically globalized, commodified, and urbanized world. The scenario analysis indicates that the long-term benefits of transformative change—ecological, social, and economic—would far outweigh the associated costs of its implementation.

GEO-7 also identifies several near- and long-term "solution pathways" within the five key human systems of economics and finance, energy, food, materials resources, and the environment, that, if applied, can deliver the most social and environmental benefits. Implemented through whole-of-government and whole-of-society approaches, these systemic solutions have the potential to secure a healthy global environment as the continued foundation of societies and people's well-being and health.

Recognizing the complexity of achieving transformative change at the global level, the report explores how

Credit: MaplesImages/Envato

system-wide transformations and solution pathways may vary across national and regional contexts. It provides tailored pathways and scenarios for countries with different economic contexts (high-income, medium-income, and low-income), and takes into account regional specificities, emphasizing the importance of regional cooperation and international partnerships in developing context-specific strategies and enabling equitable progress worldwide. GEO-7 also explores how the transformation process can be accelerated while ensuring that the solutions implemented in onesystem do not have adverse consequences in other systems.

1.2 A solution-focused approach for sustainability transformations

The report is the Seventh in a series of GEOs, a process established as part of the follow-up to the adoption of Agenda 21 in 1992 (UNEP 1995). The first GEO was released in 1997. Since the launch of the latest GEO in 2019 (UNEP 2019a), several global environmental assessment reports have been published, most notably the Intergovernmental Panel on Climate Change (IPCC) Sixth Assessment Report (2023), the UN Global Sustainable Development Report (2023), the World Meteorological Organization United in Science Report (2023), the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) "Values Assessment" (2022), and the IPBES Transformative Change Assessment Report (O'Brien et al. 2024) (**Appendix 1.1**).

GEO-7 was prepared in response to a request from the fifth United Nations Environment Assembly [UNEA-5]. According to Resolution 5/3, the core function of the GEO process is to provide, every four years, an intergovernmental, expert-led, authoritative global assessment with regional specificities that analyses and tracks trends, evaluates the effectiveness of global policy responses and assesses future perspectives. At the same time, it evaluates the drivers of environmental change and the interactions across these environmental themes while benefiting from but not duplicating existing assessments (UNEP 2022).

1.2.1 New ways of thinking and acting for systems transformations

In the past, different assessments have been criticized for their findings being too abstract for policymakers

and practitioners to implement in a practical manner (Jabbour et al. 2017; Kowarsch et al. 2017; Hallegatte et al. 2024). Moreover, they fell short of providing sufficient guidance on the best policy, governance, technology or behavioural approaches to achieve these often-ambitious targets, thus aiming at the *what* without guidance on the *how*. Therefore, and due to the urgent need to address the global environmental crises of climate change, biodiversity loss and land degradation, and pollution and waste, the primary focus of GEO-7 is not the description of facts, the assessment of state, changes and trends in globalfeatures, patterns and processes or possible opportunities, but on evidence-based and adaptive solutions. By addressing key policy questions, it can serve as a basis for sound and effective policymaking. To meet these ambitions, the report provides readers with substantial innovations.

Historically, one of the most widely used causal and conceptual frameworks for describing the interactions between human and ecological systems has been the Driver-Pressure-State-Impact-Response (DPSIR) framework. This causal framework is used to describe various interactions between human society and the environment at multiple scales and is generally well accepted to manage environmental problems (Carr et al. 2007; Ness et al. 2010; Tscherning et al. 2012; UNEP 2017; Risch et al. 2019; Gupta et al. 2020). Within GEO-7, the analysis of historical, current and projected drivers and pressures of global environmental change builds on the DPSIR model but with a re-modelling and expansion. This report provides a more in-depth exploration of the Drivers and Pressures, analysing their interlinkages and intersections with the global environmental crises (*Chapter 2, Figure 2.1*). Moreover, it outlines the implementation of a system-wide transformative change through the identified solution pathways. Additionally, GEO-7 recognizes that there are other ways of understanding human-nature interactions, such as within Indigenous Peoples relational thinking and practice, which has valuable lessons for sustainability.

The governance of human systems transformations requires new ways of thinking, being, and acting. This implies, among other things, breaking away from established, unsustainable planning and decision-making, and envisioning new solution pathways. It also involves embracing participatory, pluralist and inclusive governance structures that involve all relevant stakeholders and evaluating conditions for their feasibility.

GEO-7 offers a new framework for designing and implementing interventions to drive system transformations, combining theoretically grounded requirements for whole-system transformations with operational steps for developing solution pathways. The framework is designed to be future-proof, ensuring that the challenges, complexities, and implications of system transformations are anticipated. This accelerates the pace of deliberate, transformative change at a systemic level across temporal and spatial scales. This methodology is adaptive and integrates interdependencies involving synergies and trade-offs between and within systems. Through an iterative, holistic decision-making process, this methodology accounts for possible effects of resistances, shocks and risks. Thus, it provides guidance for designing transformative solution pathways. The 7-step methodology developed in GEO-7 focuses on identifying the system goals, solutions, levers, actors, and actions needed to achieve the desired transformations.

1.2.2 Scenarios, pathways and strategies for realizing transformative change

The GEO-7 scenario analysis shows that internationally agreed goals related to the global environmental crises can be achieved with significant benefits for people and the planet. Both transformation scenarios require unprecedented and coordinated transformations of key human systems. Furthermore, both scenarios depend on effective governance addressing inequality and inequity, high levels of technological development, and well-regulated markets where externalities are appropriately identified and consequently priced. Implementing the multiple coordinated strategies is extremely urgent. It requires orchestrating coordinated actions across diverse systems, sectors and regions, and gaining societal acceptance of specific solutions, such as changes in consumption patterns and human behaviour. For example, avoiding inefficient and unnecessary resource use and embracing the concept of circularity creates multiple synergies across systems to address planetary crises and improve human well-being.

The report confirms that three complementary perspectives can be applied to system transformation: a) a socio-ecological perspective focusing on various interactions of environmental and social components and situating intentional transformative actions within the nested practical and personal spheres; b) a socio-technical perspective aiming at the mutual shaping

Credit: Dmitry_Rukhlenko/Envato

of technology and society, commonly representing systems as partially coherent bundles of technology, policies, science, culture, and industry and markets; and c) a socioeconomic perspective highlighting the interactions of economic and social systems and the scope for institutional frameworks and response structures that modify these systems. These perspectives differ in terms of how system boundaries are drawn, how the dynamics and future pathways of transformations are represented, and the insights for governance. Key principles that can guide transformations are presented in the report, including adaptability, inclusion, and plurality.

1.2.3 A plurality of forms of knowledge can support the achievement of desired sustainable futures

Plurality means recognizing different forms of knowledge in seeking sustainability transformations, such as scientific knowledge and Indigenous Knowledge and Local Knowledge. The latter can contribute to transformations towards sustainable futures by providing valuable concepts of human-nature relations, values based on the ethics of care, and practices such as ways of caring for lands, people, and nature. Indigenous Peoples and other communities that maintain historical connections to living territories often have a deep, relational understanding of lands and ecologies. Importantly, Indigenous Peoples do not separate nature from humans but rather recognize that humans and nature are entangled and interdependent, with these relations underpinned by obligations and values of reciprocity and care, and imbued with spiritual significance. These relational rather than instrumental interactions with nature, based on the ethics of care for territories and all life, enable humans and non-humans to flourish with broader relevance for sustainability transformations.

Fundamental shifts for the desired sustainable futures identified by Indigenous Peoples in the Second Dialogue for GEO-7 include: a) territorial and life care; b) sustainable, social and solidarity economy; c) just energy transitions with equitable access; d) education that fosters intergenerational transmission of Indigenous Knowledge and Local Knowledge and the revitalization of Indigenous Knowledge, cultures, and languages; and e) strengthening Indigenous forms of organization, alliances and networks. Instead of dismissing Indigenous Peoples' ways of knowing, being, and relating, or seeking to integrate them into scientific framings and paradigms, sustainability transformations will be better served by giving greater space to Indigenous perspectives and representation in decision-making processes and defending the human rights of Indigenous Peoples.

Finally, the GEO process should identify inter-governmentally defined needs and terms to support capacity-building, knowledge generation and policymaking. The report aims at providing support services for addressing those needs. Therefore, GEO-7 has started implementing a set of supporting services

such as capacity building, technology transfer, knowledge generation, and support for policymaking. These activities are intended to assist all actors – from governments to civil society, organizations, and communities, as well as businesses and enterprises – in implementing these ambitious transformations. The supporting services approach is an outgrowth of the two year process to define the Future of GEO, which recognized that implementing the findings of the GEO assessment requires additional support.

1.3 Realizing transformative change: solution pathways and driving the transformation

To secure a sustainable future, transformative change must move beyond intent to action. The GEO-7 report outlines five interconnected solution pathways for achieving this transformation: transforming economic and financing systems, implementing circular economy principles, transforming the energy system, transforming the food system, and managing environmental systems. The pathways prioritize innovation, regional perspectives, and strategies to accelerate progress. They are not isolated; their synergies amplify the impacts, ensuring solutions that are effective, equitable, and inclusive. The urgency of this transformation demands unprecedented ambition and coordination across governments, societies, and knowledge systems. From an Indigenous Peoples' perspective, it is clear that efforts to achieve sustainability transformations should not involve 'false solutions' such as green capitalism, that continue to reproduce business-as-usual and undermine their human rights, but should instead entail shifts towards care and reciprocity and recognition of their rights to self-determination and representation in policymaking as rights-holders.

1.3.1 Transformation of economic and financing systems

Economic and financial systems must evolve by phasing out socially and environmentally harmful substances, pricing externalities such as pollution, moving beyond Gross Domestic Products as the sole measure of progress, and redirecting financial flows towards sustainability. Innovations such as the EU's Sustainable Europe Investment Plan and New Zealand's well-being budgets demonstrate how fiscal reforms can align economies with environmental goals. In developing regions, international financing can enable leapfrogging to sustainable models, with equity ensured through compensatory mechanisms for vulnerable populations.

1.3.2 Implementing circular economy principles and practices

Circular economy principles focus on minimizing waste and maximizing resource efficiency. Urban mining in Japan, which recovers metals from electronics, and Africa's informal recycling networks showcase scalable practices, as do Indigenous Peoples' care economies based on the principle of abundant sufficiency. These efforts reduce the need for raw extraction, support sustainable bio-economies, and create jobs, particularly in resource-scarce areas. Additionally, integrating circularity into energy and food systems amplifies these benefits.

1.3.3 Transforming the global energy system

Transforming the energy system hinges on decarbonization, scaling renewable sources like solar and wind and improving efficiency. Cost-competitive technologies, advanced energy storage, and smart grids drive this shift. Africa's abundant solar potential and Europe's leadership in wind energy highlight regional strengths. The electrification of transport and industry further reduces emissions, demonstrating that innovation delivers both environmental and economic benefits.

1.3.4 Transforming the food system

Food system transformation calls for dietary shifts toward plant-based options, more efficient production, waste reduction, and alternative proteins like lab-grown meat. Precision farming, regenerative agriculture, and novel proteins can reduce environmental footprints. Asia's rice-based diets and Latin America's cattle-heavy regions can adopt tailored sustainable practices, while technologies like food waste apps enhance security and resilience globally. Indigenous Peoples' food systems offer holistic biocultural solutions to sustainability.

1.3.5 Managing environmental systems

Managing environmental systems in ways that enhance sustainability involves implementing nature-friendly solutions and incorporating Indigenous Peoples' governance and care for living territories. Monitoring through the use of artificial intelligence can more effectively track the health of ecosystems. Community-

Credit: avanti_photo/Envato

led conservation in Africa and the Amazon can restore biodiversity cost-effectively. Respecting Indigenous Peoples' rights and building on Indigenous Knowledge and Local Knowledge and practices can enhance the effectiveness, equity and cultural relevance of conservation, also supporting climate adaptation.

1.3.6 Regional perspectives

Regional perspectives emphasize context-specific solutions. Africa excels in solar and circular waste systems, Latin America's Amazon Fund protects forests, Asia builds green urban hubs, and Europe leads in wind and policy innovation. Equity and justice remain critical: technology transfers and support for marginalized groups can strengthen inclusive progress, as can respect for human rights, including the rights of Indigenous Peoples.

1.3.7 Accelerating the transformation

Accelerating transformation requires urgent action, as noted throughout GEO-7. Policy innovations, such as a carbon tax in Sweden, technology-scaling through research, and cultural and value shifts via education, including the recognition of the agency and rights of non-humans, are key drivers. Strong governance, involving whole-of-government and whole-of-society approaches, is essential and also recognizes Indigenous Peoples' rights to self-determination. Private sector innovation, public-private partnerships, and education build momentum. Barriers such as vested interests and funding gaps can be overcome through blended finance and transparent communication, while remote sensing and citizen science facilitate adaptive management.

1.3.8 Unified pathways for shaping a sustainable future

The five solution pathways chart a course to sustainability, integrating economic and financial, energy, food, material resources, and environmental systems. Innovations, from green finance and

Indigenous Peoples' governance of lands to alternative proteins, unlock their potential, bolstered by regional insights and accelerated through policy, technology and collaboration.

The call to action is clear: act now, with boldness and equity, to forge a just and sustainable future where prosperity and planetary health coexist. The GEO-7 report equips us with the vision and tools to make this systemic transformation real, ensuring a resilient world for all.

All the pathways outlined are interconnected: renewables reduce emissions, circularity mitigates ecosystem strain, and dietary shifts free up land for people and nature. Digitalization that addresses equity and justice can enhance efficiency across all areas of operation. In conclusion, the transformative scenarios of behavioural and technological change, along with the five solution pathways, offer a roadmap to sustainability, blending strategies to radically transform the economic and financial, energy, food, material resources, and environmental systems. The beneficial outcomes multiply when these solutions address transformation principles such as justice, pluralism, and Indigenous Peoples' perspectives. With bold, equitable action, the GEO-7 report envisions a resilient future where prosperity and planetary health thrive together.

1.4 Structure of GEO-7

The report is divided into five parts. Each section begins with an Indigenous Knowledge and Local Knowledge chapeau that sets out Indigenous Peoples' perspectives on each of the five sections.

Part A: Overview and Context (chapters 1 and 2) sets the scene and the context while also covering the Drivers and Pressures of environmental change.

A global environmental crises chapeau expands on the global environmental crises and their interrelationships and how feedback among crises aggravates their pressures but also highlights opportunities for solution pathways with co-benefits.

Part B: State and Trends of the Environment (chapters 3 to 8) describes the State and Trends of the environment and the impacts of environmental degradation on human systems. It also analyzes the state of the environment from a regional and subregional perspective and emphasizes the urgent need for change.

Part C: Outlooks (chapters 9 to 11) presents a methodological approach for developing target-seeking scenarios, utilizing both qualitative and quantitative methods. Subsequently, it presents and discusses an explorative scenario to discuss the likely environmental and socioeconomic implications of a continuation of these trends, as well as two target-seeking scenarios to show what is needed to achieve internationally agreed goals related to the global environmental crises.

Part D: Solution Pathways towards Transformation (chapters 13 to 18), introduces the methodological approach to solution-focused pathways, followed by a detailed overview of five different solution pathways for transformation.

Finally, Part E: Implications for Regions and Groups of Countries and Driving the Transformations (chapters 19 to 21) presents some implications, regional similarities and differences, and a concluding section.

Box 1.1: Global environmental crises: the urgency of transformative action

Global environmental assessments conducted by international organizations in collaboration with the global scientific community provide critically important insights into environmental change and its underlying causes.

Environmental action is urgently needed to sustain a liveable planet. Work on planetary boundaries, which draws upon Earth system science, identifies some processes that are critical for maintaining the stability and resilience of the Earth system as a whole and shows that boundaries are being exceeded (Rockström et al. 2009; Steffen et al. 2015; Steffen et al. 2018; Richardson et al. 2023; Caesar et al. 2024).

The framework update on planetary boundaries reveals that they are closely related and generate cascading effects upon one another. Seven of the nine boundaries—biogeochemical flows, freshwater change, land system change, biosphere integrity, climate change, novel entities and ocean acidification—have already been crossed, suggesting that Earth is now well outside of the safe operating space for humanity (Richardson et al. 2023).

The current global environmental crises are primarily a result of processes such as technological innovation, economic growth, and increased environmental impacts on natural systems. This ensemble of processes has been termed The Great Acceleration, which began in the second half of the 20th century and is unique in the history of human existence (Costanza et al. 2007; Steffen et al. 2007; McNeill and Engelke 2014; Steffen et al. 2015; Dasgupta 2021; Head et al. 2022; Shoshitaishvili 2021).

Credit: Freedomnaruk/Envato

Box 1.1: Global environmental crises: the urgency of transformative action (cont.)

Given that the health of people is closely connected to the health of animals and our shared environment, as encapsulated by the "One Health" concept, promoting a healthy planet should be the collective pursuit of all. The impacts of climate change, the unsustainable use of natural resources, the pollution of air, land and water, the unsound management of chemicals and waste, and the resulting loss of biodiversity and decline in benefits provided by ecosystems all interfere with achieving a healthy, equitable, and sustainable planet (Adla et al. 2022; Bastien-Olvera et al. 2023; Lenton et al. 2023).

Effective action is needed to address the underlying causes of unsustainability, and this action must be transformative. The definition of transformative change is evolving in academic debates and science-policy assessments (Fisher et al. 2022). In recent years, GEO-6, IPBES, and IPCC, for example, have defined transformative change respectively as:

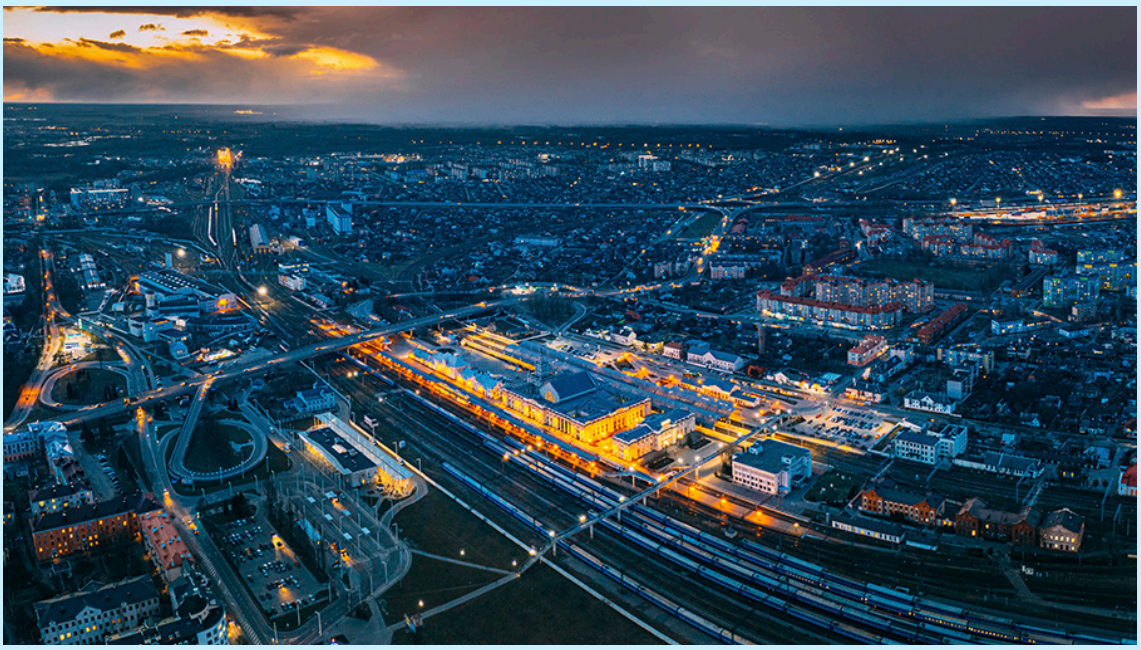
"The process whereby positive development results are achieved and sustained over time by institutionalizing policies, programmes and projects within national strategies. It should be noted that this embodies the concept of institutionally sustained results – consistency of achievement over time. This is in order to exclude short-term, transitory impact" (UNEP 2019a).

"Fundamental, system-wide reorganization across technological, economic and social factors, including paradigms, goals and values" (IPBES 2019).

"A system-wide change that requires more than technological change through consideration of social and economic factors that, with technology, can bring about rapid change at scale" (IPCC 2023).

The most comprehensive assessment of transformative changes is provided by the recent IPBES Assessment on Transformative Change, which focuses on biodiversity (O'Brien et al., 2024). It highlights

Credit: IciakPhotos/Envato



Box 1.1: Global environmental crises: the urgency of transformative action (cont.)

three underlying causes: disconnection from and domination over nature, the concentration of power and wealth, and the prioritization of short-term decision-making based on individual and material gain. It recommends certain types of changes as ways forward, such as economic system transformations moving away from growth and structural and sociocultural worldviews and values shifting from domination to care (O'Brien et al. 2024).

Well-designed and effective policies and actions undertaken by diverse actors are likely to be part of such transformative change. Shifting from 'incremental' to 'transformative' change demands a radical reassessment of the existing frameworks of economic, political, and social systems (Iversen et al. 2018). Indigenous Peoples' ways of knowing, being, and relating offer valuable practices for caring for land, people, and ecologies in ways that align with an ethics of care and challenge extractivism, appropriation, and treating nature as separate from humans and a resource for human use and benefit. Indigenous scholars and representatives have identified "…ongoing processes of colonialism, dispossession, capitalism, imperialism/globalization and patriarchy…" as the root causes of our current global environmental crises and environmental injustices (McGregor, Whitaker and Sritharan 2020; IK & LK Dialogues 2025). These insights merit consideration for achieving sustainability.

Transforming human systems, the economic and financial, energy, food, material resources, and environmental systems together with sociocultural and behavioural shifts, would contribute significantly to creating a world with a stable climate while also delivering equity and justice for all life on Earth and future generations.

Transformation processes can promote equity and justice by following key principles of inclusion, participation and plurality; by seeking to address socioeconomic and power imbalances related to gender, class, ethnicity, religion, age, indigeneity, disability, and by recognizing that geographic aspects can interact in multiple ways with environmental problems and exacerbate in policy design (UNEP 2019b; UNEP 2021; UNDP 2020). Additional care should be taken for those who are particularly vulnerable to environmental degradation, in line with human rights and considering emerging nature rights and representation.

Appendix 1.1 Key findings from previous global environmental assessments since 2019

Organization/ Author(s) and year	Title	Evaluation of Step or Procedure Check List
IPBES 2019	*Global Assessment Report on Biodiversity and Ecosystem Services*	Globally, nature is declining at rates unprecedented in human history. The decline in biodiversity, a direct result of human activity, has been accelerating despite awareness that this poses a significant threat to human well-being.
IPCC 2019	*IPCC Special Report on the Ocean and Cryosphere in a Changing Climate*	Over the last decades, global warming has led to the widespread shrinking of the cryosphere. Since 1993, the rate of ocean warming has more than doubled and by absorbing more CO_2, the ocean has undergone increasing surface acidification. A loss of oxygen has occurred from the surface to 1000 m.
UNEP 2019a	*Global Chemicals Outlook, 2nd edition*	Hazardous chemicals and other pollutants, including plastic waste and pharmaceutical pollutants, continue to be released in large quantities and accumulate in the environment, underscoring the need to prevent future legacies through sustainable materials management and circular business models.
WRI 2019	*Creating a sustainable food future*	As the global population grows and incomes grow across the developing world, overall food demand is projected to increase by more than 50 per cent till 2050.
Eggleton 2020	*The State of the World's Insects*	Recent studies have indicated a worrying decline in insect species, especially in flying insects in the northern temperate region due to agricultural intensification, urbanization, overuse of pesticides, and global climate change. However, there is too little data to warrant the belief that all insects are declining everywhere.
FAO & UNEP 2020	*The state of the world's forests*	Deforestation and forest degradation continue to occur at alarming rates, contributing significantly to the ongoing loss of biodiversity.
Royal Botanical Gardens Kew [RBGK] 2020 **(Antonelli *et al.* 2020)**	*State of the world's plants and fungi*	Two in five plants are estimated to be threatened with extinction.
SCBD 2020	*Global Biodiversity Outlook, 5th edition*	Biodiversity decline has been continuing: at the global level, none of the 20 Aichi Targets have been fully achieved, though six targets have been partially achieved.
UNDP 2020	*Human Development Report*	Humans are destabilizing the planetary systems on which they rely for their survival.
IPCC & IPBES 2021 **(Pörtner *et al.* 2021)**	*IPBES-IPCC Co-sponsored workshop Biodiversity and Climate Change. Scientific outcome*	Climate and biodiversity are inextricably connected with each other and with human futures.
International Resource Panel [IRP] 2021	*Building biodiversity*	Four principles of natural resource management – value-chain transparency, integrated landscape planning, nature-based and circular solutions, and recognize nature's benefits – can help countries effectively implement biodiversity policy.
Ramsar Convention 2021	*Global Wetland Outlook. Special edition 2021*	Although wetlands are critical to delivering on global commitments related to biodiversity, climate change, and sustainable development, their deterioration continues.
United Nations Office of Legal Affairs 2021	*The Second World Ocean Assessment*	Many pressures from human activities continue to degrade the ocean, including those associated with climate change, unsustainable fishing, the introduction of invasive alien species, atmospheric pollution causing acidification and eutrophication, excessive inputs of nutrients and hazardous substances, increasing amounts of anthropogenic noise, and ill-managed coastal development and extraction of natural resources.

Organization/ Author(s) and year	Title	Evaluation of Step or Procedure Check List
UNEP 2021	*Making peace with nature*	Humankind faces three crises: climate change, biodiversity loss and pollution. Environmental changes are undermining hard-won development gains by incurring significant economic costs and resulting in millions of premature deaths annually. They are impeding progress towards ending poverty and hunger, reducing inequalities, and promoting sustainable economic growth, work for all and peaceful and inclusive societies.
Birdlife International 2022	*State of the World's Birds 2022*	One in eight bird species is threatened with extinction, and the status of the world's birds continues to deteriorate: species are moving ever faster towards extinction.
FAO 2022	*The State of Food and Agriculture 2022*	If implemented correctly, agricultural automation can contribute to inclusive and sustainable agrifood systems.
Global Mangrove Alliance [GMA] 2022	*The State of the World's Mangroves 2022*	Halting loss means bringing global mangrove losses to zero by 2030, equating to 168 km^2 of avoided loss of mangroves. Restoring half refers to the recorded losses since 1996 and equates to some 4,092 km^2 of restoration.
International Energy Agency [IEA] 2022	*World Energy Outlook 2022*	Seventy million people who recently gained access to electricity will likely lose it. As markets rebalance, renewables, supported by nuclear power, see sustained gains; the upside for coal from today's crisis is temporary. The increase in renewable electricity generation is sufficiently rapid to outpace growth in total electricity generation, thereby reducing the contribution of fossil fuels to power.
IPCC 2022	*IPCC Special Report on Climate Change, Desertification, Land Degradation, Sustainable Land Management, Food Security, and Greenhouse gas fluxes in Terrestrial Ecosystems*	People currently use one-quarter to one-third of land's potential net primary production for food, feed, fibre, timber, and energy. Global population growth and changes in per capita consumption of food, feed, fibre, timber, and energy have led to unprecedented rates of land and freshwater use, with agriculture currently accounting for approximately 70 per cent of global freshwater use.
UNCCD 2022	*Global Land Outlook, 2nd edition*	Two in five plants are estimated to be threatened with extinction.
Wetlands International 2022	*We need wetlands*	Since 1970, 35 per cent of the world's wetlands have been lost.
World Wildlife Fund [WWF] 2022	*Living Planet Report*	An average decline of 69 per cent was found in almost 32,000 selected wildlife populations between 1970 and 2018.
Finn et al. 2023	*More losers than winners: Investigating Anthropocene defaunation through the diversity of population trends*	There is a widespread global erosion of species, with 48 per cent undergoing declines, while 49 per cent and 3 per cent of species currently remain stable or are increasing, respectively.
Independent Group of Scientists appointed by the Secretary-General 2023	*Global Sustainable Development Report 2023*	Overall progress towards the 2030 Agenda and its Sustainable Development Goals has been severely disrupted over the last three years, yet every inch of progress matters and counts. Transformations are possible and inevitable.
IPBES 2023	*Thematic Assessment Report on invasive alien species and their control*	Invasive alien species pose major global threats to nature, economies, food security and human health. For example, they have played a key role in 50 per cent of global plant and animal extinctions.

Organization/ Author(s) and year	Title	Evaluation of Step or Procedure Check List
IPCC 2023	*Synthesis Report of the IPCC Sixth Assessment Report (AR6)*	Human activities, principally through emissions of greenhouse gases, have unequivocally caused global warming, with the average global surface temperature reaching 1.1°C above 1850-1900 levels in 2011-2020. Global greenhouse gas emissions have continued to increase. Human-caused climate change is already affecting many weather and climate extremes in every region across the globe.
Lenton et al. 2023	*The Global Tipping Points Report 2023*	Climate change and nature loss could soon cause the crossing of tipping points in the natural world. These tipping points pose threats of a magnitude that humanity has never faced before.
MacAlister et al. 2023	*Global Water Security 2023 Assessment*	Alarmingly, most of the world's population lives in water-insecure countries today. Out of 7.78 billion people living in 186 countries, over 0.61 billion people, or 8 per cent, are critically water-insecure and 5.52 billion, 72 per cent, are water-insecure. In addition, 0.65 billion people, eight per cent, live in moderately water-secure countries.
UNEP 2023a	*Environmental Effects of Stratospheric Ozone Depletion, UV Radiation, and Interactions with Climate Change 2022 Assessment Report*	The Montreal Protocol has prevented significant increases in surface UV-B radiation, with the greatest benefits at high latitudes.
UNEP 2023b	*Global Framework on Chemicals*	Pollution is the world's most significant risk factor for disease and premature death, with pollution from chemicals contributing to millions of deaths, illnesses and disabilities each year. The sound management of chemicals and waste is essential for achieving the goals of the 2030 Agenda for Sustainable Development.
World Economic Forum [WEF] 2023	*The Global Risks Report 2023*	Natural ecosystems are past the point of no return.
WMO 2023a	*United in Science 2023*	Human-induced climate change is affecting life-sustaining systems. Looking beyond the 2030 time frame, new technological solutions and gradual changes in consumption patterns are needed at all levels.
WMO 2023b	*Provisional State of the Global Climate 2023*	The global mean near-surface temperature to October in 2023 was around 1.40 ± 0.12 °C above the 1850–1900 average. Based on the data to October 2023, it is virtually certain that 2023 will be the warmest year in the 174-year observational record. The past nine years, 2015–2023, will be the nine warmest years on record.
FAO 2024	*The State of World Fisheries and Aquaculture 2024*	Fishery resources continue to decline due to overfishing, pollution, poor management, and other factors, but the number of landings from biologically sustainable stocks is on the rise. Aquaculture has great potential to feed and nourish the world's growing population, but growth must be sustainable.
Health Effects Institute 2024	*State of Global Air 2024 Special Report*	In 2021, air pollution contributed to 8.1 million deaths – more than 1 in 8 deaths worldwide, being the second leading risk factor for death among children under 5 in 2021, after malnutrition.
IUCN 2024	*Red List of Mangrove Ecosystems*	Fifty per cent of the world's mangrove areas are at risk of collapse, and one out of five of these ecosystems are at severe risk of collapse.
Sachs et al. 2024	*Sustainable Development Report 2024*	On average, only 16 per cent of the SDG targets are on track to be met globally by 2030, with the remaining 84 per cent showing limited progress or a reversal of progress.
UNEP 2024b	*Food Waste Index Report 2024*	Previous estimates of consumer food waste significantly underestimated its scale. Food waste generates an estimated 8–10 per cent of global greenhouse gas emissions (including from both loss and waste), and it takes up the equivalent of nearly 30 per cent of the world's agricultural land.

Organization/ Author(s) and year	Title	Evaluation of Step or Procedure Check List
UNEP 2024c	*Global Waste Management Outlook 2024*	Every year across the globe, more than two billion tonnes of municipal solid waste is generated. For a liveable future, the current pattern of resource use needs to be halted with urgency, and zero waste and circular economy strategies must be implemented to protect the human rights of future generations.
UNEP 2024d	*Global Resources Outlook 2024*	Extraction and processing of material resources account for over 55 per cent of greenhouse gas emissions and 40 per cent of particulate matter's health-related consequences. If land-use change is considered, climate effects grow to more than 60 per cent, with biomass contributing the most at 28 per cent, followed by fossil fuels at 18 per cent, and then non-metallic minerals and metals, together at 17 per cent. Biomass from crops and forestry also accounts for over 90 per cent of the total land-use-related biodiversity loss and water stress. All environmental impacts are on the rise.
United Nations Educational, Scientific and Cultural Organization [UNESCO] 2024	*The United Nations World Water Development Report 2024: Water for Prosperity and Peace*	Climate change, geopolitical unrest, pandemics, mass migration, hyperinflation and other crises can exacerbate water access inequalities. In nearly all cases, the poorest and most vulnerable groups are those who suffer the most significant risks to their well-being.

Chapter summary

Credit: tampatra/Envato

A growing economy, increasing population and changing lifestyles are driving the demand for goods and services, such as materials, energy, and food. However, the current systems for producing and consuming these resources are unsustainable. They are shaped by poor governance structures and policies, particularly in the areas of economics and finance, as well as behaviours and technologies that promote land-use change, resource exploitation, greenhouse gas emissions, pollution, and the spread of invasive alien species. These pressures contribute to the interconnected global environmental crises of climate change, biodiversity loss, land degradation and desertification and pollution and waste. Addressing these challenges and achieving internationally agreed goals requires a deep understanding of how these drivers interact and how to transform the economic and financial, material resources, energy and food systems to manage their environmental consequences effectively.

Drivers of change

The global human population grew from 3 billion in 1960 to 8 billion people in 2022, and is projected to reach 9.7 (10.1 – 9.3) billion people by 2050 and 10.2 (9.3 – 11.1) billion people by 2100 (*well established*). Rising per capita wealth, combined with population growth and prevailing patterns of production and consumption, is likely to generate demand for goods and services that exceeds the planet's capacity to safeguard the global environment's vitality and to support sustainable and equitable human development. However, levels and forms of consumption vary widely across and within countries, depending on factors such as the level of development and income {2.2.1}.

Global population growth rate was 0.9 per cent in 2022 and is projected to decline to 0.42 per cent (0.32-0.52 per cent) by 2050 (*well established*). Many countries anticipate declining populations in the coming decades, creating opportunities for a natural and social "depopulation dividend". A further decrease in the UN projected medium fertility rate could reduce the global population in 2100 from 10.2 billion to 7 billion (United Nations 2022). Ensuring universal access to education and healthcare, particularly by advancing girls' and women's education and empowerment, as well as reducing natural resource consumption, is essential for protecting environmental sustainability for future generations {2.2.1}.

Global gross domestic product increased from US$9.14 trillion in 1960 to US$93.35 trillion in 2023 (adjusted to 2015 US dollars), and is expected to more than double

by 2050, with the fastest growth occurring in emerging economies (*well established*). Per capita gross domestic product has increased fourfold since 1960 and is expected to double again by 2050 (*well established*). There is an urgent need to reform economic policies to address current and future global environmental crises and to introduce new measures for human development in economic decision-making. The significant disparities in economic progress across regions highlight the importance of incorporating social equity and environmental factors into development strategies that better balance economic growth with environmental sustainability (*established but incomplete*) {2.2.2}.

Understanding how lifestyles impact environmental issues is crucial for promoting effective environmental action (*well established*). Since 1960, per capita consumption has quadrupled, and by 2023, advanced economies are consuming 70 per cent more than the global average. This growth is partly driven by a shift toward more resource-intensive lifestyles, fuelled by increasing per capita incomes (*well established*). By adopting demand-side strategies in key sectors such as buildings, transportation, and food, it is possible to achieve a substantial reduction in global greenhouse gas emissions, ranging from 40 per cent to 70 per cent by 2050 (*well established*). Complementing these strategies, initiatives that incorporate core values of caring for nature, Indigenous Knowledge, and Local Knowledge that protect the environment, along with leveraging sociocultural drivers, building trust, and shaping social norms, offer avenues to foster sustainable behaviours, mitigate climate change, and lay the groundwork for a more sustainable future for generations to come (*well established*) {2.2.5; 10.3; 12.2; 12.3}.

Governance and environmental quality are directly and indirectly interlinked, and the lack of a clear alignment between governance structures and environmental goals often contributes to or exacerbates environmental degradation (*well established*). Weak implementation of general governance practices that contribute to environmental degradation includes issues such as corruption control, governmental effectiveness, transparency, and accountability measures. Improving policymaking and enforcement is essential and requires urgent action to address the limited access to reliable and comprehensive information, low public awareness, and the need for more inclusive public engagement. Additionally, there is a deficiency in sustainability-related disclosures and reporting in both the public and private sectors (*well established*). Since whole-of-government and whole-of- society approaches are necessary to achieve agreed environmental and social goals, national cross-government coordination will be crucial for developing and implementing the required policies, along with international coordination {2.2.6}.

Supply chains for clean energy technologies are becoming more susceptible to issues related to the acquisition and distribution of critical minerals. This vulnerability leads to land degradation, harm to biodiversity, and increased climate-related conflicts, such as water stress for local communities, resulting from competition for global resources (*virtually certain*). Key clean energy technologies such as solar PV, wind, electric vehicles, batteries, electrolysers, and heat pumps are expanding rapidly. They are expected to drive the fastest growth in global electricity demand (*well established*) {2.2.3}.

Digital transformation can support the efficient distribution of resources, balance supply and demand, and drive the development of innovative city solutions. These efforts can positively impact the achievement of the SDGs and promote social inclusion (*well established*). However, these advances, especially in artificial intelligence, are occurring much more rapidly than traditional regulatory and legislative processes, which can also increase social risks and ethical challenges. Their lifecycle environmental impacts, for example, are uncertain, with energy and water demands expected to rise globally (*virtually certain*) {2.2.3}.

Urbanization is rapidly expanding worldwide, with 55 per cent of people now residing in urban areas. By 2030, this number is expected to increase to 60 per cent, and by 2050, 68 per cent of the global population is projected to live in cities (*well established*). Developing countries, especially in Asia and Africa, are undergoing significant growth (*well established*). Urbanization can foster economic opportunities while also bringing significant economic, social, and environmental pressures (*well established*). Urbanization has the potential to reduce per capita environmental impact through economies of scale, but so far, it has typically increased resource use due to residents' higher incomes and demand for goods and services (*well established*) {2.2.4}.

The number of natural event-driven shocks threatening over 10,000 people – through death, injury, or homelessness – has more than tripled in the past 40 years *(well established)*. They accounted for half of all

Credit: Shaiith/Envato

shocks in 1980, increasing to two-thirds by 2022. The effects of shocks on the environment, exacerbated by climate change, have led to widespread and irreversible damage in terrestrial, freshwater, cryospheric, and coastal and open-ocean ecosystems (*well established*) {2.2.7}.

Pressures that affect the global environment

Land-use changes mainly involve shifts between cropland and forest, accounting for about 30 per cent of all observed transitions. From 2000 to 2020, cropland area expanded slightly worldwide, mostly due to growth in Sub-Saharan Africa, Southeast Asia, and parts of Latin America. Meanwhile, North America, Europe, and Eastern Asia saw decreases in cropland (*established but incomplete*). However, the expansion of cropland and plantations has sometimes led to deforestation in certain areas, impeding biodiversity, ecosystem services, Indigenous Peoples' livelihoods, and carbon storage. While global forest areas have decreased, some progress has been made in reducing deforestation in specific regions. However, some policies aimed at mitigating deforestation have resulted in human rights and Indigenous Peoples' rights violations, underscoring the need for a more inclusive evaluation (*well established*) {2.3.1}.

Indigenous Peoples' traditional lands sustain much of the world's biological and cultural diversity, but are facing increasing pressure (*well established*). Indigenous Knowledge and Local Knowledge systems support numerous adaptations, interspecific relationships, and stewardship practices that enhance environmental productivity, species abundance, distribution, richness, ecosystem functioning, and social-ecological resilience (*well established*). Indigenous populations and their unique connections to their environments are threatened by global environmental change drivers and pressures. Efforts by Indigenous communities to defend their lands and waters are frequently met with penalties, intimidation, and violence. To counter these dangers, it is urgent to protect and clearly define Indigenous lands and uphold Indigenous Peoples' rights over those territories (*well established*) {2.2.1, 2.2, 2 2.2.3}.

The excessive and unsustainable use of both finite and renewable natural resources—such as fisheries, mineral deposits, and fossil fuel reserves—puts pressure on environmental systems (*well established*). Overfishing, habitat destruction, and illegal wildlife trade are accelerating biodiversity loss at unprecedented levels. The growing demand for rare earth elements and minerals, driven by urban growth and technological advancements, depletes finite reserves while causing

Credit: pilens/Envato

ecological damage and raising ethical concerns. Wood harvesting contributes to deforestation and emissions, despite efforts to promote sustainability. Overuse of freshwater, pollution, and poor management drain vital supplies {2.3.2}.

Global anthropogenic emissions of greenhouse gases – primarily carbon dioxide, methane, and nitrous oxide – reached a record high in 2023 of nearly 60 gigatons of CO_2 equivalent, driving unprecedented climate change. Of all sectors, 79 per cent of emissions originated from energy, industrial processes, transport, and buildings collectively, while 22 per cent came from agriculture, forestry, and land-use change. The pace of greenhouse gas emissions was moderated due to the increased adoption of renewable energy sources, such as solar and wind (International Energy Agency (IEA), 2023a). Although emissions from deforestation stayed high, efforts in afforestation and reforestation helped create a carbon sink, partially offsetting these emissions (*well established*) {2.3.3.1}.

The number of chemicals released into the environment, including plastics, has grown over time, with an estimated 350,000 chemicals available globally (Wang et al. 2020), and new threats arise, such as the forever chemicals (poly and perfluorinated chemicals) (*well established*). While some countries have strict regulations for new chemicals, many do not, which limits our ability to anticipate or currently measure adverse environmental and human health effects of these new chemicals on a global scale. Capabilities for improving our chemical risk assessments are being continuously developed, although they are not yet fully established {2.3.3.2}.

Invasive alien species are non-native plants and animals that are introduced outside their natural habitat and cause damage to ecosystems, human health, or the economy. The spread and introduction of these alien species are accelerating, driven by global trade and increased connectivity between regions and ecosystems (*well established*). Over 3,500 alien species with harmful impacts have been documented. Invasive alien species (IAS) have multiple adverse effects: they can spread diseases, outcompete native species, and decrease ecosystem function, especially in freshwater and island ecosystems (*well established*). Indigenous Peoples as well as local communities can view IAS as part of the landscape (*established but incomplete*) and have rights to self-determination in their management. Some IAS have positive impacts on quality of life, but most impacts are negative (*established but incomplete*) {2.3.4}.

2.1 Introduction

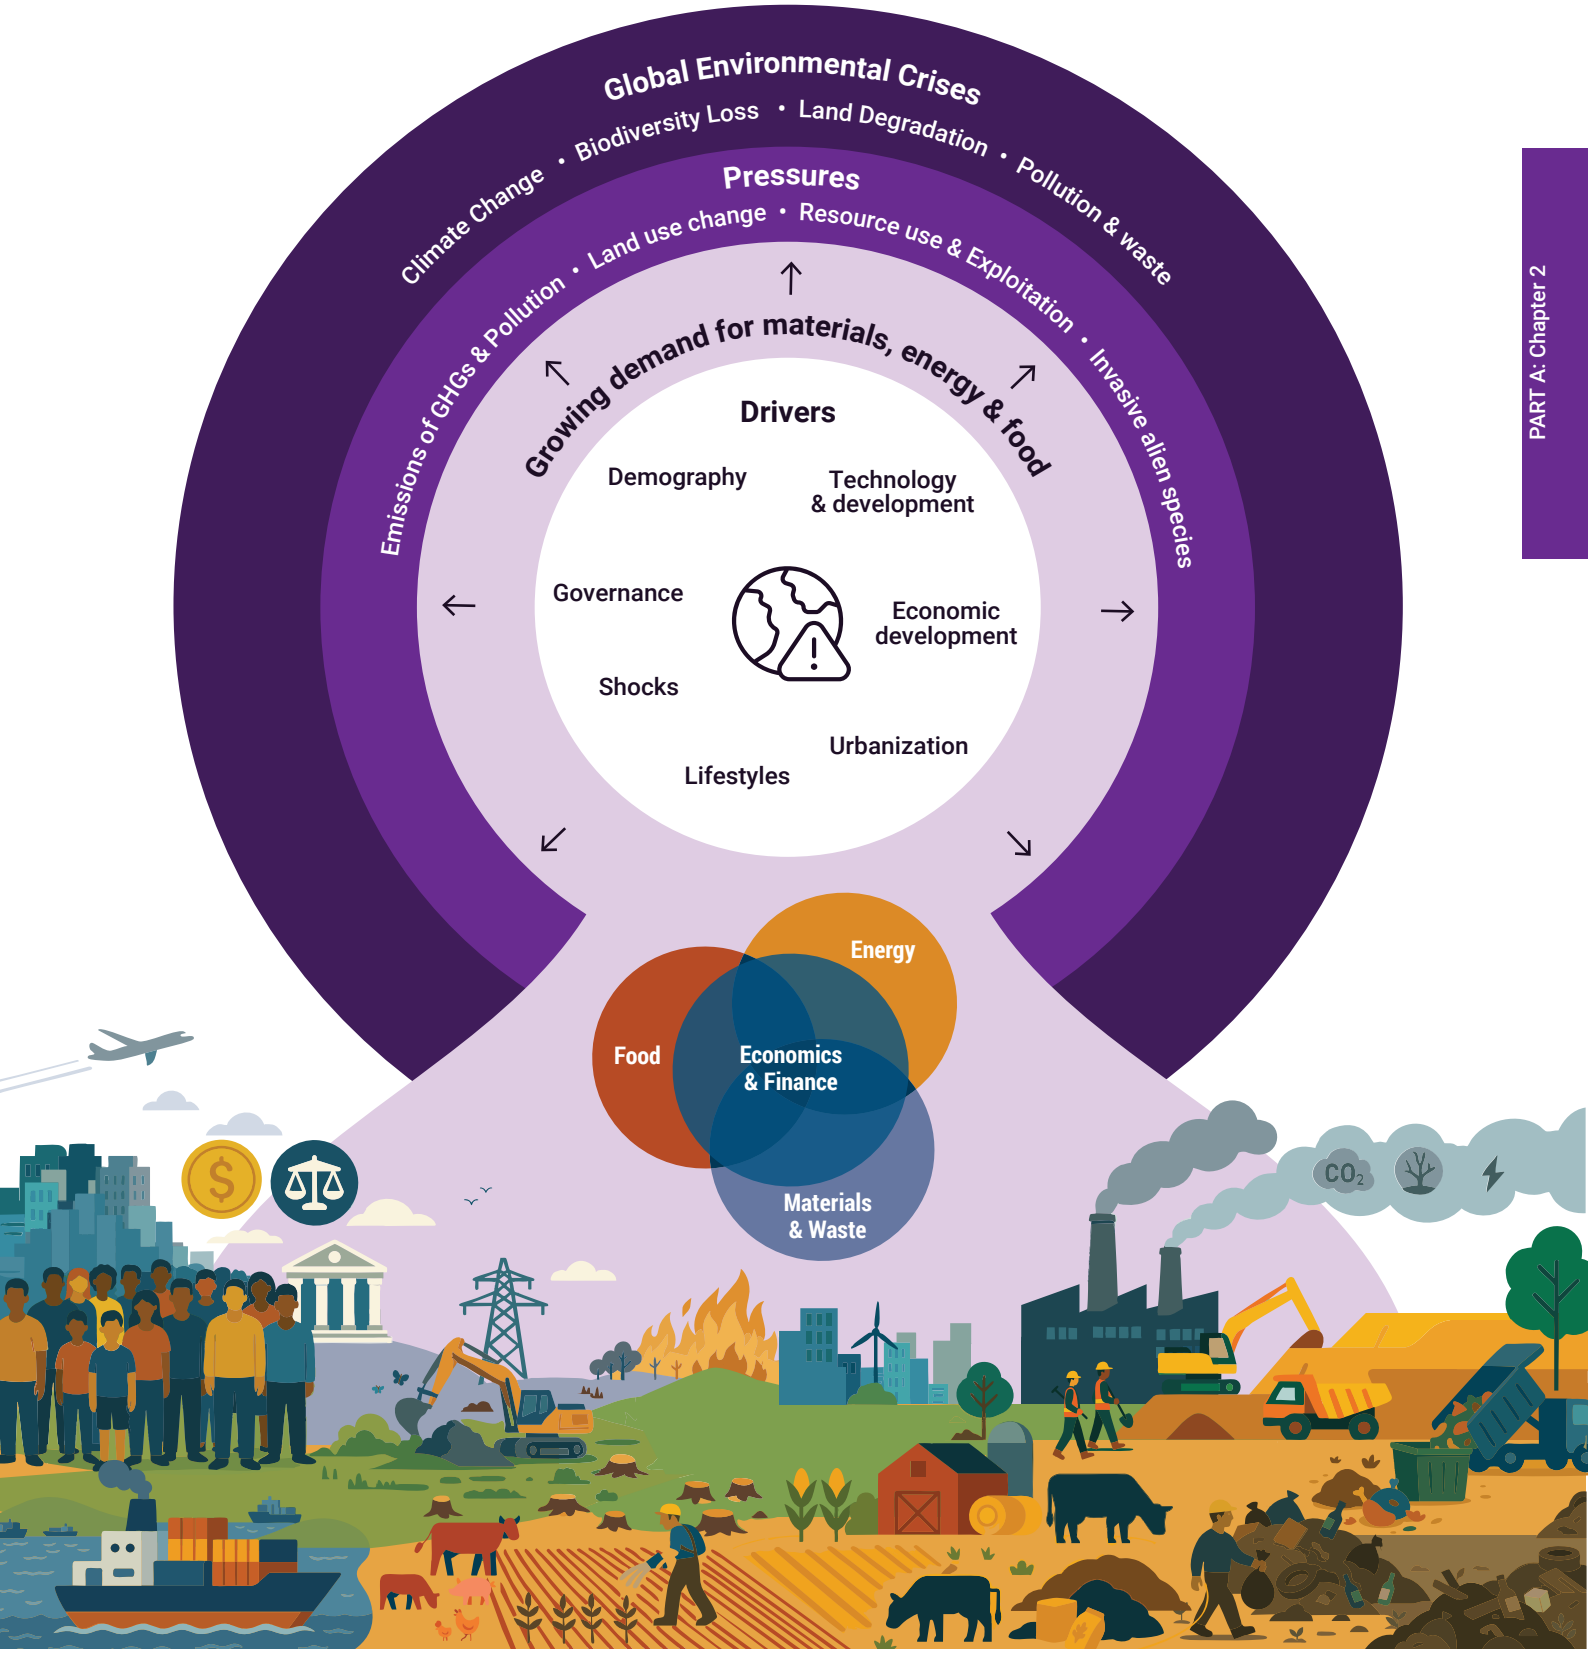
This chapter examines the historical, current, and future drivers, exploring how they interact and how they have influenced the demand for resources such as food, energy, and water. This demand, in turn, has caused ongoing pressures on the global environment. With a particular focus on solutions, this assessment draws on a comprehensive review of the IPCC, IPBES, IRP, GSDR, and previous GEO reports, as well as the Driver-Pressure-State-Impact-Response (DPSIR) Framework.

The DPSIR framework is an evolving conceptual and causal model. Alternative models of human-environment interactions exist, especially among the world's Indigenous Peoples. Indigenous models typically reject the human-environment and culture-nature dichotomies, instead viewing people as part of Earth Systems alongside other-than-human beings and forces. This relational approach often relies on respectful and reciprocal relationships between humans and the environment, aiming to maintain balance and sustainability. The DPSIR framework also rests on the idea that ecosystems and climate conditions have remained relatively stable over the past 11,700 years, allowing for the development of agriculture, cities, and modern societies. This assumption can shape how change and sustainability are understood in scientific frameworks.

In contrast, in the context of Indigenous systems, sustainability stems from Indigenous histories of influencing and adapting – or not – to environmental changes over extended periods in specific landscapes. In this grounded context, the abstract language of "systems" and "drivers" may not fully capture the lived experience or ways of understanding change (Gupta et al. 2020).

Indigenous perspectives on the current global environmental crises were highlighted through several dialogues convened with Indigenous Peoples for the GEO-7. Key causes behind environmental changes and their consequences, as observed within communities across major continents, include industrial development and pollution, degradation or displacement of local habitats and species, disruption of Indigenous relationships and practices that maintain ecosystem balance, and an increase in extreme events such as flooding that threaten local populations. Indigenous participants emphasized that these root causes of the global environmental crises must be addressed through education, policy, and practice by including Indigenous cultural and spiritual voices, values, and ways of knowing and sustaining the diversity and quality of life on Earth as part of living well (IK & LK Dialogues 2025).

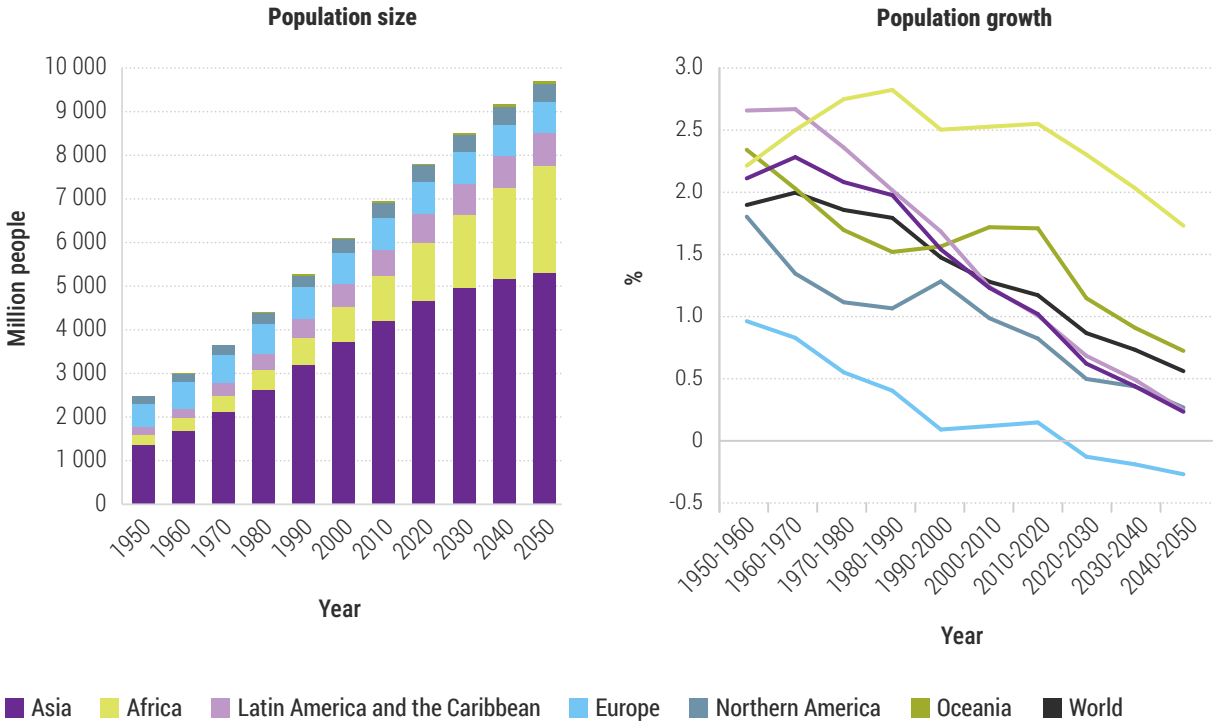
This chapter will describe the GEO-7 conceptual and methodological approach and highlight the likely relevance of GEO findings for other multilateral environmental agreements and processes. The chapter also examines the historical, current, and projected drivers and pressures of global environmental change, including the core assessment of human-environment interactions. It expands on the Driver-Pressure-State-Impact-Response (DPSIR) framework (see 1.2.1) and explores the interconnections between the drivers, pressures, and the "global environmental crises" **(Figure 2.1)** as defined by GEO-7. Formally, the global environmental crises are the crisis of climate change, the crisis of biodiversity loss, land degradation and desertification, and the crisis of pollution and waste. This chapter will treat land degradation with particular emphasis, as it represents intersections of the crises by featuring different facets.



The key elements of Chapter 2 include drivers (2.2), such as population and demographics, economic development, technology and development, urbanization, lifestyles, governance, and shocks, as well as pressures (2.3), including land-use change, resource use and exploitation, emissions such as greenhouse gases and other pollutants, and invasive alien species. It also covers the interlinkages among drivers, pressures, and environmental crises (2.4). **Figure 2.1** visually illustrates these critical nexuses and interconnections among drivers, pressures, systems, and global environmental crises described in this report.

2.2 Drivers of change

2.2.1 Demography



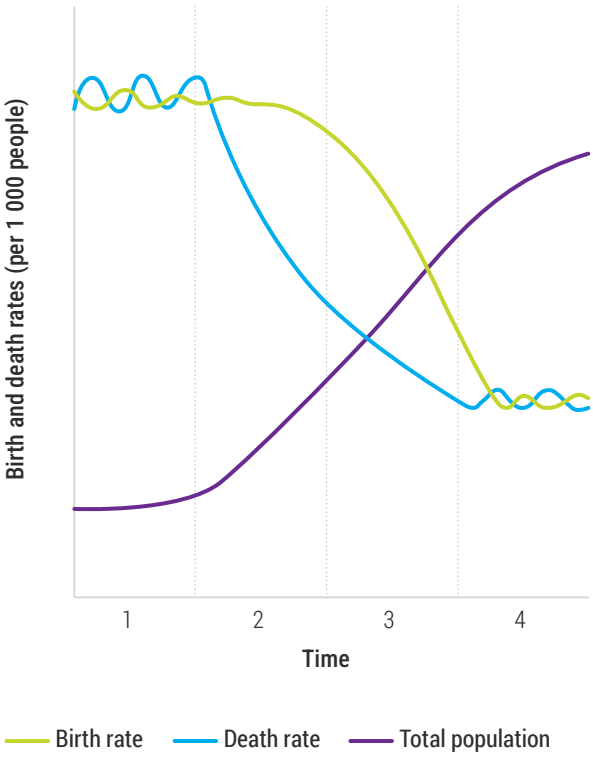
On November 15, 2022, the world population reached 8 billion people (United Nations Population Fund 2022). **Figure 2.2** illustrates how the global population has changed from 1950 to 2020, its projection to 2050, and the regional variations. The figure also shows the historical and projected growth rates for the global and regional populations during the same period (United Nations 2022). Despite the general decline in growth rates, the world population will continue to grow because

Figure 2.1: Transforming key human systems is essential to address the global environmental crises

Note: the figure shows that the ensemble of drivers results in an ever-increasing demand for materials, energy and food, which is being met using environmentally unsustainable production and consumption systems, embedded in economic, financing and governance systems which themselves are unsustainable. This results in ever-increasing pressures of emissions of greenhouse gases and pollutants, land-use change, resource use and exploitation, and invasive alien species, which in turn are the underlying causes of the global environmental crises. Therefore, addressing the global environmental crises requires transforming the dominant economics/finance, materials/waste, energy and food systems.

Figure 2.2: Past and future trends in global and regional population size and growth, 1950-2050

Source: United Nations (2022a)



the age structure includes a high proportion of people of reproductive age. This phenomenon is known as "population momentum" (Guo et al. 2020). This trend is true for all regions except Europe.

Globally, there are approximately 476 million Indigenous Peoples. While they make up only 6 per cent of the world's population, they represent about 19 per cent of people living in extreme poverty (International Labour Organization [ILO] 2019, p. 20).

Births and deaths for the global population, as well as migration for regional, national, and local populations, each contribute differently to population growth (Deuster et al. 2023). This results in varying demographic trends across regions. The demographic transition theory (**Figure 2.3**) categorizes these contributions into stages that form a timeline. This framework has been used to describe population changes worldwide and within specific countries and regions (Regional division from the United Nations: Africa, Asia, Europe, Latin America and the Caribbean, North America, Oceania).

In summary, the demographic transition involves a shift from high fertility and mortality rates to low fertility and mortality rates (Delventhal, Fernández-

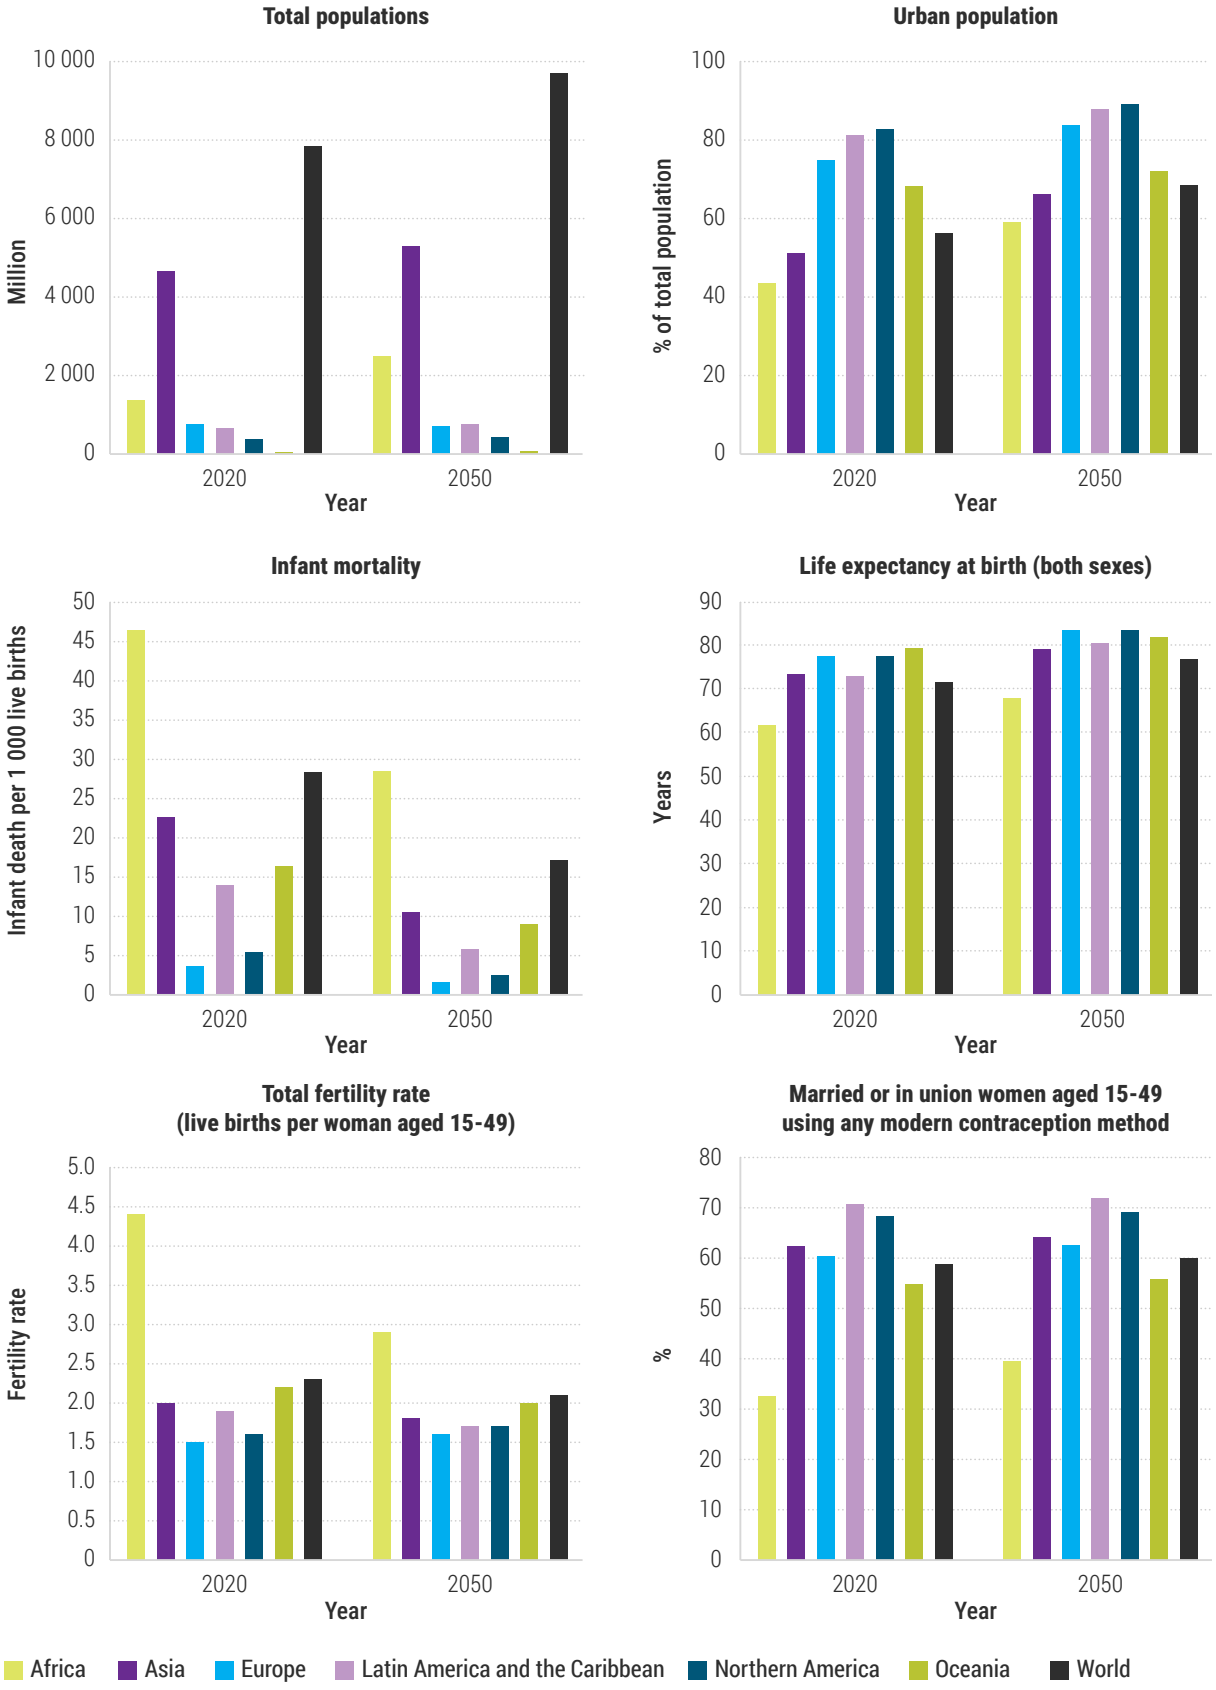
Figure 2.3: Stages of the demographic transition and the interplay of birth, deaths and total population

Source: Chorley (2015)

Villaverde, and Guner, 2021). The "demographic transition theory" describes how mortality, fertility, and growth rates change as societies transition between different demographic regimes. Initially introduced by American demographer Frank W. Notestein in the mid-20th century, this theory has been further developed by many scholars (United Nations Populations Fund 2019). In stage one, both birth and death rates are high, leading to slow population growth. During stage 2, death rates fall while birth rates stay high, causing rapid population growth. As birth rates begin to decline in stage 3, the growth rate slows. This pattern continues into stage 4, where both birth and growth rates are low, resulting in slow population growth again (Sloggett 2015; UNFPA 2019).

Trends for selected demographic indicators for the 2020-2050 period are presented in **Figure 2.4**. These numbers show the current state to 2020 and illustrate how populations in different regions are expected to change by 2050.

Regional or local differences in demographic trends and population growth result in the concentration of population in certain areas, such as cities and coastal regions. Expected changes in the spatial distribution of the world population between 2015 and 2030 are displayed in **Figure 2.5** using population densities. Larger declines are spread over extensive areas, while larger increases are concentrated in a reduced number of areas, notably on the coasts, Sub-Saharan Africa, and South and South-East Asia.



In summary, major demographic trends such as population growth and decline, population ageing, urbanization, and international migration shape our world. These trends are significant because population size, distribution, and composition, as well as demographic processes of fertility, mortality, and migration, are closely connected to the level and type of effects on natural resources and the environment (United Nations 2015; Khan et al. 2021; Wang, Wang and Li 2022). Changes in the size, age structure, and spatial distribution of populations present both challenges and opportunities. By effectively managing these challenges and leveraging the opportunities, we can accelerate progress towards inclusive and sustainable development, create pathways to eradicate poverty, improve access to social protection, healthcare, and education, promote gender equality, advance more sustainable production and consumption patterns, and safeguard the environment.

Direct effects of demographic trends include agricultural activities and commodities, waste and pollution, and overall consumption patterns of food, water, energy, and other resources. Indirect impacts include, for example, the contribution of corporate agriculture to greenhouse gas (GHG) emissions causing climate change. However, it is crucial to recognize that levels and forms of consumption, such as conspicuous consumption in high-income countries or groups versus meeting basic needs in low-income countries or groups, differ widely by region and country, and within them, and are linked to development level and income (Oswald, Owen and Steinberger 2020).

While the fertility-mortality balance determines global population growth and size, impacts on natural resources can also arise from migration and other forms of population mobility. Rural-rural migration directly affects natural resources negatively by clearing land for agriculture. Rural-urban migration, both domestic and international, directly affects resources through urbanization and urban expansion as land-use change, especially in early stages of urbanization when migration to cities usually increases. Finally, international migration has an indirect effect, either positive or negative, through remittances, which can be used for development or to increase and diversify consumption (Caulfield et al. 2019; Radel et al. 2019).

Among the major global environmental crises – climate change, biodiversity loss and land degradation, and pollution and waste – population growth is most evidently a key factor in biodiversity decline. This is largely due to increased demand for food production, which leads to agricultural expansion and land degradation (Cafaro, Hansson and Götmark 2022). As the population grows and consumption rises, fewer resources and less habitat are available for non-human species (Crist 2019). Overpopulation occurs when the total human population multiplied by per capita consumption surpasses the capacity of sustainable ecosystems and resources. Although the global human population continues to grow, per capita consumption is increasing at a faster rate. To the extent that people are disrupting natural habitats and degrading ecosystem services for future generations, despite regional heterogeneity, some research suggests that most of the world's nations may be considered overpopulated (Lianos and Pseiridis 2016; Tucker 2019).

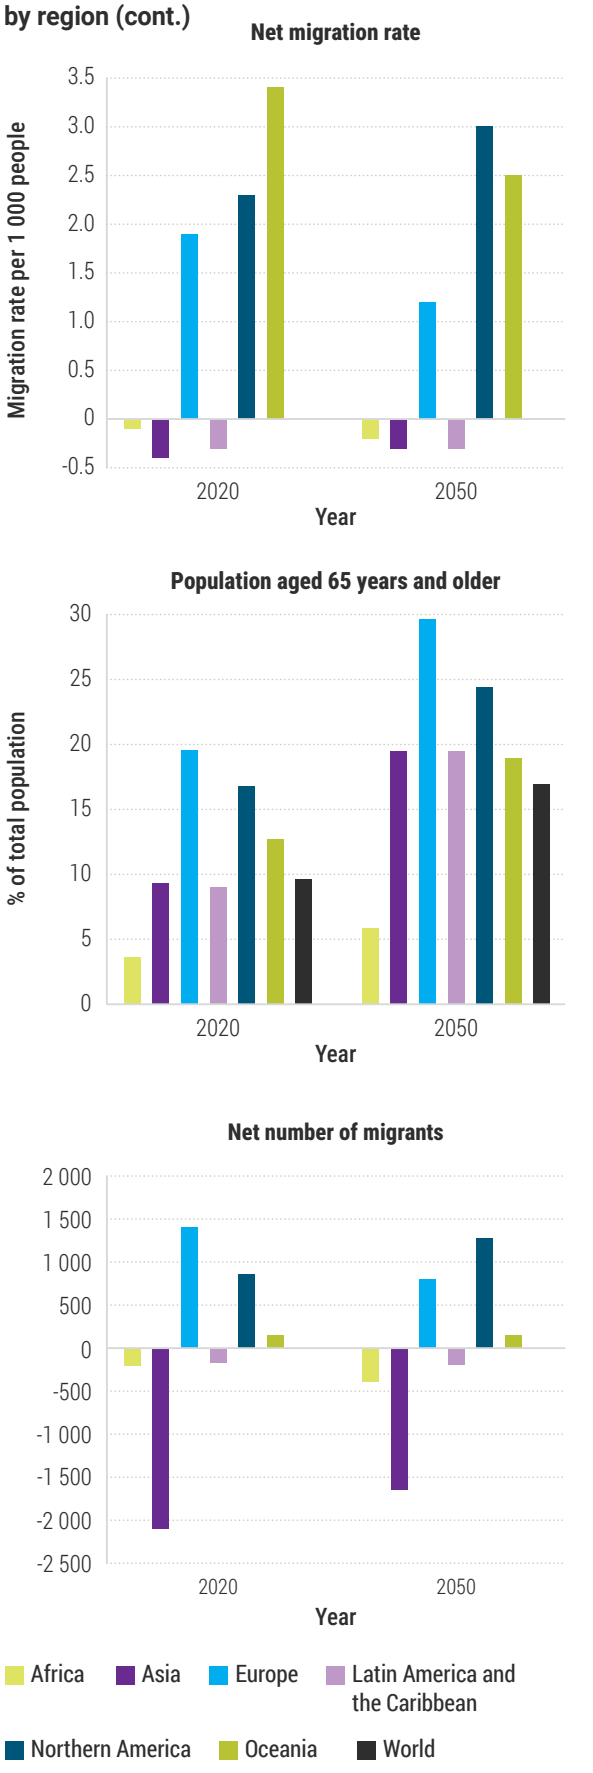


Figure 2.4: Trends in selected key demographic indicators in 2020 (estimated) and 2050 (projected) by region

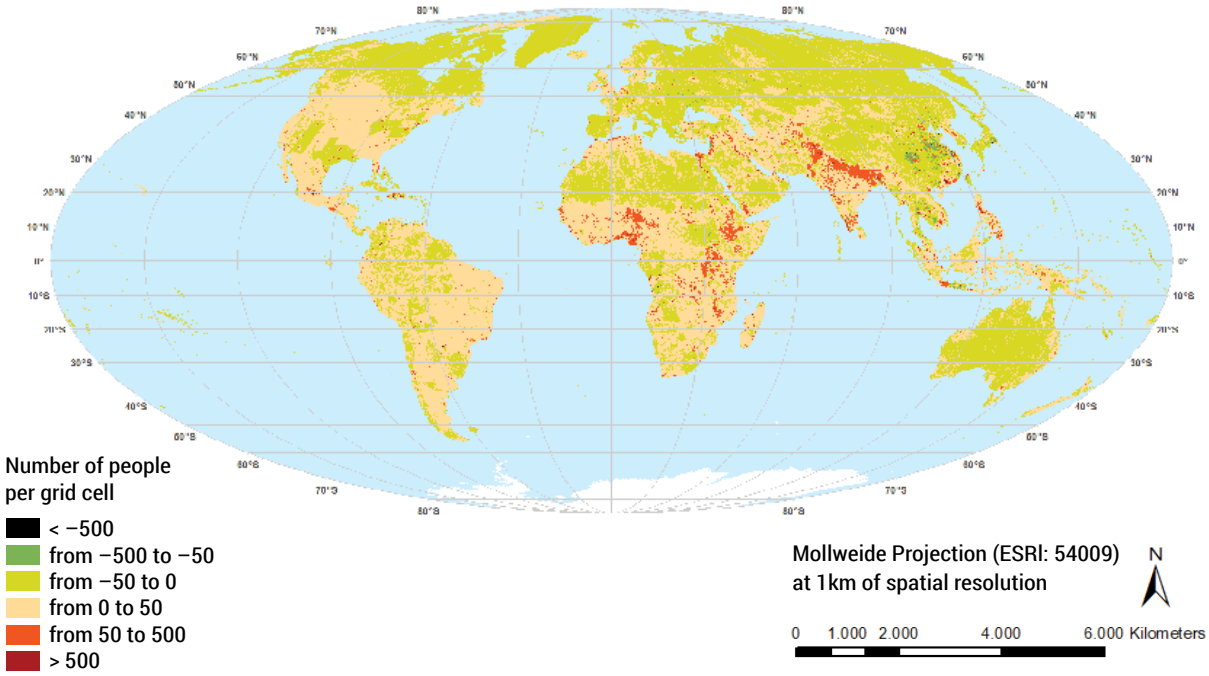
Note: The estimates for 2020 and projections to 2050 use medium fertility variant

Source: United Nations (2018; 2022a; 2022b)

Figure 2.4: Trends in selected key demographic indicators in 2020 (estimated) and 2050 (projected) by region (cont.)

Source: United Nations (2018; 2022a; 2022b)



The Global Assessment Report on Biodiversity and Ecosystem Services finds that agricultural expansion is the primary driver of land-based biodiversity loss, while overfishing is the leading cause of marine biodiversity declines (IPBES 2019). Both are worsened by an increasing human population through higher consumption and production. Rising rural populations lead to the conversion of wildlands into farmland, particularly among small farm households (Lopez-Carr and Burgdorfer 2013), while growing urban populations increase demand for animal protein, which is increasingly produced by large export farms (Marques et al. 2019). Although just under one-third of the Earth's land remains forested, population growth and higher consumption are reducing this area, with an estimated 10 million hectares cleared annually between 2015 and2020, or about 0.25 per cent of the total land area each year (Food and Agriculture Organization of the United Nations [FAO] 2022).

Population dynamics not only affect the environment but are also sensitive to environmental changes. For example, climate extremes increase population displacement in vulnerable regions, especially in Africa and Asia (Intergovernmental Panel on Climate Change [IPCC] 2023). Heat exposures are mainly caused by a combination of higher temperatures and population growth. Likewise, nearly half the global population faces water scarcity due to climate and non-climate factors, a proportion expected to rise because of climate change (Koutroulis et al. 2019; Seneviratne et al. 2021).

Although declining populations may present short-term economic difficulties, the current global population greatly exceeds levels compatible with maintaining biodiversity and ensuring sustainable human well-being, especially considering recent consumption patterns (O'Neill et al. 2018; Rees 2020). Some studies suggest that Earth could support a larger population, but recent research indicates that a sustainable world, even with improved consumption and production, should not surpass two to three billion people (Lianos and Pseiridis 2016; Dasgupta et al. 2019; Tucker 2019; Tamburino and Bravo 2021). However, UN projections (2019b) show that reducing fertility by half a child below the most likely UN medium variant rate would decrease the global population in 2100 by over 3.2 billion, from 10.2 billion to about 7 billion in the low-fertility scenario (United Nations 2022).

Further research is necessary to understand the links between population dynamics and biodiversity loss to

Figure 2.5: Projected changes in population density between 2015 and 2030

Note: The raster map depicts projected changes in population density between 2015 and 2030. Population density is defined as the number of people per square kilometre, which in this case is the size of the grid cell or pixel. Greenish shades indicate areas where population density is expected to decline, while reddish shades indicate areas where population density is expected to increase.

Data source: European Commission (2024)

determine how many people the world's countries can support while maintaining viable wildlife populations (Rust and Kehoe 2017). Nonetheless, many countries, especially those with higher consumption rates, anticipate declining populations in the coming decades, creating opportunities for wildland restoration – a natural and social "depopulation dividend" – provided that unsustainable consumption does not increase simultaneously (Matanle 2017).

Countries that promote the multiple health and economic benefits of smaller family sizes have been effective in reducing populations, whereas countries that have failed to implement such programmes continue to experience high population growth (Wyman and Yao 2017; Turner 2021). Universal access to modern contraception offers a potential win-win situation for women's empowerment and the environment (Cottingham, Germain and Hunt 2012; Engelman and Johnson 2019). Smaller family sizes can be encouraged through tax and benefits policies, as well as media outreach (Hornik and McAnany 2001; La Ferrara, Chong and Duryea 2012; Ryerson 2012; Cafaro 2021).

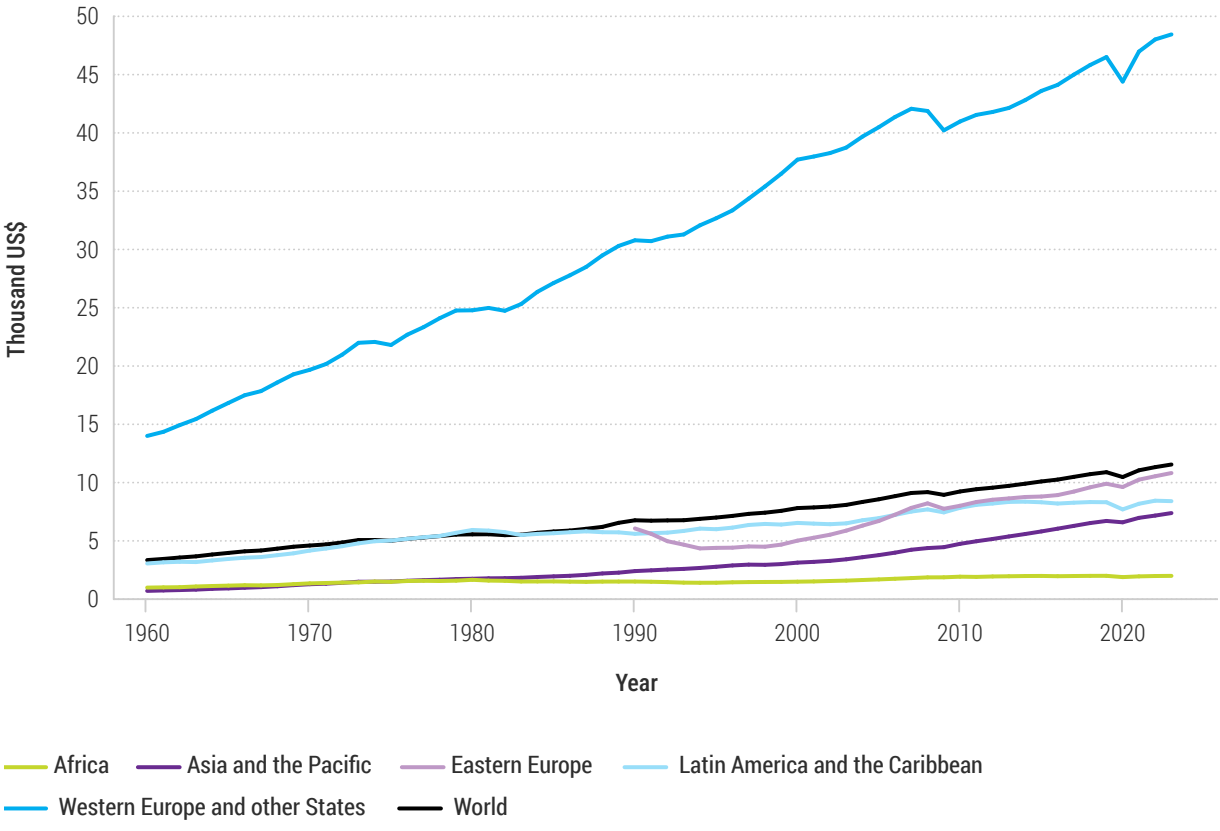
Such efforts are a moral duty that also yield environmental benefits for both nature and people. They can coexist with environmental conservation efforts. In fact, population-environment-health synergies have demonstrated how improving human health and livelihoods can align with protecting biodiversity (Lopez-Carr and Ervin 2017). In high-income countries, where populations are slowing or declining but per capita consumption remains high, reducing the use of natural resources – especially fossil fuels and animal protein – would significantly support environmental sustainability. Later chapters will explore other key environmental challenges and explore policies that can promote human well-being while preserving the resources and ecosystem services vital to everyone.

2.2.2 Economic Development

Economic development is a fundamental driver of environmental change. Key measures of economic development include gross domestic product (GDP) per capita, the Human Development Index (HDI), and growth in productivity, trade, labour force, and investment (World Bank 2023a). These measures align closely with projections from shared socioeconomic pathways, which consider factors such as physical and human capital, employment, energy demand, natural resources, and total factor productivity (Dellink et al. 2017). Shared socioeconomic pathway factors influence productivity growth and investment,

while the labour force, population (2.2.1), and technology development (2.2.3) also play important roles in economic development.

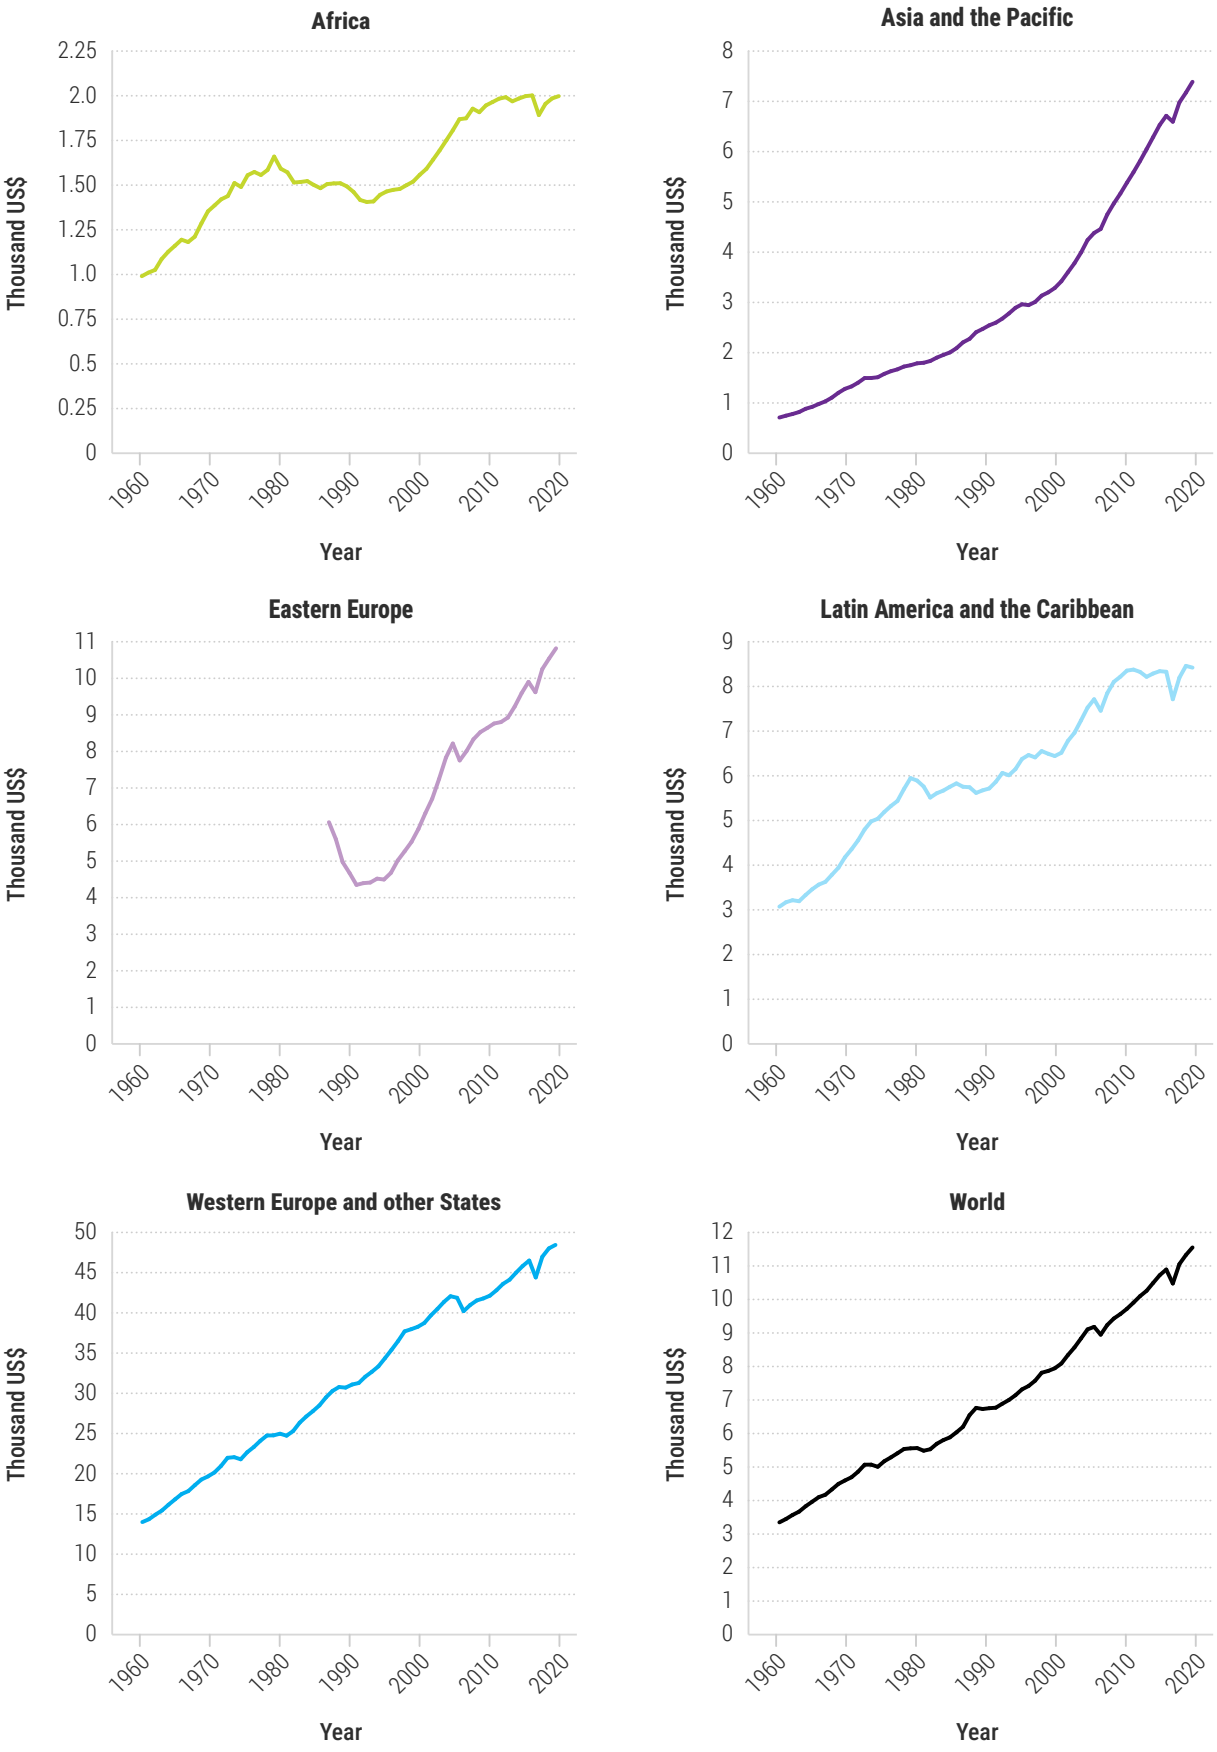
Trend in Economic Development by per capita GDP over the past six decades



Global GDP increased by over 7,000 per cent between 1960 and 2024 (Systems Change Lab 2025). Although this growth has led to positive societal gains, it has also been linked to significant social and environmental impacts, including two major downturns: the 2007-2008 global financial crisis and the 2020 COVID-19 pandemic (**Figure 2.6**). The data in **Figure 2.6** shows a generally steady trend in economic development, as measured by GDP per capita. However, substantial disparities persist across different regions. The African states have shown the least marginal improvement, followed by Asia and the Pacific states, which experienced noticeable growth starting in the late 1980s and early 1990s, which continued to widen through the 2000s. The Eastern European states and Western Europe and other states experienced similar patterns.

Trend in Economic Development as trade over the last six decades

The international trade trends shown in **Figure 2.7** from 1960 to 2023 reveal variations across various regions of the world. The importance of trade as a key element of economic development is well established in the literature. This is particularly important because it aligns with international logistics, different modes of international travel, and the global value chain, which all exert a driving force on economic activities, energy use, and the environment over the medium and long term (Akinyemi et al. 2019; Efogo, Wonyra and Osabuohien 2022). To avoid cluttering the analysis with multiple graphs, total trade – defined as the sum of exports and imports relative to GDP, and serving as a broad measure of trade openness – is plotted acro various economic group. This indicator is crucial as it reflects the comparative openness of an economy.



From the early years of the graphs (1960s to 1980s), it is clear that African States generally appear more open to trade than others. However, starting around 1990, when

Figure 2.6: Trends of per capita GDP (constant 2015 thousand US$) in the world and UN regions from 1960 to 2023

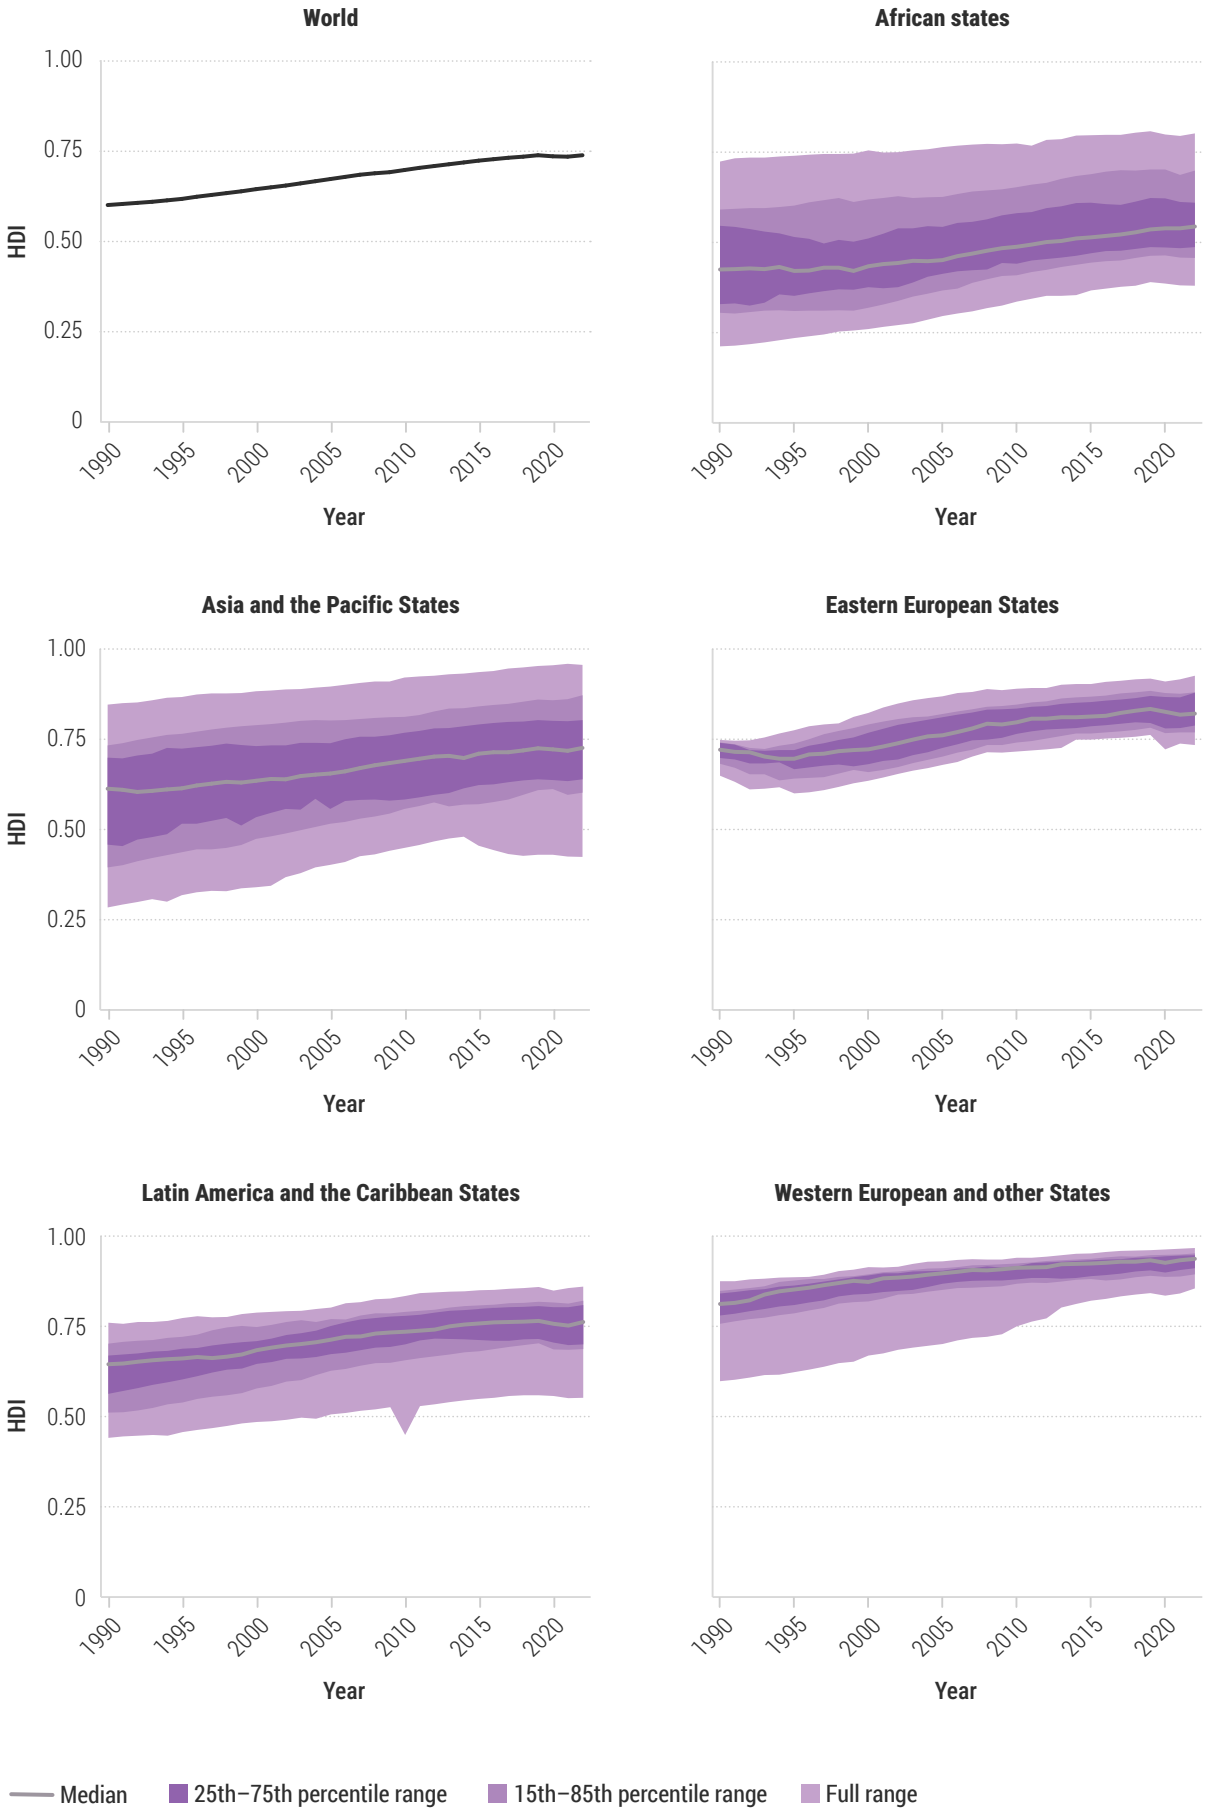
Figure 2.6: Trends of per capita GDP (constant 2015 thousand US$) in the world and UN regions from 1960 to 2023 (cont.)

Note: A distinct vertical axis scale is applied to each regional panel to better highlight the shape and evolution of the regional trajectories, e.g., steady growth, fluctuation and deceleration

Figure 2.7: Trends of Trade Openness across UNEP Regions (1960-2023)

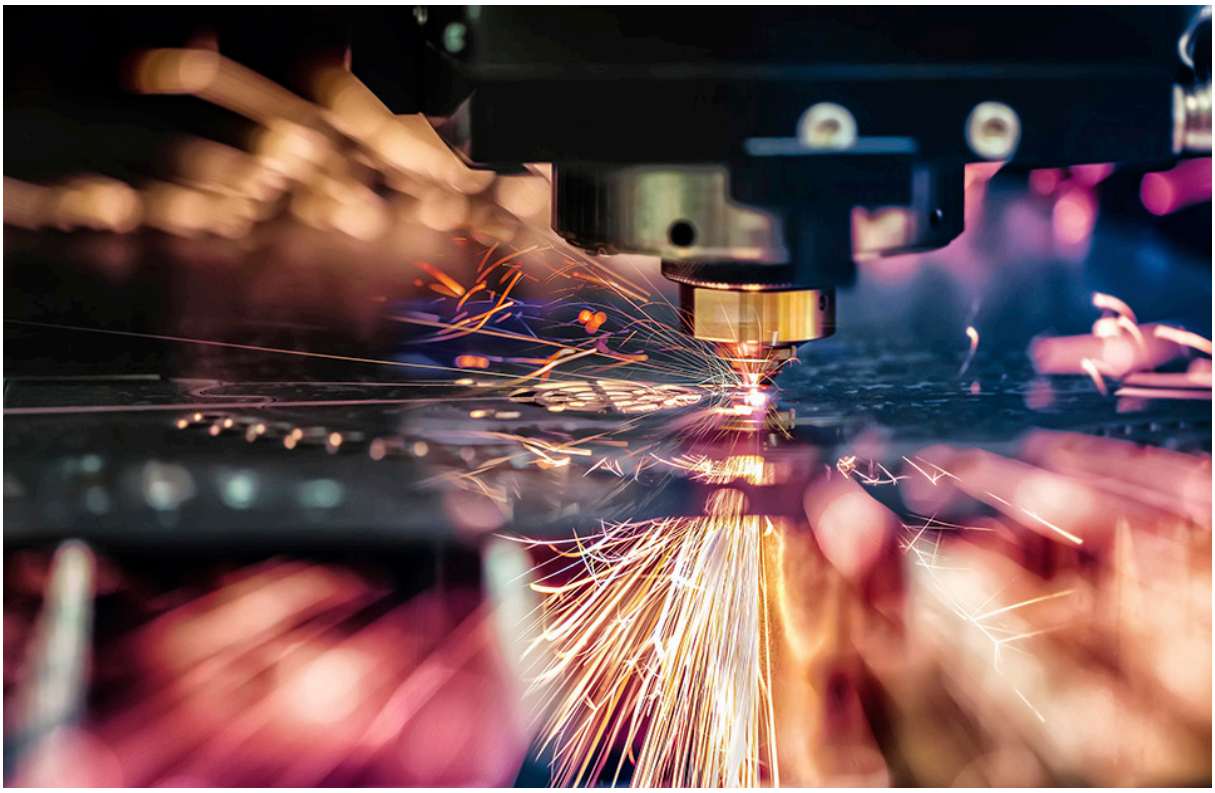
Source: World Bank | World Development Indicators

data from Eastern European States became available, different trend patterns emerge across the regions (2000-2023). The data suggests that Eastern European States have the highest trade openness, followed by Western European and Other States, Latin American and Caribbean States, with African States closely behind. Since trade openness is calculated using GDP as the denominator, this may influence the reported values. Despite this, the key insight from Figure 2.7 is that trade, as a part of economic development, likely interacts with environmental factors.



Enabling new metrics of human development in economic policymaking

HDI measures overall progress in three key aspects of human development, offering a broader perspective than GDP per capita. It encompasses health and longevity, knowledge, and a decent standard of living (United Nations Development Programme [UNDP] 2024). Currently, the global level of human development is rated as high on UNDP's development scale. HDI data, starting from 1990—the year it was first introduced—are shown in **Figure 2.8**.



The HDI estimated for the world increased from 0.601 to 0.739 from 1990 to 2022. The increase was observed across all the time series, except during the COVID-19 pandemic, as it declined from 0.739 in 2019 to 0.736 by 2020, and then to 0.735 in 2021. Despite the similarity with the overall global trend, it is important to highlight observable disparities across the UNEP regions. For the African states, the statistical median of the HDI distribution increased from 0.425 to 0.543, with the amplitude – the difference between the highest and the lowest – declining from 0.543 to 0.422. In the Asia-Pacific region, the median increased from 0.613 to 0.726, with a slight decline in the amplitude from 0.562 to 0.536. For the Eastern European states, it increased from 0.721 to 0.821, with an observable increase in the amplitude, from 0.099 to 0.183). For the Latin American region, the median increased from 0.645 to 0.762, while the amplitude exhibited a slight decline from 0.319 to 0.308. In the Western European and other states, the median increased from 0.811 to 0.937, with the amplitude declining from 0.277 to 0.112.

The scenarios might represent shocks such as wars and natural disasters that caused major declines in HDI. Such shocks include the 2014 war in Yemen among Asia-Pacific countries, the 2010 earthquake in Haiti in Latin America, and the war in Ukraine conflict in Eastern Europe beginning in 2022 that led to a notable HDI decrease in Ukraine, among others (UNDP 2024).

2.2.3 Technology and Development

Technologies play a dual role, helping to mitigate risks while also contributing to various environmental threats. Scientific and technological advancements must enhance regional adaptive capacity and strengthen the responses to future climate risks. Integrating Indigenous Knowledge and Local Knowledge into climate adaptation and mitigation efforts can lead to novel place-based solutions and innovations that can inform other regions.

Projection of future trends and the possible transition

By 2024, over 107 countries committed to achieving net-zero emissions within this 21st century, covering roughly 82 per cent of the world's emissions (United Nations Environment Programme [UNEP] and International Resource Panel [IRP] 2024). Recent extreme weather events have highlighted the potential rise in future energy demand, the vulnerability of supply systems, and the urgent need for bold actions to cut global GHGs. Resilient supply chains for manufacturing clean energy technologies are key to the global energy transition. The major clean energy technologies such as solar PV, wind, electric vehicles, batteries, electrolysers, and heat pumps have been growing fourfold since 2015, reaching beyond US$700 billion in 2023 (IEA 2024a). However, the clean energy transition to these technologies is projected to drive rapid growth in global electricity demand. As a result, more than 30 countries plan to expand their use of nuclear power, and there are other initiatives to accelerate the development of less mature technologies, including carbon capture, utilization, and storage, to meet the net-zero target (IEA 2024b).

These supply chain systems rely heavily on critical minerals and their geographic distributions. The end-use sector also consumes large amounts of energy embedded in materials, such as cement for infrastructure, steel for vehicles, and chemicals for fertilizers and consumer goods (IEA 2023b). Deep decarbonization requires more system integration across different sectors and production processes. There needs to be a better balance between supply and demand (Davis et al. 2018). Another key challenge is the shortening of innovation cycles, as only half of the technology to achieve carbon neutrality is already on the market, while the other half is still in research and development (Smith et al. 2019).

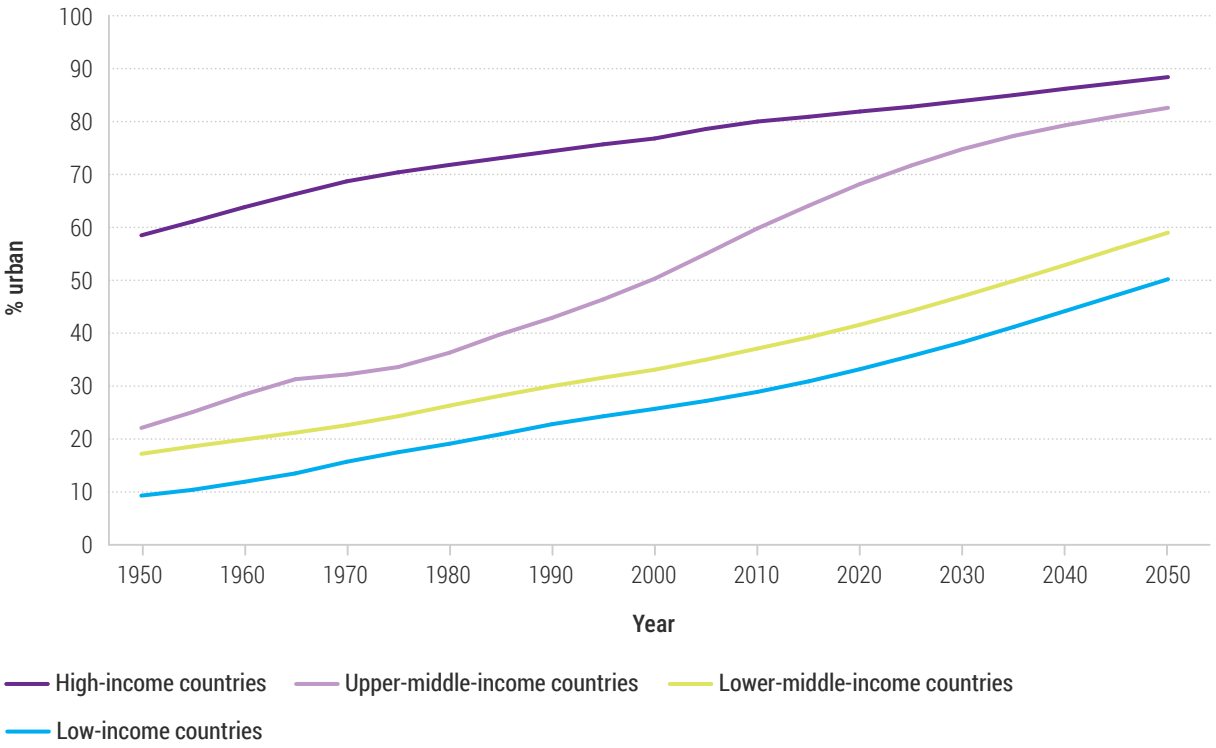
Food supply per capita has increased by more than 30 per cent since the 1960s, accompanied by a significant rise in nitrogen fertilizers and water use for irrigation.

This has led to agrifood systems emitting one-third of all global GHG emissions (IPCC 2019; FAO 2020; Crippa et al. 2021). Additionally, climate change has already affected food security and Indigenous food sovereignty, with certain extreme weather events becoming more frequent (IPCC 2019). A more integrated approach is needed, including increasing productivity, improving resilience, and reducing emissions, which is also a major challenge for safeguarding food, water, and natural systems. Nature-based solutions have great potential to sequester carbon, improve water retention, increase soil productivity, create local food production, and ultimately restore local evapotranspiration and climate cycles (United Nations 2023a; United Nation Convention to Combat Desertification [UNCCD] 2025).

The expansion of mobile technologies, remote-sensing services, and distributed computing has enhanced smallholders' access to essential services (FAO 2019). The COVID-19 pandemic underscored the need to reshape distribution networks and ownership structures to boost supply chain resilience. A territorial market approach can help revitalize local and regional production, thereby improving food system equity (High Level Panel of Experts on Food Security and Nutrition [HLPE] 2020). The trade in services has also advanced, aided by the emergence of new services. Additionally, innovative and smart financial instruments and platforms have been developed to facilitate cross-border transactions (Anser 2023). Besides increasing transparency, technological financial innovations also improve risk management and promote greater financial inclusion.

Digital transformation enhances the efficient allocation of resources, balances supply and demand, and facilitates smart-city solutions. Smart cities can comprise interconnected intelligent environments that learn from human activity patterns and adapt to behavioural changes (Batty 2018; Kandt and Batty 2021). Likewise, smart grids optimize electricity distribution using digital communication and sensing technologies, enabling the integration of renewable, green energy sources into existing electricity networks (IEA 2020).

Digital transformation and artificial intelligence (AI) are rapidly transforming society, supporting scientific progress, decision-making, social engagement, and planetary health used in climate models (Eyring et al. 2024) and the UNDP Human Development Report 2025 (UNDP 2025). AI-generated suggestions for shifting to renewable energy and AI-based forest monitoring are just some examples of how AI can be used to address urgent global environmental challenges. However, their lifecycle environmental consequences remain uncertain. For instance, the use of minerals, energy, and water is expected to rise worldwide, along with increased production of e-waste and pollution (UNEP 2024). Human rights should also be protected throughout the entire lifecycle to ensure security and reduce the digital divide and gender inequality (United Nations Educational, Scientific and Cultural Organization [UNESCO] 2021). The necessary ethical framework and governance for such emerging technologies remain unclear. Technology contributes to prosperity and maximizes well-being and social welfare when it is equally accessible and supported by an adequate social safety net (Acemoglu and Johnson 2023; AI Safety Summit 2023).



2.2.4 Urbanization

Urbanization takes many forms around the world, reflected in demographic variations such as city size, population density, growth rates, age structure, and mobility patterns (Ritchie, Samborska and Roser 2018; De Haas, Castles and Miller 2019; Sun et al. 2020). Spatially, urban areas expand unevenly, from compact cores to sprawling suburbs, creating diverse landscapes (Dadashpoor, Azizi and Moghadasi 2019). Urbanization trajectories also vary, with some regions facing rapid growth and inadequate infrastructure, while others grapple with population decline and economic downturns (Wolff and Wiechmann 2018; Meng and Long 2022). While urbanization can drive sustainable development (United Nations 2020), when poorly planned it can lead to significant environmental, social and economic challenges, emphasizing the need for effective development strategies.

Urbanization Trends

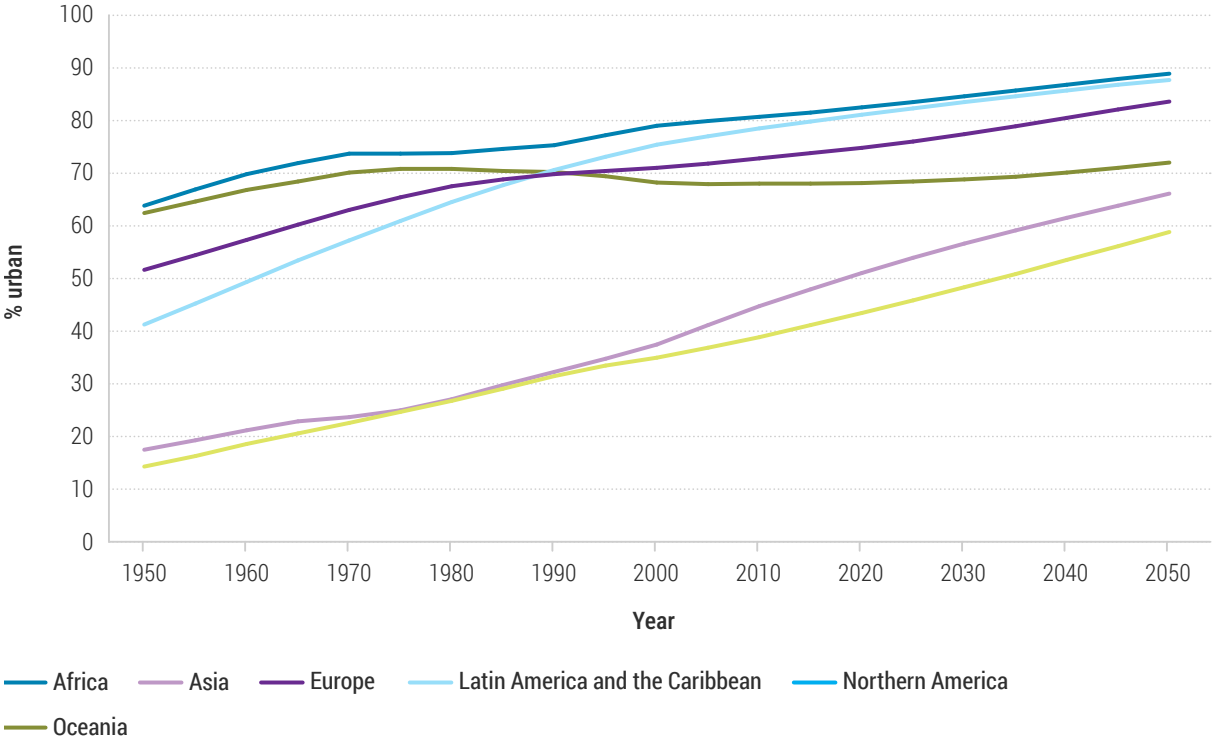
Urban areas accommodate most of the population compared to rural regions, with about 55 per cent living in urban areas in 2018, projected to reach 68 per cent by 2050 (United Nations 2019a). It is important to note that the definition of urban areas varies globally, and a standardized approach including demographic features and density grids is vital for precise policy analysis and environmental management (Organisation for Economic Cooperation and Development [OECD] and

Figure 2.9: Percentage of population residing in urban areas by income group, 1950-2050

Source: United Nations (2019a)

European Commission 2020; EU, FAO, UN-Habitat, OECD, World Bank 2021).

High-income countries tend to have a larger share of urban residents, whereas lower-middle and low-income countries are expected to undergo rapid urbanization in the coming decades (**Figure 2.9**).



Likewise, urbanization levels vary significantly across regions (**Figure 2.10**). Northern America at 82 per cent and Latin America and the Caribbean at 81 per cent have high urbanization rates, followed by Europe at 74 per cent and Oceania at 68 per cent. Conversely, Asia at 50 per cent and Africa at 43 per cent are mainly rural but are expected to collectively accommodate 74 per cent of the global urban population by 2050.

Although urbanization is expected to increase in many areas, some nations are forecast to see a decrease in their urban populations. These projections emphasize that future urban growth will mainly occur in lower and low-middle-income countries across Asia and Africa (**Figure 2.11**).

Cities display significant demographic variations in both space and time. **Figure 2.12** demonstrates this diversity, showing that nearly half of the world's urban population lives in settlements with fewer than 500,000 residents, while about one in eight resides in 33 megacities with over 10 million people. Projections for 2030 estimate there will be 43 megacities, mainly in developing regions. At the same time, some cities in low-fertility Asian and European countries have experienced population declines (United Nations 2019a).

Urban growth is primarily driven by three factors – towns transforming into cities, city expansion, and increasing city density. Densification alone accounts for 50 to 60 per cent of the growth in urban populations. Wealthier countries generally have lower city densities, whereas lower-income countries often have densities nearly four times higher. For instance, North America has an average density of 1,700 inhabitants per km², while Sub-Saharan Africa and South Asia surpass 8,000 inhabitants per km². In high- and upper-middle-income countries, larger cities tend to be denser, but in low-income nations, high density is common across cities due to smaller housing units and policies that restrict urban sprawl (OECD and European Commission 2020).

Figure 2.10: Percentage of population residing in urban areas by geographic region, 1950-2050

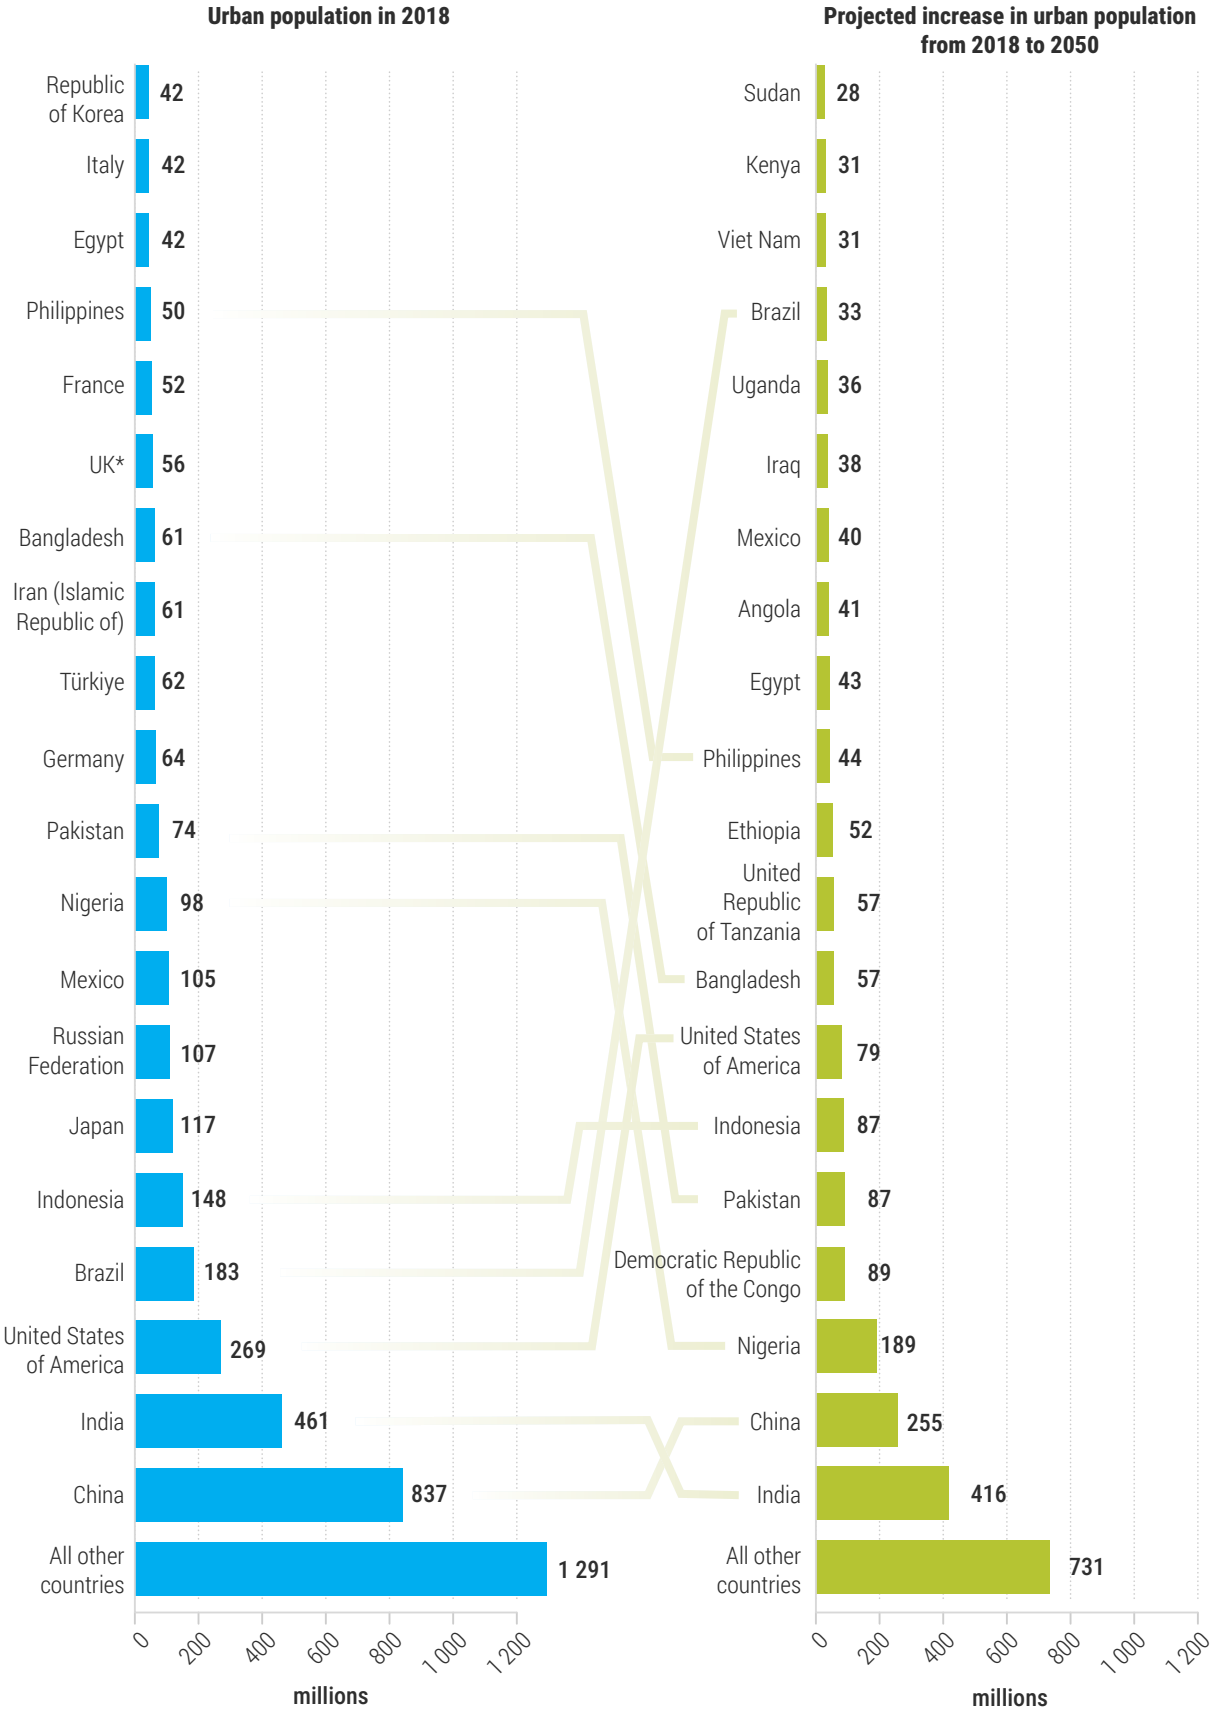
Source: United Nations (2019)

Challenges and issues faced by cities in different urbanization level

A. Economic challenges

Cities worldwide face economic, social, and environmental challenges at various stages of urbanization. Income inequality is especially severe in highly urbanized cities, particularly megacities in developing countries. Some local governments try to reduce urban-rural disparities by promoting entrepreneurial clusters (Guo et al. 2020). Employment pressures also present significant challenges, especially during crises such as COVID-19 (Su et al. 2022). In low-income regions, inadequate infrastructure and high urban poverty rates exacerbate unemployment and hinder economic resilience (Filho et al. 2019). Cities heavily reliant on specific industries, such as resource-based economies, are also vulnerable to economic fluctuations (Tan 2021).

B. Social challenges



Social issues are equally vital. Housing affordability remains a serious crisis in both developed and developing countries (United Nations Human Settlements Programme [UN-Habitat] 2022). Rising housing costs often surpass the financial capacity of low-income groups, resulting in widespread housing insecurity (Glaeser et al. 2017; UN-Habitat 2022). Disparities in public services are also evident across urban areas. For example, limited access to green spaces disproportionately deprives low-income urban populations, with inequality nearly twice as severe in developing regions compared to developed countries (Chen et al. 2022).

Informal settlements and inadequate housing conditions continue to pose major challenges. Worldwide, about one billion people live in slums (UN-Habitat 2019). **Figure 2.13** illustrates that most of this population is concentrated in three main regions: South-East Asia, Sub-Saharan Africa, and Latin America and the Caribbean.

C. Environmental challenges

Environmental challenges in rapidly growing cities are complex and multi-layered. Waste management remains a major issue, particularly in sectors such as waste collection, landfills, and recycling. The rise of municipal solid waste and new waste types like plastics

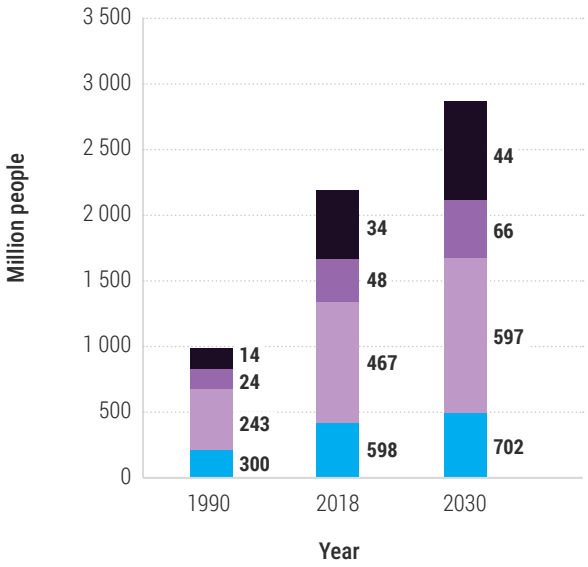


Figure 2.11: Urban population size in 2018 and increase in the projected urban population between 2018 and 2050 by countries

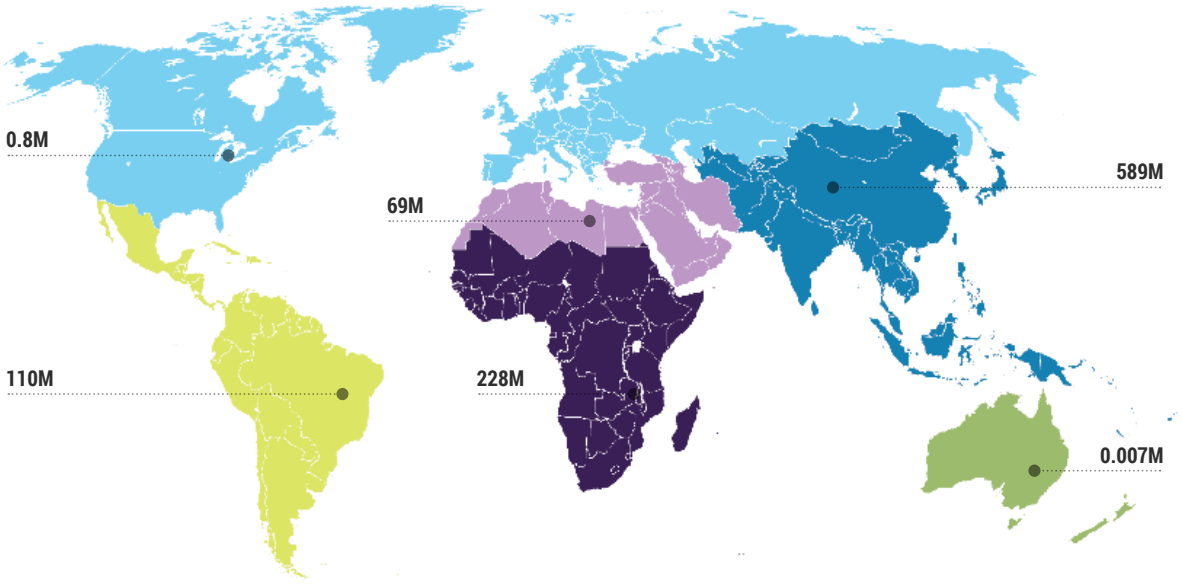
Large cities (5 to 10 million people)
Megacities (more than 10 million people)
XXX Number of cities by size

Note: Due to data unavailability, the figure does not include cities with populations below 500 000 people

Data source: World Urbanization Prospect (2018)



is happening quickly, but many cities lack enough landfill space and recycling facilities (Yang et al. 2017; Adebiyi-Abiola et al. 2019). Moreover, inadequate policies, weak regulations, and lack of enforcement worsen waste management problems. In low-income nations, 93 per cent of municipal waste is either burned or dumped in open landfills, posing serious environmental and health risks (Silpa et al. 2018).

Urbanization and human-driven emissions heighten the risk of heatwaves in cities. Additionally, continuous day-night heat waves – compound hot extremes – are more dangerous than isolated daytime or nighttime heat alone, especially for vulnerable groups like women and the elderly. Climate models project a two to fivefold rise in these events by the 2090s compared to the 2010s, increasing health risks for urban residents (Wang et al. 2021). Air pollution is also a major concern, as growing urban populations and industrial activities boost emissions from transportation, factories, and energy sectors. This worsens air quality, intensifying respiratory and cardiovascular illnesses, particularly in densely populated areas (Zhang et al. 2022).

2.2.5 Lifestyles and consumption

Lifestyles are leading drivers of the global environmental crises, as they are shaped by the everyday choices

Figure 2.13: Population per region living in slums and informal settlements

Australia and New Zealand
Sub-Saharan Africa
North Africa and Western Asia
Central and Southern, Eastern and South-eastern Asia

Source: United Nations (2019)

individuals and societies make. How people decide to live, consume, and behave has profound repercussions on the health of our planet. Many modern lifestyles involve resource-intensive habits, overconsumption, and reliance on energy-demanding technologies. The rising worldwide demand for goods and services, fuelled by these lifestyle patterns, puts significant pressure on natural resources and ecosystems. Furthermore, lifestyle-related trends in urbanization, transportation, and food consumption contribute to greenhouse gas emissions and habitat loss.

The Global Resource Outlook (UNEP and IRP 2024) highlights the sharp increase in global material extraction over the past 50 years, rising from 30.9 billion tons in 1970 to 95.1 billion tons in 2020. By 2024, extraction is expected to reach 106.6 billion tons and is projected to grow at an average rate of over 2.3 per cent annually. Developed countries are projected to have the largest environmental footprint during this period (UNEP and IRP 2024). The anticipated growth in global demand is driven by a shift towards more resource-intensive lifestyles, influenced by rising per capita incomes, unsustainable consumption, and advancements in technology and infrastructure. Rapid population growth and resource consumption, without effective management of extraction, use, and disposal, will strain resource supply systems and cause unprecedented environmental pressures and impacts. Resource extraction, including biomass, fossil fuels, metal ores, and non-metallic materials, is projected to increase by 60 per cent between 2020 and 2060, from 100 to 160 billion tons (UNEP AND IRP 2024). Importantly, adopting demand-side strategies in key sectors such as buildings, transportation, and food could cut global greenhouse gas emissions by 40 to 70 per cent by 2050, offering a practical and urgent way to reduce environmental impact – highlighting the importance of sustainable lifestyles (Creutzig et al. 2022).

The causes of environmental issues are complex and deeply ingrained in society, requiring a comprehensive strategy to effectively tackle them. The future of land, freshwater, and ocean ecosystems depends on the widespread adoption of sustainable lifestyles. Addressing these issues calls for an integrated approach that highlights the importance of core values in motivating environmental action, leverages sociocultural influences to drive change, builds trust in institutions and individuals, and recognizes the significance of shaping social norms. By understanding and integrating these interconnected elements, we can work toward a sustainable future and mitigate the urgent environmental challenges we face.

Core values, especially altruistic and biospheric ones, greatly affect individuals' choices and commitment to environmental initiatives (Dietz 2014; Steg 2016). Customizing messages and appeals to reflect these values can boost the success of environmental campaigns (Bolderdijk et al. 2013; Boomsma and Steg 2014; Stephenson et al. 2015; Klaniecki et al. 2020). Moreover, awareness, personal norms, and self-efficacy are key factors in predicting readiness to engage in environmentally friendly behaviours (Schwartz 1977; Ajzen 1985; Stern 2000). Nonetheless, individuals need support and resources to overcome obstacles at the personal, institutional, and market levels (Young et al. 2010; Bray, Johns and Kilburn 2011; Carrington, Neville and Whitwell 2014).

Sociocultural factors, such as collective identity, cultural models, behaviours, and social structures, play a significant role in influencing how people respond to environmental challenges (Climact 2018; Thornton et al. 2020; Levis et al. 2024). When individuals feel a sense of connection to collective action, their efforts towards environmental solutions tend to be more effective and widespread. UNESCO (2019) highlights that culture serves as a crucial, renewable resource for addressing climate change and environmental issues, harnessing natural heritage, intangible heritage, and traditional knowledge to support initiatives from local to global, such as agroforestry in Sub-Saharan Africa and glacier management in South Asia (Morel et al. 2022). Concepts of citizenship and moderation, as core values, reinforce the idea of interconnectedness among individuals (Gill 2022). Social and cultural processes interact with individual, structural, institutional, and economic factors, shaping the decisions people make about environmental issues (Barr and Prillwitz 2014). Indigenous cultural values and practices that honour and care for nature provide lessons on how shared values can promote sustainability (Brondízio et al. 2021). Additionally, power relations and personal agency influence the development and prominence of environmental narratives (O'Neill and Smith 2014; Schneider-Mayerson et al. 2020).

Trust serves as a fundamental element influencing the adoption of sustainable practices and innovative solutions. Trust in organizations, suppliers, and

individuals is crucial for accepting new energy services, resource-efficient products, and community initiatives (Lutzenhiser 1993; Cherry et al. 2018; Li and Wang 2020). Developing trust in various stakeholders is seen as essential for fostering sustainable behaviours.

Changing social norms can be a defining factor in tackling environmental challenges and driving societal change (Nyborg et al. 2016; Otto et al. 2020). Providing feedback on individuals' actions in comparison to others, along with the effects of current trends, can motivate both adaptation and mitigation efforts (Abrahamse and Steg 2013; Delmas, Fischlein and Asensio 2013). Behavioural contagion, which involves the spread of ideas and behaviours similar to infectious diseases, plays a significant role in the climate crisis (Sunstein 2019), but it also offers opportunities to encourage positive change. Peer influence is crucial in shaping carbon-intensive consumption habits, highlighting that individual actions can influence others (Frank 1999). Understanding the influence of lifestyles, cultures and traditions on environmental problems is essential for promoting effective environmental action.

2.2.6 Governance

Kaufmann, Kraay, and Mastruzzi (2010) define governance as "the traditions and institutions through which authority is exercised." This encompasses all processes and practices involved in making and regulating decisions on issues of common concern, as well as designing and implementing effective public policies. It also includes public respect for the state and its institutions to promote economic performance and social well-being. Since governance involves the exercise of authority, it covers laws, such as decisions, regulations, and enforcement, institutions and decision-making processes that embody this authority (World Resources Institute [WRI] 2006). Different organizations interpret good governance in various ways, but it is generally characterized by openness, participation, accountability, efficiency and consistency (Bosselmann, Engel, and Taylor 2008).

Governance and environmental quality are closely connected, as failures in governance often cause environmental degradation. Comparing two different measures – the 2022 Environmental Performance Index and the 2022 World Governance Index – there is increasing evidence that good governance helps reduce pollution levels (Shandra, Shor, and London 2008; Clapp and Dauvergne 2005; Jorgenson and Clark 2012) and supports environmental improvement (Hassan 2020). Conversely, poor governance – stemming from inefficient regulatory frameworks, lack of transparency and accountability, and weak law enforcement – tends to lead to worse environmental outcomes.

Given the current global environmental crises, which involve complex multidimensional factors beyond traditional top-down governance, it is important to consider the role of multilevel governance. This concept describes the distribution of authority across various vertical levels and among multiple horizontal actors, encompassing both political structures and decision-making processes (Bache and Flinders 2004; Schäfer 2021).

The effectiveness of multilevel governance and its ability to facilitate coordination and collaboration across various levels of government, from local to global, as well as across different sectors and stakeholders, is essential for effectively addressing environmental challenges. Flexible and adaptive multilevel governance has also demonstrated success in tackling collective action problems related to common resources amid changing environmental conditions (Ostrom 1990; Ostrom 2017). Among the core governance principles that can help improve environmental outcomes, control of corruption, government effectiveness, transparency, and accountability may require further examination.

Control of corruption

Corruption is a widespread global issue, typically defined as the misuse of public authority for private gain (Rodriguez, Uhlenbruck and Eden 2005; Werlin 2016). It is a complex and multi-layered phenomenon that poses significant challenges to the economy. The World Bank estimates that corruption costs approximately US$1.5 trillion worldwide annually, accounting for about 2 per cent of global GDP. Additionally, corruption is viewed as one of the key obstacles to reaching sustainability goals, as it directly affects the environment and leads to negative consequences, such as increased pollution (Damania, Fredriksson and List 2003; Fredriksson, Vollebergh and Dijkgraaf 2004; Cole 2007; Leitão 2010; Biswas, Farzanegan and Thum 2012; Cepparulo, Eusepi and Giuriato 2019; Pei, Zhu and Wang 2021; Song, Xie and Shen 2021; Wu et al. 2021), as well as the inefficient use of natural resources (Yuan and Xiang

2018; Sinha et al. 2019; Zhou and Li 2021; Tawiah, Zakari and Alvarado 2024). It hampers green strategies and policies and limits access to public goods and services, thus disturbing the fragile balance between economic growth, social inclusion, and environmental sustainability.

Corruption often facilitates environmental crimes. Certain sectors, like forestry, fisheries, water management, extractive industries, and construction, are especially vulnerable to corruption. For instance, Böhmer (2019) notes that corruption and illegal deforestation frequently occur together, with the world's most forest-rich nations making little progress in combating corruption (Böhmer 2019). Countries in rainforest regions, home to significant biodiversity, local communities, including Indigenous Peoples, and vital environmental functions such as climate regulation, tend to perform poorly on the global Corruption Perception Index.

Government effectiveness

Several factors are preventing governments from realizing their environmental ambitions:

- The lack of policy coherence results in conflicting actions and funding across sectors such as the economy, industry, production, and consumption, as well as large-scale infrastructure, transport, food and agriculture, construction, taxation, and social benefits. Some of these policies even oppose environmental goals (Fischer 2018). Moreover, there is a shortage of ambitious policies that more effectively leverage public and private funding, as addressing environmental challenges demands investments far exceeding current levels (**Table 2.1**).

- Political polarization (Cole et al. 2023) and short-term cycles may discourage governments from tackling complex and long-term environmental issues (Povitkina 2018).

- Poor planning, inclusion, and coordination in designing and executing environmental strategies, along with a failure to recognize key synergies, interdependencies, and trade-offs between these strategies and other policy priorities such as energy, transport, industrial growth, and digitalization. Additionally, insufficient involvement of local, regional, Indigenous governments, and rights holders in the development of environmental policies impacts their implementation and risks undermining the intended results.

- Lack of adaptive and flexible approaches that can respond to changing circumstances, uncertainties, and risks associated with environmental challenges. This includes monitoring and evaluation of policies and actions, as well as learning from experiences to improve future responses (Folke et al. 2005).

- The lack of strong global leadership and cooperation among nations hampers efforts to address worldwide environmental issues, which require a coordinated global response. For instance, COP26 on Climate Change expressed "deep regret" that wealthy nations failed to meet their 2020 goal of contribution of US$100 billion annually to assist developing countries. This highlights the need for improved leadership and greater collaborative efforts to support the most affected and vulnerable nations facing environmental degradation.

Transparency and accountability

Transparency and accountability are crucial in the policymaking process and embody a citizens-centred approach to addressing environmental degradation. Since collaboration is vital, with every part of society having to contribute, actions are still required to promote transparency and effective governance by addressing:

- Limited access to credible and comprehensive information results in a weak basis for policy decisions. It also hinders civil society and citizens from monitoring policy implementation, reducing their ability to pressure the government to act. Furthermore, this issue negatively impacts the rights of the most marginalized and vulnerable groups.

- Lack of public awareness, acceptance and support of more participatory forms of public engagement hinder citizen involvement in problem-solving, environmental policies, and the fair distribution of costs and benefits associated with addressing environmental challenges.

- Insufficient education about environmental challenges contributes to resistance to lifestyle

Table 2.1: Investment needs: Summary

Theme (US$ trillion)	Power	Iron & Steel	Cement	Chemi-cals	Trans-port	Aviation	Shipping	Agricul-ture	Build-ings	Total across sectors

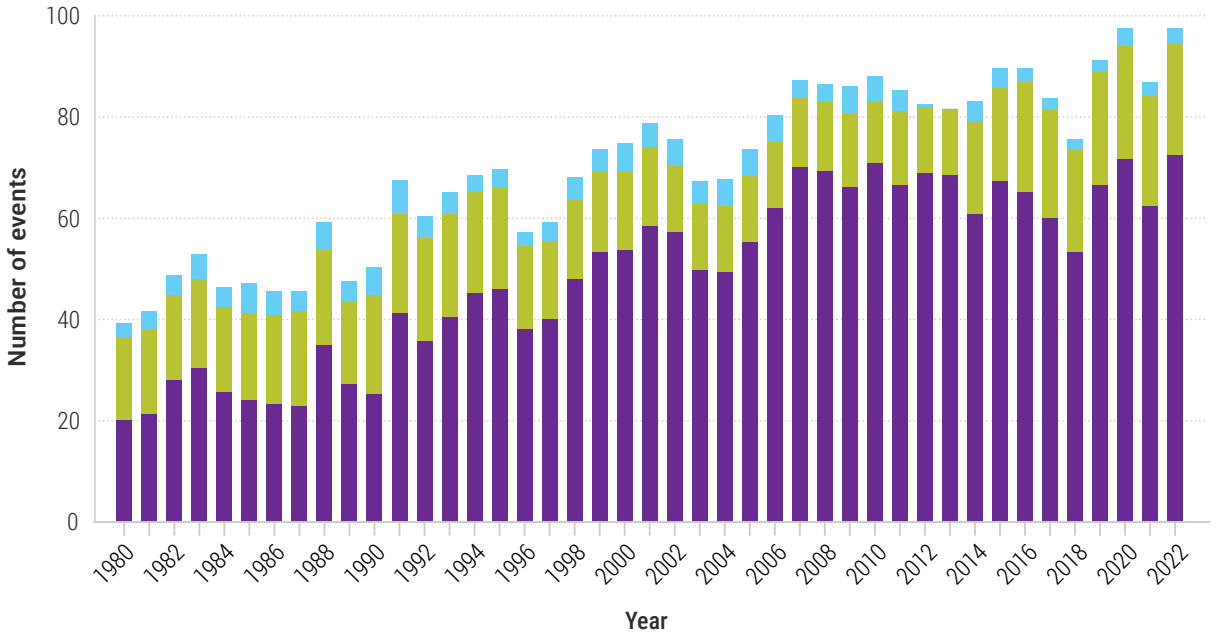
changes and, in some countries, leads to strong opposition to environmental policies and practices.

- Lack of adequate sustainability disclosure and reporting in both public and private sectors.



2.2.7 Shocks

A shock is defined as the occurrence of a largely unpredictable event, which can be natural or human-made. Unpredictability may stem from unknown aspects such as the event's intensity, timing, duration, or coverage. This definition covers a subset of hazard events listed in the UNDRR/ISC Hazard Information Profile (Murray et al. 2021), with the broader category including both predictable and less predictable hazards. Shocks can originate from natural processes that are geophysical, meteorological, hydrological, or biological. Examples include geophysical earthquakes or volcanic eruptions; hydrometeorological droughts, heatwaves, storms, and floods; and biological epidemics or pandemics. Human-made shocks can result from armed conflicts, extreme economic events like debt or financial crises, use of disease-causing agents, chemical weapons, or technological accidents, such as oil spills or industrial incidents.

Shocks can be cascading, interconnected, and multi-faceted. For example, an earthquake or landslide can generate a tsunami that destroys lives, livelihoods, and natural and built environments, cascading into an epidemic related to waterborne disease. Climate-related events such as droughts or biological events such as epidemics can be worsened by human activity and trigger a sovereign debt crisis, especially in low-income countries (International Monetary Fund [IMF] 2019; Cevik and Jalles 2022; United Nations Trade and Development [UNCTAD] 2022).

Shocks can become disasters when vulnerability combines with hazards (Blaikie et al. 2014; Taylor 2015; Gaillard 2021). Vulnerability refers to the susceptibility of people, societies, and ecosystems to harm. A high level of vulnerability to shocks is often linked to significant developmental challenges. Nearly half of low-income countries face risks from both debt and weather-related shocks, creating a cycle of ongoing vulnerabilities and economic stagnation (UNCTAD 2022). Understanding the human-made factors that

Figure 2.14: Trends in numbers of natural and human-caused shocks

Note: The armed conflicts considered in this figure are those between the military forces of two parties, at least one of which is the government of a state, and that have resulted in at least 25 battle-related deaths a year (Davies, Pettersson and Öberg 2023; Geditsch et al. 2002)

Source: Natural and technological shocks data from EM-DAT, CRED/UCLouvain, www.emdat.be; Armed conflict data from Upsala Conflict Data Programme, ucdp.uu.se; and sovereign debt default data of independent countries and regional/global financial crisis events from Reinhart and Rogoff (2011), Ams et al. (2019) and UNDP (2022).

contribute to vulnerability and shocks can help mitigate the adverse environmental impacts of shocks.

Trends in shocks over the past 40 years

The number of natural event-driven shocks threatening more than 10,000 people through death, injury, or homelessness has more than tripled over the past 40 years, as shown in **Figure 2.14**. The frequency and intensity of these events often increase due to human-induced climate change (IPCC 2022). In 2020, approximately 106 million people were affected by natural hazards such as earthquakes, tsunamis, floods, hurricanes, volcanoes, heatwaves, and wildfires – excluding biological events – with economic damages totalling US$161 billion (Ritchie, Roser, and Rosado 2022). Human-caused shocks, including armed conflicts and technological incidents, made up roughly half to a third of all shocks from 1980 to 2022.

Direct effects of shocks on environment

The effects of shocks on the environment, worsened by human-caused climate change, have led to widespread and sometimes irreversible repercussions across terrestrial, freshwater, cryospheric, atmospheric, and coastal and open-ocean ecosystems (IPBES 2019; IPCC 2022; Driscoll et al. 2024; Feehan et al. 2024; Ripple et al. 2024). Armed conflicts are inherently destructive and result in severe and lasting consequences for both land and marine environments. Major types of environmental damage caused by armed conflict include issues related to chemicals, fuels and associated infrastructure, waste and waste infrastructure, urban and critical infrastructure, agriculture and natural areas, environmental governance, and law enforcement (UNEP 2022). Armed conflicts can trigger complex, multi-faceted environmental crises with short- and long-term, often irreversible risks that create ripple effects beyond the conflict zones (UNEP 2007; Broomandi et

Credit: GreensandBlues/Envato

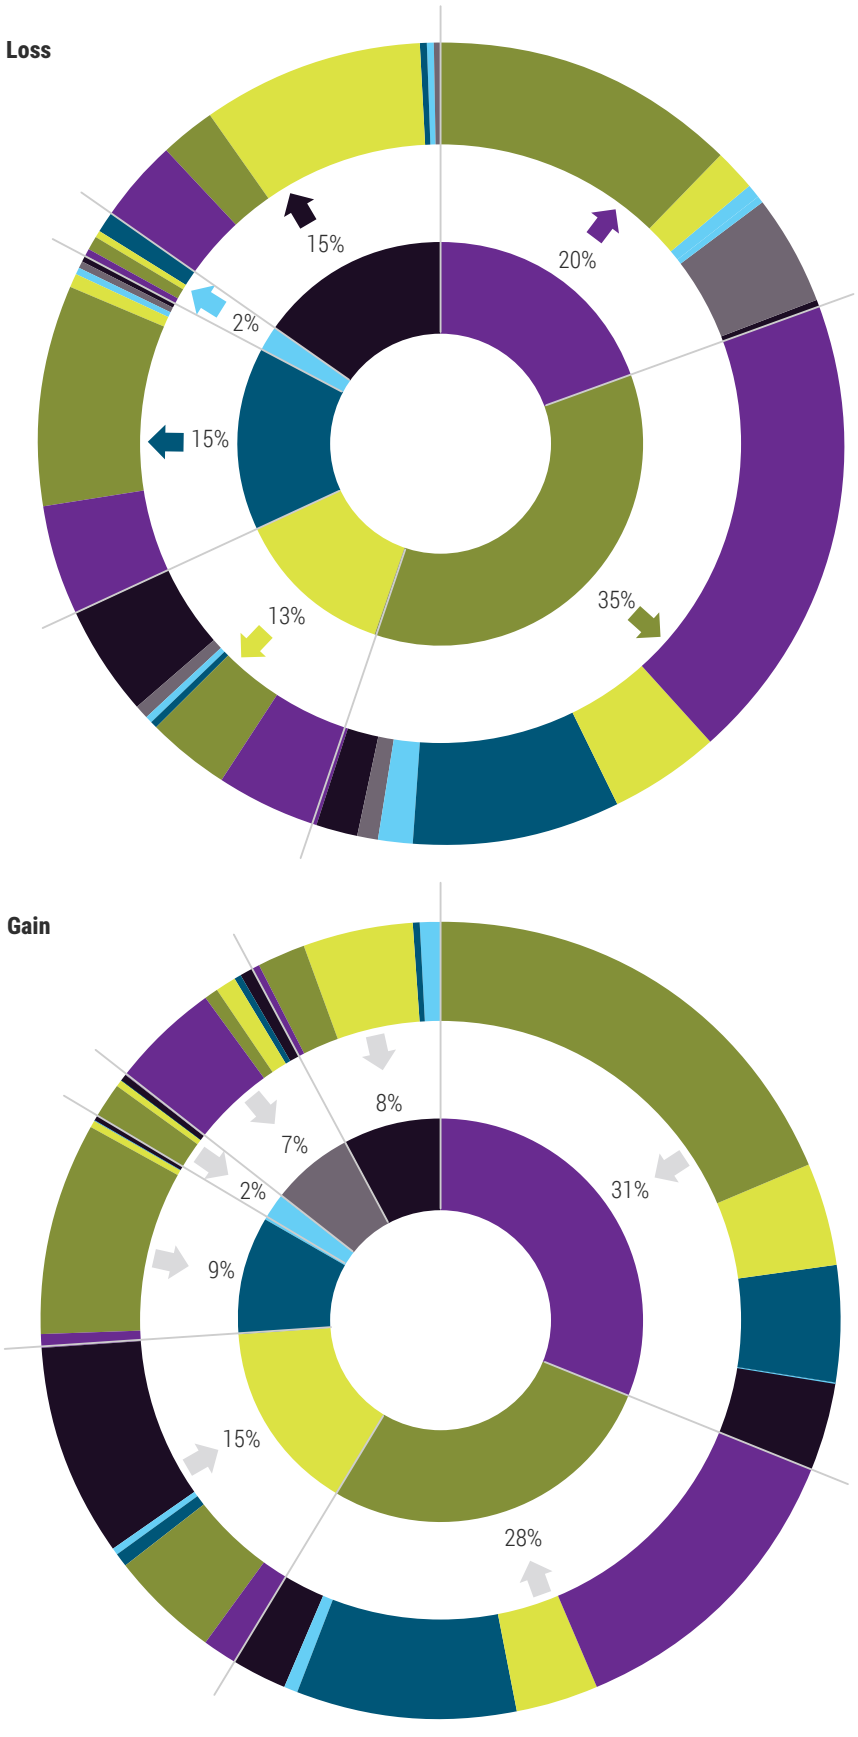
al. 2020; UNEP 2020; World Health Organization [WHO] 2021a; UNEP 2022).

Over the past 60 years, at least 40 per cent of intrastate conflicts have been linked to natural resource exploitation, including timber, diamonds, gold, oil, fertile land, and water. Studies show that conflicts over natural resources are twice as likely to reoccur within five years (UNEP 2022). Environmental impacts during armed conflicts, occupation, peacekeeping, and post-war rebuilding occur through various channels:

- Tactical strategies and unintended consequences (Gerges 1993; Biswas 2000; Organization for the Prohibition of Chemical Weapons 2022)
- Financing, especially when involving resource exploitation
- Breakdown of human security and development (Adger et al. 2014; Gates et al. 2012);
- Erosion or low prioritization of environmental governance (Bruch, Muffett, and Nichols 2016; Gaynor et al. 2016; Solomon et al. 2018; Bothe 2023); and
- Lack of recognition or enforcement of Indigenous and human rights (Tidwell and Zellen 2016).

Indirect and recursive impacts of shocks on environment

Shocks that impair food, water, and energy security, as well as socioeconomic outcomes (Bastos et al. 2020; UNEP 2022; Himaz 2022; Salmanidou et al. 2021; Syukriyah and Himaz 2024), can lead to or worsen resource conflicts. This often increases the vulnerability of affected populations, creating a cycle of worsening environmental conditions. For instance, mass displacement and survival strategies may cause deforestation, soil erosion, overuse of natural resources, and the rise of black markets for these resources (Black 1994; Jensen 2019).



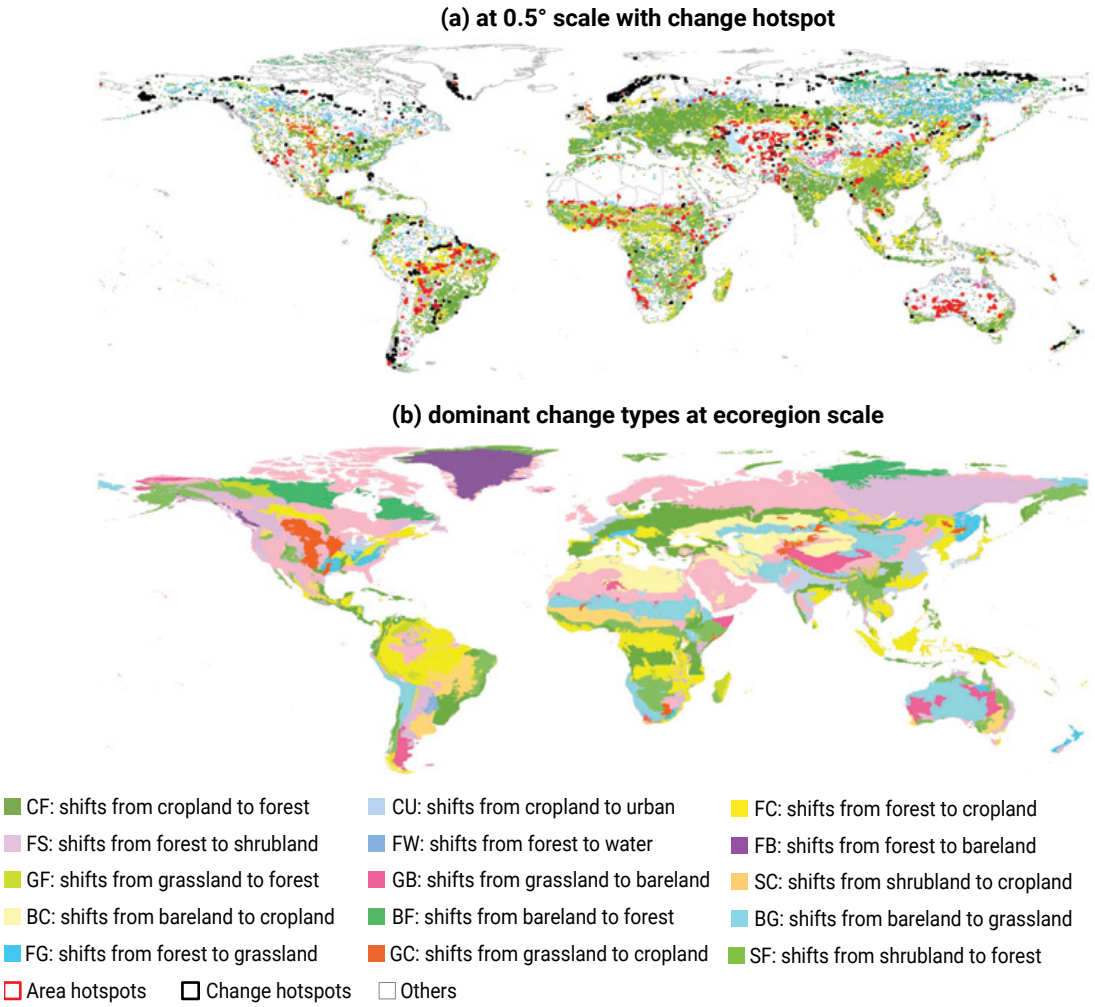
2.3 Pressures that affect the global environment

2.3.1 Land-use change

State and trends of global land-use transitions

Land-use change serves as a crucial indicator that reflects the significant influence of both human activities and natural processes on the Earth's surface (Anderson et al. 1976; Yu et al. 2022). Owing to the dedicated efforts of the European Space Agency (ESA), we have gained valuable insights into long-term land-use change patterns through the comprehensive 1992-2020 ESA Climate Change Initiative Land Cover (CCI LC) dataset (ESA 2017).

Figure 2.15: Proportions of land-use change gross loss and gross gain from 1992 to 2020



Source: Source: ESA (2017); Liu et al. (2018)

Analysing this dataset reveals that the most common land-use changes occur between cropland and forest (**Figure 2.15**). The ESA CCI-LC data shows that transitions labelled as "FC", forest to cropland, and "CF", cropland to forest, make up the largest areas of land-use change, with 129.89 and 85.70 million hectares respectively. These account for roughly 30 per cent of all land-use changes observed. Urban expansion also plays a major role in cropland loss. Around 30.61 million hectares of cropland were converted to urban areas, representing 67 per cent of urban-related land-use changes This expansion often pushes cropland into areas of natural vegetation. However, satellite data has been less effective at detecting land-use changes in other vital environments, such as grasslands and coastal marine areas, some of which have long histories of Indigenous stewardship (Chesnais et al. 2024).

The profound impact of urbanization on land-use change raises substantial concern due to the rapid pace of economic development and the surge in population density (Venter et al. 2016). Nevertheless, compared to other land-use changes, the overall global increase in urban areas remains relatively modest. From 1992 to 2020, the urban area expanded by 46.14 million hectares, representing 6 per cent of the total gross land-use changes. However, a critical concern related to urbanization is the loss of urban green spaces, which are essential for recreation and well-being.

The FC and CF types are common worldwide, as shown in **Figure 2.16**, including regions in Latin America, Eurasia, South Africa, Southeast Asia, and southern China. It is important to note that satellite data may not

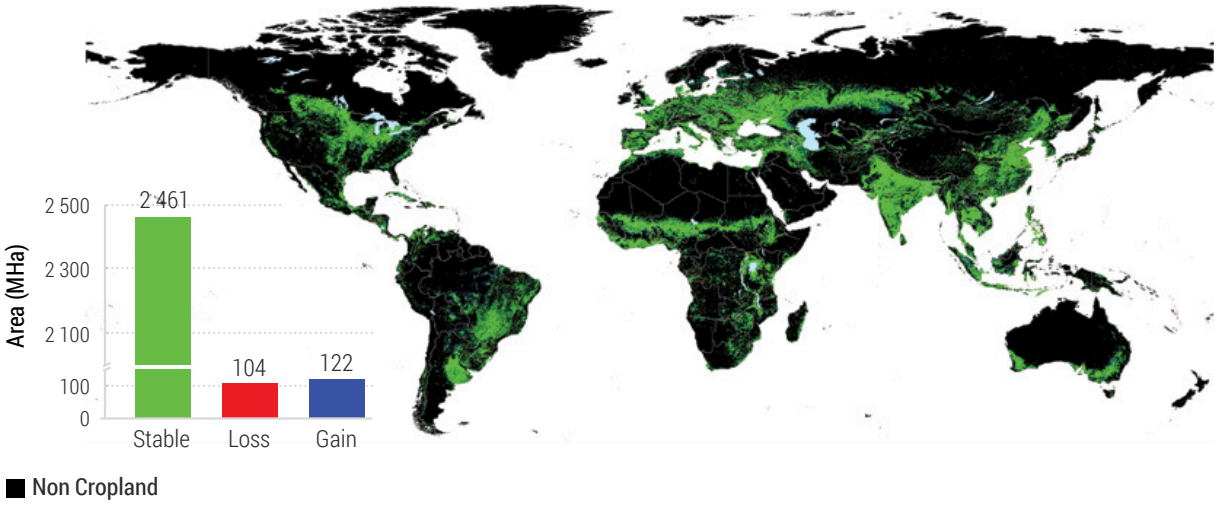
Figure 2.16: Global land-use change map (a) at 0.5° scale with change hotspot, and (b) dominant change types at ecoregion scale

Note: (CF: shifts from cropland to forest; CU: shifts from cropland to urban; FC: shifts from forest to cropland; FG: shifts from forest to grassland; FS: shifts from forest to shrubland; FW: shifts from forest to water; FB: shifts from forest to bareland; GC: shifts from grassland to cropland; GF: shifts from grassland to forest; GB: shifts from grassland to bareland; SC: shifts from shrubland to cropland; SF: shifts from shrubland to forest; BC: shifts from bareland to cropland; BF: shifts from bareland to forest; BG: shifts from bareland to grassland).

Source: ESA (2017); Liu et al. (2018)

always accurately reflect land-use changes in certain areas. Among these regions, South America stands out as having notable hotspots related to the transition FC. Deforestation in South America is extensive, covering 75.70 million hectares, which accounts for 11 per cent of the total global land-use change area and a significant 63 per cent of the regional land-use change. This region has experienced the transformation of natural vegetation, especially forests, into croplands (Zabel et al. 2019). Furthermore, Asia and Africa show considerable hotspots of cropland expansion, with especially high concentrations in Central Asia (Potapov et al. 2022). While smallholder communities contribute to this change due to population growth and rising food demands, large-scale agribusinesses and corporations also play a key role, motivated by economic incentives such as global market demand. In Australia, hotspots of "BG" transitions, shifting from bareland to grassland, are visible in the south, highlighting the combined effects of climate change and human activities in grassland restoration (Gang et al. 2014).

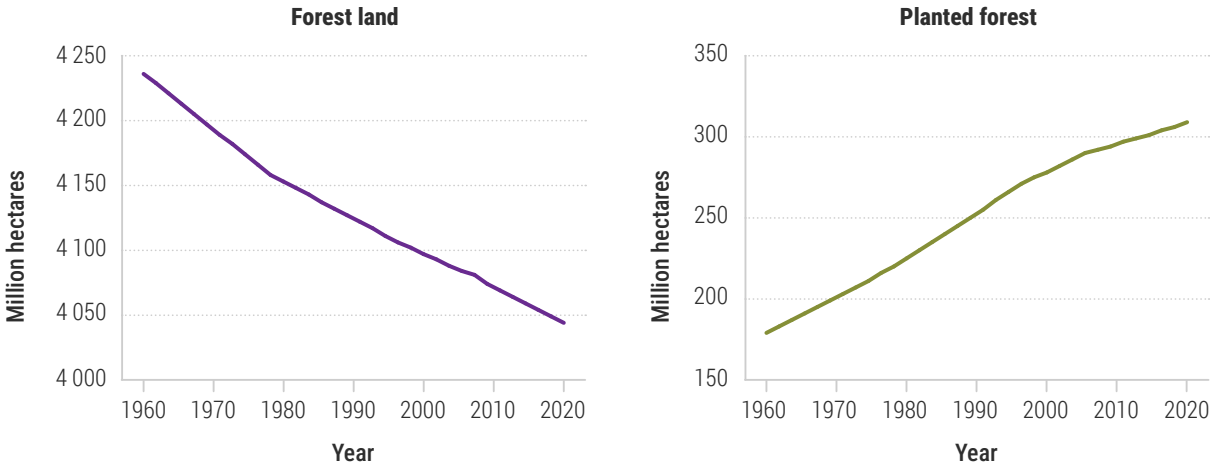
Agricultural dynamics



Cropland is vital for global food production and socioeconomic development (Brown 1981; Foley et al. 2011). From 2000 to 2020, most cropland remained stable, though a slight net increase of 17.28 million hectares indicated an overall growth trend (**Figure 2.17**). Notable variations in cropland were observed across specific regions. Sub-Saharan Africa, Southeast Asia, and parts of Latin America experienced significant cropland expansion due to factors such as population growth, agricultural intensification, and economic influences. In contrast, North America, Europe, and certain parts of Eastern Asia saw reductions in cropland due to urbanization, labour shortages, and land-use diversification (Yin et al. 2020; Crawford et al. 2024). Furthermore, the expansion of energy crops, including oil crops and solid energy crops, has also reduced cropland available for food production. This trend has been observed in various regions around the world, including the "corn belt" region in the Midwest of the United States of America (Wright, Thompson and Galloway 2013), and the proliferation of the oil/biodiesel production from rapeseed in Germany (Woźniak et al. 2019).

Delving into the analysis of three main staple crops—namely wheat, rice, and maize—revealed interesting trends. Despite fluctuations in their cultivated areas, their production has shown a steady increase since 2000. This growth has been driven by significant yield increases, ongoing population growth, and rising demand for feed and biofuel, which has stimulated expanded cultivation (Erenstein et al. 2022).

Forest dynamics



Despite the ongoing decrease in global forest area, efforts aimed at reducing deforestation have shown significant progress (**Figure 2.18**). According to FAOSTAT, from 1990 to 2000, there was an average annual forest loss of about 6.57 million hectares. After 2000, this rate decreased to 4.66 million hectares

Figure 2.17: Global cropland changes during 2000-2020

Source: ESA (2017)

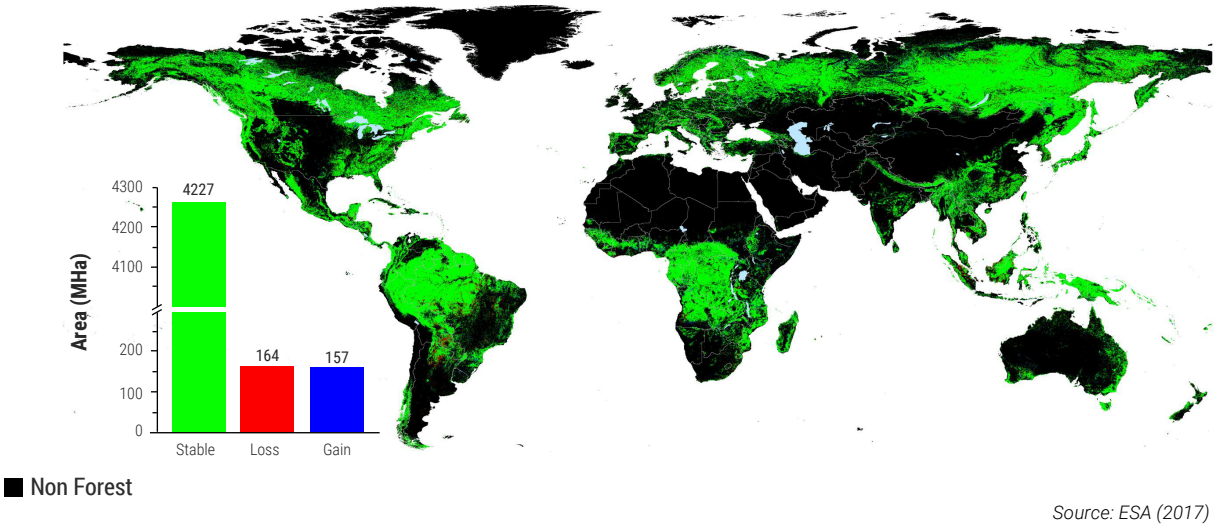
Figure 2.18: Forest land and planted forest area, 1990-2020

Data source: FAO (2025)

per year and then further dropped to 4.31 million hectares per year since 2010. Meanwhile, the area of planted forests has been increasing, with rates of 3.68 million hectares per year during 1990-2000 and 4.62 million hectares per year during 2000-2010. Since 2010, the growth of planted forests has slowed, at a rate of 2.78 million hectares per year. Significant changes in forest cover have been observed across different regions (**Figure 2.19** and **2.20**).

Forest loss remains a significant issue in tropical regions like South America, Southeast Asia, and Central Africa (Hansen et al. 2013). Deforestation here is driven by agricultural expansion, logging, infrastructure development, such as the Bi-Oceanic Railway south of the Amazon, land grabbing, and illegal activities. In contrast, North America, Europe, and parts of Asia have made progress in forest conservation through initiatives like afforestation, reforestation, and sustainable management practices. Efforts such as China's Gain for Green and the African Great Green Wall have increased forest cover, but many reforested zones are monocultures with limited biodiversity benefits. Indigenous communities are also engaging in carbon forestry on their lands, though the prospects for sustainable development and safeguards of these schemes remain uncertain (van Kooten, Nijnik, and Bradford 2019).

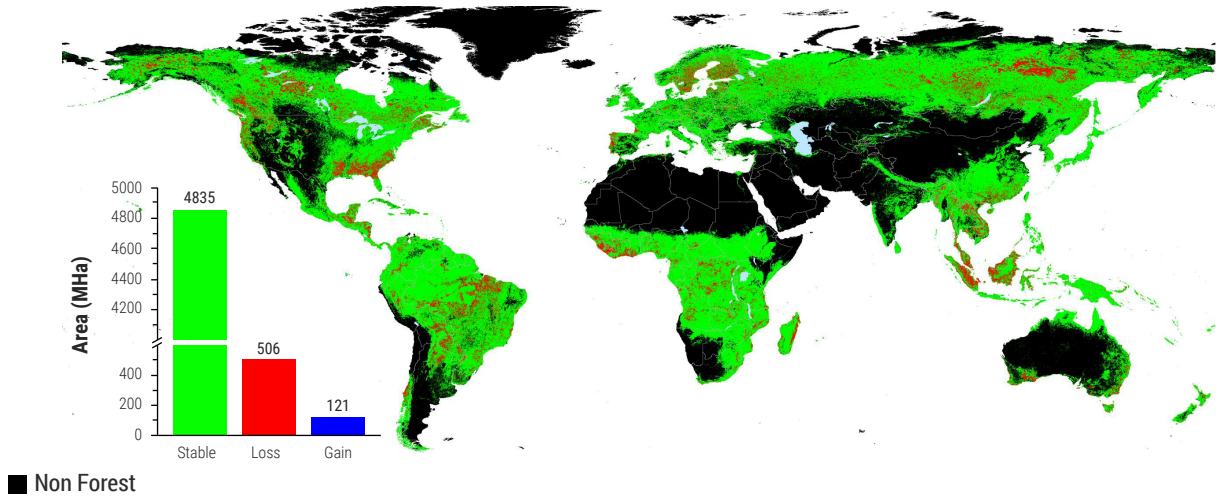
Drivers and impacts of land-use change



Many interconnected factors influence global land-use changes, affecting ecosystems and biodiversity. Population growth is a key driver, increasing food demand and prompting agricultural expansion. Simultaneously, issues like food waste, urbanization, climate change, and related factors intensify land-use pressures. Urbanization, stemming from population increase, threatens natural spaces by encroaching on habitats, destroying wildlife, and disrupting ecosystems (2.2.4). Environmental crises—such as pollution, climate change, drought, desertification, and soil degradation—are primary causes of environmental decline, while armed conflicts worsen these problems through deforestation, crop destruction, and loss of life and livestock (2.2.7). Additionally, the expansion of national parks and protected areas has contributed to regional land-use shifts.

Furthermore, resource exploitation, particularly in mining and timber industries, results in habitat destruction, pollution, and deforestation, aggravating geopolitical tensions and increasing habitat loss for various species (2.3.2). Additionally, invasive alien species, driven by global pressures such as climate change and land-use changes, disrupt native ecosystems and biodiversity (2.3.4). These pressures are closely linked and often interact in a complex way, making it harder to protect native biodiversity and natural resources (4.2). The regional growth of agriculture, driven by economic shocks, highlights the strong connection between human activities, land-use changes, and their effects on global biodiversity and natural resources, creating a cycle of growing environmental impact (2.4).

2.3.2 Resource use/exploitation



The rising demand for natural resources driven by a growing population, urbanization, economic progress, lifestyle choices, and natural disasters is putting a strain

Figure 2.19: Forest land and planted forest area (1990-2020)

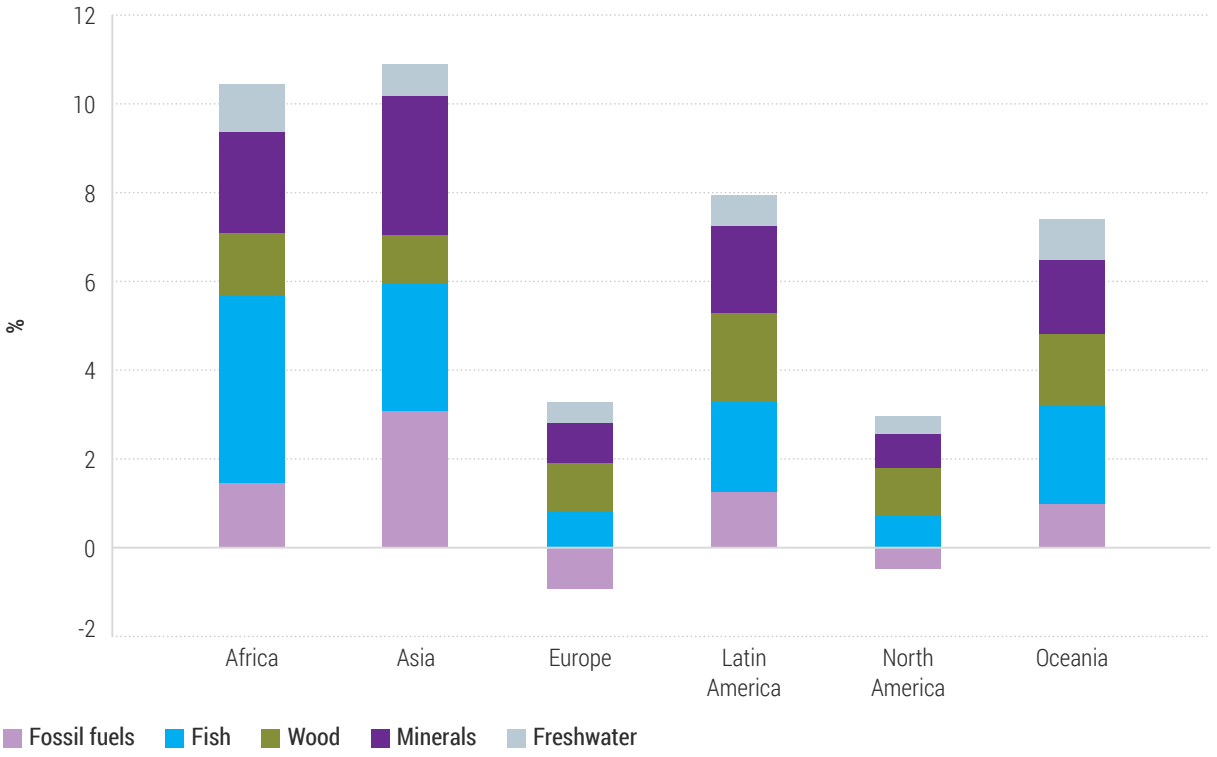
Source: ESA (2017)

Figure 2.20: Global Forest changes during 2000-2020 at 30m

Source: Du et al. (2023); Hansen et al. (2013)

on the Earth's limited resources. The extraction of these resources has resulted in significant environmental pressures, as shown in **Figure 2.21**, which illustrates the annual average growth rate of consumption for various natural resources discussed below.

Fish and wildlife



Global fish stocks are increasingly overexploited, with 37.7 per cent of fish stocks classified as unsustainably fished in 2021, up from 10 per cent in 1974, straining marine ecosystems (FAO 2024). Per capita fish consumption has also risen, doubling from 9.1 kg in 1961 to 20.7 kg in 2022 (FAO 2024).

Wildlife trafficking affects 4,000 species across 162 countries, contributing to biodiversity loss (United Nations 2024b). Since 1970, vertebrate populations have declined by 69 per cent due to exploitation and habitat destruction (World Wide Fund for Nature [WWF] 2022). Technological advancements like drones and satellite monitoring have enhanced conservation efforts but also pose risks of facilitating overexploitation (Ovando et al. 2021). Climate change worsens these problems, with rising ocean temperatures shrinking species' ranges and decreasing fish yields (IPCC 2022).

Energy

Fossil fuels – oil, natural gas, and coal – dominate global resource extraction, accounting for 80 per cent of primary energy consumption in 2023, mainly for transportation

Figure 2.21: Average annual growth rate (AAGR) in the use of key natural resources over two decades (2000 to 2023)

Source: UNdata (EDATA 2000–2021; ENV 2000–2021; ICS 2020–2021); Energy Institute (2022–2023); BP (2000–2022); FAOSTAT (2000–2021); FAO FRA (2022–2023); UN-Water (2022–2023)

and electricity (Energy Institute 2024). Their use emitted 36.8 billion metric tons of CO_2 in 2023, significantly contributing to climate change (Friedlingstein et al. 2025). Global per capita fossil fuel consumption remained stable at 1.9 tons of oil equivalent in 2023, ranging from 6.7 tons in North America to 0.6 tons in Africa (IEA 2024b). Reserves-to-production ratios in 2023 were 133 years for coal, 53 years for oil, and 52 years for natural gas (Energy Institute 2024). Industrialization and economic growth, especially in Asia, increased energy demand by 15 per cent from 2013 to 2023, though 40 per cent of this rise was met by clean energy, reducing fossil fuels' share from 82 to 80 per cent (IEA 2024b). Hydraulic fracturing has boosted shale gas production; while natural gas emits 50 per cent less CO_2 than coal, methane leaks threaten water resources and diminish climate mitigation gains. Urbanization and industry have increased fossil fuel use, but shifts like electric vehicles, or 18 per cent of 2023 car sales, are helping curb demand (IEA 2024b). The crisis caused by the 2022 onset of the war in Ukraine led to a six per cent increase in European coal use, disrupting supplies (IEA 2024b). Fossi fuel-related air pollution causes about 7 million premature deaths each year (WHO 2024).

Minerals and Rare-Earth Elements

The mining industry plays a crucial role in supporting global economic growth, providing essential resources for infrastructure, energy, and technology. Over the past 50 years, global material consumption has tripled and continues to grow by more than 2.3 per cent each year, fuelled by urbanization and industrialization (UNEP and IRP 2024). Advances in technology, including automated mining, satellite imaging, and advances in mining processes, have made it possible to extract minerals from remote areas (US Geological Survey 2021), boosting efficiency and lowering costs (United Nations 2025c). Despite these innovations, the industry faces difficulties in meeting rising global demand for minerals, expected to grow at 4 per cent annually due to the expansion of clean energy, infrastructure, and consumer products (United Nations 2025c).

The exploitation of rare earth elements has increased significantly, with demand for magnets that require them doubling from 2015 to 2023, reaching 93 kt in 2023 (IEA 2024c). The transition to green energy drives up the extraction of rare earth elements and

critical minerals, notably contributing to cobalt mining abuses and the proliferation of e-waste in Africa and Latin America (United Nations 2025c). Geopolitical conflicts and governance issues may further drive mineral extraction, potentially causing unrest (United Nations 2025c).

Wood and timber

Wood exploitation damages the environment by causing deforestation, biodiversity loss, soil degradation, and increased carbon emissions, disrupting ecosystems and intensifying climate change. Global wood product production peaked in 2018, marking the highest growth since 1947, with industrial roundwood production reaching 2.03 billion cubic metres (FAO 2019). The FAO's Global Forest Resources Assessment 2020 reported a net forest loss of 178 million hectares from 1990 to 2020, equivalent to the size of Libya (FAO 2020).

Roundwood consumption is projected to rise by 10 per cent to 2.2 billion cubic metres by 2030, mainly driven by Asia's economic growth and increasing demand for wood-based products (Lock et al. 2021). The wood products market is projected to grow at a compound annual growth rate (CAGR) of 7.1 per cent through 2025, with sustainable harvesting expected to meet demand through 2030 (Lock et al. 2021). Technological advancements, including enhanced plantation management, increased recycling, engineered wood composites, and biofuels, are expanding wood applications and improving industry sustainability.

Water

Excessive extraction of freshwater, pollution, and poor management are depleting water resources and damaging ecosystems. Mega-projects like dams disrupt natural flows, harming fish and communities. Overpumping groundwater for agriculture, industry, and domestic use often surpasses natural recharge rates, especially in urban areas with impermeable surfaces and shifting rainfall patterns, leading to unsustainable depletion. Additionally, demographic factors such as changes in population densities and movements can create further environmental pressures on water quality. This creates a vicious cycle, as securing clean water often involves exploiting other resources. Technological innovations can improve water availability, safety, efficiency, and treatment. Urbanization exacerbates freshwater stress, while lifestyle and dietary changes increase per capita water consumption. Extreme weather events exacerbate water scarcity and pollution.

2.3.3 Emissions: GHGs and other pollutants

GHGs and other pollutants adversely affect the environment across various spatial and temporal scales. This section analyzes sectoral and regional GHG emission contributions, while Chapter 3 on Air explores emission trends. Additionally, the major pollutants and their sources are also presented in this section. Chapters 3 to 6 on Air, Land, Oceans and Fresh Water provide detailed discussions on pollution in these specific resources.

2.3.3.1 Greenhouse gas emissions

Anthropogenic or human-induced emissions of carbon dioxide (CO_2) and other GHGs such as methane, nitrous oxide, sulphur hexafluoride, are primary drivers of climate change – representing one of the world's most urgent challenges. For the first time, the concentration of CO_2, methane, and nitrous oxide in the atmosphere has reached levels unseen in the last 800,000 years (IPCC 2023). During this period, atmospheric concentrations of CO_2 never surpassed 300 parts per million. However, with the industrial revolution and the burning of fossil fuels, there has been a rapid increase in emissions of CO_2, and consequently, global CO_2 levels have risen significantly in recent decades. For the first time in those 800,000 years, the CO_2 concentration is now well above 400 parts per million (IPCC 2023). What is staggering is the speed at which CO_2 concentrations have changed during this period. While historically CO_2 levels shifted over thousands of years, it has taken just a few decades to reach the current state.

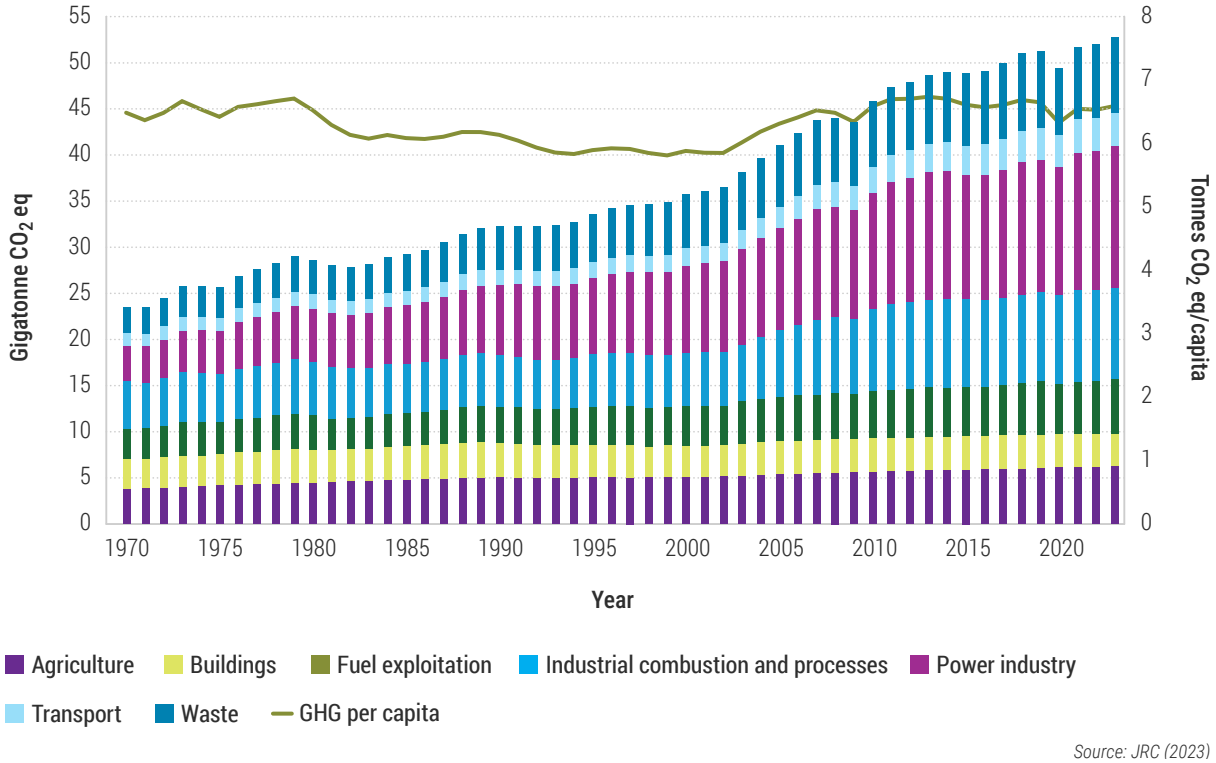
Global GHG emissions grew by 1.9 per cent in 2023 (Crippa et al. 2024). Notably, energy-related CO_2 emissions rose by 0.9 per cent, or 321 million tons in 2022, despite pandemic-related fluctuations, reaching over 36.8 billion tons (IEA 2023a). However, this increase was below business-as-usual projections, due to growth in clean energy that offset approximately 550 million tons of emissions from increased coal and oil consumption (IEA 2023a). The 321 million tons rise in CO_2 emissions included contributions from:

- 60 million tons was from cooling and heating demands due to extreme weather conditions, and 55 million tons was due to the shutdown of nuclear power plants

- Emissions from industrial processes decreased by 102 million tons, especially in China and Europe, but emissions from combustion energy increased by 423 million tons

- CO_2 emissions from oil increased by 2.5 per cent – even more than from coal – largely from aviation

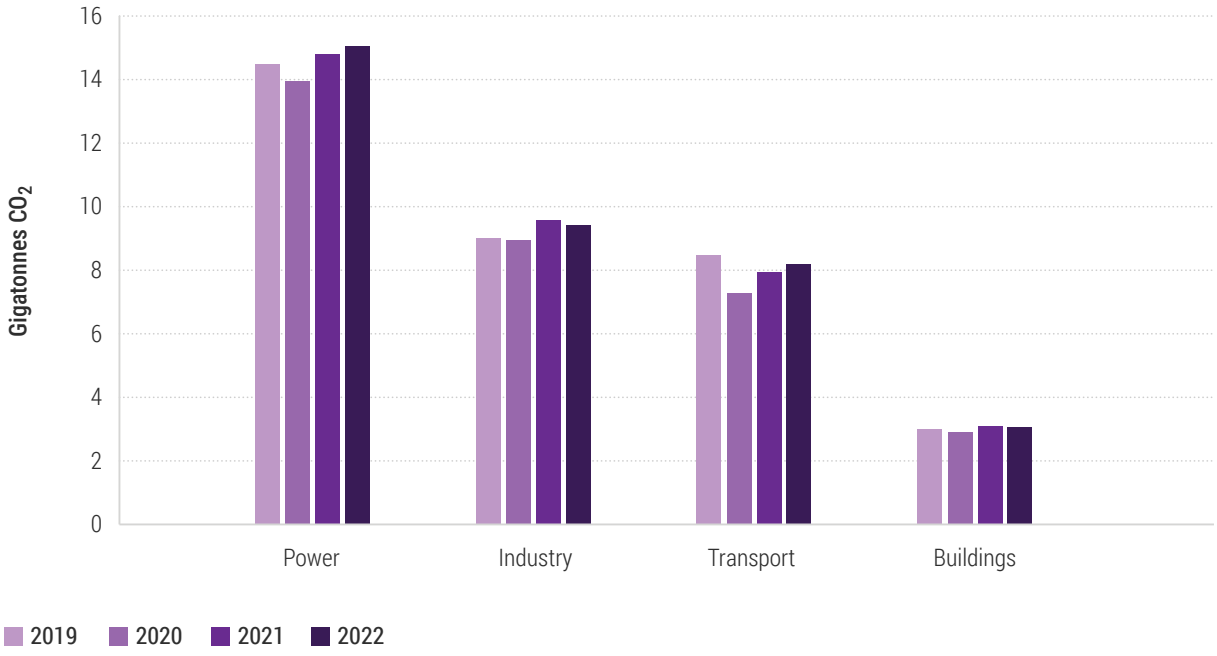
- Emission from fossil fuel increased further in 2022, relative to 2021 to 36.6 billion tons of CO_2/year



There were diverging trends across sectors and regions. CO_2 emissions grew in Asia, excluding China, and North America, surpassing the combined reductions in China and Europe. Among the various sectors, emissions from power and transport grew by 261 million tons and 254 million tons, respectively, more than offsetting reductions from industry and buildings (IEA 2023a).

Sectoral contributions

Global GHG emissions as estimated by the Emissions Database for Global Atmospheric Research (Crippa et al. 2024) for the period of 1970 to 2023 is presented in **Figure 2.22**. The total global GHG emissions in 2023 were 53 billion tons of CO_2 equivalent, about 1.9 per cent higher than the 2022 values. This represents an increase of nearly 1.5 per cent annually since 1990 – 61.8 per cent higher in 2023 compared to 1990.



Emissions from five major global economic sectors – energy supply, industry, transport, direct energy use in buildings, and agriculture, forestry, and land-use change – are included in the global emissions inventory (**Figure 2.23**). Most growth in emissions has come from the energy supply (37 per cent, 20 billion tons of CO_2) industry (26 per cent, 14 billion tons of CO_2) and transport (14 per cent, 7.5 billion tons of CO_2) sectors since 1990 (Lamb et al. 2021; Dhakal et al. 2022). The agriculture, forestry, and land-use change sector and the building sector contributed to 9.5 billion tons of CO_2 or 18 per cent and 3.1 billion tons of CO_2 or 5.7 per cent, respectively. The use of coal was lower than expected, even though emissions from the electricity sector rose by 3.4 per cent. According to IEA (2023a), CO_2 emissions from energy combustion increased by about 1.3 per cent or 423 million tons in 2022, while CO_2 emissions from industrial processes decreased by 102 million tons.

Figure 2.22: Sectoral GHG emissions and emissions per capita from 1970 to 2023

Source: JRC (2023)

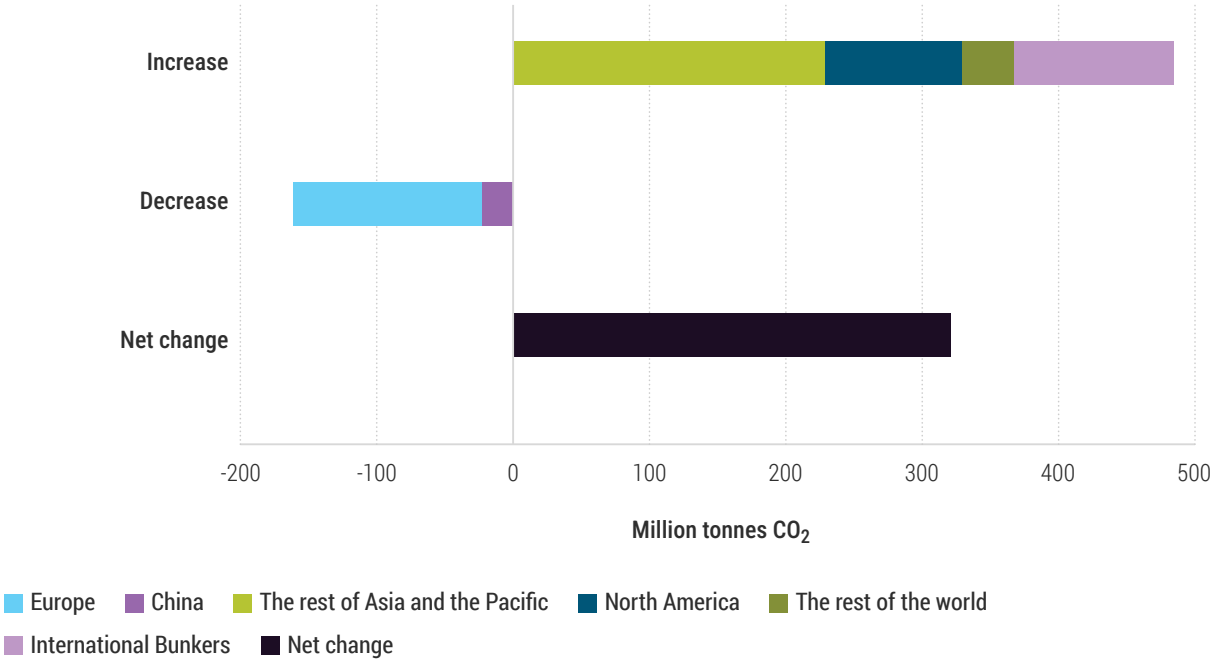
Figure 2.23: Global CO_2 emissions by sector from 2019 to 2022

Source: IEA (2023)

Regional contributions

In 2023, the GHG emissions from China, United States of America, India, the EU27, Russian Federation, and Brazil were the highest, collectively accounting for 64.2 per cent of fossil fuel consumption, and 62.7 per cent of total GHG emissions (Crippa et al. 2024). Compared to 2022, global GHG emissions increased by 1.9 per cent in 2023, reaching 53.0 billion tons of CO_2 equivalent (Crippa et al. 2024).

According to Crippa et al. (2024), among the 17 countries and regions contributing over one per cent to global GHG emissions, six experienced a decrease in emissions in 2023 compared to 2022. These include the United States of America -1.4 per cent, EU27 -7.5 per cent, Japan -6.0 per cent, Republic of Korea -2.2 per cent, Germany -10.5 per cent, and Pakistan -0.7 per cent. In contrast, all other major emitters saw an increase. India saw the highest rise at 6.1 per cent, followed by China at 5.2 per cent, and Indonesia at 4.1 per cent. Globally, per capita GHG emissions increased by 7.4 per cent, from 6.14 tons CO_2 equivalent in 1990 to 6.59 tons CO_2 equivalent in 2023.



Meanwhile, afforestation and reforestation create a carbon sink of about 0.9 ± 0.3 billion tons of carbon/year, counterbalancing emissions from deforestation (IEA 2023a) (**Figure 2.24**). The largest contributors in this sector during this period are Brazil, Indonesia, and the Democratic Republic of Congo, which together account for over half of the world's total land-use emissions (IEA 2023a).

2.3.3.2 Other pollutants

Environmental pollution has become a worldwide threat to humans and ecosystems. The key differences from over 50 years ago are the scale of the issue and the complexity of involved pollutants (Naidu et al. 2021). Although our understanding of the sources, fate, behaviour, and effects of pollutants has improved, some problems remain. The constant addition of new chemicals and the discovery of their harmful impacts on living organisms, along with the release of increasingly complex wastes and synthetic chemicals like plastic polymers (UNEP 2023a), raise concerns. This has led to discussions about a Global Plastics Treaty to combat plastic pollution.

Additionally, recent issues such as antimicrobial resistance (Hanna, Tamhankar and Lundborg 2023; Van Bavel et al. 2024) are another cause for concern, particularly for aquatic ecosystems and related human health effects. With an estimated 70,000 to 350,000 chemicals registered for production and use (Bond and Garny 2019; Wang et al. 2020) and the limitations

Figure 2.24: Change in CO_2 emissions by region

Source: IEA (2023)

of premarket assessments in many countries, we are still making little progress towards creating "benign by design" chemicals and adopting a more comprehensive life cycle approach in their evaluation as pollutants (Kümmerer, Clark, and Zuin 2020).

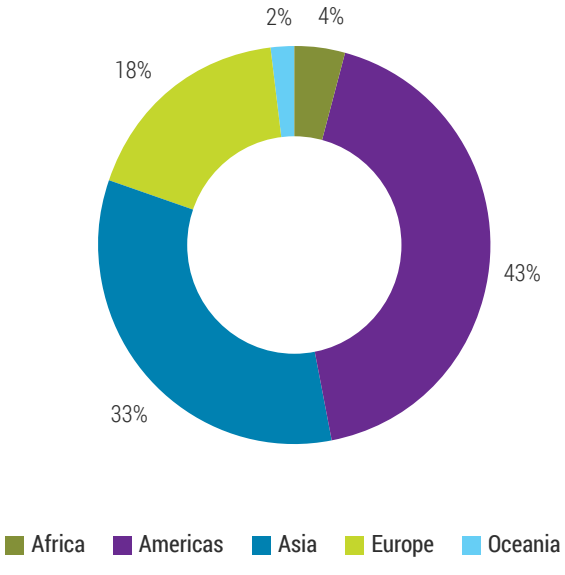
Globally, the use of chemicals continues to increase and there are no signs this trend will change in the short term across sectors such as agriculture, textiles, building, and pharmaceutical industries (UNEP 2019).

A selected group of chemical pollutants that share certain properties, such as high persistence, bioaccumulation, and toxicity (Ashraf 2017), have been and continue to be of global concern. These include persistent organic pollutants (POPs) and mercury, and more recently, the so-called "forever chemicals," such as poly- and perfluorinated chemicals widely used in modern life. The Stockholm Convention for POPs, the Minamata Convention for Mercury, and the Basel and Rotterdam Conventions, which address both the transboundary transport of hazardous wastes and the prior informed consent of countries to receive hazardous chemicals, have been instrumental in controlling sources, emissions, and waste management for these pollutants. These agreements have also implemented effectiveness assessment tools, such as the global monitoring plan for POPs, aimed at demonstrating the decreasing spatial and temporal trends of POPs levels on a global scale (Stockholm Convention on Persistent Organic Pollutants 2023).

Recently, two initiatives have been launched to combat global chemical pollution, aiming to safeguard human health and ecosystems. The first is the UNEP Global Framework on Chemicals, introduced in 2023 as a continuation of the earlier Strategic Approach for International Chemicals Management. The second is the science-policy panel, established per UNEA Res. 5/8 (2022). The science-policy panel will enhance the connection between science and policy on global chemical pollution issues, similar to how the IPCC and IPBES operate for climate change and biodiversity loss. This will be vital for promoting informed, evidence-based decisions on chemicals and waste.

At a regional and local level, pollution sources differ in contaminant types and environmental impacts, especially in developing regions. Regional pollution from extractive activities like mining (Tang and Werner 2023) has been documented in Africa, Asia, and Latin America. While mining is essential for acquiring resources to combat climate change – offering global benefits – it also causes local environmental impacts, especially in areas where water and biodiversity are heavily affected. In recent decades, the rising demand

for critical minerals such as beryllium, lithium, copper, nickel, and zirconium has spurred increased mining activities worldwide to satisfy market needs.



Critical minerals are essential elements required for developing and sustaining advanced technologies like smartphones, electric vehicles, and renewable energy systems (Hine, Gibson, and Mayes 2023). These minerals are crucial for manufacturing batteries that can reduce reliance on fossil fuels and help fight climate change. However, mining activities produce significant waste – up to 65 billion tons annually – posing serious environmental challenges related to storage and disposal (Kalisz et al. 2022).

Industrial agriculture continues to be a source of environmental pollution, considering that this activity relies on the continuous use of chemicals such as fertilizers, 136.5 kilogram per hectare in 2019 to 134.2 kilogram per hectare of arable land in 2022, the latest available data (World Bank 2023b), and pesticides increasing between 2019 and 2021 by almost 150,000 tons of active principles (FAO 2023) (**Figure 2.25**).While this ensures food security, it also causes environmental issues such as water eutrophication and pollution by pesticides.

Industrial chemicals of concern are present in many current-use articles and products, posing challenges for recycling and reuse. One example is the chemicals used in plastic materials as plasticizers or additives, whose complexity and effects have been described in the literature (Martínez-Pinna et al. 2023). Textiles also represent an emerging issue, as the global fashion market is expected to increase from US$1.5 trillion in 2020 to about US$2.25 trillion in 2025. There is growing concern regarding the chemicals used and the pollution that results when textiles become waste. Other problematic chemical classes include flame retardants with POPs properties and per- and polyfluorinated substances, widely used in many everyday products, which have gained public attention as the forever chemicals (Lim 2023).

Urbanization is increasingly a global trend, and if not managed properly, urban air pollution poses a serious threat to human health and ecosystems. Many benefits of reducing urban emissions, such as cutting greenhouse gases, also help lower urban air pollution. However, in many developing regions, levels of particulate matter remain a major challenge, and their reduction appears unfeasible under current consumption and production patterns (McDuffie et al. 2021). A global model estimates that, in 2022, 96 per cent, 82 per cent, and 53 per cent of Earth's populated areas experienced unhealthy air quality for at least one day, one week, and one month, respectively (Wei et al. 2023). The WHO, in 2022, reported that over 99 per cent of the world's population exceeded WHO air quality guidelines (WHO 2022). Urban sewage pollution and its sanitary consequences are another significant source of pollution (Howard 2021).

2.3.4 Invasive Alien Species

Invasive alien species (IAS) are species introduced either intentionally or accidentally to areas outside their native range that have become successfully established and cause substantial impacts on the new environment (Convention on Biological Diversity 2002). Against a global backdrop of habitat loss and declines in the richness and abundance of many native species, some non-native species are increasing in number and spread, sometimes invasively. Over 3,500 invasive alien species with adverse effects have been recorded (IPBES 2023). Nearly one-fifth of the Earth's surface is estimated to be at risk of invasions (Purvis et al. 2019), with hotspots in developed countries across North America, Europe, Australasia, alongside many island systems. IPBES reported that the cumulative number of alien species was increasing at a rate of 13 per cent per decade and showed no signs of slowing down. Projections under current

Figure 2.26: Number of established alien species (terrestrial and freshwater) in the 18 IPBES subregions and marine ecoregions (marine)

Source: IPBES 2023

trends suggest that the number of established alien species could rise by 36 per cent by 2050 (Seebens et al. 2020; IPBES 2023). Indigenous Peoples as well as local communities may view IAS as part of their landscape and have rights of self-determination regarding their management and eradication. Some IAS provide benefits such as resources like wood or fibre, but most impacts are negative (IPBES 2023).

Invasive species can significantly disrupt ecosystems by altering their structure and function, often outcompeting native species for resources and pushing some towards extinction (Seebens et al. 2021). They can alter nutrient cycling, fire regimes, hydrological processes, and other ecosystem functions, resulting in cascading effects on ecosystem services (IPBES 2023). Species invasion can affect agricultural productivity, damage infrastructure, and disrupt industries such as fisheries and forestry. Previous global assessments (Millennium Ecosystem Assessment 2005; IPBES 2019; IPBES 2023) identify invasive species as a major driver of biodiversity decline, alongside climate change, pollution, land-use change, and direct exploitation. The economic costs of species invasion can be significant, both in terms of direct damage and management expenses. These costs have increased exponentially over time, with aquatic invasions alone costing the global economy at least US$23 billion in 2020 (Cuthbert et al. 2021), and across ecosystems exceeding US$423 billion annually in 2019, having quadrupled every decade since 1970 (IPBES 2019).

Invasive species currently threaten 14 per cent of critically endangered terrestrial vertebrates, with birds particularly affected, often due to introduced mammalian predators. The effects of invasive species on biodiversity are particularly severe on islands (Dueñas et al. 2021), where native species may have evolved without strong competition, predation, or pathogens. Birds on oceanic islands have been especially vulnerable to introduced predators, leading to declines in island avian diversity.

The introduction and spread of non-native plants can increase local floristic diversity (Sax and Gaines 2008); however, extinction can take time (Cronk 2016), and a temporary increase in species richness may mask longer-term declines. In addition, the spread of a few highly invasive species decreases compositional differences among floras, resulting in more homogeneous species assemblages (Daru et al. 2021). The increase in non-native species and homogenization of biotic diversity is a defining feature of the Anthropocene (Olden, Comte and Giam 2016; Daru et al. 2021). Invasive species can act as disease vectors (Hulme 2014), accelerating rates of pathogen spread and increasing risk of zoonotic spillover from wildlife reservoirs. The invasive Asian tiger mosquito (*Aedes albopictus*) has spread to every continent except Antarctica and is a major vector of several human viral diseases, including chikungunya, dengue, and West Nile (Rochlin et al. 2013). Invasive pathogens also present a direct threat to many species (Crowl et al. 2008). The invasive *Batrachochytrium dendrobatidis* fungal pathogen has led to dramatic declines in amphibian communities across the globe, although there is now some evidence of emerging host resistance (Voyles et al. 2018; Scheele et al. 2019). The chestnut blight fungus, *Cryphonectria parasitica*, native to Asia, has devastated temperate forests across the eastern United States of America (Anagnostakis 1987), and the *Xylella fastidiosa* bacterium threatens olive trees across Europe (White et al. 2020). The widespread and intensive planting of agricultural crops has facilitated the expansion of plant pests and pathogens beyond their native range as they follow their hosts (Crous et al. 2016).

Aichi Target 9 aimed to address the challenge of invasive species. The Target's aspirations are clear, "By 2020, invasive alien species and pathways are identified and prioritized, priority species are controlled or eradicated, and measures are in place to manage pathways to prevent their introduction and establishment." Although there have been some notable successes in removing and controlling alien species, such as eradicating cats and rats from islands and using biological control to suppress weeds, efforts to achieve Aichi Target 9 have been insufficient (IPBES 2023).

The pressure from species invasions continues to increase (IPBES 2023), exacerbated through interactions with global pressures of climate change, land-use change, pollution, and other alien species – a process described as "invasional meltdown" (Pyšek et al. 2020).

2.4 Drivers, pressures, and the global environmental crises: Connecting the dots

The global environmental crises arise from the combined drivers (2.2) and pressures (2.3) placed on our planetary system (**Figure 2.1**). Different combinations of pressures compound each crisis, with some pressures being more influential than others, and their relative consequences varying across regions (Chapter 8) and scales. Building on **Figure 2.1**, we present a series of diagrams (**Figures 2.27** to **2.30**) to illustrate the relative strengths of the links between pressures and crises, highlighting the strength of confidence in the scientific evidence supporting them.

In each diagram, the height of the bar represents the relative contribution of different pressures to each crisis, with depth of shading indicating the confidence of the assessment. Assessments are qualitative, categorizing pressures as low, medium and high, based on expert opinion. Although quantitative evaluations are possible for some associations (Jaureguiberry et al. 2022), data are frequently lacking.

Climate change

Human-induced climate change has widespread impacts on ecosystems and is linked to shifts in precipitation, sea level rise, and the loss of glaciers and sea ice (IPCC 2023) (Global Environmental Crises Chapeau). It has led to severe adverse effects on the environment and people's well-being worldwide. Current global financial flows for adaptation are inadequate, resulting in an adaptation gap (IPCC 2023; UNEP 2023b).

Emissions from unsustainable resource use and energy practices – including lifestyles, production, consumption, and agriculture – have driven ongoing increases in GHG emissions (IPCC 2023; UNEP and IRP 2024). While CO_2 is the primary contributor to climate change, other GHGs and air pollutants such as methane, black carbon, and fine particulate matter ($PM_{2.5}$). also influence the climate (IPCC 2021). 55 per cent of CO_2 emissions come from resource extraction and use (UNEP and IRP 2024).

Demand for natural resources such as forest products, livestock grazing land, fish, crops, minerals, and fossil fuels has exceeded the Earth's capacity by more than 75 per cent (WWF 2022) – the consequences for climate change are mainly felt through increased GHG emissions generated during the creation, processing, and distribution of these resources. The adverse effects on the climate system will persist if current consumption patterns continue (FAO 2022).

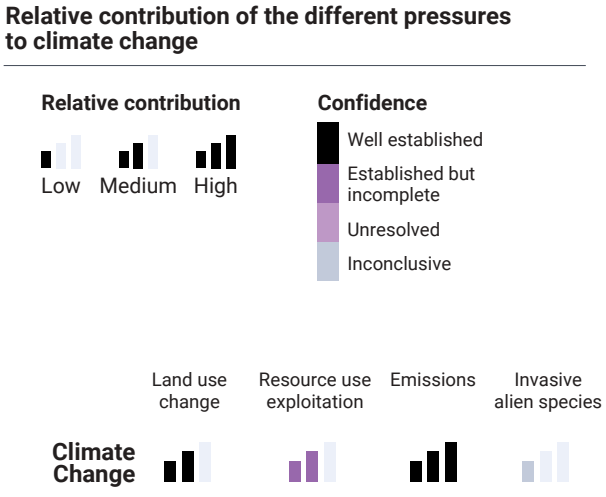
Land-use changes driven by human consumption are a major factor in climate change, since land functions both as a carbon sink and source (IPCC 2019; Martin et al. 2022). From 2010 to 2019, land-use change and management accounted for roughly nine per cent of global GHG emissions, ranking as the second largest source (IPCC 2021).

Invasive alien species may pose an additional, though lower, pressure on the climate, for example, by increasing the frequency and intensity of wildfires, particularly in hotter and drier climates. Biomass-burning emissions can significantly impair atmospheric conditions with consequences for the wider climate system (Bacher et al. 2023; Dobracki et al. 2023).

Pollution

As demand for resources increases and the current linear model of take it, make it, dispose of it persists, the planet faces a pollution crisis. Resource exploitation is the main driver of pollution (IRP 2017). Pollution

Figure 2.27: Pressures leading to climate change



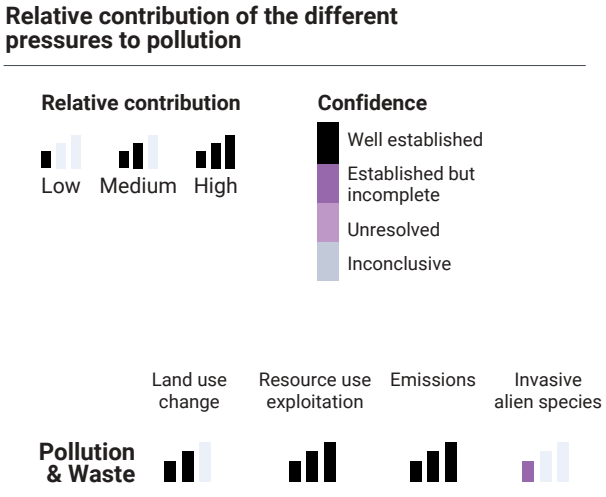


Figure 2.28: Pressures leading to pollution and waste

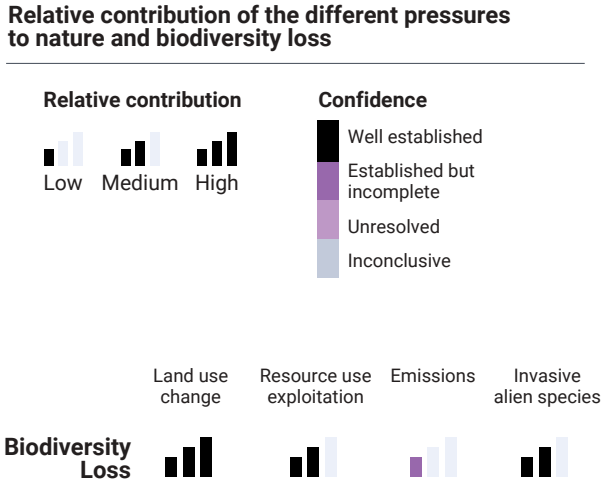
results from production and consumption patterns, aggravated by uneven distribution, overuse, and overpopulation (Wiedmann et al. 2020). Activities like deforestation, mining, and industrial agriculture lead to air, water, and soil pollution, degrading environmental quality and harming human health (Huo and Peng 2023). "Sacrifice zones," or pollution hotspots linked to significant health challenges, often accompany development. These zones frequently overlap with territories of Indigenous Peoples and other marginalized communities, raising serious environmental justice concerns (Maldonado 2018).

Emissions, including GHGs, are a category of pollutants that can have diffuse repercussions. While many regions have emissions regulations, reducing pollution is a societal challenge that requires behavioural change (Farage, Hansen and Uhl-Haedicke 2024). Technological advancements may assist in reducing pollution in some cases, such as in wastewater treatment or air emission controls (Jain 2024), but they have also historically been a source of new pollutants, like electronic waste. Technology can aid sustainability, yet there is limited empirical evidence on its role in driving transformative change to address the global environmental crises (IPBES 2024).

Land-use changes, particularly the conversion of natural habitats into agricultural land, are a major source of pollution due to the excessive use of fertilizer and pesticides. This leads to increased runoff and leaching of nutrients and pesticides into waterways and groundwater. Urbanization and higher population densities in cities contribute to air and water pollution from transport, heating, and waste. However, recent evidence shows that if properly planned, urbanization can reduce overall pollution levels (Sun et al. 2023) and diminish ecological footprints (Danish, Ulucak and Khan 2020).

Invasive species may contribute to transporting pollutants from one area to another, such as POPs carried by salmon (Montory et al. 2020). While invasive species are not usually considered a major pollutant, they have been recognized as a form of biological pollution (Elliott 2003).



Biodiversity loss

Land-use change is the leading direct threat to biodiversity (Newbold et al. 2016; IPBES 2019). The expansion of agriculture to satisfy the growing demands of an increasingly resource-consuming human population is a key cause of habitat change. Rapid industrialization and urban growth contribute further to the destruction and fragmentation of natural habitats, with adverse outcomes for biodiversity (Kondratyeva et al. 2020; Laurance and Engert 2022; Simkin et al. 2022).

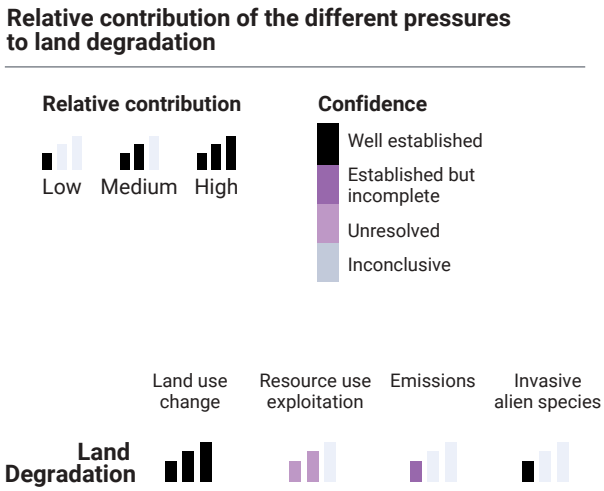
Resource use and overexploitation, whether for timber, minerals, or other natural products, can harm habitats and deplete vital ecosystem components (IRP 2017; Subramanian 2018; Huo and Peng 2023; Lu & Wang 2023). Direct exploitation of wildlife species can cause population collapses with cascading ecological consequences that are difficult to reverse (Daskalov et al. 2007; Myers et al. 2007; Huo and Peng 2023). Effective governance is essential for responsible resource management, while poor governance can result in uncontrolled exploitation and degradation of natural habitats (Springer, Campese and Nakangu 2021; IPBES 2024).

Invasive alien species are recognized as one of the five main drivers of biodiversity loss (IPBES 2023). Invasive species can displace native species through competition or predation and serve as vectors of disease, resulting in population declines and ecosystem imbalances (IPBES 2023). Increased movement of people and trade has raised the rates of alien species introductions, which show no signs of slowing (IPBES 2023).

Figure 2.29: Pressures leading to biodiversity loss

Emissions, including pollutants from industry, transport, and agriculture, can have both diffuse and localized impacts on biodiversity (IRP 2017; Villarrubia-Gomez et al. 2024). Bioaccumulation of pollutants can disproportionately effect species higher in the food chain and pose a risk to human health (Corsolini et al. 2005; Cordier et al. 2024; WHO 2021b). The effect of GHG emissions on biodiversity is largely indirect via their contribution to climate change. While the impacts of climate change on biodiversity are only beginning to be felt (Urban 2024), climate pressures are expected to accelerate rapidly over the next few decades (Pigot et al. 2023).

Land degradation



Population growth, conflict, urbanization, economic development, and associated high-consumption lifestyles can cause and worsen land degradation.

Land use change can directly cause land degradation. Agricultural expansion and intensive farming practices, which involve high pesticide and fertilizer use, are key contributors to land degradation and threaten agricultural productivity, ecosystems, and human health (Raj et al. 2023). An increase in contract farming, large-scale land acquisitions, and related processes can signify shifts in land governance towards value chain actors (Clapp 2021; Debonne et al. 2021). These shifts can lead to or intensify land degradation through land-use change and agricultural intensification (Debonne et al. 2021).

Natural resource use, such as wood and timber for bioenergy, increases competition for land, which directly affect food security and land degradation (Olsson et al. 2019; IPBES 2018). Biomass used as fuelwood and charcoal degrades forests and accounts for approximately two per cent of global GHG emissions (Olsson et al. 2019). Meanwhile, extraction of fossil fuels and minerals to meet growing demand for goods and energy is placing locally intense and growing burdens on land integrity.

Pollutants from industry and agriculture, such as industrial chemicals and fertilizers (2.3.3.1), can have both direct and indirect environmental impacts. While GHG emissions are not typically considered a direct cause of land degradation, degraded lands can increase GHG emissions, exacerbating climate change and further degrading ecosystems. In addition, the interaction between climate change and land degradation also affects food security by reducing crop yields (Rosenzweig et al. 2018; IPCC 2018; IPCC 2019), particularly in drylands – home to 2.3 billion people (Vicente-Serrano et al. 2024) – and in high mountain regions (IPCC 2019). Invasive alien species can exacerbate land degradation by disrupting native ecosystems, altering fire regimes and accelerating erosion. Various types of shocks (2.2.7), including armed conflict, can accelerate the rate and magnitude of land degradation processes and trigger new degradation patterns (Bowd et al. 2019; Olsson et al. 2019).

Global Environmental Crises Chapeau

C.1 A planet in crisis

In March 2024, the United Nations Environment Assembly called for urgent collaborative action to address the global environmental crises defined as the crisis of climate change, the crisis of biodiversity loss, land degradation and desertification, and the crisis of pollution and waste (UNEP/EA.6/HLS.1). These environmental crises risk catastrophic consequences for human well-being and may therefore also be regarded as social, economic, safety and security crises. More than 40 per cent of the global population lives in areas that have experienced significant biodiversity decline (Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services [IPBES] 2024a), while 71 per cent of the working population – 2.4 billion people – are exposed to excessive heat at work (International Labour Organization [ILO] 2019), seven million deaths annually are attributed to pollution (Fuller et al. 2022), and land degradation is increasing by 100 million hectares every year (United Nations Convention to Combat Desertification [UNCCD] n.d.; Tomalka et al. 2024). Rapid and irreversible environmental shifts, exacerbated by interactions and feedback between and among the crises that may precipitate environmental tipping points, are of increasing concern (10.5). For example, rising temperatures have the potential to accelerate land degradation and ecosystem disruption, both of which may feed back to exacerbate the climate and biodiversity crises (Pörtner et al. 2021).

C.1.1 Climate change

Climate change, unequivocally driven by greenhouse gas (GHG) emissions from human activities such as burning fossil fuels and deforestation, has warmed the Earth's surface by an average of at least 1.3°C (Intergovernmental Panel on Climate Change [IPCC] 2023a; World Meteorological Organization [WMO] 2024a; Obada et al. 2024). The last two years – 2023 and 2024 – were the warmest on record, with the 2024 global temperature averaging 1.55°C warmer than the period before widespread industrialization (Copernicus 2024; WMO 2024b). This indicates a rapid acceleration towards or beyond the 1.5°C threshold of the Paris Agreement (Lamboll et al. 2023). At 1.5°C warming, increasing extreme weather patterns, sea-level rise, loss of coral reefs, a reduction in rainforest biomass and a decline of mangrove forests can be expected. The Arctic Ocean may become ice-free in summer by the mid-2050s, a sea-level rise of more than 1.5 metres is possible due to Antarctic and Greenland ice-sheet melt, and a 70–90 per cent decline in coral reefs is likely (IPCC 2021a; IPCC 2022; Kim et al. 2023; Buis 2024; Jahn et al. 2024). The impacts of these changes are experienced differently across regions, communities and populations and are exacerbated by existing differences and vulnerabilities (WMO 2024c).

The economic, environmental, social and health costs of climate change are substantial and projected to escalate steeply, with significant cost disparities across regions and socioeconomic contexts (IPCC 2022). Women, particularly in developing countries, are more vulnerable to climate change effects due to their roles in agriculture and water collection (Fruttero et al. 2023). The global cost of climate-induced extreme weather events in the past 20 years is estimated at US$143 billion per year, with the United States incurring a cost of US$27 billion in 2024 (Newman and Noy 2023; National Centers for Environmental Information2025). Costs have increased exponentially over the last five years, and cumulative costs from 2014–2023 are estimated at US$2 trillion, affecting 1.6 billion people (Oxera 2024). Climate-related costs are compounded by the indirect risks associated with rising temperatures, especially health issues such as heat-related illnesses and deaths, and food and water security (United Nations Office for Disaster Risk Reduction 2023).

Modelled pathways show with high confidence that the projected warming by 2040 can only be avoided if rapid and deep emissions cuts are made in all sectors in this decade (IPCC 2023b). To achieve the Paris target of 1.5° C would require cuts in emissions of 42 per cent by 2030 and 57 per cent by 2035, whereas emissions in 2030 would be comparable to today even with full implementation of current nationally determined contributions (UNEP, 2024).

C.1.2 Biodiversity loss

An estimated one million species are currently at risk of extinction (IPBES 2019) and current extinction rates are calculated to be several orders of magnitude greater than background rates estimated from the fossil record (De Vos et al. 2015). The world is accumulating a large extinction debt – the number of species committed to extinction – as a consequence of humanity's past actions (Spalding and Hull 2021) (Wang et al. 2025). Many iconic species are at imminent risk of extinction, including the California Condor, Black Rhino, and the Bornean Orangutan (IUCN 2025). Genetic diversity loss since the Industrial Revolution, conservatively estimated at 5-10 per cent globally and at over 25 per cent on islands (Leigh et al. 2019; Exposito-Alonso et al. 2022), poses a threat to evolutionary potential and adaptation to future global change. In agricultural systems, the erosion of crop genetic diversity undermines productivity and resilience to climate change (Khoury et al. 2021). Almost 60 per cent of the world's land surface is now subject to moderate or intense human pressure (Williams et al. 2000U). Human activities are increasingly altering the marine environment, with marine species adversely affected across 57 per cent of their range on average (O'Hara, Frazier and Halpern 2021).

Several ecosystems are already considered ecologically collapsed, including the Rapa Nui subtropical broadleaf forests on Easter Island, and the Aral Sea between Kazakhstan and Uzbekistan (Bland et al. 2018). Rates of future collapse may be more rapid than previously anticipated (Willcock et al. 2023). Coral reefs, which are critical to marine biodiversity and the livelihoods of millions, are at risk from rising sea temperatures and ocean acidification, with mass bleaching events now occurring every six years on average. This threatens the economic backbone of coastal communities and the entire reef ecosystem (Mies et al. 2020). The Amazon rainforest, a vital global carbon store, is being ravaged by deforestation and

Credit: JuiceFlair/Envato

forest fires, transitioning from a carbon sink to a carbon source, with profound implications for global climate regulation (Butt et al. 2023). Regional warming might push the Amazon rainforest towards a tipping point where significant amounts of carbon could be released into the atmosphere, exacerbating feedbacks to the climate system (Artaxo 2023).

Biodiversity of plants, animals, fungi and microbes underlies healthy ecosystems and supports essential ecosystem services, including clean air and water, food, feed, fibre and bioenergy. It regulates disease and climate, provides protection against erosion and extreme weather events, encourages soil formation and biogeochemical cycling, and is a source of innumerable cultural benefits to all peoples (IPBES 2019). Over 75 per cent of agricultural crops are dependent at least in part on insect pollinators (Klein et al. 2007), while over 2.4 billion people may benefit from the coastal protection provided by mangrove forests (United Nations Environment Programme [UNEP] 2023). However, over 70 per cent of the global population inhabits environmentally compromised areas, where ecosystem services are being lost or degraded, and many ecosystems have already exceeded safe limits for biodiversity (Newbold et al. 2016). Globally, the degradation of ecosystems will lead to a loss of services worth between US$10 trillion and US$44 trillion annually (Mies et al. 2020; World Economic Forum 2020). Developing a stronger bioeconomy could help support sustainable development and the conservation of both biological and cultural diversity (Huddart et al. 2022).

C.1.3 Land degradation and desertification

Land degradation is the result of anthropogenic actions that exploit the land, causing a decline in the utility, fertility, biodiversity, and overall health of the environment. Land degradation adversely affects 24–40 per cent of the global land area (IPCC 2019; Edrisi et al. 2022; UNCCD 2022) and over 3.2 billion people (IPBES 2018a). From 2015 to 2019, at least 100 million hectares of fertile and productive land

were lost annually worldwide, an area equivalent to twice the size of Greenland (UNCCD 2023). Ocean degradation negatively affects approximately 66 per cent of the global oceans (IPBES 2019; IPCC 2021b), impinging on the livelihoods and food security of over 3 billion people who depend on marine resources. Overfishing, coastal destruction and pollution continue to degrade vital marine habitats, including coral reefs, mangroves and seagrass meadows (Food and Agriculture Organization [FAO] 2022). In drylands, which encompass one-third of global land area, land degradation through the expansion of croplands and unsustainable management practices, exacerbated by climate change, can lead to desertification and a loss of primary productivity (Kimmell, Fagan and Havrilla 2023). Land degradation weakens the role of forests as carbon sinks, significantly reducing their capacity to provide key ecosystem services such as carbon storage, water and nutrient cycling and support of biodiversity (IPCC 2019; Ekka et al. 2023; Winkler et al. 2023). Land degradation, in synergy with climate change, may force 50 million to 700 million people to migrate by 2050 (IPBES 2018a). In the Global South, approximately 143 million people could be displaced due to the effects of climate change on land by 2050 (Almulhim et al. 2024).

Globally, the estimated annual costs of land degradation are large, but uncertain, and range between US$18 billion and US$20 trillion (UNCCD 2019a). Projections to 2050 predict further losses of 36 gigatons of carbon from soils, and gross emissions due to forest degradation are projected to reach 10.2 gigatons of CO_2 (UNCCD 2019b; Assis et al. 2022). Water-induced soil erosion, a leading process of land degradation, is estimated to impose cumulative global GDP losses ranging from US$216 billion to US$625 billion between 2015 and 2070, which translates to an annual loss of approximately US$4 billion to US$11 billion (Sartori et al. 2024). The effect on global food production is a key concern, with a potential reduction of up to 33.7 million tons (Sartori et al. 2019) and a corresponding 30 per cent increase in world food prices by 2040 (ELD Initiative 2015a). Reversing land degradation would restore soil health and fertility, combat desertification and prevent further degradation, allowing for sustainable food production and livelihoods (Pandit et al. 2020). The estimated cost of fulfilling current global restoration commitments ranges from US$311 billion to US$2,146 billion over a 10-year period (Verhoeven et al. 2024); however, adopting sustainable land management globally could generate US$75.6 trillion in annual economic benefits (ELD Initiative 2015b). Indigenous cultural values and nature-respecting practices offer valuable insights into how collective behaviours can holistically support land sustainability (Shrivastava and Zsolnai 2022).

C.1.4 Pollution and waste

Environmental pollution is the world's largest risk factor for disease and premature death, with nine million human deaths annually attributable to some form of pollution (Fuller et al. 2022). More than 90 per cent of pollution-related deaths occur in low and middle-income countries (Fuller et al. 2022). Pollution affects women's health differently, particularly in terms of reproductive health and exposure to household pollutants. The adverse health effects of pollution on the elderly may also be disproportionate (Simoni et al. 2015; Fan et al. 2022).

Pollutants in the environment encompass a wide range of contaminants, including noise, light and radioactive pollution, as well as contaminated water, soil and land contamination, atmospheric pollution, industrial waste and plastic litter. Collectively, these pollutants threaten biodiversity, contaminate food sources, and can lead to long-term health consequences for wildlife and human populations (Lee et al. 2024). Hazardous waste, including solid waste and medical waste (Windfeld & Brooks 2015), can have both direct and indirect effects on the environment and human health (Zhang et al. 2022). Waste management practices can also be a major source of GHG emissions (Friedrich & Trois, 2011). Toxic metals, such as lead, mercury, and cadmium, are of particular concern due to their persistence in the environment and their ability to accumulate in biological systems (Lee et al. 2024). Fine particulate matter (PM2.5) pollution has been linked to cardiac and respiratory disease (Hayes et al. 2020). Chemical pollutants include pesticides in food, nutrient run-off in the sea, rivers and lakes, and endocrine-disrupting chemicals in drinking water and personal-care products (Naidu et al. 2021). In recent years, a major concern has been the emergence of new pollutants, including pharmaceuticals and microplastics that may be ingested or absorbed by plants and animals (Lim 2021; Vethaak and Legler 2021), antibiotic resistance genes and nanoparticles, as well as forever chemicals such as per- and poly-fluorochemicals (Cousins et al. 2022). These emerging

contaminants present unique challenges due to their widespread occurrence and the complexity of their effects on health and the environment.

Anthropogenic pollutants are now ubiquitous, from the highest mountain peak (Napper et al. 2020) to the abyssal sea floor (Nakajima et al. 2021), and ecosystem degradation due to pollution is observed throughout the world (Dar et al. 2025). Over recent years, there has been increased awareness of plastic pollution in the oceans: the global abundance of floating plastic particles is estimated to weigh between 1.1 million and 4.9 million tons (Eriksen et al. 2023). Dispersed pollutants may become concentrated through catchment drainage and bioaccumulation, with toxic effects at different levels of biological organization, as documented for some endocrine-disrupting chemicals (Luo et al. 2024). Chemical pollution will continue to adversely affect human health and ecosystems, given the current trends in chemical production, use and disposal (UNEP 2019).

C.1.5 Interacting global crises

The global environmental crises are intricately interconnected but are frequently addressed individually by researchers and policymakers. This overlooks the potential for understanding their interactions and the opportunity to identify solution pathways that may provide multiple co-benefits or result in trade-offs and unintended consequences. For example, a narrow focus on mitigating GHG emissions from fossil fuels by promoting biofuels or tree planting in natural grasslands can result in biodiversity loss (Bond et al. 2019; Tudge, Purvis and De Palma 2021). However, managing land through sustainable and regenerative agriculture, livestock and forestry practices can enhance soil health, carbon storage, reduce GHG emissions and promote biodiversity (Kopitkke 2019; Pörtner et al. 2021). Land restoration, including afforestation, and reduced land degradation could provide more than one-third of the cost-effective GHG mitigation activities needed by 2030 (IPBES 2018a), and allow the attainment of net zero earlier (IPCC 2023b).

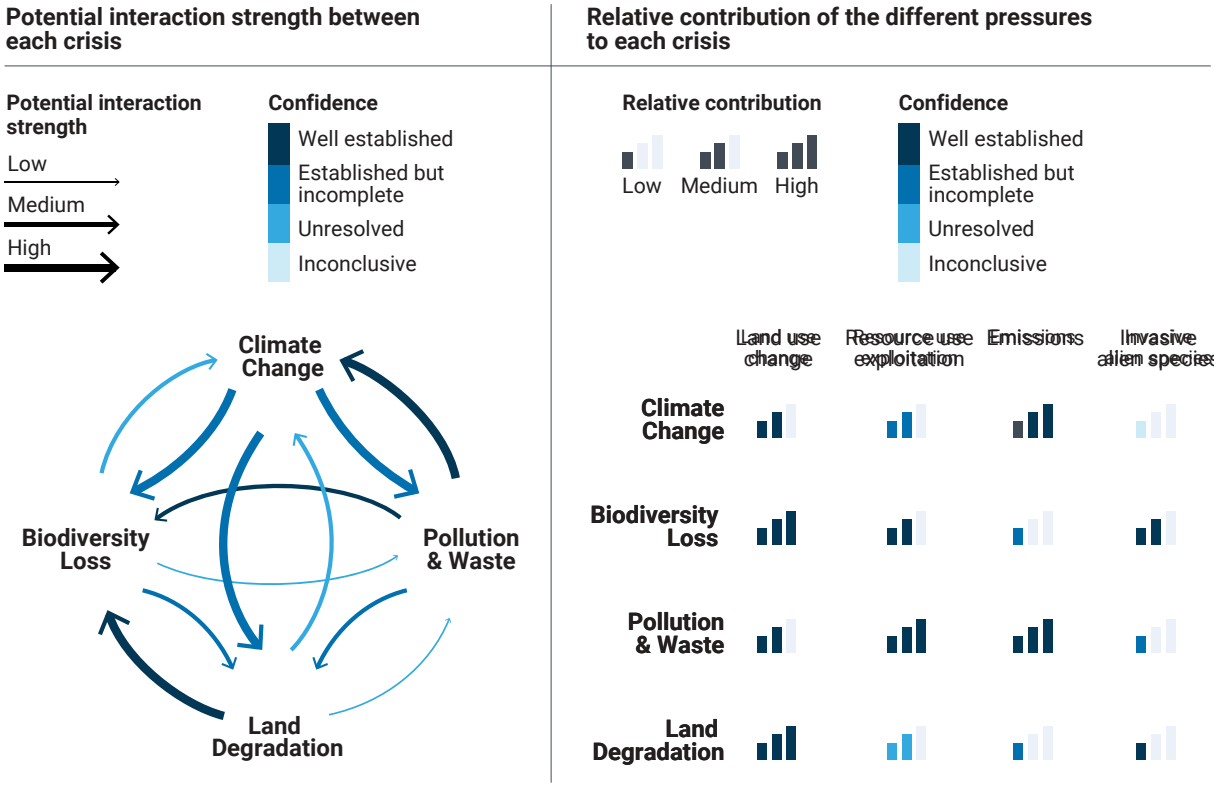

Figure C.1 illustrates the potential for interactions between crises, recognizing their asymmetrical bidirectionality. For instance, the effect of climate change on biodiversity loss is likely stronger than the effect of biodiversity loss on climate change. As an example, some models suggest climate change could lead to the complete disappearance of warm-water coral reefs by 2050 (IPCC 2023b), while the degradation of coral ecosystems may only indirectly influence the climate by altering water flow that favours sea grasses (James et al. 2023). However, the strength of interactions will also vary across temporal and spatial scales, and between regions and ecosystems. Some of this important variation can be observed through examining the different priority issues among regions (8.1). The potential pairwise interactions between crises is illustrated by overlaying maps of their pressures (Table C.1–C.6), demonstrating how each crisis is also multifaceted and can thus be described along many possible axes. In some cases, knowledge of the effects of interactions between crises may be data-limited (IPBES 2024a), or full effects may only become apparent in the future due to gradual or non-linear responses (10.5). New research approaches are needed to address these challenges (Pfenning-Butterworth et al. 2024) (Chapter 10), that also allow for integration of Indigenous Knowledge.

Considering only the pairwise relationships between crises fails to represent the complex interactions, feedbacks and interdependencies among them; they are all interconnected spatially, temporally and causally. The pairwise connections between crises can also form longer chains of interactions that may include non-linearities that challenge simple extrapolations (Pfenning-Butterworth et al. 2024). While no single representation can fully capture these complexities, they should be considered when identifying solution pathways (FAO et al. 2022; IPBES 2024a).

Each environmental crisis can be defined along multiple axes, and is subject to, and emerges from, various pressures (2.2;2.3). Pressures are as defined in Chapter 2:

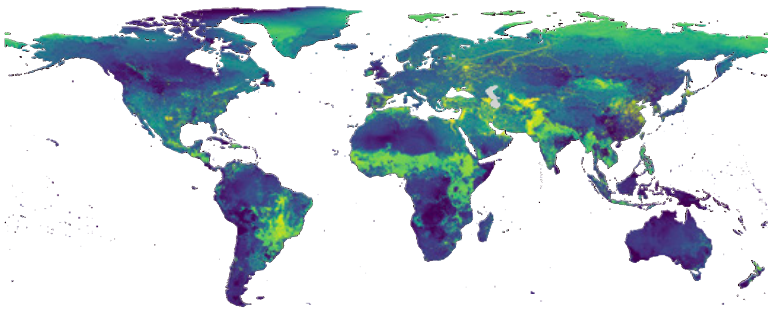
- Land-use change represents the conversion from one land-use type to another, with the most prevalent land-use transitions occurring between forest and cropland. Land-use change does not necessarily indicate a change in biodiversity.
- Resource use and exploitation consider multiple resources, including exploitation of fish and wildlife, fossil fuels, minerals and rare elements, wood and timber, and water extraction.

Figure C.1: Interconnectedness of the global environmental crises of climate change, biodiversity loss, land degradation and desertification, and pollution and waste

- Emissions encompass greenhouse gases and other pollutants, including short-lived climate pollutants, such as black carbon, and chemical pollutants from industry and agriculture.
- Invasive alien species are defined as species introduced to areas outside their native range that have become successfully established and cause substantial negative effects on the new environment.

Interactions shown as arrows between some crises are stronger than others, with arrow width indicative of potential interaction strengths (part a). Bars (part b) represent the relative contribution of the different pressures to each crisis as low, medium and high. Depth of shading reflects qualitative assessment of confidence – well established, established but incomplete, unresolved, and inconclusive – in the assigned contribution weights.

Table C.1:Potential for interactions between climate change and pollution



Heatmaps overlaying pressures illustrate the potential for interactions between the environmental crises. All pressures are standardized to a uniform scale, assuming equal weights. High pressure intensity areas, assuming additive interactions, are indicated in yellow and low intensity areas in blue. Areas of no data are shown in grey. Regions where overlapping pressures are both high might be indicative of an elevated risk of compounding pressures and could be informative for directing mitigation measures or adaptive responses. However, considerable uncertainty over the strength of interactions remains.

Heatmaps were created using the best available data, harmonizing spatial resolution and normalizing values between 0 and 1. Existing annual products or computed annual means from products of higher temporal resolution – for example, daily or monthly – were used, and multi-year trends were created by computing linear trendlines based on the annual time-series.

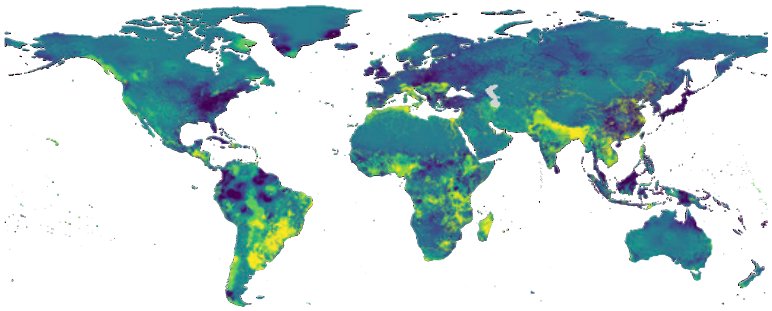


Table C.1: Potential for interactions between climate change and pollution (cont.)

Temperature and CH_4 trends (1982–2022)

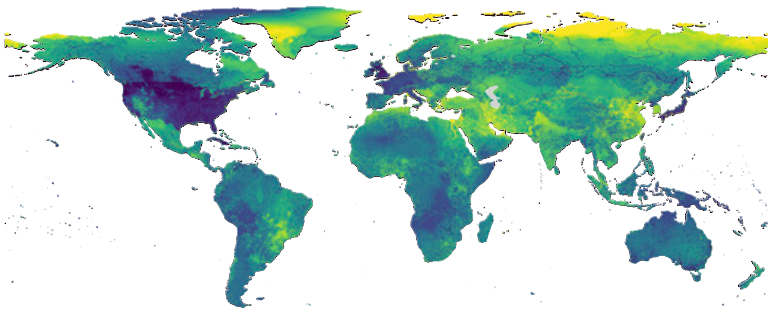
Effects of climate change → on pollution



While the mechanistic relationships between pollutant behaviour, fate, and effects is still not fully understood (Noyes and Lema 2015; Hatje et al. 2022), extreme weather events release chemicals and other pollutants into the environment, and warming temperatures can aggravate methane emission from wetlands (Feron et al. 2024). Changes in temperature and precipitation patterns can also increase fine particulate matter pollution from wildfires and drought (Xie et al. 2022).

Aerosols (2000-2022) and temperature (1982-2022) trends

Effects of pollution → on climate change

Atmospheric pollution has both regional and global effects on climate. Tropospheric ozone is a component of air pollution and mediates the longevity of methane, a potent GHG (Griffiths et al. 2021). Atmospheric particulate and aerosol pollutants include black carbon, and their climate effects are seen mainly at high latitudes, including the Antarctic (not shown). Here, they alter the albedo of snow and ice, contributing to high melt rates of glaciers, sea ice and ice sheets (Gul et al. 2021).

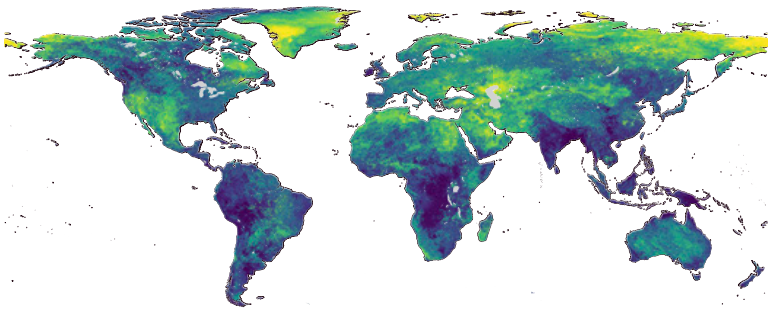
Effects of climate change → on biodiversity



Projections suggest that one in three species may be threatened by climate change under high-emissions scenarios (Urban 2024), and climate change may become the dominant extinction driver by the end of the century (IPBES 2024b). Coral reefs have been disproportionately affected by warming seas and ocean acidification (Hoegh-Guldberg et al. 2017). More extreme and more frequent weather-driven events, such as wildfires, directly threaten wildlife populations, although mortality rates are uncertain (Jolly et al. 2022). Many species are shifting their distributions to cooler climates, moving polewards or upwards in elevation (Chen et al. 2011). Climate-induced changes in the timing of life history events risk generating trophic asynchronies, for instance, a mismatch between flowering times and pollinator availability (Fuentes, Hamann and Limpus 2010; Thackeray et al. 2010). Differences in species' ability to acclimatize and adapt may also exacerbate disease outbreaks (Cohen et al. 2019).

Effect of changes in biodiversity → on climate change

Changes in biodiversity can affect climate at regional and local scales (IPCC 2023b). At high latitudes, climate warming has led to the revegetation of tundra, resulting in a feedback cycle as increased vegetation furthers warming as albedo decreases. At mid-latitudes, the replacement of forests by grasslands can increase albedo (Hasler et al. 2024); however, this can also reduce carbon storage capacity (Gibbs et al. 2007). At local scales, forest loss can lead to shifts in atmospheric water vapour concentrations, altering cloud cover and evapotranspiration rates.

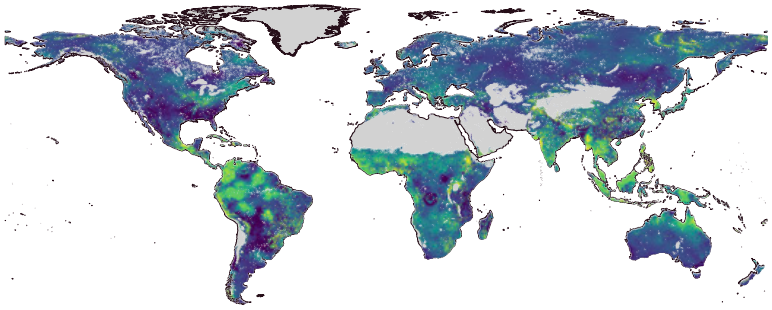


Table C.3: Potential for interactions between climate change and land degradation

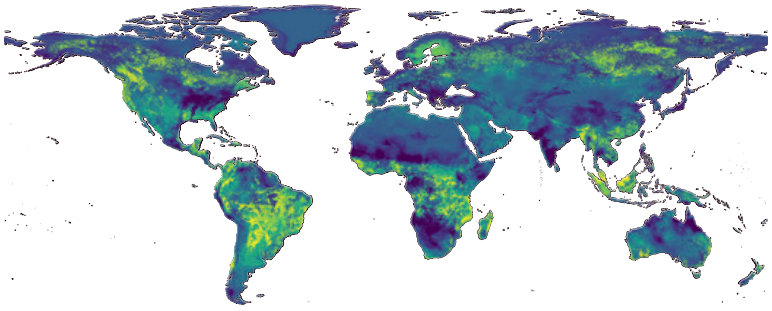
Temperature trend (1982–2022) and land productivity trend (2007–2022)

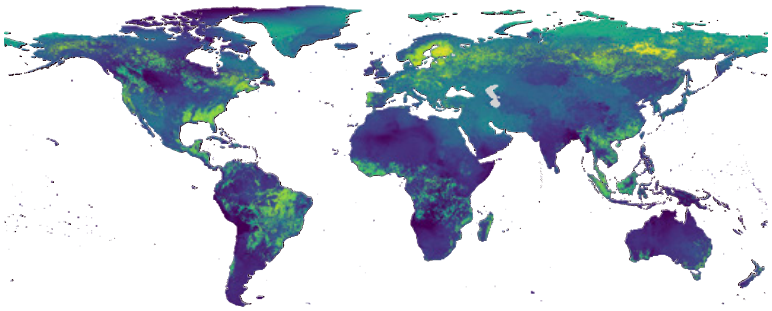
Source: Temperature data University of East Anglia Climatic Research Unit et al. (2024) and land productivity data Ivits and Cherlet (2013). Land productivity is presented through its inverse component (1- land productivity) in this combined map.

Precipitation trend (1982–2012) and soil erosion (2012)



Source: Precipitation data University of East Anglia Climatic Research Unit et al. (2024) and soil erosion data European Commission (2017).

Effects of climate change → on land degradation



The effects of climate change on land degradation occur at multiple scales. One primary process is the reduction of soil organic matter pools directly triggered by the effects of rising temperatures (Crowther et al. 2016). The Middle East has been particularly affected, with elevated dust levels damaging people's health (Mousavi, Moshir and Kalantari 2024). Climate change-induced extreme weather events such as hurricanes, wildfires, droughts, floods and landslides can additionally increase land degradation (Bandh et al. 2021; Talukder et al. 2021). Precipitation shifts that enhance plant growth and land productivity, can reduce land degradation (Abbasi et al. 2020). However, higher precipitation intensities, especially following prolonged drought, can lead to increased erosion and flooding, exacerbating land degradation (Olsson et al. 2019)..

Source: Forest loss data Hansen et al. (2013) and temperature data University of East Anglia Climatic Research Unit et al. (2024)

Effects of land degradation → on climate change

Deforestation and habitat conversion for agriculture and other land uses release stored carbon, increasing GHG emissions (Houghton 2020). Forest degradation and land clearing can also alter surface albedo, further aggravating warming trends (Olsson et al. 2019) (Worlanyo and Jiangfeng 2021). Degraded land, especially through deforestation and soil erosion, reduces carbon sequestration, depleting vital carbon sinks (Lal 2019; Olsson et al. 2019). Loss of soil fertility in agricultural systems prompts increased inorganic fertilizer use that releases nitrous oxide, a potent GHG (IPBES 2018b; IPCC 2019), initiating a feedback loop.

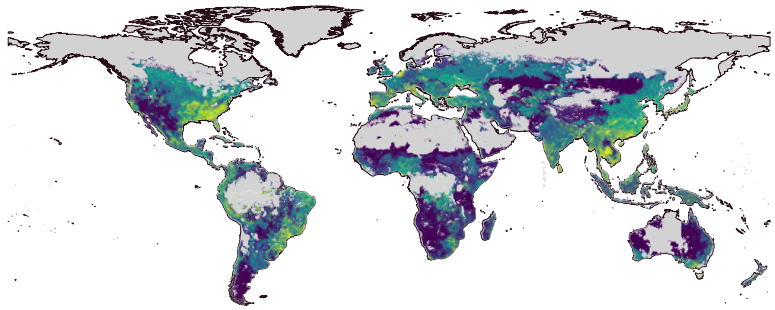

Table C.4: Potential for interactions between pollution and biodiversity loss

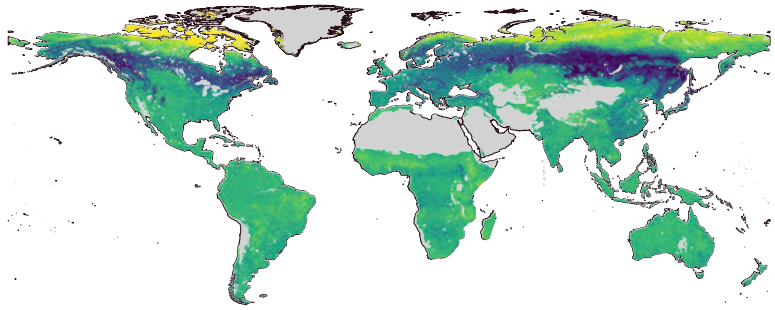
Source: Pesticide pollution data Tang et al. (2021) and global extinction probabilities for freshwater fish species data from data Verones et al. (2022)

Effects of pollution → on biodiversity loss



Environmental pollution by hazardous chemicals can have significant adverse effects on terrestrial and aquatic life (Jaureguiberry et al. 2022; Sigmund et al. 2023). Examples include the decline in pollinators linked to pesticide use (Goulson et al. 2015), sediment, sewage and fertilizer pollution in freshwater systems, and a vast number of manufactured chemicals that pollute the marine, freshwater and terrestrial environments (Sigmund et al. 2023). Air pollution, including ground level ozone, has effects on ecosystems and human health (Nowak et al. 2015). Pollutants of new or increasing concern include micro- and nanoplastics (Sharma and Chatterjee 2017), persistent organic pollutants that can accumulate in the food chain, endocrine-disrupting chemicals (Encarnação et al. 2019), and microorganisms (Paruch et al. 2019).

Effect of changes in biodiversity → on pollution

Biodiversity loss affects pollution in several ways, including via the reduction of vegetation cover, especially in forests, which play a role in reducing air pollution from ozone, nitrous oxide, and particulate matter (Nowak et al. 2018), in addition to sequestering CO_2. Wildfires can adversely affect biodiversity and simultaneously lead to increases in atmospheric pollution (Yue and Unger 2018). The reduced resilience of ecosystems to pollutants in stressed ecosystems is well documented (Vallero 2019; Horton and Barnes 2020; Zaghloul et al. 2020).

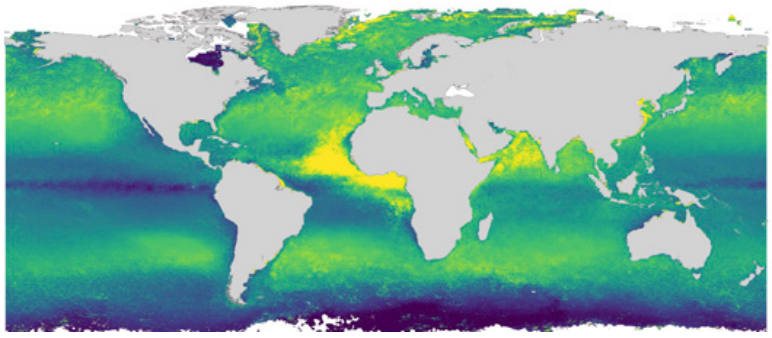
Effects of pollution → on land degradation

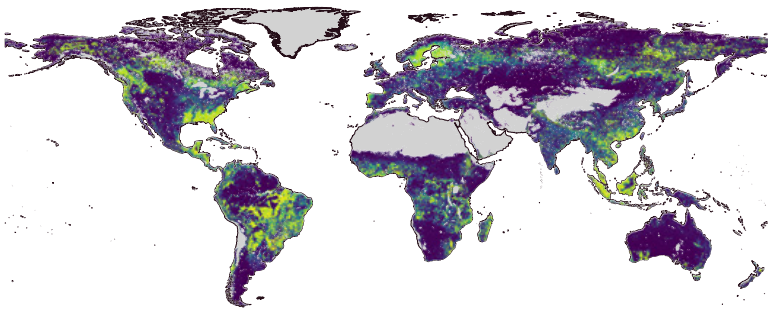


The use of pesticides and fertilizers in agriculture has increased over time (Food and Agriculture Organization [FAO], 2023), leading to land degradation. Overextraction of groundwater and irrigation practices can alter soil salinity, leading to changes in soil structure, pH, oxidation-reduction potential, and the ability to support plant growth (Rengasamy 2016). Chemical pollution of the soil with pesticides and particulate material, including micro- and nanoplastics, produces shifts in soil microbial and mesofauna, altering soil functions (Grantz, Garner and Johnson 2003; Majumder et al. 2021). Nitrogen deposition results in a fertilizer effect, accelerating plant growth. It also stimulates soil carbon loss from the acceleration of microbial metabolism, causing soil acidification (Chen et al. 2016; Xiao et al. 2020). Sulphur emissions from fossil fuels further contribute to acid deposition and reduced soil fertility (UK Centre of Ecology and Hydrology 2016).

Run-off and pesticide pollution (2015)

Source: Run-off data Abatzoglou et al. (2021) and pesticide pollution data Tang et al. (2021)

Seawater total suspended matter and plastic pollution in the oceans (2020)



Source: Seawater total suspended matter data from https://resourcewatch.org/data/explore/ocn011-Total-Suspended-Matter and seawater plastic pollution data derived from the predicted concentrations of plastic items on the ocean surface Kaandorp et al. (2023).

Effects of land degradation → on pollution

Deforestation, along with other forms of land clearing, such as clearing for agriculture, infrastructure development, and mining, indirectly affects the quality of land and water by increasing the rates of soil erosion and sediment transport, and accelerating the loss of nutrient-rich soil surface (Artiola et al. 2019). Land degradation resulting in soil erosion can also lead to increased pollution and sedimentation in streams and rivers (Phuong, Shrestha and Chuong 2017). Mining activities are linked to deforestation, soil erosion, and contamination of water bodies with heavy metals (Pandey et al. 2022). Surface run-off is also a major source of plastic pollution in the oceans (Lebreton et al. 2017).

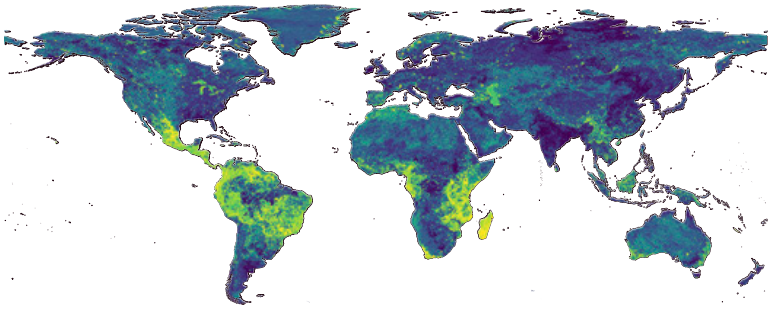


Table C.6: Potential for interactions between biodiversity and land degradation

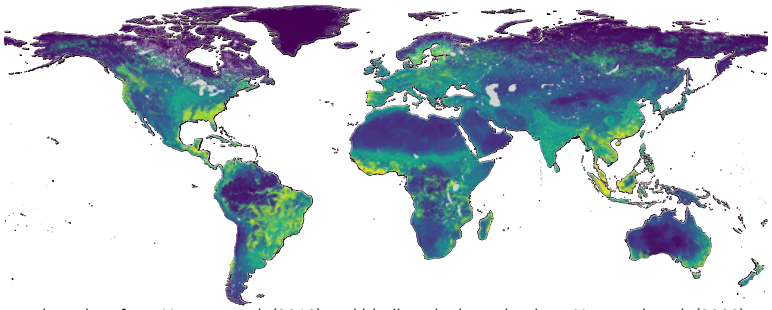
Forest loss (total for 2000–2012) and soil erosion (2012)

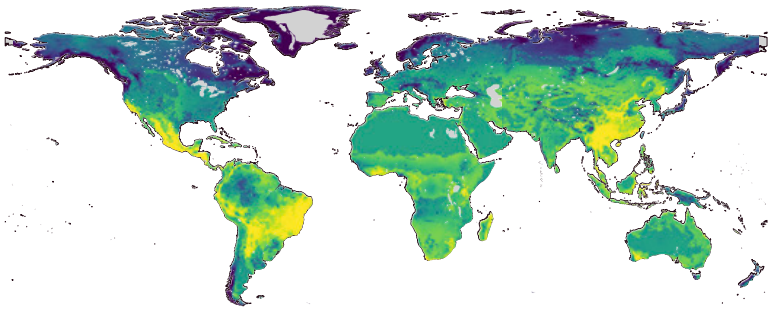
Source: Forest loss data Hansen et al. (2013) and soil erosion data European Commission (2017)

Plant extinction risk (1950–2022) and land productivity trend (2007–2022)



Plant extinction risk derived from data of plants listed by IUCN (https://www.iucnredlist.org/) as either Critically Endangered (CR), Endangered (EN), or Vulnerable (VU) and land productivity data (Ivits and Cherlet 2013). Land productivity is presented through its inverse component (1- land productivity) in this combined map.

Effect of changes in biodiversity → on land degradation



Biodiversity loss has a direct effect on land degradation. Forest loss or thinning reduces biodiversity, causing a decline in forest productivity and carbon stocks (IPBES 2018). Forest loss also reduces the amount of plant residues and organic matter in the soil and removes the protective layer that controls run-off and soil erosion (Orgiazzi and Panagos 2018; Mayer et al. 2020). The local extinction of large herbivores, carnivores and primates has led to what has been termed Empty Forest Syndrome (Pires and Galetti 2023). This biotic impoverishment has cascading ecological consequences, altering plant species composition, nutrient cycling, and forest regeneration (Pires and Galetti 2023).

Forest loss (total for 2000–2020) and biodiversity habitat integrity (2020)

Forest loss data from Hansen et al. (2013) and biodiversity integrity data Harwood et al. (2022). Biodiversity integrity is presented through its inverse component (1-biodiversity integrity) in this combined map.

Aridity index (average of 1982–2019) and species extinction risk (2019)

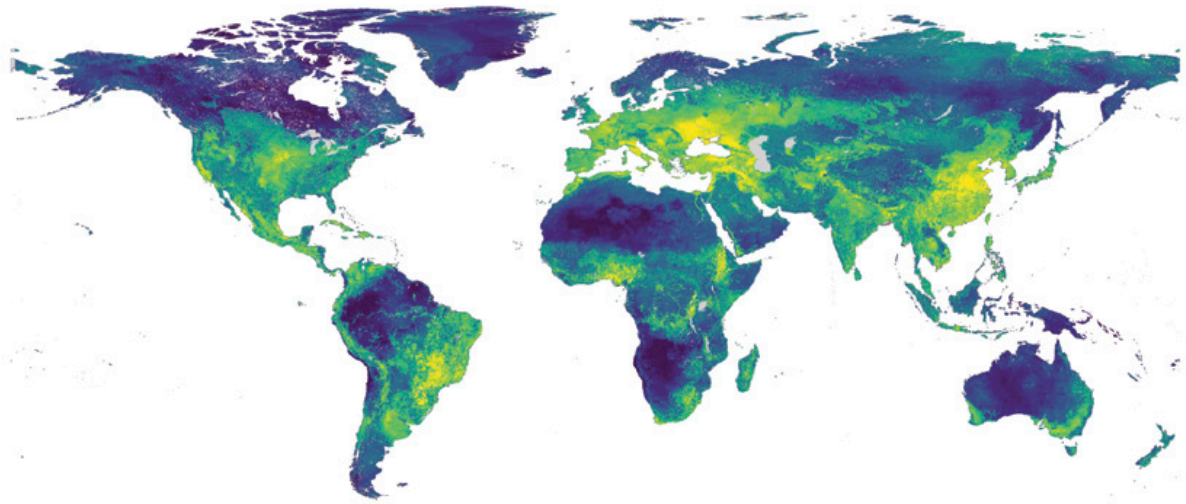
Aridity index calculated as the ratio of precipitation to evapotranspiration data (Abatzoglou et al. 2021) and species extinction risk data (UNEP-WCMC 2020). Aridity index is presented through its inverse component (1- aridity index) in this combined map.

Effects of land degradation → on biodiversity loss

Land degradation significantly contributes to biodiversity loss primarily by altering or destroying natural habitats. Desertification reduces ecosystem productivity and the biotic-carrying capacity of the environment. Declines in soil quality and vegetation cover can additionally disrupt ecosystem integrity and increase habitat fragmentation (Banks-Leite et al. 2020), while degraded ecosystems can facilitate invasion by non-native species (Heringer et al. 2020) that are major drivers of biodiversity decline (IPBES 2019).

C.2 The crisis in human–nature relationships

The global environmental crises can be considered together as a single crisis: the crisis in human–nature relationships. Changes in sociocultural values and worldviews, that is, natural resources and land as commodities, as well as rapid urbanization and deforestation, are key drivers of the disconnection of humans from nature, leading to the devaluation of nature, thereby facilitating and legitimizing destructive practices (Barragan-Jason et al. 2022; Barragan-Jason et al.2023).



Climate change, biodiversity loss and land degradation and pollution and waste are mostly driven by socioeconomic systems that run on unsustainable resource extraction and consumption patterns. They also have major socioecological effects, including resource-driven disputes, human conflict, and the proliferation of environmental refugees (Beery et al. 2023; World Economic Forum 2023; SDG16). The scale, pace and intensity of anthropogenic environmental change have increased inequality and inequity, threatening stability, resilience and sustainability (McPhearson et al. 2021). Armed conflicts lead to compounded, multidimensional environmental crises with both short and long-lasting, frequently irreversible effects (UNEP 2022; UNEP 2024; Krampe Kreutz and Ide 2025).

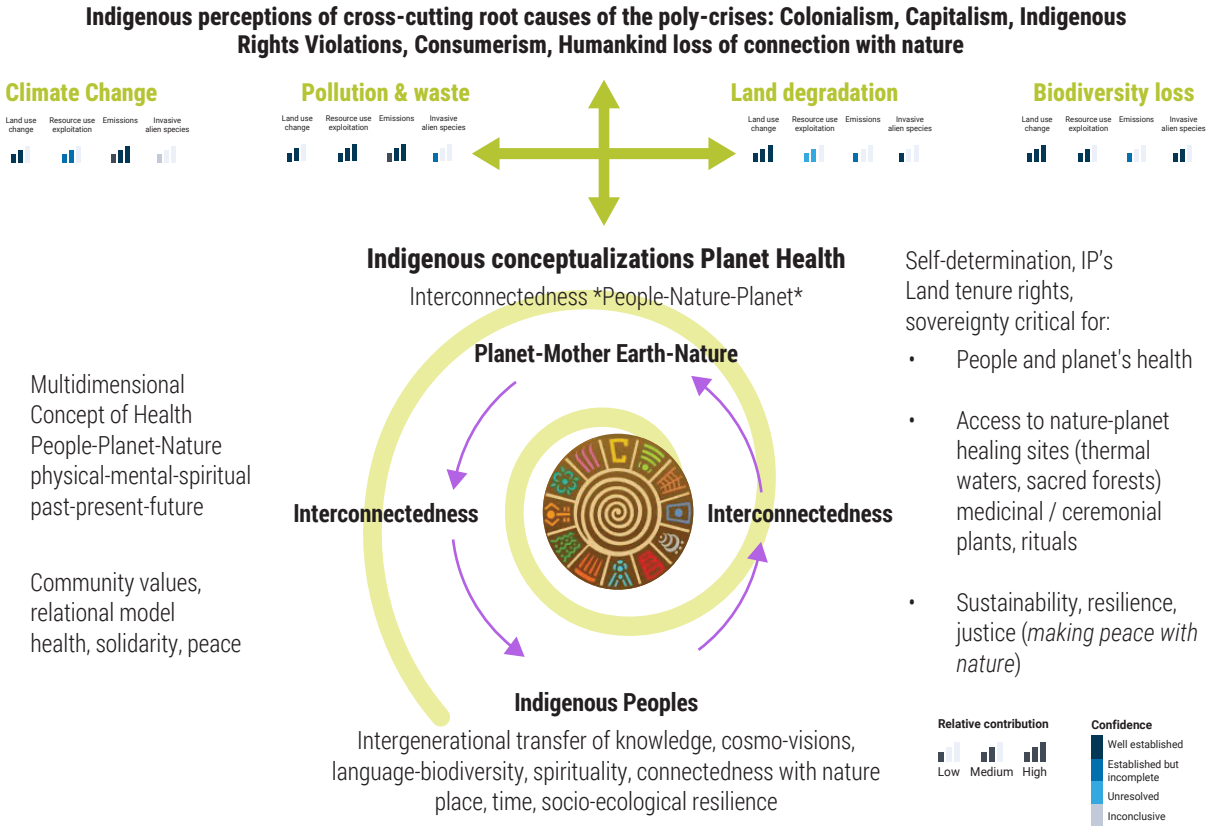
The literature suggests that humans are now living beyond planetary limits (e.g. IPCC 2021; IPBES 2019; Brondizio et al. 2021; Díaz, et al. 2019; McPhearson et al. 2021;), with adverse effects on quality of life (Díaz et al. 2019) and ecosystem health (Persson et al. 2022). Exceeding the Earth's capacity (Chapter 10) will affect or displace millions of people (Caesar et al. 2024), with coastal communities, small islands and peoples in drylands and the Arctic at disproportionate risk (IPCC 2023b). Indigenous Peoples and displaced populations and refugees are particularly vulnerable to the global environmental crises, and the homelands and territories of traditional communities that depend on the lands and ecosystems are often exposed to overlapping adverse effects (IPCC 2023a; IPCC 2023b) (**Figure C.2**).

C.2.1 Indigenous Peoples' perspectives and the values crisis in the human–nature relationship

A reconnection with nature is key to human and planetary health, and to valuing the shift towards sustainability. The Intergovernmental Panel on Climate Change and the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services provided evidence of the need for transformative change in human–nature interactions to achieve sustainable targets, including a better valuation of nature (IPBES 2019; Pörtner et al. 2021). The extent to which people

Figure C.2: Geographical variation in intensity of overlapping pressures associated with the global environmental crises

Note: summation of change in global temperature (1982–2022) (University of East Anglia Climatic Research Unit et al. 2024), soil erosion (2012) (European Commission 2017), pesticide pollution (2015) (Tang et al. 2021), change in drought severity (Drought Severity Index 1982–2022) (Abatzoglou et al. 2021), and an index representing biodiversity habitat integrity (2020) (Harwood et al. 2022). All variables were normalized between zero and one. Yellow shading indicates regions of high-pressure intensity across the crises, blue shading indicates regions of low pressure-intensity. Regions where pressures overlap might represent locations with high potential for interactions between crises (Tables C.1–C.6).



recognize themselves as part of nature, referred to as human-nature connectedness, is a societal trait that facilitates achieving sustainability. This requires a transformative change, including an awareness of connectivity among the environmental crises and new norms for human-nature interactions (Barragan-Jason et al. 2022; Barragan-Jason et al. 2023).

Indigenous conceptualizations of planetary health provide crucial intergenerational perspectives on addressing the drivers of the global environmental crises. The holistic views on people, nature and the planet as Mother Earth found in many Indigenous Knowledge systems and sciences, and rooted in Indigenous languages, also compels the view of the global environmental crises as interconnected or as different aspects of a single crisis – the crisis in human-nature relationships. Embracing more holistic worldviews (**Figure C.3** and **Figure 1. IK & LK Chapeau B**) may provide both a better perspective on the roots – pressures and drivers – of the environmental crises and a deeper understanding of their effects on local communities and Indigenous Peoples who live on, own and manage over a quarter of the world's land area (IPBES 2022).

Nature and customary laws govern Indigenous Peoples' lifeways, considering future generations. Indigenous community-centred values related to lands, peoples and cultures offer opportunities to learn how collective values and behaviours can support sustainability for the next seven generations (Brondízio et al. 2021). This requires self-determination, land tenure rights, sovereignty, agency and inclusive governance.

Indigenous Knowledge and Local Knowledge can offer alternative options to address the complex adverse effects of the environmental crises. More holistic solutions may be found through considering different knowledge systems, sovereignty, ethics of co-existence, ancestral connections to the landscapes and nature, and socioecological approaches to resilience, focusing on human–nature interactions. Indigenous women play a crucial role in biodiversity conservation and climate resilience, leveraging traditional knowledge and sustainable practices; yet women are disproportionally excluded from decision-making (Akalibey et al. 2024; Lima and Cunha 2024). However, Indigenous Knowledge and Local Knowledge is currently at risk from multiple pressures (Fernández-Llamazares

Figure C.3: Interconnected worldview of the global environmental crises recognizing that the crises can be considered together as a single crisis – the crisis in human–nature relationships

Credit: © Brent Stirton/Getty Images for FAO, CIRAD, CIFOR, WCS

et al. 2021) – another facet of the crisis in human-nature relationships.

The geographic variations in the intensity of the crises and their influences on Earth's systems differ among socioeconomic groups and countries. To remain within Earth's limits and to achieve a just and sustainable future will require unprecedented, radical, and coordinated systems transformations (McPhearson et al. 2021) across the human-dominated systems of economy, energy, circularity and food (Chapters 14–17).

Indigenous Knowledge and Local Knowledge Chapeau B

Indigenous Peoples maintain a profound connection to the land, viewing it not merely as a resource but as living territories that form an essential part of their identity and existence (Nelson and Shilling 2018). Consequently, any change in natural processes directly affects their ways of life and well-being. Indigenous territories and cultures are threatened by the expansion of resource extraction, pollution, and appropriation that prevent traditional land-use practices (Ford et al. 2020; Ibarra et al. 2023). Industrial-scale mining, energy production and the agricultural, forest and fisheries sectors lead to landscape degradation, biodiversity loss and land dispossession (Scheidel et al. 2023), impacting Indigenous Peoples ways of life. Water pollution and poor governance compromise the quality of freshwater resources, increasing water insecurity and risks to public health and contributing to spiritual and cultural losses (Sajwan 2020). Land use change and degradation resulting from unsustainable practices contribute to habitat and biodiversity loss, affecting all aspects of ecosystem health including freshwater cycles and air quality with cascading effects on the health and well-being of Indigenous Peoples (Isbell et al. 2017; UNPFII 2023). Biological and cultural diversity are intertwined and are affected by extractive operations and resource appropriation that threaten the livelihoods of Indigenous Peoples, as well as their cultural and spiritual practices (UNESCO 2019; Kuklina et al. 2022; IK & LK Dialogues 2025).

Many Indigenous Peoples live in areas where the effects of the global environmental crises overlap (Leal Filho et al. 2021; IPCC 2023a; IPCC 2023b; Rockström et al. 2023; Reyes-García et al. 2024). Crossing Earth's tipping points can result in accelerated groundwater depletion, glacier melting, extreme heat or sea level rise, affecting or even displacing millions of people (Caesar et al. 2024). Indigenous Peoples living in remote drylands, mountains, deltaic and coastal communities from the Arctic to small islands are particularly at risk (IPCC 2023b). In this context, the Indigenous conceptualizations of Planetary Health and their understanding of the changes in the environment are crucial to addressing the unprecedented human-made drivers of the global environmental crises and their consequences (Nkuba et al. 2020). Prevention, coping, adaptive capacities and resilience inherent in Indigenous ways of life and their connection with the land have much to offer (Ford et al. 2020; Ibarra et al. 2023; UNESCO 2024).

Policy decisions can be better informed if Indigenous Peoples livelihoods and economies in relation to changes in nature climate change, biodiversity, land

Credit: jkraft5/Envato

and provision of ecosystem services are well understood and efforts are made to reverse harmful changes (Reyes-García et al. 2024). Since biological and cultural diversity are intertwined and the loss of one correlates with the loss of the other, revitalizing Indigenous worldviews, cultures and languages is crucial for the recovery of lands and the protection of biodiversity (Mathez-Stiefel et al. 2007; Eriksen 2021). Alleviating the consequences of climate change for Indigenous Peoples health and well-being requires a focus on Indigenous perspectives, emphasizing Indigenous Knowledge and movements for decolonization, health and human rights (IPCC 2023a). A multi-faceted approach is required, an approach that respects human rights, upholds Indigenous legal orders, fosters collaboration, recognizes Indigenous Knowledge and Local Knowledge and enhances communication (López-Maldonado et al. 2024). The SDG goals and corresponding targets framework are limited in this regard, as they lack Indigenous perspectives on sustainability and development and do not affirm collective rights over land, resources and territories (Odulaja and Halseth 2018; O'Sullivan 2023).

Chapter summary

Credit: SteveAllenPhoto999/Envato

The planet faces global, interconnected environmental crises of climate change, biodiversity loss and land degradation, and pollution and waste that affect the Earth's atmosphere in complex ways, posing a threat to sustainable development and to life on Earth.

Anthropogenic greenhouse gas emissions are not on target to limit global warming to 2°C above pre-industrial levels (*well established*). These emissions resulted in a warming planet, with an effective radiative forcing that averaged +2.79 W/m^2, the measure for solar irradiance, over the period 1750-2023. Efforts to reduce atmospheric pollution by reducing sulfur dioxide emissions from shipping have led to additional radiative forcing of +0.1 to +0.2 W/m^2, offsetting efforts to limit warming to 1.5°C and demonstrating the potential unintended consequences of some policy measures. Mobility restrictions and industry shutdowns during the COVID-19 pandemic led to a temporary reduction in global greenhouse gas (GHG) emissions. However, lifting restrictions resulted in a rapid increase in global emissions the following year. This highlights the importance of sustained reductions in GHG emissions from multiple sectors. Military operations and armed conflicts have generated additional GHG emissions and worsened air quality in Europe, Africa and the Middle East since the start of those conflicts {3.2.1} {3.2.4} {3.4.3}.

The average global surface temperature continues to rise and heatwaves are becoming more frequent and prolonged (*well established*). The average global temperature for 2014–2023 increased by an average of 1.19°C above the 1850–1900 baseline. This value masks considerable regional variability, with polar regions warming much faster than the global mean. Increasing global surface temperature resulted in the ten years between 2015 and 2024 being the warmest since records began in 1850, and the World Meteorological

Organization stating that 2024 was the hottest year on record, exceeding the 1.5°C threshold. The 2024 record-high global temperature was partly due to the 2023–2024 El Niño effect and likely related to decreased low-level cloudiness and albedo over the oceans, as a result of restrictions in the sulfur content of shipping fuels.

Extreme weather events, such as heatwaves – periods of hot weather exceeding a temperature threshold over consecutive days – are becoming more frequent and intense, affecting larger populations (*well established*). The urban heat island effect has also intensified, leading to night-time urban warming much greater than the average global warming, accompanied by increasing heat-related mortality and morbidity risks {3.2.2} {3.4.1}.

Intense precipitation events have increased globally, although there is also evidence of certain regions experiencing worsening droughts (*established but incomplete*). Precipitation over land has increased since 1950, with this trend accelerating since the 1980s. Extreme rainfall has caused flash flooding and landslides in regions such as southern Brazil, while warmer temperatures and reduced precipitation have resulted in prolonged droughts in other regions such as the Middle East and southern Australia. The intensity and frequency of extreme rainfall and drought will worsen as the climate continues to warm, with negative consequences for human health and infrastructure and for ecosystems {3.2.3}.

Globally, 99 per cent of the world's population is exposed to harmful levels of air pollution (*well established*). Outdoor and indoor air pollution have a combined effect equivalent to approximately eight million deaths every year. Outdoor air pollution trends vary substantially by pollutant and region. Global $PM_{2.5}$ concentrations slightly declined from 2000-2019 but increased in South Asia. Rising temperatures affected air pollution trends by contributing to higher tropospheric ozone (O_3) levels, particularly in cities, to more frequent and intense wildfires and related smoke events, and to longer pollen seasons. Global population exposure to O_3 increased mainly in southern and eastern China and central Africa, and the annual nitrogen dioxide mean concentration increased in 71 per cent of cities in those regions {3.2.4} {3.4.2}.

Wildfires, particularly in boreal forests, increased in frequency and intensity over the period 2002–2020 due to changes in climate, land use and fire management, destroying ecosystems and carbon sinks, and emitting large quantities of smoke (*well established*). Increased emissions from wildfires severely deteriorate air quality, leading to high levels of $PM_{2.5}$ and other pollutants. Wildfires also release large quantities of black carbon, which has a significant radiative-forcing effect. Beyond the immediate adverse effects of wildfires at a local scale, large fire events affect atmospheric composition on a regional to even hemispheric scale and constitute a persistent transboundary air pollution challenge. Without effective interventions, the probability of extreme wildfires will increase globally by a factor of 1.31 to 1.57 by the end of the century. Significant health impacts associated with wildfires include physical and mental health effects from direct exposure to fires, as well as from wildfire smoke. With a growing and ageing global population, the health effects of wildfire smoke are likely to become more substantial in the future {3.4.3}.

Climate change is affecting pollen and dust particle concentrations in certain regions (*established but incomplete*). The combination of rising temperatures and reduced rainfall due to climate change results in more severe sand and dust storms in regions such as Western Asia, Central Asia and Sub-Saharan Africa. Warmer temperatures and higher atmospheric concentrations of carbon dioxide (CO_2) tend to prolong and intensify the pollen season, increasing population exposure to airborne allergens and aggravating respiratory diseases such as rhinitis and asthma {3.4.6} {3.4.7}.

Changes in biodiversity affect the climate system, especially through the loss of carbon sinks, while climate change affects biodiversity through a decline in ecosystem functioning, integrity and resilience (*established but incomplete*). Tropical forests are vital for carbon storage and their capacity varies around the world. Tropical eastern Amazonian forests have declined as a carbon sink due to deforestation and fires, while African forests remained stable for three decades up to 2015. An estimated 10 to 47 per cent of Amazonian forest is exposed to a combination of warming temperatures, extreme droughts, deforestation and wildfires. This could result in an irreversible ecosystem transition if certain critical thresholds or tipping points are reached, potentially exacerbating regional climate change {3.3.1} {3.3.2}.

Food production is affected by climate change, extreme weather events and tropospheric ozone (*established but incomplete*). Specific crop yields are decreasing due to more frequent extreme events, particularly in low-income countries with lower adaptive capacity. Tropospheric ozone also damages crops, affecting yields and food security. Warmer temperatures could lead to an increased risk of the proliferation of microorganisms that cause food-borne diseases, such as Salmonella and Campylobacter {3.4.10}.

The global environmental crises disproportionally affect socioeconomically disadvantaged groups, especially women, children, the elderly, Indigenous Peoples, people with illness or disability and those living in informal settlements (*established but incomplete*). This creates a trend of widening socioeconomic inequalities and environmental injustice. For example, warming temperatures pose numerous risks to health, including cardiovascular, respiratory, neurological and mental, especially in ageing populations. Globally, around 489,000 heat-related deaths occurred every year over the period 2000–2019, with annual heat-related mortality for people over 65 years of age increasing by approximately 85 per cent in the period 2013–2022 compared with 1991–2000, due to climate and demographic changes. There is also emerging evidence that exposure to higher temperatures during pregnancy is linked to adverse perinatal health outcomes, including preterm birth, low birth weight and stillbirth, particularly in lower socioeconomic groups {3.4.1} {3.4.12}.

Indigenous Peoples' health and well-being are disproportionally affected by climate change due to limited access to healthcare services, socioeconomic inequities, historical trauma, land dispossession and loss of cultural identity (*established but incomplete*). Direct effects include increased mortality, injuries, respiratory diseases, mental health distress and poverty due to territorial displacement. Indigenous Peoples can experience anxiety, emotional grief and spiritual anguish from witnessing deterioration of their territories and culture, while increased risk of climate-related infectious diseases result from ecosystem damages and biodiversity loss. Changes in the availability and quality of Indigenous Peoples' food lead to multiple forms of malnutrition and increased risk of chronic health conditions. Conversely, Indigenous and local knowledge sources and their observations can be used to adapt to environmental change, for example by managing wildfires more effectively {3.4.12}.

The health benefits associated with reductions in air pollutant concentrations can provide a strong incentive for climate change mitigation through reductions in co-emitted greenhouse gases and short-lived climate pollutants (*well established*). When both co-benefits and trade-offs are fully considered, optimal climate change policies and air quality mitigation policies result in immediate net benefits globally. The most ambitious plausible transition to a net-zero society provides benefits for climate change mitigation and air quality from decadal to centennial timescales {3.4.13}.

Stratospheric ozone recovery continues, albeit with significant inter-annual variability (*established but incomplete*). Such variability was observed in Antarctic total column ozone, particularly in September annually, and is related to the dynamics of the polar vortex. Continued recovery is contingent upon full compliance with the Montreal Protocol {3.2.5} {3.4.9}.

Many countries have taken substantial steps to align their national climate policies with the Paris Agreement's objectives (*well established*). The Nationally Determined Contributions (NDCs) are vital tools for countries to outline their specific climate actions. The combined GHG emissions of the Parties could decrease by an average of 64 per cent by the year 2050 compared to the levels observed in 2019, if NDCs are fully implemented. These projected emissions reductions are inconsistent with restricting warming to 1.5°C. According to the 2024 United Nations Environment Programme (UNEP) Emissions Gap Report, current policies could lead to a 2.6–3.1°C increase in global mean surface temperature with full implementation of the unconditional and conditional NDCs. Furthermore, many countries are currently not on track to achieve their NDCs; to remain on the pathway to 1.5°C, current emissions must reduce by 42 per cent by 2030 and 57 per cent by 2035 {3.5.1}.

There is an urgent need for substantially increased commitments to NDCs by 2030, or for a significant overachievement of the most recent NDCs, to limit warming to 1.5°C (*well established*). A combination of both approaches is necessary to achieve the cost-effective emission levels proposed in numerous scenarios analysed by the Intergovernmental Panel on Climate Change that aim to keep global warming under 2°C or even limit it to 1.5°C {3.5.1}.

3.1 Introduction

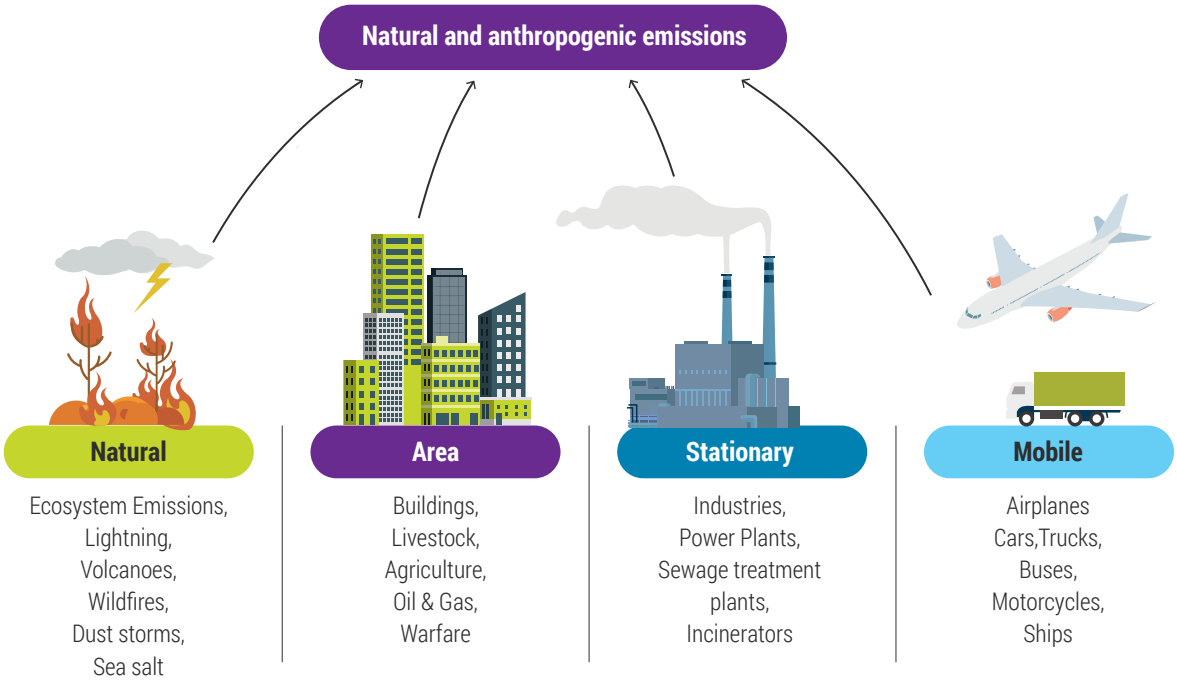
Climate change affects the Earth system's primary biogeochemical cycles – carbon, hydrogen and water – and is intricately linked with risks to air quality, biodiversity and human health. Since the GEO-6 report (United Nations Environment Programme 2019), GHG concentrations in the atmosphere continued to increase due to human activities (Intergovernmental Panel on Climate Change [IPCC] 2021), reaching mixing ratios of 418 parts per million (ppm) for carbon dioxide (CO_2), 1923 parts per billion (ppb) for methane (CH_4), and 336 ppb for nitrous oxide (N_2O) in 2022 (World Meteorological Organization [WMO] 2023a).

The global surface temperature anomaly in 2011–2020 was +1.09 [0.95–1.20] °C with respect to 1850–1900, with larger increases over land than over the ocean. Moreover, the frequency and intensity of extreme events – such as heatwaves, wildfires and intense precipitation – have increased globally, with some of this attributable to climate change (IPCC 2021).

The GEO-6 report stated that emissions of stratospheric ozone-depleting substances (ODSs) had decreased substantially as a result of generalized compliance with the Montreal Protocol. Moreover, stratospheric ozone over Antarctica had shown signs of recovery.

The GEO-6 report also indicated that environmental concentrations of persistent organic pollutants had declined in Europe, North America, Asia and the Pacific, and the Arctic. However, it highlighted challenges related to emerging pollutants and cautioned that unless more substantial policy measures and environmental governance were adopted to address both air pollution and climate change, no significant improvements would occur. Indeed, climate change impacts have continued to become more severe, while additional interventions have led to improvements in air quality in many regions.

This chapter focuses on the state and trends of major atmospheric components and their interactions with multiple environmental variables such as air pollutants, including trace gases, particulate matter, heavy metals, ODSs and GHGs in the context of climate change. It also examines interactions between the atmosphere and human systems and ecosystems, and the progress towards the goals of relevant global agreements.



Atmospheric concentrations of long-lived GHGs, short-lived climate forcers, ODSs and chemical pollutants, including microplastics, influence air quality, stratospheric ozone and the climate, affecting human systems and ecosystems directly and indirectly.

Changes in biodiversity affect the climate, especially through their influence on the nitrogen, carbon and water cycles. These interactions can generate complex feedbacks between climate, biodiversity and human systems, potentially leading to adverse outcomes.

For example, higher temperatures and changes in evapotranspiration due to climate change make forests drier and more prone to wildfires, which in turn release gases, heavy metals like mercury, and fine particulate matter ($PM_{2.5}$). The risk of wildfires is increasing due to numerous factors, including climate change, changes in land use and land-management practices, and demographic change (United Nations Environment Programme [UNEP] 2022). In turn, wildfires release more CO_2 into the atmosphere, exacerbating the greenhouse effect and accelerating global warming. The effects of land degradation and biodiversity loss on climate change and air quality are also multifaceted and interconnected (Chapter 4).

This report includes a Global Environmental Crises Chapeau. explaining the main connections among the global environmental crises, the crisis of climate change, the crisis of biodiversity loss, land degradation and desertification, and the crisis of pollution and waste, as well as their stressors and effects.

Climate change strongly affects air pollution and waste generation, as represented by the large arrow. For example, tropospheric warming due to climate change directly affects tropospheric ozone (O_3) and secondary aerosol formation, since many chemical reactions are temperature dependent. Sources of air pollutants and greenhouse gases are illustrated in **Figure 3.1**.

Climate change greatly amplifies biodiversity loss and is a driver of species extinction. It also affects land degradation, since warmer temperatures and decreased water content in soils are associated with a reduction in organic matter. Precipitation patterns and intensity changes often lead to increased soil erosion, landslides and desertification, contributing to atmospheric dust concentrations.

This chapter also presents the progress towards internationally agreed environmental goals, regulations and targets aimed at reducing adverse effects on the atmosphere and the global environment, and consequently on human systems. These include the World Health Organization's updated air quality guidelines, including for harmful $PM_{2.5}$ and tropospheric O_3; outcomes from the Montreal Protocol on Substances that Deplete the Ozone Layer, which is located in the stratosphere and protects life from ultraviolet radiation; the Paris Agreement contributions to limiting GHG emissions; and pledges to reduce short-lived climate forcers.

3.2 State and trends of atmospheric composition

3.2.1 Long-lived and short-lived climate forcers

Atmospheric concentrations of long-lived (CO_2, N_2O) and short-lived (CH_4, O_3 and its precursors; some hydrofluorocarbons) GHGs and aerosols affect the Earth's radiative balance. Interactions with solar and terrestrial thermal radiation (Kramer et al. 2021) result in a substantial and positive Earth energy imbalance (Forster et al. 2021; Hansen et al. 2023). The estimated imbalance for 2011–2023 was +0.96 [0.67–1.26] W/m2 (Forster et al. 2023a). The resulting warming is attributable to emissions of well-mixed GHGs and other forcings, such as aerosol–radiation interaction, aerosol–cloud interaction, tropospheric ozone, black carbon deposited on snow, and land-use changes (Eyring et al. 2021).

Emissions of GHGs have continued to increase (Forster et al. 2024) **(Figure 3.2a**). However, widespread restrictions during the COVID-19 pandemic caused a temporary worldwide decline in GHG emissions in 2020 of 5.8 per cent (International Energy Agency [IEA] 2022). Methane emissions have increased by approximately 20 per cent in the period 2000–2020 (Saunois et al. 2024).

Short-lived climate forcers are reactive compounds with atmospheric lifetimes typically shorter than two decades that contribute to global warming and air pollution. Their emissions have also continued to increase (Szopa et al. 2021).

Tropospheric aerosols have a net cooling effect on the climate system (IPCC 2021) and degrade air quality (Fowler et al. 2020). The reduction in shipping emissions of sulfur dioxide (SO_2) due to restrictions in the sulfur content of fuel for maritime vessels contributed to a decrease in cloud condensation nuclei, which resulted in a reduction in low-level cloudiness and an albedo decrease over the oceans that accelerates global warming (Hansen et al. 2025). The additional radiative forcing was estimated to be approximately +0.1 to +0.2 W/m2, averaged over the global ocean (Yuan et al. 2024; Yoshioka et al. 2024; Gettelman et al. 2024).

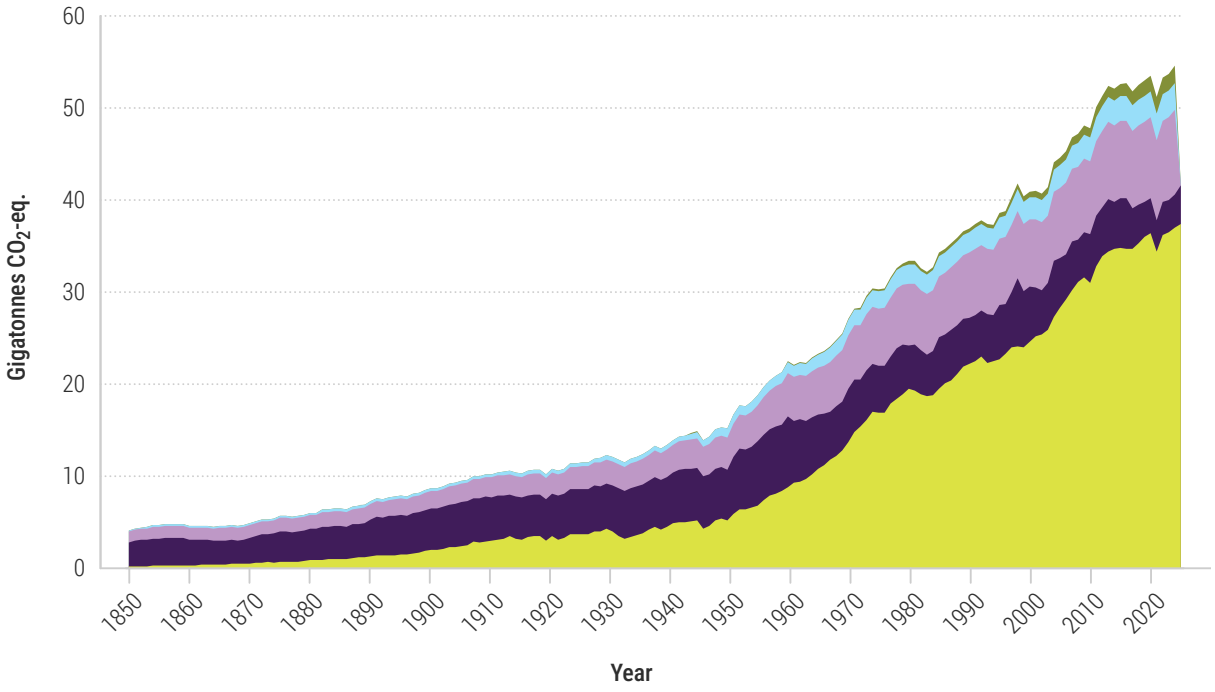
Figure 3.2b shows an updated estimate of the contribution of each anthropogenic component to the effective radiative forcing from 1750 to 2023 (Forster et al. 2024). Land-use change and aerosols contribute negatively with a cooling effect, partially compensating for the GHG positive contributions with a warming effect, resulting in an effective radiative forcing of +2.79 [1.78–3.61] W/m_2.

3.2.2 Temperature

The Intergovernmental Panel on Climate Change (2021) reported a global mean surface temperature of +1.09°C [0.95–1.20] above the pre-industrial (1850–1900) levels for the period 2011–2020, with larger increases over land (1.59 [1.34–1.83] °C) than over the ocean (0.88 [0.68–1.01] °C). The World Meteorological Organization (WMO) reported that 2015–2024 was the warmest 10-year period since 1850, and 2024 the hottest year with temperature 1.5°C above pre-industrial levels (WMO 2025a).

While a cool La Niña effect dominated from 2020, the strong El Niño that developed in 2023 contributed to the warmest annual global surface temperature on record (WMO 2024a). The reduction in shipping emissions due to restrictions in the sulfur content of maritime fuel also likely contributed to this warming effect (Hansen et al. 2025).

The temperature anomaly reached +1.19°C [1.00–1.4] (above 1850–1900) for 2014–2023 (**Figure 3.3**, Forster et al. 2024). The temperature change over land for the same period was estimated as +1.65°C [1.36–1.90]. The mean surface global temperature rise masks considerable regional variability, with the Arctic warming up to four times faster (Rantanen et al. 2022).



The current global average temperature trend is 0.26 [0.2–0.4] °C per decade over the period 2014–2023. The WMO (2025) confirmed that the global average temperature in 2024 was 1.55°C above pre-industrial levels.

The Earth energy imbalance has affected the whole atmosphere: the troposphere has warmed since at least the 1950s, and the stratosphere has cooled (IPCC 2021). The tropical upper-troposphere has warmed faster than the surface since 2001 and the height of the tropopause has risen globally over the period 1980–2018 (Ladstädter et al. 2023). This rise of the tropopause may have long-term effects on climate and weather by influencing stratosphere-troposphere exchanges (Meng et al. 2021).

Heatwaves – periods of hot weather exceeding a temperature threshold over consecutive days and nights – have increased in frequency and intensity globally (Seneviratne et al. 2021). Trends for heatwave

Source: Forster et al. (2024)

frequency, duration and intensity vary spatially, with average intensity increased in northern Canada and Greenland by 0.4–0.6°C per decade for the period 1970–2014 (Perkins-Kirkpatrick and Lewis 2020; Han et al. 2022). Three heatwaves were observed during boreal spring–summer 2023 affecting southwestern North America, Europe and southwestern and Central Asia (WMO 2024a), and temperatures in Beijing exceeded 40°C for three consecutive days (Qian et al. 2024).

3.2.3 Precipitation, cyclones and drought

Increased global temperatures and additional atmospheric moisture have contributed to changes in regional precipitation patterns and intensity. Precipitation over land has likely increased since 1950 and this trend has accelerated since the 1980s (Szopa et al. 2021).

Extreme precipitation events have increased in frequency and intensity, resulting in floods and soil erosion (Seneviratne et al. 2021). Intense rainfall resulted in several floods in 2023 in Europe (WMO 2024a).

The Global South was heavily affected in 2024 by changes in the precipitation seasonal cycle and intensity, leading to flash floods and landslides. Dry conditions in South America were interrupted by persistent heavy rainfall that resulted in flooding in southern Brazil. Precipitation increased by 50 per cent in the Sahel in 2024, resulting in flooding in the wider region (WMO 2025).

Rapid intensification of tropical cyclones has increased (Li et al. 2023) and intensity at landfall has doubled between 1982 and 2020 (Wang and Toumi 2022), with increased damages to coastal regions (WMO 2025).

Globally, 12-month droughts have increased from 15–26 per cent over the period 1980–2020 (Ndehedehe et al. 2023), partly driven by increases in the southern hemisphere since 2000 (Douville et al. 2021). Multi-year droughts have become more frequent in Chile (Fuentealba et al. 2021), while Europe's 2018–2020 drought was unprecedented over the past 250 years (Rakovec et al. 2022).

3.2.4 Air pollution

Air pollutants are hazardous to human health (WHO 2021), ecosystems and crops (UNEP 2019a), and their emissions from anthropogenic sources affect atmospheric composition.

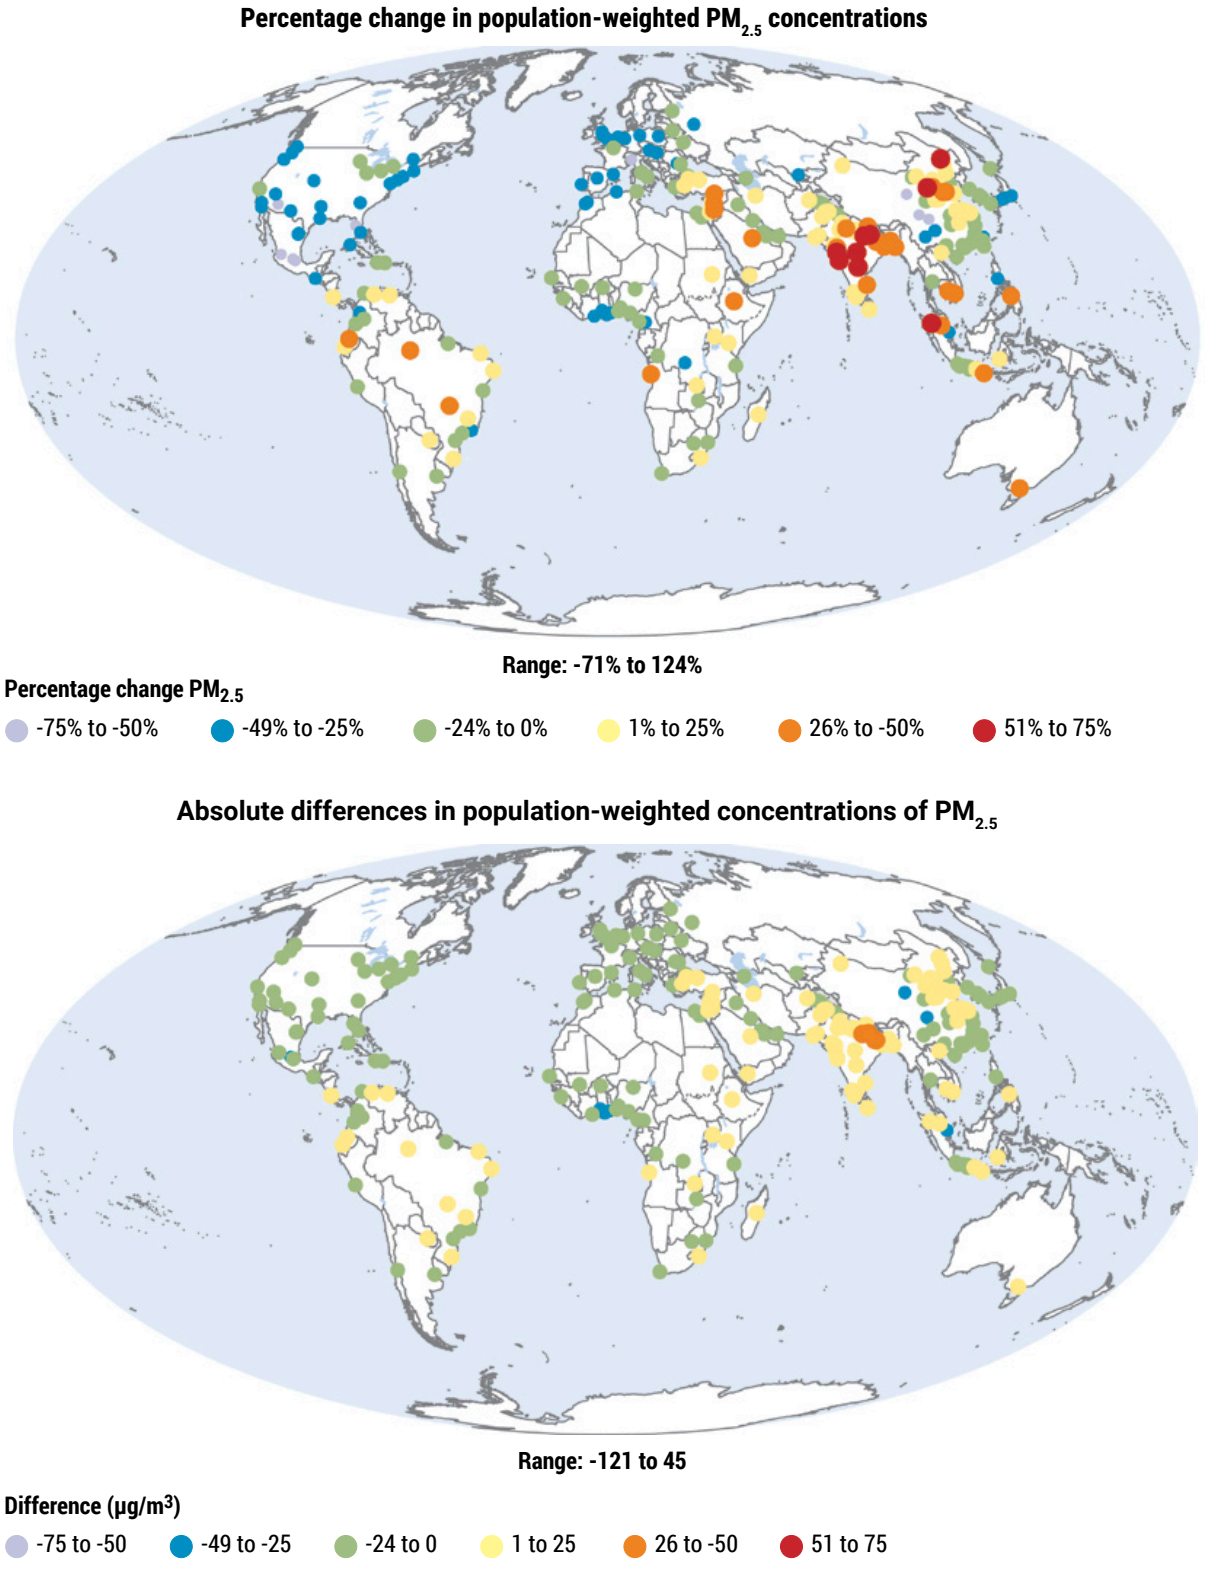
Polluting particles in the atmosphere are categorized as primary if they come from combustion processes, industrial activities, fires, brake and tyre wear, road wear,

soil erosion and resuspension. Secondary particles form from gaseous precursors such as SO_2, nitrogen oxides, ammonia and non-methane volatile organic compounds. These atmospheric particles vary in size from ultrafine to coarse and in composition, which determine their radiative effect. Their composition typically includes sulfates, nitrates, ammonium, carbonaceous compounds and toxic metals. Black carbon, a primary particulate pollutant emitted from the combustion of fossil fuels and biomass, absorbs solar radiation, contributing to climate warming. By contrast, most inorganic components of particulate matter scatter solar radiation, resulting in cooling.

In Western Europe and North America, SO_2 and nitrogen dioxide (NO_2) has decreased between 2000 and 2019, but increased in regions of Asia (Aas et al. 2019; Aas et al. 2024). From satellite measurements, global SO_2 emissions trends over 2005–2021 are negative (Fioletov et al. 2023). By contrast, CH_4 emissions from human activities increased by around 20 per cent from 2000–2020 (Saunois et al. 2024). Landfills and waste management facilities are one of the top three global sources of methane (IPCC 2021). Landfill methane emissions can be two to three times larger than reported due to unmonitored leaks (Wang et al. 2024), underreporting (Balasus et al. 2025) and emissions from legacy landfills (Fraser-McDonald et al. 2022).

Trends in population-weighted mean 8-hour tropospheric ozone (O_3) concentrations are variable around the world. Estimates from 250 cities indicate decreases between 2000 and 2019 in North and Central America, Eastern Europe, the Middle East and some regions in China. Cities in South America, Africa, Western Europe and south and South east Asia show more than 24 per cent increases. Estimates of attributable mortality show a 46 per cent increase worldwide between 2000 and 2019 (Malashock et al. 2022).

Trends in $PM_{2.5}$ concentrations from 13,160 cities for 2000–2019 indicate a decrease in regional averages in North and Central America, Europe, sub-Saharan Africa and southeastern Asia. Decreases in most regions coincide with O_3 reduction, except in Africa (Southerland et al. 2022) (**Figure 3.5**).



Air pollution control actions in several megacities, such as London and Beijing, have delivered improvements in air quality. Monthly averages of $PM_{2.5}$ in Beijing were reduced by two-thirds between 2013 and 2019 (Li et al. 2020) but high levels of air pollution persisted in other megacities in Asia and Africa, such as Tehran, Delhi and Lagos (Fuller et al. 2022).

The control of pollutants emitted from point industrial sources is more straightforward than line sources, such as road transport, and area sources, such as agriculture and domestic emissions (Vardoulakis et al. 2018). The control of O_3 is complex, with no single mitigation option. For example, while daily maximum O_3 decreased in Mexico City from peak concentrations in 1990 due to systematic

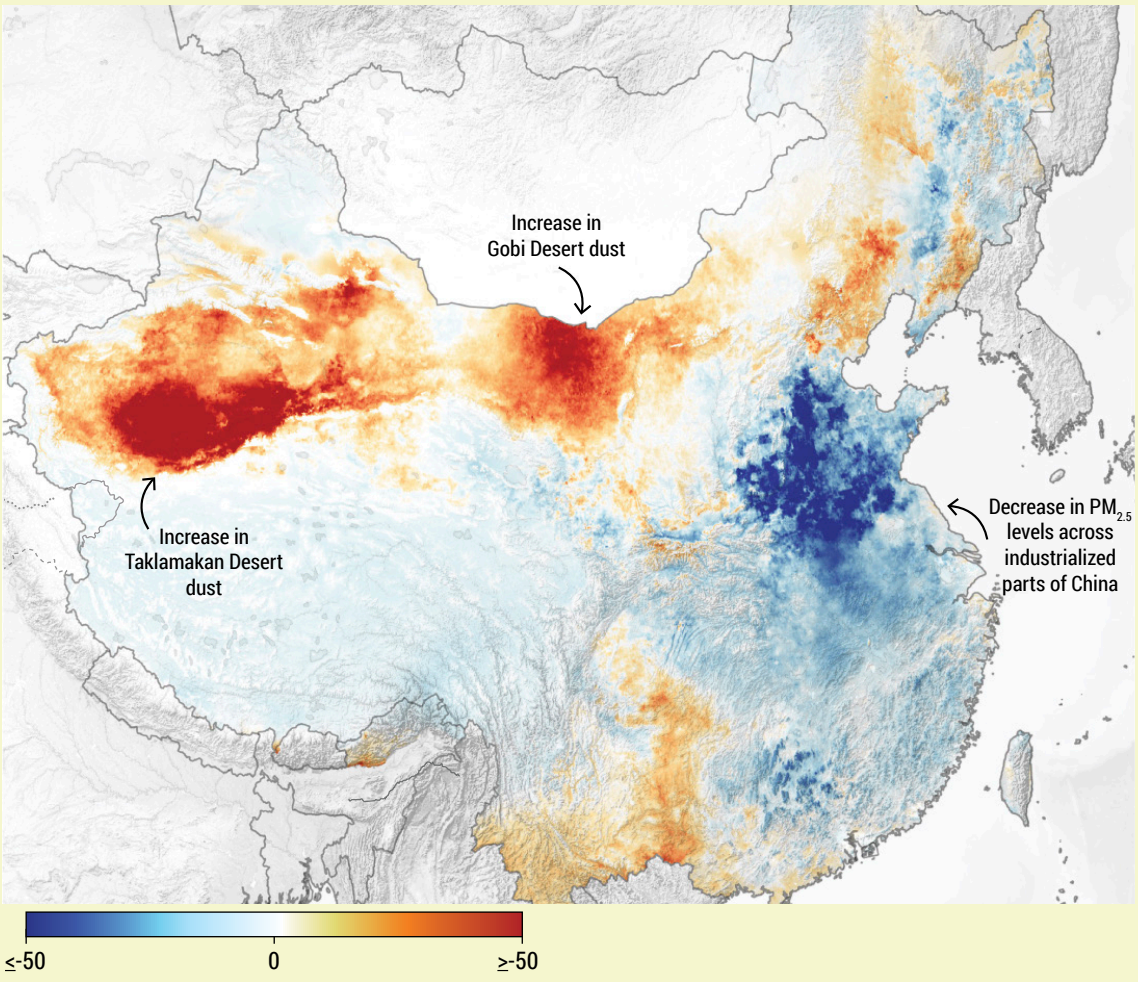
Figure 3.4: Change in population-weighted $PM_{2.5}$ concentrations between 2000 and 2019

Source: Southerland et al. (2022)

measures implemented – gasoline reformulation, catalytic converters, vehicular restrictions – annual O_3 and $PM_{2.5}$ concentrations have levelled in the last 15 years (Velasco and Retama 2017; Molina, Retama and Zavala 2023).

Fireworks emissions substantially increase particulate matter concentrations during traditional or religious celebration days in Mexico and India (Retama et al. 2019; Yadav, Mishra and Gurjar 2022).

Open burning of waste in landfills and other spaces remains one of the uncontrolled sources of pollution, mainly of particulate matter containing heavy metals and black carbon, in low- and middle-income countries. Burning of plastics also produces toxic, persistent and bioaccumulative pollutants such as volatile organic compounds, furans and dioxins (Weidinmyer et al. 2014; Patak et al. 2023; Kreel et al. 2021).



The COVID-19 pandemic and related mobility restrictions reduced atmospheric emissions of combustion-related air pollutants and GHGs, leading to a global decrease in NO_2 and $PM_{2.5}$ concentrations in many cities (**Box 3.1**). However, these reductions were short-lived, as emissions increased again soon after the lifting of restrictions (Salmond et al. 2022).

Box 3.1: Various examples of air pollution during the COVID-19 pandemic

During the COVID-19 lockdowns, clean skies were observed globally (Sokhi et al. 2021) and in many cities, due to reductions in $PM_{2.5}$, NO_2 and SO_2 (Dai et al. 2021; Pratap et al. 2021) (**Figure 3.5**). This short-lived urban air quality improvement averted premature mortality in many cities, with a 60 per cent reduction in $PM_{2.5}$ and O_3 attributable deaths in Delhi (Maji et al. 2021), and a 27 per cent reduction in NO_2-attributable deaths in Australian cities (Chaston et al. 2024).

However, tropospheric O_3 concentrations increased or did not significantly change during lockdowns in several cities, for example in eastern China (Wang et al. 2022) and Mexico City (Peralta et al. 2021). In these cases, high O_3 concentrations partially offset health benefits mainly associated with NO_2 reductions.

While not routinely measured in current air quality networks, the presence of nanoparticles in urban areas is an emerging health concern. Energy generation from fossil fuels, vehicle transport and industrial activities can produce nanoparticles that deteriorate air quality. Additionally, growing evidence indicates that microplastics can impact regional (Sridharan et al. 2021) and transboundary (Peries et al. 2024) air quality and affect human systems (Chen, Chen and Liao 2025).

Another emerging concern is associated with particles in the stratosphere that contain metals from the burn-up of satellites and rocket stages during re-entry into the atmosphere. While the presence of particles may have implications for stratospheric composition, health effects on humans at the surface are unlikely. With increasing numbers of satellites and rocket launches planned in coming decades, metals from their re-entry could change stratospheric composition (Murphy et al. 2023).

3.2.5 Stratospheric ozone

A small increasing trend in total column ozone of 12 per cent per decade in September over the period 2000–2019 was observed over Antarctica, consistent with the decreasing trend in concentration of most ODSs (WMO 2022). Recovery is expected to continue, contingent upon full compliance with the Montreal Protocol (Section 3.5.2). Unreported emissions of trichlorofluoromethane (CFC-11) over 2012–2019, increased emissions of chloromethane (CH_3Cl) in China over 2000–2020 (Hu, Yao and Fang 2022), and of halocarbons in Tibet (Cong et al. 2024), if they persist, could slow the rate of recovery by up to three years (WMO 2022).

Over the Arctic, total column ozone has shown a non-significant increasing trend. Outside the polar regions, total column ozone shows a small statistically significant increasing trend (0.4±0.2 per cent per decade) over 1996–2020, driven mostly by changes in the southern hemisphere.

Volcanic eruptions may sporadically introduce gases and particles and change atmospheric composition. The Hunga Tonga-Hunga Ha'apai eruption in January 2022 injected large amounts of water vapour into the stratosphere (Nedoluha et al. 2023), modifying the tropical tropopause height and decreasing stratospheric ozone (Evan et al. 2023). Warming due to water vapour added to the stratosphere was offset mainly by the increased attenuation of solar radiation by stratospheric aerosol (Schoeberl et al. 2023). The climate forcing of the injected water vapour decreased to near zero by the end of 2023.

Unprecedented wildfires in Australia in 2019–2020 injected gases and aerosols into the stratosphere that contributed to stratospheric ozone depletion (Wang et al. 2023).

3.3 Connections between the atmosphere and biodiversity loss and land degradation

3.3.1 How biodiversity loss and land degradation affect the atmosphere

Changes or loss in biodiversity affect the climate system, primarily through their impacts on nitrogen, carbon and water cycles. The interplay among climate, biodiversity and human activities can result in intricate feedback loops (Handa et al. 2014). For example, there is evidence that the fertilizing effect of elevated atmospheric CO_2 concentrations resulting from deforestation has enhanced the water-use efficiency of boreal forests in the northern hemisphere (Keenan et al. 2013; Allen et al. 2024; Liu et al. 2024). Different ecosystem responses highlight the various adaptive strategies employed by different vegetation types, which play a crucial role in the climate system's biosphere–atmosphere interactions (Oki and Kanae 2006; Joos et al. 2024).

The higher biodiversity of some ecosystems, such as marine and forest ecosystems, increases their potential and stability as carbon sinks (Kinnunen et al. 2025). Natural processes mitigate global climate change by absorbing over half of human-generated CO_2 through photosynthesis and subsequent carbon storage in biomass and organic matter. Of that, oceans absorb approximately 30 per cent and land, including forests and soils, absorbs around 25–30 per cent of the CO_2 emitted into the atmosphere (Malhi et al. 2002; Crisp et al. 2022). However, CO_2 absorption by oceans often leads to ocean acidification (Abbasi and Abbasi 2011), and natural carbon sinks are declining (Blunden and Boyer 2022; Curran and Curran 2025). Ignoring the interrelationship of climate, biodiversity and humans will lead to suboptimal solutions that aggravate planetary crises (Pörtner et al. 2021).

Over the past two decades, the annual net carbon emissions from deforestation and land degradation have remained relatively stable. However, compared to the steadily increasing fossil fuel emissions, their proportion has decreased (Houghton 2012). A possible decline in estimated emissions resulted from declining tropical deforestation rates (IPCC 2023).

3.3.1.1 Forest ecosystems

Amazonia, Earth's largest tropical forest and an important carbon sink (Brienen et al. 2015; Philips, Brienen and the Rainfor Collaboration 2017; Hubau et al. 2020), is currently in decline due to deforestation, warming and moisture stress. This is particularly the case in eastern Amazonia during the dry season, with the South East experiencing most of the decline (Barkhordarian et al. 2019; Leite-Filho, de Sousa Pontes and Costa 2019; Flores et al. 2024).

An estimated 10 to 47 per cent of the Amazon's forests are exposed to a combination of warming temperatures, extreme droughts, deforestation and wildfires, which could result in an irreversible ecosystem transition if certain critical thresholds or tipping points are crossed, potentially exacerbating regional climate change (Flores et al. 2024).

Deforestation caused by industrial-scale cattle farming in the Brazilian Amazon significantly affects biodiversity. Increased deforestation was associated with increased wildfire count by 39 per cent from 2012 to 2019 in the Brazilian Amazon, negatively affecting regional air quality (Butt et al. 2021). In addition to deforestation, temperature increases and precipitation reductions in Amazonia increased carbon emissions due to forest degradation (Artaxo et al. 2022; Artaxo 2023; Oliveira et al. 2023). After 2010, deforestation in Amazonia surged, peaking in 2018 at rates reminiscent of the early 21st century, highlighting its role in biomass burning emissions, particularly $PM_{2.5}$ from deforestation fires (Mataveli et al. 2021).

In contrast to the Amazon rainforests, which have shown a long-term decline in carbon sequestration capacity, African tropical forests have consistently maintained their ability to absorb carbon. Over a three-decade period ending in 2015, these African forests have continuously captured 0.66 tons of carbon per hectare each year (Hubau et al. 2020). The Amazon forests were adversely affected due to extreme drought in 2023, whereas tropical Africa remained wetter than normal (Espinoza et al. 2024). For example, during the months of October to December 2023, drastic carbon losses occurred in the Amazon and were reported as the largest contributor to the decline in the yearly global terrestrial carbon sink (Ke et al. 2024). Moreover, in Southeast Asia, both bottom-up and top-down models reported a net carbon sink that approaches zero in October to December (Ke et al. 2024). Additionally, Ke et al. (2024) reported overall extreme heat in 2023 would lead to a gross carbon loss of 1.73 gigatons across terrestrial regions globally, signalling a substantial adverse effect of climate warming on land ecosystems as carbon sinks.

Biodiversity loss and land degradation also affect the climate by changing the albedo or reflectivity of the Earth's surface (Duveiller, Hooker and Cescatti 2018; Mirzabaev et al. 2019). For example, darker forests induce positive radiative forcing, reducing the cooling effect of carbon sequestration (Zhao and Jackson 2014). Therefore, reducing deforestation in high latitudes could potentially increase warming. By contrast, deforestation in the tropics leads to a total global warming effect due to reduced evapotranspiration, which outweigh the cooling effects produced by increased albedo (Perugini et al. 2017; Butt et al. 2023).

As part of its nationally determined contributions to the Paris Agreement, India aims to generate an additional carbon sink of 2.5–3.0 billion tons of CO_2 equivalent (CO_2eq) by 2030 by enhancing its forest and tree cover From 2005 to 2019, India had achieved an extra carbon sink of 1.97 billion tons of CO_2eq (Government of India 2024). Furthermore, forests are a contributor to atmospheric particulate matter removal. In addition, 1361.28 tons of $PM_{2.5}$ were removed by forests in India in 2019 (Bagaria et al. 2023). Deposition of particulate matter was high in swamp forests, tropical semi-evergreen forests, and moist deciduous and subtropical pine forests.

Several countries aim to increase their forest cover. For example, Pakistan launched its ecosystem restoration initiative Ten Billion Tree Tsunami Project in 2019, which aimed to plant 10 billion trees by 2023 to prevent land degradation and restore ecosystems (UNEP 2021). Saudi Arabia has undertaken significant initiative to increase forest cover, aiming to plant 10 billion trees across the country to rehabilitate over 74 million hectares of land. This initiative aims to restore important ecosystem services, improve air quality and reduce sandstorms (El-Juhany et al. 2022).

Effective conservation measures like afforestation and reforestation can increase forest cover through the dynamic distribution of carbon sinks (Yu et al. 2022). For example, the forest carbon sink has increased significantly in northern China, showing an average increase in net ecosystem productivity between 2000 and 2020 of 7.0 gCm^{-2} yr^{-1} (Huang, Rodríguez-Iturbe and Calabrese 2024). Land-use and land-cover changes in China, characterized by rapid forest expansion from 1980 to 2019, contributed to nearly 44 per cent of the national terrestrial carbon sink (Yu et al. 2022).

Grassland ecosystems also play an important role by storing carbon in soil. The goal of the Bonn Challenge and Initiative 2020 is to restore 350 million hectares of degraded landscapes through grassland restoration globally by 2030 (van der Esch et al. 2022). Forest landscape restoration and encouraging tree planting should not be the reason for the loss or conversion of open, non-forested ecosystems like grasslands (Schweizer, van Kuijk and Ghazoul 2021). Letting land rest from livestock grazing, seeding it with native grasses and clearing woody encroachment are the most effective methods for restoring grasslands and protecting their capacity to store carbon and help mitigate climate change. For grasslands restoration, the most efficient method is to control overgrazing, planting native grasses and clearing woody encroachment, which contributes to climate change mitigation by storing carbon (Bai et al. 2024; Parr et al. 2024).

3.3.1.2 Soils

The global soil carbon sink is over three times greater than the combined carbon content of the atmosphere and biosphere, positioning soil as a vital component of the Earth's carbon cycle (Jones et al. 2020; Yu, Weintraub and Hall 2021). Subsoil can store more carbon than topsoil, underscoring the depth of soil's carbon sequestration capacity (Luo et al. 2020). Recognizing soil's ability to sequester approximately 2,500 gigatons of CO_2, its role is pivotal in climate change mitigation strategies (Kumar, Ananta and Ashutosh 2020). Implementing soil regenerative practices has a vital role in improving soil health and increasing soil organic carbon sequestration, and they contribute to the European Union's goal of increasing healthy soils by 75 per cent by 2030 (Villat and Nicholas 2024).

Changes in carbon fluxes and reserves, mainly due to alterations in land use and land cover, as well as the burning of fossil fuels and biomass, have a significant effect on the long-term viability of ecosystem services at both regional and global scales. The accuracy of terrestrial carbon sink estimates is further complicated by political and socioeconomic factors, along with varying carbon sequestration potentials of different management approaches (IPCC 2022).

Annually, soil emissions contribute 6.8–7.9 gigatons of CO_2eq to the atmosphere. These emissions primarily consist of CH_4 from undisturbed peatlands and rice cultivation, N_2O from both managed and unmanaged

soils, and CO_2 from changes in land use. Additionally, other wetlands release CH_4, accounting for an extra 1.6–3.8 gigatons of CO_2eq (He et al. 2024).

Since 1990, cultivated cropland soils have experienced a 20–60 per cent reduction in organic carbon content (Scharlemann et al. 2014). Traditional agricultural practices continue to contribute to GHG emissions. The primary sources of non-CO_2 GHGs are agricultural lands and wetlands (Chen et al. 2018). Climate change is intensified by the significant effects and associated emissions from the growth of rice farming that increases CH_4 sources, the expansion of ruminant populations and manure management that increases CH_4, N_2O and NH_3 emissions, and excessive nitrogen fertilization coupled with soil acidification that increases N_2O emissions (Oertel et al. 2016).

Regarding emissions from peatland, Indonesia, China and the Russian Federation contributed 31 per cent of the global peatland emissions of carbon. Europe is a net exporter of 104 Mt CO_2eq/yr of embodied peatland emissions, and Africa and the Middle East regions are the largest net importers (64 Mt CO_2eq/yr) (Mattila 2024). Another critical factor is emissions from paddy fields in Asia, where single-season rice contributes more than 80 per cent of the total carbon emissions. However, CH_4 emissions from Monsoon Asia have remarkably declined since 2007 with the adoption of three mitigation methods: waste management techniques, off-season straw return, and straw-to-biochar, which can reduce CH_4 emissions by 27, 23, and 21.78 per cent, respectively (Zhou et al. 2024a).

Mangrove forests, marshes and seagrasses, common in sediment accumulation areas, represent crucial coastal ecosystems. The deterioration or substitution of these ecosystems with alternative vegetation is causing a significant release of carbon, estimated between 0.15 and 1.02 gigatons per year globally (Rosentreter et al. 2023).

The depletion of organic carbon in soil is a key indicator of land degradation, which poses a significant threat to sustainable development, biodiversity conservation, and efforts to address climate change through mitigation and adaptation strategies. Land degradation is the diminishment or loss of the land's biological or economic productivity and complexity. In arid regions, this phenomenon is called desertification (Caretta et al. 2022) (Chapter 4). Soil erosion, the most common type of soil degradation, removes the top layer of soil that typically contains the highest concentration of organic carbon. This process can promote the conversion of carbon into CO_2 through mineralization. However, counteracting mechanisms like carbon burial may offset this effect, potentially making soil erosion a long-term carbon sink (Wang et al. 2017). Both natural and human-caused erosion can lead to net carbon storage in highly stable buried reservoirs at deposition sites. Consequently, degradation in these areas has a significant potential for carbon release. The radiative effect of dust particles released by human activities from degraded land appears to have both positive and negative radiative-forcing effects (Mousavi et al. 2024).

The Earth's surface albedo exhibits significant variation depending on the types of surfaces and vegetation present. Of all the physical consequences of land degradation, alterations in surface albedo have the most important consequences for the global net radiative balance and overall climate warming or cooling (Zhang et al. 2022). For example, in a study conducted in Michigan, it was observed that croplands and forests had on average 7.8 per cent higher and 0.7 per cent lower albedo than other land covers, respectively (Sciusco et al. 2020). Additionally, most urban areas, particularly in industrialized countries, encourage investment in vegetation cover to counter the urban heat island effect and they are also decreasing reflectivity of radiation back into the atmosphere (Wu et al. 2024). These urban centres are likely to experience greater (positive) surface radiative forcing. The effects on albedo resulting from forest deterioration or removal are heavily influenced by the specific latitudinal and climatic zone in which these events occur (Lodh and Haldar 2024).

Changes in surface albedo since 1750, primarily attributed to deforestation, have resulted in a global average radiative forcing of approximately −0.2 W/m^2, leading to a cooling effect. This has played a moderate role in the overall global net anthropogenic radiative forcing, estimated at around 1.6 W/m^2 (Zelinka et al. 2023). In the case of boreal forests, the destruction or deterioration of tree cover leads to an increase in albedo, producing a net cooling effect as the reflective snow beneath becomes visible. This cooling effect can potentially surpass the net radiative effect of the associated carbon released into the atmosphere (Salisbury et al. 2023).

3.3.2 How changes in the atmosphere affect biodiversity loss and land degradation

Anticipated shifts in climate and the introduction of non-native species are expected to constrain the ability of

The Snake River basin of southwest Idaho is a diverse, arid landscape. Repeated cycles of fire and invasive annual grasses threaten the unique assemblage of native plants and wildlife, posing a wildfire risk. Removing invasive grasses that promote fires and restoring native species such as perennial forbs, sagebrush and other shrubs are critical to the health of the ecosystem. Credit: Bureau of Land Management of the United States of America

particular species to migrate, consequently accelerating the loss of biodiversity.

Invasive species in the terrestrial and freshwater ecosystems of the Antarctic and Southern Ocean region, where approximately 13 per cent of species are considered locally invasive, are an example of changes in biodiversity due to climate change (Hughes and Convey 2022; Leihy et al. 2023). An additional example from the Sikkim Himalayas shows that up to 87 per cent of 124 endemic species have undergone geographical shifts due to warming, posing a risk of extinction for these species (Telwala et al. 2013).

Climate change has significantly influenced changes in species richness (Bhattacharjee et al. 2017). Vegetation species like *Betula utilis* (Himalayan birch) exhibit a trend of moving towards the Eastern Himalayas, while showing a decline in numbers towards the west (Hamid et al. 2018). Moreover, climate change combines with biological invasions to hamper biodiversity. For example, in California, nitrogen deposition, climate-change-induced plant invasions, high CO_2 concentrations and fire interact in various complex ways to change ecosystem processes (Harrison et al. 2024). Invasive annual grasses lead to novel fire regimes in California's deserts, resulting in adverse ecological effects (Abatzoglou and Kolden 2011; Weber et al. 2019; Harrison et al. 2024). Climate change is also expected to promote and increase this grass–fire cycle (Abatzoglou and Kolden 2011).

In certain ecosystems, the growth of forests may increase as atmospheric levels of CO_2 increase. However, climate change could force species to adjust their ranges much more rapidly than they can (Sáenz-Romero et al. 2020; Zhang et al. 2023a). Consequently, some species might become extinct. For instance, in Canada, it is improbable that white spruce populations will be able to migrate at a speed that keeps up with the rate of climate change (Lima, Lenoir and Hylander et al. 2024).

Forests are also threatened by pests, pathogens and wildfires, rendering them more susceptible to invasive species (Panzavolta et al. 2021). Climate change contributes to biodiversity loss and consequently leads to decline in ecosystem functioning and services. Moreover, acute and synchronous climate impacts can harm biodiversity. For example, a study of the timing and synchronicity of climate effects on around 30,000 species worldwide and found that long-term increases in average annual temperatures threatened their viability (Trisos et al. 2020). Also, increased sunshine

Credit: bilanol/Envato

significantly affects vegetation growth, evapotranspiration and water cycle processes, which affect ecosystem functions and services (Zhou et al. 2024b).

Changes in air quality also cause biodiversity loss due to the effects of different primary and secondary air pollutants. For instance, tropospheric ozone as a secondary air pollutant harms plants and diminishes biodiversity. In 2020, critical thresholds necessary for forest protection were surpassed in 59 per cent of the total forest area of the 32 European Environment Agency (EEA) Member nations (Maes et al. 2023). From 2000 to 2020, there was a general decline in the proportion of agricultural land in EEA Member countries exposed to ozone levels above the protective target for vegetation, reaching a minimum of 6 per cent in 2020 (Sonwani et al. 2022). However, in 2019, the economic damage incurred from the effects of ground-level ozone on wheat production amounted to €1,418 million across 35 European countries.

While 2020's harmful levels of nitrogen deposition were detected in 75 per cent of the total ecosystem across the 27 European Union Member States, this marked a decrease of 12 per cent since 2005 (EEA 2022) The zero-pollution action plan has established a goal of reducing nitrogen deposition by 25 per cent from 2005 levels by 2030 (Etzold et al. 2020). In 2020, only 4 per cent of the European ecosystem experienced deposition levels of sulfur dioxide, nitrogen oxides and ammonia that surpassed the thresholds leading to ecosystem acidification, owing to effective emission reduction efforts for sulfur dioxide (EEA 2024).

3.3.2.1 Stratospheric ozone and UV radiation

Decreased stratospheric ozone results in increased ultraviolet (UV) radiation at the Earth's surface with detrimental effects on biodiversity, GHG emissions (Silva et al. 2021; Shiraishi and Hirata 2021), carbon storage, ecological resilience, and the productivity of forests and crops, leading to species replacement and potential deterioration of ecosystem functioning (Bornman et al. 2019). Excessive UV-B radiation combined with other potential stressors, such as heat and drought, may harm plant growth and chances of survival (Zandalinas et al. 2021).

The annual Antarctic stratospheric ozone hole and periodic severe Arctic ozone depletion result in increased solar UV radiation at ground level, which may harm vegetation, although these events generally occur in early spring when many plant species are dormant (Bernhard and Stierle 2020). However, when record-breaking increases in UV radiation and the Antarctic ozone hole occur simultaneously, plants and animals may be damaged. For example, in 2020, the return of many migrating animals to breed in Antarctica coincided with the persistent ozone hole, which risked exposing them to an unusually

high UV index from mid-November to late December (Robinson et al. 2024).

3.3.2.2 Snow cover and land degradation

Extreme high temperatures generally lead to less snowfall and accelerated snow melt in cold regions, exposing ground flora and fauna to solar UV radiation earlier in the spring. However, UV radiation received by organisms around the snowpack may sometimes be reduced due to decreases in reflection when the snowpack melts (Robson and Aphalo 2019).

When black carbon, which absorbs solar radiation, is deposited over snow-covered mountains, the heat released accelerates the melting of snow (Grogan et al. 2020; Slatyer, Umbers and Arnold 2022; Roychoudhury et al. 2022; Yang et al. 2022; Hugelis et al. 2024).

Although the threshold for a global temperature, above which extensive and irreversible tipping-point thawing of permafrost could occur is uncertain, permafrost thaw is likely to increase gradually with climate warming (Nitzbon et al. 2024). This could lead to substantial CO_2 emissions by releasing stored carbon and CH_4, potentially accelerating climate change (Huissteden 2020; Natali et al. 2021; Miner et al. 2022).

3.4 Impacts on human systems

Atmospheric emissions affect air quality, the stratospheric ozone layer and the climate, which all affect human systems – including health and well-being, agriculture, education, tourism, the built environment, transport and other services – and in many cases exacerbate inequities directly and indirectly.

3.4.1 Heat and heatwaves

One of the main effects of climate change is the increased frequency, duration and intensity of heatwaves, as well as a general increase in ambient temperatures, which directly affect physical and mental health (Romanello et al. 2023). Globally, around 489,000 heat-related deaths occurred every year over the period 2000–2019 (Zhao et al. 2021), with annual heat-related mortality for people over 65 years of age increasing by approximately 85 per cent in the period 2013–2022 compared with 1991–2000, due to climate and demographic changes (Romanello et al. 2023).

Rising temperatures pose a risk to cardiovascular, neurological and mental health (Liu et al. 2021; Thompson et al. 2023; Byun et al. 2024), especially in ageing populations (Chang et al. 2022), with data showing elderly women at higher risk of mortality compared to men (van Steen et al. 2019). Higher temperatures also increase the risk of kidney disease, particularly in agricultural workers (El Khayat et al. 2022). There is emerging evidence of associations between higher temperature exposure during pregnancy and adverse perinatal health outcomes, including preterm birth, low birth weight and stillbirth, particularly in lower socioeconomic groups (Chersich et al. 2020).

In Indigenous communities, extreme temperatures cause an increase in acute and chronic physiological impacts, such as the prevalence of cardiovascular, nephrological and respiratory diseases, including asthma (Ford et al. 2010; McNamara, Westoby and Chandra 2021; Sahu et al. 2022). Mental health challenges were also reported – emotional responses of worry, sadness, anger and emotional distress – and were often more prevalent in Indigenous Peoples compared to their non-Indigenous counterparts (Middleton et al. 2020; Sahu et al. 2022; Romanello et al. 2024).

The urban heat island effect, associated with urban, anthropogenic heat sources and the use of absorbing materials together with the climate change-related warming trend, has led to night-time urban warming much higher than the global average (IPCC 2021; Li and Chen 2023). Urban heat islands contribute to heat-related deaths, heat cramps, heat exhaustion, heat strokes, and the exacerbation of respiratory health conditions (Heaviside, Macintyre and Vardoulakis 2017). Without adequate adaptation, heat-related mortality is projected to increase substantially (Gasparrini et al. 2017; Lüthi et al. 2023).

3.4.2 Air pollution

Air pollution, predominantly from the fine particles termed $PM_{2.5}$, was the leading contributor to the global disease burden in 2021, contributing 8.0 per cent of total disability-adjusted life years (GBD 2021 Risk Factors Collaborators 2024). Outdoor and indoor – or ambient and household respectively – air pollution was associated with approximately 8.1 million deaths in 2021 (Health Effects Institute 2024).

Globally, 99 per cent of the world's population is exposed to harmful levels of air pollution (Health Effects Institute 2024), which causes substantial adverse health effects and related economic losses. Emissions of combustion-related pollutants, including $PM_{2.5}$., nitrogen oxides and sulfur dioxide, as well as the formation of secondary pollutants such as tropospheric ozone, contribute to local and regional air pollution that affects multiple human systems (Manisalidis et al. 2020).

The effects of outdoor air pollution on respiratory and cardiovascular health are well established, even at low concentrations of air pollutants, including $PM_{2.5}$ (Hoffmann et al. 2021). Cognitive decline, including an increased risk of dementia, has also been associated with air pollution (Delgado-Saborit et al. 2021). Emerging evidence indicates that air pollution is a significant risk factor for diabetes, with approximately 20 per cent of the global burden of Type 2 diabetes attributable to $PM_{2.5}$ (GBD 2019 Diabetes and Air Pollution Collaborators 2022).

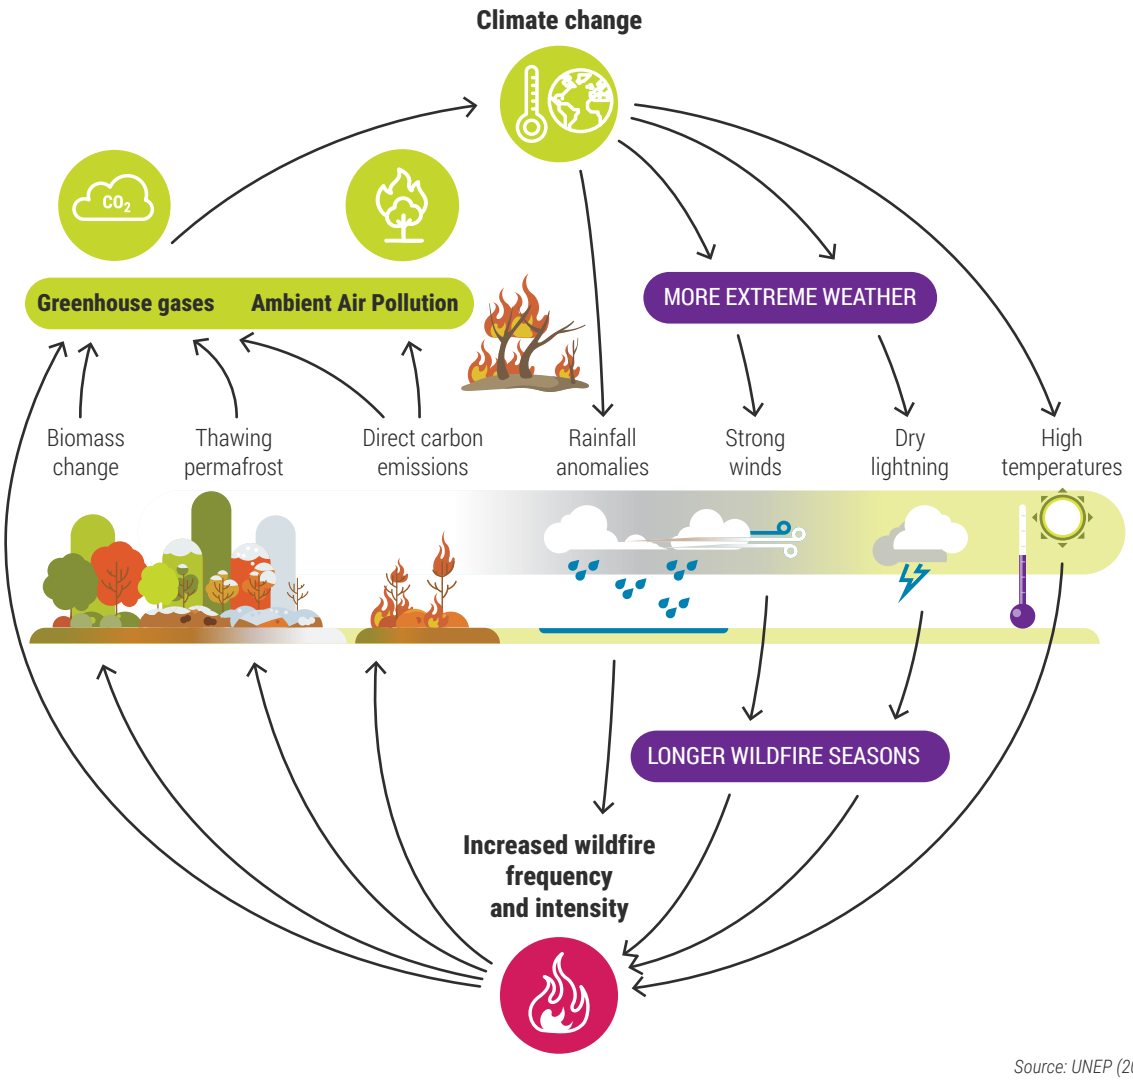
Children are more vulnerable to air pollution because of its impact on lung growth and function. Preterm birth and low birthweight have been associated with maternal exposure to air pollution (Niu et al. 2022; O'Sharkey et al. 2023; Aziz et al. 2024). Smaller particles (PM_1) may have greater short-term effects on childhood pneumonia in comparison to larger particles ($PM_{2.5}$ and PM_{10}) (Wang et al. 2021). Furthermore, in-utero $PM_{2.5}$ exposure has been associated with stunted growth in children (deSouza et al. 2022).

Outdoor air quality has improved in some regions, such as Western Europe, eastern North America and China in recent years (Yang and Zhong 2022; EEA 2023a). For example, the number of deaths attributable to $PM_{2.5}$ in the European Union in 2020 declined by 45 per cent, compared to 2005 (EEA 2023a). Consequently, the European Union is likely to meet its zero-pollution action plan target of reducing premature deaths attributable to $PM_{2.5}$ by 55 per cent by 2030, compared to 2005 (EEA 2023a). The progress made in these regions should motivate collective action to improve air quality globally. However, these improvements have been mainly observed in high-income cities and neighbourhoods, with socioeconomically disadvantaged or vulnerable population groups, such as the elderly, children and those in poor health, typically being exposed to higher air pollution levels (EEA 2023a). Further improvements in air quality require a stronger focus on disadvantaged and vulnerable population groups. They will also need to counterbalance the effect of population ageing, since most adverse health outcomes attributable to $PM_{2.5}$ exposure are in people aged 75 and above (Chen et al. 2023).

Compliance with the WHO 2021 guidelines could prevent 549,715 (95 per cent CI: 276,204–815,023) deaths attributable to NO_2 in cities around the world (Song et al. 2023). The age-standardized mortality rate per 100,000 people attributable to NO_2 ranged from 51.3 (95 per cent CI: 25.8–76.0) in Central Asia to 3.4 (95 per cent CI: 1.7–5.1) in Oceania. Although there was a substantial decrease in premature mortality attributable to NO_2 globally, driven by decreases in NO_2 emissions from road transport and power plants, particularly in high-income countries in North America and Western Europe, certain cities in Central Asia and Latin America exhibited an upward trend (Song et al. 2023). Regionally, the number of deaths attributable to NO_2 was highest in East Asia (139,989, 95 per cent CI:70477–207,241), followed by South Asia (75,397, 95 per cent CI: 37,812–111,942), and Eastern Europe (46,840, 95 per cent CI: 23,597–69,307) (Song et al. 2023).

Population exposure to O_3 has increased worldwide at a rate of 0.25 ppb from 2000 to 2019 (Malashock et al. 2022). Tropospheric O_3, generated through chemical reactions in the atmosphere, adversely affects respiratory health in humans (Zhang et al. 2019), as well as vegetation and crops, thus affecting ecosystem services and food security (Manisalidis et al. 2020). It has been estimated that in 2021, exposure to O_3 caused half a million premature deaths worldwide (Health Effects Institute 2024). Atmospheric concentrations of methane have increased over the last decades (Lan et al. 2025) and are currently contributing about 35 per cent of the O_3 burden globally (Butler et al. 2020). While O_3 peaks have declined, baseline O_3 levels are increasing because the reduction of NO_2 emissions is counterbalanced by the increasing role of CH_4 (Bessagnet et al. 2024).

3.4.3 Wildfires



Climate change, wildfires and air pollution create a vicious cycle with negative repercussions for human health, ecosystems and agriculture (WMO 2024c). Climate change directly affects the frequency and magnitude of extreme weather, including high temperatures

and prolonged droughts, that are conducive to the outbreak and spread of wildfires in many regions (Xie et al. 2022; Jones et al. 2024; Burton et al. 2025). It also leads to wildfires of higher intensity and to longer wildfire seasons. Wildfire activity has increased worldwide over the last several decades and is likely to continue to increase due to climate and land-use change, and fire suppression, that is, removing less-extreme fires (Bowman et al. 2020; Cunningham et al. 2024; Kreider et al. 2024). Without effective interventions, the probability of wildfires will increase globally by a factor of 1.31 to 1.57 by the end of the century (UNEP 2022). Increased wildfire activity exacerbates GHG emissions and forest loss, reinforcing climate change drivers (**Figure 3.6**) (UNEP 2022).

Emissions from bush and forest fires, as well as from agricultural burning, vary spatially across the world (van Wees et al. 2022), and smoke plumes lead to poor regional air quality and increased $PM_{2.5}$, and O_3 concentrations, as well as toxic metals including mercury, affecting human health. Wildfires also emit black carbon, which has a significant radiative-forcing effect. The health risks associated with wildfires include direct dangers from exposure to fires, as well as exposure to the smoke (Xu et al. 2020). Wildfires also release viable bioaerosols or microbes that can be transported long distances in plumes, with human-health implications (Kobziar et al. 2022). In combination with a growing and ageing global population, adverse health effects associated with wildfire smoke are likely to become more significant in the future (Reid and Maestas 2019).

In the period 2010–2019, population-weighted average $PM_{2.5}$ and tropospheric O_3 concentrations associated with fire emissions were about 6.1 per cent of all-source $PM_{2.5}$ and 3.6 per cent of all-source O_3, representing a slight increase in $PM_{2.5}$ compared to 2002–2009, but not

Figure 3.6: Potential reinforcing feedback loop of climate change on wildfires

Box 3.2: Local and Indigenous practices in biomass burning

Weather and climate parameters control wildfire activities in the presence of vegetation, atmospheric oxygen and numerous ignition sources (Grillakis et al. 2022). Over 90 per cent of fires in most biomes are caused by human activities (Chuvieco et al. 2021). Due to climate change, frequent-fire-prone areas are likely to increase by 29 per cent globally and the fire season will lengthen significantly by the end of the 21st century (Senande-Rivera, Insua-Costa and Miguez-Macho 2022). Several region-specific practices, including those of Indigenous Peoples, have been used to manage biomass burning on different continents.

Africa

Wildfires in Africa predominantly occur in the savannah ecosystem and contribute approximately 29 per cent of global fire emissions (Russell-Smith et al. 2021; Dabengwa et al. 2022). Emission reductions are possible through cooler, early dry-season fire-management programmes. For example, the Khwe and Mbukushu communities of Namibia already use early-season fires for historical and livelihood reasons, highlighting the relevance of ancestral practices in fire policy planning (Humphrey, Gillson and Ziervogel 2021; Tear et al. 2021). Environmental communication through folk theatre, as with the Shona people of Zimbabwe using the song Ndiani apisa moto (Who has caused a veld fire?), is incorporated in social gatherings to combat biomass burning (Chari 2020).

Oceania

Image 3.1: A controlled fire burn occurs near Whitfield in the King Valley, Victoria, Australia. Credit: FiledIMAGE/envato

In the fire-prone regions of Australia, Indigenous Knowledge and Local Knowledge is used to manage savannah fires. Indigenous rangers work across multiple Indigenous Protected Areas, burning biomass to reduce the fuel load before the bushfire season. Biomass burning emissions are managed by developing seasonal calendars for fire management with ecological indicators and seasonal conditions that integrate natural and cultural values (McKemey et al. 2020; McKemey et al. 2021). Applying Indigenous Knowledge to develop collaborative fire-management strategies that respect local practices can provide mutually beneficial outcomes for biodiversity, cultural heritage and human assets (Rodrigues et al. 2022).

Meso and South America

Indigenous communities in the Chiapas pyrobiocultural landscapes of Mexico and Lomerío in Bolivia use

Indigenous Knowledge for fire management to reduce extreme wildfire events. Indigenous Peoples apply their observations and memories of major extreme events and integrate cultural fire-management practices rooted in the Indigenous way of life, emphasizing harmony and the relationship between humans and nature (Pasiecznik and Goldammer 2022; Rodríguez et al. 2023). Pyrocultural refers to the strong relationship between traditional fire practices, territorial knowledge, and management (Pasiecznik and Goldammer 2022).

Indigenous Knowledge integrates a seasonal calendar with local weather patterns to optimize food production. This practice involves using the land in cycles: 2–3 years for crop production followed by a long rest period of at least 10 years after an initial burning to allow the soil to recover (Tschakert, Coomes and Potvin 2007). This system is deeply intertwined with Indigenous sociocultural and spiritual practices, reflecting a holistic approach to land management that prioritizes ecological balance and cultural continuity (Catacora-Vargas et al. 2015; Fundación Xavier Albó and Centro de Investigación y Promoción del Campesinado 2017).

The Pantanal area in South America has experienced a severe drought since 2019 (Marengo et al. 2021) that resulted in intense and widespread fires in 2020 (Garcia et al. 2021). Predominantly intentional fires (Libonati et al. 2020; Oliviera et al. 2022) consumed large areas of converted and Indigenous lands, even in regions inhabited by the Kadiwéu, who are trained in fighting fires in their territory (UNEP 2022).

North America

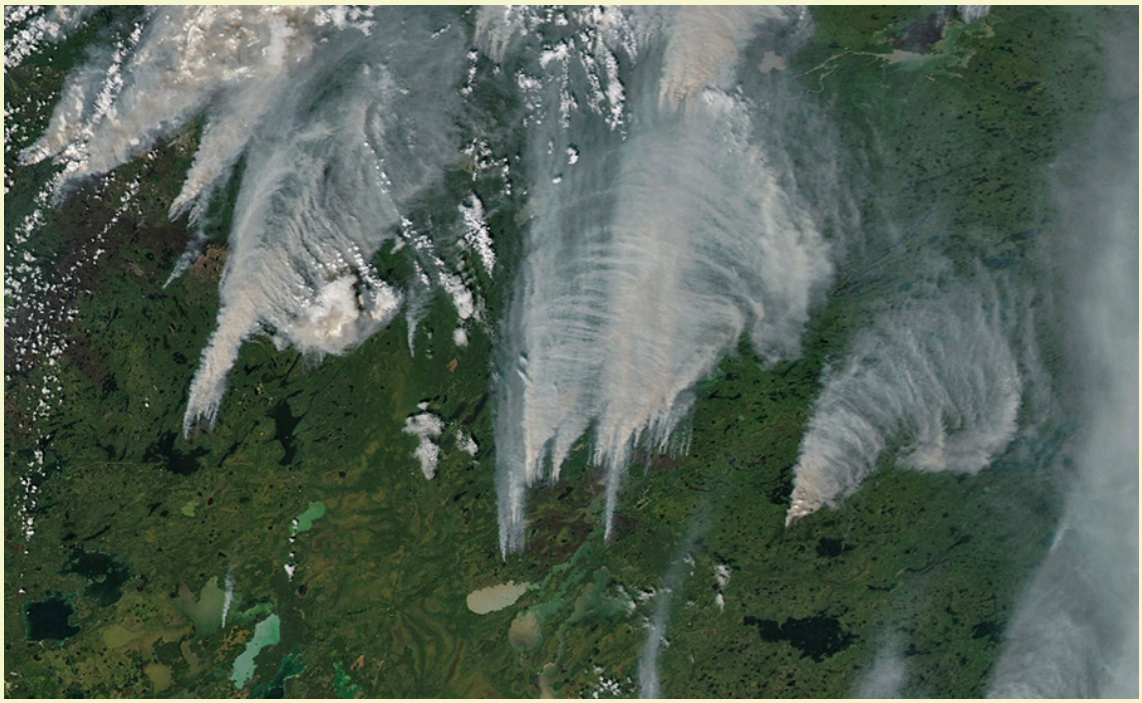

Image 3.2: Dense smoke plumes from large fires in the Manitoba province of Canada on 9 July 2025 - Source: NASA Earth Observatory

Indigenous fire management has contributed to the development of fire-adapted landscapes in Canada, strengthening cultural connections and protecting the well-being of future generations (Nikolakis and Roberts 2020). In British Columbia, Indigenous fire practices were historically used to promote ungulate browsing, reduce understory vegetation, and control the overgrowth of conifers and sagebrush (Nikolakis et al. 2020). The revitalization of Indigenous cultural burning practices can present an alternative that reduces wildfire risk and enhances community protection, while maintaining a balanced relationship between fire, humans and other beings (Hoffman et al. 2021).

for O_3 (Xu et al. 2023). Central Africa, Southeast Asia, South America and Siberia had the highest $PM_{2.5}$ and O_3 concentrations associated with fires, with pollutant levels approximately four times higher in low-income countries compared to high-income countries.

Wildfire-driven increases in $PM_{2.5}$ concentrations are likely to grow as the climate continues to warm (Burke et al. 2023). However, current trends show significant regional variability in wildfire-related atmospheric emissions. Furthermore, increases in O_3 formation due to wildfires have been reported in the literature (Byrne et al. 2024; Cooper et al. 2024; Lee and Jaffee 2024). Wildfires in Australia in 2019–2020 and Canada in 2023 resulted in extremely poor regional air quality, affecting population health in much of eastern Australia (Borchers-Arriagada et al. 2020) and North America (McArdle et al. 2023) and highlighting environmental and health disparities (Vardoulakis et al. 2020a; Yu et al. 2024).

People with pre-existing cardiovascular, neurological and respiratory diseases, the elderly, women often as primary caregivers, young children, pregnant women and infants, and outdoor workers are at higher risk from wildfire smoke and face additional burdens during and after wildfires (Holm, Miller and Balmes 2021; Vardoulakis et al. 2020a; Elser et al. 2025; White 2024).

Indigenous communities are disproportionately affected by wildfires as well (Casey et al. 2024). Between 2014 and 2019, exposure to smoke from fires in South America was greater in the Indigenous territories of the Amazon compared to the rest of South America (Bonilla et al. 2023). Amazon's Indigenous territories experienced 1.1 [± 0.4] $\mu g/m^3$ higher total $PM_{2.5}$ and 0.64 [± 0.21] $\mu g/m^3$ higher fire-related $PM_{2.5}$ (Bonilla et al. 2023). More research is needed to understand the long-term health effects of extreme wildfires in the general population and in Indigenous and at-

Box 3.3: Air pollution from fires caused by the conflict in Gaza

Many fires have broken out in Gaza since the start of the bombing in October 2023. Fires that occur at chemical storage sites pose a high risk of toxic pollutant emissions (Griffiths et al. 2022). In temporary shelters with a high density of displaced people, air pollution increases the risk of respiratory and cardiovascular distress, as well as longer-term risks of respiratory and cardiovascular disease and cancer (Velis and Cook 2021). Armed conflict escalations bring further environmental degradation, harming people and ecosystems (UNEP 2024a).

Image 3.3 Fires burning in Gaza, 16 November 2023 Source: Sentinel 2 [10 m resolution] retrieved by GRID Geneva, March 2024 (UNEP 2024a)

risk communities. It is also essential to understand Indigenous Knowledge and Local Knowledge practices in biomass burning that may help reduce the extent and impact of wildfires (**Box 3.2**).

3.4.4 Conflict and atmospheric emissions

Wars and conflicts have deteriorated air quality in particular regions, including parts of Europe (Meng et al. 2023), Africa (Solomon et al. 2018), and the Middle East (UNEP 2024a) (**Box 3.3**). Conversely, reduced economic activity due to armed conflict in East Africa may have reduced NO_2 levels in certain cities in Sudan (Abushama et al. 2023).

Russia's war on Ukraine led to an average $PM_{2.5}$ increase of approximately 9.8 per cent, an NO_2 increase of 10.1 per cent, and an average decrease in tropospheric ozone of approximately 7.9 per cent in cities in the war zones. Emissions from military activities have also contributed to degraded air quality in the Middle East and Africa. The increase in atmospheric emissions of harmful pollutants caused by war poses a substantial challenge to regional air quality in Europe (Meng et al. 2023).

The use of explosive munitions generates large quantities of dust that causes an additional health hazard during armed conflicts, as well as during post-conflict clean-up and recovery operations. Inhalation of the dust generated during the bombing of buildings or other infrastructure can be harmful because of potential contamination with asbestos, organic chemicals, heavy metals from munitions, and other toxic substances (UNEP 2024a).

The GHG emissions of the world's militaries, apart from the direct consequences of combat, such as fires and other damage to infrastructure and ecosystems, are estimated to be approximately 5.5 per cent of global GHG emissions (Parkinson and Cottrell 2022). These emissions are likely to have grown in the wake of Russia's war on Ukraine (Bun et al. 2024) and conflicts in the Middle East and Africa (Neimark et al. 2024).

3.4.5 Household air pollution from solid fuels and other indoor sources

Household air pollution caused by the burning of solid fuels – firewood, coal, charcoal, animal dung, crop residues, and plastic waste – or kerosene in inefficient stoves indoors affects approximately 2.3 billion people, around a third of the global population (Lee et al. 2020; Khavari et al. 2023; WHO 2024b). These people mainly live in low and middle-income countries in sub-Saharan Africa, Asia and Latin America, where there is limited access to clean energy for cooking and heating (WHO 2024). For example, around 20 per cent of rural households in India used solid fuels exclusively for cooking in 2020 (Mani et al. 2021), while in Paraguay, 49 per cent of rural households still relied on solid fuels for cooking in 2022 (Paraguayan Government 2022). Household air pollution from these sources is associated with around 3.2 million deaths each year, including over 237,000 deaths of children under the age of 5 years (WHO 2024). Polluting fuels and technologies disproportionately affect women and children in low-income households, as they are typically involved in household chores such as collecting firewood and cooking, and they spend more time indoors exposed to harmful smoke from inefficient stoves (WHO 2024).

From 2000 to 2021, there has been a 61 per cent reduction in the death rate from household air pollution (Health Effects Institute 2024). Although the burden of maternal and child illnesses linked to household air pollution declined by a third worldwide from 2000 to 2017, it remains high in the lowest-income countries and regions, particularly in Southeast Asia and Africa (Lee et al. 2020). The African and Western Pacific regions experienced modest reductions in the related disease burden, with larger reductions in India and China (Lee et al. 2020). The patterns of diseases associated with household air pollution varied substantially, with respiratory infections nearly halved, but noncommunicable diseases such as lung cancer increasing (Lee et al. 2020).

Particulate emissions from wood heaters persist as a significant environmental and public health problem in many countries. For example, in Australia, wood heaters contribute about 13 per cent of ambient $PM_{2.5}$ concentrations annually (Borchers-Arriagada et al. 2024). Emissions of formaldehyde and other volatile organic compounds from indoor sources, such as furniture, timber, paints, adhesives and cleaning products, have a deleterious effect on the household environment (Vardoulakis et al. 2020b). More airtight houses in the future may result in higher indoor air pollution and overheating, unless adequate air ventilation, filtration and cooling are provided.

3.4.6 Sand and dust storms

Particles from sand and dust storms affect human health and degrade materials and visibility. There is a significant association between this type of dust and adverse respiratory and cardiovascular health effects (Lwin et al. 2023). Sand and dust storms are strongly linked to climate change due to the combined effect of rising temperatures and reduced rainfall, which lead to droughts, land degradation, and desertification (Wu et al. 2021). Droughts are a major threat to sustainable development in dryland Asia, with drought conditions projected to worsen for climate scenarios consistent with 1.5 and 2.0°C warming, particularly for Northwest China and Kazakhstan (Miao et al. 2020).

Sand and dust storms in many world regions, including Africa and Asia, present an increasing threat to global health (United Nations Convention to Combat Desertification [UNCCD] 2022; Touré et al. 2024; Li et al. 2025). The main component of sand and dust storms that threaten human health is inhalable particles (PM_{10}), which are associated with all-cause mortality and morbidity, especially from respiratory and cardiovascular illnesses. These storms can also expose individuals to harmful microorganisms and allergens present in coarse particles (Wu et al. 2021). Concurrent heatwaves and drought conditions in the past two decades, particularly over inner East Asia and West Asia, have exacerbated the soil drying that causes sandstorms (Zhang et al. 2020).

3.4.7 Aeroallergens

Airborne allergens such as pollen degrade both outdoor and indoor air quality (Beggs et al. 2023). Climate and weather affect plant phenology, which refers to the timing of recurring biological events in the plant life cycle, and airborne pollen concentrations. Atmospheric CO_2 that causes climate warming also promotes plant growth, with associated releases of airborne allergens, such as pollen (Dhimal et al. 2021).

Various weather and climate variables affect the pollen concentration in the atmosphere and the timing and duration of the pollen season for different plant species (Schramm et al. 2021). Precipitation, for example, may increase grass pollen levels in the air. Ongoing increases in temperature extremes might contribute to longer pollen seasons and greater allergenic pollen loads in regions across the northern hemisphere (Ziska et al. 2019). Overall, warmer temperatures and higher atmospheric concentrations of CO_2 tend to prolong and increase the intensity of the pollen season, which may affect allergic respiratory diseases such as rhinitis and asthma, especially in sensitive individuals with pre-existing respiratory conditions (D'Amato et al. 2020).

3.4.8 Vector-borne diseases

Climate change will likely extend the geographical range and length of the transmission season of several vector-borne diseases (Caminade et al. 2019). Temperature and precipitation both affect the distribution of climate-sensitive vector-borne diseases transmitted by mosquitoes and ticks. Warmer temperatures generally favour vector-borne disease transmission, while precipitation creates adequate vector breeding sites for mosquitoes and ticks (Caminade et al. 2019). Furthermore, climate change affects infectious disease dynamics for several pathogens (Wu et al. 2016).

The transmission potential of some mosquito-borne diseases, such as malaria, dengue, Zika and chikungunya, is expected to increase, particularly under higher GHG emission scenarios (Semenza et al. 2022). Climate change is also projected to contribute to the wider distribution of tick-borne diseases, such as Lyme disease and tick-borne encephalitis (Semenza et al. 2022).

3.4.9 Stratospheric ozone and UV irradiance effects

Stratospheric ozone, affected by ODS emissions and climate change, may contribute to changes in UV-B exposure patterns at ground level and related skin cancer incidence (Parker 2021). The universal ratification of the Montreal Protocol has led to the regulation and phase-out of ODSs (3.5.2). In addition to protecting the ozone layer and hence human health from harmful UV radiation that can cause erythema and skin cancer (Tang et al. 2024), the Montreal Protocol is making a substantial contribution to reducing stratospheric ozone-depleting GHGs also included in this treaty (Bernhard et al. 2020). Although the Montreal Protocol has prevented significant increases in UV-B irradiance and related skin cancer cases (Neale et al. 2021; Neale et al. 2023), there are substantial uncertainties in the future evolution of UV exposure patterns at ground level due to climate change (Zerefos et al. 2023).

3.4.10 Food security and safety

Food security is affected by climate change, extreme weather events and tropospheric ozone, all of which can affect food production, availability, access and affordability. Increasing atmospheric CO_2 concentrations and temperatures could produce greater crop yields (Mirón, Linares and Díaz 2023). However, the increasing frequency and intensity of climate-related extreme events, such as floods, heatwaves and droughts, can cause more frequent crop failures, particularly in low-income countries that have lower adaptive capacity. Agriculture absorbed 26 per cent of the overall effect of medium- to large-scale natural disasters over the period 2000–2018 in low and middle-income countries (Monteleone et al. 2023). Tropospheric ozone also damages vegetation and reduces the yield of crops such as wheat in Asia (Anagha and Kuttippurath 2025; Xu et al. 2024), threatening global food security (von Schneidemesser et al. 2020).

Low-income households and particularly women are disproportionately affected by food insecurity, given their vulnerability to extreme weather events and restricted access to resources in certain regions (Food and Agriculture Organization of the United Nations 2015). Food security and climate change have strong gender and equity dimensions, with women disproportionately affected by price spikes (Mbow et al. 2019). Furthermore, warmer temperatures due to climate change could lead to an increased risk of proliferation of microorganisms that cause food-borne diseases, such as Salmonella and Campylobacter, affecting food safety (Mirón, Linares and Díaz 2023), as well as increased risks for the spread of food pathogens (Tirado et al. 2010).

Overall, the agriculture sector has been adversely affected by climate change, resulting in crop losses and food insecurity (Pande et al. 2023). Adopting traditional knowledge of preserving ecosystem services from Indigenous Peoples' practices and lifestyles provides insights into biodiversity restoration and climate change adaptation. The adoption of such practices can be promoted through sustainable resource management and local community engagement, encouraging Indigenous Peoples' full and effective participation in decision-making (Zurba and Papadopoulos 2023; Edwards et al. 2024).

3.4.11Biodiversity

Anticipated impacts of climate change on biodiversity include a decline in ecosystem functioning, integrity and resilience, beginning

at about 1.5°C of global warming. This will lead to the degradation of nature-based economic livelihoods and to food insecurity (IPCC 2022). Communities reliant on ecosystems and species that cannot easily establish themselves in different habitats and are already close to reaching the maximum extent to which they can adapt to climate change, are disproportionately affected by biodiversity loss (Pörtner et al. 2021).

3.4.12 Indigenous Peoples and local communities

Some of the primary mechanisms of how climate change affects Indigenous Peoples include their close relationship with the environment and their reliance on natural resources for livelihoods, food, water and health security that are compounded by the historical effects of socioeconomic and political marginalization (IPCC 2022; Redvers et al. 2023). Changes in precipitation and water quality and increased temperatures lead to more injuries, more airborne and waterborne diseases, and more malnutrition. They also cause mental distress due to disruptions in cultural and spiritual practices, and in community cohesion (Middleton et al. 2020; Reyes-García et al. 2024a). Climate change poses the risk of increasing Indigenous Peoples' exposure to harmful levels of heavy metals, including mercury, by altering their transport pathways (Stern et al. 2012), creating food security and safety issues for Indigenous diets (Feingold et al. 2020; Adlard et al. 2024).

Additionally, the loss of traditional lands and resources disrupts access to medicinal plants and jeopardizes cultural continuity, further affecting health and community well-being, especially when access to culturally appropriate healthcare services is lacking (Oster et al. 2014; Bourke et al. 2018; Rolleston et al. 2020; IPCC 2022). Similarly, due to biodiversity loss from climate change or other environmental factors, Indigenous Peoples' livelihoods were reportedly altered as a loss of ecosystem services, particularly provisioning and cultural services, also brought changes in ecosystem structure and function (Loring and Gerlach 2015; Kipp et al. 2019).

Rising temperatures, drought-related dust storms and degraded infrastructure lead to poor air quality, as observed among Indigenous communities in Arizona and New Mexico (Gamble et al. 2016). People living in Indigenous territories within the Amazon region are twice as likely to die prematurely from smoke exposure compared to the general population (Bonilla et al. 2023). Indigenous Peoples' respiratory health has been affected by industrial air pollution, land dispossession, and other socioeconomic structural conditions that have exacerbated inflammatory responses in the body's airways (Fernández-Llamazares et al. 2020; Ayejoto et al. 2023; Smirnova et al. 2023; Kamurasi et al. 2024). Climate change, through wildfires, presents a new threat that risks creating compounding effects for Indigenous Peoples' health.

Despite the disproportionate effects of climate change on the health of Indigenous Peoples and local communities, and the often-overlooked value of their knowledge by mainstream science, emerging evidence indicates that observations from Indigenous Peoples and local communities are crucial for supporting global analyses of climate change and its environmental impacts (Reyes-García et al. 2024b). Indigenous Peoples and local communities have noted a decline in crop production and quality, an increase in pest and plant diseases, shifts in animal migration patterns, disruption of the life cycles of wild animals, and changes in the timing of fruiting in plants (Savo et al. 2016). Such changes have implications for both local and global food security and the health of ecosystems (Savo et al. 2016).

Indigenous Peoples' observations and knowledge are central to their adaptive capacity to identify, predict and manage environmental changes, including adjusting to changing climatic conditions (Ford et al. 2020). Indigenous Peoples' knowledge, institutions and collective action have underpinned climate change adaptation to protect their health and well-being (Vidal-Cuellar et al. 2024; Leal Filho et al. 2022). Indigenous Peoples have long recognized the crucial and complementary roles that both women and men play in responding to environmental changes, highlighting the importance of valuing context-specific gender Indigenous perspectives for climate change adaptation (UNEP 2024b).

Climate change effects on Indigenous Peoples' health can be worsened by pre-existing health inequities and limited healthcare access (Romanello et al. 2022). Indigenous populations still experience historical trauma based on their respective first encounters with colonizers or dominant country governments. These experiences have exacerbated climate change impacts

on Indigenous health and well-being (Redvers, Aubrey, Celidwen and Hill 2023; Matthews et al. 2023). Trauma memories, such as marginalization of their Indigenous health practices, can be manifest in different aspects of their health; for example, past experiences can prevent Indigenous community members from visiting and seeking healthcare in their respective official health systems (Knibb-Lamouche 2012; Mbuzi, Fulbrook and Jessup 2017; Curtis et al. 2019; Arotoma et al. 2022).

Furthermore, the implications of climate change for Indigenous Peoples' health may span multiple generations. One aspect relates to the medium- and long-term effects on Indigenous children and adolescents who have been exposed to heat stress early in life (Olson and Metz 2020). Emergent literature investigates the potential impact of meteorological variations, such as high temperatures and precipitation levels, on fetal development (MacVicar et al. 2017). These effects are influenced by the combination of various pre-existing socioeconomic and health challenges, particularly among low- and middle-income countries, where populations are transitioning from a resource-poor condition to one of plentiful resources (Popkin et al. 2012). Climate change may worsen this transition, affecting nutritional status and overall mental well-being (Middleton et al. 2020; Vecchio et al. 2023).

3.4.13 Human system co-benefits from actions to reduce atmospheric emissions

Policy action to reduce GHG and air pollutant emissions and waste and chemicals in the environment can provide multiple co-benefits for human systems. Air quality improvements in the outdoor and indoor environment are essential in reducing the global burden of noncommunicable diseases (Campbell-Lendrum and Prüss-Ustün 2018). Integrated clean energy and health interventions are needed to reduce the health burden of household air pollution in low and middle-income countries (Lee et al. 2020). For example, introducing cleaner technologies and fuels for heating, cooking and lighting (WHO 2024b) can reduce the burden of household air pollution on maternal and child health (Woolley et al. 2021).

The health benefits of reductions in air pollutant concentrations can provide a strong incentive for climate change mitigation through reductions in co-emitted GHGs and short-lived climate pollutants (Szopa et al. 2021; UNEP 2023b). For example, reducing emissions of CO_2, $PM_{2.5}$ and nitrogen oxides from road transport through increased use of electric vehicles and more active travel, such as cycling and walking in cities, will directly benefit public health by improving local air quality (Vardoulakis et al. 2018), as well as mitigating climate change (IPCC 2023). Reducing GHG and air pollutant emissions from power generation can also benefit both climate and public health (Tong et al. 2021). Policies aiming to reduce emissions of short-lived climate pollutants, such as methane emissions from the agriculture and waste sectors, can have substantial co-benefits in terms of climate change mitigation and the reduction of ground-level ozone pollution (UNEP & Climate and Clean Air Coalition [CCAC] 2021; EEA 2023b).

However, reducing air pollutant emissions from industry, transport and power generation may also have unintended consequences, as some associated secondary atmospheric aerosols prevent warming by scattering sunlight rather than absorbing it. Globally, aerosols offset around one-third of the atmospheric warming imposed by anthropogenic GHGs (IPCC 2021), although substantial atmospheric warming occurs in regions such as South America and East and South Asia where the proportion of absorbing aerosols is relatively high compared to scattering aerosols (Li et al. 2022). When both co-benefits and unintended consequences are fully considered, combined air quality and climate change mitigation policies result in net benefits globally (Scovronick et al. 2019; Shindell and Smith 2019; Szopa et al. 2021). Therefore, ambitious and well-integrated climate change mitigation and air quality management policies are needed to maximize their co-benefits and minimize any unintended consequences (Karlsson et al. 2020).

3.5 Progress towards the goals of global agreements

3.5.1 Paris Climate Agreement and Sustainable Development Goals

The Paris Agreement, adopted in 2015 at the 21st Conference of the Parties (COP21) to the United Nations Framework Convention on Climate Change (UNFCCC), marked a significant turning point in the global effort to combat climate change. Its central aim is to limit global warming to well below 2°C above pre-

industrial levels, with the objectives of GHG emissions peaking before 2025 at the latest and declining by 43 per cent by 2030. This ambitious target is closely linked to Sustainable Development Goal 13 (SDG 13) which calls for urgent action to combat climate change and its impacts, as well as SDG 7 for affordable and clean energy. As of 2025, all but three of the 196 countries that negotiated the agreement have ratified it. The impacts and implications of the United States Government's decision in January 2025 to withdraw from the Paris Agreement have yet to be assessed.

Since adopting the Paris Agreement, many countries have taken substantial steps to align their national policies with the accord's objectives. The Nationally Determined Contributions (NDCs) serve as vital tools for countries to outline their specific climate actions. Notable advances have been the growing commitment to afforestation and renewable energy. The declining costs of solar, wind and other clean energy sources have made renewables increasingly competitive with fossil fuels (Osman et al. 2023). Many nations have expanded their renewable energy capacities and set targets for achieving carbon neutrality. The rise of electric vehicles, innovations in battery storage and investments in green technologies further underline progress towards decarbonization.

The NDC Synthesis report suggests that the combined GHG emissions of the Parties could decrease by around 64 per cent, within a range of 59–69 per cent, by the year 2050 compared to the levels observed in 2019 (UNFCCC 2023), if NDCs are fully implemented. However, many countries are currently not on track to achieve their NDCs. To be on the pathway to 1.5°C, current emissions need to be reduced by 42 per cent by 2030 and 57 per cent by 2035. According to the UNEP Emissions Gap Report (UNEP 2024d), current policies could lead to an increase of global mean surface temperature of 2.6–3.1°C, even with full implementation of the conditional and unconditional NDCs.

Further variability in GHG mitigation potentials is rooted in the difference between conditional and unconditional contributions, which may affect the actual emission reductions achieved. By 2050, the average individual emissions per year would be approximately 2.4 metric tons of CO_2eq. In scenarios where efforts are made to limit global warming to below 2°C, which holds a likelihood of over 67 per cent, the yearly per capita emissions would be around 2.2 metric tons of CO_2eq. Research has shown that many key indicators are consistent with emission scenarios that keep temperatures below 2°C. However, the continued lack of large-scale action on reducing emissions – for instance, through CO_2 removal measures such as carbon capture and storage – threatens 2030 targets and the longer-term Paris ambition of net-zero emissions (Peters et al. 2017).

The outcomes of the Global Stocktake, a process under the Paris Agreement to assess collective progress towards its goals, state, regarding mitigation, that "…significant collective progress towards the Paris Agreement temperature goal has been made, from an expected global temperature increase of 4°C according to some projections prior to the adoption of the Agreement to an increase in the range of 2.1–2.8°C with the full implementation of the latest nationally determined contributions" (UNFCCC 2025). However, significant challenges remain. While the Paris Agreement is vital, implementation has proven to be complex. At the same time, the impacts of climate change are becoming more evident and severe (UNEP 2023a), as GHG emissions reach new highs (Friedlingstein et al. 2020), temperature records continue to be broken, and sea levels rise.

Developing nations and Small Island Developing States are often the least responsible for historical GHG emissions; however, they are disproportionately threatened by the impacts of changing climate. This consequence highlights the need for capacity development as well as financial and technological support from developed countries to achieve implementation of the agreement on a global scale.

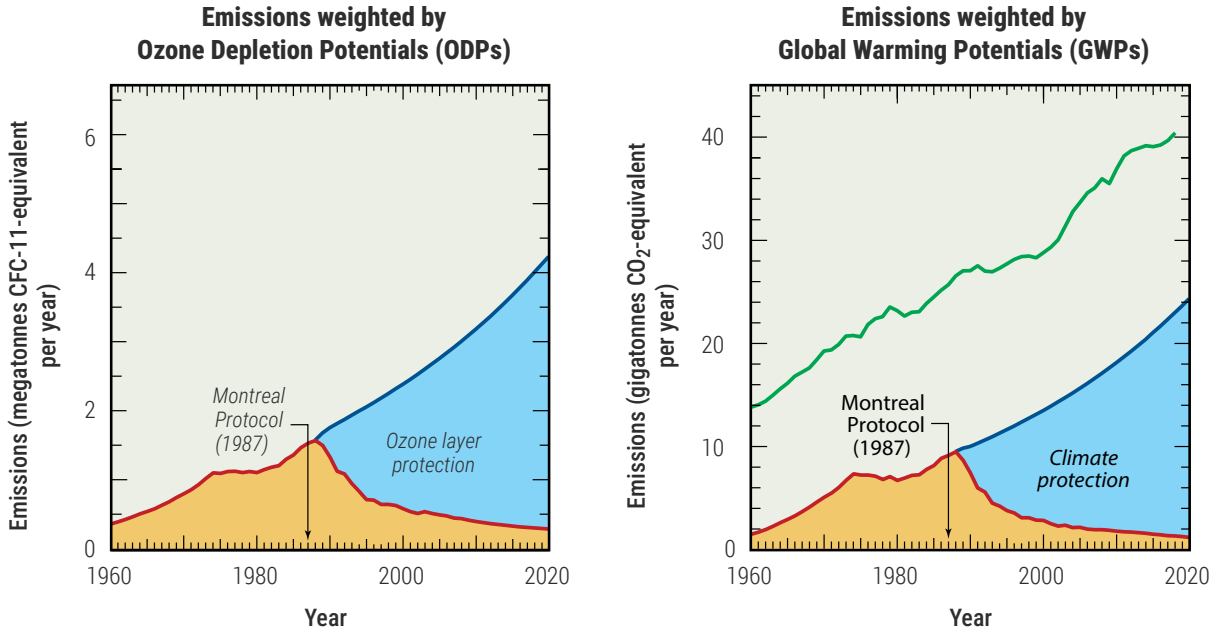
In the context of SDG 13, progress is closely linked to progress on the other SDGs because climate action intersects with poverty eradication, health, education, and gender equality and equity. Integrated approaches that consider multiple dimensions of development are crucial for achieving meaningful progress. Furthermore, SDG 7 calls for affordable, reliable, sustainable and modern energy for all by 2030, which is directly relevant in the context of national reduction targets for GHG emissions.

To track progress towards emission targets more robustly, the WMO is establishing a new monitoring initiative, Global Greenhouse Gas Watch, to support

WMO Members in mitigation actions with respect to the Paris Agreement (WMO 2024b).

3.5.2 Montreal Protocol

The Montreal Protocol on Substances that Deplete the Ozone Layer was adopted in 1987 and entered into force on 1 January 1989 (**Figure 3.7**). Since then, it has been revised in several steps, most recently in 2016 in Kigali. The 2007 Montreal Amendment covered the agreement to an accelerated phase-out schedule for hydrochlorofluorocarbons, with the aim to achieve full compliance by developed countries by 2020 and developing countries by 2030. In 2016, the phase down of hydrofluorocarbons was agreed in the Kigali Amendment. While hydrofluorocarbons are not considered to deplete the stratospheric ozone layer, their high Global Warming Potential (12,000–14,000) justified adding them to the list of controlled substances to protect the global climate system.



In its 2022 Scientific Assessment of Ozone Depletion, the WMO (2022) and its partner organizations associated with the Protocol, emphasized that "Science has been one of the foundations of the Montreal Protocol's success." Among the achievements highlighted by the report, the reduction in emissions of ODS has contributed to a recovery of total ozone column measurements, which are projected to return to 1980 levels within the following decades. In addition, the reduction in ODS emissions has avoided global warming by approximately 0.5–1°C by the mid-21st century, compared to a scenario of unregulated ODS increase of emissions by 3–3.5 per cent annually. Without global controls, hydrofluorocarbons were projected to contribute 0.3–0.5°C to global surface warming in 2100. The controls of the Kigali Amendment reduced this to 0.04°C in 2100 (Velders et al. 2022).

Overall, the Montreal Protocol and its Amendments have contributed to phasing out 98 per cent of ODS globally, relative to 1990 levels, and it is estimated that it has contributed to preventing up to 0.5°C of global temperature rise overall by 2100, in addition to reversing the depletion of stratospheric ozone. However, emerging challenges such as detecting unexpected emissions of CFC-11 and other ODS (Lickley et al. 2021) require further scientific research and regulatory policy attention. Additional gaps in scientific understanding (Dhomse et al. 2019; Lickley et al. 2020) and data for monitoring progress towards emission and ozone layer recovery targets remain.

3.5.3 WHO guidelines for ambient and indoor air quality

Air quality, despite its global role in public health as identified by the Global Burden of Disease studies,

Figure 3.7: Montreal Protocol protection of ozone and climate

Source: Salawitch et al. 2019

does not have a dedicated SDG and only one SDG indicator (SDG 11.6.2), which is solely focused on $PM_{2.5}$ (GBD 2019, GBD 2021). While $PM_{2.5}$ is a key driver of air pollution-related human health impacts, it may not be sufficient to capture the full range of air pollution consequences for human health and even less so on ecosystems. In addition, progress in epidemiological and toxicological evidence suggests that adverse effects of particulate air pollution on human health occur at much lower concentrations than previously thought (Papadogeorgou et al. 2019; Hoffmann et al. 2021; Stafoggia et al. 2022). Consequently, the WHO adjusted its guidelines (WHO 2021) for air quality in 2021, reducing the guideline value for annual mean concentrations of $PM_{2.5}$ as shown in **Table 3.1**. In addition, the WHO 2021 guidelines for PM_{10} and NO_2 are more stringent than the 2005 guidelines. While these guidelines do not have defined target dates, WHO has set interim targets for several pollutants, highlighting the importance of stepwise improvements in air quality and the reduction of exposure to air pollution over time.

Table 3.1: WHO 2005 and 2021 Air Quality Guidelines

Pollutant	Averaging time	2005 AQGs	2021 AQGs
$PM_{2.5}$ (µg/m^3)	Annual	10	5
	24–hour	25	15
PM_{10} (µg/m^3)	Annual	20	15
	24–hour	50	45
O_3 (µg/m^3)	Peak season		60
	8–hour	100	100
NO_2 (µg/m^3)	Annual	40	10
	24–hour		25
SO_2 (µg/m^3)	24–hour	20	40
CO (mg/m^3)	24–hour		4

Note: µg = microgram, a is 99th percentile (i.e. 3–4 exceedance days per year); b is Average of daily maximum 8-hour mean O_3 concentration in the six consecutive months with the highest six-month running-average O_3 concentration; Annual and peak season is long-term exposure, while 24 hour and 8 hour is short-term exposure (WHO 2021).

According to estimates (Pai et al. 2022), in 2019, 90 per cent of the global population were exposed to ambient concentrations of $PM_{2.5}$ in exceedance of the 2021 guideline. The State of Global Air Report 2024 states that 99 per cent of the global population is exposed to unhealthy air pollution (Health Effects Institute 2024). By 2030, the target year for achieving the SDGs, a general reduction of population-weighted concentrations of $PM_{2.5}$ could be achieved in most world regions, according to recent modelling studies (Yue et al. 2024). However, long-term increases in air pollution-related mortality are estimated by other studies under different climate scenarios (Chen et al. 2023).

Although people typically spend more than 90 per cent of their time indoors, most countries do not have legislated indoor air quality standards for public or private spaces (Morawska et al. 2024). The WHO published indoor air quality guidelines for selected chemicals in 2010 (WHO 2010), but indoor air is still mainly regulated through building codes and ventilation standards. The importance of indoor air quality for human health is becoming increasingly evident in high-income countries (Vardoulakis et al. 2020b), particularly in relation to airborne infectious disease transmission since the COVID-19 pandemic (Morawska et al. 2024), as well as in low- and middle-income settings concerning solid fuel use for domestic cooking and heating (Section 3.4.5).

3.5.4 Stockholm Convention

Persistent organic pollutants (POPs) continue to be a challenge since the incorporation of new pollutants on the original list of 12 chemicals and their derivatives in the Stockholm Convention (UNEP 2023a). One challenge is the ability of POPs to travel large distances in the atmosphere from their sources. Evidence of the effectiveness of the measures proposed by the Convention is the global monitoring plan (GMP) which monitors POPs in the atmosphere through passive and active sampling (Secretariat of the Stockholm Convention 2019).

The GMP has already performed three rounds of monitoring on background sites, providing sufficient data to determine trends for many of the listed POPs, but not all. Overall, concentrations are declining and starting to level off where regulatory action was taken decades ago. However, in some cases, such

as hexachlorobenzene, slight increases, likely due to releases from secondary sources and the effects of climate change, can be identified. The patterns and trends for POPs listed since 2009 are complex and vary across chemicals, media and areas. Analyses linking to localized actions could assist in understanding such variability. There is insufficient data to detect trends for many newly listed POPs (UNEP 2023a). Exposure to chemical mixtures, including both known and unknown chemicals that are similar to persistent organic pollutants and their transformation products, can impair human health and the environment. Increased accessibility to high-resolution analytical equipment is rapidly enabling advanced research in this area (UNEP 2023b).

3.5.5 Minamata Convention

The Minamata Convention regulates mercury as a global pollutant. Atmospheric transport is the primary transmission pathway for this chemical. The current most important sources of mercury releases into the atmosphere are gold mining and coal combustion. The Background Report to the Global Mercury Assessment in 2018 estimated that human activities have increased total atmospheric mercury concentrations by about 450 per cent above levels common before 1450 A.D. (UNEP 2018; UNEP 2019b). Recent research shows the increase in mercury emissions to be 40 per cent larger than previously estimated, indicating the need for further emission reduction efforts (Zhang et al. 2023b). Furthermore, there are potential co-benefits of GHG strategies for mercury and other heavy metal emissions control (Pan et al. 2024).

3.5.6 Other relevant agreements and conventions

The United Nations Economic Commission for Europe (UNECE) Convention on Long-Range Transboundary Air Pollution, signed in Geneva on 13 November 1979 (United Nations Economic Commission for Europe 2025) has been instrumental in driving air pollution control efforts primarily in the northern hemisphere. The Air Convention is implemented through several protocols and activities at the science-policy interface addressing emissions, monitoring and modelling of transboundary air pollution, and its effects on human and ecosystem health. With the establishment of a new Forum for International Cooperation on Air Pollution in 2023, knowledge exchange and engagement with other world regions beyond the original geographical scope of the Transboundary Air Pollution Convention are a new objective.

The Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and their Disposal (2025) is the only legally binding global environmental agreement on hazardous and other wastes. It regulates transboundary movements of hazardous and other wastes and addresses plastic pollution. By reducing waste at the source, its implementation will substantially contribute to the reduction of atmospheric emissions of air pollutants and GHGs.

Finally, the Rotterdam Convention on the prior informed consent procedure for certain hazardous chemicals and pesticides in international trade (2025) is a multilateral treaty to promote shared responsibilities concerning the importation of hazardous chemicals.

In addition to these conventions and agreements, further activities will likely affect emissions of pollutants and greenhouse gases into the atmosphere, either directly or indirectly. For instance, the United Nations Global Framework on Chemicals (2025) fosters global collaborative actions to reduce pollution. In June 2025 a new Global Science-Policy Panel on Chemicals, Waste, and Pollution (2025) has been established, following an earlier agreement by the United Nations Environment Assembly in 2022. The resulting body, similar to the IPCC and the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES), will offer independent scientific assessments, identify knowledge gaps, and provide policy-relevant advice, particularly to support countries – especially in the Global South – in managing chemicals and waste more effectively. This marks a significant step in strengthening the global framework for tackling pollution comprehensively, in an integrated context with climate change and biodiversity loss (UNEP 2024c).

Chapter summary

Credit: Mumemories/Envato

Globally, about 20-40 per cent of Earth's land area is degraded, jeopardizing the livelihoods of about 40 per cent of the world population, disproportionally affecting women and older people (*well established*). According to the United Nations Convention to Combat Desertification, we are losing the equivalent of four football fields to land degradation every second, amounting to over 4 million km^2 of degraded land each year. At the same time, desertification threatens a third of the world's land surface. {4.1, 4.3.2}

Human pressures on land and soil resources are rising sharply, with over 70 per cent of the Earth's land area already transformed by human activity (*well established*). Competition for land is high, and resources are finite. As competition for land intensifies, the projections suggest that by 2050, only about 10 per cent of land will remain in a near-natural state. Deforestation continues to be the leading driver of land use change. {4.1, 4.2}

Terrestrial biodiversity continues to decline in abundance and richness, primarily due to changing land cover and land use. Some estimates suggest that 200,000 species may have become extinct during the 20th century (*established but incomplete*). One million species are estimated to be at risk if current trends continue. {4.3.4} Biodiversity decline, across terrestrial biomes, including grasslands, forests, deserts, tundra, and taiga, still continues (well established). {4.2, 4.3.4.1}

An estimated 95 per cent of the world's food and feed supplies are produced in soils that also play a crucial role in climate change mitigation by storing more carbon than the biosphere and atmosphere combined (*well established*). Yet, global soils are degrading at alarming rates, with predictions that almost 95 per cent could be degraded by 2050, an increase from one-third today. Each year, more than 24 billion tonnes of soil are lost to erosion, amounting to 3.4 tonnes of soil lost annually for every person on the planet. {4.3.2}

The global environmental crises, the crisis of climate change, the crisis of biodiversity loss, land degradation and desertification, and the crisis of pollution and waste, have already caused extensive harm to land and soil resources (*well established*). Without urgent

action, the damage will intensify. Soils act as both sources and sinks of carbon, making their management crucial in determining whether soils help mitigate or accelerate climate change. {4.3.1.7, 4.3.2}

Chemical pollution, including greenhouse gas (GHG) emissions, represents some of the largest human impacts on the planet. Non-GHG chemical pollution is estimated to be five times greater in scale than GHG emissions (*established but incomplete*). These gases and chemicals now circulate the planet, contaminating the atmosphere, soil, fresh water, oceans, and global food supply, profoundly affecting all life forms. International conventions have failed to curb this unsustainable growth or even keep track of new chemical releases. The living environment's health deteriorates as the population and global economy expand. {4.3.1, 4.4, 4.5.3}

While there are many point sources of chemical contamination of land and soil, the contaminants released through economic activities are of major concern (*established but incomplete*). Globally, chemical contamination is primarily driven by industrial activity, such as mining, farming, manufacturing, energy production and the displacement of topsoil for development. At the same time, novel pollutants with largely unknown toxic effects, such as micro and nanoplastics, nanochemicals, and "forever chemicals", are also being released into the environment. {4.3.1.1, 4.3.1.2, 4.3.1.3, 4.3.1.5}

By 2050, global annual waste generation is projected to increase by 70 per cent, contributing to nearly a million deaths annually (*established but incomplete*). With municipal solid waste exceeding 2 billion tonnes annually, land, water, and soil contamination is severe. Dumping of waste has significant implications for natural resources, particularly affecting marginalized and Indigenous Communities and undermining efforts towards circularity in material use. {4.3.1.6}

Climate-related extreme events have become more frequent, prolonged and severe, causing more wildfires, droughts and permafrost thawing (*established but incomplete*). Shifts in air temperature, precipitation patterns, warm season length, and heat waves drive these changes. As a result, soil carbon is being released into the atmosphere at a higher rate, disrupting nutrient cycles. Climate change and its associated extremes are predicted to become major drivers of terrestrial biodiversity decline, with far-reaching political, economic, and ecological consequences. {4.3.3.3, 4.3.3.4, 4.3.3.5, 4.3.3.6}

Rising carbon dioxide emissions from forest loss, soil erosion, climate extremes, and permafrost degradation are compromising the role of soil as a carbon dioxide sink in mitigating climate change (*established but incomplete*). Despite that, land still absorbs 29-30 per cent of the total carbon dioxide emissions. However, the role of this carbon sink is increasingly compromised by higher contributions of other GHGs, namely methane and nitrous oxide from fertilized fields, manures, livestock, and other agricultural sources. {4.3.2.2, 4.3.3.2, 4.3.3.3}

The loss of terrestrial aboveground genetic diversity is a major concern, particularly pronounced on islands, where it significantly impacts the local population (*established but incomplete*). Large agribusiness and international corporations promoting intensive agriculture, monoculture, synthetic fertilizers and pesticides have accelerated the loss of genetic and agrogenetic diversity. Land and soil degradation, habitat destruction, and human activities have contributed to the deterioration of genetic variability in recent decades. {4.3.4.3}

Soil biodiversity is crucial for maintaining healthy ecosystems (*well established*). Hosting more than 50 per cent of life on Earth, from microbes to mammals, soils are the most biodiverse habitat. However, despite its importance, only 1 per cent of soil biodiversity is known to the scientific community. {4.3.4.4}

Changes in the physical environment are already affecting natural and human systems, which are closely interconnected (*well established*). Land use change, land degradation, intensive agriculture, livestock expansion, urban sprawl, and habitat loss are accelerating biodiversity loss. The ongoing extinction of terrestrial species is evident in the widespread decline of insects and overall species richness, in both number and diversity {4.3.4.2}. Permafrost thawing drives ecosystem changes, affecting the freshwater cycle, destroying infrastructure and releasing GHGs {4.3.3.3}. Meanwhile, droughts and wildfires are negatively impacting agriculture and forestry, even though these effects may be partially offset by increased productivity in colder climates due to longer growing

period and improved vegetation cover due to the "carbon fertilization" effect. {4.3.3.1, 4.3.3.5}

Essential provisioning, regulating, supporting, and cultural ecosystem services are under increased stress from the interconnected impacts of natural resource overexploitation, conventional and emergent pollutants, land use change, intensive and unsustainable farming, deforestation, climate change, and biodiversity loss. Meanwhile, these ecosystem services are essential for human health, food security, and the regulation of water and nutrient cycles. {4.4.1, 4.4.2}

Marginalized, vulnerable, nature-dependent communities, including Indigenous Peoples, experience the effects of changes in the natural environment most acutely. Land degradation and biodiversity loss directly impact livelihoods, sociocultural traditions, economies and overall well-being of Indigenous Peoples and local communities (*well established*). {4.3.2.4 and 4.3.1.2} Integrated sustainable land, soil and water management practices, rooted in Indigenous Knowledge systems, offer some of the best available solutions to overcome the impacts of land degradation and biodiversity loss. {4.6} Furthermore, through a combined conservation in crop, livestock, and forestry sectors, Indigenous practices offer valuable entry points to climate change adaptation (well established). {4.3.3.5} Numerous studies demonstrate that Indigenous soil conservation and management methods are embedded within cultural belief systems and continue to be practiced today. Additionally, Indigenous Knowledge holders and scholars highlight the importance of Indigenous governance in the stewardship of land and other natural resources, including biodiversity. However, the lack of sufficient international climate financing to support these efforts remains a key barrier. {4.6}

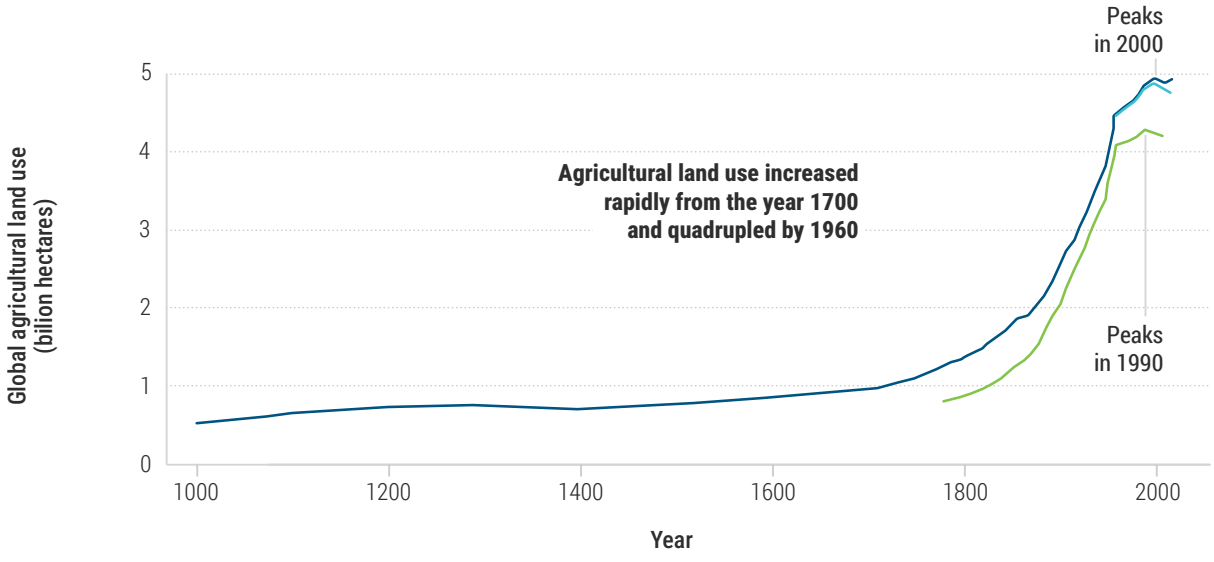
The world is not on track to meet the international targets for land quality, biodiversity and soil health (*well established*). Progress monitoring of land degradation neutrality goals for 2030 reveals deteriorating trends in land productivity, declining land cover quality, and a slower pace of soil organic carbon stocks replenishment – all of which are linked with severe environmental damage. {4.5.1}

Furthermore, the goals of the Paris Agreement to limit global temperature increase to well below 2 degrees Celsius, while pursuing efforts to limit the increase to 1.5 degrees, are unlikely to be met. This shortfall will further accelerate land surface temperatures, which are rising faster than the ocean and global mean temperatures. {4.3.3.1, 4.5.2}

In addition, none of the 20 Aichi Biodiversity Targets for terrestrial biodiversity, agreed in 2010, were fully achieved by 2020. While good progress was made on the components in four out of 20 targets, including protected area coverage and preparation of national biodiversity strategies and action plans, the progress on the other six targets was slow. Overall, 12 out of 16 indicators used for reporting showed significantly worsening trends. The Kunming-Montreal Global Biodiversity Framework, endorsed at the 15th Conference of the Parties of the Convention on Biological Diversity in 2022, has a set of indicators that are presently being operationalized. {4.5.4} **Efforts under internationally agreed conventions to tackle soil pollution and contamination have shown severe implementation challenges.** {4.5.3}.

4.1 Introduction

Is the world running out of productive land? How much is left for food, biodiversity, housing, infrastructure, and leisure? What is the effect of land grabbing on land availability? Land grabbing can drive land use changes, biodiversity loss, and carbon sequestration and lead to conversion from smallholder to commercial use, impacting Indigenous as well as local communities (Gilbert 2017; Wilkinson 2017).



In 2019, the urban population exceeded the rural population (McNabb 2019), and by 2050, 68 per cent of the global population will reside in urban areas (Schug et al. 2023; Tang et al. 2024), occupying some of the most fertile soils on the planet. The rapid expansion of built-up areas can lead to environmental pressures worldwide (Yan et al. 2022). For instance, since the mid-1950s, the total surface area of cities in Europe increased by 78 per cent (Build Europe 2022), contributing significantly to soil sealing and its adverse effects on biodiversity loss, flooding, contamination (Espinoza-Tofalos et al. 2025) and water scarcity.

These effects can have major impacts on food security, regional weather patterns, climate change, hydrology, biodiversity and livelihoods (Hang et al. 2020; Wang et al. 2022) as the world continues to experience rapid environmental degradation (Diaz et al. 2019). Humans have substantially changed the Earth's surface, especially over the last two centuries (Wiedenhofer et al. 2021; Potapov et al. 2022), causing dramatic impacts on ecosystems **(Figure 4.1).**

Globally, between 20 per cent and 40 per cent of Earth's land area – more than 2 billion hectares – is degraded, jeopardizing the livelihoods of more than 3.5 billion people (mostly women and older people), about 40 per cent of the world population (UNCCD 2022; Chinweze 2023). According to the United Nations Convention to Combat Desertification (UNCCD), we are losing the equivalent of four football fields to land degradation every second.

A full 71 per cent of the Earth's surface is covered by water, and only half of the remaining 29 per cent of land is suitable for biomass production. The United Nations

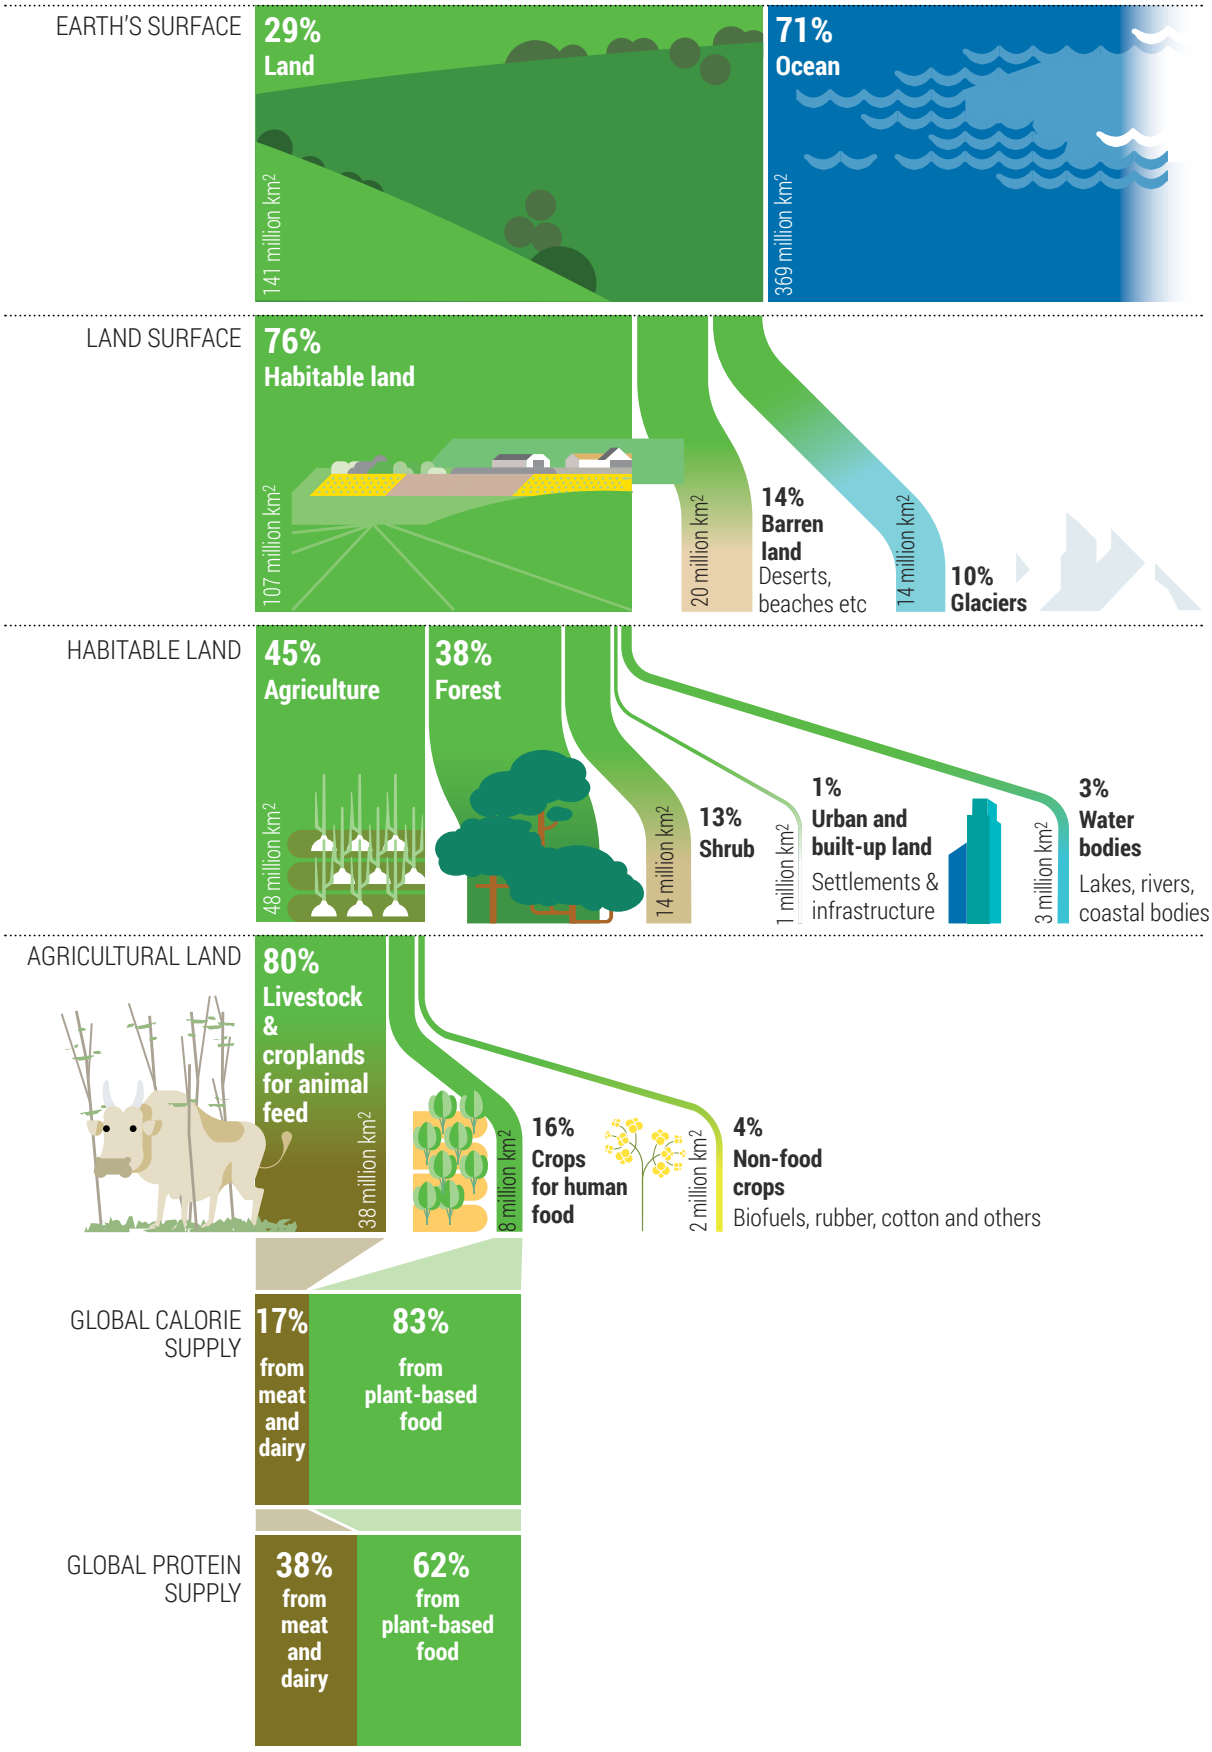
Food and Agriculture Organization (FAO) estimates that food production should increase by 60-70 per cent (FAO 2022b; van Dijk et al. 2021) to meet the needs of a population projected to reach almost 10 billion by 2050. Meanwhile, about 30 per cent of global food produced is still being wasted (Jaglo et al. 2021; United Nations Environment Programme (UNEP 2024c). In Italy alone, yearly food waste costs €15.6 billion (International Observatory on Food and Sustainability, 2024). According to the Food System Economics Commission, food systems have an enormous impact on the environment, as one-third of greenhouse gas emissions worldwide and 70-80 per cent of global biodiversity losses are related to food systems, suggesting a radical overhaul of how food is produced, distributed and consumed. Changing tax incentives and human diets could create US$10 trillion of yearly benefits through reduced carbon emissions, pollution, biodiversity loss, and positive impacts on human health (Ruggeri Laderchi et al. 2024).

Soil provides 95 per cent of our food needs (Kopittke et al. 2019). However, the world has used much of the available arable lands **(Figure 4.2)**, while converting forests, grasslands, and natural areas into cropland poses significant risks to biodiversity and the release of carbon. Furthermore, land abandonment can also have consequences on biodiversity (Crawford 2024). At the same time, millions of hectares of unproductive land could be converted into conservation zones that enhance biodiversity and soil carbon sequestration (Xie et al. 2019; Folberth et al. 2020) or used for renewable energy production (Muscat et al. 2020).

Data from FAO shows an increase in forest surface area between 2015 and 2019, from 39 to 40 million km^2, and shrubland, from 12 to 17 million km^2, while agricultural land shrank by 3 million km^2, largely due to urban sprawl (Bren d'Amour et al. 2016; Xie et al. 2023; Canadians for a Sustainable Society, 2023). Most agricultural land is used for livestock, about 77 per cent or 37 million km^2. In comparison, only 23 per cent or 11 million km2 is used for crops (**Figure 4.2**). Small farms, those smaller than 2 hectares, make up 84 per cent of all farms globally but operate only about 12 per cent of the world's farmland, whereas the largest 1 per cent of farms in the world control more than 70 per cent of the world's farmland (FAO 2019). Organic agriculture accounted for 75 million hectares globally, just 1.6 per cent of total global agricultural land (FAO 2024b).

Land and soils deliver vital ecosystem services beyond their provisioning role in agricultural production. Notably, soils play a crucial role in sustainable development as both sinks and sources of carbon. Soil holds more carbon than aboveground vegetation and the atmosphere combined (Lehmann and Kleber 2015), but whether this carbon remains stored depends on how soil is managed.

The amount of carbon stored in soils is roughly 300 times greater than that released annually from burning fossil fuels. Emissions from land use change due to loss of biomass and soil organic matter are estimated to contribute 25 per cent of atmospheric carbon dioxide (CO_2) (Le Quéré et al. 2015; Intergovernmental Panel on Climate Change [IPCC] 2019). Over the past 12,000 years, the global expansion of arable farmland has released approximately 110 billion metric tonnes of carbon from topsoil (Sanderman et al. 2017), roughly equivalent to 80 years of current US emissions (US EIA 2020).



Land and soil only caught the attention of decision makers in the context of climate change in the past two decades, even as the world continues to face land degradation and resource depletion. **Box 4.1** reports new findings from global assessments since GEO-6 (UNEP 2019).

4.2 Pressures on land and soils

The latest global land use data reveals a diverse picture with contrasting trends and intense competition for land resources, especially between forests and cropland. From 2000 to 2020, cropland mainly increased in Sub-Saharan Africa (Masolele et al. 2024), South East Asia, and Latin America, but declined in North America, Europe, and East Asia. While deforestation is decreasing in some regions, it is increasing rapidly in others.

South America exhibits the most prominent transition from forest to cropland. Deforestation in the region amounts to 75.70 Mha or 11 per cent of the total global land use change with conversion of natural vegetation, particularly forests, into croplands (Zabel et al. 2019; Armenteras et al. 2017; Móstiga et al. 2024). Colombia hosts unique ecosystems for biodiversity, such as páramos that hold vast amounts of water, but 57 per cent of these ecosystems have been lost (Moran Cortes et al. 2022). Those converted to agriculture have lost their biodiversity and vegetation and become compacted from the excessive use of agricultural machinery, resulting in significant degradation.

Figure 4.2: **Global land use for food production in 2019**

Source: Adapted from UNEP (2023)

Box 4.1: Key findings on land and soils from assessments published since GEO-6

Humans have transformed over 70 per cent of the global land cover, and up to 40 per cent of the planet's land is degraded (UNCCD 2022). Erosion remains severe, exceeding 10 to over 100 times the rate of soil formation (IPCC 2019, IPCC 2023a). As well, 40 per cent of the world's agricultural land is already damaged, and more than three-quarters is experiencing drier conditions (UNCCD 2022). The most significant sources of carbon emissions from land use change are tropical deforestation and peatland burning and draining (IPCC 2022a). Peatlands alone emit 1,941.2 megatonnes of CO_2 equivalents annually (UNEP 2022).

Despite the declining rate of global deforestation, 10 million ha of forests per year were lost between 2015 and 2020 (FAO 2022a). As of 2020, the total carbon stock in forests was estimated to be 662 Gt, an average of 163 tonnes/ha (FAO 2020). However, efforts in reforestation and improved forest management are paying back; between 2011 and 2020, forests absorbed more carbon than they emitted (FAO 2022a).

Of the world's 823 terrestrial regions, 42.4 per cent have at least 17 per cent of their area protected (Secretariat of the Convention on Biological Diversity [CBD] 2020). In addition to protected areas, Indigenous lands help maintain higher biodiversity and species abundance (Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services [IPBES] 2019). However, terrestrial biodiversity continues to be negatively impacted by habitat loss, invasion, pollution, overexploitation, and climate change. Local species populations have declined in around 50 per cent of observed terrestrial plant and animal species, often due to extreme climate events (IPCC 2022a). Approximately 9 per cent of the world's estimated 5.9 million terrestrial species are at risk of extinction in the coming decades due to insufficient habitat for long-term survival (IPBES 2019).

Forest area is expanding in Europe, North America, and certain parts of Asia, where notable strides have been made in forest conservation, restoration, and rejuvenation efforts (Du et al. 2023). The area planted with forest in Central Asia has been rising at rates of 3.68 MHa/year and 4.62 MHa/year for 1990-2000 and 2000-2010, respectively (Potapov et al. 2022). However, after 2010, planted forest expansion slowed to a rate of 2.78 MHa/year.

Satellite data for land-use change patterns between 1992 and 2020 show that the most prevalent land use transitions occurred between cropland and forest and vice versa. Global changes from forest to cropland represented 129.89 Mha, while changes from cropland to forest were only 85.70 Mha. Urban encroachment expanded from 1992 till 2020 primarily at the expanse of cropland, accounting for 46.14 Mha, or 67 per cent of the urban-related land use changes, representing a worrying trend that may have consequences on food supply and food security (Nuissl and Siedentop 2021). Urbanization occurred primarily in Europe, India, China (Li et al. 2024), and Latin America (Giobellina and Vitale 2022), coinciding with the conversion of croplands and natural habitats.

Terrestrial ecosystems include a variety of biomes, including tundra, taiga, temperate deciduous forest, tropical rainforest, mangroves, grassland, permafrost, deserts, Mediterranean scrub, and coniferous forests. Each of them has unique ecosystem functions and services. Rangelands cover 54 per cent of the Earth's land and sustain 69 per cent of agricultural areas for animal production (International Livestock Research Institute et al. 2021). The northern permafrost region that covers approximately 15 per cent of the Earth's land area, extending from the Arctic Ocean's coastline through much of Alaska, northern Canada, and North Eurasia, contains roughly one-third of all soil carbon in its frozen soils, equivalent to more carbon than humans have ever released (Patzner et al. 2020). The global climate would be significantly affected if those carbon stores were released due to permafrost thawing. Other important ecosystems are karst landscapes that occupy approximately 20 per cent of terrestrial ice-free areas globally and are major geomorphological features in North America, Europe, the Middle East, Asia and Australia (Goldscheider et al. 2020; Zhang et al. 2023).

Terrestrial ecosystems are under pressure from anthropogenic factors and climate change. Tropical forests are affected by deforestation, many grasslands are overgrazed, while large deciduous forest areas were severely damaged by forest fires, as in Canada in 2023 (National Aeronautics and Space Administration 2023). With over 75 per cent of the Earth's land already degraded, and over 90 per cent that could become degraded by 2050 (Hill et al. 2018), humanity has reached the point where, without action, the situation will further degrade with severe consequences and irreparable damage and reach a point of no return. Moreover, forest degradation emits the same or more carbon than deforestation, and it can cause a disruption in the hydrological cycle and cause further biodiversity loss (Lapola et al. 2023).

One third of the world's land surface is threatened by desertification, and over 4 million km^2 of land is being degraded yearly, while one-third of global soils are already degraded (UNCCD 2022). Land degradation, particularly soil erosion, combined with climate change, is estimated to reduce global crop yields by about 10 per cent by 2050. The greatest impacts are expected in India, China and Sub-Saharan Africa, where land degradation could halve crop production, mainly due to the prevalence of monoculture farming systems (The World Counts 2023).

The pressures on land and soils described in Chapter 2.3 and section 4.2 above each contribute to a varying degree to the global environmental crises of climate change, biodiversity loss, land degradation and desertification, and pollution and waste. Section 4.3 below shows how the global environmental crises interconnect with the natural system of land and soils.

4.3 State and trends of the land

4.3.1 Land and soil pollution

Chemical pollution is currently the most serious environmental threat to humanity. With approximately 220 billion tonnes of chemical substances emitted yearly, chemical pollution is five times greater than climate emissions (Cribb 2023). According to the World Health Organization (WHO 2016), every year 13.7 million deaths, or 24 per cent of deaths globally, and 600 million disabilities are linked to chemical pollutants. Despite its severity, the global understanding of chemical pollution remains fragmented (Naidu et al. 2021).

Chemical pollution has point or non-point sources in soil, water and air (Naidu et al. 2021). Point-source pollution refers to industry effluent containing toxic chemicals (e.g. heavy metal(loid)s or hydrocarbons), the source of which can be easily identified. Non-point sources are challenging to locate as they could come from various sources. As a sink for many chemical pollutants, soil is a major source of chemical exposure to humans and other organisms (Rodríguez-Eugenio et al. 2018).

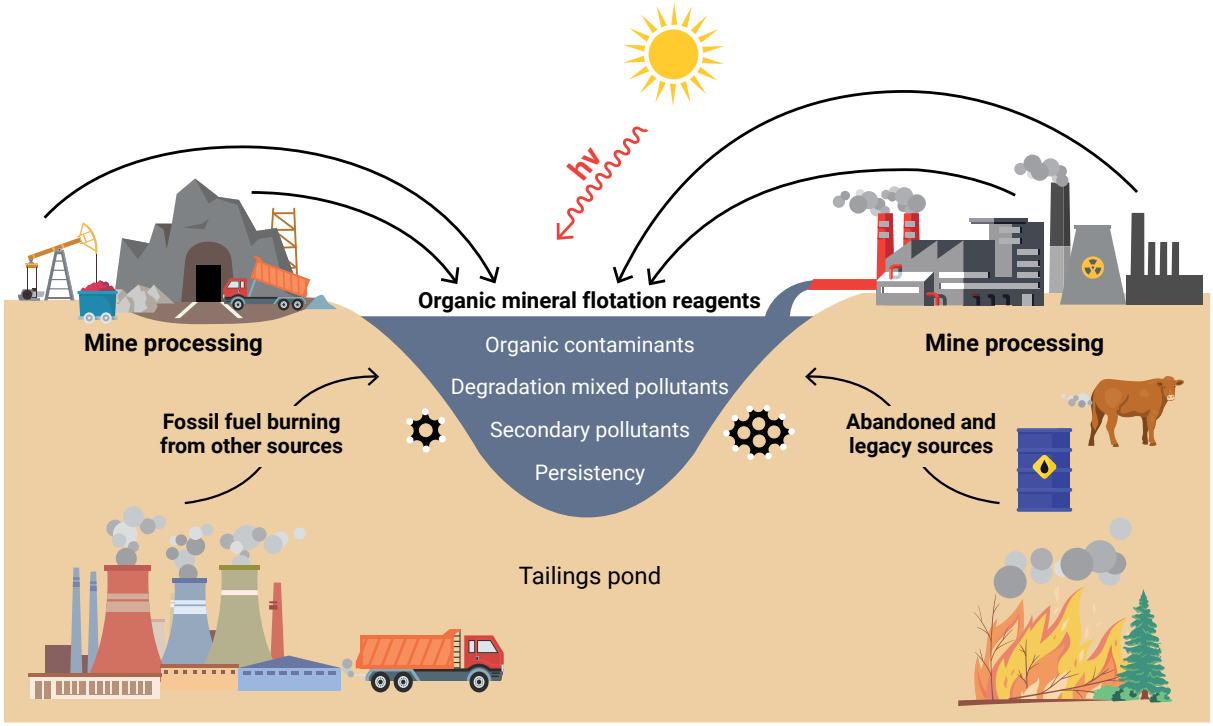
Soil pollution is driven by multiple factors, including inadequate legislation in many countries to prevent, manage or remediate contaminated sites, resulting in continued chemical pollution. Significant gaps remain in identifying the location of highly contaminated sites and their environmental consequences and understanding the effects of the contamination caused by chemical dispersal (FAO and UNEP 2021). Industries, such as mining, mineral processing, farming, and construction, discharge trillions of tonnes of chemically active material into the environment each year (Cribb 2021). Global chemical inventories suggest that there are over 350,000 chemicals registered for production and use (Wang et al. 2020), many of which could be toxic even in small doses, whether alone or in combination with other pollutants or as breakdown products following release in the environment. This chapter focuses on pollution drivers primarily associated with chemicals of concern and chemicals that receive less attention. These are detailed in 4.3.1.1 to 4.3.1.6.

4.3.1.1 Pollutants associated with mining

Mining has long been the primary source of earth materials such as coal and iron ore. Although advances in recycling technologies have reduced dependence on mining for some resources, overall mining activity continues to rise due to growing demand for such materials as copper, lithium, and other rare earth oxide materials. Mining waste contains harmful heavy metals, including cadmium, lead, zinc, arsenic, and mercury, which pose significant risks to biodiversity and human health. Mining activities release these metals into the atmosphere, from where they settle in the soil, contaminating water through direct infiltration, surface runoff, accumulation and precipitation, or absorption by plants (Moghimi Dehkordi et al. 2024). Rare earth oxide material production reportedly reached nearly 300,000 metric tonnes in 2022, a dramatic increase compared to the previous decade (Statista 2023). Mining rare earth minerals results in significant emissions (Golroudbary et al. 2021), disrupting the soil nutrient cycle and generating large quantities of waste during extraction, with waste comprising often more than 90 per cent of the total volume of mined materials.

Mining operations in many countries remain one of the largest polluting sectors, accelerated by increasing economic growth and the industrialization of lower-income agrarian economies (FAO and UNEP 2021). Significant sources of contaminants are the tailings (leftover extractants and residues stored in mining sites), acid drainage, dust generation and deposition, and hydrogeological alterations caused by mining **(Figure 4.3)**.

Chen et al. (2022) analyzed metadata from reports on 102 copper mine sites worldwide. Contamination levels from exposure to copper and cadmium were recorded as moderate to alarming at sites in Oman, China, Australia, and the United Kingdom of Great Britain and Northern Ireland. Associated metalloids, such as arsenic, were also found to be toxic to the ecological receptors in the mines or their surroundings.



The Minamata Convention on Mercury mandates reducing or eliminating mercury in mining and artisanal activities (Chapter 3.5.5).

4.3.1.2 Chemical pollution from the application of agrochemicals

Agrochemicals, including fertilizers, pesticides, insecticides, and herbicides, are major contributors to diffuse pollution. For example, cadmium linked to phosphate, nitrogen and phosphorus fertilizers, or pesticide migration through the soil layers can cause diffuse pollution of rivers, coastal areas, lakes, and other waterbodies. The extent and severity of contamination often correlate with the country's economic development level. A significant concern is the export of prohibited chemicals from affluent countries (e.g., within the European Union) to lower-income nations. This practice, sometimes referred to as "chemical colonization," has resulted in widespread contamination in regions such as South America, Africa, and Asia, where regulatory frameworks are often weak due to political and economic pressures from wealthier producer countries (Bombardi 2019).

Pollution caused by agrochemicals has complex, far-reaching impacts. Soil is the initial repository where

Figure 4.3: Organic pollutants' source and transport linking to mining operations

Source: Modified from Zhang et al. (2020)

these chemicals accumulate or migrate (Foster and Chilton 2021). The United Nations Environment Programme's global partnership on nutrient management states "an excess of nutrients in the environment because of industrial and agricultural activity has profound impacts, from the pollution of water supplies and hence eutrophication to the undermining of important ecosystems and the services and livelihoods they support." (UNEP 2023a).

Despite its strong links with agriculture and cities, diffuse pollution is yet to be recognized in most countries. Even in low concentrations (ranging from microgram/g to ng/g), agrochemicals can pose potential risks to human and environmental health due to their bioaccumulation in the food chain and their potential to disrupt ecosystems and human biological processes. While diffuse pollution is linked to agriculture, no specific policies currently exist to regulate it. Furthermore, current monitoring systems are limited to detecting conventional pollutants, leaving recently emerged and emerging pollutants largely undetected.

4.3.1.3 Recently emerged and emerging pollutants

Contaminants of emerging concern (CECs) are recently identified chemicals, materials, and biological agents whose environmental and human health impacts are not yet fully understood. Growing concerns surround CECs, such as per- and polyfluoroalkyl substances (PFAS), microplastics, pharmaceuticals, and antimicrobial resistance, all of which raise concerns for land and soil health (Knapp et al. 2021; Pagaling et al. 2023; Wang et al. 2024). Along with these, contamination by radioactive materials originating from uranium mining and nuclear accidents, such as caesium-137 in Chernobyl, and their persistence in soils are yet to be thoroughly investigated and understood.

Aqueous film-forming foams that contain PFAS, commonly known as "forever chemicals" and used to extinguish fuel-based fires in training and fire suppression activities, have resulted in numerous contaminated sites (Das et al. 2013), including airports, defence facilities, mineral and petroleum industrial sites, firefighting training facilities and oil refineries. Wide ranges of consumer products incorporate PFAS, including textile, water-resistant fabrics, cleaning products, grease-resistant paper, non-stick cookware, refrigerants, building materials. More than 10,000 PFAS exist, but only a fraction is routinely monitored by most laboratories. These chemically stable, toxic compounds represent a serious global problem for environmental regulators, practitioners, and owners of the affected sites.

Plastic pollution has gained significant attention in recent decades. In agricultural settings, plastic mulch is a major source of small plastic particles in soil. More broadly, large quantities of plastics are dumped in landfills, rivers and oceans, representing a significant source of pollution (Chapter 5.2.2.1). An estimated 70-80 per cent of ocean plastics originates from land-based sources, transported via rivers and coastal run-off. Previous studies suggested that a small number of rivers contribute disproportionally to this pollution: (Li et al. 2016), one study estimated that the top ten rivers were responsible for 50-60 per cent; another study put the figure at over 90 per cent (Lebreton et al. 2018). Of the roughly 9.2 billion tonnes of plastic produced during 1950-2017, nearly 76 per cent has ended up as waste, carried through rivers (UNEP 2024a). Over time, plastics break down into micro- and nanoplastics that are ubiquitous due to their small size and interactions with organic matter, affecting both terrestrial and aquatic ecosystems (Lang et al. 2024; Sobhani et al. 2022). As the efforts to manage plastic pollution are increasing, the emerging risks associated with micro- and nanoplastics are gaining attention, driven by increasing research efforts to understand their environmental effects (Udovicki et al. 2022; Cheng et al. 2024).

Microplastic and nanoplastic pollution disrupts ecosystems and may pose serious risk to human health. (Yang et al. 2021; Nature Medicine 2024). MacLeod et al. (2021) highlighted the potential of plastic pollution to affect nutrient cycles and biodiversity, while Masson et al. (2023) suggested that nanoplastics can modify soil properties, release contaminants and harm soil biota.

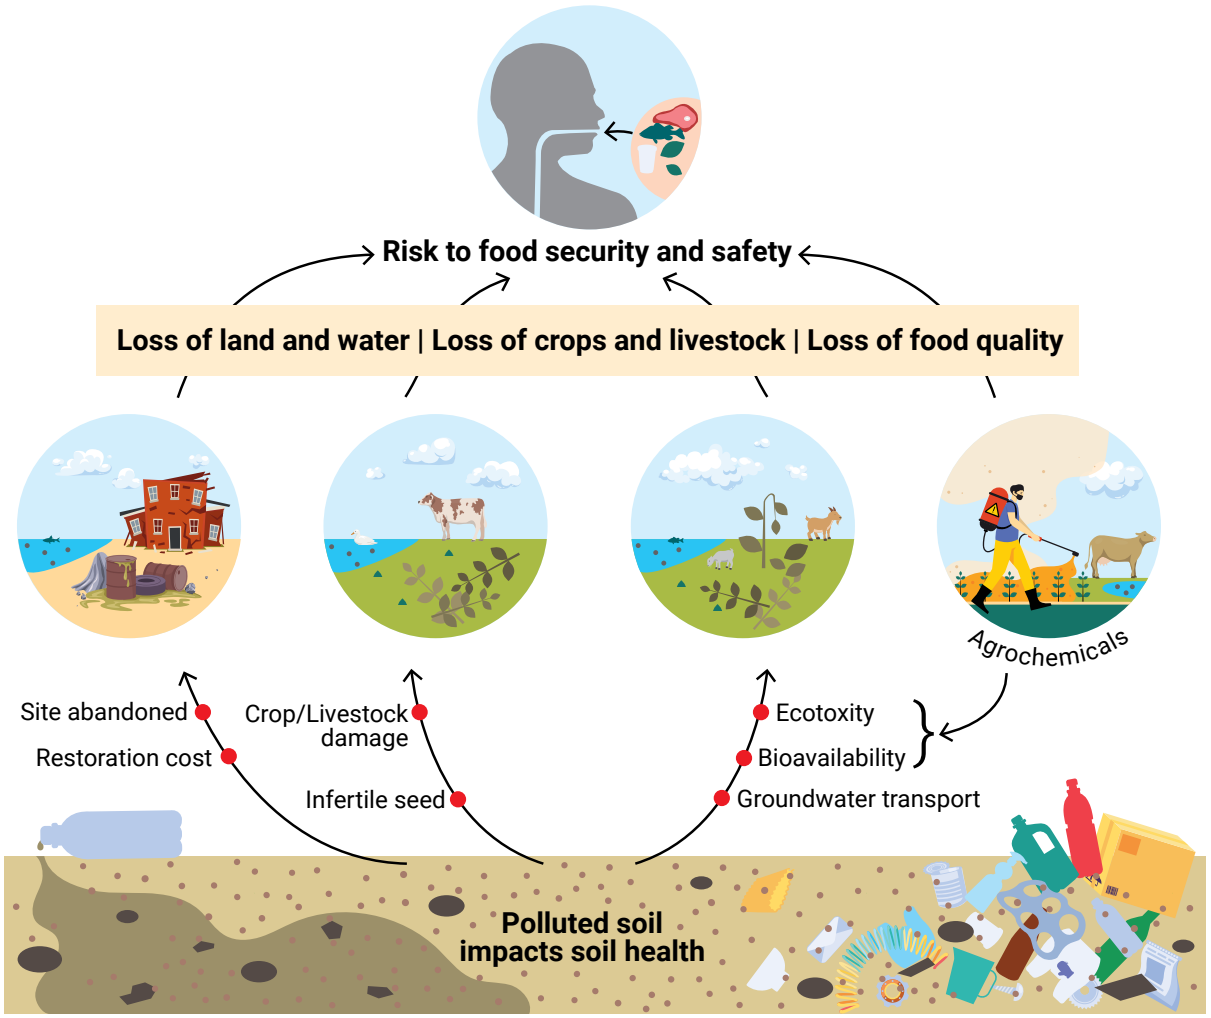
Along with microplastics, growing concerns are linked to emerging contaminants (Persson et al. 2022) associated with pharmaceuticals, pesticide metabolites and thousands of synthetic chemicals released into the environment every year. Despite their widespread use, less than 20 per cent of these chemicals are assessed for potential environmental and human health risks, mainly due to gaps in global policies on synthetic chemicals. Contaminants from soils can accumulate in plants and animals, threatening food quality.

4.3.1.4 Aerosol deposition

Aerosols are liquid or solid particles suspended in the atmosphere with complex chemical compositions originating from various sources, such as burning biomass, transport cooking, volcanic ash, and sandstorms. When aerosols carry chemical pollutants such as sulfates, nitrates, heavy metals, hydrocarbons, microplastics, and mineral dust, they pose an environmental risk.

Soil pollution from aerosol deposition can occur in several pathways (Tong et al. 2023). Pollutants settle on surfaces from precipitation, climatic events, or the movement of aerosol contaminants in the air, increasing human exposure risk. Aerosol pollutants migrate globally through airborne particles, gases and aerosols, water-borne suspended particles, and dissolved pollutants (Naidu et al. 2021).

4.3.1.5 Persistent Organic Pollutants



Climate change's critical yet highly uncertain effect is its impact on harmful pollutants, such as PFAS, DDT, and dioxins, that resist degradation, travel long distances through the atmosphere and hydrosphere, and enter food chains, affecting animals and humans. While the potential impacts are significant, they remain under-researched. Key concerns include changes in UV radiation, re-mobilization of persistent organic pollutants due to melting ice, extreme events, and the resulting effects on human health (Nadal et al. 2015) and crop production (Zandalinas et al. 2021).

4.3.1.6 Waste

Globally, the annual volume of municipal solid waste amounts to 2.1 billion tonnes (UNEP 2024) and is projected to increase to 3.8 billion tonnes by 2050 (Alves 2023; UNEP 2024). This trend becomes even more pronounced when hazardous wastes are included. For example, in 2023 alone, the medical, industrial, electronic, mining and agricultural sectors in the United States of America generated over 350 million tons of hazardous waste (Hazardous Waste Haulers Environmental 2023).

Worldwide, irrespective of country or production lifecycles, industrial waste is often stockpiled and dumped, frequently on Indigenous lands (Paul and Caplins 2020), or ineffectively recycled. This mismanagement has negative environmental and human health consequences, lost land productivity and high material management costs.

Figure 4.4: The effect of chemical pollutants on food security and food safety

Source: Naidu et al. (2021)

While multiple conventions address waste management, the mandate differs from country to country. In high-income nations, the concept of waste circularity is more widely recognized and implemented, while in low-income countries, a lack of financial investment and regulation hinders progress. As waste continues to pose significant environmental challenges, advancing an integrated, circular economy-driven waste management is a critical priority at national, regional, and global scales. Notably, many Indigenous Communities practise principles of circularity, offering alternative solutions (Beamer et al. 2023; Siragusa and Arzyutov 2020).

4.3.1.7 Impacts on carbon/nutrient cycle, ecosystems and biodiversity

Contaminants know no boundaries; they can be found anywhere and, by definition, pose a risk to human health and ecosystems (Fuller et al. 2022). Globally, around 10 million potentially contaminated sites have been recorded (Li et al. 2024), though the actual number is likely much higher. Compounding this issue is the emergence of new chemicals that humanity has yet to assess for their environmental impact, which may pose a greater risk to ecosystems as exposure increases.

Contaminants may enter the food chain and bioaccumulate, undermining food quality and ultimately food security and safety **(Figure 4.4)**. Wildlife, fish, and humans are exposed to persistent organic pollutants, heavy metals, pesticides, radioactive nucleotides, and substances from the persistent bioaccumulative and toxic and persistent mobile and toxic hazard classes, which are all detrimental to food safety and pose serious health risks (Kelly et al. 2007; WHO 2022a; Johnson et al. 2020).

Credit: irestock/Envato

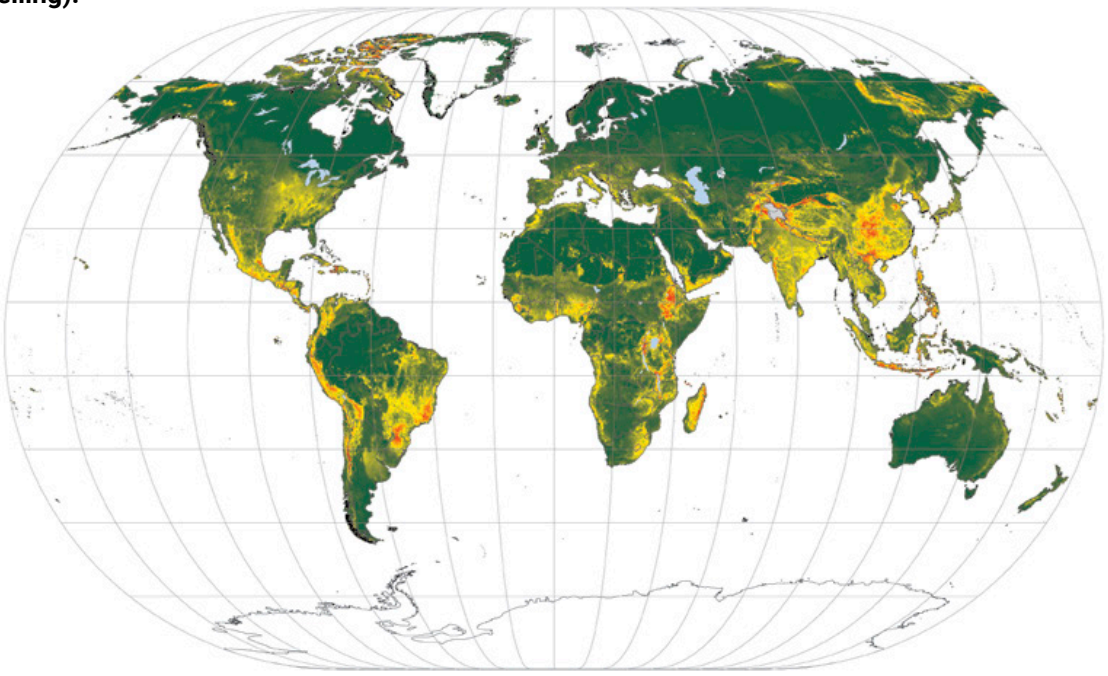
Pollution affects agricultural productivity, resulting in lower yields or loss of cropland (Biswas et al. 2018; Naidu et al. 2021). Excessive use of agrochemicals and chemical pollution from other sources damages soil quality, leaving it more vulnerable to the effects of climate change and associated aridity that contributes to soil salinity (Okur and Örçen 2020). In addition to soil pollution, air pollution – including black carbon, hydrofluorocarbons, and tropospheric ozone – also significantly reduces crop yields, with potential losses of up to a 50 per cent decrease in expected production (Burney and Ramanathan 2014; Liu and Desai 2021).

4.3.2 Land and soil degradation

Land degradation results from a combination of drivers and pressures such as population growth, poor land management, unsustainable agriculture, pollution, land use conversion, bush encroachment, and deforestation (UNCCD 2022a). These pressures have severe consequences on food security and migration. Key land degradation processes in arable land include aridity, vegetation decline, soil erosion by water and wind, soil salinization, and soil organic carbon decline (Prăvălie et al. 2021). Other processes include soil contamination, compaction, soil sealing and landslides. Aridity affects 40 per cent of arable lands, and erosion affects 20 per cent of land globally (Prăvălie et al. 2021). These two factors represent the most significant pressures, singly and in combination, on land resource degradation. Some estimates predict that up to 95 per cent of the Earth's soils could be degraded by 2050 (Save Soil 2024).

In 2022, the UNCCD estimated that 20-40 per cent of the world's land area was degraded to various degrees (UNCCD 2022), a significant increase from just under 20 per cent in 2017 (UNCCD 2019; United Nations Economic and Social Council 2019). The rise is attributed mainly to unsustainable land use and management practices. In the European Union, 60-70 per cent of soils are considered unhealthy, and more than 2.8 million

potentially contaminated sites have been identified (European Commission 2020).



Unsustainable agricultural practices – including continuous cultivation of arable lands, tillage practices such as up and down slope cultivation, degradation of vegetation cover, and a lack of intercropping, diversification and crop rotations – intensify soil erosion. Such practices cause an estimated loss of 24 billion tonnes of fertile soil every year, the equivalent of 3.4 tonnes for every person on the planet (International Assessment of Agricultural Knowledge, Science and Technology for Development (IAASTD), 2009) (**Image 4.1**; **Figure 4.5**). Erosion depletes soil nutrients, diminishes soil productivity and soil organic carbon, and deteriorates ecosystem services. Often, the off-site damage from erosion, such as flooding and sedimentation, is far more severe than on-site (Boardman et al. 2019). Panagos et al. (2024) estimated that removing 1 billion m^3 of sediments due to erosion in the European Union costs €5-8 billion annually.

Coastal erosion remains a significant issue. The economic toll of coastal erosion and associated coastal defences is substantial, particularly in Africa, Europe, the Caribbean, Australia and the the United States of America (Heger and Vashold 2021; European Environment Agency 2006; Ellis and Bajracharya 2023). Arctic coastlines are especially vulnerable, with erosion rates reaching up to 10 m per year. Arctic coastal erosion is predicted to become increasingly sensitive as global temperatures rise, reaching 0.4–0.8 metres per year for every 1°C of warming and releasing 2.3–4.2 teragrams of carbon annually per degree of warming by the end of the century (Nielsen et al. 2022).

4.3.2.1 Drought

Land degradation driven by drought can severely affect local populations (Hill et al.2018; Walker and Van Loon 2023; European Commission Joint Research Centre and UNCCD 2024), particularly affecting women, older people and children. There are four types of droughts: meteorological, hydrological, agricultural, and socioeconomic. While the first three focus on physical processes, socioeconomic drought reflects broader impacts of water shortages on supply, demand, and socioeconomic systems

Figure 4.5: Soil erosion estimates predicted through the GloSEM platform (Global Soil Erosion Modelling).

The map illustrates the soil erosion rates divided into seven classes according to the European Soil Bureau classification

(Wilhite and Glantz 1985; Lee et al. 2022) (Chapter 3.2.3, Chapter 6.3.2.1). Agricultural drought can lead to crop failure, food insecurity and forced migration (**Image 4.2**). Droughts are considered the second most difficult to cope with after hurricanes (National Geographic, 2023), severely impacting local populations. (McDowell et al. 2022).

Since 2000, the frequency of droughts has increased globally by nearly 30 per cent (IPCC 2022a; UNCCD 2022; United Nations Office for Disaster Risk Reduction 2022), posing a significant threat to agricultural systems and resulting in billions of global economic losses. Droughts can take the form of flash droughts or dry spells with intensified severity due to climate change and devastating impact. Europe, North Africa, North, Central and East Asia, the Sahel and the west coast of South America are particularly vulnerable to drought and climate change (Chiang et al. 2021). However, attributing these trends on a global and continental scale remains challenging due to high uncertainty (Rojas 2020).

In Central Asia, almost a third of the population, 75 million people, lack access to reliable water sources

Image 4.2: A family relocating to another town 70 kilometres away due to drought episodes in Bale Goba, Ethiopia in 2022. Credit: © UNICEF Ethiopia/Nahom Tesfaye

(Yuan et al. 2023). In China the number of hot days is rising, while the average number of rainy days is decreasing (Wang et al. 2023). Eastern China experienced an extreme drought in July–August 2022, affecting 38.3 million people in 21 provinces, including Sichuan and Chongqing, destroying more than 4.1 million hectares of crops with direct economic losses exceeding 32.8 billion yuan (Cao et al. 2024).

Observations indicate increased frequency, duration, and severity of droughts worldwide (Spinoni et al. 2014; Chapter 3.2.3), especially in the Mediterranean (Dittus et al. 2024). Shifting drought regimes are reducing the productivity of natural ecosystems (Feng et al. 2021) and accelerating the severity of heatwaves and wildfires (Vicente-Serrano et al. 2024).

4.3.2.2 Carbon emissions and storage in terrestrial ecosystems

Global CO_2 emissions from land use, land use change, and forestry averaged 1.2 ± 0.7 GtC per year (4.5 ± 2.6 $GtCO_2$ per year) for the 2012–2021 period with a preliminary projection of 1.1 ± 0.7 GtCper year (3.9 ± 2.6 $GtCO_2$ per year) for 2022 (Friedlingstein et al. 2022). Among the tropical forests, the Congo basin has the highest carbon sink (-0.61 Gt CO_2 per year), followed by the Amazonian basin (-0.10 Gt CO_2 per year). In comparison, forests in South East Amazonia have become net emitters (+0.49 Gt CO_2 per year) (Hubau et al. 2020). The highest carbon emitters during 2012–2021 in descending order were Brazil, Indonesia, and the Democratic Republic of the Congo, together accounting for more than half of the global land-use emissions, primarily due to higher deforestation rates (Friedlingstein et al. 2022).

Image 4.3: Aerial view of a palm oil plantation in Sentabai Village, West Kalimantan, Indonesia. Credit: © Nanang Sujana/ CIFOR

Over the past two centuries, net CO_2 emissions from soils have increased by 8 per cent due to land conversion and unsustainable management (Wang et al. 2021). While native grasslands store a significant amount of carbon, drylands, covering more than 40 per cent of the total land area, while supporting 3.2 billion people (Prăvălie et al. 2016) and hosting 50 per cent of global livestock, also play a crucial role. Though drylands store less organic carbon per hectare than humid regions, the vast surface area they cover makes them a significant global carbon sink with high inorganic carbon stocks. Black soils (chernozems) are crucial, holding vast amounts of organic carbon. So are peatlands that cover only 3-4 per cent of the Earth's surface but contain around one-third of the world's soil carbon, double the amount of the world's forests (UNEP 2022). Despite their importance, only 17 per cent of peatlands fall within a protected area. Coastal wetlands also have exceptional carbon storage capacity, storing three to five times more carbon per unit area than tropical rainforests (Teng 2025).

Tropical rainforests store 25 per cent-40 per cent of global soil carbon, despite only covering 7 per cent of Earth's land area (Cusack et al. 2023). Tropical rainforest ecosystems store massive amounts of aboveground carbon and harbour rich biodiversity (Fischer et al. 2023). Unfortunately, tropical forests have experienced the most significant carbon losses due to land use change. Deforestation **(Image 4.3)**, second only to fossil fuels use in terms of greenhouse gas emissions, remains a major driver, with the Brazilian Amazon being the world's deforestation hotspot (Levy et al. 2023). Although deforestation rates in the Brazilian Amazon have recently declined, the region still lost 5,000 square kilometres of rainforest in 2023, an area three times the size of Greater London (Stafford 2024).

Other riparian countries in the Amazon region, such as Bolivia, Peru and Colombia, also face rapid deforestation. For instance, Bolivia lost more than 3.3 million hectares of humid primary forest between 2002 and 2021, with annual deforestation rates exceeding 5.5 per cent yearly (Global Forest Watch 2023). This is especially concerning because primary forests store significantly more carbon than younger regrowth forests (Hong et al. 2025). In Brazil, cattle ranching and increased soybean production for trade with China and Europe continue to drive deforestation (da Silva et al. 2023).

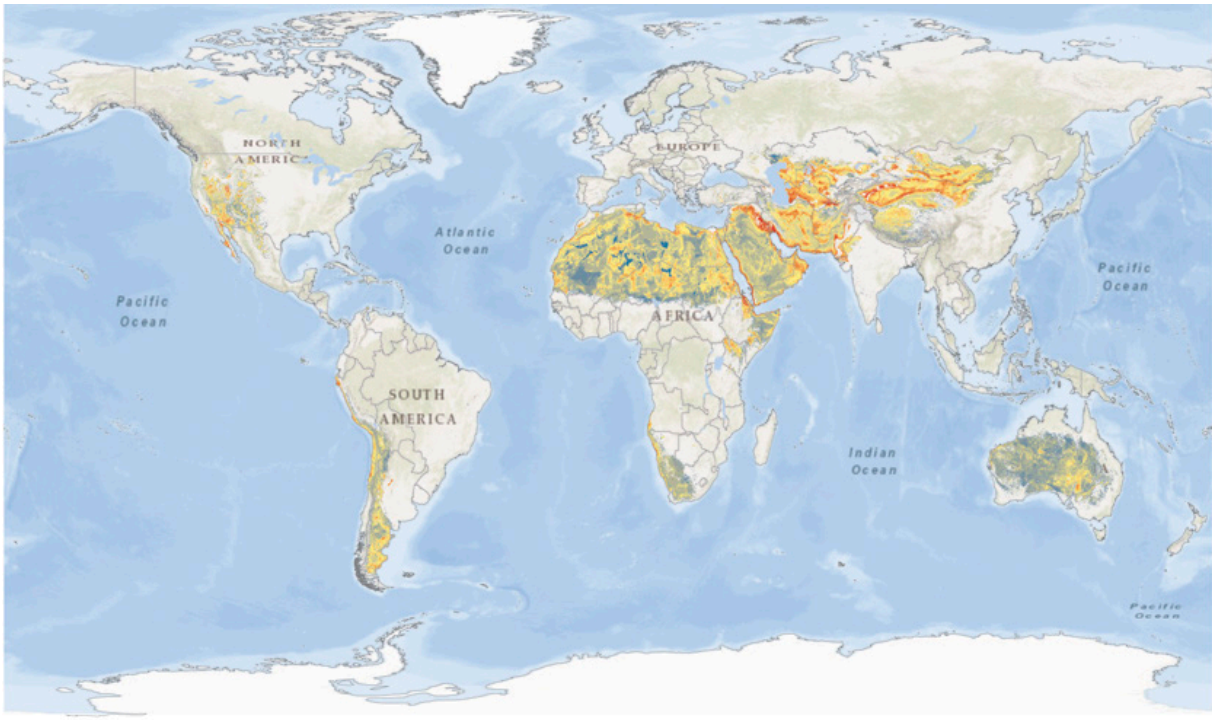
Globally, about 10 million hectares of forest are lost each year, an area the size of Portugal. 95 per cent of deforestation happens in the tropics (Heinrich et al. 2023). Only half of this deforestation is compensated for by forest regrowth. In 2024 alone, Indonesia lost 261,575 ha of primary and secondary forests, more than 4,000 ha (AFP 2024).

Tropical soils are expected to be the first to respond to climate change, with significant carbon losses due to higher mineralization and carbon release. To achieve global conservation and sustainability goals, at least 79 per cent of the world's remaining vegetation must be retained (Simmonds et al. 2023). However, accurately measuring carbon stocks is challenging due to limited field data in many countries; therefore, models are used, but the results of these assessments should be interpreted with caution.

If adequately managed, soils could help mitigate the effects of climate change (IPCC 2019, Harvey 2023). The Coalition for Soil Health (2023) estimates that widespread adoption of sustainable soil management practices could sequester up to 1.8 GtC annually by 2030. Addressing land degradation with sustainable land and soil management could add US$75.6 trillion to world income annually (Economics of Land Degradation Initiative 2019).

The voluntary action plan 4 per 1000: Soils for Food Security and Climate, adopted in Paris in 2015 (Lal 2015), aims to boost global agricultural soil carbon stocks by 4 per 1000 each year to help mitigate climate change and improve food security. This improvement could compensate for all greenhouse gas emissions associated with agriculture while ensuring soil health. Another major effort is the Bonn Challenge, which seeks to restore 350 million hectares of degraded forest landscapes by 2030.

Proven sustainable land management practices (World Overview of Conservation Approaches and Technologies 2025), such as conservation, no tillage (Wang et al. 2025), cover cropping, and crop rotation, demonstrate that reversing land and soil degradation is possible when the right policies are implemented and local communities are meaningfully involved. Healthy land and soils are essential for achieving more than half of the Sustainable Development Goals (SDGs), including climate change mitigation, adaptation, and biodiversity (Lal et al. 2021).



4.3.2.3 Sand and dust storms, and soil erosion

Sand and dust storms can have significant transboundary impacts on the environment, climate, health, livelihoods, agriculture, food security and the well-being of millions of people **(Image 4.4)** affecting 151 countries in Africa, Asia, North and South America, and Oceania, sand and dust storm events can severely impact economic development **(Figure 4.6)**. A single sand and dust storm event can cause economic losses amounting to hundreds of millions of dollars. For instance, a major dust storm in Mongolia in March 2021 killed 200,000 livestock and destroyed 121 animal shelters (FAO 2023c).

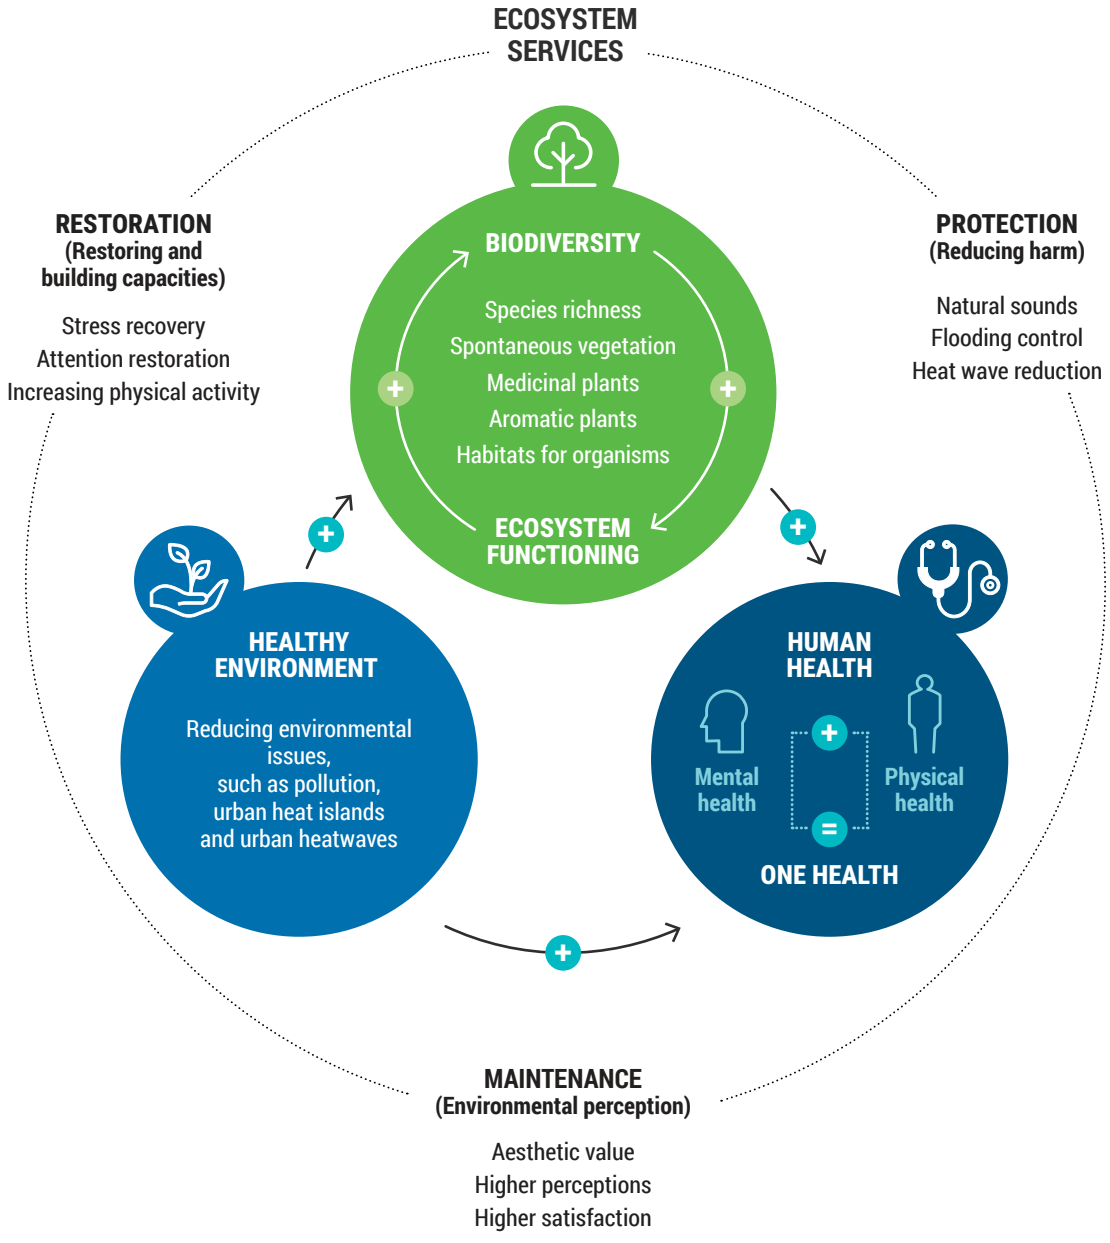
Source: UNCCD (2024a)

Saharan dust frequently reaches southern Europe and the Americas, carrying bacterial and fungal pathogens (Das et al. 2023). It also contributes to soil and ocean fertilization, adding phosphorus, iron and other nutrients through deposition (Ohnemus et al. 2025). Massive dust storms in the Gulf of Alaska can last for days, releasing tonnes of fine sediment into the atmosphere and influencing the global climate system (Barr et al. 2023).

Soil erosion by water is a severe degradation process, affecting soil quality, water resources, biodiversity, carbon cycling, land productivity, and socioeconomic conditions. Studies (e.g. Borrelli et al. 2023) suggest that cropland expansion can potentially accelerate global soil erosion, with the highest increase in Sub-Saharan Africa at 3.51 Mg per hectare per year, South America at 3.53 Mg per hectare per year and South East Asia at 3.47 Mg per hectare per year. Despite considerable research on arable agriculture, almost half of global soil erosion by water occurs in semi-natural ecosystems (Borelli et al. 2017).

Topsoil loss by water or wind erosion is the most significant cause of soil material displacement, with water erosion affecting about 56 per cent of the total land area subject to human-induced soil degradation, and wind erosion affecting a further 38 per cent of that. Chemical and physical soil deterioration affects about 12 per cent and 4 per cent, respectively (UNCCD 2024b).



Due to limited data availability, global soil erosion estimates often rely on coarse-scale models. As a result, semi-empirical approaches are used in physical models and to inform policy. (Borrelli et al. 2020) **(Figure 4.6)**. Conservation agriculture, agroecology (Bezner Kerr et al. 2023) and regenerative agriculture –based on minimal soil disturbance, crop rotations and cover cropping – now cover an estimated 11 to 14 per cent of agricultural land globally, or ~1.42 billion hectares (FAO 2022b). These practices could reduce global soil erosion by 7.1 per cent (Borrelli et al. 2017), while maintaining biological soil crusts can reduce erosion and mitigate sandstorms (Zucca et al. 2022).

4.3.2.4 Land degradation, climate change and pollution impact on biodiversity

Land use changes drive biodiversity loss and diminish ecosystem functions and services, with significant consequences on human well-being, especially that of Indigenous Peoples (Isbell et al. 2017; 2023; Tsuji et al. 2023; Brubacher et al. 2024). These impacts vary depending on geographic location and sociological, economic, and political context (Bruley et al. 2021; Folkard-Tapp et al. 2021; DeClerck et al. 2023).

The conceptual framework **(Figure 4.7)** illustrates the link between biodiversity, ecosystem functioning and services, and human well-being, highlighting the crucial role of biodiversity. Restoration, protection and maintenance maintain balance across ecosystems, including urban areas (Zhang et al. 2022). Land degradation, global warming and pollution contribute to the decline of terrestrial biodiversity (Malhi et al. 2020; Ekka et al. 2023) and the ability of ecosystems to provide their services (IPBES 2019; Santini et al. 2022; Petrosillo et al. 2023). Habitat degradation,

Figure 4.7: Conceptual framework showing the interdependence of biodiversity, healthy environment and human health regulated by ecosystem services (protection, maintenance, and restoration)

Source: Zhang et al. (2022)

extensive use of alien species, and overexploitation of bioresources, together with climate change and air pollution, further exacerbate the damage to terrestrial biodiversity and ecosystems (Shivanna et al. 2022; Kanakidou et al. 2022).

4.3.3 Climate change and changes on land

4.3.3.1. Land changes in a warming world

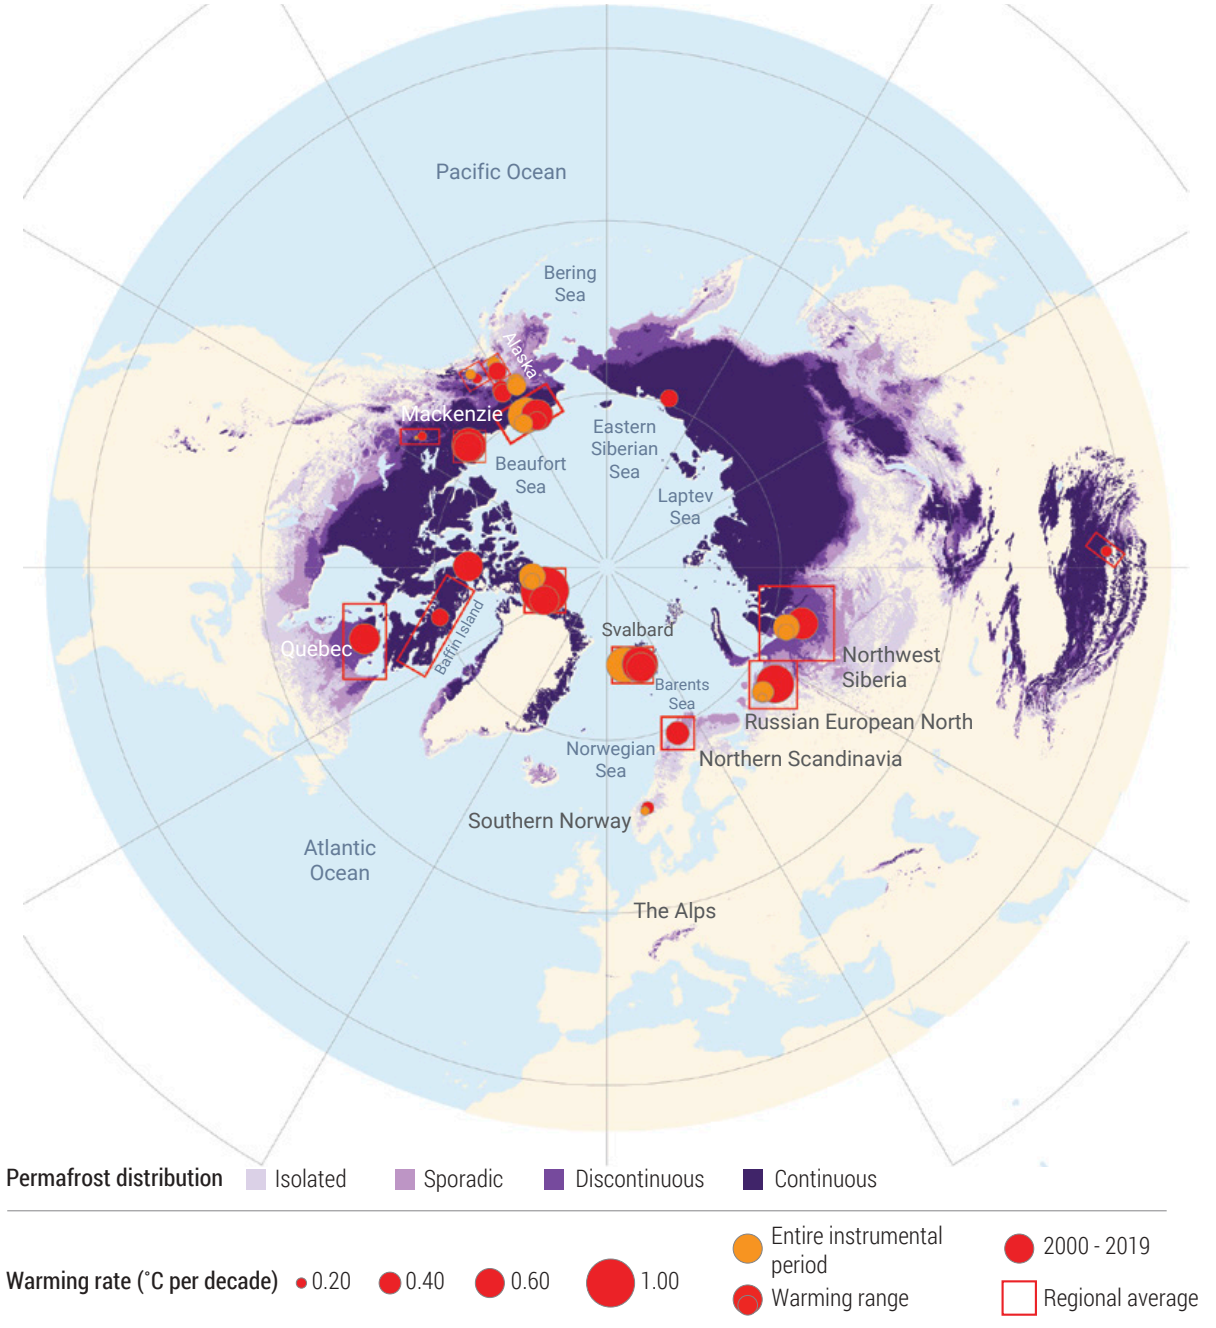
Globally, land has warmed by 1.6°C (IPCC, 2023); if this trend continues, the temperatures would breach the "preferred maximum" threshold described in the Paris Agreement (United Nations Framework Convention on Climate Change, 2016) and raise concerns about crossing the "point of no return" (Hansen et al. 2025). Over 20 per cent of humanity already experiences a warming of 1.5°C during at least one season of the year (Jones 2023). Future climate trends are discussed in Chapter 10.4.1.

The changes related to land warming, such as air temperature, seasonality, precipitation patterns, heatwave incidents, and droughts will affect natural and human systems. Fire weather conditions have intensified in length and severity over the past 40 years globally, counteracting the effects of landscape fragmentation and forest clearing on fuel build-up and fire propagation (Jones et al. 2022). Increases in the frequency, duration, and severity of droughts (Spinoni et al. 2014) are undermining agricultural productivity.

Permafrost thawing drives ecosystem changes, affecting the freshwater cycle, and destroying infrastructure. Climate change-driven shifts in environmental conditions force species to shift their ranges (Chen et al. 2011; Pecl et al. 2017; Davidson et al. 2020; Feeley et al. 2023), threatening ecosystem composition. Land warming also alters phenological events, such as flowering, migration, and hibernation, affecting many species (Inouye 2022; Piao et al. 2019).

4.3.3.2. Changes in terrestrial carbon storage and nutrient cycles

The net land CO_2 flux reflects carbon sequestration through photosynthesis in plant and microbial biomass and soils. In contrast, the release of carbon to the atmosphere is driven by deforestation, shifting cultivation, and land degradation. Land use change generates a carbon pulse of 1.1±0.7GtC/yr, accounting for roughly 10 per cent of anthropogenic CO_2 emissions (Friedlingstein et al. 2022), while the soil carbon sink of 3.1±0.6GtC/yr offsets about 30 per cent of the total CO_2 emissions.



The increase in terrestrial carbon sink is primarily driven by rising atmospheric CO_2, anthropogenic nitrogen input, and the effects of climate change, such as lengthened growing seasons and enhanced productivity in boreal forests and collectively known as "the CO_2 fertilization effect" (Friedlingstein et al. 2022). Elevated temperatures, frequent droughts, heatwaves, and other climate change impacts can counteract these gains. Nutrient availability can constrain the CO_2 fertilization effect (Reich and Hobbie 2013; Wang et al. 2020) as the lack of nitrogen and phosphorus limit productivity on 18 per cent and 43 per cent of land, respectively (Du et al. 2020). Due to deforestation, tropical forests are shifting from carbon sinks to carbon-neutral systems or even carbon emitters (Tagesson et al. 2020; Wigneron et al. 2020; McFarlane et al. 2024). By the end of the century, the land carbon sink will likely stop growing or reach saturation (Shi et al. 2021).

Anthropogenic nitrous oxide emissions increased 30 per cent over the past four decades (Tian et al. 2020) and is responsible for 6.2 per cent of global warming, undermining environmental health, and modifying global biogeochemical cycles. At least 60 per cent of nitrous oxide emissions are from agriculture (Grecequet et al. 2022).

4.3.3.3. Permafrost thaw

Permafrost soil, found beneath a quarter of the northern Hemisphere, is warming. Climate change accelerates permafrost thawing, triggering microbial breakdown of soil carbon, releasing CO_2 and methane to the atmosphere (Schuur et al. 2015; Canadell et al. 2021). Permafrost warming is faster at higher elevations and latitudes, reaching up to 1°C/decade, as compared to <0.3°C/decade in sub-Arctic latitudes (Smith et al. 2022), with a mean of 0.4°C/decade (Gudmundsson et al. 2022); abrupt thaw can release large amounts of CO_2 and methane within time frames of days to years (**Figure 4.8**).

Figure 4.8: Permafrost warming trends

Source: Smith et al. (2022)

Permafrost thawing disrupts biogeochemical cycles, modifies hydrology, and restricts ecosystems' ability to cope with climatic changes (Volkova et al. 2021; Namsaraev et al. 2023; Baltzer et al. 2014; Jin et al. 2021). It also triggers secondary environmental impacts, such as transforming forests into shrublands, wetlands, and lakes, further accelerating thawing (Jin et al. 2021) and affecting future water availability (Chapter 6.2.2). Permafrost thawing damages infrastructure, restricts transportation, increases landslide risks, and raises construction costs (Hjort et al. 2022; Debortoli et al. 2023).

In the Russian Federation, permafrost thaw-related damages affect 10 per cent of buildings in Yakutsk and Norilsk, and 80 per cent in Vorkuta (Hjort et al. 2022). Additionally, thawing releases contaminants previously stored in frozen soils, which can enter the food chain, impairing human health (Ray 2024).

4.3.3.4. Climate change, terrestrial ecosystems and biodiversity

While climate change is shifting species' ranges (Anderegg et al. 2019; Román-Palacios and Wiens

2020), land use change, agriculture, habitat loss and fragmentation are increasing stress on biodiversity. Compound effects from intensive agriculture and climate change can reduce insect abundance and species richness by 50 per cent and 27 per cent, respectively. (Outhwaite et al. 2022; Muller et al. 2023). Notably, some species adapt to a warmer climate, triggering outbreaks of agricultural and forest pests (Jactel et al. 2019), such as locusts in East Africa (Salih et al. 2020). The ongoing biodiversity loss is similar in terms of scope to the previous five mass extinctions (Halam and Wignall 1997; Cowie et al. 2022), yet is occurring more abruptly (Ceballos et al. 2015, Ceballos and Ehrlich 2018).

Warmer temperatures can also disrupt phenological relationships. Since the 1980s, leaf unfolding began to occur earlier, shifting by 3-4.2 days per decade in Europe and 5.5 days per decade in China (Piao et al. 2019). Before the 1980s, little change was observed (Vitasse 2022). This change disrupts plant-animal interaction, such as pollination and seed dispersal (Teixido et al. 2022), weakening the ability of ecosystems to deliver essential services (Mooney et al. 2009). Protected areas provide habitats and maintain microclimate conditions crucial for biodiversity under global warming (Xu et al. 2022). For instance, large-scale reforestation in China has increased forest connectivity by bridging isolated patches and creating extensive core forests. Forests larger than 100 km^2 provide more than twice the cooling capacity than areas ≤ 10 km^2 (Huang et al. 2022).

4.3.3.5. Impacts of climate change on agricultural productivity

The effect of climate change on agriculture varies by region (Jägermeyr et al. 2021), generally increasing yields in colder regions and decreasing yields in warmer areas (IPCC 2022a). In addition to temperature change and shifts in precipitation, increasing incidents of extreme events, such as agricultural droughts and wildfires, are increasingly harming forestry (Chapter 2.3.1) and agriculture. Meanwhile, productivity gains in colder climates might also be attributed to technology advancements (Kirilenko and Dronin 2022). For example, prior to the war in Ukraine, Ukraine and the Russian Federation had become the second and third leading world wheat exporters (FAO 2021), even though the yield models have projected a drop in productivity related to climate change (Pavlova et al. 2019; Lobell et al. 2011).

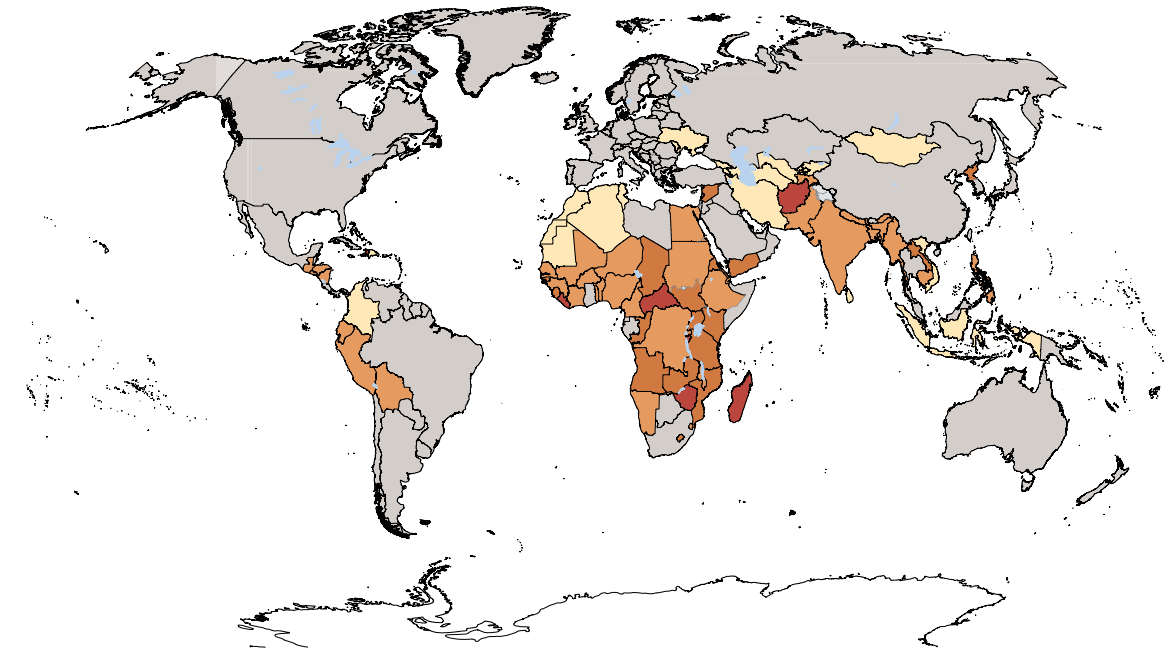
Atmospheric carbon enrichment influences crop yields through the "carbon fertilization" effect (Canadell et al. 2021). Free Air Carbon Enrichment experiments and crop model simulations show that higher levels of CO_2 can increase crop yields and improve water use efficiency, depending on the crops. However, this may decrease crop quality (Toreti et al. 2020), especially regarding nutritional value (Soares et al. 2019).

Total factor productivity, which accounts for labour and capital input, is a more appropriate measure of agricultural performance than raw yields (Organisation for Economic Cooperation and Development 2001). Econometric models show that climate change has reduced the agricultural total factor productivity by about 21 per cent since 1961, with adverse effects generally observed across the Global South (Ortiz-Bobea et al. 2021). Unfavourable weather in conjunction with conflicts and other drivers increase food insecurity, especially in Africa at 40 per cent **(Figure 4.9)** and Asia at 23 per cent (Cardell et al. 2024).

In response, agriculture and forestry are adapting to climate change. Multiple surveys (World Overview of Conservation Approaches and Technologies 2025) have demonstrated that most farmers across different regions are aware of the effects of climate change on crop production, including shifting precipitation patterns, drought and flood risks, and hotter temperatures. Common adaptation strategies include shifting planting dates to earlier in the year to avoid heatwaves, switching to more profitable climate-suitable crops, introducing improved crop varieties and animal breeds, planting trees in pastures andfields for shade, switching to an integrated agroforestry approach **(Image 4.5)**, crop diversification, using mixed crop-livestock systems, improving irrigation

Image 4.5: Silvopasture is an agroforestry practice that deliberately integrates trees, pasture and grazing livestock on the same land. Trees provide shade and shelter to livestock, vegetation provides high quality forage, and animal waste provides nutrients to grass and trees. This practice can also increase wildlife diversity and improve soil and water quality. Credit: Mack Evans/National Agroforestry Center (CC-BY-2.0)

and increasing the number of ponds (Aguliera et al. 2020, Nkuba et al. 2020a). In India, farmers responded to hotter summers and more frequent droughts by planting trees surrounding fields, switching to lower water requirement crops, and increasing irrigation (Singh 2020). In Uganda, pastoralists and arable farmers use Indigenous forecasting (Nkuba et al. 2023), and smallholder farmers are adopting drought-resistant cultivars and fallowing (Atube et al. 2021). In Ethiopia, farmers adapt through crop diversification, planting date adjustment, water management improvements, crops with livestock integration, and tree planting for shade (Belay et al. 2017).



A recent study suggests that even accounting for adaptation, global food production declines 120 kcal per person per day, 4.4 per cent of recommended consumption, per 1°C warming (Hultgren et al. 2025). Adaptation options are limited for smaller, poorer households due to restricted access to knowledge, funds, and credit and to insecure tenure (Khan et al. 2020), compounded by soil degradation. While autonomous adaptation is widely studied, most research focuses on Africa (Oladele et al. 2024) and South East Asia, with fewer studies from Latin America (Fierros-González and López-Feldman 2021) and countries in the northern hemisphere (Soubry 2020). In addition, the social dimension of adaptation to climate change remains underexplored (Davidson 2016).

In the forestry sector, the examples of adaptation outside of carbon management are scarce. Interventions focused solely on carbon sequestration frequently result in monocultures rather than restoring forest biodiversity (World Overview of Conservation Approaches and Technologies 2025). As a critical supplier of provisioning services, forestry is highly vulnerable to land use change (Keenan 2015), affecting the livelihoods of millions of people in forest-dependent communities and many others. The Intergovernmental Panel on Climate Change (IPCC) (2022a) outlined multiple adaptation options, primarily for tropical regions, but warns that, under high-impact scenarios, dieback of some forests in Sub-Saharan Africa and South Asia may be unavoidable. Certain risks, such as heatwaves, loss of pollinators, invasive species and diseases, can only be addressed through large-scale interventions beyond the capacity of the forest sector alone (IPCC 2022a).

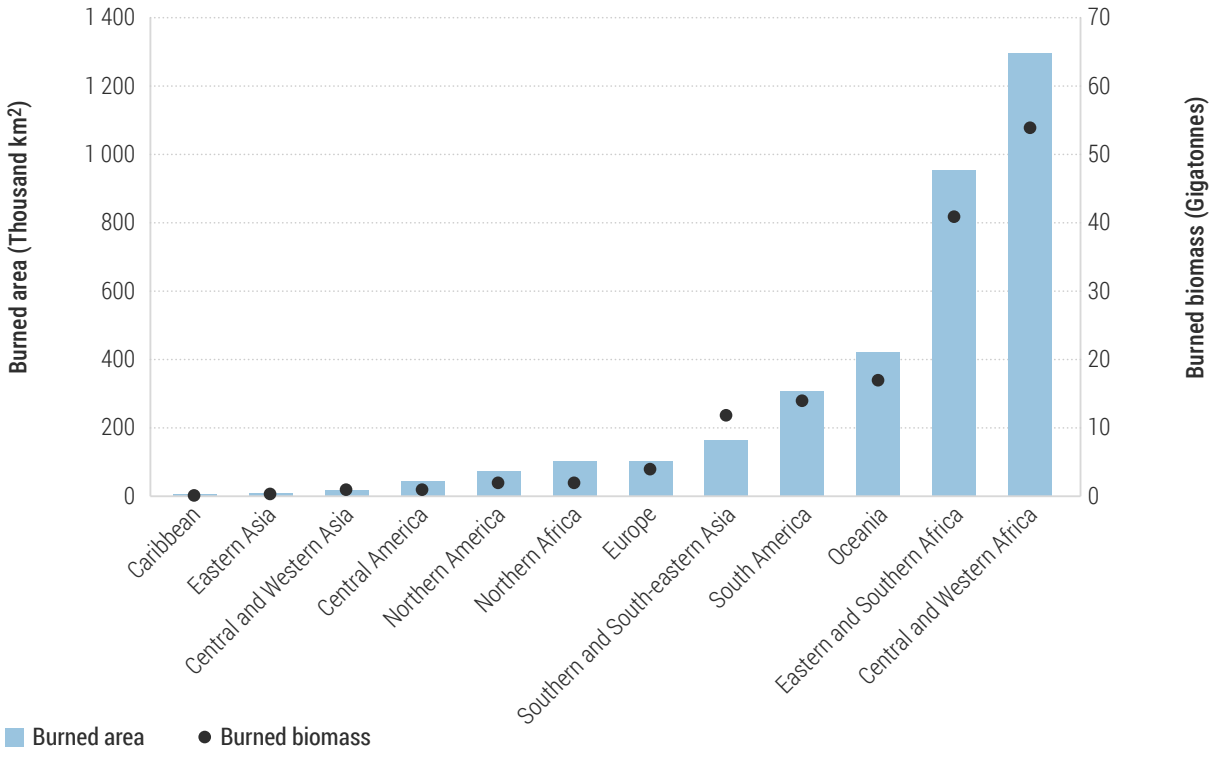
4.3.3.6. Extreme events

Climate change has likely increased the frequency and intensity of extreme events, including heatwaves, droughts, storms, and floods (Seneviratne et al.

Figure 4.9: Food insecurity in Sub-Saharan Africa

Note: IFSA = International Food Security Assessment

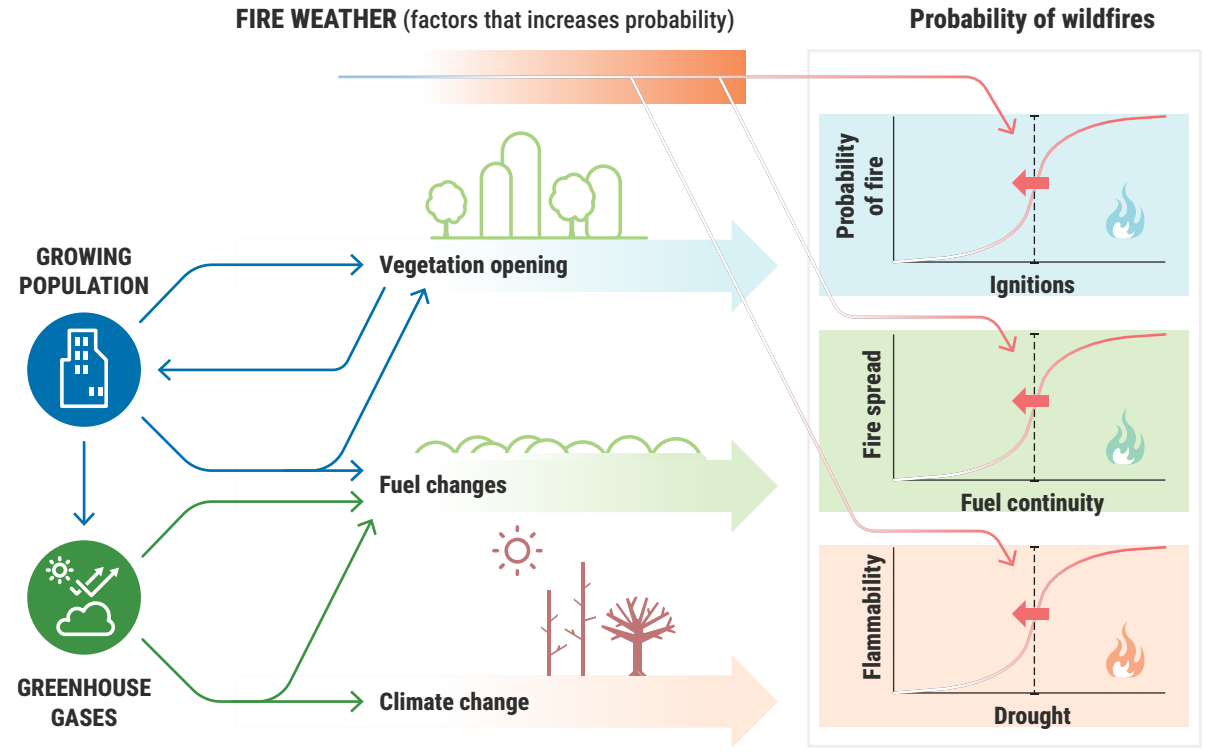
Source: Cardell et al (2024)



2021). Examples include compound heatwave-drought events in Europe in 2003 and 2022 (Ciais et al. 2003; Tripathy et al. 2023), the Russian Federation in 2010 (Sedlmeier et al. 2018), and California and South America in 2020 (Marengo et al. 2022).

One example of this compounding effect is wildfire hazard. Wildfire is a natural phenomenon essential for ecosystem health, yet it poses a significant risk to human safety, health, and property, and causes rapid thermal, hydrological, and vegetation changes. Two-thirds of wildfires occur in Africa **(Figure 4.10)**, followed by Oceania and South America, regions with extensive grassland and savanna areas where fires occur cyclically (FAO 2020). Forest fire trends are evolving (Tyukavina et al. 2022; Agbeshie et al. 2022). It is estimated that over the last 250 years the frequency of fire regime change has increased 10-fold compared to the previous ten millennia (Sayedi et al. 2024).

Wildfires are influenced by human population growth, forest clearing, landscape fragmentation, fire management practices such as forest clearing and prescribed burning, and climate change (Pausas and Keeley 2021) **(Figure 4.11)**. Research shows an increase in severity and length of extreme fire weather incidents, driven by decreasing air humidity, increasing temperature, and longer fire season (Jain et al. 2022; Jolly et al. 2015; Jones et al. 2022) **(Figure 4.12)**. More than half of the documented increases in aridity since the 1970s and the expansion of cumulative forest fire area across western United States of America forests since 1984 are attributed to anthropogenic climate change (Williams and Abatzoglou 2016). In 2023, Canada experienced its worst wildfire season on record (Byrne et al. 2024). Even Arctic wildfires are accelerating, with burned area and CO_2 emissions reaching record highs in 2021 (Zheng et al. 2023).

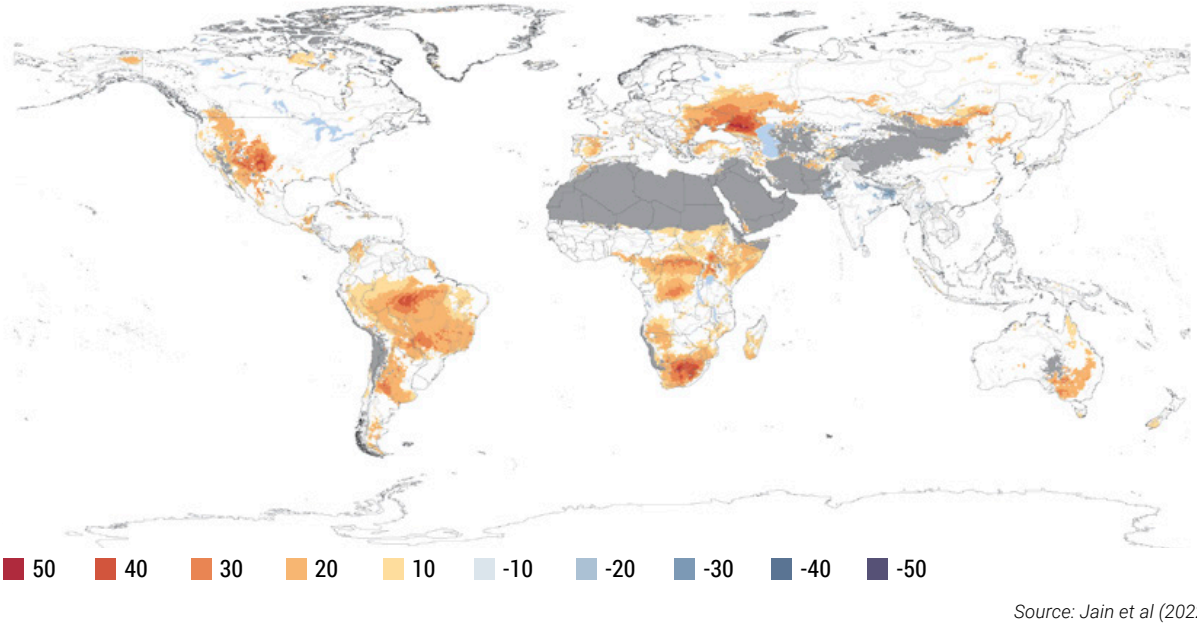


Models indicate a 22 per cent increase in days with extreme fire danger across global burnable land area, including Amazonia, southern Europe, Scandinavia, western United States of America, Canada, and other regions (Abatzoglou et al. 2019). This trend can be dampened by landscape fragmentation, forest clearing, and fire management efforts. However, overall burned area is declining (FAO 2023b), primarily due to agriculture expansion in savannas and grasslands (Andela et al. 2017), while the associated CO_2 emissions are stable (Zheng et al. 2023). The seeming contradiction is explained by a higher burned biomass density in forests than in savannas (Zheng et al. 2023; **Figure 4.13)**.

Figure 4.10: Mean annual burned area and burned biomass by forest and savanna fires

Source: FAO (2024)

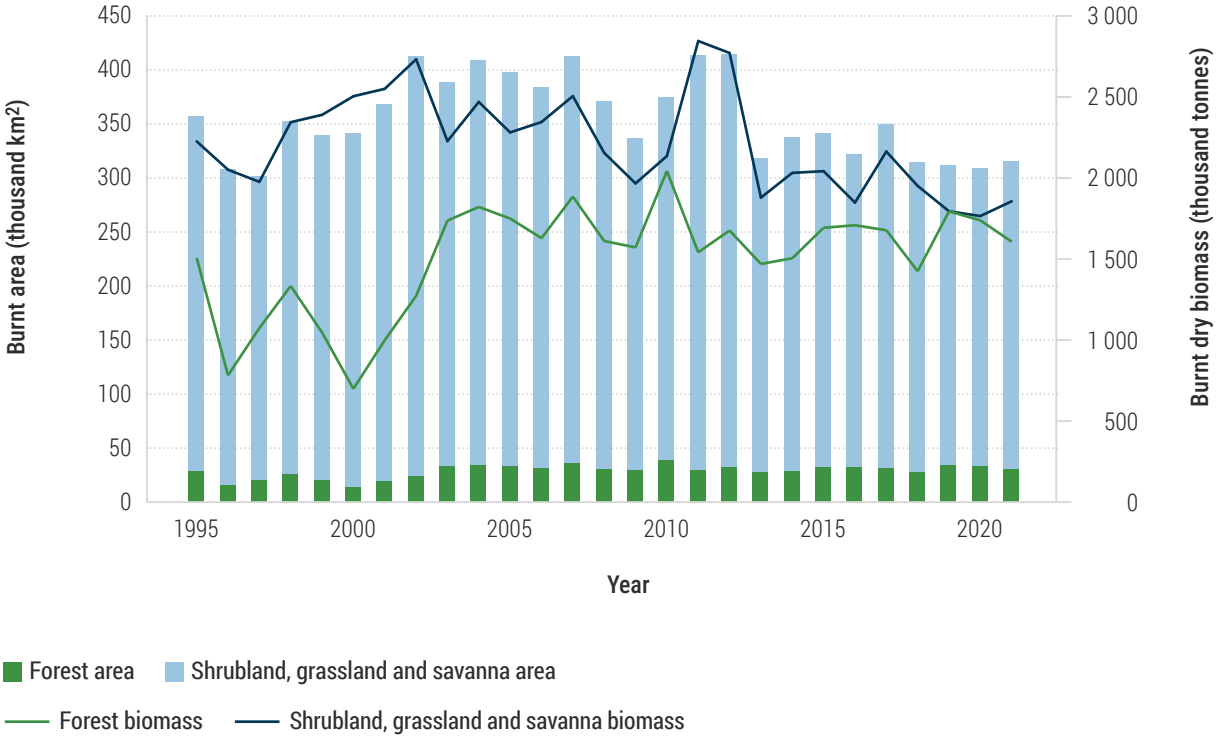
Figure 4.11: A conceptual model showing the drivers affecting wildfire occurrence and severity



Source: Pausas and Keeley (2021)

4.3.4. Terrestrial biodiversity

The interdependence among biodiversity, climate, and human societies is a key finding of the 6th IPCC assessment report, highlighting trade-offs and synergies between climate and biodiversity actions (Pörtner et al. 2021; IPCC 2023).



Under IPCC medium (SSP2-4.5) and high (SSP3-7 and SSP5-8.5 8.5) emission scenarios, potential terrestrial

Figure 4.12: Extreme fire weather trends from 1979 to 2020

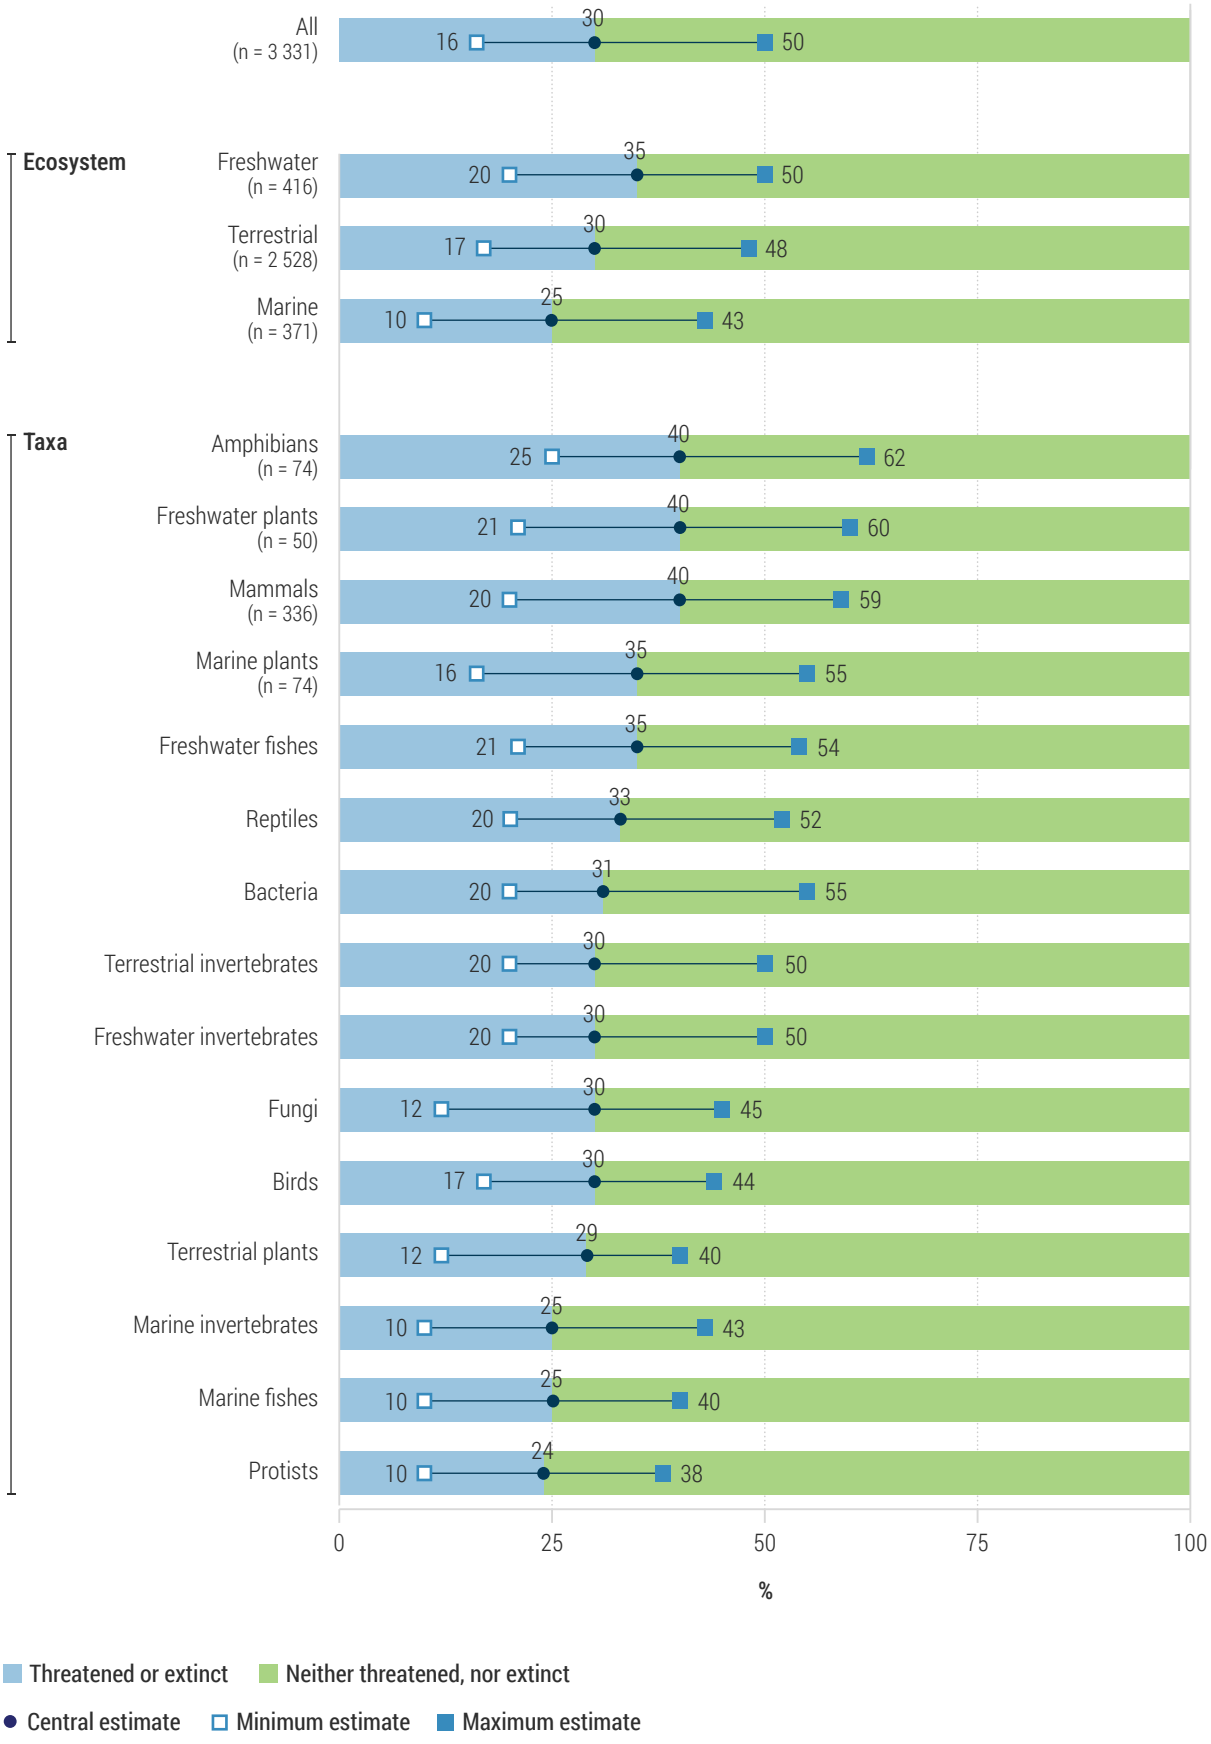
Source: Jain et al (2022)

Figure 4.13: Burned area and biomass of forests, grasslands, shrublands, and savannas globally

Source: FAOSTAT (2023)

biodiversity loss has an exponential trajectory and can occur much faster than expected and on a vast scale. If temperature rises from 1.5°C to 3°C, the risk of extinction for endemic species in biodiversity hotspots could increase at least tenfold. At 3°C, risks in many regions reach high or very high levels, suggesting widespread systemic impacts, irreversible change, and significant limits to adaptation. Warming increases the risk of species extinction and irreversible biodiversity loss in forest ecosystems and in Arctic regions (IPCC 2023).

The global rate of species extinction is increasing rapidly, with 30 per cent of species at risk of extinction, mainly in the tropics. This decline is driven by the loss of genetic diversity and the collapse of many wildlife populations (IPBES 2019). Biodiversity loss diminishes ecosystem functioning and nature's contributions to people by 10-70 per cent **(Figure 4.14)**.



Land use change and intensification of agricultural practices, climate change, pollution, invasive alien species (IPBES 2023), overexploitation and illegal trade are the main direct drivers of biodiversity loss (IPBES 2019; Van Der Putten et al. 2023) and diminishing ecosystem services, including resilience to pests, pathogens, pandemics, and climatic changes (Harvey et al. 2023). Human population dynamics and trends, technological innovations, production and consumption models, and local and global governance are powerful indirect drivers of biodiversity loss (IPBES 2019).

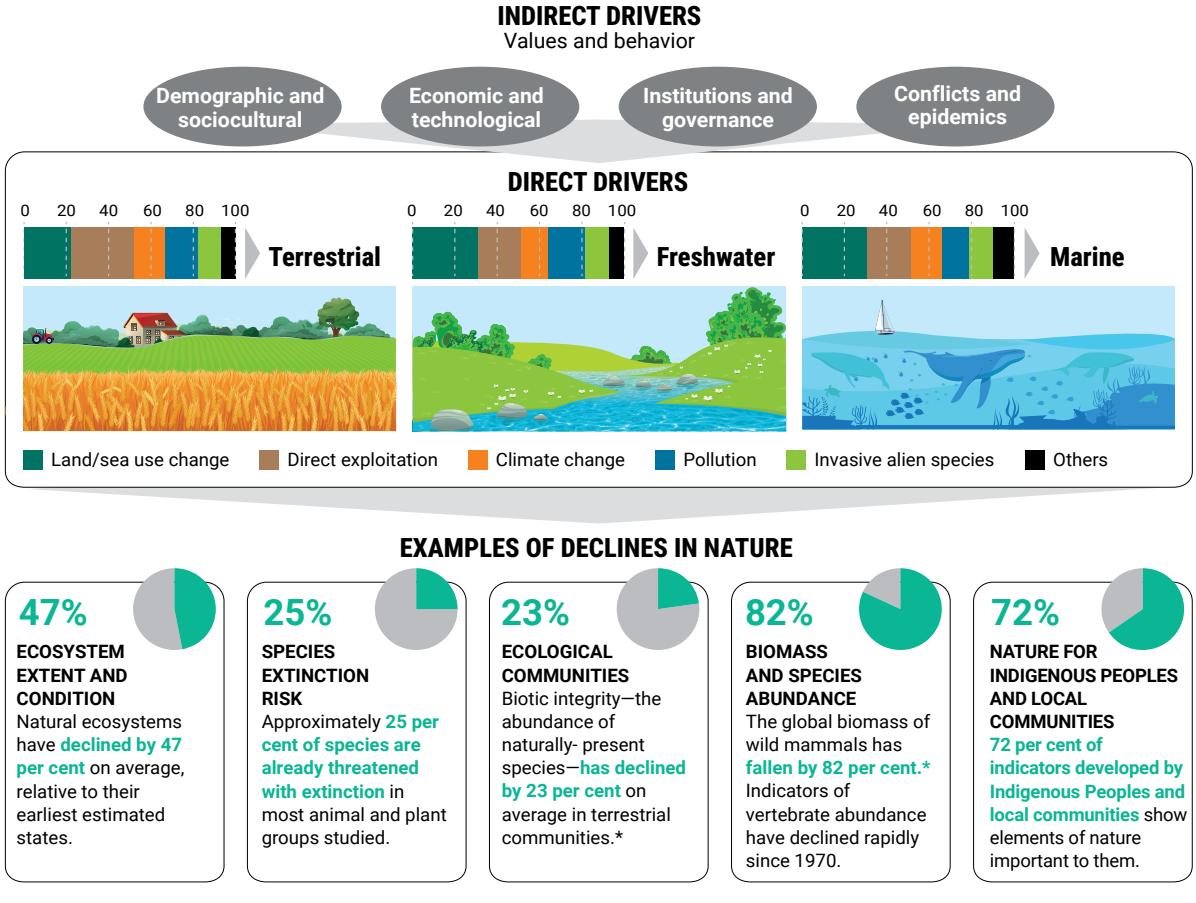
Terrestrial ecosystems provide essential services, but these are diminished due to the widespread biodiversity loss, especially in highly biodiverse areas, such as the Neotropics and Afrotropics. Climate change increasingly generates critical pressure, rivalling the impacts of land use change (Pereira et al. 2024).

An estimated 200,000 or 2.3 ± 1.7 per cent of the planet's 9 million species, including approximately 1.2 per cent of vertebrates, went extinct during the 20th century (Pereira et al. 2024). If current trends persist, another 1 million species are at risk of extinction (IPBES 2019). Despite considerable data gaps, particularly for terrestrial invertebrates, amphibians are considered the most at-risk group, followed by mammals, while birds are currently the least vulnerable (IPBES 2019).

Deforestation and agriculture (Pereira et al. 2024) are primary drivers of extinction for mammals and

Figure 4.14: Expert estimates of global biodiversity loss

Source: IUCN



amphibians in the northern boreal region, the Amazon and central Africa, which together support 62 per cent of the Earth's terrestrial biodiversity (FAO 2020; Pillay et al. 2022). Grasslands are affected by climatic extremes, land degradation, fires, and herbivory (Petermann et al. 2021). Mountain drylands and tundra are highly sensitive to climate change, and while less biotically rich, harbour many unique species adapted to extreme environments (Lewin et al. 2024; Maes et al. 2024).

Protected land area is increasing in some regions, but habitat loss continues globally; most protected areas are effective at halting the expansion of built-up areas but are not so successful in preventing deforestation and conversion to agricultural land (Li et al. 2024). The targets of the Kunming-Montreal Global Biodiversity Framework (Secretariat of the CBD 2022) for 2030 include halting the extinction of threatened species by 2050 and conserving 30 per cent of Earth's land and sea area by 2030.

4.3.4.1. Ecosystems

Protection of all 14 global terrestrial biomes and their 846 ecoregions has declined. Restoration through conservation strategies, including Indigenous-led strategies (Goolmeer et al. 2022) and the empowerment of Indigenous Peoples, could protect half the terrestrial realm by 2050, while supporting livelihoods (Dinerstein et al. 2017). **Figure 4.15** illustrates the main direct and indirect drivers of biodiversity loss. Key indicators show significant declines in biomass and species abundance, including an 82 per cent drop in global wild mammal biomass and a 23 per cent decline in naturally occurring species, with cascading effects on ecological and terrestrial communities (Diaz et al. 2019; Declerk et al. 2023). Biodiversity loss, such as declines in insect populations and changes in density and composition linked to climate change and air pollution, diminishes ecosystem functioning and nature's contributions to people, including the

Figure 4.15: Biodiversity loss: drivers and examples of loss in nature

* Since prehistory

Source: Diaz et al (2019)

potential to rehabilitate degraded lands and restore land biodiversity and ecosystem health (Isbell et al. 2023; Harvey et al. 2023).

Biodiversity loss threatens human well-being and ecosystem health through land degradation and food insecurity (Diaz et al. 2006; Malhi et al. 2020; Read et al. 2022; Petrosillo et al. 2023). Land degradation drives biodiversity loss, contributing to climate change and inducing poverty. Land degradation harms habitats, ecosystems' adaptive capacity, and their ability to provide ecosystem services, while it exacerbates biodiversity loss, environmental hazards, poverty and climate change (Ekka et al. 2023). The growing demand for export commodities for foods, livestock feed, and biofuel drives land degradation and biodiversity loss (Santini et al. 2022; Hughes et al. 2023).

Large-scale, intensive, unsustainable practices, such as biofuel production and rapid land use change, contribute to biodiversity decline. Driven by the need to feed livestock and satisfy booming demands for meat, croplands are now expanding 58 times faster than 20 years ago (Meng et al. 2023). On the other hand, sustainable livestock and grazing management can play a positive role in food security and support ecosystems (Leroy et al. 2022; Escobar and Ferrari 2024).

Biodiversity loss has hindered our ability to achieve the Sustainable Development Goals (SDGs) (Adebayo 2019). Addressing this challenge requires solutions that improve resources efficiency and build resilience to climate change, boosting ecosystem services and human well-being (Santini et al. 2022; Petrosillo et al. 2023). Established in 1993 and signed by 196 nations, the United Nations Convention on Biological Diversity plays a central role in tackling biodiversity loss and promoting conservation efforts.

4.3.4.2. Species loss

According to the Red List, released annually by the International Union for the Conservation of Nature (IUCN), the conservation status of only 2 per cent of invertebrates, 17 per cent of plants, and 0.5 per cent of protists and fungi have been assessed (IUCN 2024). Updated reports show 241 mammals, 223 birds, and 798 amphibians as Critically Endangered. Hunting and trapping are prominent drivers of bird and mammal biodiversity loss (World Wildlife Fund 2022). Nearly 39.5 per cent of plant species are at risk of extinction, with many newly identified species are already endangered (Antonelli et al. 2023). Declines in plant and fungal diversity, as well as in detritivores that support plant diversity by feeding on decomposing organic matter, weaken ecosystem resilience (Rubio-Ríos et al. 2021).

Areas from the Himalayas, the dry forests of Madagascar, and the Amazon basin, among others, are high-priority areas for biodiversity conservation (World Wildlife Fund 2022). The Living Planet Index shows that there has been a 73 per cent decline in the average size of monitored populations between 1970 and 2020, with wild mammal populations dropping by 85 per cent, despite representing only 4 per cent of all species (World Wildlife Fund 2024). Tropical forests host 62 per cent of global terrestrial vertebrate species, more than double the biodiversity of any other biome on Earth. Up to 29 per cent of global vertebrate species are endemic to tropical forests, over 20 per cent of these species are at risk of extinction (Pillay et al. 2020).

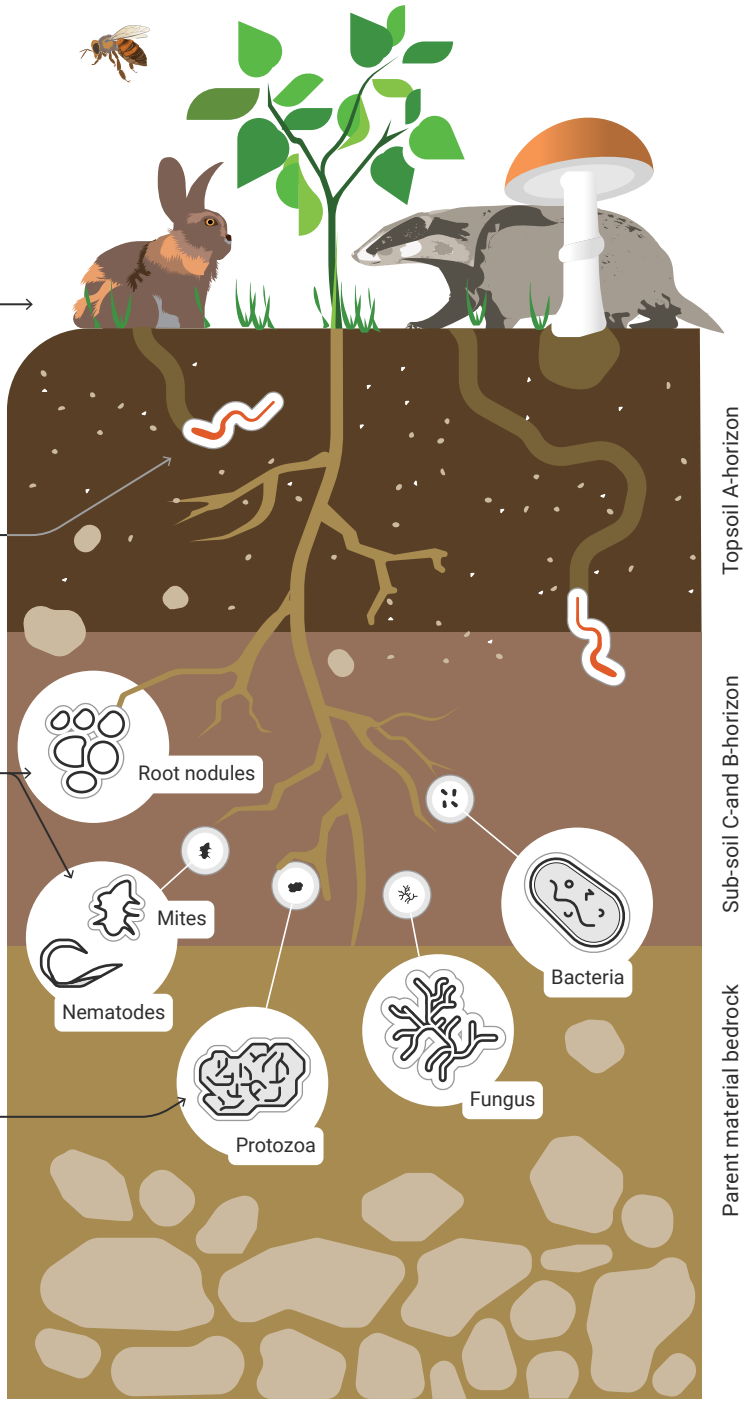
4.3.4.3. Genetic diversity

Genetic composition can be observed at four levels: species as differentiation in the sense of number and distance of genetic units; populations as diversity richness and heterozygosity; inbreeding and effective population size; and individuals' diversity and heterozygosity) (Hoban et al. 2022). Genetic diversity is increasingly threatened by habitat fragmentation and destruction; resource overexploitation of forests, peatlands, and grasslands; and other anthropogenic activities, including creation of genetically modified seeds, with significant social and cultural implications (Jaques and Jaques 2012). Protecting genetic integrity of populations is crucial for biodiversity conservation (Hoban et al. 2023). Recent DNA-based studies report high genetic variability loss in the past 50 to 100 years, including 28 per cent loss in island species and 14 per cent in harvested fish species (Leigh et al. 2019). The Kunming-Montreal Global Biodiversity Framework (Secretariat of the CBD, 2022) emphasizes the importance of conserving diversity among and within populations of all species, re-establishing genetic connectivity, and developing national genetic conservation strategies and indicators to monitor policy progress (Hoban et al. 2023). Despite ongoing population declines due to habitat destruction or other factors, off-site seed banks remain crucial for preserving plant genetic diversity and enabling the reintroduction of endangered, rare, and extinct species (Wambugu et al. 2023).

4.3.4.4. Soil biodiversity

Soil is likely home to over 50 per cent of life on Earth, from microbes to mammals (Anthony et al. 2023), making it the most biodiverse habitat and the main global reservoir of biodiversity **(Figure 4.16)**. A single gram of soil can contain more than 40,000 different organisms (FAO 2020). Soil biota play a vital role in nutrient dynamics, carbon sequestration and biodiversity (Labouyrie et al. 2023). While only 1 per cent of soil biodiversity is known, it underpins ecosystem health and is pivotal for most ecosystem services, such as food supply, human health, and climate control (Angst et al. 2019; Maaroufi et al. 2020; Coyne et al. 2022). Specific measures that can be undertaken to preserve and enhance native soil biodiversity (FAO 2017) and the risk of soil biodiversity loss are available and must always be considered (Tibbett et al. 2020). Unfortunately, soil biodiversity remains underrepresented in the international,

Figure 4.16: The complex nature of soil biodiversity



Plants support a hidden ecosystem of soil-dwelling organisms, which in turn nourish and safeguard them.
This rich variety of life maintains the soil's vitality and productivity. Known as soil biodiversity, this intricate web of life drives essential biogeochemical cycles that sustain life on our planet.

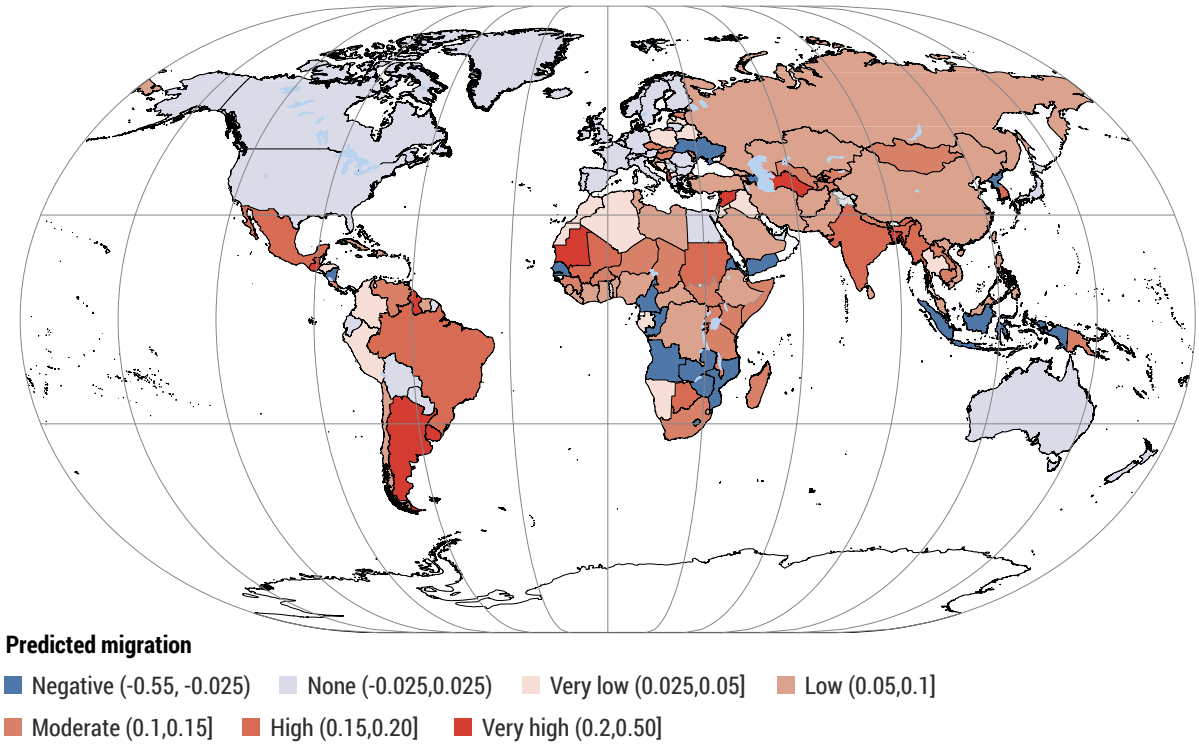
national and regional IUCN Red Lists, despite its importance.

4.4 Impacts of natural ecosystems on human well-being and human systems

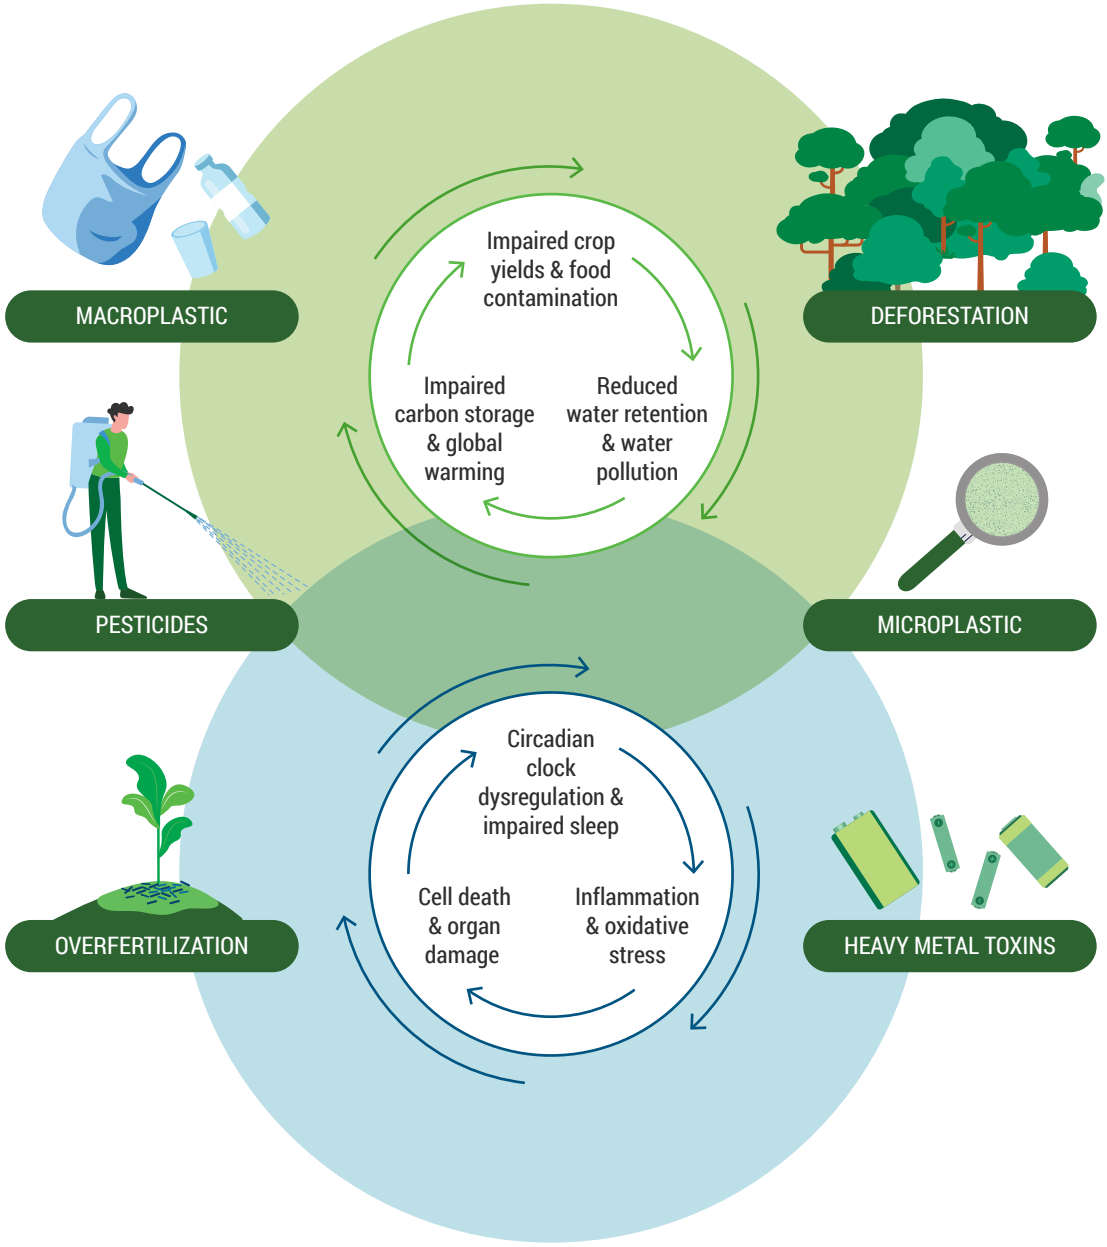
4.4.1 Impacts on human health and well-being



Land use changes significantly affect various aspects of human well-being, including physical and mental health, financial and job security, and social and spiritual needs. Deforestation, agricultural expansion, soil degradation and desertification, permafrost thawing, biodiversity loss, and extreme events all contribute to these impacts. While migration can be seen as a traditional reaction to environmental change, (Hsiao et al .2024) environmental degradation, along with wars and conflicts, has displaced tens of millions of people, leading to a growing number of environmental refugees (Myers 2002; Internal Displacement Monitoring Centre 2023; UNEP 2023b; Kaczan and Orgill-Meyer 2020), particularly affecting developing countries **(Figure 4.17)**.

Shortages of clean water and nutritious food pose serious risks to human health (WHO 2023; De-la-Torre 2020). In 2022, 735 million people experienced hunger, 258 million faced acute food insecurity (WHO 2023a), and another billion were obese. Growing evidence suggests that long-term exposure to microplastics in drinking water, food, and the environment may also pose risks to human health (WHO 2023b; Münzel et al. 2023) **(Figure 4.18)**.

Wildfire exposure is linked to several health issues, including respiratory and infectious diseases, cardiovascular mortality, reduced lung function, mental disorders, and stunted growth of children (Gao et al. 2023). These risks will likely increase as climate change advances (Clarke et al. 2023). Severe droughts increase the likelihood of dust storms linked to various respiratory diseases (Schweitzer et al. 2018). Thawing permafrost elevates the risk of exposure to bacterial, fungal, and viral pathogens currently trapped in permafrost (Miner et al. 2021) and the increased mobility of contaminants.



Access to green space significantly benefits physical and mental health. For instance, improving the distribution of green spaces in Barcelona could

Figure 4.17: Predicted environmental migration worldwide measured in standard deviation changes in migration

Figure 4.18: Implications of human health affected by agricultural management practices

Source: Münzel et al. 2023

prevent 178 premature deaths each year (Iungman et al. 2025). Sustainable and climate-resilient planning, especially with adequate tree cover, can help mitigate the impacts of climate change, including premature deaths linked to the urban heat island effects (UNEP and the United Nations Human Settlements Programme 2021, Iungman et al. 2023).

Studies have found links between proximity to rich biodiversity and reduced depression (Cox et al. 2017), lower blood pressure (Lindemann-Matthies and Matthies 2018), self- perceived restoration (Hoyle et al. 2019; Hussain et al. 2019), and self-reported health and well-being (Houlden et al. 2021; Mavoa et al. 2019; Mavoa et al. 2019b). These benefits are often more pronounced in groups with low socioeconomic status (Rigolon et al. 2021), yet such communities frequently have limited access to green spaces (Rigolon et al. 2016; Rigolon et al. 2018; Sun et al. 2022), as do ethnic minority communities (Comber et al. 2008; Dai et al. 2011; Liu et al. 2021), and youth and older people (Sikorska et al. 2020). In the context of Indigenous Peoples, access to land is a fundamental factor of well-being (Tsuji et al. 2023). In this context, soil and land degradation must be viewed from a political economy lens, particularly regarding the role of large enterprises and agribusiness (Blaikie 1985).

4.4.2 Land systems, economy and equity.

Land degradation reduces agricultural productivity, income, livelihoods, and resilience and can provoke social tensions. It affects millions of people's lives, with economic losses reaching up to US$ 10.6 trillion annually (Le et al. 2017), approximately 10 per cent of the global gross domestic product (IPBES 2018).

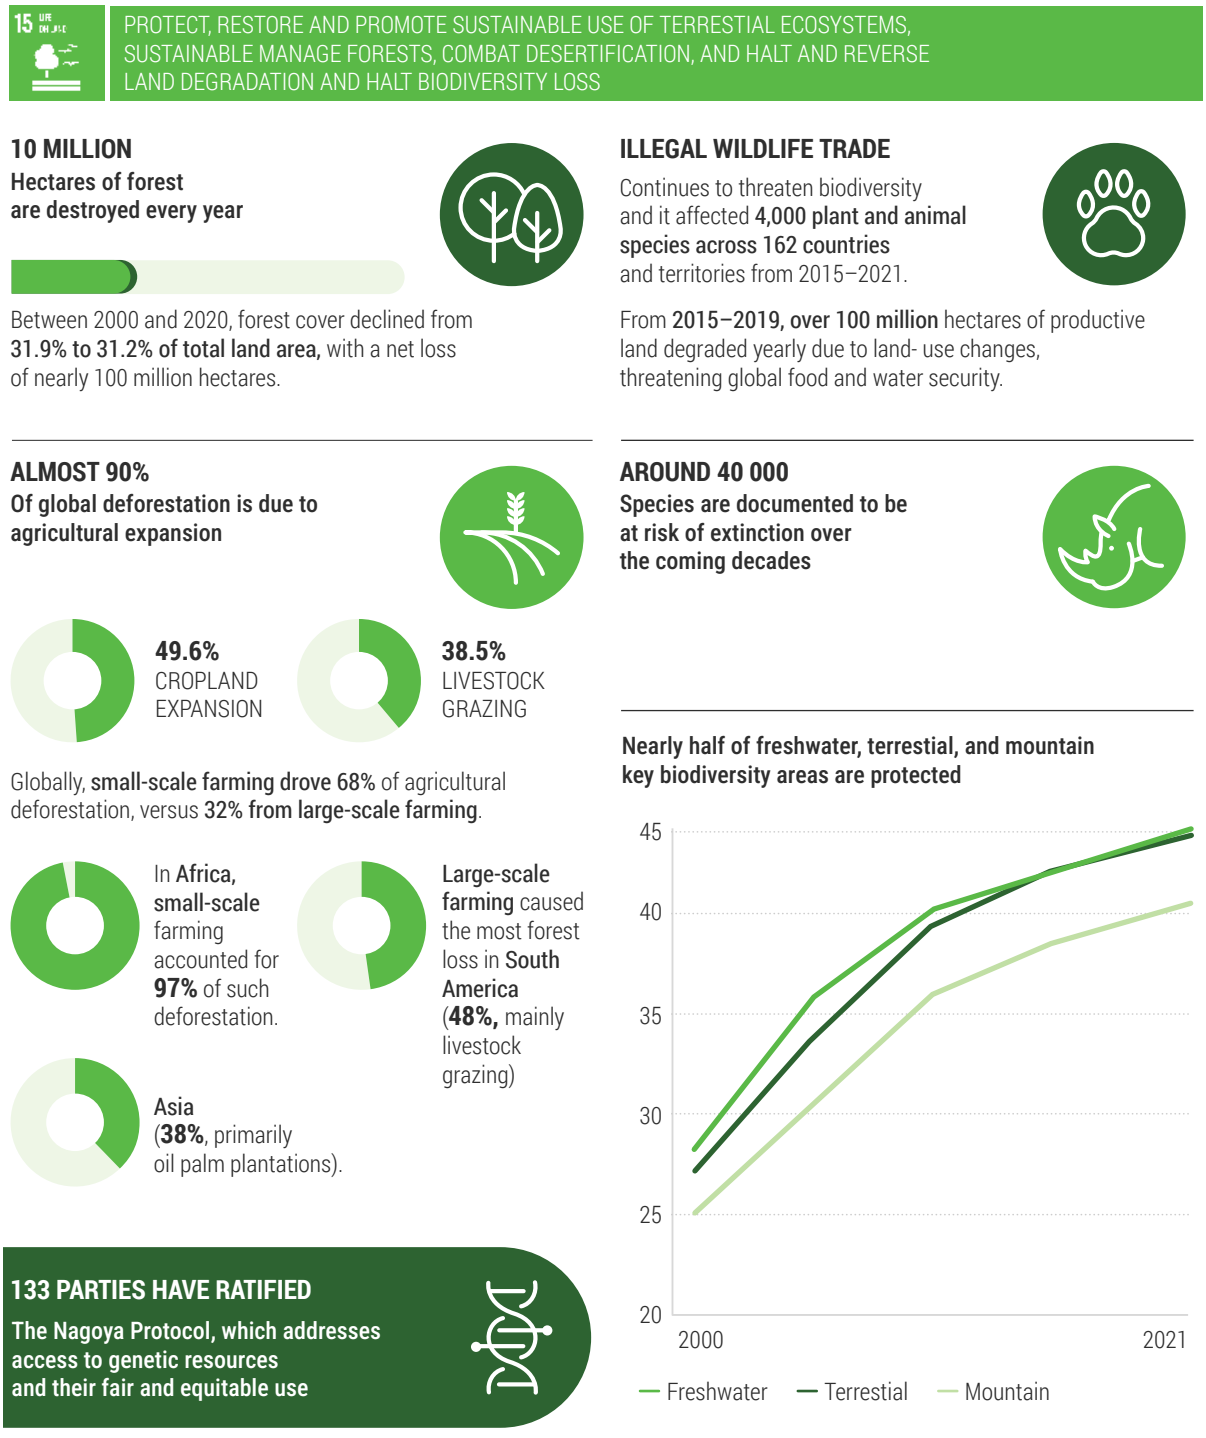
Issues with land availability and ownership, including land grabbing that is often driven by international capital markets, are closely related to gender inequalities. In many contexts, women and men have different roles, responsibilities, and dependencies on land. Women are disproportionately affected by biodiversity loss, facing higher domestic work burdens, income loss, declining health, increased exposure to gender-based violence, eroded cultural and traditional knowledge, and poorer well-being overall (Booker et al. 2022). For example, in India in the Nilgiri Biosphere Reserve, market-driven expansion of chemically intensive agriculture and monoculture tea plantations encroached on Indigenous lands (Sudhakar Reddy et al. 2018), disrupting ecosystem services, soil and forest health, and local livelihoods for both women and men (Krishnakumar and Roy 2021; Tsuji et al. 2023).

Women's extreme poverty is driven by multiple factors, including insecure land rights, limited access to finance and technology, poor market conditions, and structural gender inequality, such as underpaid or unpaid labour (UNEP 2016). Despite these challenges, women have proven to be effective land stewards and managers. In developing countries while facing desertification, land degradation and drought, women produce up to 80 per cent of the food (FAO 2011). UNCCD's Gender Action Plan 2018-2030 (UNCCD 2018) is a powerful and strategic tool aimed at transforming the livelihoods of millions of families.

4.5 Progress towards internationally agreed environmental goals

The SDG 15: Life on Land focuses on managing forests sustainably, halting and reversing land and natural habitat degradation, combating desertification, and stopping biodiversity loss. **(Figure 4.19)**. Targets 15.1 and 15.4, related to global protected and conserved area coverage of terrestrial and mountain ecosystems, showed substantial improvements before 2000, but this growth has stagnated over the last two decades. Particularly worrying are Central, South and West Asia, and North Africa, where less than 30 per cent of Key Biodiversity Areas are protected (United Nations Department for Economic and Social Affairs 2024). In contrast, countries in North America, Europe, Sub-Saharan Africa, Latin America and the Caribbean, as well as Australia and New Zealand have increased their protected Key Biodiversity Area coverage to over 40 per cent (United Nations Department for Economic and Social Affairs 2021).

4.5.1 Land degradation neutrality



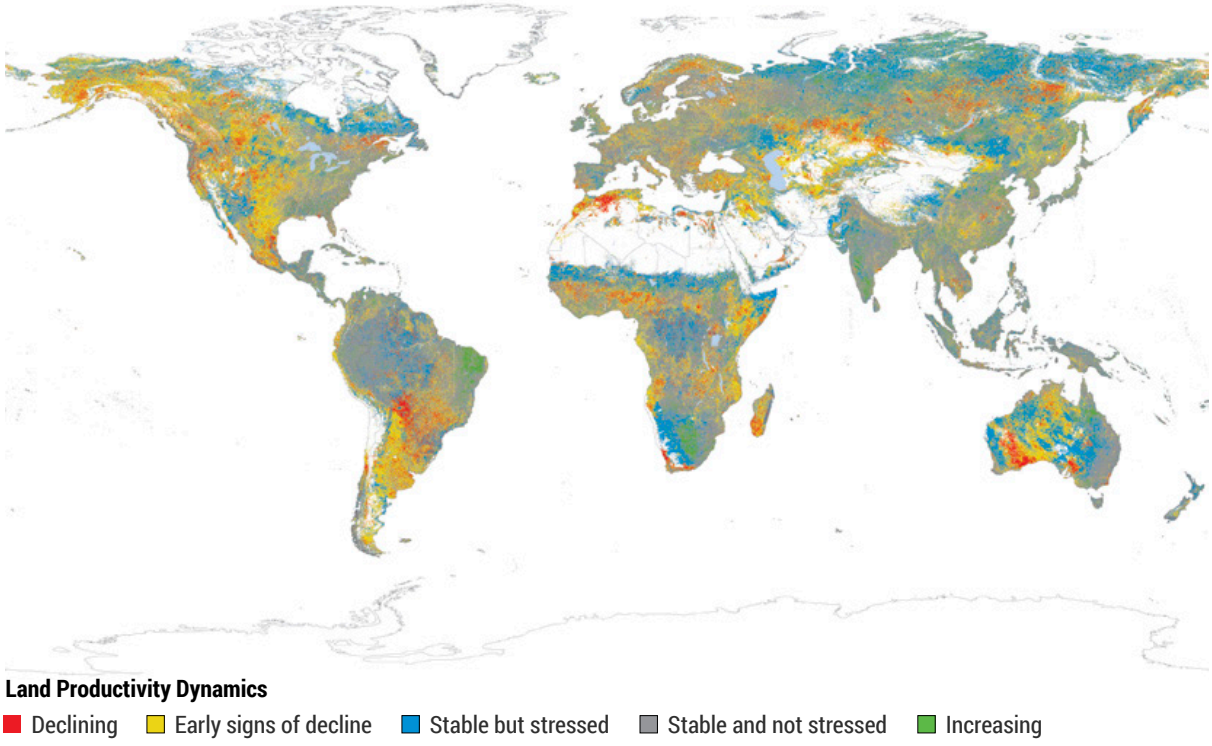
The SDG target 15.3 is: "By 2030, combat desertification, restore degraded land and soil, including land affected by desertification, drought and floods, and strive to achieve a land degradation-neutral world." It is monitored through indicator SDG 15.3.1., which the UNCCD tracks by using trends in land cover, land productivity, and carbon stocks above and below ground (Sims et al. 2021). Land productivity is estimated by Net Primary Productivity, represented in kg/ha/yr. Land cover is assessed using local knowledge and observed land degradation trends, while soil organic carbon is assessed based on land cover over 20 years.

Global Earth observation systems provide key metrics for tracking changes in land productivity and land cover dynamics. The results for each Target 15.3 sub-indicator are integrated using a "one-out-all-out" method, where if any one metric shows decline, the entire area is classified as degraded (Teich et al. 2019; Teich et al. 2023). The one-out-all-out approach has limitations: it can be overly sensitive to short-term fluctuations and may potentially overlook localized improvements, suggesting the need for complementary methods to depict a more nuanced picture.

These criteria align with the concept of land degradation neutrality (UNCCD 2016, Decision 3/COP12). The neutrality principle allows for trade-offs among competing interests across a landscape (Orr et al. 2017), and it supports coordination between the mandates of the three Rio Conventions to which land is central.

To support achieving this objective by 2030, the UNCCD Global Mechanism established the Land Degradation Neutrality Target Setting Programme, resulting in

Figure 4.19: Status of SDG 15 and the main issues of concern



Source: UNSTATS

voluntary commitments to restore over 450 million hectares of degraded land. However, the world is falling short on reaching land degradation neutrality by 2030. Indicators show worrying trends in land degradation with declining land productivity (**Figure 4.20**) (Li et al 2025), worsening land cover, and slowing growth of soil organic carbon stocks (FAO 2024c)

Based on present trends, SDG Target 15.3 is unlikely to be met by 2030, unless further action is taken to avoid, reduce, and reverse land degradation, indicating that land governance is the main obstacle (Debonne et al. 2021). Strengthening governance frameworks and implementing reforms could enhance accountability and performance, while

Figure 4.20: A 30-meter resolution global land productivity dynamics dataset from 2013 to 2022

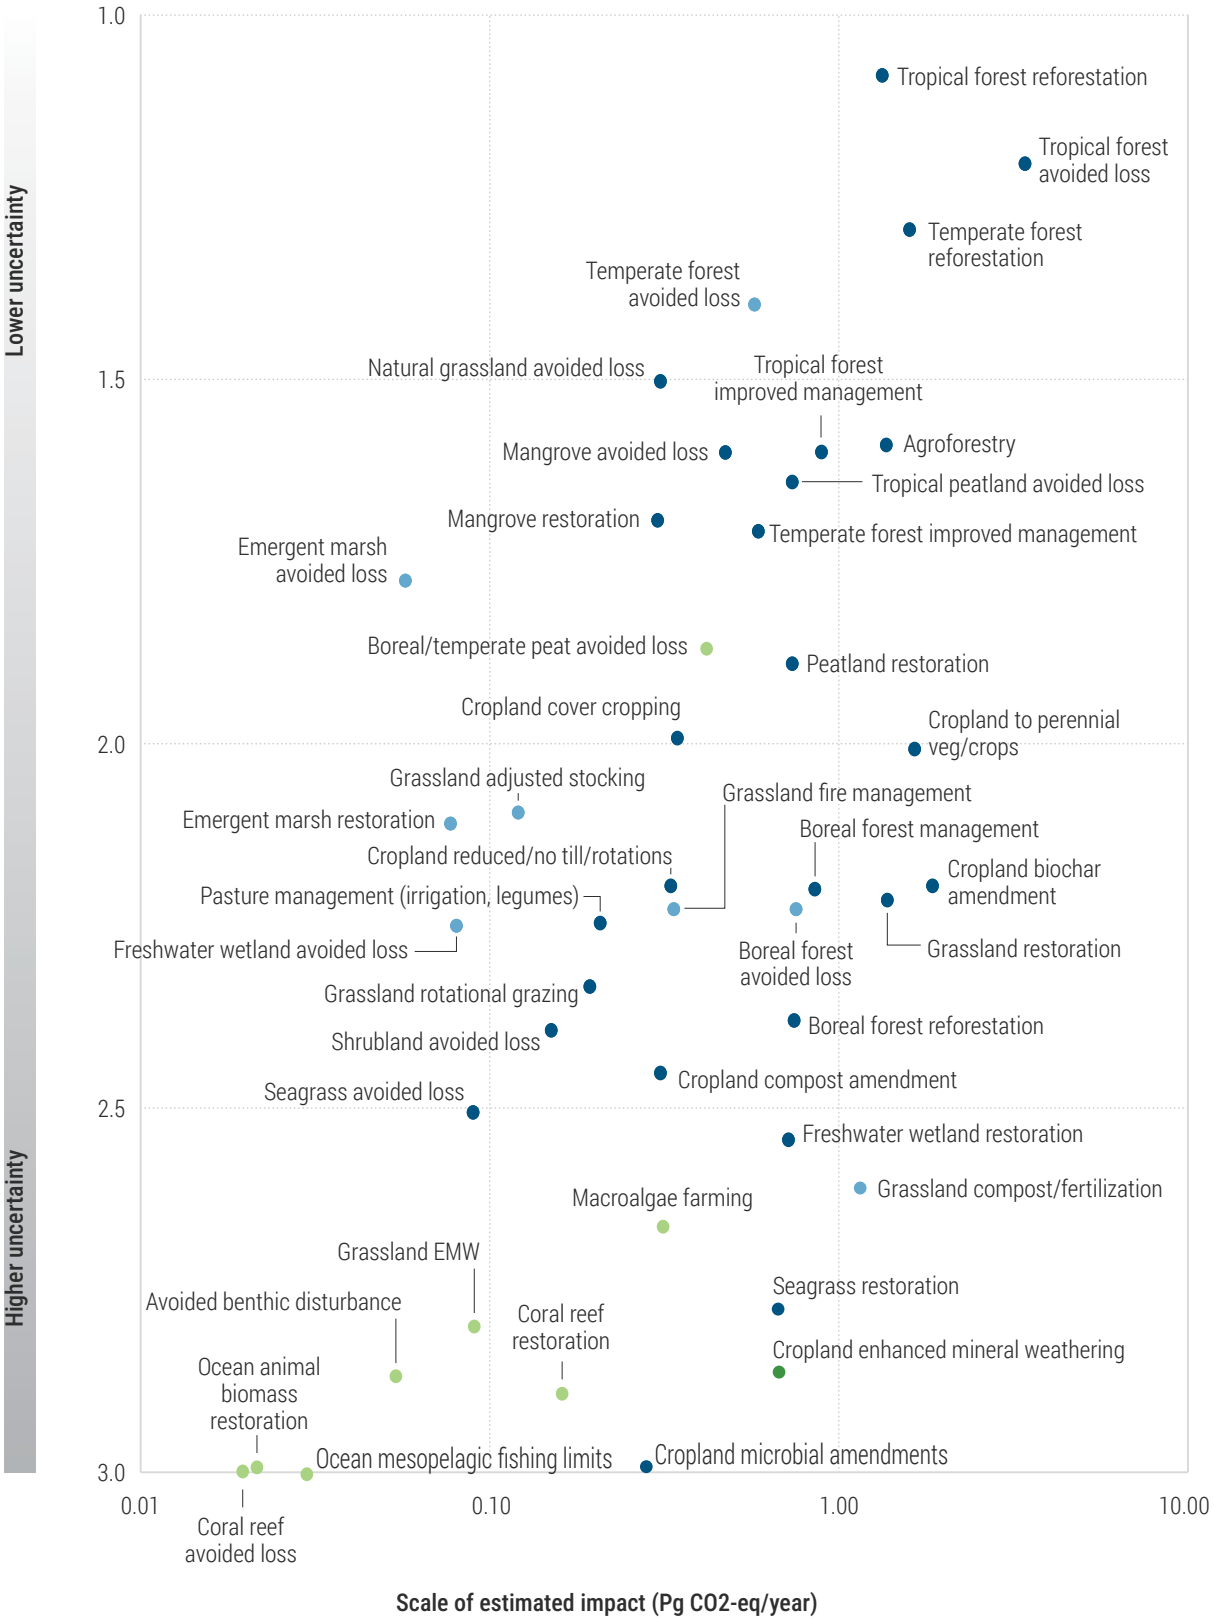
Source: Li et al, 2025

using such emerging technologies as artificial intelligence could have profound implications for addressing land and soil environmental challenges, including land degradation neutrality. Furthermore, international financial support is needed for developing countries to achieve these goals.

4.5.2 Achieving the Paris Agreement through land-based solutions

Article 5 of the Paris Agreement reinforces the role of land use activities in climate change mitigation, building on the 2013 UNFCCC COP19 Framework for REDD+, which provides key guidance on several essential aspects of REDD+ implementation. At COP27 in 2022, parties also launched joint efforts to implement climate action on agriculture and food security. According to the IPCC 6th Assessment Report, the Agriculture, Forestry and Other Land Use sector holds the most significant mitigation potential between 2020 and 2050, particularly targeting measures in forests and other natural ecosystems (IPCC 2022b).

Nature-based solutions aim to increase carbon sequestration and reduce greenhouse gas emissions, while delivering benefits to human well-being, ecosystem services, resilience and biodiversity. Nature-based solutions often combine various actions to protect, conserve, restore, and sustainably manage natural or modified terrestrial, fresh water, coastal and marine ecosystems (Nolan et al. 2021, Sun et al. 2024). Nature-based solutions could deliver up to 30 per cent of the emission reductions needed to meet the 2°C target (Griscom et al. 2017) and reduce peak warming by 0.3°C this century (Girardin et al. 2021).



However, land-based mitigation needs to consider ecological limits, taking biodiversity impacts and conservation into account (Deprez et al. 2024). A recent study by Buma et al. 2024 identified the types of nature-based solutions that are supported by scientific evidence and those lacking demonstrated effectiveness **(Figure 4.21)**.

4.5.3 International conventions on chemical and waste pollution

Fuller et al. (2022) summarized progress on addressing chemical pollution: "We cannot continue to ignore pollution. We are going backwards."

While international agreements for managing pollution tend to be generic and broad in scope by addressing

Figure 4.21: Mean categorization of each nature-based solution pathway and its scale of estimated potential impact

Source: Buma et al. (2024)

pollution occurring in air, soil or water, some of them target specific pollutants, such as solid waste.

The Basel Convention covers a range of hazardous wastes and their effects on human and environmental health. Considering that plastic pollution has a footprint in every stage of its life cycle, the Convention adopts actions to assist in managing plastic waste (Secretariat of the Basel Convention 2023). It also emphasizes the management of transboundary waste.

Disposal of electronic waste generated in one country and transferred to another raised concerns, often due to a lack of capacity building, regulatory harmonization, and unclear responsibility (Shittu et al. 2021).

The Global Framework on Chemicals, a voluntary initiative, provides a comprehensive plan to manage chemicals across their entire lifecycle and enable a holistic approach. With five strategic objectives and 28 targets, it promotes stakeholder collaboration in phasing out harmful chemicals, enhancing capacity building, and fostering connections across the health, agriculture, energy, and transport sectors.

The success of these conventions and agreements heavily depend on the number of participating countries and their levels of compliance. For example, even though many developing countries are signatories of the Basel Convention, some continue to import hazardous toxic waste, mainly due to socioeconomic pressures, which has caused them to become the dumping ground for wealthier countries. The United States of America is a signatory without ratification, exempting a major waste-producing country from obligations (Kummer 2000; Shukla 2020).

4.5.4 Biodiversity Targets 2011-2020 and the Kunming-Montreal Global Biodiversity Framework 2022-2030

In 2010, Parties to the Convention on Biological Diversity agreed on a Strategic Plan for Biodiversity 2011-2020, setting the 20 Aichi Biodiversity Targets. These targets aimed to tackle the fundamental drivers of biodiversity loss, address direct pressures on biodiversity, improve the status of biodiversity, enhance biodiversity benefits, and accelerate implementation. Each target included several components.

In summary, by 2020, none of the 20 Aichi Biodiversity Targets were fully achieved, while for three targets, there was insufficient data to assess progress (IPBES 2019). Notable setbacks included a steep decline in monitored populations of birds, mammals, reptiles and fish between 1970 and 2016. While biodiversity financing has doubled, these advances were overshadowed by activities harmful to biodiversity, such as fossil fuel extraction and use and agricultural subsidies (Secretariat of the CBD 2020).

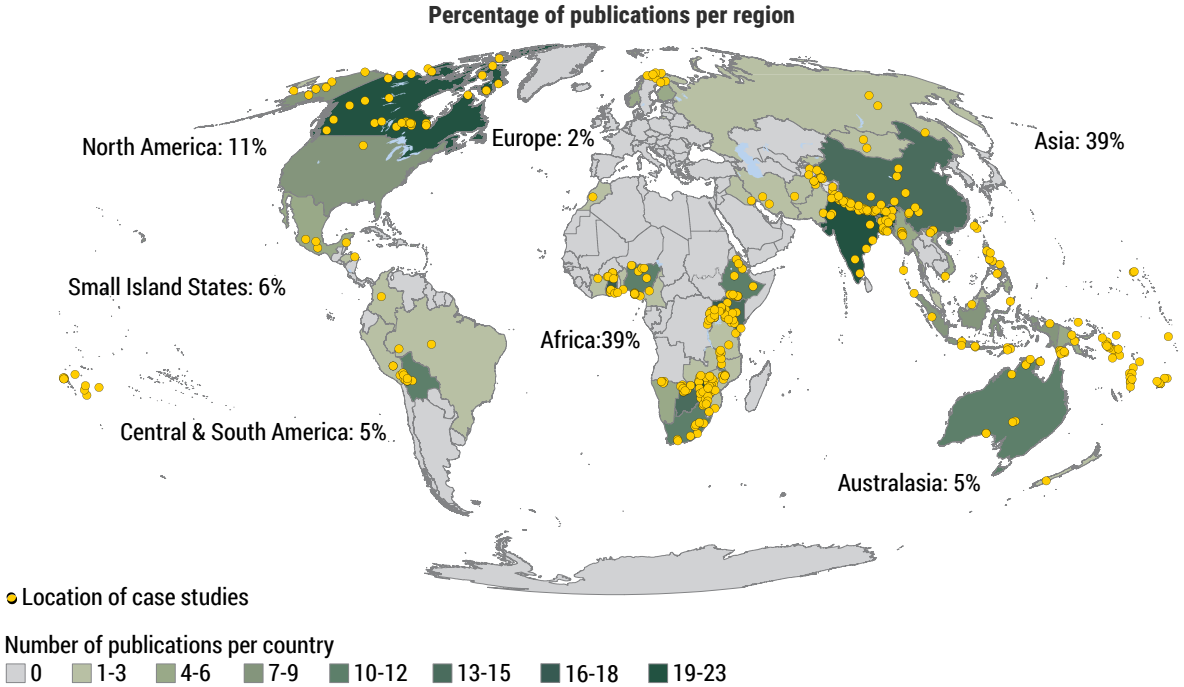
Nonetheless, there were some positive developments. Conservation actions have prevented some extinctions, protected area coverage increased both on land and at sea, and many countries developed national biodiversity strategies and action plans, including those for the recovery of fish stocks in well-managed fisheries. However, the overall trend was negative, with 12 of 16 indicators used for reporting showing significantly worsening trends.

The Kunming-Montreal Global Biodiversity Framework was adopted in 2022, replacing the Aichi Targets. It includes 23 targets, four overarching goals, and a monitoring framework endorsed at COP 15 in 2022. An interim assessment of global progress towards these targets is pending; however, some of the headline indicators adopted are already operational. For example, as of 2024, 17.4 per cent of Earth's terrestrial and inland waters have been protected or conserved, an increase from 16.6 per cent at the beginning of the decade. (UNEP-WCMC and IUCN 2024). These indicators relate to Target 3, which is to protect 30 per cent of land, waters, and seas by 2030.

4.6 Indigenous as well as Local Knowledge in land and soil management

Indigenous Communities as well as local communities, particularly Indigenous women (Kermoal and Altamirano-Jiménez 2016; Snehlata et al. 2020), deeply understand their environments, including environmental changes related to their daily activities. For instance, Indigenous Communities in the Pachmarhi Biosphere Reserve of India have developed their own soil classification system and apply it to land-use decision-making in crop production systems (Kala 2013). Similarly, Indigenous savannah communities in Ghana use such indicators as the presence of specific plants, plant vigour, soil colour, texture, tilth, and compaction to understand soil health and adjust land management (Omari et al. 2018). Farmers in Uganda use biotic environmental signals for climate forecasts and early

warning systems, shaping their crop and livestock management practices (Nkuba et al. 2020a, 2020b).



Examples of long-term sustainable land management include Inca platforms in Altiplano, Peru, the terraces of Cinque Terre in Italy, the tea terraces of Sri Lanka, and the agroforestry practices in the Amazon (Gebara 2023). Apple growers in the Himalayas successfully adapt to climate change (Vedwan 2006). Indigenous Knowledge has enabled Indigenous Communities to survive in harsh climates, from the arid oases of Africa with only 50 mm of rain to the icy and rocky landscapes of Greenland. This rich knowledge is based on the sustainable management of the agroecosystems inhabited by communities deeply connected to their land (Santini and Miquelajauregui 2022). These lands are usually rich in agrobiodiversity, supported by traditional knowledge, and constitute invaluable cultures and landscapes that are sustainably managed by farmers, herders, fishers, and forest people in ways that contribute to their livelihoods and food security (FAO 2024a).

Nevertheless, despite its recognized value, Indigenous Knowledge and Local Knowledge are rarely integrated into mainstream land management planning, and when it is, the local communities are unlikely to benefit. The World Overview of Conservation Approaches and Technologies and FAO's Globally Important Agricultural Heritage Systems aim to collect and preserve traditional practices for future generations. Yet, studies of Local Knowledge on climate adaptation mostly concentrate on a few regions **(Figure 4.22)** (Petzold et al. 2020), leaving Local Knowledge in much of the world unrepresented.

In Indigenous Communities, biodiversity is significantly better preserved than in typical agricultural landscapes (Farrell et al. 2021). Data from Australia, Brazil and Canada shows that Indigenous-managed lands have equal or higher biodiversity than officially designated protected areas, mainly due to sustainable land management (Fa et al. 2020). Land management practices used by Indigenous Peoples include traditional burning, fishing traps, and forestry practices that are often uniquely adapted to local ecosystems. This wealth of knowledge can also be incorporated into the ecological restoration of degraded lands. Furthermore, integrating Indigenous Knowledge in conservation efforts can safeguard cultural diversity (Levis et al. 2024).

Unfortunately, the benefits of Indigenous Knowledge rarely flow back to community members. This disconnect can be attributed mainly to a lack of recognition of Indigenous governance that promotes land

Figure 4.22: Global distribution of publications on Indigenous Knowledge and Local Knowledge in climate change adaptation practices. Each yellow dot is a case study

Source: Petzold et al (2020)

stewardship (Fernandez-Llamazares et al. 2024). According to the International Fund for Agricultural Development (2024), between 2011 and 2020, less than 1 per cent of climate finance supported Indigenous land and tenure management. Additionally, failure to uphold the principles of "free, prior and informed consent" and "do no harm" in land-use decisions and resource extraction contribute not only to resource exploitation and land degradation, but also to the appropriation of Indigenous Knowledge, particularly using digitization techniques (Smyth et al. 2020). Inequitable benefit sharing, despite the Nagoya Protocol, contributes to the overall vulnerability of Indigenous Peoples (IK and LK Dialogues 2025).

Gebara (2023) surveyed representatives of the Indigenous Communities in the Brazilian Amazon on their concerns about the bioeconomy, using as a case study the traditional medicine kambo, derived from the secretion of a tropical frog. The study unveiled significant concerns regarding the transfer of Indigenous Knowledge and Local Knowledge, along with general mistrust towards protective initiatives. Another study (den Braber et al. 2024) revealed that incomes in Indigenous territories were as much as 36 per cent lower than in areas with other land uses, underscoring the trade-offs decision makers face when establishing and expanding forest conservation projects.

Globally, Indigenous Peoples manage or hold tenure rights to a quarter of land (Garnett et al. 2018). This intersects with 40 per cent of ecologically intact and protected territories (Garnett et al. 2018). However, at least 16 per cent of Indigenous-managed land is at risk globally from future development and resource extraction.

On Indigenous-managed lands, outsiders deforest areas frequently without consent (Fa et al. 2020), leading to the loss of life, land, livelihoods, and conflicts over land. Between 2009 and 2019, more than 300 people, many of whom were members of Indigenous Communities, were killed in land-use disputes in the Amazon (Gómez-Upegui 2021). Restrictions on hunting and fishing, integral to the Indigenous way of life, further jeopardize their lives and livelihoods (Schuster et al. 2019).

Crucially, Indigenous Knowledge holds transformative potential for creating a shared vision of a prosperous future for all and ways to shift the current trajectories of climate change, environmental degradation and broader planetary crisis (van Velden et al. 2025).

Chapter summary

Credit: tan4ikk/Envato

The global oceans and coastal ecosystems are undergoing accelerated degradation *(well established)*. The global ocean, with its coastal seas, covers more than 70 per cent of the Earth's surface. It absorbs around 25 per cent of anthropogenic carbon dioxide emissions, regulating the Earth's climate system and supporting 90 per cent of the planet's biosphere. Temperature increase, pollution, deoxygenation, acidification, over-exploitation and habitat destruction are altering the distribution, abundance and behaviour of marine organisms, often synergistically. Ocean warming – including the effects of marine heatwaves, altered seasonality and increased storm activity – destroys habitats and disrupts the life cycles of many species {5.2.3}.

Notably, polar and tropical species are severely affected. For example, 99 per cent of coral reefs are predicted to be lost if global temperatures rise by 2°C. Species' range shifts from tropical and subtropical to temperate regions are increasingly common and can introduce non-native species and pathogens. These range shifts, combined with human activities via aquaculture and shipping, are changing marine food webs, marine ecosystems, and thus human livelihoods and food sources. Ocean acidification affects the shells and skeletons of marine organisms, leading to a loss of species fitness, and death. Ocean deoxygenation, often from increased wastewater and organic material inputs, can result in hypoxic zones that impede marine life {5.2.2.2; 5.2.3}. Pollution from sewage, agriculture, aquaculture and industry continuously and severely contaminates the marine environment. Sea level rise and associated saltwater intrusions into soil and groundwater are causing coastal habitat and land loss. Coastal ecosystems such as mangrove forests, saltmarshes, macroalgal forests and seagrass meadows are threatened by sea level rise, habitat destruction, land degradation and polluted coastal run-off {5.2.3}.

Climate change, biodiversity loss, land degradation and pollution continue to drive significant physical, chemical and biological changes *(well established)*.

Climate change is causing accelerated ocean warming, acidification and sea level rise {5.2.1}. Marine heatwaves have doubled in frequency and intensity

since 1982, with some areas predicted to experience near-permanent heatwave conditions by the late 21st century, under high-emission scenarios. Marine heatwaves have significant implications for the ocean-weather system {5.2.1.1}. The ocean has become 26 per cent more acidic as the pH has decreased from 8.11 in 1985 to 8.05 in 2021, due to the absorption of atmospheric carbon dioxide. Ocean acidification is projected to increase by 0.3 to 0.4 pH units towards more acidic conditions by 2100 under high emissions scenarios {5.2.1.6}. Global mean sea level increased by an average of 0.20 m over the period 1901 to 2018, with the rate of rise accelerating to an average of 3.7 mm for the period 2006–2018 (high confidence). Low-lying nations, especially Small Island Developing States, are severely affected. Under a high emissions scenario, sea levels are projected to rise by 0.63 to 1.01 metres per year by 2100, with up to 630 million people living below the projected annual flood levels {5.3.1}. These changes are causing significant adverse effects on marine and coastal ecosystems, biodiversity and human coastal infrastructure {5.3}.

Ever-increasing forms of marine pollution are of growing concern *(well established)*. Marine pollution loads, sources and new contaminants are increasing rapidly in the global ocean. Most are from coastal and land-based activities, entering via rivers; direct atmospheric pollution includes soot and aerosols, and is less understood and known. Plastic pollution is a major contributor from extraction to disposal and along its routes into the sea and in the sea; it impacts aquatic wildlife and ecosystems and affects coastal socioeconomic activities {5.2.2.1}. The accumulation of plastic, particularly microplastics, varies across marine environments, and its occurrence is influenced by hydrography such as gyres and currents. Aquaculture pollution including organic matter, nutrients, chemicals and pathogens in coastal and shelf seas is of great concern, especially with the rapid increase in aquaculture operations in recent years. As the demand for seafood increases, pollution from aquaculture is expected to increase, so legislation and efforts to improve farm management practices are needed {5.2.2.3}. Industrial pollution, which includes heavy metals, persistent organic pollutants, per- and polyfluoroalkyl substances, industrial solvents {5.2.2.5}, and oil pollution {5.2.2.4}, both from land sources and point sources at sea, continue to pose significant environmental challenges. Interaction with local stakeholders and local knowledge is imperative in understanding the real effects on human livelihoods. Continued monitoring and assessment are crucial to mitigation strategies and ensuring the health of marine ecosystems.

Increasing coastal use and development significantly contribute to habitat degradation at the land–ocean interface *(well established)*. Coastal and shelf sea development varies in intensity and type across regions and countries. Approximately 40 per cent of the global population resides within 100 km of the coast, an area that houses significant infrastructure supporting various human activities. However, coastal development including coastal activities such as sand extraction, dredging and land reclamation often results in increased habitat degradation and loss, pollution, erosion, sediment deposits and conflicts of use in the coastal zones and shelf seas. The levels of pollutants entering the ocean via riverine and coastal waters are on the increase. Urbanization and industrialization intensify pressures on coastal and shelf seas for offshore energy production. The trend is accelerating and is often damaging due to inadequate environmental and political governance over marine areas. Environmental refuges for marine organisms are declining. This trend is projected to escalate globally but particularly in developing countries and emerging economies, underscoring the need for corrective, adaptive and integrated management strategies. These strategies include Integrated Coastal Management that can better accommodate the diverse demands and interests of various stakeholders. Traditional knowledge and the ecosystem awareness of local communities should be better integrated into holistic management strategies and practices {5.2.4.1; 5.2.4.2}.

Pollution of the ocean with various types of waste of terrestrial and land-use origin enters the sea via run-off and rivers *(well established)*. Compounds of synthetic origin used for domestic, agricultural and industrial purposes mainly enter the sea from land-based sources. These are increasingly a threat to marine life and disrupt food webs. These substances often bio-accumulate in marine organisms and move up the food web {5.2.3.3}. Agricultural and wastewater run-off, rich in nutrients, causes eutrophication and hypoxia in many coastal areas, often disrupting marine species and food security. Since the mid-20th century, oxygen-minimum zones in the ocean have expanded globally by about 4.5 million km². Sea level

rise results in habitat erosion and saltwater intrusion of coastal systems. Soil erosion causes sediment run-off, which can bury coral reefs and seagrass beds, blocking sunlight and hindering photosynthesis. Furthermore, water quality is degraded, posing risks to human health and livelihoods {5.3.3}. Pollution from catchment run-off needs be prevented by reducing the use and disposal of chemicals and nutrients on land and in aquaculture. Mining waste continues to enter rivers and coastal waters. The best possible use management practices, which may be underpinned by regulations and enforcement, and the upgrading of wastewater systems, are urgently needed. Restoration and protection of natural habitats to enhance their capacity to buffer erosion and pollution are crucial. Involving local expertise and long-term knowledge of the affected ecosystems is often key to better coastal habitat management.

Biodiversity change threatens the provision of important ecosystem services *(well established)*. Ocean and coastal ecosystems provide a range of contributions to human well-being, such as food, livelihoods, space to live, recreation, carbon sequestration and coastal protection. However, these services are threatened by the alteration, degradation and loss of invaluable marine ecosystems and their biodiversity. For example, the annual value of global fisheries is estimated to decline by 10–12 per cent by 2050 due to climate change and overfishing. Overfishing has escalated in recent decades, with over 37 per cent of the fish stocks monitored by the Food and Agriculture Organization now overfished. This situation urgently calls for the regulation and enforcement of sustainable fishing management practices, including ecosystem-based fisheries management. The loss of ecosystem services reduces the economic value of marine resources, disrupts the productivity of marine food sources, and disproportionately affects vulnerable human communities. These changes threaten livelihoods, exacerbate inequalities, and increase the costs of climate change adaptation {5.3}. Consideration of local requirements and involving local and long-term knowledge of the affected ecosystems and species is imperative and needs to be implemented as a matter of course.

Progress towards internationally agreed goals is insufficient and uneven *(well established)*. Numerous international and national policies and initiatives are in place to conserve and restore biodiversity in coastal and marine environments. While there have been some successes, the global targets set for oceans and coasts under the Aichi Biodiversity Targets, Kunming-Montreal Global Biodiversity Framework, and Sustainable Development Goal 14 require sustained global action to address the drivers and pressures of biodiversity loss. The urgent need for more ambitious and coordinated action to protect and restore the ocean and its resources has not yet been met. As of March 2025, over 8 per cent of marine areas within national waters were under protection, constituting 16,503 Marine Protected Areas {5.4}. The aim to reduce sound emissions at sea needs to be rapidly furthered internationally. Consultative processes around marine mining, particularly deep-sea mining, and resource use in polar regions must be sped up and processes to resolve conflicts implemented. The recognition of Indigenous Peoples' interests and local co-ownership of coastal resources needs to be established worldwide. Global guidelines based on stakeholder needs and long-term knowledge are urgently required for spatial use management in coastal and shelf seas.

5.1 Introduction

Coasts, shallow seas and oceans play a critical role in securing human survival and promoting well-being and prosperity. These regions host highly productive marine ecosystems and support biodiversity, as well as a wide and growing range of human uses such as tourism, offshore energy production, transport, land reclamation, and resource extraction, including desalination. They also protect socioeconomic activities and infrastructure from storm surge and filter out pollutants from catchment run-off. However, pressures such as climate change, biodiversity loss, land degradation, pollution, and over-exploitation hinder the marine systems' capacity to continue providing benefits (United Nations Environment Programme [UNEP] 2021a; Intergovernmental Panel on Climate Change [IPCC] 2023). Immediate and proactive measures have the potential to safeguard these valuable environments for the well-being of both present and future generations.

Knowledge of the marine system continues to improve (United Nations [UN] 2021a), but at the same time, pressures on the ocean due to human activities increasingly affect ocean health (UNEP 2019), causing severe degradation of critical habitats (UN 2021a), mass mortality events of species from coral to cetaceans (Garrabou et al. 2022; IPCC 2023), and increasingly irreversible losses in coastal and open-ocean ecosystems. Loss of maritime livelihoods is increasing rapidly and climate injustices imposed on poor coastal communities, Small Island Developing States, and Indigenous Peoples' communities is rife. Pollution, unsustainable practices, rapid urbanization and the adverse effects of climate change pose significant threats to the socioeconomic systems of communities sustained by the marine system (Pecl et al. 2022).

The 6th Synthesis Report of the International Panel for Climate Change (IPCC 2023) highlighted several projections related to ocean ecosystems. Climate risks increase with every increment of warming but differ depending on the ocean and coastal socio-ecosystems. Ocean carbon sinks will take up a decreasing proportion of emissions, causing other changes, including increased ocean acidification and deoxygenation. Ocean ecosystems are predicted to suffer biodiversity loss due to climate change alongside other pressures, such as overfishing and maritime use. Some future changes are irreversible and will persist for thousands of years, such as sea level rise due to continued ocean warming and land-ice melt. However, the rate of change can be reduced, allowing for mitigation efforts and more time for ecosystems and communities to adapt.

The sixth Global Environment Outlook (GEO-6) report assessed three major pressures on oceans and coasts: coral reef bleaching, marine litter, and unsustainable fishing practices. Coral bleaching events, driven largely by rising sea surface temperatures, are increasing in frequency, now recurring approximately every six years. These events undermine fisheries, tourism, livelihoods and biodiversity, with recovery for many reefs projected to take centuries (UNEP 2019). Marine litter, primarily from land-based sources, continues to accumulate across marine environments, from coastal zones to deep-sea sediments and polar regions, posing environmental, social, and potential human health risks (UNEP 2019). Unsustainable fishing remains a critical concern, with one-third of global fish stocks overexploited and catch levels declining in many regions. This threatens food security, economic development and the resilience of marine ecosystems, particularly in developing coastal and island nations (UNEP 2019).

In response to these escalating challenges, a variety of international and national initiatives are under way to address these threats to the oceans, including funding for global adaptation strategies (Global Center on Adaptation 2024). These include the expansion of protected areas, strengthened regulation and oversight of fisheries, and waste reduction and recycling programmes. The IPCC stated that conservation of 30–50 per cent of ocean areas is required to maintain resilience and ecosystem services (IPCC 2023). Management approaches such as Marine Protected Areas (MPAs) have improved, with coverage increasing from the 7.3 per cent of the world's oceans protected in 2019 (UNEP 2019; UN 2021a). However, additional efforts are required to meet targets, and further work is needed to assess and ensure MPA management is effective and equitable (UNEP 2019).

International cooperation, including active participation in global treaties and agreements, plays a crucial role in coordinating efforts aimed at restoring and protecting vital marine ecosystems and ensuring the economic and social sustainability of communities

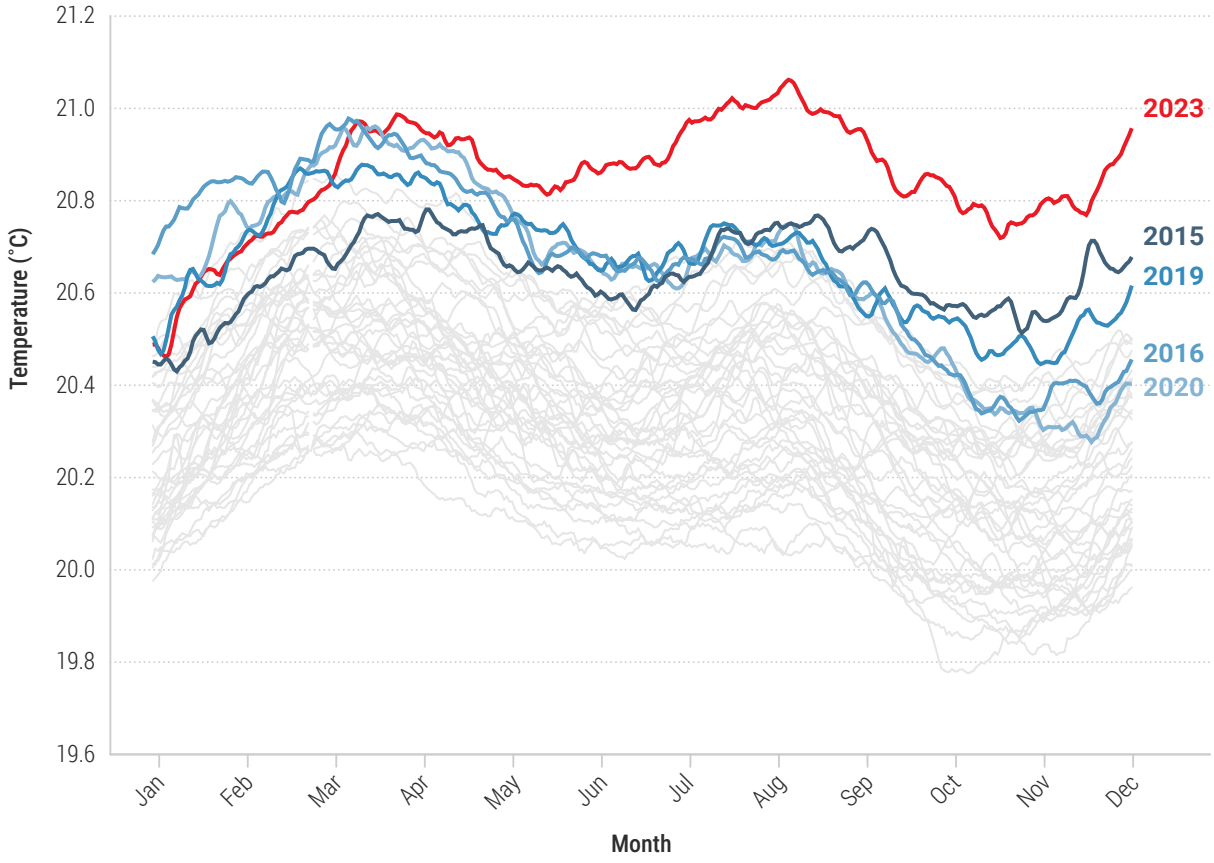
dependent on the sea (UN 2021a). Equally important is the adoption and enforcement of national legislation that implements international obligations. Local community efforts, such as those by Indigenous Peoples, also play a vital part in gathering, preserving and applying knowledge of the marine environment. Indigenous Peoples and local communities often have sophisticated governance structures for managing aquatic resources, such as the establishment of locally managed marine areas according to the Fa'a Samoa, traditional marine management practices, of Samoa (Food and Agriculture Organization [FAO] 2023b). These structures are typically based on principles of sustainability, community stewardship and equitable resource distribution. Diverse types of policy instruments and governance approaches are needed to respond to the key drivers and pressures facing the oceans (UNEP 2019). By integrating these governance models with modern management practices, the effectiveness of marine conservation efforts can be enhanced.

The following sections will expand on these topics. Section 5.2 primarily covers the state and trends of marine and coastal environments in terms of climate change, pollution, biodiversity loss and habitat degradation. Section 5.3 then briefly addresses the impact of environmental changes on human systems. Lastly, Section 5.4 assesses the progress towards selected internationally agreed goals.

5.2 State and trends

5.2.1 Climate change

5.2.1.1 Ocean warming



Ocean warming is one of the key indicators of human-induced climate change, with the ocean having absorbed approximately 90 per cent of the Earth's excess heat since the 1970s (IPCC 2021; von Schuckmann et al. 2023), when widespread subsurface ocean observations began. This trend has been traced back to at least the 1900s, consistent with long-term increases in sea surface temperature (Zanna et al. 2019). The rate of increase in sea surface temperature has accelerated from 0.06°C per decade during 1985–89 to 0.27°C per decade during 2019–23 (Merchant, Allan and Embury 2025), a more than fourfold increase in rate over less than 40 years. This acceleration culminated in 2023, when sea surface temperatures reached record-breaking levels, with daily averages remaining at record highs from April onward and achieving an all-time high in August (**Figure 5.1**, next page).

Since the 1990s, ocean warming has intensified (Gulev et al. 2021; Storto and Yang 2024), with unprecedented global ocean temperatures recorded in 2023 and 2024 (National Oceanic and Atmospheric

Credit: PedaltotheStock/Envato

Figure 5.1 (top panel): Daily sea surface temperatures averaged over 60˚N to 60˚S from 1980 to 2023

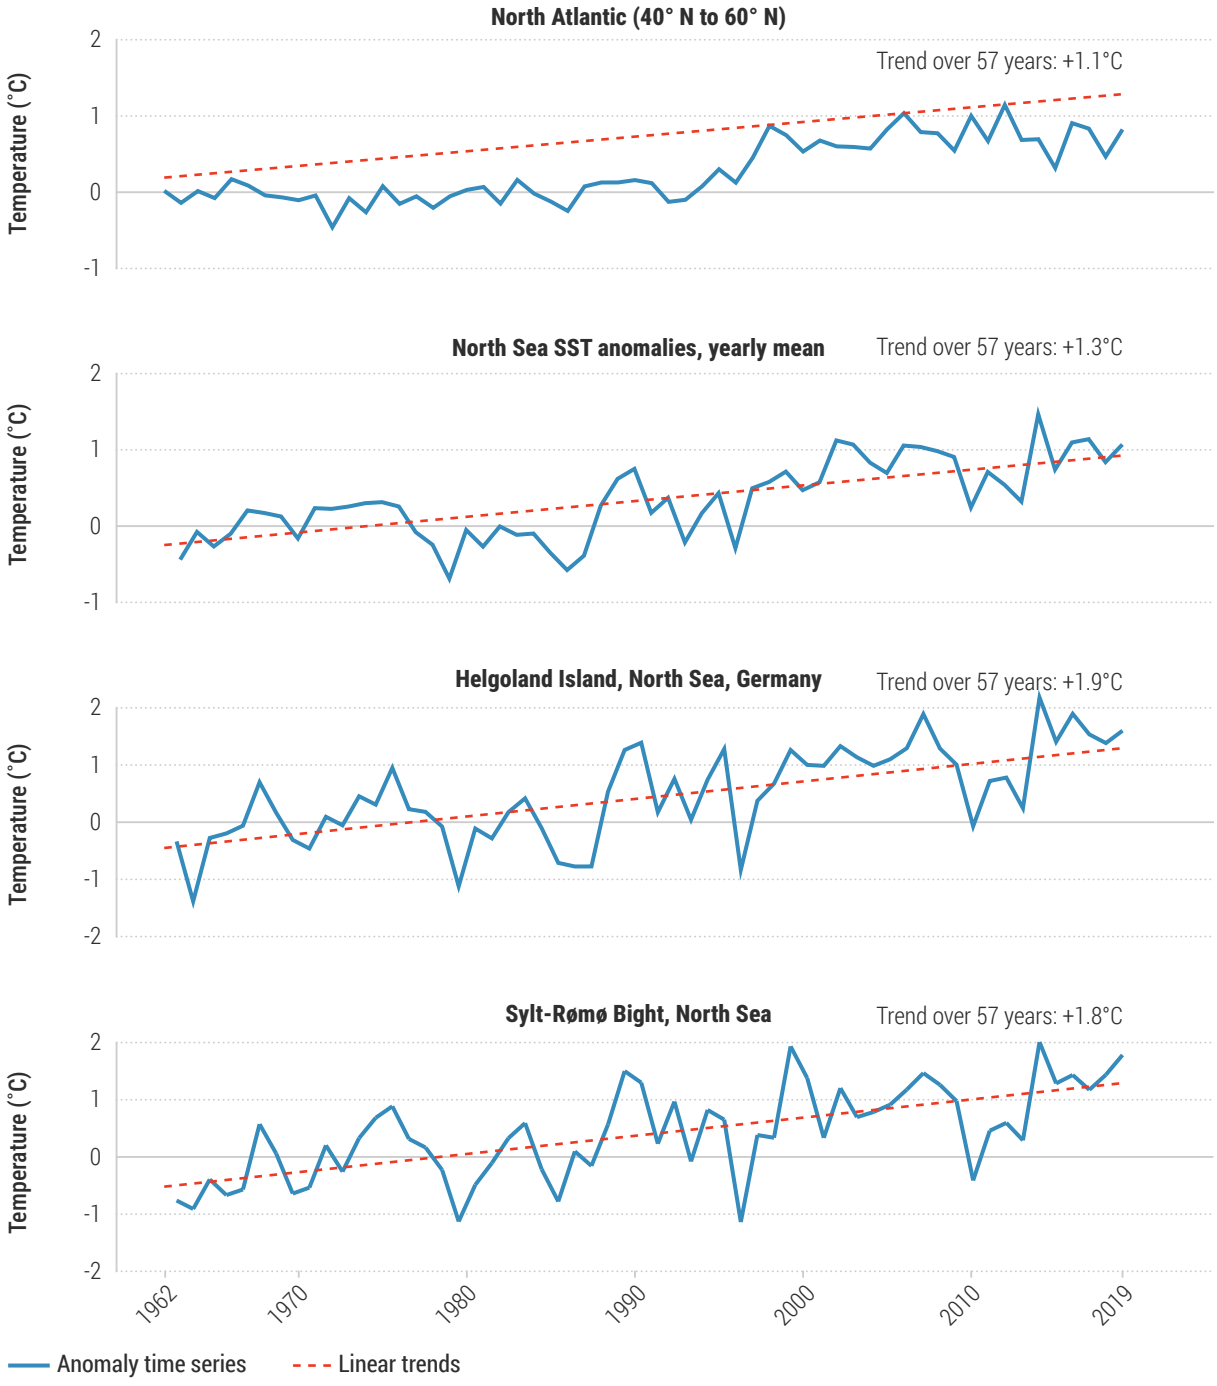
Agency 2025). Some regions have experienced anomalies of 4–5°C above average, with extreme cases such as waters near Florida exceeding 38°C in July of 2023 (Hobday et al. 2023).

This rapid warming is evident in rising sea surface temperatures and heat penetration to deeper layers in the ocean, driving more frequent, intense and prolonged marine heatwaves (Giménez, Boersma and Wiltshire 2024). The upper ocean (0–700 m) accounts for 62 per cent of the total ocean heat content increase, while intermediate layers of 700–2,000 m and depths below 2,000 m contribute 28 per cent and 10 per cent, respectively (Gulev et al. 2021).



Warming trends are observed across all major ocean basins, with spatial variations influenced by ocean circulation patterns and climate variability (Fox-Kemper et al. 2021). Enhanced heat uptake occurs along major water-mass pathways; localized cooling is observed in some regions due to heat redistribution by currents. The Arctic Ocean is warming rapidly due to polar amplification (Zhou, Leung and Lu 2024). Semi-enclosed, coastal and shelf seas, such as the North Sea, South China Sea, and Mediterranean Sea, are warming nearly twice as fast as the open ocean and with distinctly higher rates in shallow coastal seas. (**Figure 5.1**, bottom panel) (de Amorim et al. 2023).

Ocean warming is projected to continue throughout the 21st century under all emissions scenarios (Fox-Kemper et al. 2021; Varela et al. 2023). High emissions scenarios could result in permanent marine heatwaves in parts of the tropical and Arctic Oceans, while low emissions scenarios could significantly mitigate this risk. However, even with ambitious mitigation, warming from past and ongoing emissions will persist for centuries due to the ocean's thermal inertia and long-term heat storage (IPCC 2023).

5.2.1.2 Ocean circulation

Proxy records suggest the Atlantic Meridional Overturning Circulation (AMOC), the conveyor-

belt-like system of currents moving horizontally and vertically in the Atlantic, remained stable for 8,000 years before weakening since the late 19th century (Caesar et al. 2021; Gulev et al. 2021). Observations since 2004 remain too short to confirm anthropogenic weakening and show higher variability than climate-model simulations (Frajka-Williams et al. 2023). Models consistently project 21st century weakening of the Atlantic's overturning circulation but there are significant uncertainties about the size, timing, and potential abruptness of changes (Fox-Kemper et al. 2021; IPCC 2023). Given the potential for severe consequences (van Westen, Kliphuis and Dijkstra 2024), risk mitigation strategies are crucial (Rahmstorf 2024) and sustained monitoring is essential for improving trend detection and projections (Srokosz, Holliday and Bryden 2023). However, efforts are hampered by the complexity of

model biases, system interactions, methodological differences, and observational limitations contributing to ongoing uncertainties (Menary et al. 2020; Jackson et al. 2023; Romanou et al. 2023; Ben-Yami et al. 2024; Lee et al. 2024; Baker et al. 2025).

5.2.1.3 Polar ice melt

Sea ice is melting at both poles. Arctic sea ice has been diminishing under heightened warming four times more rapidly than the global average (Rantanen et al. 2022). Over the 46-year satellite record, the last 18 years were the lowest 18 Arctic sea-ice extent ever recorded, with the largest departure from average conditions occurring in October 2020 (National Snow and Ice Data Centre 2024). Antarctica is also facing rapid warming, resulting in substantial loss of floating sea ice, from the ice shelves around the coastline and from the continental ice sheet. In 2023, Antarctic sea-ice extent reached a record low in the observational record (Fetterer et al. 2017; Purich and Doddridge 2023), with 2024 being the second-lowest year on record. Globally, sea-ice extent reached an all-time low on 5 February 2025 with an extent of 16.20 million km2, more than 12 per cent below the median minimum (1979–2020) (Copernicus 2025a).

Numerous studies using observations or satellite images show shortening ice-covered seasons on lakes and rivers across the northern hemisphere (Newton and Mullan 2021; Wang et al. 2024). Seasonal ice cover is decreasing both in duration and extent (Sharma et al. 2021; Wang et al. 2021a), with many implications for ecosystems and human activity (Hampton et al. 2024).

Glaciers are retreating at an accelerating pace worldwide (Hugonnet et al. 2021), driven mostly by human activity (Marzeion et al. 2014). Melting mountain glaciers threaten annual cycles of water supply and food security throughout their drainage basins and all the way to the coasts. Eventually new cycles will result in altered terrestrial, freshwater and marine ecosystems (Bosson et al. 2023).

The world's largest ice sheets, on Antarctica and Greenland, are losing ice mass at alarming rates, mainly through thawing and calving from marine-terminating glaciers (Hanna et al. 2024). Combined, these two ice sheets contribute 1.1 mm per year of sea level rise, outstripping losses from all the world's mountain glaciers (Otosaka et al. 2023; Dussaillant et al. 2024). The Antarctic Ice Sheet is surrounded by floating ice shelves that buttress the continental ice mass – these are disintegrating at an accelerating rate, potentially further destabilizing the ice sheets (Fürst et al. 2016). The most rapid Antarctic changes are occurring in the Antarctic Peninsula and West Antarctica (The IMBIE Team 2018). This ice loss is altering the biogeochemical cycles and physical processes of the Southern Ocean and may be pushing Antarctic sea-ice levels into a new state of diminished ocean coverage (DeConto et al. 2021; Alley, Scambos and Alley 2023).

Globally, snow conditions are also changing. In some regions, such as the Alps, the length of snow cover has decreased by 36 days, mostly over the past century (Carrer et al. 2023). Every degree of warming lowers the proportion of precipitation falling as snow worldwide. Since snow is a critical source of water for agriculture worldwide, changes to snow cover are changing our global food security and economy.

5.2.1.4 Permafrost thawing

Polar ice includes sea ice floating on the ocean, lakes and rivers, continental ice sheets, high latitude glaciers and snow. All these components of the frozen Earth are changing (Druckenmiller et al. 2024, World Meteorological Organization, 2024, 2025).

Permafrost, the frozen ground that contains organic matter and stores large amounts of carbon, is warming at a global scale, both on land (Biskaborn et al. 2019) (4.3.3.3) and beneath the Arctic shelf seas. In the northern hemisphere, permafrost underlies almost 15 million km^2 of land, and thaw is driven by rapidly rising air temperatures and changes in snow cover, vegetation and hydrology (Ran et al. 2022). An additional estimated 2.5 million km^2 of permafrost lies beneath the Arctic Ocean (Sabino et al. 2024). This permafrost originated on land but was submerged following the last ice age and has been warming ever since (Overduin et al. 2019). As sea ice continues to disappear, the ocean water will warm, and this permafrost is expected to thaw more rapidly (Wilkenskjeld et al. 2022).

Permafrost thawing contributes to global warming in a positive feedback loop through the release of greenhouse gases. Land permafrost contains about

Credit: AlbertoCarrera/Envato

twice as much carbon as the atmosphere; even more is contained in submarine permafrost (Miesner et al. 2023). When this thaws, the organic matter trapped within it decomposes and releases carbon dioxide (CO_2) and methane into the atmosphere (Ramage et al. 2024; Wild et al. 2022). The permafrost region has already become a net greenhouse gas source (Hugelius et al. 2023), contributing further to global warming (Schuur and Mack 2018; Turetsky et al. 2019).

Permafrost thaw leads to coastal land loss, subsidence and flooding, creating risk for communities and infrastructure (Wang et al. 2023). Around coastal regions, permafrost thaw affects sea cliffs and beaches and, in combination with sea-ice push processes and wave action, increases coastal erosion (Lim et al. 2020). Permafrost compounds erosion and sea level rise with ground subsidence driven by ground-ice melt: by mid-century, more land will be submerged by seawater than will be eroded along the coast of the Alaska coastal plain (Creel et al. 2024). Ice melting in permafrost almost equals losses from the Antarctic Ice Sheet (Nitzbon et al. 2023) and may be contributing to sea level rise.

Permafrost thaw beneath the Arctic margins is associated with the release of CO_2 and methane into the water column (Wild et al. 2022). Subsea and coastal permafrost thaw may affect sediment and water-column ecosystems through gas release and altered biogeochemistry of the Arctic shelf seawater (Nielsen et al. 2024).

5.2.1.5 Ocean deoxygenation

Oxygen is essential for marine life and for many chemical processes in the ocean. Since 1970, the open ocean has lost 0.5–3.3 per cent of dissolved oxygen in the upper 1,000 metres, with the largest declines in the equatorial and North Pacific, Southern Ocean, and South Atlantic (Schmidtko, Stramma and Visbeck 2017; Canadell et al. 2021). More than 700 coastal areas have reported new or worsening low-oxygen conditions (Limburg et al. 2020). This process, known as ocean deoxygenation, is becoming more severe and is a serious concern due to its potentially large impacts on marine ecosystems at both global and local scales. This decline is mainly driven by ocean warming, which increases stratification, reduces ventilation, and lowers oxygen solubility (Schmidtko, Stramma and Visbeck 2017; Roach and Bindoff 2023; Portela et al. 2024).

Tropical oxygen-minimum areas, or hypoxia zones, are expanding (Stramma et al. 2008; Limburg et al. 2020). Over 700 coastal sites are now classified hypoxic due to eutrophication, warming, and circulation changes (Limburg et al. 2020). Models project subsurface oxygen losses of 32–71 per cent greater than previous estimates, with a total decline of 1–7 per cent by 2100, depending on emissions scenarios and relative to 1870–1899 (Kwiatkowski et al. 2020). Even if emissions cease today, deep ocean oxygen loss could exceed 10 per cent of pre-industrial levels (Oschlies 2021), highlighting the

Credit: wirestock/Envato

urgent need to reduce human-driven emissions to slow the process. Ocean deoxygenation, especially when combined with other environmental stressors, poses a major threat to organisms and is potentially related to strandings of sealife and thus affects the sustainable use of marine resources (Waller et al., 2024). These changes often occur in conjunction with ocean acidification (Section 5.2.1.6), and along with their extreme events, create compounding stresses on marine ecosystems (Ross et al. 2020; Wong et al. 2024).

5.2.1.6 Ocean acidification

Oceans absorb about 25 per cent of human CO_2 emissions, accelerating acidification (Canadell et al. 2021; Friedlingstein et al. 2022; Gruber et al. 2023). Since the 1750s, ocean acidity has increased 30 per cent, a rate unprecedented in at least 26,000 years (Gulev et al. 2021). Acidification affects all ocean basins, including subsurface waters (Fassbender et al. 2023), with vertical penetration occurring through ventilation processes (Iudicone et al. 2016).

The rate of acidification is slowest in the tropics and subtropics and fastest in the Arctic Ocean (Jiang et al. 2023). Tropical Pacific upwelling zones show acidity increases from both anthropogenic CO_2 and natural deep-water upwelling. Coastal waters are made more acidic through terrestrial inputs, eutrophication, and other human contributions (Canadell et al. 2021).

High emissions scenarios project global ocean absorption of CO_2 to increase by 2100, potentially increasing acidity by 150 per cent compared to pre-industrial levels (IPCC 2023), with the Arctic facing the most dramatic changes. However, even with aggressive atmospheric CO_2 removal, ocean acidification will persist for generations due to slow deep-ocean turnover (IPCC 2021; Jiang et al. 2023). The combined and interactive effects of acidification and deoxygenation (Section 5.2.1.5), along with their extreme events, present significant challenges for marine ecosystems and the communities that depend on them (Grix et al. 2025; Tai et al. 2021).

5.2.1.7 Sea level rise

Global mean sea level is rising at accelerating rates, increasing the frequency and severity of both minor and extreme coastal flooding events (IPCC 2021; IPCC 2023). The 20th-century rate of sea level rise is unprecedented in the past 3,000 years, with rapid acceleration since the 1960s–1970s (Gulev et al. 2021; Dangendorf et al. 2024; Wang et al. 2024). Satellite observations since 1993 reveal a 103 mm rise, at an average rate of 3.4 mm per year (Gulev et al; Guérou et al. 2023; National Aeronautics and Space Administration 2024).

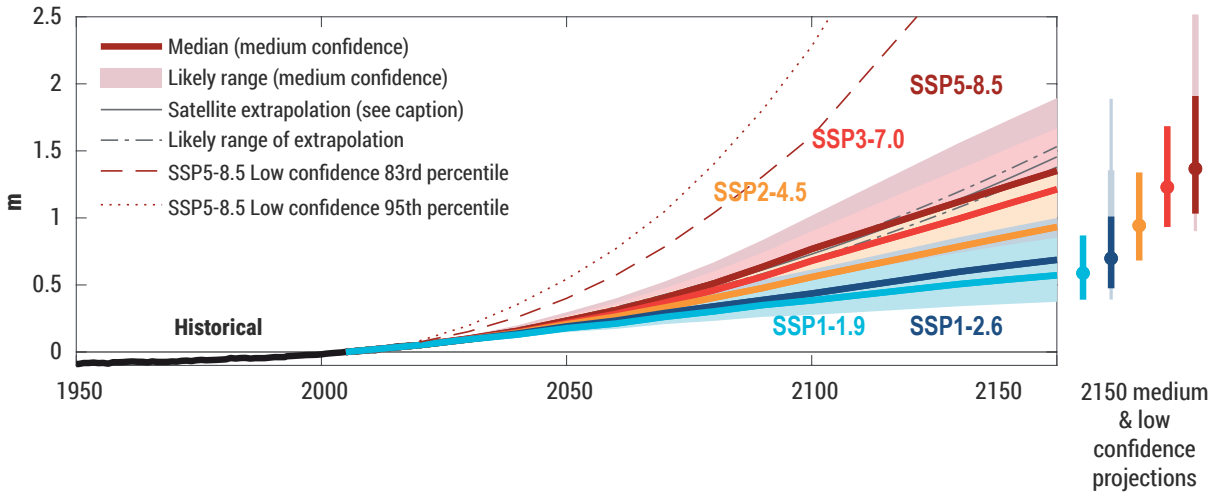
Major drivers include the thermal expansion of warming oceans and land-based ice loss (Fox-Kemper et al. 2021). Ice-sheet meltwater contribution quadrupled from 1992–1999 to 2010–2019. Terrestrial

water storage plays a minor role globally but can have a significant impact regionally.

Regional and local sea levels often deviate from global averages (Hamlington et al. 2020; Cazenave and Moreira 2022; Woodworth 2022). Since the 1960s, ocean circulation and density changes in response to atmospheric forcing – including changes in radiation, temperature and precipitation – have dominated climate-driven coastal sea level rise, except where geological features near former ice sheets counteract this (Dangendorf et al. 2021; Wang et al. 2021a).

IPCC projections indicate continued acceleration throughout the 21st century under all emissions scenarios (**Figure 5.2**), with near-term mitigation resulting in smaller rises by 2100 (Fox-Kemper et al. 2021; IPCC 2023). Relative to 1995–2014, projections by 2100 range from 0.28–0.55 m at 1.5°C warming to 0.63–1.60 m with high emissions, and potentially higher considering ice sheet uncertainties (IPCC 2023).

Most non-polar coastlines will experience sea level rise within 20 per cent of the projected global mean by 2100, intensifying extreme events (Church et al. 2013; Fox-Kemper et al. 2021). Even with 1.5°C warming, by 2100, extreme events that used to occur once per century are projected to occur annually at over 50 per cent of tide-gauge locations, especially in the tropics (Tebaldi et al. 2021). Global models may underestimate these projections due to challenges in resolving fine-scale processes that they cannot capture directly (Hewitt et al. 2022; Slangen, Haasnoot and Winter 2022; Jevrejeva et al. 2023; Wickramage et al. 2023).



Sea level rise will continue for millenniums due to slow ocean warming and ice-sheet responses (Church et al. 2013; Fox-Kemper et al. 2021), which are effectively irreversible under high-emissions scenarios. Current emissions could trigger critical thresholds this century, resulting in metres of rise over coming centuries (IPCC 2023). While stopping emissions immediately would not halt sea level rise, it would dampen its acceleration and continuation over the long term (Church et al. 2013; Oppenheimer et al. 2019; Fox-Kemper et al. 2021; Turner et al. 2023; Palmer and Weeks 2024).

Climate change adaptation measures, such as the development of resilient coastal infrastructure, managed retreat, and ecosystem-based solutions like wetland restoration, are essential to mitigate the adverse effects of rising sea levels on vulnerable communities and ecosystems (IPCC 2023).

5.2.2 Pollution

Pollution from human sources is increasing in the global ocean, including from land-based industrial, agricultural and urban waste, as well as light and sound. Maritime activities – particularly from marine traffic, fisheries and aquaculture – also contribute to pollution in the global ocean (Joint

Figure 5.2: Projected global mean sea level rise under different warming scenarios

Source: IPCC (2021)

Credit: GreensandBlues/Envato

Group of Experts on the Scientific Aspects of Marine Environmental Protection 2015; Sheppard 2019; Micella et al. 2024). Pollution in coastal and marine environments harms marine ecosystem function and integrity, the health of organisms, and human livelihoods (Sheppard 2019).

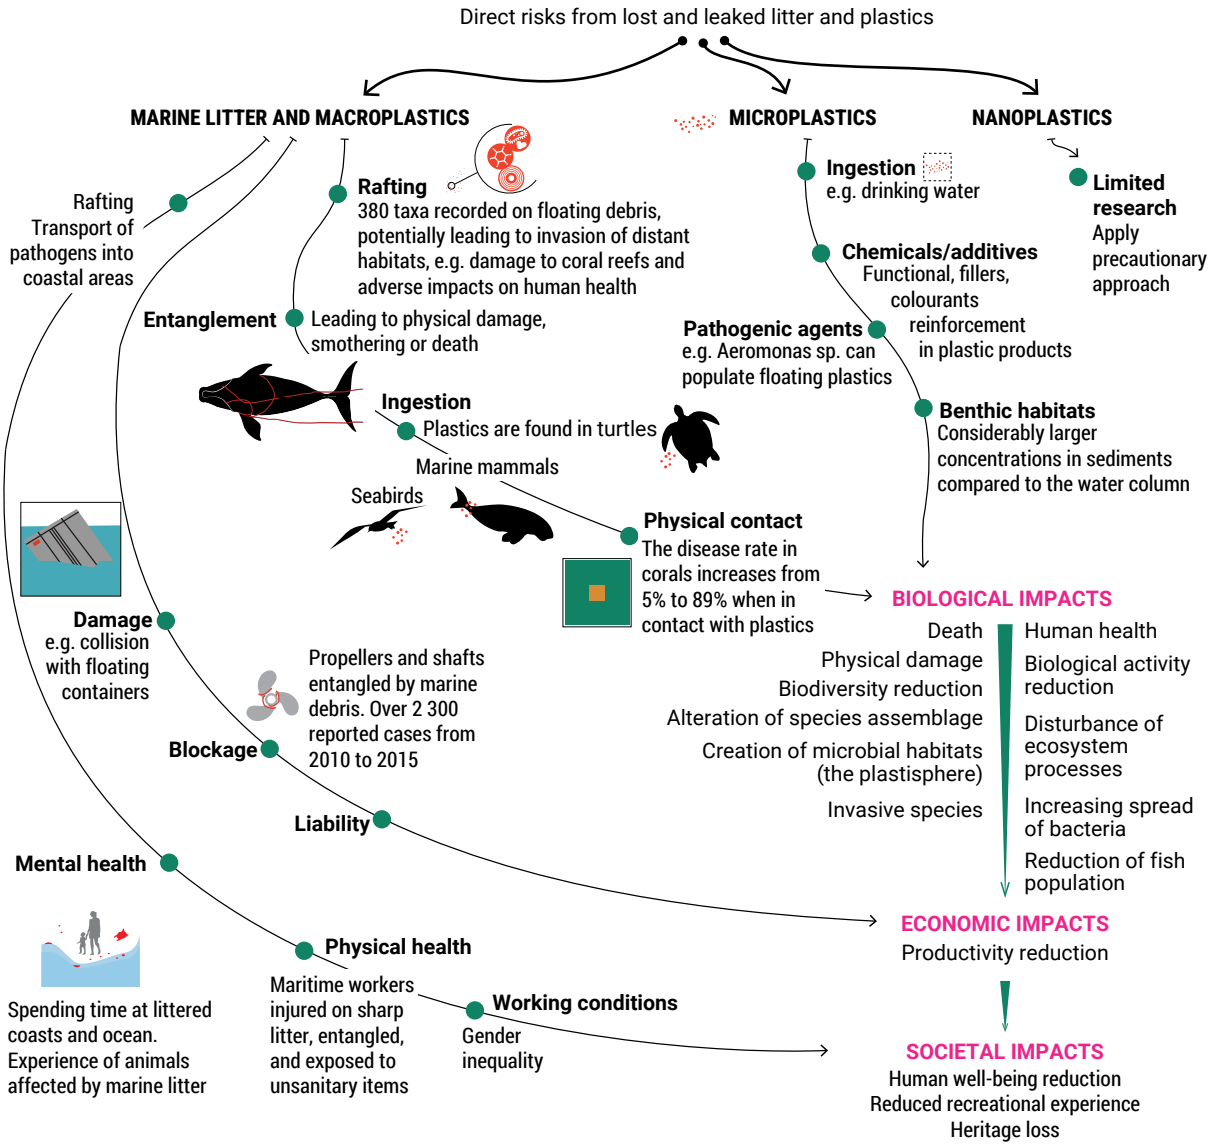
Prominent pollutants include:

- **Plastics** – such as litter, breakdown particles and plasticizers
- **Nutrients** – such as nitrogen, phosphorus, and organic matter that cause eutrophication and deoxygenated areas (O'Boyle 2020; Devlin and Brodie 2023; Bhuiyan et al. 2024)
- **Noise pollution** – from point sources such as shipping, energy rigs, offshore prospecting including seismic surveys, and construction
- **Industrial pollutants** – such as persistent organic pollutants, oils, heavy metals, xenobiotics, mining waste, per- and polyfluoroalkyl substances, and thermal pollution from cooling waters

The increasing diversity of land- and sea-based industries and the corresponding introduction of new products and processes is increasing pollutant release to the oceans. Most of these emerging pollutants are unmonitored and unmanaged, and their consequences are poorly understood.

5.2.2.1 Plastic pollution

Plastic pollution is found in all areas of the ocean, from the depths of the Mariana Trench to the ocean's surface (Peng et al. 2020; Agnelli and Tortora 2022) and has been shown to interact with around 700 species and counting (Gall and Thompson 2015; International Union for the Conservation of Nature [IUCN] 2022; Section 5.2.3). As of 2010, an estimated 14 million metric tons of plastic enter the global ocean each year (Jambeck et al. 2015; IUCN 2022). The global abundance of floating plastic particles is estimated to weigh between 1.1 million and 4.9 million tons (Eriksen et al. 2023). Long-term data from multiple ocean basins have demonstrated an increasing trend of floating plastic debris (Wilcox, Hardesty and Law 2020; Isobe and Iwasaki 2022).



While approximately 80 per cent of marine litter comes from land-based sources, contributors

include wastewater treatment plants, fisheries estimated to lose 6 per cent of all nets and 29 per cent of all lines per year, maritime traffic, and rivers (UNEP 2021a; González-Fernández et al. 2021; Richardson, Hardesty and Wilcox 2019; **Figure 5.3**). Plastic in the environment varies considerably depending on waste-management practices, geographical regions, hydrography and topography. Water body connectivity and hydrography, such as in ocean gyres and medium-scale ocean characteristics, are pivotal to floating litter accumulation (UNEP 2021a; Strokal et al. 2023). The North Pacific Subtropical Gyre is responsible for the Great Pacific Garbage Patch, a 1.6 million km^2 North Pacific Ocean area with an accumulated 79,000 tons of mostly plastic debris (Lebreton et al. 2018).

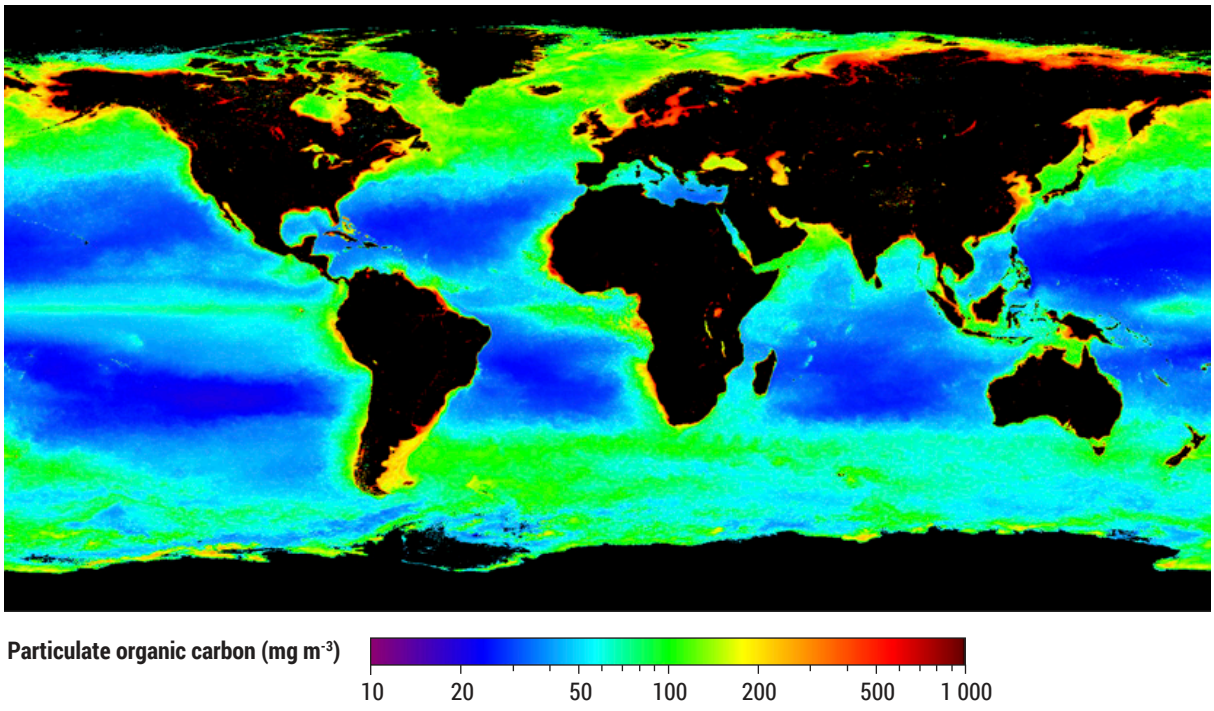
5.2.2.2 Nutrient pollution

Nutrient input into coastal and marine systems occurs from both natural processes, such as rock weathering and ocean upwelling, and anthropogenic processes such as agricultural run-off, sewerage, and aquaculture (Chislock et al. 2013). With increasing human populations, particularly in coastal areas,

Figure 5.3: Direct risks and impacts of marine litter and plastics

Sources: UNEP 2021, adapted from Aliani and Molcard 2003; Boerger et al. 2010; Fossi et al. 2012; Fossi et al. 2014; Goldstein et al. 2014; Avio et al. 2015; Kiessling et al. 2015; Santos et al. 2015; Rech et al. 2016; Rochman et al. 2016b; Hong et al. 2017b; Lusher et al. 2017a; Sbrana et al. 2017; Steer et al. 2017; Anbumani and Kakkar 2018; Godoy and Stockin 2018; Duncan et al. 2018a; Duncan et al. 2018b Fossi et al. 2018; Lamb et al. 2018; Lavers et al. 2018; Schymanski et al. 2018; Waite et al. 2018; Akhbarizadeh et al. 2019; Alimba and Faggio 2019; Battisti et al. 2019; Besseling et al. 2019; Bucci et al. 2019; Koelmans et al. 2019; Li et al. 2019; Windsor et al. 2019; Woods et al. 2019; Zhu, C. et al. 2019; Zhu, L. et al. 2019; Amaral-Zettler et al. 2020; Harris 2020; Landrigan et al. 2020; Prata et al. 2020a. Illustrated by GRID-Arendal

and the intensification of farming practices, nutrient pollution – particularly of nitrogen and phosphorus – is increasing. Alongside direct input from rivers, marine nutrient balance may also be affected by factors such as alterations in ocean currents (Rogers et al. 2020), and inputs from dust storms (UNEP 2020) and wildfire smoke (Herbert-Read et al. 2022).



Excessive nitrogen and phosphorus in marine systems lead to excessive phytoplankton and algal growth, and to anoxic conditions which can kill all oxygen-breathing organisms, such as bivalves and fish, due to eutrophication. In the United States, 78 per cent of coastal waters and 65 per cent of European Atlantic coastal waters are eutrophic (Malone and Newton 2020; **Figure 5.4**), and over 20 per cent of coastal waters in China are now classified as "affected by eutrophication" (People's Republic of China, Ministry of Ecology and Environment 2024; Wang et al. 2021b). Statistics on eutrophication in other marine and coastal areas are difficult to find, intercalibrate and collate (Graves et al. 2021).

The resulting degradation leads to declines in ecosystem services, including aquaculture production, fish and shellfish stocks, and overall amenity value (Smith and Schindler 2009). The economic costs to fisheries, tourism and other coastal livelihoods are already in tens of billions of dollars annually. The importance of interconnecting some of the solutions with sustainable agriculture cannot be overemphasized, especially when watersheds drain directly into the seas and oceans.

5.2.2.3 Pollution from aquaculture

Aquaculture – the breeding, raising and harvesting of fish, shellfish and aquatic plants (National Oceanic and Atmospheric Agency 2023) – is one of the fastest-growing food sectors in the world (Organisation for Economic Co-operation and Development/FAO 2021; FAO 2022; **Figure 5.5**). The State of World Fisheries and Aquaculture reports that global fisheries and aquaculture production in 2022 surged to 223.2 million tons, a 4.4 per cent increase from the year 2020. Production comprised 185.4 million tons of aquatic animals and 37.8 million tons of algae (FAO 2024). Although aquaculture is accelerating to meet growing aquatic food demand, many current operations severely

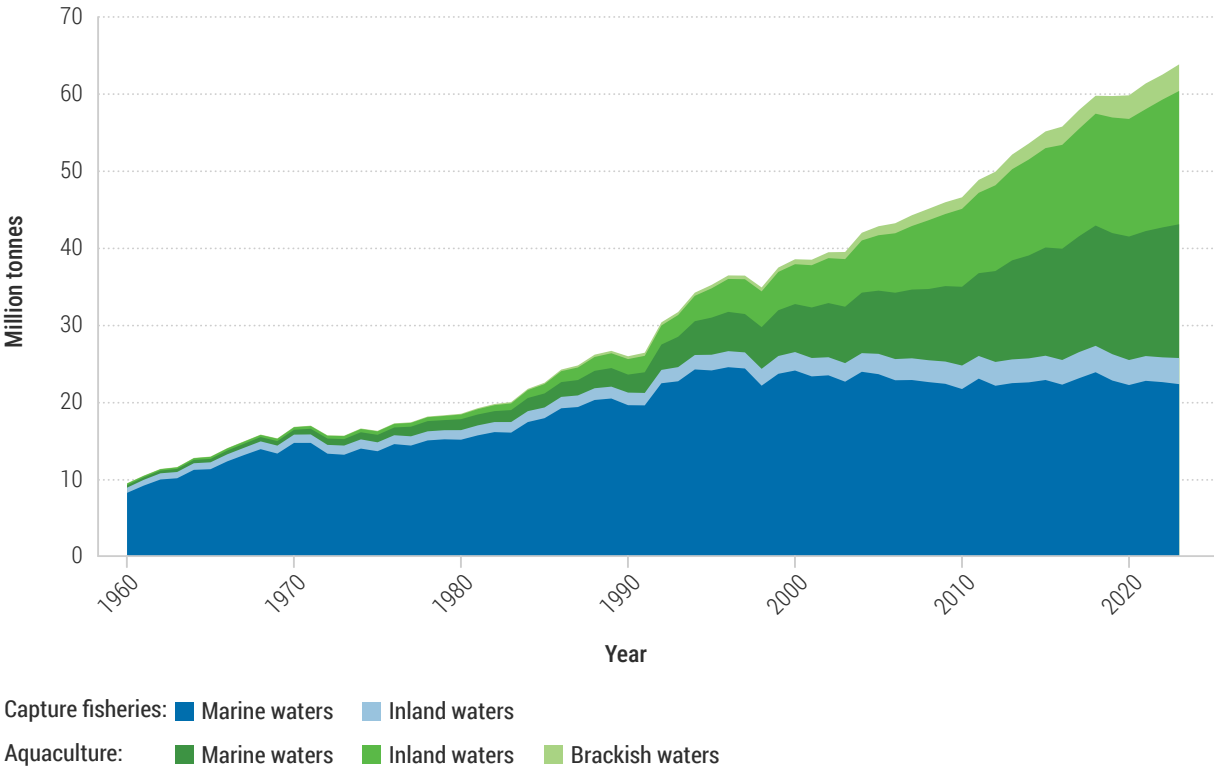


Figure 5.4: Global distribution of particulate organic carbon in seawater, implying marine eutrophication

Note: Elevated levels of particulate organic matter signal excessively nutrient-rich waters, which can lead to oxygen-depleted "dead zones" as a result of eutrophication

Source: National Aeronautics and Space Administration (2024)

Figure 5.5: Global fishery and aquaculture production from 1960 to 2023

Source: FAO (2025)

affect the marine environment and human health in the long term, for example, in sediments (Bergland et al. 2020; Stentiford et al. 2022). The waste generated by aquaculture farms includes animal and fish faeces, fertilizers, sediments, dead fish, pathogens, non-native species, therapeutic compounds such as antibiotics, feed additives and nutrients. These can have detrimental effects on water quality, biodiversity, ecosystem functioning, food webs and human health. Thus, this maritime industry increasingly contributes significantly to ocean pollution (Braithwaite, Carrascosa and McEvoy 2007; Amirkolaie 2011; Schar et al. 2020).

5.2.2.4 Oil pollution

Oil pollution in marine waters still happens anywhere crude oil is drilled, transported or used and may originate from tankers, rigs, wells and offshore platforms. Pollution from point-source oil spills has declined substantially in recent years, although the data available in some regions remains sparse. The reduction is due to the implementation of stricter regulations and the development of new shipping technologies (Jernelöv 2010). The average number of large oil spills – greater than 700 tons – per decade has decreased from 24.5 in the 1970s to 1.7 in the 2010s (International Tanker Owners Pollution Federation 2024). Similarly, the total amount of oil spilled from tankers per decade declined from 3.2 million tons in the 1970s to 138,000 tons in the 2010s. This decline in oil pollution has had a positive effect on the environment and human health.

5.2.2.5 Other prominent sources of industrial pollution

Chemical pollution of industrial origin in marine systems is a multifaceted issue, encompassing a variety of pollutants, including heavy metals, persistent organic pollutants, per- and polyfluoroalkyl substances, xenobiotics, and industrial solvents (Tornero and Hanke 2016), as well as pharmaceuticals (Mezzelani and Regoli 2022).

All synthetic compounds which are foreign to natural ecosystems, such as industrial chemicals, pharmaceuticals, pesticides, artificial fertilizers and plasticizers, pose a significant threat to all aquatic systems, particularly those near the shore

Credit: stockfilmstudio/Envato

(Piwowarska et al. 2024). These compounds have been reported in surface waters throughout the world (Kumar et al. 2012), including those in Europe (Sablayrolles et al. 2011; Milić et al. 2018), and even in the Arctic (Lehmann-Konera et al. 2020).

While most industrial contaminants enter the marine environment from land-based sources, they are increasingly emitted from point sources at sea such as rigs and offshore installations. These sea-based pollutants can also be recirculated in the marine environment and are difficult to assess, due to monitoring challenges offshore.

Some regions are more heavily affected by chemical pollution due to multiple rivers as sources and a long history of industry. Marine waters most seriously impaired by industrial pollutants are the North Sea, Mediterranean Sea, the Baltic Sea, and Asian estuaries (Joerss et al. 2020).

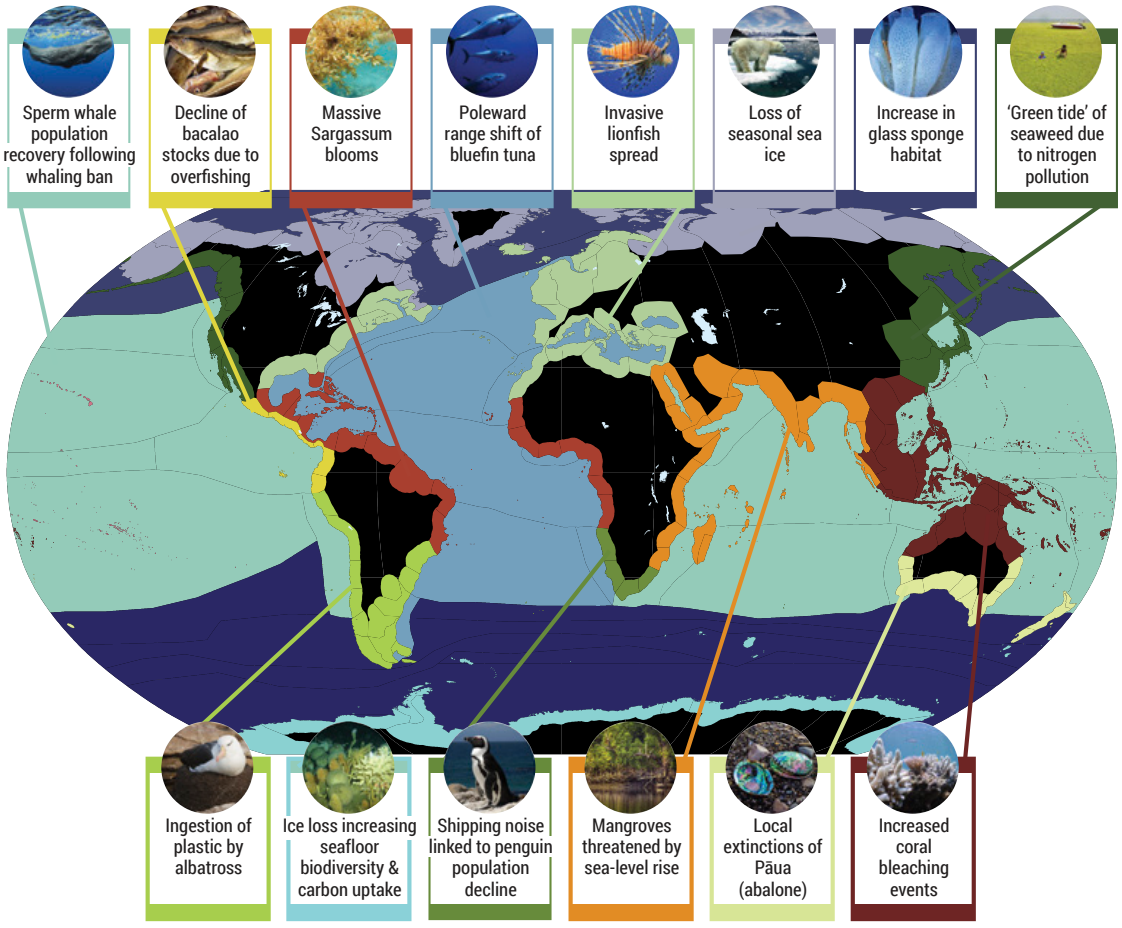
Heavy metals such as lead, mercury, cadmium, copper, and zinc can enter systems from various sources, including industrial emissions, mining operations, wastewater and riverine discharges, and from shipping and offshore sources. Direct inputs of metals via antifouling chemicals, mainly copper and tin, and corrosion anodes, mainly zinc, create hotspots in and around marinas, harbours and along shipping routes. The level of pollution by heavy metals varies regionally in coastal and shelf seas (Larsen and Hjermann 2022).

Comprehensive monitoring and comparison of the ocean and coastal seas are rare. Current protocols include stringent controls of heavy metal emissions and facilitate the assessment of countries in Eastern Europe, South-Eastern Europe, the Caucasus and Central Asia (United Nations Economic Commission for Europe 1998).

Persistent organic pollutants are a group of chemicals that resist degradation and can therefore accumulate in the environment (Wenning and Martello 2014). They include polychlorinated biphenyls, dioxins and furans, polycyclic aromatic hydrocarbons and many pesticides. They enter the global ocean from sources that include industrial emissions, agricultural run-off, and waste disposal. Persistent organic pollutants can accumulate in marine animals such

as shellfish, posing an additional risk to human health through consumption of contaminated seafoods (Camacho-Jiménez et al. 2023).

Per- and polyfluoroalkyl substances, encompassing thousands of compounds, are of increasing concern in human health and ecosystems due to their environmental persistence and toxicity. They have been detected in global surface waters since the early 2000s (Muir and Miaz 2021).



Industrial solvents are chemicals used in various industrial processes. They can enter the global ocean through industrial emissions, wastewater discharges and accidental spills.

5.2.3 Biodiversity

The oceans represent around 70 per cent of the Earth's surface and contain almost 245,000 known species (World Register of Marine Species 2023), with potentially 33–66 per cent of marine species yet to be discovered (Appeltans et al. 2012; Costello and Chaudhary 2017). Marine biodiversity patterns are undergoing significant shifts due to human influence. Around 59 per cent of the world's marine ecosystems are classified as experiencing significantly increasing human impacts and only 13 per cent are classified as wilderness with low human impacts (Jones et al. 2018; Halpern et al. 2019). These adverse effects include loss or decline of species, range shifts and introductions, and in some cases a disruptive increase in species abundance (Box 5.1; **Figure 5.6)**.

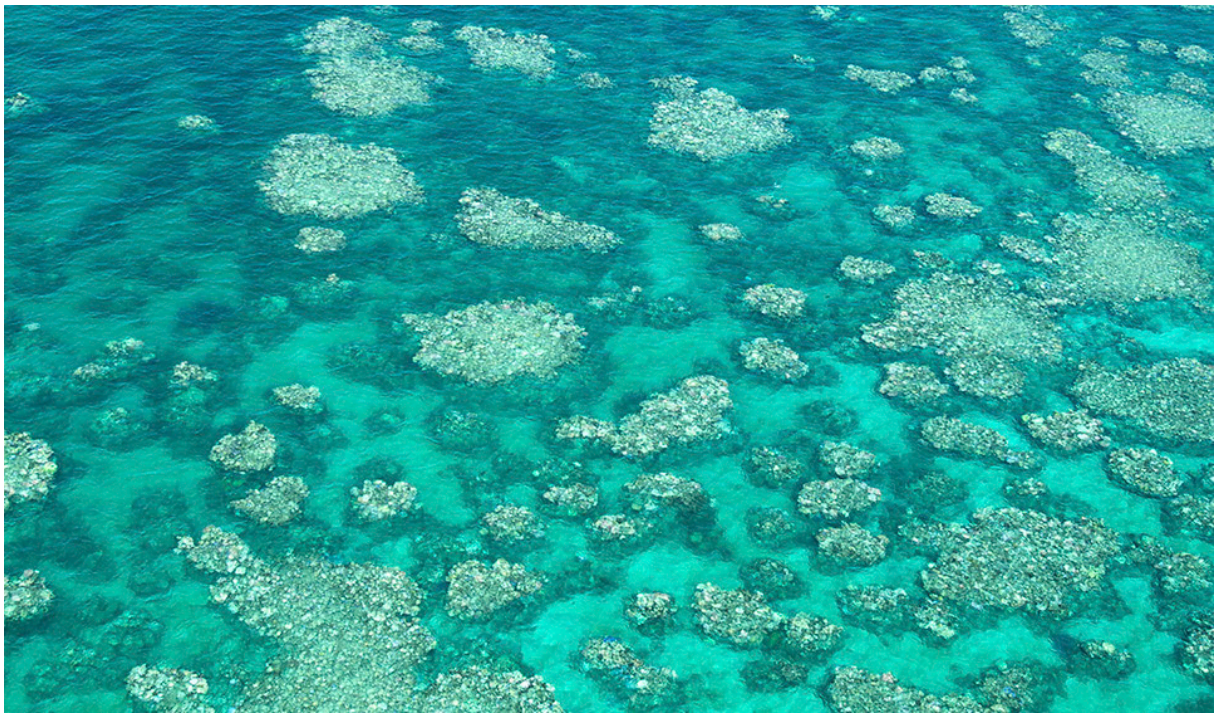
A major trend of ocean biodiversity is a poleward shift of species, with cold-water species being lost and warm-water species either being lost or migrating poleward. This decreases biodiversity in the tropics and increases biodiversity in temperate areas due to the arrival of new species (Chan and Briski 2017; IPCC

Figure 5.6: Examples of biodiversity changes within global marine regions demonstrating the variety of impacts and changes seen in marine ecosystems

Sources: Marine ecoregions taken from (Spalding et al. 2007) (coastal); (Spalding et al. 2012) (pelagic). Examples from (Godwin 2003; Jiménez et al. 2015; Ward et al. 2016; Andradi-Brown 2019; Pontón-Cevallos et al. 2020; Wang, Wang and Gu 2020; Bennett-Jones et al. 2021; Beazley et al. 2021; Steiner et al. 2021; Morley et al. 2022; Pichegru et al. 2022; Skliris et al. 2022; Whitehead and Shin 2022; Crear et al. 2023; Virgen-Urcelay and Donner 2023; Zhang et al. 2024

Box 5.1 Ecological and social consequences of shifts in Sargassum ecology

An extreme example of a highly habitat-disrupting organism class is the Sargassum seaweeds, encompassing 300 species. Since 2011, a floating aggregation of Sargassum known as the "Great Atlantic Sargassum Belt" has been recorded stretching nearly 9,000 km across and extending from West Africa into the Caribbean Sea and the Gulf of Mexico (Wang et al. 2019). This unusual abundance has been linked to global shifts in wind patterns, warming, increased nutrient input from rivers, and changed hydrography stemming from land degradation (Robledo et al. 2021). Although normal levels of Sargassum are beneficial as a habitat for fish and other species (Polte and Buschbaum 2008), the extreme proliferation has become problematic.



Credit: FabianMontano/Envato

For coastal Caribbean communities, such massive blooms and stranding of two pelagic species of this seaweed, *Sargassum fluitans* and *Sargassum natan*, have become an economic and social problem, meaning that they are now perceived to be invasive even where they are native to the area. Upon coastal stranding, Sargassum begins to rot, often releasing hydrogen sulfide and ammonia. These noxious gases travel long distances, affecting livelihoods, especially tourism, and both marine and human health, causing respiratory, eye, and possibly neurological effects. Caribbean countries are struggling to predict, prevent, contain, or utilize Sargassum blooms to limit the consequences for the economy, the environment, and health (Schmidt 2023).

2019; Antão et al. 2020; Benedetti et al. 2021; Boag, Gearty and Stockey 2021; Chaudhary et al. 2021).

Although relatively few marine extinctions have occurred in the last 500 years (del Monte-Luna et al. 2023; Nikolaou and Katsanevakis 2023), combined factors such as climate change, pollution, over-exploitation, and habitat destruction (Section 5.2.3.1) mean that many marine species' populations are declining (Pacoureau et al. 2021; Fortuna et al. 2024; Hendrix and Pérez-Espona 2024; Plön et al. 2024). The average global biomass of exploitable fish is predicted to decline by at least 5.3 per cent by 2050 as a result of climate change alone, even under low emissions scenarios (Blanchard and Novaglio 2024). However, 717 local extinctions have been recorded globally (Nikolaou and Katsanevakis 2023), with 26 per cent of cetacean species, 32 per cent of

Coral bleaching in the Great Barrier Reef, Australia. Credit: ARC CoE for Coral Reef Studies/Terry Hughes (via flickr) (CC BY-ND 2.0)

sharks, skates and rays, and estimates of up to 13 per cent of marine bony fish threatened with extinction (Dulvy et al. 2021; Braulik et al. 2023; Loiseau et al. 2024). Habitat loss is occurring for key marine and coastal ecosystems, such as seagrasses, coral reefs and mangroves (Dunic et al. 2021; Eddy et al. 2021; FAO 2023a). Ocean productivity is declining overall; the maximum sustainable yield of fisheries decreased by 4 per cent on average between 1930 and 2010, with some regions such as the Sea of Japan and Celtic Biscay Shelf decreasing by up to 35 per cent (Free et al. 2019). Overall biomass is predicted to decline on average by 5 per cent for every 1°C of warming (Lotze et al. 2019).

5.2.3.1 Causes of biodiversity change

While some stressors have specific and unique impacts on ecosystems as outlined in the following subsections, in many cases changes in biodiversity are the result of multiple interacting factors (Baag and Mandal 2022). Coral bleaching, for example, is caused by stress-induced expulsion of algae living in tissues and may be induced by high temperatures, salinity or light stress, pollution, and ocean acidification (IPCC 2019; Suggett and Smith 2020). The presence of marine litter may decrease ecosystem resilience to climate change (Lincoln et al. 2022); deoxygenated water may make blue sharks more likely to be caught by long-line fisheries (Vedor et al. 2021); and the vulnerability of organisms to metal pollution can be increased by ocean acidification and rising temperatures (Roberts et al. 2013; de Almeida Rodrigues et al. 2019).

Ocean Warming

Ocean warming affects the distribution, abundance, physiology, behaviour and life cycles of marine organisms (IPCC 2019), which may be more vulnerable than terrestrial species to extreme temperatures (Pinsky et al. 2019). Rising ocean temperatures are linked with a relative decrease of equatorial biodiversity and an increase in biodiversity at mid latitudes, as tropical species that are unable to tolerate higher temperatures die off or are forced to migrate polewards (IPCC 2019; Antão et al. 2020; Benedetti et al. 2021; Boag et al. 2021; Chaudhary et al. 2021). Warming also changes ocean current patterns, which may adversely affect ecosystems (Rogers et al. 2020). Warming-induced thinning and loss of Arctic and Antarctic sea ice, alongside contributing to sea level rise, directly threatens ice-dependent species such as polar bears, seals and seabirds (Lannuzel et al. 2020) and destabilizes food webs based on ice algae (Deb and Bailey 2023).

Both chronic and acute heat stress can cause damage and die-offs of marine species. Mass mortality events associated with heatwaves are

increasing globally (Garrabou et al. 2022) and adverse effects may be exacerbated by repeated exposures (Harris et al. 2018; Brown et al. 2023; Levitan et al. 2023). Coral bleaching events can also be triggered by heat stress; up to 91 per cent of the reefs surveyed on the Great Barrier Reef were affected by coral bleaching in 2022 (Great Barrier Reef Marine Park Authority 2022). Furthermore, 99 per cent of coral reefs are predicted to be lost worldwide if global temperatures rise by 2°C (IPCC 2018).

Acidification

Ocean acidification is particularly harmful to species with carbonate shells and exoskeletons – such as coral, crustaceans, urchins, starfish, some plankton species, oysters, clams and scallops – as it leaves them unable to form such structures (Figuerola et al. 2021). Global mean production of mollusks is predicted to decline by 7.7–12.8 per cent by 2100 under a high emissions scenario (IPCC 2019). Ocean acidification may also have physiological effects in organisms such as fish, particularly fish larvae, with growth, survival and metabolism affected by high CO_2 levels (Esbaugh 2018).

Sea level rise

Sea level rise negatively affects coastal ecosystems such as salt marshes, mangroves, reefs, and seagrass meadows through changes in light availability, sediment dynamics, salinity, mechanical wave action, and temperature (Trégarot et al. 2024; Saintilan et al. 2024). In some cases, these systems can adapt, migrate inland, or increase productivity and sedimentation to migrate vertically in response (Daru and Rock 2023). However, this may be constrained by high rates of sea level rise, human activities and other stressors that limit their resilience (Sadat-Noori et al. 2021; FAO 2023a; Saintilan et al. 2024).

Pollution

Plastic pollution accounts for around 85 per cent of total marine waste (UNEP 2021a) and significantly impinges on marine life and ecosystems globally, at all levels of food webs (Eriksen et al. 2014; Geyer, Jambeck and Law 2017; Choy et al. 2019; Omeyer et al. 2023; Vered et al. 2024). It causes harm to marine animals primarily through ingestion or entanglement, leading to injuries such as constriction or loss of limbs (Jepsen and de Bruyn 2019), digestive tract damage (Roman et al. 2019), and reduced fitness associated with ingestion of both macro- and microplastics (Al-Salem, Uddin and Al-Yamani 2020; López-Martínez et al. 2021; Pal et al. 2025).

Beyond direct impacts, plastic pollution affects marine habitats such as coral reefs, mangroves, and seagrass meadows (Ballesteros, Matthews and Hoeksema 2018; Harris, et al. 2021; Navarrete-Fernández et al. 2022) by smothering them, changing sediment composition, and preventing photosynthesis (Walther and Bergmann 2022). Movement of plastic in ocean currents may facilitate invasive species spread (García-Gómez et al. 2021; González-Ortegón et al. 2024), as well as movement of harmful chemicals or pathogens (Andrade et al. 2021; Bowley et al. 2021; Sanganyado et al. 2021) as plastic debris may act as substrates with the potential to absorb, accumulate or leach harmful substances.

Nutrient pollution or eutrophication may trigger algal blooms – reducing water clarity, producing toxins, and depleting water oxygen levels with a resulting die-off of marine life and destabilization of ecosystems (Fredston-Hermann et al. 2016; Mardones et al. 2023; Mack et al. 2024). In addition, sediment run-off associated with nutrient pollution may reduce water clarity, hindering photosynthesis or foraging behaviour. It may also physically bury marine habitats such as coral reefs and seagrass beds (Magris and Ban 2019).

Pollution from aquaculture, including the release of pathogens and parasites from farmed stock, can change the composition of ecosystems, alter behaviour and movement of wild fish stocks, and affect local water quality (Bergland et al. 2020; Casadevall et al. 2021). Some forms of aquaculture, particularly the "unfed" aquaculture of shellfish and algae, may have a large footprint and cause substantial hydrological and chemical changes in their local area (Harvey et al. 2024).

Exposure to chemical pollutants – including heavy metals, pharmaceuticals, sunscreen, and organic pollutants (petroleum products/oil pollution, pesticides, and industrial chemicals) – can cause direct physiological damage and the interruption of neurological, reproductive and immune function in

a wide range of marine organisms and shorebirds (Mayer-Pinto et al. 2020; National Academies of Sciences, Engineering and Medicine et al. 2022; Camacho-Jiménez et al.2023; Bielmyer-Fraser et al. 2024; Aarif et al. 2025). This represents a potential health hazard for human consumption. Muscle tissue of the Peruvian lorna drum *(Sciaena deliciosa)*, a fish eaten by coastal residents, has been found to exceed international standards for arsenic, mercury and lead (Gubloche et al. 2024). Persistent organic pollutants were detected in 100 per cent of samples of traditional marine food animals, including bowhead whale and various seal species, in a recent Alaskan study, although at lower concentrations than in previous assessments, possibly reflecting some global regulation success (Byrne, 2022).

Noise pollution affects animal communication and hearing, behaviour, navigation, foraging ability, and organ integrity and function (Middel and Verones 2017; Weilgart 2018; Duarte et al. 2021; ZoBell, Hildebrand and Frasier 2024).

Over-exploitation

Global sustainable exploitation of marine species is possible (Costello and Chaudhary 2017) and practised at local levels by Indigenous Peoples and local communities enforcing seasonal restrictions. Examples include the law enforcing fishing restrictions during turtle breeding seasons in the Niger Delta, no-take zones of Fijian tabu areas, and protection of spawning areas by the Haida Nation of British Columbia to preserve salmon habitats. However, an increasing proportion of fish stocks are currently fished beyond biologically sustainable levels, with 10 per cent in 1990 rising to 34.2 per cent exploited beyond sustainability in 2017 (FAO 2020) and over 37 per cent of fish stocks now classified as overfished (FAO 2024). In parallel, illegal, unreported and unregulated fishing continues to undermine effective fisheries management and poses a significant threat to marine biodiversity. It accelerates stock depletion, disrupts food webs, and erodes ecosystem resilience on a global scale (FAO 2024).

Fishing beyond a sustainable level causes a decline in stocks such that even with more than doubled effort, catch sizes have reduced since a maximum in 1994 (Worm et al. 2006), with catch per unit effort decreasing by over 80 per cent between 1950 and 2015 (Rousseau et al. 2019). Species with long generation times and low population growth rates, such as sharks and whales, are particularly vulnerable to the effects of over-exploitation. The global abundance of sharks has declined by 65 per cent between 1951 and 2021 (Dulvy et al. 2024), but relief of hunting pressure on whales since the 1980s means that populations are slowly beginning to recover (Calderan et al. 2020; Whitehead and Shin 2022). Particular fishing techniques may also adversely affect non-target species, such as the by-catch of marine mammals, birds and sea turtles in gillnet and long-line fisheries (Lewison et al. 2014), or disturbance to seabed communities from bottom trawling (Thrush, Ellingsen and Davis 2015; Eigaard et al. 2016).

Other forms of marine resource use or exploitation – including the construction of artificial structures such as marine platforms for oil and gas extraction, offshore wind turbines or desalination plants; laying of submarine cables; sand mining; and shipping – may also disrupt marine ecosystems. Disturbance or pollution including chemical, noise, light, and brine from desalination plants may occur during the installation, decommissioning and lifetime of artificial structures, but they may also function as new habitats or artificial reefs (Taormina et al. 2022; Stranddorf et al. 2024). The effects on biodiversity of novel forms of marine exploitation, such as deep-sea mining of metal nodules, are currently unclear (Katona et al. 2023). Such mining has the potential to cause mechanical damage to species and habitats, change local water chemistry, and result in the creation of smothering plumes of sediment (Filho et al. 2021).

Invasive species

The arrival of non-native species into marine habitats may occur due to shifts in species range or via the transport of species through human activities such as shipping ballast-water (de Souza et al. 2024), aquaculture (Chan and Briski 2017), and movement of plastic debris (García-Gómez et al. 2021). Incoming species may appear to bolster declining biodiversity within habitats but can also severely disrupt ecosystem dynamics and cause further decline of native species and ecosystem functioning (Occhipinti-Ambrogi 2021; Olenin et al. 2024), particularly in high latitudes, around islands, and in areas with low natural biodiversity (Alidoost Salimi et

Credit: © FAO/Veejay Villafranca

al. 2021; Gjedde et al. 2024). For example, the arrival of tropical herbivore species is increasing pressure on kelp forests (Zarco-Perello et al. 2021) and temperate seagrasses (Hyndes et al. 2016). However, the arrival of non-native species may also present opportunities for exploitation that relieve pressure on native stocks and can facilitate the maintenance of overall ecosystem function, despite loss of local native species (Kleitou et al. 2021).

5.2.3.2 Assessing biodiversity loss

As oceans are vast, international and typically remote and difficult to sample, monitoring their biodiversity is frequently challenging, and marine systems receive comparatively little conservation research effort (Caldwell et al. 2024). Marine biodiversity metrics are often patchy, both in terms of the areas studied – deep-sea, offshore, and tropical or polar regions are relatively under-studied (Menegotto and Rangel 2018; Danovaro 2024; Pertierra et al. 2025) – and in terms of the species assessed. The focus is usually on large, charismatic, or commercially important species (Troudet et al. 2017; Smith et al. 2021; Deb and Bailey 2023), however, recent advances in techniques such as DNA barcoding mean that species identification and biodiversity assessments are improving (Nguyen et al. 2020; Fan et al. 2023; Jiang et al. 2025). The influence of non-native species may be hard to assess due to long timescales and the complications of other sources of environmental degradation involved (Tiralongo et al. 2022).

Local community monitoring makes up a large part of marine biodiversity assessment; in particular, Indigenous coastal communities are among the first to experience the impacts of climate change on marine environments. Their detailed knowledge of local ecosystems allows them to observe and document changes such as rising sea levels, shifts in species distribution and alterations in water quality. This knowledge is essential to understanding the localized effects of climate change and for developing culturally appropriate adaptation strategies. For example, Inuit observations of sea ice and marine resource availability changes in the Canadian Arctic have been critical in both developing new hunting strategies and informing scientific research on the effects of climate change in the Arctic. There are several projects aggregating biodiversity metrics and data across the world's oceans, but differences in methods and reporting between studies and reports make comparison, and therefore global assessment, challenging (Katona et al. 2023).

5.2.3.3 Consequences of biodiversity change

Climate change

Biological marine carbon uptake and sequestration removes around 10 billion tons of carbon per year from the surface oceans (Siegel et al. 2023), which represents around 25 per cent of the excess CO_2 produced by human activities. CO_2 is absorbed by marine plants and phytoplankton before entering the food chain and being transported away from the ocean surface, with around 20–200 million tons per year sequestered in sediment (Siegel et al. 2023). Changes in phytoplankton communities affect this both positively and negatively; for example, blooms resulting from increased nutrient flow from melting glaciers may increase uptake (Hodson et al. 2017), while shifts in dominant species as a result of acidification and warming decrease it (Boot et al. 2023).

Blue carbon refers to the aspects of marine carbon uptake that may be managed or cultivated, such as tidal marshes, mangroves, and seagrass meadows (Macreadie et al. 2019), many of which are vulnerable to sea level rise, storm surges, heatwaves and elevated CO_2. These ecosystems sequester and store more carbon per unit area than terrestrial forests (UNEP 2021b; IPCC 2022); their loss releases sequestered CO_2 back into the atmosphere and exacerbates climate change. It is estimated that emissions from the destruction of these ecosystems account for 0.15–1.02 billion tons of CO_2 annually, amounting to between US$ 6 billion and US$ 42 billion in economic damages (Pendleton et al. 2012).

Pollution

Marine species may accumulate or ingest pollutants such as plastic or chemicals, enabling the substances' spread through the system. Some species act as reservoirs of pollutants. This could be due to a number of individuals each carrying small amounts, such as microplastics in marine copepods and persistent organic pollutants in deep-sea amphipods (Fagiano et al. 2024). Alternatively, it could result from bioaccumulation in top predators consuming many contaminated prey, such as mercury in predatory fish, persistent organic pollutants in orcas, and heavy metals in shorebirds (de Almeida Rodrigues et al. 2019; Atkinson et al. 2019; Desforges et al. 2024; Aarif et al. 2025). In other cases, coastal biological structures such as mangrove trees may trap floating debris, preventing dispersion into the ocean environment (Martin et al. 2019; Maghsodian et al. 2021).

Biodiversity loss

Loss of marine biodiversity causes a decrease in ecosystem productivity, stability, resilience to disturbances and water quality, with a higher probability of fisheries collapse and local extinction of species (Worm et al. 2006; Rastelli et al. 2020; Zerebecki et al. 2022). Some ecosystems also provide structural protection for neighbouring habitats: the degradation of coral reefs combined with sea level rise may lead to losses of seagrass and mangrove habitat in lagoons as wave action increases (Saunders et al. 2014).

Habitat degradation

Changes in ecosystem composition may cause shifts in ecosystem function, particularly when the affected species are responsible for physical or chemical alterations to the area. For example, reef-building species such as corals or shellfish on oyster reefs disrupt wave action and thereby contribute to natural coastal protection against storm surges and erosion (Saunders et al. 2014; Bitterwolf et al. 2024), as do mangroves and seagrass meadows (Ondiviela et al. 2014; De Dominicis et al. 2023; Veettil et al. 2024). The loss of these species or ecosystems removes this protection and leaves coastlines vulnerable.

Terrestrial ecosystems

The loss of coastal areas due to erosion and sea level rise will disrupt terrestrial biodiversity, particularly in islands, mangroves, wetlands and swamps, with a 1 m sea level rise predicted to cause the extinction of at least 100 endemic species globally (Menon, Soberón and Peterson 2010). Ecosystems in the Caribbean, Sundaland and Polynesia-Micronesian islands, as well as areas in northeastern South America, eastern North America, Southeast Asia, and

Credit: Image-Source/Envato

western Alaska will be most affected (Menon et al. 2010; Bellard et al. 2014).

Shifts in land–sea nutrient exchange as a result of a loss of marine species will also damage coastal terrestrial biodiversity. Species that move between marine and terrestrial environments – such as seabirds, penguins and seals – transfer nutrients between the two, increasing terrestrial biodiversity even beyond where those species are found (Bokhorst et al. 2019).

5.2.4 Land degradation

5.2.4.1 Coastal development

As of 2019, nearly 2.5 billion people live in coastal regions, with that number projected to increase disproportionately to other regions (UN 2021a). This poses significant challenges for ocean management, especially in the context of climate change. Key issues include sea level rise, safety, aquaculture, tourism, shipping, and sustainable ecosystems (Taherkhani et al. 2020).

While many studies have addressed these topics in relation to sustainable coastal zone management, comprehensive international cooperation and resource studies are urgently needed to develop effective global policies and avoid conflicts of interest (Jackson et al. 2001; Tõnisson et al. 2011; Vandenbruwaene et al. 2011; Lusher et al. 2013).

Coastal development can provide economic benefits and recreational opportunities, but it also poses significant environmental challenges, including habitat loss and degradation, pollution, erosion, sedimentation, and conflicts with other uses of the coastal zone.

Coastal fisheries and aquaculture, along with waste from inland fisheries, are major global management issues. The coastal environments in which aquaculture is practised, for example in the

mangroves of Indonesia, Brazil and Malaysia, and sensitive fjord ecosystems such as those of Norway and Chile, are increasingly threatened by overuse (FAO 2016; Bertram et al. 2021; de Lacerda et al. 2021). Globally, coastal development and associated pollutants threaten almost 25 per cent of the world's reefs; the largest proportion of threatened reefs are in Southeast Asia where small islands with densely populated coastlines put pressure on at least one-third of the region's corals (Burke et al. 2011; Dehm et al. 2024).

An increasing coastal environmental issue is the construction of artificial structures such as harbours, beaches and sea walls, especially in terms of land reclamation and artificial structures in the sea (Sengupta et al. 2023; Wang et al. 2023). This has become particularly pronounced in the Mediterranean, with over 8 per cent, and the North Sea with 16 per cent affected, where countries like Germany and the Kingdom of the Netherlands have the highest conversion of shorelines to man-made surfaces (European Environment Agency 2013).

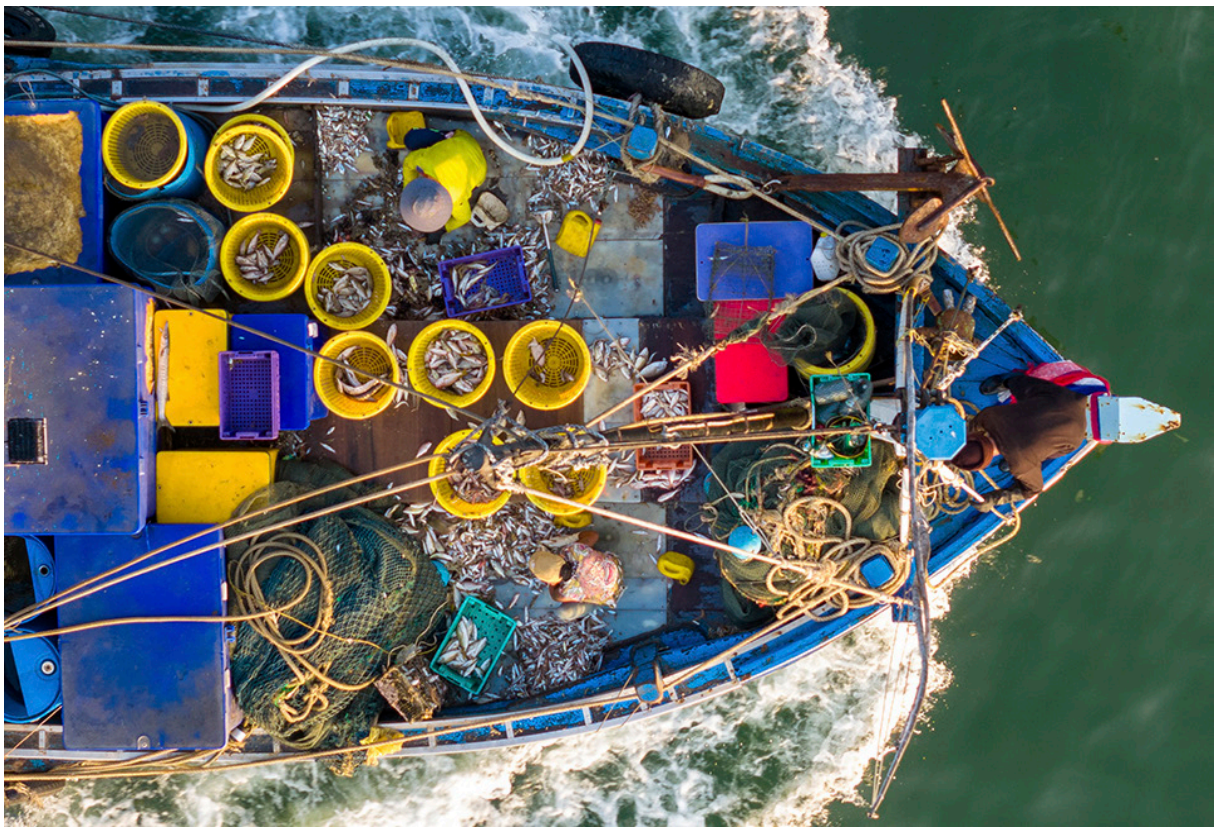
Energy companies should design future facilities with nature-based ideas and decommissioning in mind. However, the renewable energy sector has not fully applied lessons from the offshore oil industry, and environmental legislation in Exclusive Economic Zones varies considerably. As renewable energy structures reach the end of their lifespan, decommissioning poses significant challenges, both financially and due to materials that may now be considered harmful (Kaiser and Snyder 2010).

Coastal ecosystems are increasingly shaped by these artificial structures, affecting sediment and geological processes. To reduce reliance on artificial surfaces, new strategies such as controlled flooding, innovative materials and structure recycling need further research. Nature-based solutions need to be increasingly utilized in new marine structures (Justine and Seenath 2025; Sakr and Altieri 2025).

Policies, regulations, incentives and governance arrangements at different levels also influence coastal development. In order to avoid conflicts of interest, multidimensional and international cooperation as well as resource studies, ending in globally useful legislation, are urgently required (European Environment Agency 2013). A renewed focus on sustainability and the implementation of strong joint governance is needed to address various conflicts of interest (FAO 2016).

5.2.4.2 Catchment run-off

When rainfall, irrigation or wind displaces topsoil, it may be transferred to nearby water bodies and rivers may carry it to the ocean (Borrelli et al. 2017). Such catchment run-off may discharge pesticides, nutrients, sediments and other contaminants such as industrial chemicals or plastic debris into the marine system, particularly from agricultural land, urban areas or waste disposal sites.



Although most pesticides are degraded by soil microorganisms or retained in terrestrial environments, around 760 metric tons of active ingredients from pesticides are discharged into oceans via rivers every year (Maggi et al. 2023). This can harm non-target organisms and disrupt food chains even in relatively small quantities. Increases in agriculture, animal waste, and use of fertilizers mean that inputs of nitrogen and phosphorus into the ocean have escalated over the 20th century (Beusen et al. 2016; Section 5.2.2.2).

Extensive nutrient-reduction efforts in the Chesapeake Bay watershed in the USA have yielded mixed results to date (Hyer et al. 2021). Other examples include the Baltic Sea, where biogeochemical functioning was affected by increasing nutrient loads in the second half of the 20th century, despite changes from the 1980s onwards (Kuliński et al. 2022). On the Great Barrier Reef, sediment loads from most catchment basins have increased substantially since European settlement, with negative implications for coral reefs and seagrass beds (Lewis, Bainbridge and Smithers et al. 2022).

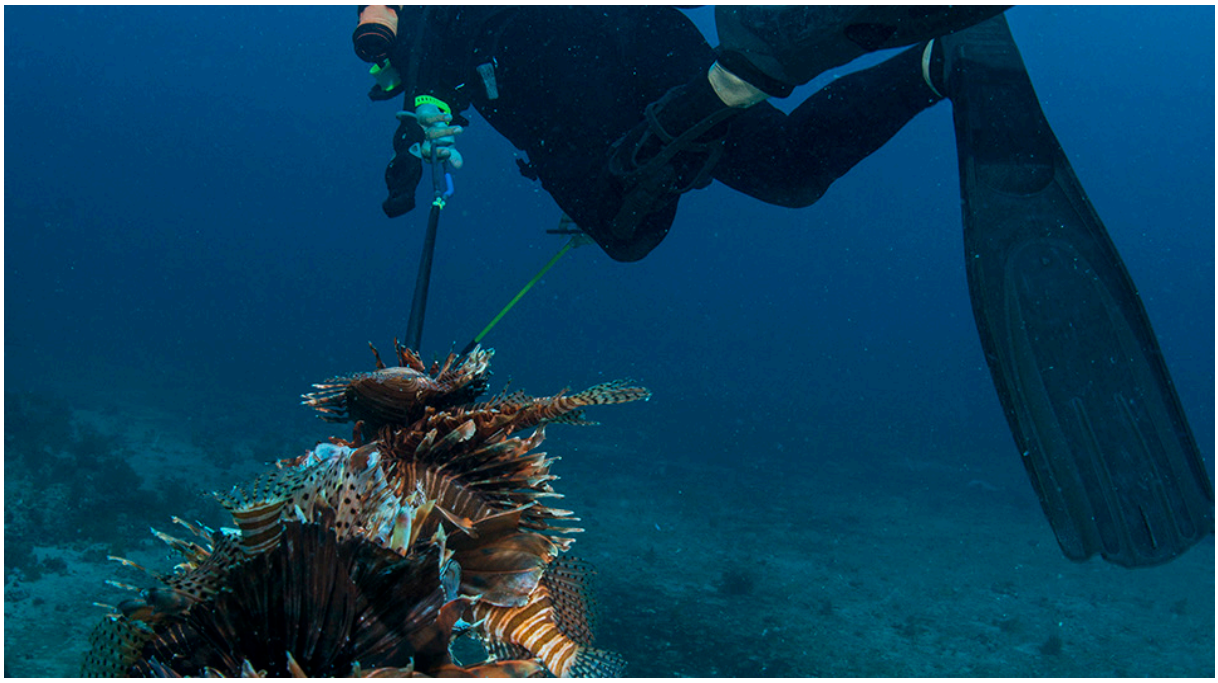
5.3 Human systems

5.3.1 Economic benefits

The ocean is a rich source of resources, including food, fuel, fibre, biochemicals, pharmaceuticals, minerals and raw materials. These are essential for numerous industries and play a significant role in the global economy. According to the Food and Agriculture Organization, approximately 58.5 million people are

Credit: Bluesandisland/Envato

employed in primary fish production worldwide. Taking into account subsistence and secondary-sector workers and their dependants, an estimated 600 million people worldwide rely on fisheries and aquaculture for their livelihoods (FAO 2022).



Marine recreational activities, such as fishing, whale watching and enjoying scenic coastal views, generate substantial revenue and benefit local coastal economies. Additionally, the spiritual, religious and cultural significance of ocean and coastal environments attracts cultural tourism, further contributing to both local and national economies (UNEP 2021b). In many Indigenous Peoples' communities, economic activities related to marine resources are closely linked to cultural practices and community well-being. These activities are managed in ways that ensure equitable distribution of benefits within the community and this holistic approach strengths social cohesion while promoting the sustainable use of marine resources.

Maritime industries are major contributors to global trade and the overall economy. For instance, shipping is responsible for transporting 80 per cent of the volume of international trade in goods, with this figure often even higher in many developing countries (UN 2024a).

Ocean energy – encompassing wind, wave, tidal and thermal energy – represents an important source of renewable energy and promotes sustainable development by reducing reliance on fossil fuels (Garavelli et al. 2024). Ocean energy has the potential to generate between 45,000 and 130,000 terawatt hours of electricity annually, which could theoretically meet the world's electricity needs more than twice over (International Renewable Energy Agency 2020).

Lastly, ocean processes have significant economic implications by mitigating potential costs associated with climate change impacts. The ocean acts as the planet's largest carbon sink, absorbing greenhouse gases and significantly reducing the effects of climate change (Sections 5.2.2.6 and 5.2.3.1). Additionally, photosynthesis by marine plants and algae contributes to oxygen production.

Alteration, degradation and loss of invaluable marine ecosystems and their biodiversity threatens many economic benefits associated with coastal and marine ecosystems. Similarly, changes associated with climate change have significant implications for the development of human settlements and activities in coastal areas. For example, under a high emissions scenario, sea levels are projected to rise by 0.63–1.01 metres by 2100, placing up to 630 million people living on land below the projected annual flood levels (Kulp and Strauss 2019). Storm surges, intensified by sea level rise and extreme weather events, can cause severe disruption to coastal infrastructure, displace

Credit: Image-Source/Envato

communities and result in significant economic losses in tourism, fisheries, transport and housing sectors, compounding the vulnerabilities of coastal development (IPCC 2019).

5.3.2 Food security

Food security means that all people, at all times, have physical and economic access to sufficient, safe and nutritious food to meet their dietary needs for an active and healthy life. Fisheries and aquaculture are essential for global food security, with production reaching an unprecedented 182 million tons of aquatic animals and 36 million tons of algae in 2021 (Intergovernmental Oceanographic Commission of United Nations Educational, Scientific and Cultural Organization [IOC-UNESCO] 2024). In numerous low-income food-deficit countries across Africa, Asia, Latin America and the Pacific Islands, small-scale fisheries contribute approximately 40 per cent of the global fisheries catch, sustaining the livelihoods of nearly 500 million people (FAO et al. 2023). While capture fisheries have remained relatively stable since the mid-1990s, averaging about 92.1 million tons, aquaculture has grown at an annual rate of 5.2 per cent during the same period (IOC-UNESCO 2024).

The apparent per capita consumption of aquatic food was estimated at 20.4 kg per year in 2021 (IOC-UNESCO 2024). Aquatic food consumption accounts for over 20 per cent of the average per capita animal protein intake for 3 billion people, and more than 50 per cent in some developing countries (UN 2021b). Seaweed farming and harvesting also contribute to food security and nutrition by providing edible seaweed, animal feed, fertilizers and biofuels (Nagula et al. 2022; Choulot et al. 2022), as well as absorption of CO_2 (UN 2021b).

Aquatic foods also offer greater sustainability, as the production of aquatic animal-source foods typically has a lower environmental impact than the production of most terrestrial animal-source foods (IOC-UNESCO 2024). However, overfishing has escalated in recent decades, with over 37 per cent of fish stocks now classified as overfished (FAO 2024). Furthermore, by 2100, global fish biomass production is projected to decline under both low and high emissions scenarios. Some of the largest declines are expected in countries that rely heavily on aquatic foods for protein – such as the Solomon Islands, Federated States of Micronesia, Nauru, Portugal, and Palau – or are major producers in global marine fisheries, including China and Peru (Blanchard et al. 2024).

5.3.3 Health

Health is a case of whole mental, physical and social well-being and is not restricted to the absence of disease or even infirmity (World Health Organization 1984). Living near the sea offers numerous benefits

for human health, including enhanced air quality, opportunities for exercise, and access to novel marine-derived pharmaceuticals (UNEP 2021a).

Human health is interconnected with a healthy environment and is defined as the ability to adapt to emerging threats (The Lancet 2009). Such threats arising from the marine environment include:

- The continuous rise in sea surface temperatures, coupled with pollution, is contributing to the increased abundance and wider geographical distribution of certain marine pathogens, particularly the Vibrio species. Among these, *Vibrio cholerae*, which is responsible for cholera, is of particular concern (Baker-Austin et al. 2024).

- Non-native species in marine environments are a growing concern as they can adversely affect the health of both humans and animals, which in turn can disrupt economic activities and livelihoods (Katsanevakis et al. 2014).

- Microplastics pose significant threats to marine life, particularly through the transmission of pathogens. They can act as carriers for a variety of bacteria, viruses and other pathogenic organisms, representing a risk for both marine ecosystems and the broader marine environment (Zhong et al. 2023). Notably, zoonotic human pathogens, including *Escherichia coli,* Salmonella, Cryptosporidium, and rotavirus, can adhere to microplastics (Metcalf et al. 2022; Moresco et al. 2022).

- Risks arise from antimicrobial-resistant bacteria and genes in estuarine and coastal waters, driven by antibiotic use in agriculture and aquaculture. These residues enter coastal areas via run-off and wastewater, posing risks to human health through contaminated seafood and recreational water use, while also reducing the effectiveness of antibiotics (Salma et al. 2025).

5.3.4 Equity/distributional effects

The ocean provides a multitude of benefits to humans, from food and raw materials to climate regulation and recreational opportunities. However, the distribution of these benefits is not uniform across different regions, countries and groups of people. Certain regions and countries are more exposed and sensitive to adverse environmental changes due to their geographical location, socioeconomic status, governance capacity and dependence on marine resources. For instance, Small Island Developing States and coastal communities in developing countries often rely heavily on fisheries and tourism for their livelihoods, making them particularly vulnerable to changes in marine ecosystems (UNEP 2021a).

Similarly, some groups of people are more vulnerable and marginalized than others due to factors such as gender, age, ethnicity, culture or occupation. Women, for example, often play crucial roles in small-scale fisheries and seaweed farming but may lack access to resources, rights and decision-making power. They constitute a significant portion of the workforce in processing and trading fish; however, they frequently engage in low-paid, informal jobs without adequate protection (IOC-UNESCO 2024). Indigenous Peoples also have deep cultural connections to the ocean but may face threats to their traditional territories, knowledge systems, and food sovereignty (UNEP 2021a). These inequities can exacerbate existing social and environmental injustices by disproportionately affecting those who are already disadvantaged or marginalized.

Equitable access to marine resources is paramount, particularly for small-scale fisheries. Climate change, pollution and other human activities disproportionately affect marginalized communities, highlighting the need for relevant policies that promote justice and sustainability in ocean governance (IOC-UNESCO 2024).

Addressing these inequities is essential to ensure a fair and sustainable future for all, as they can undermine human rights and dignity by limiting people's access to resources, opportunities, and justice (UNEP 2021a).

5.3.5 Indigenous Peoples

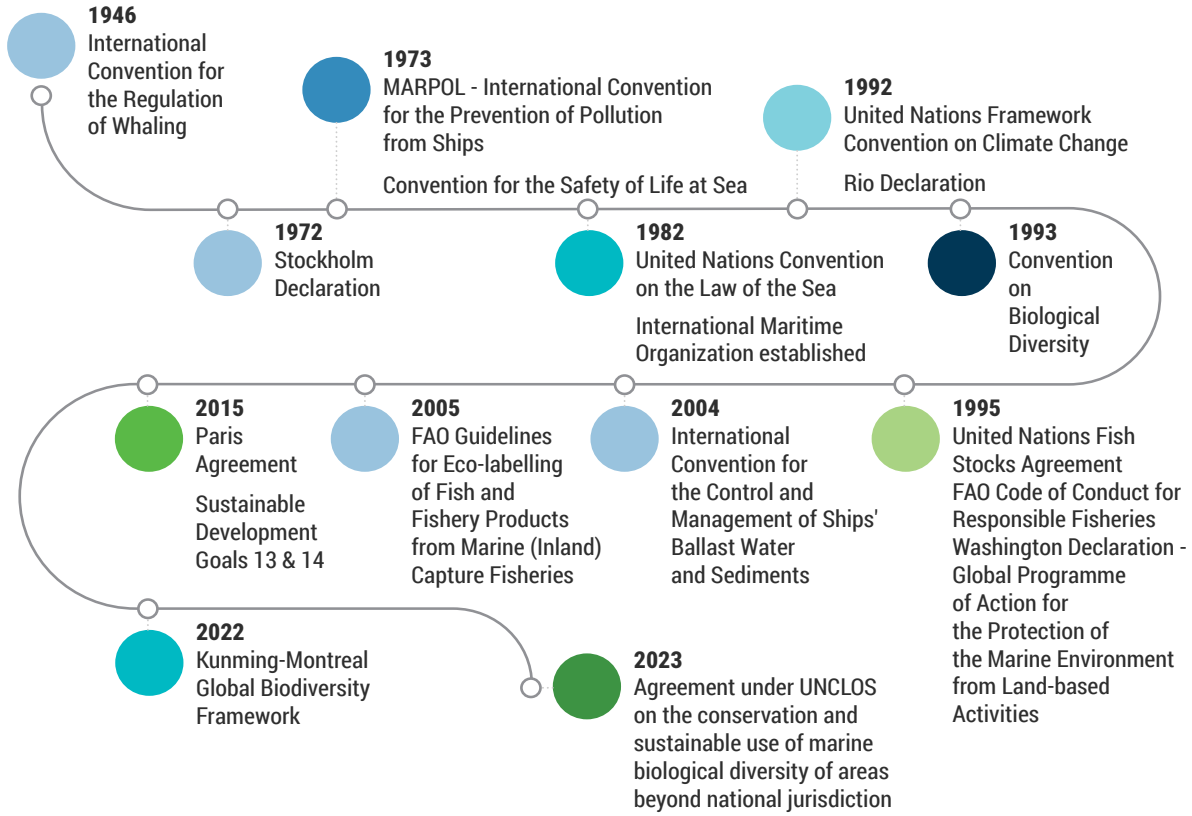
Coastal Indigenous communities are especially vulnerable to the effects of rising ocean temperatures, acidification, sea level rise and pollution. Projections show that increased ocean hypoxia, combined with acidification and marine heatwaves, will lead to significant declines in Dungeness crab populations,

resulting in economic losses for the Hoh, Makah, Quileute, and Quinault Indian Nation tribes along Washington State's Olympic coast (Alin et al. 2023). Similarly, the depletion of shellfish populations due to ocean acidification adversely affects the livelihoods of Indigenous communities in Alaska and along the West and Gulf Coasts of the United States of America (Environmental Protection Agency 2024)

In Tasmania, Aboriginal communities on the east coast, one of the world's fastest-warming marine areas, face climate-driven challenges such as the decline of giant kelp and the increasing prevalence of urchin barrens, which are overgrazed areas in kelp forests. These changes complicate adaptation efforts, leading to cultural losses related to governance and connections to the coastlines where they have lived for countless generations and the resources they have adapted with over that time, their sea country (Pecl et al. 2019). Additionally, Māori communities in New Zealand are experiencing a decline in their cultural functioning capacity due to similar environmental changes (New Zealand, Ministry for the Environment and Stats NZ 2022). Arctic Indigenous communities such as the Russian Sakha, Evenkis and Evens peoples have their ways of life threatened by thawing permafrost and ice that cause coastal erosion and reduce ice road availability, intensification of winter storms, and changes in the seasonality and abundance of fish stocks (Povoroznyuk et al. 2023).

In response to the challenges posed by climate change, many Indigenous communities have adapted their marine resource management practices. These adaptations are often based on traditional knowledge, which is continuously updated to reflect new environmental realities. Indigenous strategies for coping with environmental change emphasize resilience, the sustainable use of marine resources, and the protection of biodiversity. Examples include the people of the Pacific island of Kiribati adapting traditional practices in fish-trap construction in response to rising sea levels and the preservation of native wetland species and sustainable management of water resources by the Lafkenche in Chile. Further examples can be found in mangrove restoration projects by Indigenous communities in the Sundarbans of India and Bangladesh and Ogoni people in the Niger Delta.

5.4 Progress towards internationally agreed goals



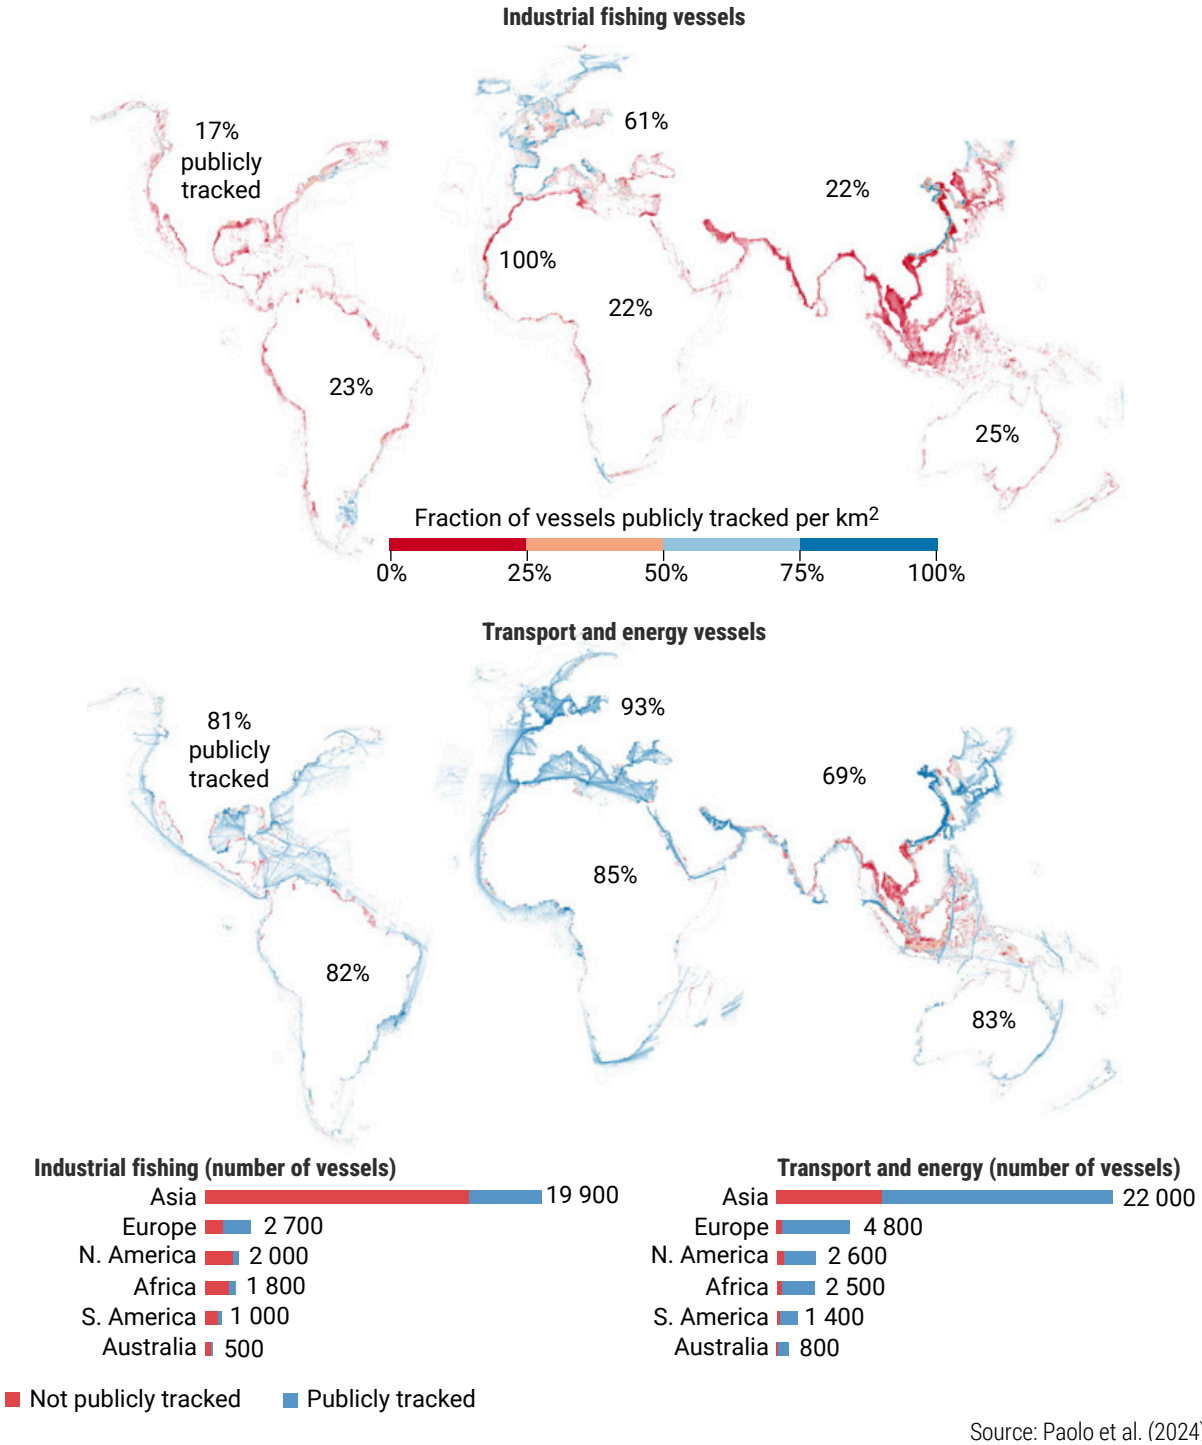
Many international agreements, conventions and treaties exist to protect and conserve ocean resources and regulate their use, including those aimed at improving specific aspects of ocean management (**Figure 5.7**). These cover various topics, including climate change, pollution, energy, fisheries, mining, and transport (**Box 5.2**). This section examines progress towards selected internationally agreed goals, particularly biodiversity targets and Sustainable Development Goal (SDG) 14. It also addresses progress and ongoing negotiations towards establishing new agreements addressing emerging issues such as biodiversity in areas beyond national jurisdiction, plastic pollution and deep-sea mining.

5.4.1 Aichi Biodiversity Target 11

Aichi Biodiversity Target 11, set by the Convention on Biological Diversity (CBD), aimed to conserve at least 17 per cent of terrestrial and inland water areas and 10 per cent of coastal and marine areas by 2020. These areas, important for biodiversity and ecosystem services, were to be conserved through well-managed, ecologically representative and connected protected areas, along with other effective area-based conservation measures.

The Aichi Biodiversity Target 11 was assessed as partially achieved, contributing to the greatest global Marine Protected Area (MPA) network growth since 2000 (Secretariat of the CBD 2020). Nevertheless, the total protected area fell short of the 10 per cent goal, with 7.74 per cent of coastal waters and oceans protected (The United Nations Environment Programme World Conservation Monitoring Centre [UNEP-WCMC] 2021). Some progress was made towards covering areas of ecological and biodiversity importance, for example, 46.1 per cent of marine ecoregions had at least 10 per cent coverage, and an additional 9.1 per cent had at least 5 per cent coverage (Secretariat of the CBD 2020; European Commission Joint Research Centre 2020). Questions remain about ecological representation due to the generally low coverage (Carr et al. 2020). As of March 2025, 8.34 per cent – 16,503 MPAs – of marine areas within national waters were under protection (**Figure 5.10**) (UNEP-WCMC and IUCN 2024).

Figure 5.7: International treaties on marine law and management



Box 5.2 Example of how selected international agreements apply to different sectors and activities

Human activity is rapidly expanding ocean infrastructure, including offshore energy, artificial islands, submarine cables, and mining operations. These developments impact land–ocean interfaces, cause substrate change, hydrography shifts, affect biodiversity and ecosystem structures, and increase maritime logistic and security pressures. Unregulated fishing persists alongside these increased pressures (**Figure 5.8**) (Paolo et al. 2024).

The UN Sustainable Development Goals 13 and 14 emphasize the need for sustainable ocean use under the United Nations Convention on the Law of the Sea (UNCLOS) framework. While UNCLOS regulates seafloor mining and high seas freedoms such as fishing and navigation, it lacks specifics on renewable resource collection and carbon sequestration. Mining of polymetallic nodules from the seafloor, a controversial activity, is regulated under UNCLOS by the International Seabed Authority. The freedom to utilize renewable resources – for example, wind, light, heat and currents – is, however, not explicitly dealt with (Soria-Rodríguez 2022).

The High Seas Treaty addresses some gaps by promoting ocean heritage, biodiversity loss, and ecosystem sustainability. However, for all marine industry and urbanization and especially in the case of the Offshore Renewable Industry international environmental agreements, standards and best practices must be applied and reported, both within jurisdictional areas in national or international waters (United Nations 2024b). As is clear from the evaluation of shipping trends by the International Maritime Organization (IMO), there is an urgent need to reduce emissions, such as carbon dioxide, and noise from shipping. Indeed, the role of other bodies such as the IMO, International Renewable Energy Agency, OSPAR Commission, International Council for the Exploration of the Sea and Baltic Marine Environment Protection Commission in reducing ocean and coastal industrialization and urbanization impacts cannot be overemphasized. As an example of progress, the IMO's revised GHG Strategy, adopted at the 80th session of its Marine Environment Protection Committee, targets net-zero emissions for international shipping by 2050, with interim goals of reducing emissions by 20 per cent by 2030 and 70 per cent by 2040 (IMO 2023a) (**Figure 5.9**).

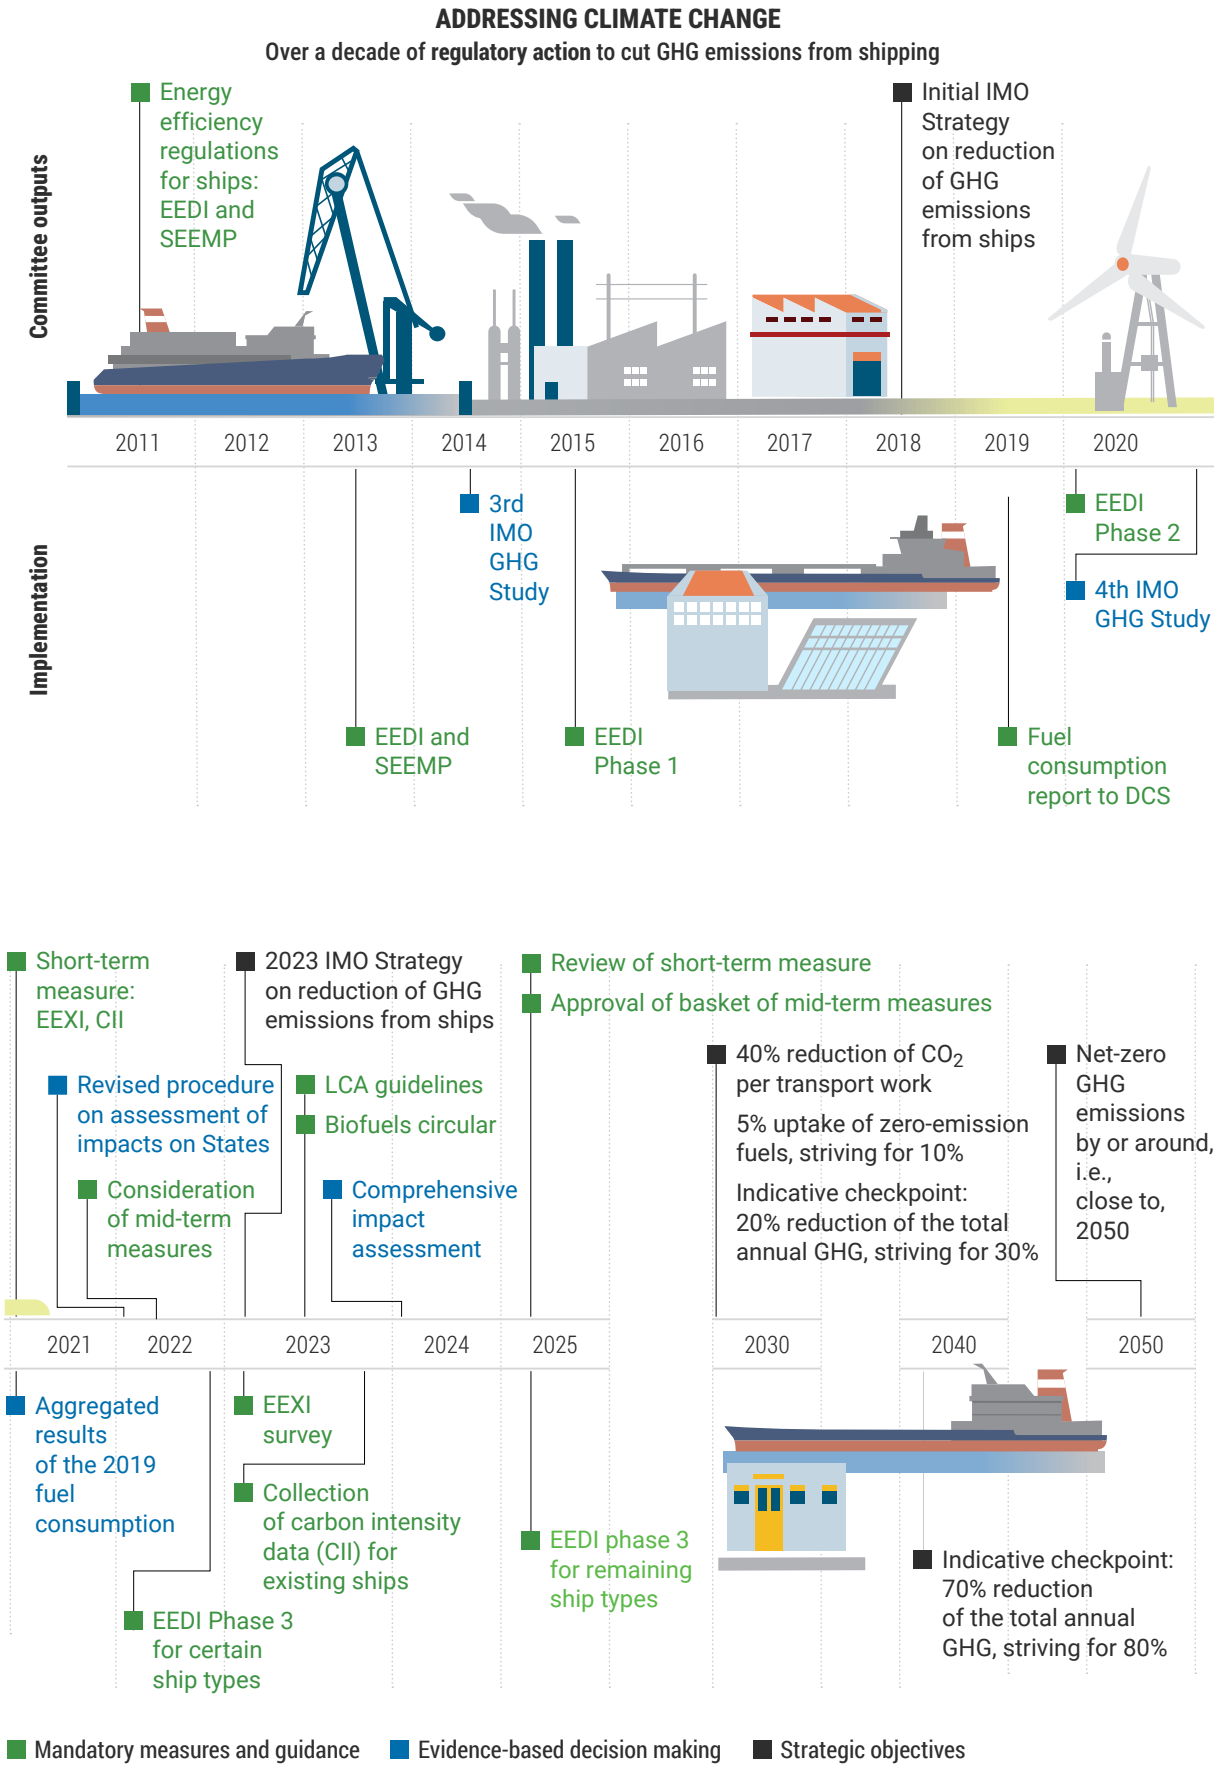


Figure 5.8: Industrial fishing and other uses of oceans and coasts, 2017–2021

Source: Paolo et al. (2024)

Area-based measurements have been criticized for falling short of adequately protecting threatened areas (Kuempel et al. 2019) and the diversity of marine habitats (Fischer et al. 2019; Carr et al. 2020). The level of protection varies within MPAs, and in 2023 only 2.9 per cent of such areas were classed as fully or highly protected from extractive activities (Marine Conservation Institute 2023). In addition, one-quarter of the 100 largest MPAs, which cover 90 per cent of the world's total, are not implemented, and one-third allow high-impact activities. Fully protected MPAs make up one-third of the area but are unevenly distributed, often in remote territories (Pike et al. 2024). A further limitation is that data on the effectiveness of governance and management in existing protected areas remains poor (Carr et al. 2020; UNEP-WCMC 2021). The Global Database on Management Effectiveness of Protected Areas has only conducted

assessments covering approximately 1 per cent of coastal and marine areas (Secretariat of the CBD 2020).

5.4.2 Kunming-Montreal Global Biodiversity Framework

The Aichi Biodiversity Targets (2011–2020) have been replaced by the Kunming-Montreal Global Biodiversity Framework (GBF), which will guide actions through to 2030. These include restoring at least 30 per cent of degraded ecosystems and protecting at least 30 per cent of terrestrial, marine, and coastal areas by 2030 (Secretariat of the CBD 2022).

Achieving the new goals may be challenging, particularly in implementing the framework at the national level, as the Aichi national indicators showed inconsistent alignment with global targets (Secretariat of the CBD 2020). Nationally differentiated targets have been identified as more effective for meeting global conservation goals (UNEP-WCMC 2021). The new framework includes indicators for parties to report and monitor progress (Secretariat of the CBD 2022). The Kunming-Montreal GBF's interim goals and targets are more specific than previous Convention on Biological Diversity iterations (Streck 2023), moving away from a set-and-forget approach to international agreements of 2002 and 2010 (Phang et al. 2020).

Nevertheless, questions about the Kunming-Montreal GBF targets' measurability arise from a lack of clear metrics, limited data availability and the complexity of biodiversity itself. Tracking is further complicated by the variability in national capacities to monitor progress, especially in resource-limited regions. Ecological changes often occur over long time frames, making short-term measurement difficult, and cross-sectoral impacts from industries such as agriculture and fisheries can distort progress assessments (Hughes et al. 2023). Addressing these issues is critical in ensuring effective monitoring and reporting of the Kunming-Montreal GBF's ambitious goals.

5.4.3 Sustainable Development Goal 14

While some regions and countries have made advances, overall progress towards achieving SDG 14: Life Below Water is insubstantial and inadequate in pace and scale (UNEP 2019; Andriamahefazafy et al. 2022; Haas 2023).

A key barrier to accurately measuring SDG targets is the lack of specific and quantifiable metrics common to many such targets (McArthur et al. 2019; UNEP 2019). For Target 14.1, which aims to prevent and reduce all forms of marine pollution by 2025, progress can be inferred by tracking trends in different types of pollution. One key indicator is plastic pollution, with the volume of plastic entering the ocean expected to triple by 2040. Another is Chlorophyll-a levels in Exclusive Economic Zones, which serve as an indicator of the risk of algal blooms and eutrophication. These levels decreased by 20 per

cent from 2018 to 2020 (UN 2022a). However, despite this decline, hypoxic zones caused by fertilizer run-off and untreated wastewater remain widespread (Section 5.2.2.2). Insufficient data on plastic pollution at regional and global levels, and the lack of globally comparable nitrogen and phosphorus measurements for coastal areas (IOC-UNESCO 2022), pose significant challenges to measuring progress on Target 14.1.

Progress towards SDG 14 Targets including 14.2, 14.4, 14.5 and 14.6, set to be achieved by 2020, varied. For Target 14.2, 53 countries or 34.8 per cent, made good progress in sustainably protecting and managing marine and coastal ecosystems, (Andriamahefazafy et al. 2022). The number of countries using marine spatial planning – an approach that analyzes and allocates human activities in marine areas to achieve ecological, economic and social objectives – surged from a few before 2006 to 100 in 2022 (UN 2022b).

For Target 14.4, over 61 per cent of countries have made only "low progress" in sustainable fishing through regulation of "fish harvesting, elimination of illegal, unreported, and unregulated fishing" and implementation of science-based management plans. In 2019, 35.4 per cent of global fish stocks were overfished, up from 34.2 per cent in 2017 and significantly higher than the 10 per cent recorded in 1974 (UN 2021c). Contributing factors to overfishing include the illegal, unreported, and unregulated fishing; advances in fishing technology; population growth; and a rising demand for fish. Global aquatic fish consumption increased by 3 per cent annually since 1961, compared to a population growth rate of 1.6 per cent (Bardey 2020; FAO 2022). At the same time, the rate of underfished stocks has decreased, showing slight recovery in 2018 and 2019 (FAO 2022). Despite prevalent reports of low progress, a notable lack of data on sustainable fishing practices remains.

Target 14.6 aims to prohibit specific fisheries subsidies that contribute to overcapacity and overfishing; eliminate subsidies that support illegal, unreported, and unregulated fishing; and prevent the introduction of new harmful subsidies. This target also highlights the importance of special and differential treatment for developing and least developed countries in the World Trade Organization's fisheries subsidies negotiations.

Target 14.5, conserving at least 10 per cent of coastal and marine areas, is classified as "met or almost met" at a global level; even though only 55 countries achieved it by 2018 (Mustajoki et al. 2022). Pacific island nations, along with regions in Central and Southern Asia and Northern and Western Africa, are categorized as "far from target" (UN 2022c). Furthermore, despite Target 14.3's goal to minimize ocean acidification by 2030, acidification is expected to worsen (UN 2022a). Notably, there are significant data gaps regarding coastal waters near Asia and Africa, as well as in open waters such as the South Atlantic, Pacific, Indian, and Southern Oceans (UN 2021c).

Lastly, achieving SDG 14 is as significant for Indigenous Peoples as it is for other communities. However, except for a few countries, actions have not sufficiently addressed Indigenous rights to fisheries and ocean and coastal resources, nor adequately incorporated Indigenous opinions and perspectives (Yap et al. 2019). Encouragingly, Australia's Great Barrier Reef Marine Park Authority has been increasingly working with Aboriginal and Torres Strait Islander peoples to ensure the health of both marine life and Indigenous communities (Great Barrier Reef Marine Park Authority 2019). Similarly, Canada's national approach to SDG 14 acknowledges Indigenous rights to the ocean and its resources and includes Indigenous-led marine and coastal initiatives, such as establishing Indigenous Protected Areas. In New Zealand, traditional Māori knowledge has benefited the management of coastal and ocean resources, as seen in the restoration of mussel populations in Ōhiwa Harbour through the use of Mātauranga Māori, alongside other knowledge sources (Clapcott et al. 2018).

In the Arctic, the traditional knowledge of Indigenous Peoples such as the Inuit and Sámi is crucial for monitoring climate change and managing marine resources sustainably. Indigenous-led conservation efforts, such as those in Canada and Greenland, help safeguard biodiversity and food security while fostering co-productive governance approaches (Buschman 2022; Buschman et al. 2023).

Indigenous communities in Fiji have established MPAs that contribute to the country's efforts to meet the SDGs. These protected areas are managed using traditional knowledge, which ensures the sustainable use of marine resources and the protection of biodiversity. However, research remains limited on

Indigenous communities in coastal ecosystems in the Global South (Loch and Riechers 2021).

5.4.1 Emerging international agreements

5.4.4.1 Agreement on Marine Biodiversity of Areas Beyond National Jurisdiction

On 19 June 2023, the United Nations adopted the Agreement on the Conservation and Sustainable Use of Marine Biological Diversity of Areas Beyond National Jurisdiction under the United Nations Convention on the Law of the Sea (UNCLOS). This Agreement, which encompasses the high seas and the international seabed area, covers over two-thirds of the ocean (UN 2024b)and aims to enhance the scope and specificity of the Convention (Harden-Davies et al. 2024).

The Agreement addresses marine genetic resources and fair and equitable sharing of benefits, alongside measures such as area-based management tools, including MPAs, environmental impact assessments, capacity-building and the transfer of marine technology (UN 2023). It contributes to marine biodiversity protection beyond national borders, cleaner oceans through pollution control, sustainable fish stock management, ecosystem resilience to climate change effects, and the achievement of the 2030 Agenda, including SDG 14, by enabling marine conservation and equitable resource management. The Agreement is not yet in force and has been ratified by 15 states as of December 2024 (United Nations Treaty Collection 2025).

5.4.4.2 International Legally Binding Instrument on Plastic Pollution

In March 2022, the United Nations Environment Assembly adopted resolution 5/14, mandating the creation of a new international legally binding instrument to combat plastic pollution, including in the marine environment. This process involves five negotiation rounds over two years, facilitated by an Intergovernmental Negotiating Committee established

by the Executive Director of the United Nations Environment Programme. The instrument aims to address plastic waste comprehensively, covering its entire life cycle from production to disposal, which is crucial for preventing marine plastic pollution by reducing waste leakage into the ocean. The target completion date for this instrument was set for the end of 2024 (UNEP 2024). However, negotiators failed to reach an agreement, and negotiations are scheduled to resume during the second part of the fifth session in August 2025.

5.4.4.3 International Seabed Authority – Exploitation Regulations

Since 2014, the International Seabed Authority (ISA) has been developing regulations for the exploitation of mineral resources in the international seabed area, known as "the Area" (Pickens et al. 2024). These regulations include legally binding standards for contractors and the ISA, along with supplementary guidelines (International Seabed Authority 2022). The ISA did not meet the 9 July 2023 deadline, which was triggered in 2021 when the Republic of Nauru invoked a provision of the UNCLOS. Instead, at the second part of its 28th session in 2023, the ISA outlined a road map to adopt regulations during its 30th session in 2025. The negotiation process is supported by four working groups focusing on financial terms, environmental protection, compliance and enforcement, and institutional matters, as well as additional informal discussions (International Seabed Authority 2023).

This underscores the crucial role of the ISA's regulations in shaping the future of deep-sea mining, which according to Article 145 of UNCLOS must ensure effective protection of the marine environment from the industry's harmful effects (UN 1982). The delay in finalizing these rules highlights the complexity and importance of getting them right for effective ocean governance. Without clear and enforceable regulations, deep-sea mining could proceed without adequate safeguards, potentially leading to habitat destruction, biodiversity loss and harm to deep-sea species that are not yet fully understood. Metal contamination from mining activities could disrupt marine food webs (Martins et al. 2023), and interactions between deep-sea mining and fisheries may significantly affect the economies, livelihoods and well-being of coastal communities, particularly in Pacific Small Island Developing States and coastal States (Amon et al. 2023).

Chapter summary

Credit: Great_bru/Envato

Water pollution continues to degrade freshwater quality and exacerbate water insecurity (*well established*). It stems both from resource extraction, agricultural intensification, industrial effluents, and urban development. Due to their hydraulic connection, pollution of surface water systems also affects groundwater quality, and vice versa {6.2.1; 6.4.1}.

Approximately 42 per cent of global municipal wastewater sewage is still discharged into the environment untreated (*established but incomplete*). In 2021, the combined global annual volume of domestic and industrial wastewater production was at 359x109 m^3, approximately twice the flow of the Danube River {6.2.1}.

Emerging contaminants, now found in fresh water worldwide, have been linked to serious human health and environmental impacts (*established but incomplete*). They contribute to cancer, cardiovascular disease, respiratory and reproductive health problems, neurodegeneration and a weakened immune system. The list of emerging contaminants continues to grow and includes micro and nano plastics, pharmaceuticals, personal care products, hormones, per- and polyfluorinated substances, flame retardants, plasticizers and corrosion inhibitors {6.4.1}.

Unregulated artisanal and illegal mining are causing freshwater pollution in 173 large river basins across 49 countries (*established but incomplete*). The water quality impacts are degrading ecosystems, contributing to freshwater biodiversity loss, and threatening human health especially in many low- and middle-income countries and vulnerable communities {6.2.1}.

Global freshwater withdrawals, currently estimated at 4,300 km^3 per year, have nearly doubled since 1980 (*well established*) and have reached unsustainable rates in many regions, including North Africa, parts of Southern and Western Asia, Central America, and the Southwestern United States of America (*established but incomplete*). This trend is mostly driven by irrigation for rising food production, population growth, and industry and mining expansion. However, total withdrawals have started to stabilize due to declining per capita water extraction. As of 2020, agricultural production accounted for the majority of freshwater withdrawals at 67 per cent, followed by industrial at 14 per cent, municipal at 12 per cent, and energy at 7 per cent {6.2.2}.

Unsustainable groundwater withdrawals for agriculture, municipal and industrial water supply needs

contribute to severe groundwater depletion in several regions (*well established*). Globally, groundwater supplies around 25 per cent of the water used in irrigated agriculture. Since 2000, groundwater levels have declined in more than 30 per cent of the world's regional aquifers. However, groundwater depletion has slowed in 20 per cent and reversed in 16 per cent of aquifers worldwide {6.2.2; 6.3.1}.

Dam construction, driven by needs for clean energy and water supply, presents a major threat to freshwater biodiversity worldwide (*well established*). The world's 35,000 dams with mapped reservoir areas fragment habitats, disrupting natural water flow patterns, and altering nutrient and suspended sediment circulation. Since the 1990s, these developments have added 49,715 km^2 of new surface water coverage, with the most significant increases in Asia, Africa and South America {6.2.3; 6.5.3}.

Climate change is intensifying the global hydrological cycle, leading to more extreme floods, glacier and permafrost melt, declining snow cover, prolonged droughts, and freshwater biodiversity loss (*well established*). Extreme flood events often damage ecosystems especially in South America, Africa, Asia and Europe. The loss of glaciers, land ice, and snow cover is widespread, especially in mid- and high latitudes and at higher elevations {6.3.1; 6.3.2}.

Global drought trends are primarily driven by climate-related changes in precipitation, temperature, and evapotranspiration and vary by region (*well established*). The frequency, duration and intensity of droughts are increasing in parts of the Americas, Africa, Asia, and Europe. Drought has also been linked to the drying of inland water bodies, including wetlands {6.3.2}.

Harmful algal blooms and freshwater eutrophication are increasing in magnitude and frequency, threatening drinking water supplies and aquatic ecosystems (*well established*). These phenomena are mainly driven by nutrient pollution from fertilizers and untreated wastewater, combined with climate-induced changes in seasonal water temperatures. Between 1982 and 2019, 9 per cent of monitored lakes globally showed increases in harmful algal blooms, damaging economies and the health of billions of people {6.4.1}.

Approximately 40 per cent of the world's largest rivers are experiencing increased sediment pollution from land degradation, damaging freshwater ecosystems and reducing reservoir capacity (*established but incomplete*). Sediment deposition impairs reservoir performance for hydropower and water supply. Suspended sediments lower water quality and aquatic habitat across entire catchments. Globally, about 396 major rivers, spanning 35,000 river kilometres or approximately 6 per cent of large tropical river reaches are affected by suspended sediments, primarily in the regions with intensified land degradation {6.2.1; 6.4.1; 6.4.2}.

Freshwater ecosystems are experiencing the highest rates of biodiversity loss, with an estimated 89 species confirmed extinct, and 178 more suspected extinct (*well established*). Currently, about 24 per cent of freshwater species are threatened with extinction, driven by habitat fragmentation, invasive species, overexploitation, pollution, and climate change. Among the various types of freshwater ecosystems, wetlands face the greatest threats, vanishing three times faster than forests {6.5.1}.

Overexploitation of aquatic species poses a significant threat to the health and stability of freshwater ecosystems (*well established*). This trend is largely driven by the fisheries and aquaculture industries, contributing to biodiversity loss and decline in catch of some important subsistence fisheries {6.5.6}.

Invasive, or non-native, species in freshwater ecosystems are also a major cause of biodiversity decline (*well established*). These species compromise the freshwater ecosystems, alter local hydrological processes, and damage water supply infrastructure {6.5.5}.

Water stress from physical scarcity and pollution is increasing globally due to climate change and persistent drought (*well established*). Limited fresh water availability for human use in some regions, particularly in densely populated cities and in arid or semi-arid regions, hinders sustainable development efforts, especially in Central and Southern Asia and Northern and Southern Africa {6.6.1}.

In 2022, around 22 per cent of the world's population was using a drinking water source that had been contaminated with sewage (*well established*). The resulting microbial contamination poses the greatest health risk to safe drinking water globally, particularly in highly populated areas of Africa, Asia, and Latin America {6.4.1}.

Provision of clean water remains a significant challenge amid growing water demand, leading to widespread water insecurity, especially for Indigenous Peoples, women, and girls (*established but incomplete*). Contributing factors include water quality degradation, inadequate infrastructure, inequitable access to water supplies, poor water governance, and climate-driven physical scarcity {6.6.1; 6.6.5}.

Irrigated agriculture and aquaculture, both highly dependent on fresh water, play a crucial role in securing the global food supply in the face of a growing population (*well established*). However, current irrigation practices on over half of irrigated lands are unsustainable due to high freshwater use and loss. As irrigated land expands, so does the demand on freshwater sources. The expansion of irrigation has also been associated with increased use of pesticides and fertilizers, further contributing to freshwater pollution {6.6.3}.

Global water use efficiency has improved by approximately 19.3 per cent across all sectors, rising from US$17.4 of added value per m^3 in 2015 to US$20.8 per m^3 in 2021 (*well established*). The most significant gains were in the irrigated agriculture sector, which saw a 35.6 per cent improvement over six years {6.2.2}.

Trade of water-intensive products, known as virtual water trade, is offsetting water stress in some countries while contributing to unsustainable irrigation practices in others (*established but incomplete*). Approximately 20 per cent of water used for agriculture is embedded in traded goods, rather than consumed domestically. The most water-intensive exports include livestock products and high-demand cash crops. Between 1986 and 2022, the volume of international virtually traded water tripled, representing 16 per cent of unsustainable water use and 11 per cent of global groundwater depletion. This trade can limit local freshwater availability, which affects Indigenous Peoples and small-scale producers as well as water and food security {6.6.4}.

Transboundary waters, shared by at least two countries, account for around 60 per cent of the world's freshwater flows, including 313 rivers and lakes and 468 aquifers (*well established*). As of now, only 43 out of the 153 countries sharing transboundary waters have operational cooperative arrangements, though a near doubling since 2017. Most cooperation occurs in Europe, North America, and sub-Saharan Africa. Strengthening transboundary water governance and cooperation is vital to reducing the risk of water conflicts {6.6.1}.

New analytical tools, including remote sensing, enhanced data-collection and analysis, artificial intelligence, and robust modelling, are enhancing the understanding of the state of freshwater systems and the underlying trends, causes and interlinkages (*established but incomplete*). Increasingly, these technologies enable real-time monitoring of water consumption in agriculture, improved water management, large-scale assessment of contaminants and analysis of temporal changes in water systems. However, disparities in access to technology and funding could limit the widespread application of these tools {6.3.1}.

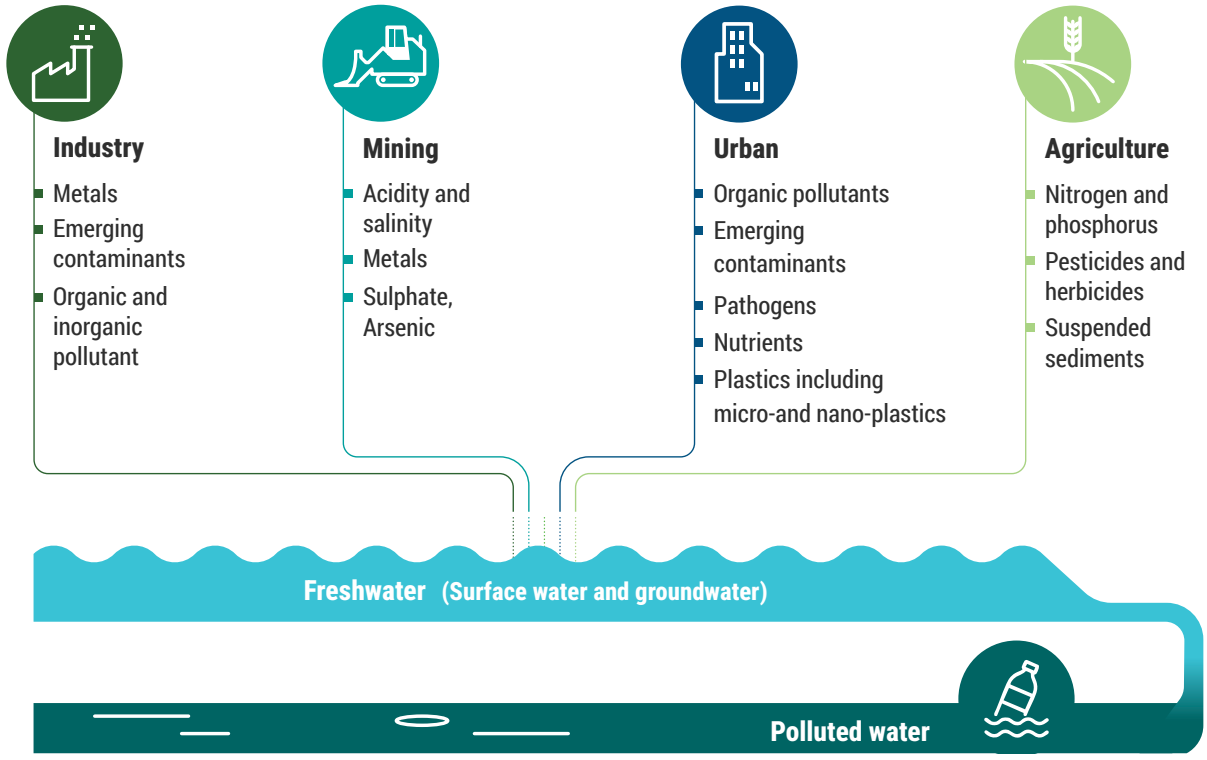
Indigenous Knowledge has significantly contributed to the improvement of water risk management systems (*established but incomplete*). Indigenous Peoples have developed sophisticated water harvesting techniques, such as terraces and canals for water capture and distribution and employed water purification and distribution methods, like the Maya. Their observation-based climate forecasting methods and knowledge of astronomy complement modern scientific weather predictions {6.3.1; 6.6.5}.

Indigenous Peoples across the globe maintain deep cultural and spiritual connections to water and freshwater ecosystems (*well established*). Water is sacred and central in many Indigenous cultures, livelihoods and daily practices. The cultural connections are often rooted in natural sites, like rivers, lakes, lagoons, and springs. Disruptions to these water bodies due to pollution, water scarcity, water withdrawals, climate change and other pressures, can break traditional relationships with the hydrological cycle and may lead to the displacement of Indigenous Peoples, threatening their cultural identity, way of life and even survival {6.2.3; 6.3.1; 6.6.5}.

6.1 Introduction

Healthy freshwater systems are essential for human health, vibrant communities, sustainable economic development, and the protection of ecosystems. However, rivers, lakes, wetlands and aquifers continue to face stress from the global environmental crises (the crisis of climate change, the crisis of biodiversity loss, land degradation and desertification and the crisis of pollution and waste), dam construction, and increasing water demands. These freshwater systems are also vital for Indigenous Peoples, as they provide critical resources for traditional food systems, supporting cultural practices and nutritional health through diverse aquatic species and plant life.

Building on the work of other recent global assessments, such as the Intergovernmental Panel on Climate Change (IPCC) report, Climate Change 2022: Impacts, Adaptation and Vulnerability (Caretta et al. 2022), and World Water Assessment Programme series from United Nations Water (UN-Water) and United Nations Educational Scientific and Cultural Organization (UNESCO) (UN Water and UNESCO 2021; UN-Water and UNESCO 2022; UN-Water and UNESCO 2023; UN Water and UNESCO 2024), this chapter examines the unique pressures on freshwater systems, alongside the current state and trends in water resources, water quality and freshwater biodiversity. Additionally, the chapter summarizes some of the most consequential effects of freshwater changes on human well-being, including those affecting Indigenous Peoples, and provides a brief update on internationally agreed water environmental goals.



6.2 Pressures on freshwater systems

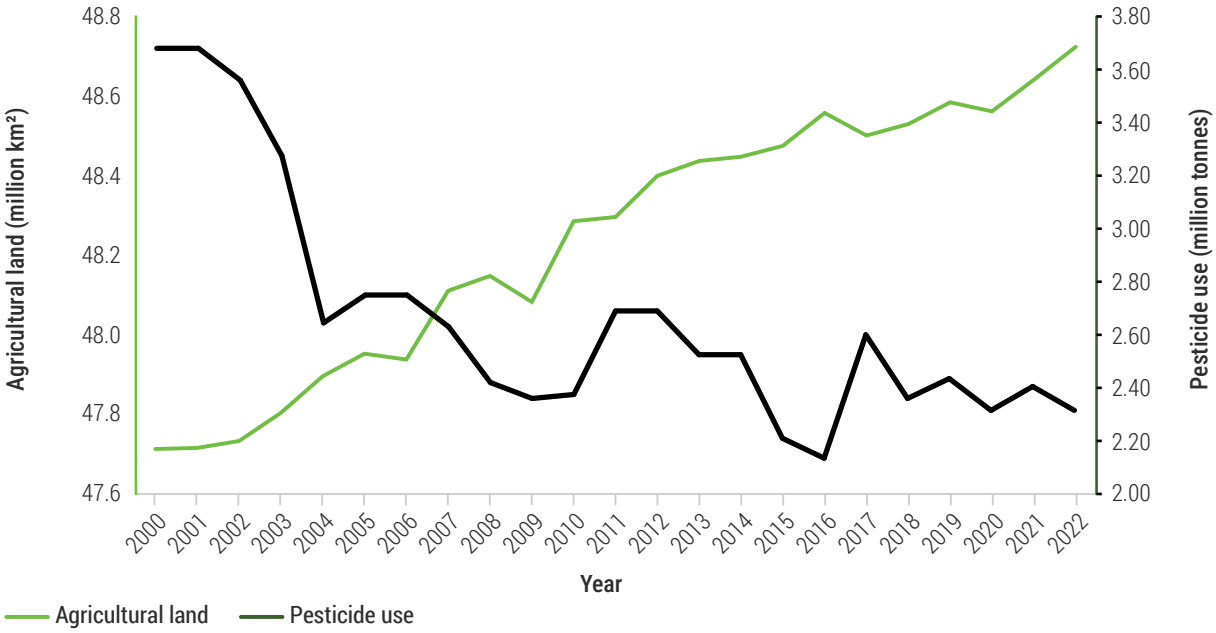
Alongside the global environmental crises and pressures outlined in Chapter 2, freshwater systems face water-specific pressures, such as freshwater pollution, water use and withdrawals, and dams for hydropower and water supply.

6.2.1 Freshwater pollution

Freshwater pollution has widespread effects on ecosystems, human health, and economic productivity. Freshwater quality continues to deteriorate globally due to increases in water pollution from agricultural intensification, urbanization, expansion of mining, industry, land-use changes, and inadequate waste

Figure 6.1: Primary sources of global pollution

management from these activities (**Figure 6.1**). Water pollution of surface water and groundwater systems often extends across these resources due to their hydrologic connection.



Globally, the human population, including Indigenous Peoples and other marginalized groups, is highly exposed to numerous polluting activities. The impacts of pollution affect freshwater supply, often resulting in serious health problems (Fernández-Llamazares et al. 2019; Basta et al. 2021). Achieving improvements requires the involvement of all stakeholders to participate in the economic activities of a region without affecting freshwater quantity, quality, and biodiversity for all who depend on it.

6.2.1.1 Agriculture

Agricultural practices that pollute fresh water include the application of synthetic fertilizers, the use of pesticides and herbicides, soil disturbance, livestock grazing, concentrated livestock operations, flood irrigation, and the clearing of land for agricultural expansion, which causes soil erosion (Zou et al. 2020; FAO 2022a; Tan et al. 2022; FAO 2023; Ma et al. 2023). Agricultural run-off is driven by heavy rainfall and snowmelt events, combined with poor vegetation cover and over-irrigation due to the use of inefficient irrigation methods. Run-off results in the discharge of synthetic fertilizers, pesticides, and other contaminants, such as degraded plastic mulch, into freshwater systems (Jansen et al. 2024). The run-off from intensive livestock farming also contains harmful residues of veterinary antibiotics and other pharmaceuticals, agrochemicals, growth hormones and nutrients that negatively affect water quality (FAO and IWMI 2018; Ray and Shaju 2023; Liu et al. 2024). The spread of antibiotic-resistant microorganisms represents a serious problem for aquatic ecosystems and human health. In many countries, the use of broad-spectrum pesticides remains common; however, there is a recent trend towards using newer pesticides with greater selectivity and reduced toxicity to humans and the environment (FAO 2022a).

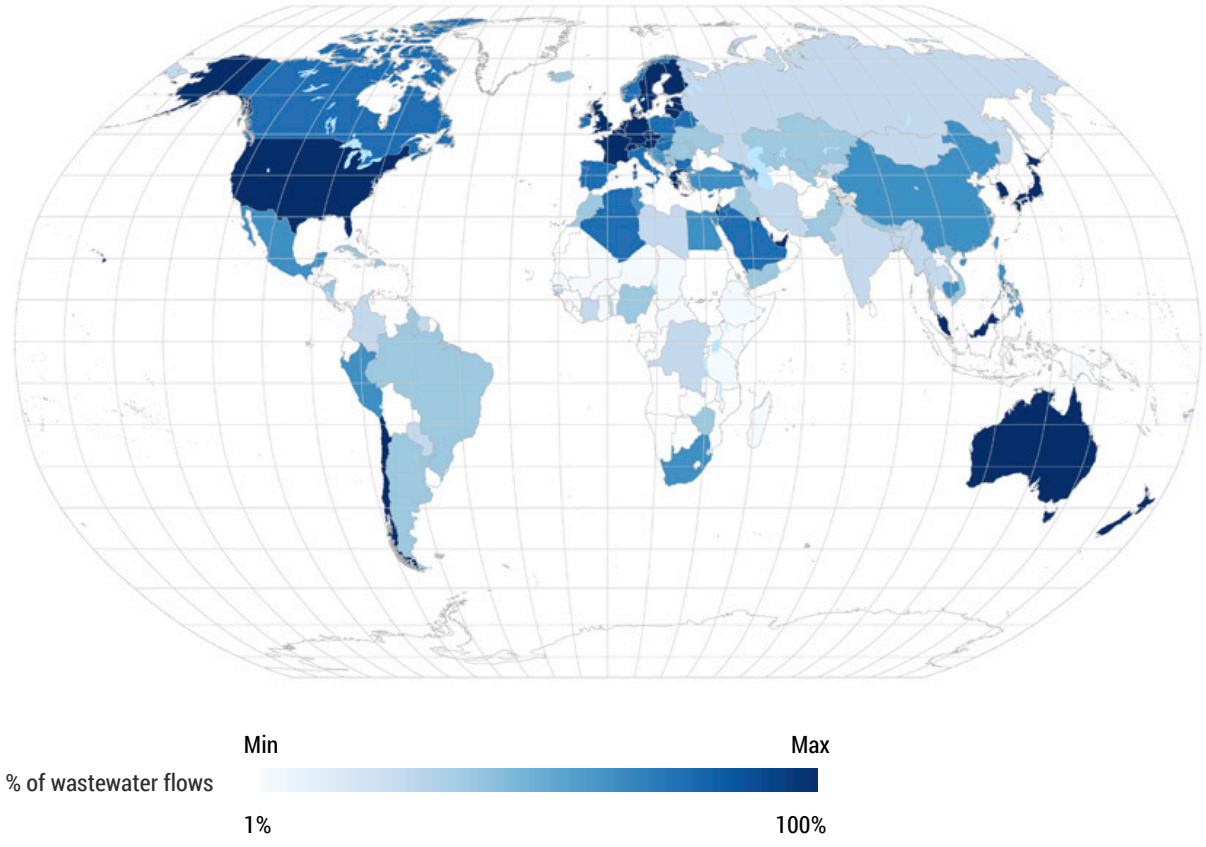
On a global scale, the area of agricultural land under production has shown a decreasing trend, falling from 48.7 million km² in 2000 to 47.8 million km² in 2022. This could suggest a shift from rain-fed agriculture to technology-supported practices. Conversely, pesticide usage increased during the same period, rising from 2.2 million tons to 3.7 million tons, reflecting the heightened intensity of agricultural systems and irrigation, which leads to higher agricultural inputs (**Figure 6.2**).

Figure 6.2: The decreasing trend of global agricultural land and increased use of pesticides from 2000 to 2022

Note: For clearer contrast of the trend lines, the vertical axes do not start at 0.

Source: FAOSTAT (2025)

6.2.1.2 Urban



About 56 per cent of the world's population, 4.4 billion, lives in cities. The urban population is projected to double by 2050, at which point nearly seven out of ten people will reside in urban areas (World Bank 2023; Chapter 2.2.4). This population growth leads to increased urban pollution due to wastewater (sewage) generation, stormwater, and leachate from solid waste disposal.

Globally, approximately 42 per cent of the world's municipal wastewater is not safely treated before its release into the environment (UN Water and UNESCO 2023), and only 11 per cent of sewage is treated and reused (UNEP 2023). The global combined volume of annual domestic and industrial wastewater production was estimated at 359×10^9 m^3 in 2021, roughly double the flow of the Danube River. The proportion of safely treated domestic wastewater improved by 2 per cent, rising from 56 per cent in 2020 to 58 per cent in 2022 (WHO 2022; UNEP2024a) (**Figure 6.3**). Although progress is being made, many regions still lack adequate infrastructure for wastewater treatment.

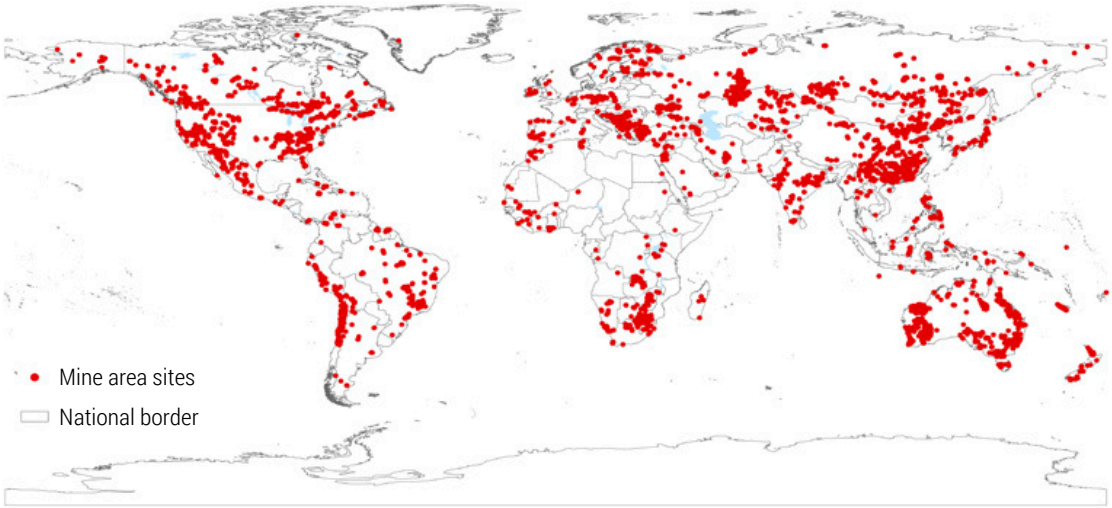
Consequently, many urban rivers experience high levels of pathogens and organic pollution (Wen et al. 2017), disproportionately affecting women and girls, as they are often the primary collectors of water (Chapter 7.3.6). Municipal wastewater also contributes approximately 1.57 per cent of global greenhouse gas emissions (UNEP 2023) through the breakdown of organic waste and the energy used during treatment processes (Dickin et al. 2020). Addressing the discharge of untreated sewage requires the implementation of effective waste management systems, the promotion of wastewater treatment, and the enforcement of environmental regulations to protect ecosystems and human health.

Stormwater runoff from roads and other impervious surfaces mobilizes pollutants, including heavy metals (Maeaba et al. 2019), hydrocarbons, suspended sediments, debris, litter (Werbowski et al. 2021; Awonaike et al. 2022), nutrients (Brudler et al. 2019) and microplastics from degraded tyres (Johannessen et al. 2021; Goehler et al. 2022; Cao et al. 2022). Increases in

Figure 6.3: Percentage of domestic wastewater flows that are safely treated

Source: WHO 2022

Image 6.1 Aerial view of copper mining waste that flooded the village of Geamăna, Romania. Credit: erika8213/Envato



flooding and intense rainfall may contribute to regional increases in the discharge of untreated sewage into rivers (Petrie 2021).

Appropriate solid waste management in urban areas remains a challenge, particularly the disposal of waste in environmentally sensitive areas such as coastal zones and wetlands (Nicholls et al. 2021; Khan et al. 2022; Aslam et al. 2022). Even properly designed landfills, while significantly better than open dump sites, can still be sources of water pollution through leachates (Igboama et al. 2022) that contain heavy metals, organic pollutants, and nutrients (Przydatek and Kanownik 2019). In some areas, tourism exacerbates waste production, further contributing to freshwater pollution.

6.2.1.3 Mining

Mining and mineral processing pollute surface water and groundwater through the discharge of chemicals, the leaching of metals from tailings and disposed low-grade rocks, as well as through the disturbance of land and water. Mining activities on every continent have the potential to contaminate freshwater resources (Liang et al. 2021) (**Figure 6.4**). Mining areas for critical minerals such as copper, lithium, nickel, cobalt, and rare earth metals that are essential components of new energy technologies are rapidly expanding across the world (Sonter et al. 2020), and, in some cases, they present an elevated risk of toxic metal pollution from mercury, lead, cadmium, uranium and others (Zhou et al. 2020; **Image 6.1**). Moreover,

Figure 6.4: Global distribution of mine areas

Source: Liang et al. (2021)

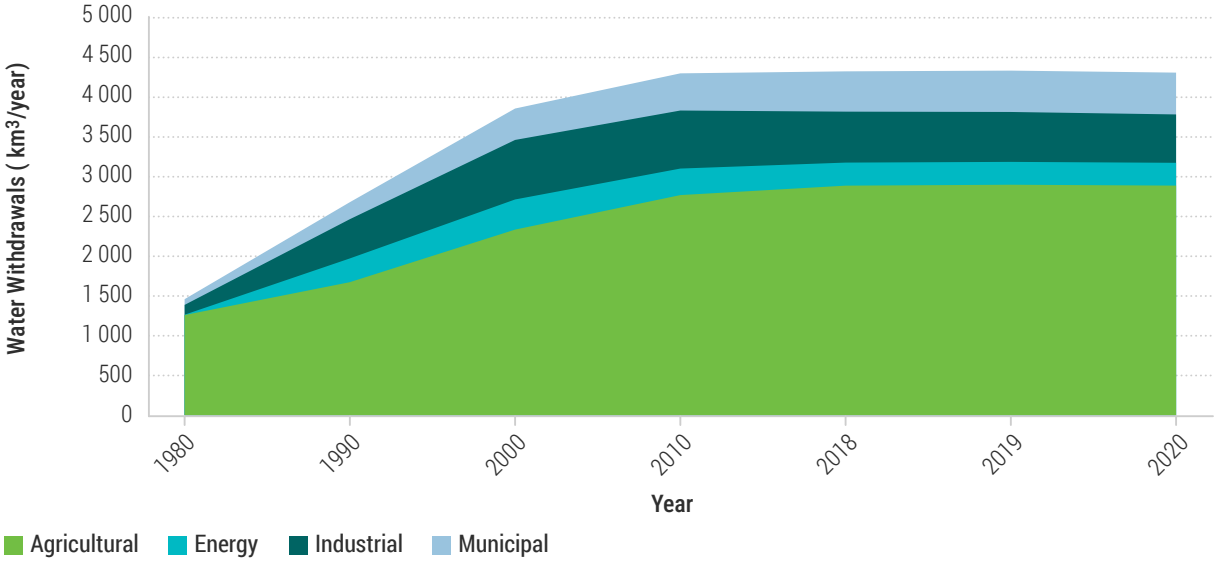
Image 6.2 Sand mining from a lake. Credit: YouraPechkin/Envato

mining operations are known to generate suspended sediments in many river systems (Dethier et al. 2023).

Globally, sand mining has accelerated primarily due to infrastructure demands linked to population growth and rapid urbanization (**Image 6.2**). Sand mining occurs in small river channels, large rivers, deltas, and coastal areas with consequences for natural sediment transport. For example, in the Vietnamese Mekong Delta, sand extraction ranges from 8.5 Mm^3/yr to 45.7 Mm^3/yr (Park 2024). Reduced upstream sediment supply from dam construction and sand mining in the delta has led to 2 cm/yr increases in tidal amplification (Eslami et al. 2019).

Sand and mineral extraction activities are also affecting areas with sparse population densities in the Northern Hemisphere. For example, erosion caused by the melting of the Greenland Ice Sheet has resulted in the deposition of sediments along the coasts of Kalaallit Nunaat, Greenland, which has driven sand extraction activities and caused environmental damage to the coastal areas (Bendixen et al. 2022). Yet, the impacts of mineral extraction are unevenly distributed, with Indigenous Peoples facing greater consequences globally (Fernandez-Llamazares et al. 2020).

Unregulated artisanal and illegal gold panning along rivers has surged over the past 20 years, affecting water quality in 173 large river basins across 49 countries. These activities are known to release mercury and cyanide into freshwater systems and can be mitigated through innovative techniques aimed at reducing freshwater pollution. Globally, approximately 396 major rivers are affected by suspended sediment due to river-based mining, representing 35,000 river kilometres and 7 per cent of all large tropical river reaches, including the Amazon River (Dethier et al. 2023; Voosen 2023).



6.2.1.4 Industry

Disposal of untreated industrial effluents, which include chemicals, radioactive substances, hydrocarbons, and organic and inorganic wastes, continues to be a major source of global pollution with direct repercussions on freshwater ecosystems (Iloms et al. 2020; Afrad et al. 2020). Industrial effluent contributes an estimated 300–400 million tons per year of waste discharged into freshwaters (du Plessis 2022). The growth of manufacturing in low and middle-income countries over the past decades has increased the disposal of industrial waste into freshwater systems. For example, approximately 2.55 million m^3/day of wastewater was discharged into the Ganga River without any treatment (Kumar et al. 2021; Muduli et al. 2021; Brunner, Das, and Starkl 2023). The Buriganga River and its tributaries in Bangladesh receive about 60,000 m^3/day of toxic wastes containing organic matter from industrial discharges (Uddin and Jeong 2021; Nargis et al. 2021).

6.2.2 Water use and withdrawals

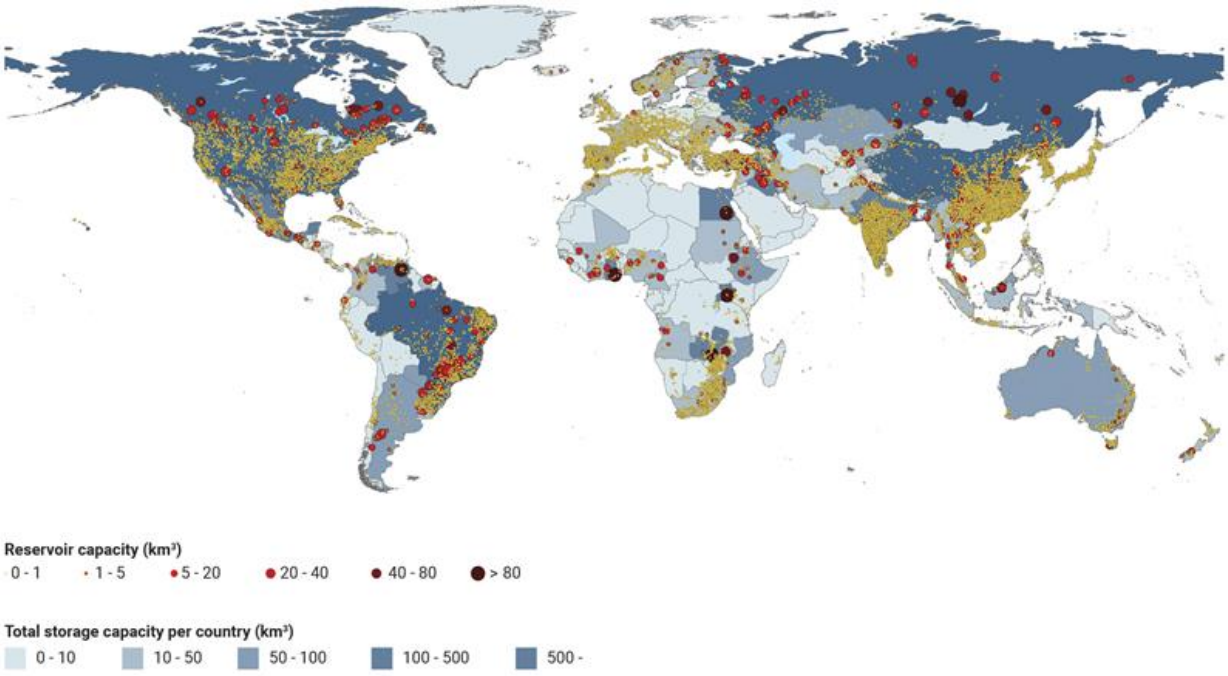
Fresh water is essential for households, agriculture, irrigation, industry and power generation. Total freshwater withdrawals were estimated to be approximately 4,300 km^3/year in 2020, nearly doubling

Figure 6.5: Summary of global freshwater withdrawals between 1980 and 2020 calculated as the sum of all country data reporting sectoral water withdrawals

Source: AQUASTAT Database 2023

the amount of water withdrawn in 1980 (AQUASTAT 2023) (**Figure 6.5**). This increase is driven by global demand for fresh water which has been increasing by just under 1 per cent annually between the 1980s and 2024 (UNESCO 2024).

Most freshwater withdrawals for human use come from surface waters. However, groundwater accounts for half of the volume withdrawn for domestic purposes worldwide and about 25 per cent of all water withdrawn for irrigation (UN Water and UNESCO 2024). Total withdrawals have levelled off in recent years, indicating a reduction in per capita water withdrawals globally. Due to gender-based roles and responsibilities, women and girls bear a disproportionate burden of water use and collection at the community level (UNICEF 2023).



In 2020, most freshwater withdrawals were for agricultural production at 67–70 per cent (Aquastat 2023; UN Water and UNESCO 2024), followed by industry at 14 per cent,domestic or municipal uses at 12 per cent, and energy at 7 per cent (UN Water and UNESCO 2024). However, water-use efficiency has improved globally by approximately 19.3 per cent across all sectors, rising from 17.4 US$/$m^3$ in 2015 to 20.8 US$/$m^3$ in 2021. The largest improvements have occurred in the irrigated agriculture sector, which has seen a 35.6 per cent improvement over those six years (FAO and UN Water 2024). Nevertheless, Rosa et al. (2019) estimated that 52 per cent of global irrigation practices are unsustainable with consumption rates exceeding natural renewable recharge rates, and that unsustainable water consumption increased by 18 per cent between 2000 and 2015. Increasing global irrigation and municipal water demand is resulting in hotspots of groundwater depletion around the world (UN Water and UNESCO 2022; 2023). Approximately 47 per cent of the global land area exceeds the locally estimated Earth system boundary for sustainable groundwater withdrawals (Rockstrom et al. 2023).

Water withdrawal by the mining industry is increasing, particularly in arid and semi-arid regions where the extensive use of fresh water for mining activities competes with other economic sectors (Meißner 2021; Statista 2023). Moreover, one of the most critical issues in water extraction for consumption is the high rate of loss from inefficient distribution systems – up to 40 per cent in developing countries and 15 per cent in developed countries – threatening both the availability and sustainability of water resources (UN Water and UNESCO 2021). Unsustainable water withdrawals contribute to seawater intrusion, impacting coastal aquifers that are critical potable water sources (Tschaikowski et al. 2024).

6.2.3 Dams for hydropower and water supply

The construction of dams for hydropower and water supply has been critical in addressing water security

Figure 6.6: Global distribution of dams and river barriers

Source: Lehner et al. (2024)

in many parts of the world and provides the largest source of renewable energy globally (IEA 2021). There are currently an estimated 35,000 dams worldwide with mapped reservoir areas (Zhang and Gu 2023; Lehner et al. 2024). Irrigation and hydroelectricity are the primary purposes of dam construction, representing 25 per cent and 20 per cent of dams, respectively (Zhang and Gu 2023). Water supply, flood control, recreation, livestock and navigation follow as additional primary purposes for dams (Zhang and Gu 2023). Furthermore, changes in precipitation and temperature patterns are driving climate adaptation needs for greater water storage, often in the form of reservoirs, to compensate for losses in snow, permafrost, and glaciers (Caretta et al. 2022; Fox-Kemper et al. 2021).

However, dams also fragment aquatic habitats, disrupt natural flow patterns, alter nutrient cycling and sediment transport, and interfere with fish migration, thereby threatening freshwater ecosystems (Fearnside 2016; Latrubesse et al. 2017; Belletti et al. 2020; Su et al. 2021; Haase et al. 2023, Zhang and Gu 2023). New dams also frequently displace upstream human communities, and the risk of dam failure jeopardizes the security and livelihoods of downstream communities, often with disproportionate repercussions on Indigenous Peoples (Fearnside 2016; Latrubesse et al. 2017; IHA 2021a; IHA 2022b).

Globally, dam construction has been declining in most developed countries while increasing in many developing countries. There have been notable increases in dam decommissioning in North America and Europe (Zhang and Gu 2023). Nonetheless, over the past three decades, new dam construction has added 49,715 km² of surface water in upstream catchments, a 30 per cent increase over the pre-dam levels, with the most significant increases occurring in Asia, Africa, and South America (Zhang and Gu 2023) (**Figure 6.6**). As this trend continues, new dams for hydropower and water storage are projected to disproportionately affect important areas for freshwater biodiversity in South America, South and East Asia, and the Balkan region (Zarfl et al. 2019).

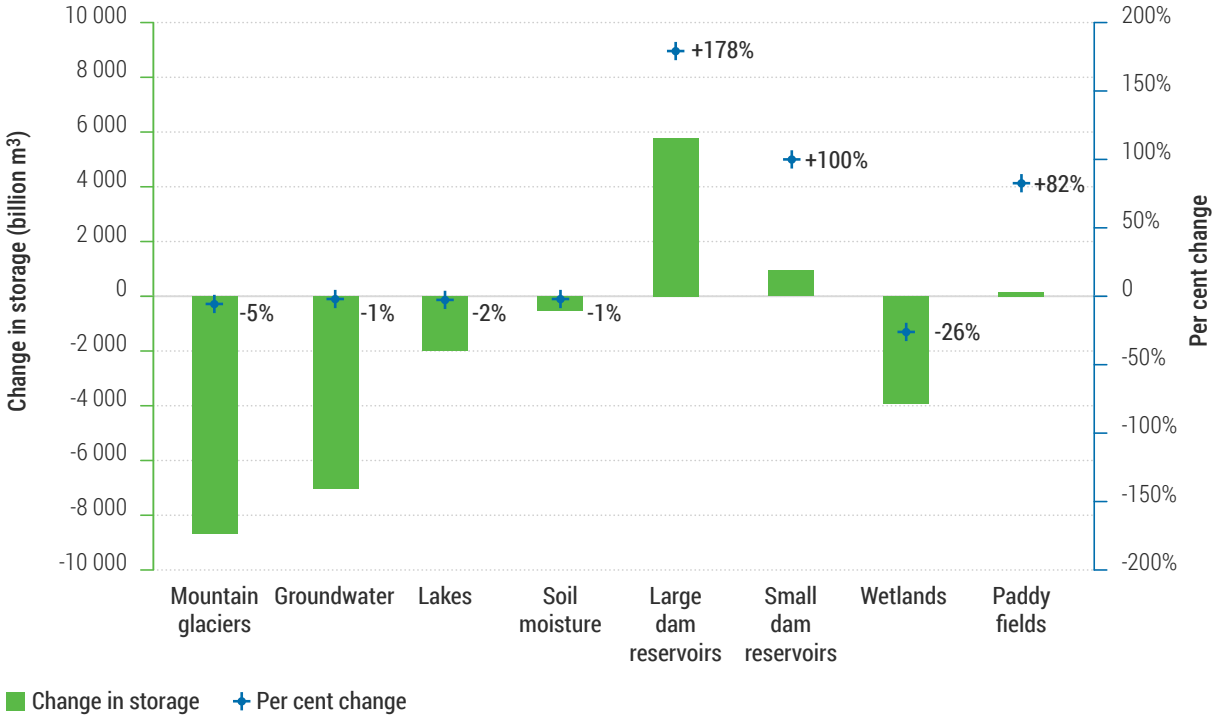
6.3 Water resources

6.3.1 State and trends of global water resources

6.3.1.1 Global freshwater storage

Globally, of the estimated 42 million km³ of freshwater storage, only about 2 per cent, or 850,000 km³, is available for direct human use (McCartney et al. 2022). Most of the fresh water available for human use is found in groundwater, mountain glaciers, and lakes,

while less than 1.5 per cent is stored in human-made reservoirs (McCartney et al. 2022). Changes to the water cycle linked to climate change, water withdrawals, and land-use changes are driving changes in water storage worldwide (**Figure 6.7**). Between 1971 and 2020, natural storage declined by 33,944 km³, which was partially offset by an increase of 6,865 km³ in reservoir storage and paddy fields (McCartney et al. 2022). The most significant reductions in natural storage are occurring in ice sheets, mountain glaciers, groundwater, wetlands and lakes (**Figure 6.7**). These trends are manifesting differently across the globe. While fresh water is accumulating in certain regions of North America, Europe, Asia, and the wet tropics, the most significant losses of non-frozen fresh water due to drying are occurring in the mid-latitudes (Rodell et al. 2018; Immerzeel et al. 2020; Huggins et al. 2022; McCartney et al. 2022). Climate change is also affecting the timing and reliability of freshwater storage in ice and snow, leading to accelerated melting of mountain glaciers and snowpacks worldwide (Rodell et al. 2018; McCartney et al. 2022).



Groundwater level declines (>0.5 m/year) have accelerated in more than 30 per cent of the world's regional aquifers since 2000, when compared to trends from 1980-2000 (Jasechko et al. 2024). However, groundwater level declines have slowed in 20 per cent and reversed in 16 per cent of the world's regional aquifers (Jasechko et al. 2024), reflecting changes associated with natural variation, climate change, drought, human withdrawals, and relevant policy interventions (Jasechko et al. 2024).

6.3.1.2 Environmental flows

Environmental flows are essential for sustaining freshwater ecosystems and encompass measures of quantity, timing, and quality. However, these flows vary by region and catchment, making it challenging to assess global trends. Overall, stream flows are estimated to deviate from pre-industrial ranges across 18.2 per cent of the global land area (Porkka et al. 2024; GCEW 2024).

Groundwater is a critical contributor to sustaining environmental flows, especially during low-flow periods when the risk of losing minimum flows is highest. It has recently been estimated that groundwater sustains 59 per cent of global river flows (Xie et al. 2024). Environmental flow thresholds caused by groundwater extraction have already been exceeded in an estimated 15 to 21 per cent of catchments, particularly in dry climates where the irrigation use of groundwater resources is significant

Figure 6.7: Estimated change in water storage for the period 1971–2020

Source: McCartney et al. (2022)

and natural stream flows are generally lower (de Graaf et al. 2019). These areas include catchments in the High Plains and Central Valley regions of Northern America; arid parts of Mexico; the Upper Ganga basin; the Indus basin; Northeastern America; the Arabian Peninsula including Saudi Arabia, the United Arab Emirates, Oman, Yemen and parts of Argentina (de Graaf et al. 2019).

6.3.1.3 Hydrologic monitoring

Indigenous Peoples across various climate zones have reported observations regarding changes in the hydrological cycle (López-Maldonado et al. 2024; Reyes-Garcia et al. 2024). In the Himalayas, for instance, Indigenous communities have noted alterations in water availability, including drying springs, shifts in freshwater biodiversity (Mukherji et al. 2015), and altered seasonal patterns of local wildlife (Hernandez et al. 2025). In Arctic regions, Indigenous communities have also documented changes in snow types, layers, and permafrost conditions (Krupnik and Jolly 2002; Laptander 2023).

The application of satellite-based Earth observation, along with Indigenous Peoples' observations of components of the water cycle, is helpful in monitoring water quantity and usage by various economic sectors, both in surface water and groundwater. These sources include results from the GRACE gravity method, the Global Precipitation Measurement, and the Tropical Rainfall Measuring Mission (Jasechko et al. 2024; López-Maldonado et al. 2024).

6.3.2 Climate change and the water cycle

The influence of climate change on the water cycle, combined with a growing population and increasing per capita demand for water, profoundly impacts freshwater systems and the communities that depend on them. A warming climate leads to warmer air that holds more water vapour, thereby accelerating aspects of the global water cycle (Held and Soden 2006). However, global models indicate that these climate-driven changes will be unequally distributed in the future, with wet areas becoming wetter and dry areas drier (Konapala et al. 2020). In addition, increases in evapotranspiration may overwhelm precipitation changes over much of the world's land areas in the future (Zaitchik et al. 2023). As climate change intensifies precipitation extremes, accelerating the melting of glaciers, snow, and ice-rich permafrost, and alters the extent of water bodies, future water projections remain highly uncertain, posing challenges for water managers, policymakers, and society.

6.3.2.1 Drought

Trends in drought and their attribution to climate change are related to regional changes in precipitation, temperature, and evapotranspiration patterns (Otkin et al. 2018; Spinoni et al. 2020). Since the 1950s, drought frequency, duration, and maximum intensity have increased in many areas of the world, particularly in parts of the Americas, Africa, Asia (Chiang et al. 2021), and Europe (Böhnisch et al. 2021). Soil moisture has been estimated to deviate from pre-industrial ranges in 15.8 per cent of the global land area (Porkka et al. 2024; GCEW 2024). The IPCC attributes the increase in drought in Southern Australia, Southern Africa, and Southwestern South America to climate change (Caretta et al. 2022). Other regions of Africa, Asia, South America, Australia, and Europe are also experiencing more drought, though with lower confidence in direct attribution to climate change. Conversely, several areas have experienced decreased drought, but with little evidence of anthropogenic influence. These areas include Northern and central Australia, Southeastern South America, central North America, and Northern Europe, Western and Eastern Siberia (Caretta et al. 2022).

Flash droughts refer to those droughts that develop and intensify rapidly compared to typical drought patterns (Otkin et al. 2018). From 1980 to 2015, there was an increase in the occurrences and coverage of flash droughts in central Northern America, central Mexico, the Iberian Peninsula, Asia Minor, Brazil, the Sahel, and Southeastern Australia (Christian et al. 2021). Several other regions experienced a decreasing trend in flash droughts, including India, the Great East African Rift Valley, and Northern Australia (Christian et al. 2021). With high confidence, IPCC (Caretta et al. 2022) reported that the increasing extent and duration of drought are linked to the drying of continental water bodies, including wetlands, thus affecting freshwater ecosystem services. Drought also affects ecological, agricultural, and land-based ecosystems (Chapter 4.3.2.1), as well as human water security (Section 6.6.1).

6.3.2.2 Extreme floods

Floods are one of the most common natural hazards, causing significant repercussions on society (CRED 2023). They can be extremely destructive, disproportionately affecting vulnerable populations (Nearing et al. 2024).

Since the mid-20th century, the frequency of heavy precipitation events, a key driver of extreme floods, has increased in more regions than it has decreased, with high confidence in well-observed areas, such as Western Europe and North America (IPCC 2022).

Land-use change and management also contribute to flooding by increasing impervious cover and reducing the water-absorbing capacity of soils and wetlands (Rogger et al. 2017; McGrane et al. 2016). In temperate climate zones, the magnitude of extreme flood events has increased, whereas in arid, tropical, polar and cold climates, flood magnitudes have generally decreased (Slater et al. 2021). Flood events have been documented to affect human communities across many countries (WMO 2022).

In terms of flood occurrence rates, recent large events across Europe, Asia, Latin America, and Africa suggest an increasing trend. However, millennial-scale records of flood magnitude show that extreme floods have occurred throughout the record when human influence was minimal (Benito et al. 2003; Ngo et al. 2023; Yu et al. 2023).

More consistent and accessible data sets, spanning both time and space and not limited to regional records or post-event compilations, would enable a more accurate assessment for a global picture of the occurrence of extreme floods and droughts (Schlef et al. 2019; He et al. 2020). The application of new tools, such as artificial intelligence, enhanced data-collection and analysis, and remote sensing technologies, also presents tremendous potential for monitoring floods and developing sustainable solutions (Das and Chowdhury 2024).

6.3.2.3 Snow cover and glaciers

Climate change is driving substantial changes to glaciers, permafrost, land ice, and snow cover worldwide, particularly in middle and high latitudes and high-mountain areas (Caretta et al. 2022). The melting and thawing of glaciers and land ice, along with decreased snow cover and shifting seasonal melting patterns, are driven by rising temperatures and changes in precipitation (Caretta et al. 2022). The combination of long-term monitoring by Indigenous Peoples (Deemer et al. 2018; Hauser et al. 2023) and innovative remote sensing techniques has enabled better tracking of these declines in recent years (Roessler and Dietz 2022).

The extent, mass, and duration of snow cover are changing in many areas of the world. Changes in snow cover extent are most pronounced in the Northern Hemisphere, where snow cover peaked in the mid-20th century and has followed a steady decline since 2000 (Mudryk et al. 2020). Globally, snow cover duration has decreased on average by 0.44 days per year between 2000 and 2022 (Roessler and Dietz 2023). These declines are most significant in the Northern Hemisphere, where the length of snow-dominated seasons has declined at a rate of 2 to 6.5 weeks every decade, primarily due to earlier season snowmelt (Fox-Kemper et al. 2021). These changes further impacted the seasonality and magnitude of flow in snow-fed streams, particularly in the Southwest of the Russian Federation, Western United States of America, and Central Asia (Huss et al. 2017; Caretta et al. 2022).

Rising temperatures continue to drive substantial rates of loss in global glaciers (Fox-Kemper et al. 2021; Caretta et al. 2022; Rodell et al. 2018; McCartney et al. 2022; Immerzeel et al. 2020). At the regional level, most glaciers are declining in mass, with some exceptions in Central Asia and South America (Fox-Kemper et al. 2021; Caretta et al. 2022), where changes in debris cover on glacier surfaces are reducing rates of melt (Compagno et al. 2022). Increasing glacial melt is driving a notable 50 per cent increase in the volume and area of glacial lakes (Shugar et al. 2020). The expansion of glacial lakes and the collapse of unstable natural dams are also increasing glacial lake outburst flood events, further threatening downstream populations in high-risk regions such as India, Pakistan, Peru, and China (Taylor et al. 2023). Glaciers in the Canadian Rocky Mountains, European Alps, tropical Andes, and Northern Caucasus have reached or exceeded their peak water stage (Caretta et al. 2022).

Snowmelt is often harnessed into agriculture as irrigation water. It is estimated that 16 per cent of this snowmelt is used for agricultural products, with over 70 per cent of these products originating from Pakistan, India, China, the United States of America and countries of the former Soviet Union (Qin et al. 2022). Irrigation systems in regions dependent on glacial and snowmelt run-off are threatened by the accelerated melting of glaciers, earlier snowmelt, and a transition in some areas from precipitation falling as snow to rain (Caretta et al. 2022). Changes in snowmelt run-off require climate change adaptation strategies that address reduced water storage in snowpacks and reflect landscape changes such as sediment transport and erosion (Li et al. 2022a).

6.3.2.4 Evaporation from lakes and reservoirs

Each year, nearly 340 km³ of fresh water evaporates from the world's largest 7,242 reservoirs (Tian et al. 2022). These losses, recorded between 1985 and 2016, are rising by about 2 km³ per year due to climate change and the construction of new dams in middle-income countries (Tian et al. 2022). Additionally, the evaporation volume from 1.42 million natural lakes globally was estimated at 1,500 km³ per year from 1985 to 2018 (Zhao et al. 2022), increasing at a rate of 3.12 km³ per year. Since evaporation from an open water body is inevitable, particularly in the case of reservoirs, planning for additional storage upstream to compensate for this water loss will be necessary in the future.

6.3.3 Land degradation and the water cycle

Land degradation affects the hydrological system by altering run-off, rainfall infiltration, erosion, and evapotranspiration, which decreases the water availability for both humans and the environment (UNESCO 2019; Hrachowitz et al. 2021; IPCC 2022). Land degradation also releases stored soil organic carbon, contributing to climate change and associated consequences for the water cycle (Amelung et al. 2020; Prăvălie et al. 2021).

6.4 Water quality

6.4.1 State and trends of freshwater quality

Freshwater quality has declined globally since the 1990s and is expected to worsen further, leading to increased threats to human health and ecosystems (du Plessis 2022). Numerous sources of pollution drive the deterioration.

6.4.1.1 Nutrients, eutrophication, and harmful algal blooms

Eutrophication of freshwater occurs when excess nutrients, primarily nitrogen and phosphorus, accumulate in the water column and bottom sediments (Rathore et al. 2016; Zhang et al. 2023). Nutrient pollution typically comes from agricultural run-off containing fertilizers and animal waste, as well as municipal wastewater and urban stormwater. This process often leads to harmful algal blooms and toxin production, along with low dissolved oxygen levels (Pilla and Williamson 2023), which have known impacts on aquatic ecosystems and human health (Namsaraev et al. 2020). The concentration of dissolved oxygen levels in freshwater is critical for healthy fisheries, since few fish species can grow or reproduce in oxygen-poor water (Luo et al. 2024). Often, the most affected freshwater systems are those located downstream of sewage discharges and agricultural areas that generate nutrient run-off from fertilized fields.

Satellite imagery analysis of freshwater lakes, covering 57 per cent of the global lake area, shows that nearly 9 per cent experienced an increase in the severity of harmful algal blooms between 1982 and 2019. The frequency of harmful algal blooms also rose globally, with the most significant increases observed in Asia, South America, and Africa. These regions also show the highest dependence on agricultural fertilizers (Hou et al. 2022). Notable examples of freshwater lakes severely affected by harmful algal blooms include Lake Erie (United States of America/Canada) (Schaefer et al. 2024), Lake Okeechobee (United States of America) (Dang et al. 2023), Lake Winnipeg (Canada), Lake Victoria (Uganda/Kenya/the United Republic of Tanzania), and Lake Taihu (China) (Sha et al. 2021).

6.4.1.2 Pathogens

In 2022, around 22 per cent of the world's population was using a drinking water source that had been contaminated with sewage. The resulting microbial contamination poses the greatest health risk to safe drinking water globally, particularly in highly populated areas of Africa, Asia, and Latin America (WHO 2023). Fecal coliforms and pathogens primarily originate from untreated sewage, wild animals, livestock waste, stormwater discharge, and agricultural run-off. Contaminated waters may contain total coliforms, E. coli, Enterococci, Cryptosporidium parvum, and Clostridium perfringens, along with pathogens, such as Salmonella and Vibrio cholerae O1 or O139, which cause cholera (Kanungo et al. 2022). The health repercussions from waterborne pathogens are discussed in section 6.6.2.1.

6.4.1.3 Suspended sediment

Suspended sediments in freshwater systems result in increased water turbidity and degradation of freshwater quality. Sediment pollution in water bodies is related to increased erosion associated with deforestation, intensification of agriculture, and urbanization. Erosion is known to facilitate the transport of other pollutants, including nutrients, hydrocarbons, humic

Image 6.3 Plastic waste in a remote mountain lake. Credit: bilanol/Envato

substances, and metals, which are typically mobilized during high discharge events (Rügner et al. 2019; Sandström et al. 2020). Suspended sediments also reduce water clarity and obstruct the exchange of gases and nutrients between aquatic habitats and the water (Chen et al. 2022).

At a global scale, approximately 40 per cent of the world's largest rivers have undergone significant changes in suspended sediment flux. Notably, there are increasing trends in water and sediment fluxes in large rivers – the Yellow River in Asia, the Mississippi River in North America, and the Amazon River in South America, for example– over the past 5 to 10 years (Li et al. 2020a; Li et al. 2020b).

Satellite-based estimates of suspended sediment concentration in 414 major rivers reveal strong links to human activity. In the Northern Hemisphere dam construction has reduced sediment flux in downstream rivers compared to pre-dam conditions. For example, an analysis of sediment flux in six rivers in China showed that, from the mid-1950s to 2020, dam construction, water consumption, and land-use changes have reduced sediment delivery to the sea by 49 per cent, 25 per cent, and 19 per cent, respectively (Wang et al. 2022a; Yin et al. 2023). In contrast, in the Southern Hemisphere, land degradation driven by urbanization, forest clearing, and agricultural intensification has increased soil erosion, with suspended sediment concentration averaging 41 per cent higher than levels observed in the 1980s (Dethier, Renshaw and Magilligan 2022; Gardner et al. 2023).

6.4.1.4 Emerging contaminants

Emerging contaminants represent a category of pollutants that are not yet widely monitored or regulated despite their presence (Li et al. 2024). This category includes per- and poly-fluoroalkyl substances (PFAS), hormones, cyanotoxins, detergents, pharmaceuticals, industrial chemicals, personal care products, flame retardants, veterinary medicines, nanomaterials, and microplastics (Anagnostopoulpou et al. 2022; Chakrborty et al. 2023; El-Kalliny et al. 2023; Lim 2023; Mariano et al. 2023; Naeem et al. 2023; Osuoha et al. 2023).

Emerging contaminants are noted for their low biodegradability and recalcitrance characteristics (Olatunde et al. 2020) and are found in nearly all water supplies globally (Pastorino and Ginebreda 2021; Wilkinson et al. 2022; Chandra and Walsh 2024). For instance, up to 74,500 microplastic particles/L have been identified in the Brazilian Amazon and its tributaries (dos Santos Silva et al. 2024), in urban streams (Rico et al. 2023) (**Image 6.3**), and in drinking water sources in the United States of America and Europe (Kosuth et al. 2017), as well as in remote mountain lakes (Machate et al. 2023). In low-income countries, the direct disposal of medical waste into rivers is a common practice, often containing pharmaceuticals alongside harmful microorganisms.

Many pharmaceuticals and other personal care products remain in wastewater after treatment

Image 6.4. Credit: wirestock/Envato

(Ferrando-Climent et al. 2014; Archer et al. 2023; Malnes et al. 2023; Su et al. 2023) and can persist and be biologically active, as endocrine disruptors for instance, in the environment (Feng et al. 2023). A recent study involving 1,052 sampling sites in 258 rivers across 104 countries and all continents reported the presence of pharmaceutical compounds in all samples (Wilkinson et al. 2022).

Derived from many consumer products, PFAS have also been reported in rivers, streams, lakes, water supply wells, and treated wastewater (Sims et al. 2014; Haddaoui and Mateo-Sagasta 2021; Shehu et al. 2022; Maggi et al. 2023), rainwater (Evich et al. 2022), stormwater run-off (Kali et al. 2025), and aquifers (Xu et al. 2021). Most PFAS withstand degradation from normal chemical, physical, or biological processes, while some degrade into other PFAS (Gaines 2022). The use of PFAS-contaminated water affects growth, learning, and behaviour in infants, lowers fertility in women, increases cholesterol levels, compromise and weaken the immune system and potentially reduce the effectiveness of vaccines (Anderko and Pennea 2020).

Nanomaterials may have cellular-level human toxicity suggesting potential health risks for non-human species as well (El-Kalliny et al. 2023; Kumah et al. 2023; Singh et al. 2024). A new category of micropollutants that threatens natural environments is microfibres. Their rapid degradation could release toxic compounds and result in long-term accumulation in groundwater and sediments (Balestra et al. 2024).

6.4.2 Land degradation and water quality

Soil erosion and sediment transport to low-lying areas are natural geological processes. However, human activity intensifies this phenomenon through deforestation, agriculture, mining, and changes in land use, including urban expansion. Erosion generates a complex mixture of fine sediments, minerals, chemicals, and organic matter that is transported to freshwater systems (FAO 2019) (**Image 6.4**). Land degradation is estimated to affect 34 per cent of cropland and pasture through erosion (FAO 2022b). Globally, the mean annual soil loss ranges from 8 to 50 t/ha per year (FAO 2019). This sediment build-up disrupts ecosystems by choking bottom-dwelling organisms. As sediments are deposited in streams and reservoirs, storage capacity gradually declines, and reservoirs eventually become unusable. At the catchment level, revegetation and soil conservation can reduce system vulnerability (Adeloye and Dau 2019).

There are also accounts of land degradation resulting from poor water quality. For example, soil salinization through hypersaline water intrusion or irrigation with saline water can render land unsuitable for agriculture over time. Similarly, soil hypersalinity has been reported to coincide with drought and waterlogging (Issanova et al. 2022), effectively resulting in land degradation.

6.4.3 Climate change and water quality

Climate change is driving increases in the temperature of freshwaters with effects on water quality, chemical

reactions, and aquatic ecosystem health (Souaissi et al. 2021). Furthermore, warmer water temperatures have been linked to the growing frequency and severity of harmful algal blooms worldwide (Gobler 2020; IPCC 2021; Sha et al. 2021; IPCC 2022; Nijhawan and Howard 2022; Elhabashy, Li and Sokolova 2023), especially in semi-arid regions (Ali, Abiye and Adam 2022; Johnson et al. 2024). An increase in ambient temperature is also linked to higher concentrations and persistence of E. coli in surface water used for human consumption and recreation (Nijhawan and Howard 2022). Higher temperatures further accelerate the evaporation of surface water, resulting in more saline water with diminished quality. Likewise, drought caused by increased temperatures also concentrates contaminants in smaller areas due to water loss from evaporation.

Increased rainfall intensity, linked to climate change, leads to high run-off and stormwater overflows, accelerating the transport of pollutants to freshwaters. Furthermore, extreme flooding events in urban areas damage wastewater treatment and drinking water infrastructure, causing the release of untreated wastewater and contamination of drinking water supplies (Nijhawan and Howard 2022). Additionally, flooding of dry soils promotes nutrient leaching, raising nutrient levels in water bodies (Kelly et al. 2020; Jansen et al. 2024; Khan et al. 2024).

Rising sea levels, driven by climate change, combined with excessive withdrawals of groundwater, are resulting in the seawater intrusion and subsequent salinization of important coastal aquifers around the world, compromising drinking water sources for many coastal populations (Ketabchi et al. 2016; Hussain et al. 2019; Basack et al. 2022), particularly affecting the most vulnerable communities in small island developing states (UNESCO 2015).

Large wildfires have become common around the world, partly due to climate change, with examples in Greece, Australia, Canada, Chile, Brazil, Argentina, South Africa, and California in the United States of America (Girona-García et al. 2021). The loss of vegetation due to large fires contributes to soil erosion, which reduces water quality in rivers and reservoirs. For example, following the 2021 fires in Greece, erosion accelerated on 3,600 km² of land (Evelpidou et al. 2022).

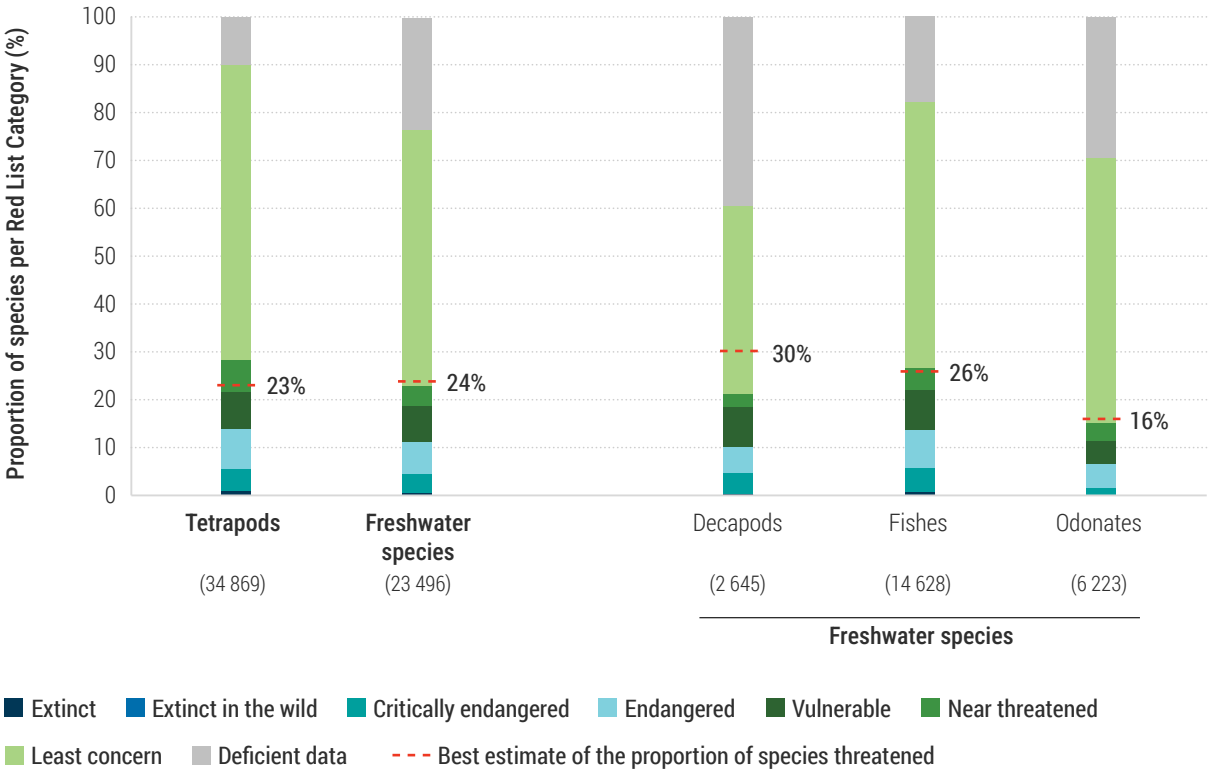
The environmental fate of persistent organic pollutants in Arctic ecosystems depends on a multitude of complex, interrelated factors, including environmental conditions, the persistent nature of these pollutants, and biological conditions. Climate change is concurrently altering many of these processes, particularly in polar regions (AMAP 2021).

Despite the wealth of literature on the role of climate change in water quality, the influence of water quality on climate is poorly understood. Similarly, climate change adaptation strategies seldom focus on the water quality challenges intensified by climate change, which increases vulnerability for freshwater systems and human communities in the short term (Bartlett and Dedekorkut-Howes 2023).

6.5 Freshwater biodiversity

Climate change, invasive species, pollution, overexploitation, and land-use change have all been reported to drive biodiversity loss in freshwater ecosystems (Taniwaki et al. 2017; Petsch et al. 2022; Geng et al. 2022; Liu et al. 2023). The combined occurrence of these pressures impacts global freshwater biodiversity change, especially in large basins (Jaureguiberry et al. 2022; Haase et al. 2023). Dams alter water and sediment fluxes, affecting habitat availability and limiting migratory patterns, which in turn modify local population dynamics and freshwater community composition. Pollution and land-use changes in the terrestrial landscape pressure freshwater biodiversity by selecting against non-resistant and slow-growing species. Climate change impacts water temperature and hydrologic patterns, further compounding these effects on freshwater ecosystems.

6.5.1 State and trends of freshwater biodiversity



Freshwater ecosystems show the steepest rates of decline when compared to most terrestrial and marine ecosystems. Among the various types of freshwater ecosystems, wetlands face the greatest threats, vanishing three times faster than forests (Fluet-Chouinard et al. 2023). Globally, less than 13 per cent of the wetland area that existed in 1700 remains today (Ramsar Convention on Wetlands 2018). Freshwater species are declining at an alarming rate, with recent estimates suggesting that 24 per cent of all freshwater species are threatened

with extinction (Sayer et al. 2025). Recent surveys estimate that 89 freshwater species are extinct, and an additional 178 are suspected of being extinct (Sayer et al. 2025). Aquatic tetrapods are the most threatened group (**Figure 6.8**) and, among them, amphibians represent the most endangered class, with 40.7 per cent of species threatened worldwide (Luedtke et al. 2023).

The probability of extinction is not evenly distributed among different regions. Tropical areas of South America, Africa, Southeast Asia, and the central parts of the United States of America display the highest probabilities of new extinctions of freshwater vertebrates (He et al. 2021; Verones et al. 2022). The richness, distribution, and abundance of certain aquatic invertebrates – aquatic insects, mollusks, and plankton species – are generally much less understood than those of freshwater vertebrates and large invertebrates. However, there is a documented decline across all major insect orders. Among aquatic invertebrates, decapods, such as shrimps and crabs, exhibit the highest percentage of threatened species at 30 per cent, followed by odonates, including dragonflies and damselflies, at 16 per cent (Sayer et al. 2025).

Other aspects of biological diversity – including genetic diversity, functional diversity, community composition, and ecosystem diversity – have been less assessed on large geographical scales. For example, genetic diversity of freshwater fish species shows only weak correlation with species diversity and is declining faster than species richness (**Image 6.5**) (Van Leeuwen et al. 2018; Manel et al. 2020). Future losses of 10 to 20 per cent in the functional diversity of freshwater fish may occur if currently near threatened (NT) and threatened species, including critically endangered (CR), endangered (ER), and vulnerable (VU), on the International Union for the Conservation of Nature (IUCN) Red List, become extinct (Toussaint et al. 2021), with the Palearctic, Neoarctic, and Australia being the most threatened realms. If data deficient (DD) species are included, these figures could reach 30 per cent, and the data-poor Neotropical and Indo-Malay realms would likely be similar (Toussaint et al. 2021).

Figure 6.8: Extinction risk of tetrapods and freshwater species

Note: The numbers in brackets are the total numbers of species assessed.

Image 6.5. Credit: GreensandBlues/Envato

Changes in community composition typically occur at much lower levels of environmental threat than the established thresholds of altering species richness. In many parts of the world, the composition of fish communities displays remarkable changes even with low levels of urbanization and agricultural land use (Chen and Olden 2020; Cantera et al. 2022). Early changes in community composition are associated with the loss of native specialist species and the range expansion of more tolerant non-native species under degraded conditions (Chen and Olden 2020). Community composition can also shift gradually in response to long-term environmental changes. For instance, rising surface water temperature over the past century has led to the homogenization of cyanobacterial community composition in European alpine lakes (Monchamp et al. 2018).

The loss of freshwater biodiversity results in significant ecological impacts, including decreased ecosystem productivity and resilience. It can also affect cultural diversity, Indigenous Knowledge systems, food security, health, and livelihoods (IPBES 2019). Additionally, it contributes to economic, social, and cultural consequences, such as lost opportunities for recreation and tourism.

6.5.2 Pollution and freshwater biodiversity

Pollution remains one of the main threats to freshwater biodiversity (Le Moal et al. 2019), with various pollutants threatening natural freshwater systems in ways that are hard to measure because of their cumulative effects (Taniwaki et al. 2017). Among these pollutants, inorganic and organic nutrients are of particular concern, along with emerging contaminants. The effects of pollution on freshwater biota include behavioural disruptions, physiological damages, morphological abnormalities, and embryonic and developmental changes (Malik et al. 2020). Pollution also leads to diversity loss and ecological simplification of freshwater communities, as seen in the lakes of the Yangtze River Delta, the most industrialized region in China (Mei et al. 2020; Chen et al. 2020; Wang et al. 2021; Zhang et al. 2021).

Elevated levels of nutrients from urban, industrial, and agricultural catchments contribute to the accelerated growth of primary producers, especially nutrient-demanding species like cyanobacteria, through eutrophication. This excessive growth reduces the diversity of the primary producer community, leading to biotic homogenization (Li et al. 2022b). Additionally, these primary producers, sometimes toxic, are often less palatable to their consumers, causing disruptions in food webs and a decline in diversity across trophic levels (Karpowicz et al. 2020). The unconsumed surplus biomass produced by these primary producers accumulates in sediment, where its decomposition depletes oxygen resulting in a condition called anoxia, intensifying the release of greenhouse gases, like methane and nitrous oxide, and can trigger mass die-offs. For example, seven fish mass mortality events in Moroccan freshwater ecosystems were directly linked to elevated nutrient levels, algal blooms, and anoxia (Baladia et al. 2025).

Assessing the impact of other anthropogenic pollutants in natural settings at broader scales, such as heavy metals, pesticides, hormone and microplastics, remains challenging. However, their potential harm to biota, mainly through processes like

bioaccumulation, is significant (Reid et al. 2019; Bhatt and Chauhan 2023). Overall, pollution has caused widespread deterioration in the quality of freshwater ecosystems. This decline threatens the sustainability of aquatic life and the essential services these ecosystems provide.

Microplastics interact with fish tissues; however, the extent of bioaccumulation in organisms and biomagnification in food webs remains unclear (Azevedos-Santos et al. 2021). Emerging contaminants in water such as microplastics and agrochemicals can persist in invertebrates, fish, and reptiles, causing toxic effects, disrupting reproductive and developmental functions (Marlatt et al. 2022), and altering their feeding and migration behaviours, for example (Saha & Dutta 2024).

Due to their small size and resistance to degradation, microplastics can be consumed by fish and accumulate in aquatic organisms. Furthermore, they have the potential to enter the food chain, posing risks to both ecosystems and human health. Evidence of microplastic ingestion has been reported in more than 150 fish species from both freshwater and marine systems (Khan et al. 2024). The ability of microplastics to translocate to other tissues depends on fish size (McIlwraith et al. 2021), and retention time and bioaccumulation dynamics may vary across fish species (Sulaiman et al. 2023). Similarly, in plants, the effects of microplastics vary depending on polymer type, particle size, dosage, time, and plant species (Wang et al. 2022b). Thus, across plant and animal species, the movement of pollutants may be influenced by the level of biodiversity.

6.5.3 Land degradation, dams, and freshwater biodiversity

Dam construction, wetland drainage, fragmentation, and modification of river channels alter the structure and functioning of freshwater ecosystems, thereby threatening freshwater biodiversity. Since the 1970s, over a third of the world's wetlands and floodplains have been lost due to drainage, agricultural conversion, excessive irrigation, and river modification (Ramsar Convention on Wetlands 2018; Convention on Wetlands 2021).

Habitat fragmentation caused by dam construction has led to a decline in global freshwater biodiversity (Wu et al. 2019; Su et al. 2021). Overall, the most vulnerable species are those adapted to habitats with fast currents, structural complexity and flood pulsing, or those dependent on inter-basin connectivity for their life cycle (Arantes et al. 2019). For example, habitat alteration, division, and loss significantly contribute to the decline of migratory freshwater fish (Deinet et al. 2024), despite some successes using fish ladders and other methods to mitigate these consequences. Comparing the historical and current distribution of migratory freshwater fish in Europe and China, a significant decline in the number and abundance of species was observed (van Puijenbroek et al. 2019; Huang and Li 2024). The remaining viable populations are limited to very few rivers that are unaffected by dams (van Puijenbroek et al. 2019).

6.5.4 Climate change and freshwater biodiversity

Climate change poses a substantial threat to global biodiversity, with freshwater species and ecosystems being disproportionately vulnerable (Urban 2024). Freshwater ecosystems are warming and losing oxygen due to climate change. However, the main risks to global freshwater biodiversity arise from changes in flow patterns and water temperatures. Reduced water flow causes freshwater ecosystems to shrink and disrupts connectivity among them. This results in declines in the population sizes of low-dispersal freshwater species (Troia et al. 2019) and changes in the interactions among species, such as competition and predation (Costa et al. 2022).

Simultaneously, increases in water temperature have profound effects on the physiology of aquatic species, pushing them towards their thermal maximum during extreme heat conditions (Li et al. 2022b; de Visser et al. 2023). These threats are worsening, posing the greatest risk to species with limited dispersal capabilities, smaller body size, and restricted geographical ranges, particularly in tropical and subarid regions worldwide (Barbarossa et al. 2021; Manjárres-Hernández et al. 2021; Li et al. 2022b). In severe cases, drought can cause freshwater systems to dry out (**Image 6.6**), leading to mass die-offs of all freshwater organisms, as seen in the 2023 Amazon drought (Braz-Mota and Luis Val 2024).

Climate change has received greater attention regarding its impact on freshwater fish compared to other groups of freshwater organisms. In a warming world, 36 per cent of freshwater species have more than half of their

Image 6.6 Dried up reservoir. Credit: freedomnaruk/Envato

current geographic range exposed to climate extremes (Barbarossa et al. 2021). Alarmingly, nearly half of all freshwater fish species face the potential complete loss of their spatial ecological niches (Manjárres-Hernández et al. 2021). Amazonian and African fishes are especially threatened. Nearly one-sixth of African freshwater fishes have already been classified as endangered or vulnerable to extinction by the IUCN Red List assessment (IUCN 2025) with accelerating trends of species decline (WWF 2025). Climate change further threatens their survival, with almost 40 per cent of African freshwater fishes considered vulnerable to climate change (Nyboer et al. 2019).

Certain African regions, such as the African Rift Valley lakes, the Congo River basin, and the coastal rivers of West Africa, face increased risks. In the Andean Amazon, a significant share—ranging from 60 to 68 per cent—of freshwater fishes are expected to see a reduction in their distribution range, with 7 to 17 per cent at risk of losing all suitable habitats (Herrera-R et al. 2020). Compounding the issue, over 60 per cent of freshwater fish species are not covered by protected areas that meet the minimum required range for species survival under future climate scenarios for (Frederico et al. 2021). This limitation diminishes the potential effectiveness of these protected areas in the future conservation. Finally, while less extensively studied, other groups of aquatic organisms will also face significant consequences from climate change, including aquatic insects, amphibians, and mammals (GEO BON and FWBON 2022). Notably, nearly three-quarters of native freshwater decapod species are expected to be significantly affected by climate change (Toh et al. 2022).

6.5.5 Biological invasions and freshwater biodiversity

Aquatic invasive species – transported in ballast water, by boating, and through illegal trade – can alter hydrology and diminish water quality, and they are one of the primary threats to freshwater biodiversity. Freshwater aquatic invasive species are increasing globally across all taxonomic groups, including invertebrates, vertebrates, and plants across wetland, lake, and river habitats (Seebens et al. 2023). Globally, riparian habitats are among the most invaded habitats by all groups of animal taxa except insects (Seebens et al. 2023). Mollusks and crustaceans exhibit the highest increasing rates of invasive species among several terrestrial and aquatic groups (Seebens et al. 2023). Other examples of species that have damaged the ecological health of rivers include the Amazonian water hyacinth (Eichhornia crassipes), the feral African common hippo (Hippopotamus amphibius) outside Africa, and the Asian Basa catfish (Pangasianodon hypophthalmus) in the Magdalena River (Salgado et al. 2022).

Aquatic invasive species are often associated with changes in water quality, geomorphology, and flow patterns of aquatic ecosystems. The introduction of bivalve mollusks is a clear example. Without natural predators, their populations can expand rapidly, greatly affecting the ecosystem. For example, high abundances of zebra mussel (Dreissena polymorpha), quagga mussel (Dreissena rostriformis bugensis), and golden mussel (Limnoperna fortunei) enhance water clarity, remove pollutants, and reduce

eutrophication by decreasing turbidity and suspended organic matter in the water column (Burlakova et al. 2023). However, these organisms also colonize drinking water and energy infrastructure in reservoirs, where consolidated substrates are plentiful (Catford 2017).

North American mussel populations are facing alarming declines, including species loss and a significant decrease in abundance (Aldridge et al. 2023). This situation is caused by multiple factors. The widespread proliferation of non-native competitors, such as zebra and quagga mussels, has resulted in declines of native mussel populations due to intense competition. The invasion of zebra mussels in the Great Lakes, North America, has reached densities over 700,000 individuals per square metre, leading to reduced water flow in infrastructure and significant economic impacts (Strayer 2009; Rosaen et al. 2012). Extensive overexploitation of food resources and pearls has significantly depleted native mussel population. Additionally, dam construction has disrupted sediment and nutrient transport, altering the presence of quality habitats in major river basins, directly affecting the occurrence of native species and their feeding behaviour. Droughts induced by climate change have further worsened the crisis, causing mass mortalities. Although these primary drivers are well understood, less-recognized chronic stressors also play a substantial role in the ongoing decline of mussels (Haag et al. 2019). As a result, nearly 50 per cent of North American mussels are now classified as extinct, possibly extinct, critically endangered, endangered, or vulnerable according to the latest IUCN assessment (IUCN 2022).

Introduced fish species, used for recreational fishing, pest control, and aquaculture, can also affect water quality in freshwater ecosystems. Introduced fish, including tilapia native to Africa (Yongo et al. 2023), non-native trout (Fausch 2007; Tiberti et al. 2014; Miró and Ventura 2020), Nile Perch (Syanya et al. 2024), and invasive carp (Camargo and Amorim 2020), are linked to the destruction of native aquatic communities, increased eutrophication and higher nutrient pollution, the spread of pathogens, and higher concentration of suspended materials in the water column (Tiberti et al. 2014; Yongo et al. 2023). The presence of tilapia is linked to high levels of eutrophication in some ecosystems, similar to invasive carp and crayfish in other regions (Camargo and Amorim 2020). The introduction of Nile perch (Lates niloticus) to Lake Victoria in 1954 has led to the extinction of over 200 endemic fish species through predation and competition for food (Syanya et al. 2024).

6.5.6 Overexploitation and freshwater biodiversity

Overexploitation of aquatic species endangers the health and stability of aquatic ecosystems. This problem is especially severe among large-bodied top-predator species due to indiscriminate harvesting and incidental by-catch (Reid et al. 2019). The spectrum of overexploitation spans various taxa, especially fishes, reptiles, and amphibians, driven by diverse factors, such as food demand, recreation, and cultural activities (Stuart et al. 2004; Tregidgo et al. 2020). Historical records of overexploitation of freshwater species date back to the colonial era, exemplified by extensive turtle captures and the destruction of millions of their eggs by Portuguese settlers in Amazonia for meat and oil. The lasting effects of such actions are apparent in the ongoing recovery efforts for affected populations (dos Santos and Fiori 2020). Notably, populations of exploited species are drastically reduced in prominent freshwater bodies. For example, native freshwater mussels in Northern American ecosystems have seen a significant decline in catch per unit effort over the past century, leading to the collapse of the fish industry (Cooke et al. 2023), which affects the food security of key subsistence fisheries. Recent trends in large river basins in China show consistent declines in fish populations and catches (Cao et al. 2024), including Chinese sturgeon in the mainstem Yangtze River, which decreased from about 2,176 individuals in 1980 to fewer than 1,000 in 1989, and around 20 in 2017 (Chen et al. 2020). These trends highlight the current challenges faced by aquatic ecosystems (Chen et al. 2020; Mei et al. 2020). Such high exploitation rates mainly continue in poorer regions where freshwater fishing remains a vital source of sustenance for local communities (Aguirre et al. 2021; Bahtiar et al. 2022).

6.6 Impacts of freshwater system changes on human well-being and human systems

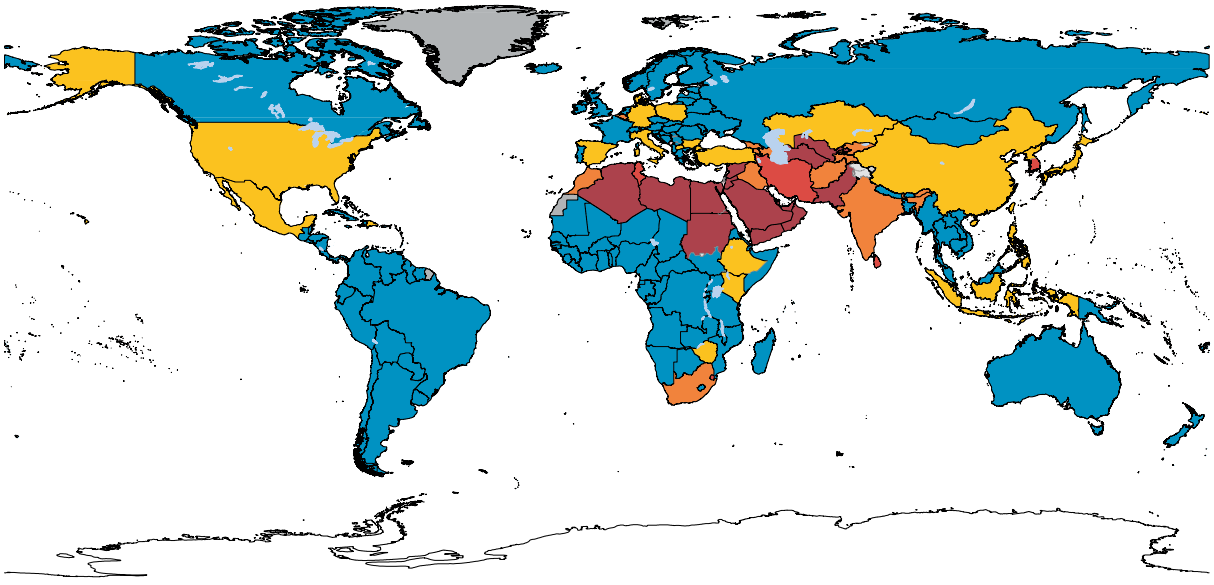
6.6.1 Water security

Global water security refers to the reliable availability of clean freshwater resources to meet social and

economic demands. In this context, security depends on availability, access to services, safety, quality, and effective management of water resources (Gain et al. 2016). Its definitions and measurements continue to evolve. Water security is of particular concern in some regions of Africa and West Asia (Gain et al. 2016).

Regional and national statistics do not reveal water security disparities within individual countries. For instance, Indigenous Peoples in some high-income nations face higher levels of water insecurity compared to the rest of the population (Harper et al. 2020). Water security also disproportionately affects women and girls. Compared to men, women play a larger role in water sanitation and hygiene activities such as washing, bathing, and cooking, making women the most challenged by water scarcity (Kayser et al. 2019). Consequently, women and girls may experience health, psychosocial, political, educational, economic effects, and threats to their well-being due to water insecurity (de Guzman et al. 2023). The gendered dimensions of water security highlight how women's access to water is vital for their health, economic empowerment, and overall well-being.

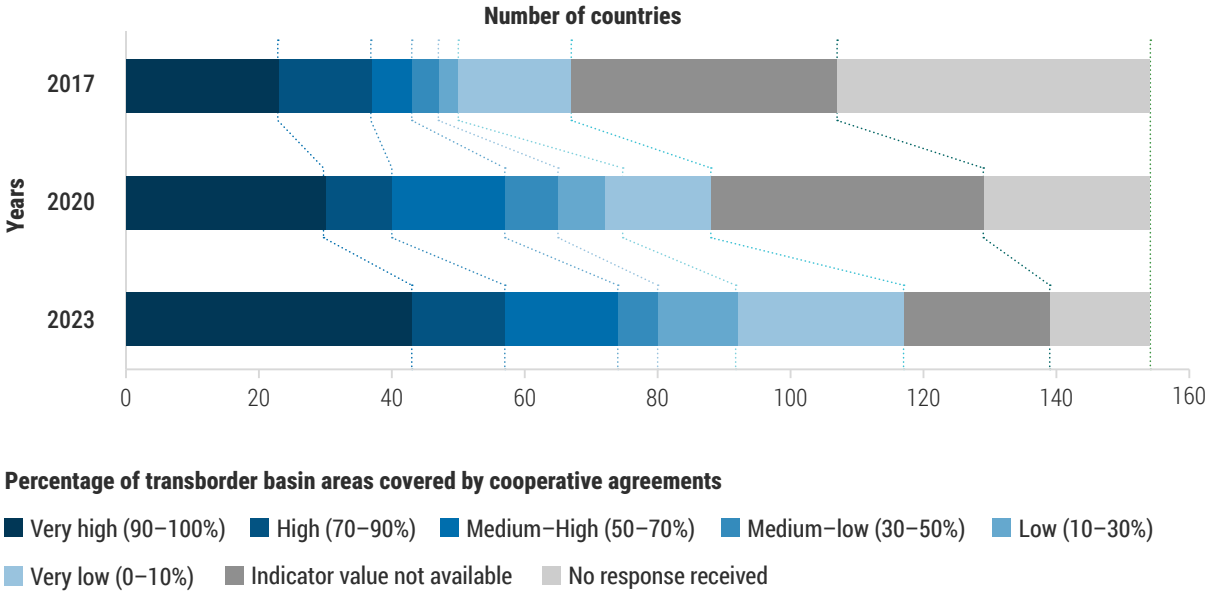
For small island developing states, water security is particularly concerning due to infrastructure vulnerability to cyclones and storms, saltwater intrusion into freshwater aquifers caused by sea level rise (Filho et al. 2020; Sharan, Lal and Datta 2023), disruptions to the hydrological cycle (Gheuns, Nagabhatla and Perera 2019; Martyr-Koller et al. 2021), and coastal aquifer over-pumping (Hussein et al. 2019; Basack et al. 2022).



Disasters further reduce water security by causing immediate water shortages. For example, if a community already faces water insecurity, sudden or slow-onset disasters will intensify vulnerabilities, preparedness, response, and recovery efforts (Ho et al. 2019).

6.6.1.1 Water stress

Water stress happens when water demand surpasses the supply of available and safe water resources. Physical water availability per person varies greatly across regions but has been decreasing worldwide due to population growth, drought, climate change, socioeconomic shifts in water needs, and overextraction of vital aquifers. This leads to increased water scarcity and threatens food and energy security (Boretti and Rosa 2019; UN Water and UNESCO 2023).



From 2015 to 2020, global water stress measured as freshwater withdrawals as a proportion of total renewable freshwater increased from 18.03% in 2015 to 18.24% in 2020 (FAO and UN Water 2021). These effects are distributed unevenly across the world with

Figure 6.9: Level of water stress by country

Source: FAO and UN-Water 2021

Figure 6.10: Number of countries with 90% or more of their transboundary basin covered by operational arrangements

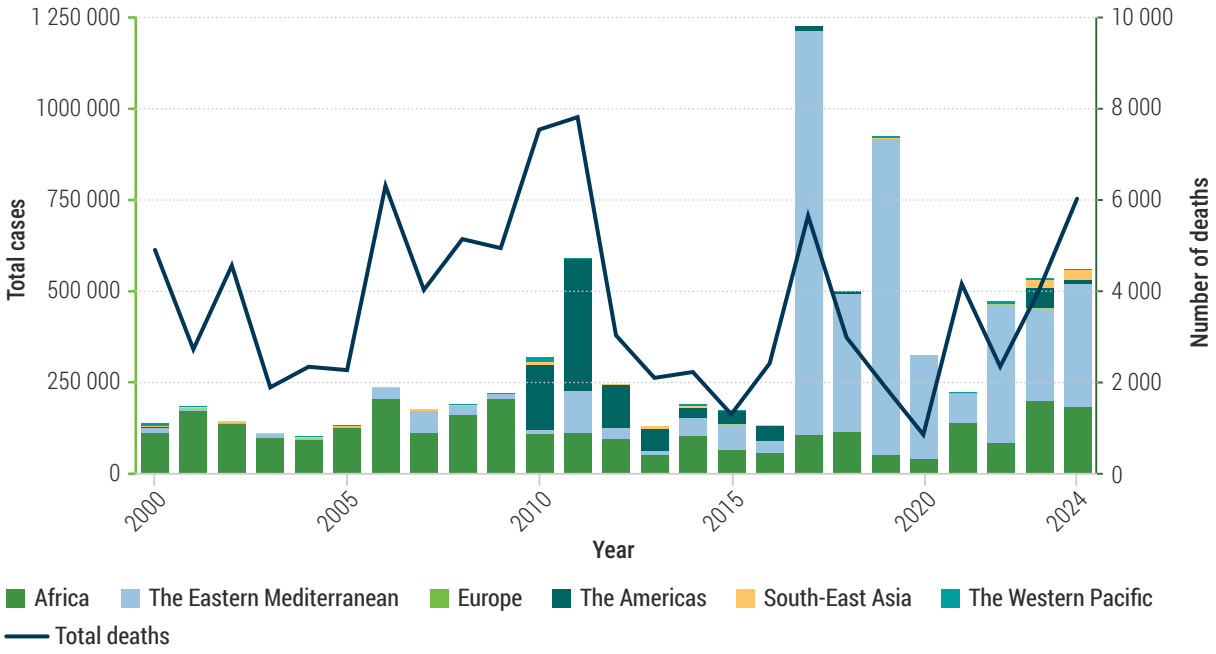
Source: UNECE et al. 2024

the most water stressed areas found in Northern Africa, and West Asia and the least water stressed areas in the tropics and at high latitudes (**Figure 6.9**).

6.6.1.2 Transboundary waters: Conflict and cooperation

In most parts of the world, water security relies on cooperation in transboundary water management. About 60 per cent of the world's freshwater flows are found in transboundary basins, which include roughly 313 rivers and lakes, as well as 468 aquifers shared by at least two countries. Although only 43 out of the 153 countries sharing transboundary waters have operational cooperative arrangements covering at least 90 per cent of these waters, this reflects nearly double the number reported in 2017 (**Figure 6.10**). The highest levels of cooperation are found in Europe, North America, and sub-Saharan Africa (UNECE et al. 2024). In 2023, the Water Conflict Chronology database recorded 379 armed conflicts related to water resources, showing a sharp upward trend over the past several years (Pacific Institute 2024). Most of these conflicts occurred within a single country, although 38 per cent involved at least two countries. Generally, knowledge-based management and cooperative use of transboundary surface and groundwater are essential to diminish the risk of water conflict.

6.6.2 Human health



6.6.2.1 Waterborne disease

Waterborne diseases caused by viral or bacterial contamination of drinking water, such as cholera, typhoid fever, giardiasis, gastroenteritis, diarrhoea, hepatitis A, and salmonellosis, are a major cause of death and disability globally. These water-related illnesses lead to 4 billion cases and 3.4 million deaths in children under five years old each year (Osiemo et al. 2019), being especially prevalent among children in developing countries due to poor sanitation (Bhagwat 2019; Rather et al. 2023). The World Health Organization (WHO) reports that in 2019 more than 1 million deaths were caused by diarrhoea, linked to unsafe water, sanitation, and hygiene (WHO 2023). Since 2017, the world has experienced a sharp increase in the seventh cholera pandemic that began in Indonesia in 1961 (Luo et al. 2024), with alarming mortality rates, especially in Asia (**Figure 6.11**). According to the WHO (2023) factsheet on typhoid fever, as of 2019, an estimated 9 million people fall ill from typhoid fever and 110,000 die from it annually worldwide.

6.6.2.2 Health effects of toxic pollutants in water

Many freshwater pollutants are toxic to humans, with effects depending on the type of the pollutant,

Figure 6.11: Cholera cases reported by WHO regions from 2000 to 2024

Source: WHO 2025

the duration and intensity of exposure (Shetty et al. 2023), and the presence of co-pollutants (Chandra and Walsh 2024). Toxicities in humans from heavy metals and metalloids includes neurotoxicity, nephrotoxicity, carcinogenicity, hepatotoxicity, immunological toxicity, cardiovascular toxicity, skin toxicity, genotoxicity, and reproductive and developmental toxicity (Mitra et al. 2022; Saravanan et al. 2022). Pesticides are linked to immunosuppression, hormonal and reproductive system disruptions, and decreased intelligence (Syafrudin et al. 2021). Water pollutants known to affect the heart include lead, mercury, cadmium, arsenic, polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons, dioxins, brominated flame retardants, plastic-related chemicals, such as bisphenol A and phthalates, organochlorine pesticides, perfluorinated compounds, hydrocarbons, and pathogens (Rajagopalan and Landrigan 2021; Kshirsagar et al. 2022). Disinfection by-products, heavy metals, dioxins, and PCBs have been shown to affect liver function (Zheng et al. 2021). Human and animal fertility and development are influenced by endocrine disruptors, pesticides, molecules in packaging, plastics, metals, solvents, flame retardants, preservatives, and fracking chemicals (Shulhai et al. 2023), as well as pharmaceuticals associated with industrial and livestock waste (Gonsioroski et al. 2020).

An increasing concern stemming from the use of personal care products and pharmaceuticals contaminated water is the elevated risks by gender. Women are particularly vulnerable, with reported links to higher rates of breast and ovarian cancers, miscarriages, and infertility (Shabaan and Alhajri 2020). Among men, prostate cancer rates are linked to certain chemicals found in hair dyes (Llanos et al. 2023). The long-term impacts of water contaminated by chemicals on young children have also been identified as a critical issue (Shittu et al. 2023).

Metals such as cadmium, chromium, and platinum are known to bioaccumulate in fish due to contaminated water and can pose carcinogenic risks for humans when consumed (Erasmus et al. 2022). Additionally, eating fish contaminated with methylmercury, PCBs, dioxins, pesticides, and plastic waste can cause cancer, kidney failure, adverse neurological effects, and cardiovascular diseases (Abera and Admas 2024).

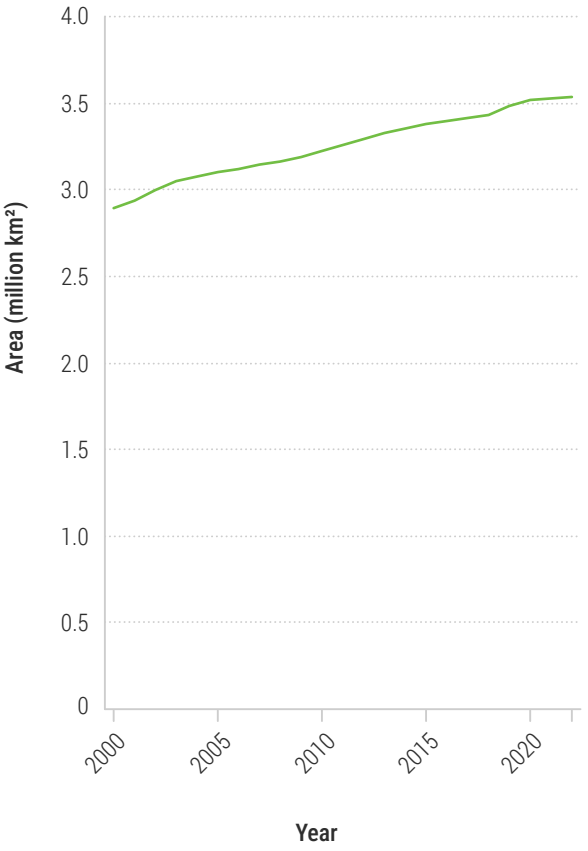
There are approximately 14 cytotoxin classes identified from various cyanobacteria taxa (Igwaran et al. 2024), including liver toxins, neurotoxins, and others linked to protein disruption, kidney and respiratory failure, and weakened muscles (You and Hua 2019; Silveira and Odebrecht 2019; Filatova et al. 2021; Mohammed and Arockiaraj 2024). Human exposure to cytotoxins can range from mild infections to severe illness or to death (Igwaran et al. 2024). Biosynthetic toxic compounds from plants and cyanobacteria form a chemically diverse

family of at least 20,000 compounds, with phytotoxin monitoring showing that one or more natural toxins are always present in surface water (Hansen et al. 2021).

6.6.2.3 Health effects of elevated fluoride and arsenic in drinking water

Fluoride and arsenic are released from host rocks through water-rock interactions and contaminate groundwater supplies, adversely impacting human health (WHO 2022). High fluoride-containing aquifers are found in the East African Rift Valley with concentrations exceeding 200 mg/L (Mengistu et al. 2019; Mwiathi et al. 2022) and in Asia (Podgorski and Berg 2022). High concentrations of fluoride in drinking water (>1.5 mg/L) are known to cause dental and skeletal fluorosis, while consuming water with arsenic levels above 10 µg/L is associated with cancer and skin lesions. The high toxicity of arsenic has been reported globally, with particularly high incidence in India and Bangladesh (Medunić et al. 2020; Shaji et al. 2021; Stuyfzand and Bonte 2023).

6.6.3 Food security



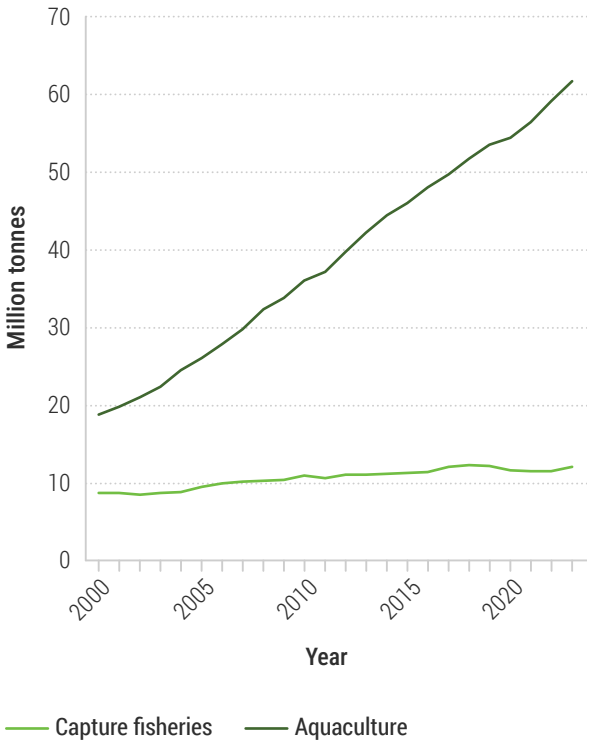
6.6.3.1 Irrigated agriculture

Irrigated agriculture is crucial in securing food supplies for a growing global population, drawing heavily on freshwater from groundwater, rivers, lakes, and reservoirs. About 70 per cent of worldwide groundwater withdrawals are used for food production, supplying water to an estimated 38 per cent of irrigated land (FAO 2022b). However, the overexploitation of groundwater for irrigated agriculture is increasing at a rate of 2.2 per cent per year, leading to a global loss of aquifer storage of approximately 250 km³ annually (FAO 2022b).

Based on FAOSTAT (2025), from 2000 to 2022, irrigated agriculture shows an increasing trend globally (**Figure 6.12**), from 2.9 million km² to 3.5 million km². These increases have been critical to attaining food security for the global population and must be managed as populations grow (FAO 2022b).

The quality of water used in food production and processing affects food quality and safety (Bhagwat 2019). In densely populated areas that generate high volumes of wastewater, using untreated sewage in agriculture presents health risks due to contamination from bacteria, heavy metals, pharmaceuticals, and microplastics (Jaramillo and Restrepo 2017; Pérez-Reverón et al. 2022; Abusah 2023; Mishra et al. 2023). For example, a salmonella outbreak was caused in the United States of America by peppers contaminated with untreated or partially treated wastewater used for irrigation (Uyttendaele et al. 2015). Untreated or partially treated wastewater reuse in agriculture has also been associated with spreading parasitic diseases, such as trichuriasis, ascariaris, and giardiasis, through vegetables in many parts of the world (Amahmid et al. 2023). At the same time, using safely treated wastewater for agricultural activities can help meet the growing water demand globally (Mishra et al. 2023).

Figure 6.12: The trend in the areas equipped for irrigated agriculture from 2000 to 2022



Source: FAOSTAT, 2025

6.6.3.2 Freshwater fisheries and aquaculture

Fisheries and aquaculture production mainly rely on the availability and good quality of freshwater. Inland fisheries are limited to natural freshwater systems such

Figure 6.13: Decadal trend in the capture fisheries and aquaculture production in inland waters

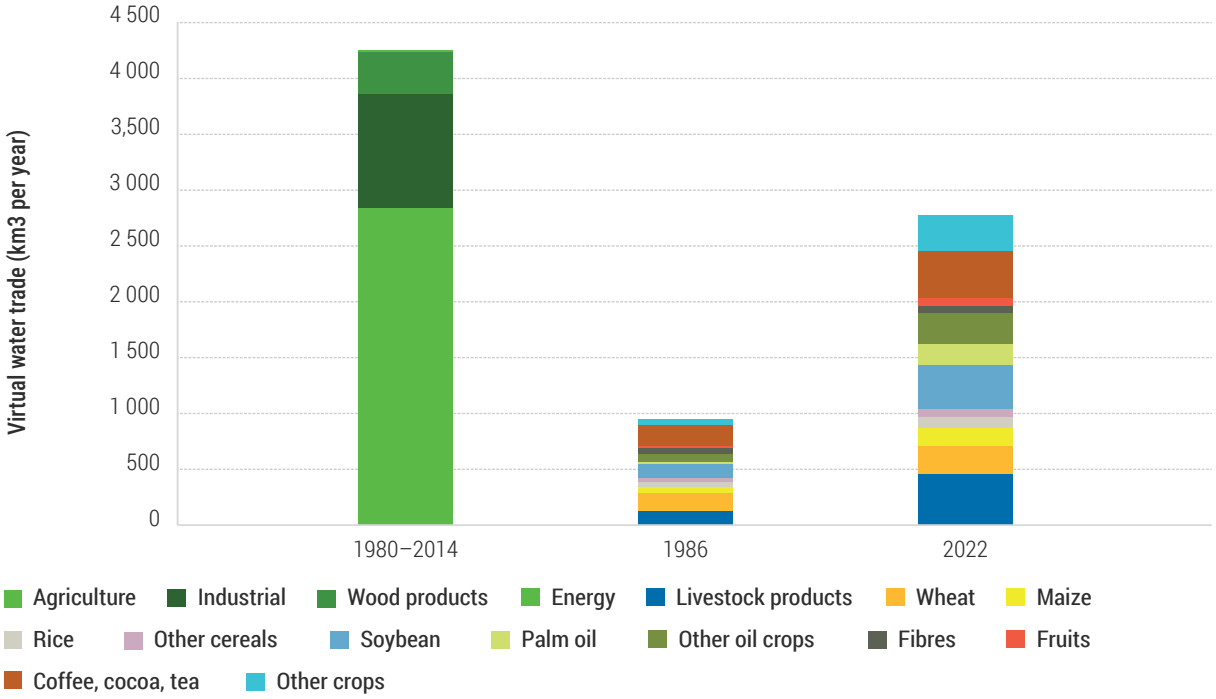
Source: FAO 2024

as lakes, dams, and rivers. Globally, the fisheries and aquaculture sector has become increasingly important for providing food and nutrition, with production steadily rising from 2000 to 2022 (FAO 2024) (**Figure 6.13**). Aquaculture contributes to the economy, reduces poverty, and improves food security. However, researchers highlight that overstocking and excessive feeding of fish can lead to degradation of water bodies, manifesting as eutrophication, toxic algal blooms, loss of biodiversity, anoxia and, in extreme cases, the collapse of fisheries (Legaspi et al. 2015).

6.6.4 Economics and freshwater

6.6.4.1 Value of water-related ecosystem services

Water-related ecosystem services include regulating water flows such as floods, controlling erosion and sediment transport, providing water supply and water purification. On a per-area basis, freshwater wetlands have the highest estimated ecosystem service value of all types at US$1,000,000 per hectare annually (De Groot et al. 2012; UN Water 2021).



Changes to freshwater systems driven by climate change, water quality decline, and aquatic invasive species have affected various sectors of the economy, including agriculture, industry, navigation and tourism. Examples of these economic impacts include:

- Of the world's total food production, 55 per cent is located in areas experiencing drying or unstable trends in total water storage (Mazzucato et al. 2024).
- Drought and flood-related disasters are estimated to have cost US$34.2 billion and US$44.9 billion in 2022, respectively (CRED 2023).
- The annual costs of eutrophication in freshwater ecosystems are estimated to be US$2.4 billion in the United States of America (Wurtsbaugh et al. 2019).
- Tourism and recreation activities have suffered due to declining snow cover, glaciers, and permafrost in high mountains (Fox-Kemper et al. 2021; Caretta et al. 2022).
- Globally, aquatic invasive species have cost the economy US$345 billion since 1971, with the most significant costs related to invasive invertebrates in North America that have damaged water infrastructure and resources. Generally, costs increased exponentially between 1971 and 2020, with annual costs estimated at US$23 billion in 2020 (Cuthbert et al. 2021).

6.6.4.2 International trade

Virtual water trade refers to the amount of water "embedded" in goods traded internationally (Graham et al. 2020; Mekonnen et al. 2024). It accounts for water stress offset through imports, rather than local production, of water-intensive products (D'Odorico et al. 2019; Rosa et al. 2019; Graham et al. 2020; Mekonnen et al. 2024). Between 1986 and 2022, the volume of virtually traded water across borders increased by 2.9 times, representing 16 per cent of unsustainable water use and 11 per cent of groundwater depletions globally (Rosa et al. 2019; Mekonnen et al. 2024). Around 20 per cent of water used in agriculture is embedded in traded goods rather than domestically consumed. The most

Figure 6.14: Changes in contribution of different products to global virtual water trade (VWT)

Note: Only consumptive water use (green water and blue water) is considered. Between 1980 and 2014, agricultural products accounted for 66% of total virtual water trade, with wood products at 9% and industrial, energy and mining products at 24%. Agricultural virtual water trade is driven largely by livestock, wheat, maize, soybean, oil palm, coffee and cocoa

Source: Mekonnen et al. (2024)

water-intensive exports include livestock products and cash crops such as wheat, maize, soybean, palm oil, coffee and cocoa (D'Odorico et al. 2019; Rosa et al. 2019; Mekonnen et al. 2024) (**Figure 6.14**). Resiliency is threatened by the ongoing dependence on rain-fed agricultural products in international markets, especially in areas where cropland is expanding (Rosa et al. 2019; Aldaya et al. 2010; D'Odorico et al. 2019).

6.6.5 Indigenous Peoples' water monitoring and governance

Through generational experience and careful observations, Indigenous Peoples have developed sophisticated, accurate, and extensive knowledge about Earth processes (Huntington 2011; Nakashima et al. 2012). They were among the first to observe and understand changes in natural phenomena and acquire critical knowledge to adapt to these changes (Reyes-Garcia et al. 2024), especially regarding water systems (López-Maldonado et al. 2014). Research and experience also indicate that nature tends to degrade more slowly on lands owned, managed, and occupied by Indigenous Peoples (Garnett et al. 2018) as their traditional knowledge helps conserve vital ecosystems and biodiversity worldwide (Hill et al. 2020; McElwee et al. 2020).

Indigenous practices can improve water management systems, as shown by the revitalization of traditional techniques in Nepal, where communities restore stone spouts and build biodykes to adapt to climate change (Shrestha et al. 2022). These methods not only supply essential water but also reduce natural hazards. Similarly, the Mayas in Mexico created advanced water management systems, including reservoirs and canals, which enabled them to manage water resources efficiently, demonstrating a remarkable understanding of hydrological systems (López-Maldonado 2021).

The concept of cultural connection to nature is mediated through sacred natural sites, including areas of water or land with special spiritual significance, such as rivers, lakes, lagoons, and springs (UNESCO 2021). Although not all Indigenous Peoples worldwide may consider water sacred, most do appreciate it as a fundamental sacred element for their existence and cultural practices since water plays a crucial role in their livelihoods and rituals (Samakov and Berkes 2016; López-Maldonado et al. 2017).

With illegal and overfishing driving the species to near extinction, Brazil adopted a total ban for pirarucu fishing in 1996. The Paumari and Deni Peoples have played a crucial role in bringing back the pirarucu population through sustainable, community-based fishery management. Credit: © FAO/Adriano Gambarini/OPAN

Water has long been central to many Indigenous Peoples, who see it connected to their ancestors and identity. Indigenous communities also lead efforts to grant legal personhood to rivers, showing a deep understanding of nature as sentient and interconnected with human well-being (Kramm 2020; Cribb et al. 2024) (**Image 6.7**). They have a profound knowledge of the water cycle, actively monitor water and atmospheric processes, including climate change, and have developed effective systems to manage and use their water resources. Examples are widespread in the scientific literature and encompass various aspects of the hydrological cycle, including cryosphere processes involving snow, ice and permafrost (Breanna et al. 2025), groundwater systems (López-Maldonado 2021), lakes (Knopp et al. 2022) and the atmosphere (Reyes-Garcia et al. 2024).

Women play a vital role in sustainable water practices, as they are often the primary managers and users of water resources in their communities, leading to better water management outcomes. The success of Indigenous strategies in maintaining healthy freshwater habitats and biodiversity is well documented (Turnhout et al. 2012; Ford et al. 2016), as are Indigenous Peoples' methodologies for monitoring and observing changes in some components of the hydrological cycle (López-Maldonado et al. 2024). There is abundant evidence of sophisticated Earth observations by Indigenous Peoples across the globe, developed over millenniums. Examples include the navigation techniques of groups in the Pacific islands and Indigenous Knowledge of cryosphere and snow processes in the Arctic, among others. Other cases include the Māori guardianship principles to monitor freshwater (Forster 2022; McAllister 2023) and the Navajo Nation in the United States of America to observe and manage their natural environment (NASA 2020). However, the relationship between Indigenous Peoples and water has been disrupted by several factors, including colonization, globalization, settlement and industrial expansion (Fernandez-Llamarez et al. 2020; McGregor et al. 2020).

6.7 Progress towards meeting internationally agreed-upon freshwater goals

6.7.1 Environmental aspects of Sustainable Development Goal 6

A recent review of progress on primary environmental aspects of Sustainable Development Goal Targets 6.3 and 6.6 is summarized below. See Chapter 7.3.6 for discussion of the social and economic aspects of Sustainable Development Goal 6, including 6.1, 6.2, and 6.4.

- Water quality and wastewater in Sustainable Development Goal Target 6.3: In 2022, UNEP (2024a) reported that an estimated 42 per cent of all domestic wastewater worldwide was not safely treated before being released into the environment. This figure was derived from data from 128 countries, accounting for 80 per cent of the global population. However, a more detailed global quantification by Jones et al. (2021) indicated that 48 per cent of wastewater was disposed of directly without treatment. Based on this limited data, approximately 56 per cent of the world's water bodies were classified as having 'good' ambient water quality (UN-Habitat and WHO 2024).

- Water-related ecosystems in Sustainable Development Goal Target 6.6: The wetlands extent index indicates an approximately 80 per cent loss since the pre-industrial period. Currently, half of the countries are observed to have one or more water-related ecosystem types in a state of degradation (UNEP 2024b).

6.7.2 Aichi targets and the Global Biodiversity Framework

Almost all the Aichi Biodiversity Targets (2011-2020) include some implicit connection to freshwater biodiversity by addressing the underlying causes of freshwater biodiversity loss, promoting the sustainable use of freshwater resources, and improving freshwater biodiversity conditions. None of the 20 Aichi Biodiversity targets were fully achieved

(SCBD 2020). Target 11 was the most advanced, and it related to conserving at least 17 per cent of terrestrial and inland water areas.

However, freshwater species were seldom included in broad-scale conservation strategies and spatial planning. For example, conservation plans focused on terrestrial species only overlapped with those based on freshwater species by 22 per cent (Leal et al. 2020). In summary, the limited progress made by 2020 has little connection to aquatic biodiversity.

In 2022, the Aichi targets were replaced by 23 new global goals under the Kunming-Montreal Global Biodiversity Framework (CBD/COP/DEC/15/5). Unlike the Aichi targets, the Global Biodiversity Framework includes more specific and measurable objectives, emphasizing national implementation and the inclusion of local communities as well as Indigenous Peoples. It builds on some unachieved Aichi targets, such as the new 30 x 30 commitment, Targets 2 and 3, to conserve and restore 30 per cent of land, freshwater, coastal, and marine areas by 2030. However, its implementation remains uncertain due to the lack of secure funding.

Freshwater ecosystems and biodiversity are directly addressed in several Global Biodiversity Framework targets:

- Target 1: Plan and Manage All Areas to Reduce Biodiversity Loss
- Target 2: Restore 30 per cent of All Degraded Ecosystems
- Target 3: Conserve 30 per cent of Land, Waters, and Seas
- Target 7: Reduce Pollution to Levels That Are Not Harmful to Biodiversity

Currently, the data to evaluate progress on these targets in freshwater ecosystems is still lacking.

6.7.3 Ramsar Convention on Wetlands

The Ramsar Convention on Wetlands is an intergovernmental treaty that provides "…a framework for the conservation and wise use of wetlands and their resources…" (Convention on Wetlands 2021). The world continues to make limited progress towards meeting wetland conservation and restoration targets, with advances confined to a few regions. The 2018 Global Wetland Outlook estimates that the total global wetland area ranges from 1.5 to 1.6 billion hectares, with declining trends observed worldwide (Ramsar Convention on Wetlands 2018). An estimated 35 per cent of wetland areas have been lost since 1970 (Convention on Wetlands 2021). Wetland losses are primarily driven by land-use change, pollution and climate change.

Chapter summary

Credit: crshelare/Envato

The global environmental crises – climate change, biodiversity loss, land degradation and desertification, and pollution and waste – are damaging human well-being and hindering progress of the economic and social dimensions of all the SDGs (*well established*). Addressing these crises is a prerequisite for achieving the SDGs. Therefore, environmental goals and targets must be given higher priority to minimize the scale, speed, and costs of environmental damage.

Global environmental crises are intensifying multidimensional poverty and putting some middle-income populations at risk of falling into poverty (*well established*). These crises are threatening access to essential services and rights, such as safe water, housing, energy, food, health, education, decent work, and sustainable livelihoods for all. The degradation of ecosystem services and goods is worsening this situation, especially for vulnerable and disadvantaged groups, including displaced people, refugees, economically disadvantaged people, particularly women and children, persons with disabilities, and marginalized populations, such as Indigenous People, as well as traditional local communities {7.2.1, 7.2.3, 7.2.10, 7.2.11}.

Environmental crises are undermining energy security (*established but incomplete*). Both fossil fuels and renewable energy are threatened by climate change-related disasters and natural hazards, which damage energy infrastructure and hinder progress towards affordable and clean energy for all {7.2.7}.

Climate change and environmental degradation are undermining global food security (*well established*). Climate change impacts, such as sea level rise, extreme weather events, biodiversity loss and various forms of pollution, undermine agricultural productivity and contribute to food price inflation. Pollution also contaminates food sources. More than three-quarters of global food crops depend, at least partially, on pollination by insects and other animals, a process at risk from environmental degradation {7.2.2}.

Water security is also under threat (*well established*). Pollution is contaminating water supplies and reducing the availability of clean water for households, industry and agriculture. Climate-related droughts, floods and sea level rise are further intensifying water scarcity {7.2.6}.

Environmental crises are affecting housing security. Climate-related extreme weather events, such as severe storms, wildfires, landslides, flooding, and sea level rise are damaging homes and infrastructure {7.2.11}.

Environmental crises are undermining human health and health systems (*well established*). Environmental risks account for a quarter of the global disease burden, and pollution is estimated to cause 9 million premature deaths annually. Climate change is exacerbating heat-related health risks, non-communicable diseases, malnutrition, premature mortality, and mental health issues, as well as communicable diseases, including vector-borne, waterborne, and food-borne illnesses. People who are highly vulnerable to heat stress include, but are not limited to, the chronically ill, older adults, young children, pregnant persons, outdoor workers, persons with disabilities, and displaced and socially marginalized population groups in cities, informal settlements, and refugee camps. Air pollution caused an estimated 8.1 million deaths in 2021 and led to 93 billion days lived with illness in 2019. In addition, widespread emerging contaminants, originating from over 350,000 commonly used chemicals, are present in many water supplies and have been linked to serious environmental and human health deterioration {7.2.3, 7.2.6}.

Environmental crises are reducing basic educational capacity, especially for disadvantaged groups (*well established*). Pollution and extreme heat impair individual learning ability, while extreme weather and disasters damage infrastructure and disrupt educational systems and services, limiting access to instructional time. The effect is particularly severe on young children, especially girls, from rural areas and on Indigenous Peoples as well as local communities {7.2.4, 7.2.5, 7.2.10}.

Critical infrastructure and basic services, especially in cities, are increasingly vulnerable to environmental crises (*well established*). Climate change and associated disasters damage buildings, housing, water supply and sanitation, telecommunication, power supply, and transport networks, including railways and roads. These disruptions will increasingly affect essential urban services {7.2.6, 7.2.9, 7.2.11}.

Environmental crises are also inflicting significant damage on industry and business (*established but incomplete*). Climate-related disasters are damaging industrial facilities and disrupting supply chains, while extreme weather and pollution are endangering worker health, safety, and well-being and reducing productivity. Heat stress alone is projected to cut total working hours worldwide by 2.2 per cent and reduce global GDP by US$2.4 trillion by 2030. Biodiversity loss is diminishing the availability of raw materials and inputs for certain industries. Migration from certain areas may reduce workforce availability {7.2.8, 7.2.9}.

Jobs and decent work are also at risk (*established but incomplete*). About 1.2 billion jobs – about 40 per cent of global employment and primarily in Africa, Asia and the Pacific – depend directly on ecosystem services. Employment is further threatened by damage to infrastructure. To protect livelihoods, environmental solutions should be designed and managed to more directly support economic and social goals and targets, particularly in terms of creating jobs and promoting decent work {7.2.1, 7.2.8}.

Economic growth is increasingly undermined by the escalating costs from environmental damage caused by the cascading consequences of interconnected environmental crises (*well established*). In 2020, about half of the world's GDP, approximately US$44 trillion, was moderately or highly dependent on nature and its services. Between 2000 and 2019, losses from recorded disasters were US$2.97 trillion. The estimated annual loss of ecosystem services from 1997 to 2011 ranged from US$4.3 to US$20.2 trillion. Between 1970 and 2020, small island developing states (SIDS) experienced a cumulative GDP loss of approximately US$153 billion due to extreme weather, water hazards, and climate change. In 2019, health-related air pollution costs were about US$8.1 trillion, about 6.1 per cent of global GDP (PPP adjusted). As a result, the cost of implementing the SDGs is rising, while the available financial resources are being increasingly diverted to managing the damage from environmental crises. Indigenous Peoples' ways of organizing economies, based on the ethics of care, offer alternative models that move away from extractivism and consumerism {7.2.8, 7.2.9, 7.2.11, 7.2.17}.

Environmental crises deepen inequalities and inequities, disproportionately affecting vulnerable and marginalized groups, including Indigenous Peoples as well as local communities, and urban and rural populations with limited resources (*well established*). Many people depend on natural ecosystems and resource-based economies for their livelihoods and well-being, while others face systemic barriers to social and economic security. Structural and political challenges, including gender

discrimination, economic disparities, legal barriers, and social exclusion, shape these inequities. Affected populations include, but are not limited to, economically disadvantaged people, particularly children and women, older adults, displaced persons, persons with disabilities, LGBTQ+ individuals, women and girls in rural developing areas, and other marginalized populations, such as stateless displaced persons and Indigenous Peoples as well as local communities {7.2.5, 7.2.10}.

Environmental crises are driving increased resource use, pollution and waste (*well established*). As climate-related disasters become more frequent and intense, there is an urgent need for greater investment in disaster risk reduction and climate adaptation. Extreme weather events generate a large volume of debris due to damaged landscapes, infrastructure and buildings, while also disrupting the management and disposal of hazardous chemicals and waste {7.2.11, 7.2.12}.

Environmental crises are diminishing the availability of ecosystem services that support human well-being, affecting all ecosystems and people globally (*well established*). The decline is particularly significant for SDG 14 and 15 targets, which aim to increase benefits for SIDS and least developed countries (LDCs) through the sustainable use of forest and marine resources, conservation of mountain ecosystems, and securing access for Indigenous Peoples as well as local communities, including small-scale artisanal fishers {7.2.14, 7.2.15}.

Environmental crises can undermine nature-based solutions aimed at achieving environment-related SDGs. Some interventions targeting one environmental crisis may unintentionally worsen others (*well established*). Global warming above 1.5 degrees increases the risk of ecosystem collapse and intensifies extreme weather events, which in turn damages nature and infrastructure for both renewable and fossil-based energy. Additionally, mining and production of materials for climate mitigation technologies can cause significant environmental harm, which needs to be addressed {7.2.7; 7.2.12}.

Environmental crises are contributing to conflicts, political instability, and large-scale displacement, particularly among rural populations in LDCs, including Indigenous Peoples as well as local communities (*well established*). Resource scarcity, intensified by environmental degradation and unsustainable consumption, contributes to conflicts and violence. Natural resource exploitation has been linked to 40 per cent of intrastate conflicts since the mid-20th century. Climate change, climate-linked disasters and land degradation are directly displacing populations, with projections estimating up to 216 million people by 2050. Crises such as wars, disaster events, and pandemics amplify the social and economic damage of environmental crises, underscoring the urgency of implementing sustainable solutions rather than delaying them {7.2.16}.

Environmental crises have serious, high magnitude, long-term cascading and compounding effects, particularly for vulnerable and marginalized populations, including Indigenous Peoples as well as local communities (*well established*). The food-energy-water nexus is a key example, where the disruption of one resource's production further destabilizes the others. Many studies illustrate the complex interlinkages among the SDGs. Moreover, wars, conflicts, disasters resulting from natural hazards, economic shocks, and pandemics further exacerbate environmental crises {7.2.1, 7.2.2, 7.2.3, 7.2.4, 7.2.5, 7.2.6, 7.2.8, 7.2.10, 7.2.14, 7.2.15, 7.2.16}.

The socioeconomic repercussions of the environmental crises will affect everyone, including middle class working people and those in developed countries. While regional and national disparities will shape the severity of impacts, the adverse effects on SDG achievement will be widespread, extending beyond people in vulnerable situations, to harm people in both developing and developed countries alike.

7.1 Introduction

The Sustainable Development Goals (SDGs) are a global action plan, employing an integrated approach to transform the environment, economy, and society, with the aim of achieving sustainable development worldwide. However, numerous reports have found that the SDGs are not on track (Sachs et al. 2024; United Nations 2024).

This chapter examines the implications of the environmental crises of climate change, biodiversity loss and land degradation, and pollution and waste – explained in this report's Global Environmental Crises Chapeau – that affect human well-being through the lens of the economic and social dimensions of the SDGs, building on UNEP's *Making Peace with Nature* (UNEP 2021b). The chapter complements other state and trend chapters (Chapters 3 to 6), which discuss the repercussions of environmental crises for human systems but are not organized by SDGs.

This chapter highlights how environmental crises significantly impede progress on the economic and social aspects of the SDGs. The environment is a vital life support system, sustaining humanity on Earth (Steffen et al. 2015). Earth system boundaries, such as the climate, biosphere, water, nutrient cycles, and aerosols, define the safe and just limits within which human civilization can operate (Rockström et al. 2023). Unfortunately, unsustainable development has led to breaches of seven out of eight globally recognized boundaries, endangering human society, as detailed in Chapters 3 through 6. Therefore, tackling environmental crises is essential to achieving the SDGs and supporting human society within the Earth system boundaries.

This chapter does not address the progress of the environmental dimensions of the SDGs, the current status of SDG implementation, methods of achieving SDGs or SDG targets, or interlinkages among SDGs. It also does not offer a thorough analysis of the reasons for the slow progress on most SDGs. Instead, it primarily concentrates on the impact of the global environmental crises on socioeconomic dimensions of the SDGs.

Additionally, the chapter differs significantly from GEO-6's discussion of the SDGs, which examined achievement levels of environment-related SDG targets and developed quantitative future scenarios for selected indicators to explore their interconnections across environmental, economic, and social dimensions (United Nations Environment Programme [UNEP] 2019). The 17 SDGs cannot be simply categorized into environmental or socioeconomic goals (Elder and Olsen 2019). Most SDGs have an integrated design, with each including at least one target related to society, the economy, and the environment. Therefore, this chapter examines the economic and social aspects of all SDGs, except SDG 13 on climate, which is itself a part of the environmental crises. It does evaluate how the climate crisis affects the economic and social facets of the other 16 SDGs, treating climate as a cross-cutting issue. Generally, this chapter does not focus on solution-oriented targets, except in a few cases where environmental crises clearly influence them.

The discussion of each SDG covers the broad headline goals as well as their relevant targets, rather than the indicators. This is because the targets are broader and more multidimensional, capturing the essence of each SDG. Most targets are qualitative, while the quantitative indicators tend to focus on narrow, unidimensional, and easily measurable aspects of the targets, which may oversimplify complex issues (Elder and Olsen 2019) and hinder integrated approaches.

This assessment focuses on individual SDGs so that each goal's results are visible to its stakeholder community. Certainly, the SDGs are deeply interconnected in complex ways (Pradhan et al. 2017; Kroll et al. 2019; Independent Group of Scientists 2023). Additionally, there are many ways to group SDGs, but there is no widely accepted clustering method or other practical approach for conducting this particular assessment.

Nevertheless, this chapter synthesizes the common trends and patterns identified in the assessment, including the compounded effects of environmental crises impeding the progress of the SDGs' socioeconomic dimensions. There are various commonalities and overlaps among some SDGs regarding the impacts of environmental crises. Several poverty-related SDGs, such as SDGs 1 to 3, are also connected to SDGs on gender and inequality, SDGs 5 and 10. SDGs 7 to 12 are directly related to the economy and infrastructure, but all other SDGs also contain economic elements. There are many interlinkages among SDGs, but a substantial body of literature already exists on this subject (Pradhan et al. 2017;

Kroll et al. 2019; Independent Group of Scientists 2023). Analysing SDG interlinkages is beyond the scope of this chapter, which focuses on impact assessment.

The chapter's structure begins by assessing the socioeconomic consequences of environmental crises on each SDG. Then, it synthesizes the common trends, including the compounded effects of environmental crises, and concludes with the implications of the assessment.

7.2 Implications of the global environmental crises on the socioeconomic dimensions of individual SDGs

7.2.1 SDG 1. No Poverty

Poverty affects every socioeconomic aspect of human well-being, including access to land, food, safe water and health care. The global goal of ending extreme poverty by 2030 will not be achieved (World Bank 2022), and poverty remains disproportionately high in rural areas (Barbier and Hochard 2016). While poverty has many drivers, this section focuses on the role of environmental crises in contributing to poverty. Climate change alone could push between 35 and 122 million more people into poverty by 2030. Limiting global warming to 1.5°C could reduce the number of people exposed to climate-related risks and vulnerable to poverty by several hundred million by 2050 (UNEP 2021b).

There is a well-established link between poverty and climate change events (World Bank 2015; WHO and the Secretariat of the Convention on Biological Diversity [CBD] 2015; Fujii 2016). These events are becoming more frequent, intense, and long-lasting, and can cause flooding, droughts, wildfires, and damage to farmland infrastructure. The socioeconomic impacts are significant, worsening livelihoods, health, and poverty, as well as driving migration and displacement. Poverty often increases social vulnerability to climate hazards, so the severity and the scale of extreme weather events are not the only factors behind livelihood disruptions.

Many impoverished communities rely on biodiversity for their livelihoods (Roe, Walpole and Elliott 2010; WHO and CBD 2015; IPBES 2019). Biodiversity offers these communities an affordable and accessible form of insurance against various risks, including food insecurity threats, environmental hazards, and health issues (CBD 2010, p.7). When biodiversity resources become degraded, their situation worsens. Some rural poor depend mainly on forests for their income. However, these forests are rapidly degrading due to climate change, land conversion, mining, and the collection of wood fuel. Additionally, conserving biodiversity can serve as a pathway out of poverty (CBD 2010; Allendorf 2022). Effective conservation efforts strengthen livelihoods, especially for Indigenous Peoples as well as local communities. Global environmental crises are intensifying poverty in many forms and pose risks of some middle-income individuals slipping into poverty. The decline of ecosystem services and resources will further impair the livelihoods of both urban and rural populations, particularly affecting women and vulnerable Indigenous Peoples as well as local communities.

Land degradation and pollution are closely linked to poverty, with a well-documented relationship (Barbier and Hochard 2016; UNCCD 2019). Over recent decades, global land quality has deteriorated rapidly (UNCCD 2019). A significant number of people live on degraded lands: 1.7 billion in Asia, 621 million in Africa, and 355 million in Latin America. These lands suffer from poor soil quality, decreased water retention, disaggregated soil particles, reduced microorganism activity, and toxic salt build-up. Each of these deficiencies leads to lower crop yields and lost production (UNCCD 2022). The resulting shortfalls prompt increased expenditure on expensive fertilizers, water, and land reclamation. Access to fertile land is essential for alleviating rural poverty, but these low-yield lands cannot generate enough income for impoverished farmers, often causing them to abandon the land. This cycle results in more debt, unemployment, poverty, land degradation, and migration (Afifi 2011).

Degradation of natural resources like land and soil directly reduces farmers' income, disrupts food markets, and makes crops more vulnerable to climate change. This can hinder income-generating activities and raise the risk of poverty among vulnerable populations, creating a negative cycle that exacerbates both poverty and environmental degradation (Banerjee and Duflo 2011; Amiraslani 2021).

7.2.2 SDG 2. Zero Hunger

Progress on ending hunger has nearly stalled, posing a serious risk of disaster. In 2022, 691 to 783 million

people experienced hunger, an increase of about 122 million since 2019, using the mid-range estimate of around 735 million. Women and those living in rural areas are disproportionately affected (FAO et al. 2023). These trends are deteriorating due to various causes (FAO et al. 2023). The interconnected environmental crises – climate change, biodiversity loss and land degradation, and pollution and waste – are adversely impacting agrifood systems and the global food supply. This worsens food price inflation, food insecurity, and malnutrition (**Table 7.1**).

More frequent extreme weather events disrupt plant hydraulic transport, alter key minerals, and increase pest and pathogen occurrences, threatening crop yields and food security (Ziska and Bunce 2007; McDowell et al. 2008: Kang, Khan and Ma 2009; Goulart et al. 2023; Pickson et al. 2024). Vulnerable groups, especially Indigenous Peoples and subsistence farmers, are particularly affected by climate extremes (Dumenu and Obeng 2016; UNFCCC 2018). Severe drought in many areas reduces pasture and livestock feed, while heat stress diminishes fish productivity and growth (Islam, Kunzmann and Slater 2022). If left unaddressed, these issues will drive up food prices, increasing malnutrition and hunger, especially among marginalized communities worldwide (FAO et al. 2023; Mirzabaev et al. 2023).

Biodiversity provides essential ecosystem services like soil fertility, pollination, and pest control, which underpin agricultural productivity and support households that depend directly on natural resources for their livelihoods (Garrido-Jurado, González-Mas, and Youse-Yousef 2023; Prangel et al. 2023). The loss of biodiversity clearly diminishes the productivity and resilience of both food systems and human communities (Asafu-Adjaye 2003; Robinson, Ryan, and Newman 2012). Communities relying on food crops for nutrition become more vulnerable to crop failures, food shortages, and rising food prices. Consequently, biodiversity loss has

Table 7.1: The impact of environmental crises on food security

	Climate change	Pollution	Biodiversity loss	Land degradation
Availability and stability	Extreme weather events reduce crop yields and threaten food and aquaculture production (Godde et al. 2021; Rezaei et al. 2023)	Crop contamination, and increased parasites and diseases harm livestock and fish, making food unsafe for consumption (Deb 2018; Shaheryar et al. 2025)	Reduced soil fertility, pest control function, and destruction of aquatic habitats, decreased food production (Katumo et al. 2022)	Reduced soil nutrients, crop yields, water availability, livestock grazing land, and threatened aquatic systems all reduce food production (Hossain et al. 2020)
Accessibility	Crop and harvest losses reduce supply and lead to higher food prices (Vargas 2011)	Soil, water and air pollution reduce food access (Mateo-Sagasta et al. 2018)	Loss of income from fisheries and agriculture reduces purchasing power of the affected communities (Scheper et al. 2023)	Lower soil quality reduces crop yields, reducing food access (Hossain 2020)
Utilization and nutrition	Climate change affects nutritional content of food and its quality by decreasing dietary and food diversity (Fanzo et al. 2018)	Higher atmospheric carbon reduces protein and mineral content in most plant species (Taub, Miller and Allen 2008; Gojon et al. 2023) Mining waste contaminates soil, degrading crop quality, affecting plant and human health (Angon et al. 2024)	Limited availability of diverse and nutritious foods leads to deficiencies in essential vitamins and minerals (Heywood 2013)	Soil erosion limits crop production (Pimentel 2006; Naorem et al. 2023)
Food safety	Climate change worsens food safety hazards at various stages of the food chain (Tirado et al. 2010; Mirón et al. 2023)	Water and soil pollution, especially heavy metals, cause various human health risks (Lu et al. 2015)	Reduced biodiversity makes food production more vulnerable to pests and diseases (Lin 2011)	Soil erosion affects safe and stable crop production (Roy et al. 2006)

significant implications for hunger by increasing food shortages, instability, and malnutrition and by decreasing dietary diversity, income, and overall well-being.

Pollution involves the uncontrolled release of industrial, vehicular, and human waste into the environment, contaminating food and water sources (He et al. 2022). Polluted water bodies damage aquatic ecosystems and decrease fish populations (Liu et al. 2022). Heavy metal from electronic and mining waste dumping contaminate fish meant for human consumption (Hu et al. 2021; Qin et al. 2021), while deforestation and water scarcity from land degradation hinder crop growth (Kumeh, Bieling and Birner 2022). Communities near industrial waste sites that rely on aquatic systems for protein and nutrition face pollution-related health issues (He et al. 2022; Liu et al. 2022). Countries experiencing high hunger and food insecurity are particularly vulnerable to rising pollution, land degradation, and waste.

7.2.3 SDG 3. Good Health and Well-Being

The interconnected environmental crises and the declining health of the planet hinder progress towards achieving healthy lives and well-being for everyone (SDG 3). About 25 per cent of the global disease burden stems from environmental risks, such as climate-related non-communicable diseases (NCDs), infectious diseases, malnutrition, mental health issues (**Table 7.2**), and exposure to pollution and toxic chemicals via air, food, and water (WHO 2023).

Climate change is leading to increasing health and environmental risks, including premature mortality, heat-related illnesses, climate-sensitive NCDs, infectious diseases like zoonoses, malnutrition, and mental health threats, all exacerbated by rising temperatures (Intergovernmental Panel on Climate Change [IPCC] 2022). Rising temperatures, shifts in precipitation, flooding, heatwaves, droughts, and wildfires heighten dangers, such as heat-related health issues, food insecurity, malnutrition, vector-borne diseases like dengue, malaria, chikungunya, yellow fever, Zika, and water- and food-borne illnesses, as shown in **Table 7.2** (FAO 2020; IPCC 2022). Climate-related risks to animal and plant health are also emerging, with the increased use of antimicrobials and pesticides for managing these issues contributing to antimicrobial and pesticide resistance (FAO 2020; EFSA 2021). Vulnerable groups – including people living in poverty, children, women and girls, Indigenous Peoples, displaced persons, the impoverished, the undernourished, persons with disability, homeless individuals, and those in insecure or degraded environments – face greater risks due to limited access to resources, education, and health care, which significantly reduces their resilience (WHO 2018).

Pollution is responsible for approximately 9 million premature deaths each year, with many more deaths related to other environmental health risks. Over 90 per cent of pollution-induced fatalities occur in low- and middle-income countries (Fuller et al. 2022). In 2021, air pollution alone caused 8.1 million deaths worldwide, ranking as the second leading risk factor for death, including among children under five (Health Effects Institute 2024). Outdoor pollution from fossil fuel combustion and indoor pollution from biomass or traditional stove use contribute to around 7.5 million premature respiratory-related deaths annually, and this threat is expected to persist (UNEP 2021b). Additional health hazards stem from environmental exposure to heavy metals and industrial chemicals through air, water, food, and soil, as well as from climate change interacting with marine food webs (Alava et al. 2017). Chemicals like lead are linked to 1.8 million deaths each year globally (Fuller et al. 2022). Elevated blood lead levels are associated with reduced IQ in children, lower educational achievement, decreased economic productivity, and a global economic loss nearing US$1 trillion annually (Fuller et al. 2022). The widespread presence of emerging contaminants in many water supplies from over 350,000 chemicals poses serious health and environmental risks (Wang et al. 2020). Pollution also damages the stratospheric ozone layer, which is slowly recovering. This damage allows excessive ultraviolet radiation from the sun to reach the Earth's surface, increasing the risk of skin cancer, cataracts, and other health problems in humans (UNEP 2021b).

Natural green and blue spaces significantly contribute to physical and mental health and well-being. The decline in biodiversity and ecosystem services, along with nature's reduced ability to regulate air and water quality, limits opportunities for recreation and relaxation that support health. Biodiversity loss hampers nature's capacity to provide medicines and traditional remedies. Over 4 billion people, more than half of the global population, depend mainly on natural medicines for health care,

and about 70 per cent of cancer treatments derived from natural sources or inspired by nature (UNEP 2021).

The deterioration of land, water, oceans, and ecosystems threatens food and water security, nutrition, human health, and the many benefits that nature provides to billions of people (IPCC 2019; Mbow et al. 2019). Land degradation, droughts, and desertification contribute to desert dust storms, which can spread infectious diseases, affect cardiovascular and respiratory health, and have other long-term consequences (IPCC 2022; Vergadi et al. 2022) (**Table 7.2**). Preventing land degradation, restoring degraded areas, and avoiding deforestation can benefit billions by supporting sustainable food systems, promoting other ecosystem services, and enhancing human health and well-being now and in the future.

Table 7.2: The impacts of environmental crises on SDG 3

	Climate change	Pollution	Biodiversity loss	Land degradation
Reproductive, maternal and child health	Low birth weights, premature births Reduced access to reproductive maternal child health care	Chronic respiratory diseases in children, asthma Reproductive and neurotoxicity from persistent organic pollutants, industrial chemicals (halogenated flame-retardants, plasticizers, dioxins), and toxic metals Water contamination leads to 1.7 million deaths/year from diarrheal diseases, mostly in children under five	Reduced dietary diversity contributes to malnutrition and under-nourishment	Desertification, can lead to desert dust storms and exposure to dust particles which have long-term impacts in pregnancy, cognitive difficulties, and birth problems
Infectious diseases	Increases in vector-borne (dengue, malaria, chikungunya, yellow fever, Zika), waterborne (cholera, vibriosis), and food-borne diseases (salmonellosis)	Air pollution may exacerbate respiratory infections	Loss of biodiversity increases risk of zoonotic diseases (One Health)	Dust storms can contribute to infectious diseases such as pneumonia, tuberculosis coccidioidomycosis, COVID-19 etc.
Non-communicable disases (NCDs)	Climate-sensitive NCDs include cardiovascular disease, cancer, diabetes and chronic respiratory diseases	Air, water and soil pollution causes 9 million premature deaths/year. Millions more die yearly from other environmental health risks	Decreased agrobiodiversity and dietary diversity contribute to NCDs	Dust storms contribute to cardiovascular and respiratory chronic diseases (IPCC 2022)
Mental health	Increased PTSD, depression and anxiety linked to injuries, displacement, loss and disasters	Air pollution from climate-related wildfires worsens mental health outcomes	Positive impact from contact with nature and biodiversity (urban green and blue spaces) and negative impact from loss of natural spaces	Desertification, loss of livelihoods, food insecurity and undernutrition erode mental. health and resilience
Health care systems environmental health and water, sanitation, hygiene	Reduced access to health systems, reproductive services, family planning, vaccines, water, sanitation Increased antimicrobial resistance	Health damage from indoor and outdoor air pollution	Biodiversity loss reduces access to natural medicines, threatening Indigenous Peoples' health and wellness	Land degradation and desertification reduce access to health care and reproductive services, water, and biomass

A healthy planet, achieved by addressing climate change, air and water pollution, and land and ecosystem degradation, is essential for human health, well-being, and achieving the SDGs.

7.2.4 SDG 4. Quality Education

The environmental crises, especially climate change and pollution, undermine the general provision of education as well as equitable access to it.

Climate change affects education by damaging educational infrastructure through events, especially floods, which disrupt all kinds of educational services. For example, in 2022, severe floods and landslides damaged schools, roads and other infrastructure, causing lengthy school closures in some parts of KwaZulu-Natal, South Africa. This area experienced similar disasters in the past (Bopape et al. 2021). These disasters often significantly reduce the incomes of poor households, who frequently respond by pulling their children out of school, for example in Indonesia (Rush 2018).

Such disasters also decrease enrollments at all education levels, adversely affecting lifelong learning. Consequently, this leaves more people vulnerable because fewer individuals have enough knowledge about climate risks and adequate disaster responses (Muttarak and Lutz 2014).

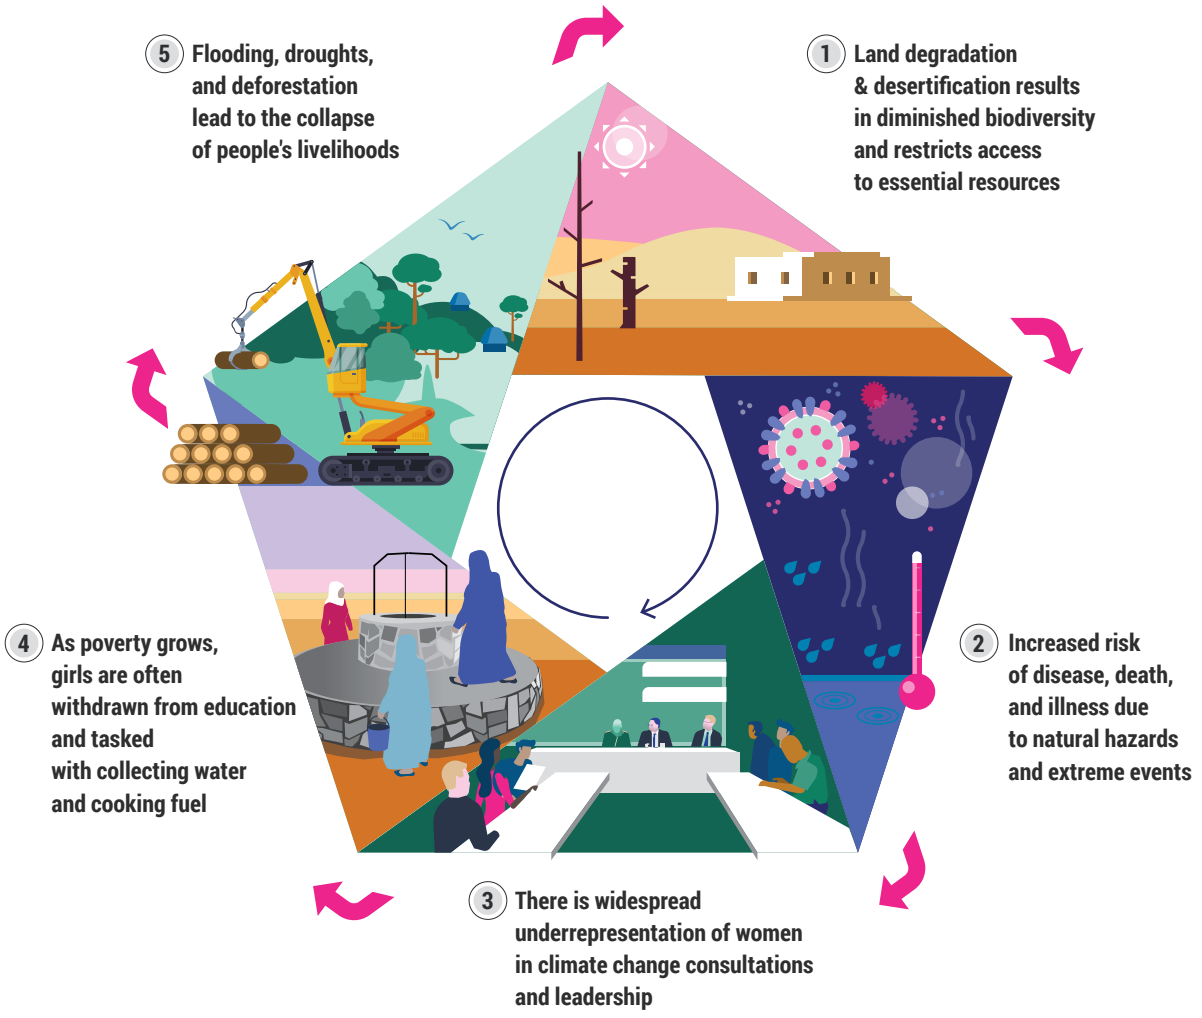
Climate-related disasters disproportionately affect people in vulnerable situations such as Indigenous Peoples as well as local communities, further reducing access to education. In areas inhabited by these groups, weather forecasts are often inaccurate due to sparse distribution of meteorological stations (Reyes-García et al. 2024). This heightens their risk of displacement (UNESCO 2020) and limits their educational opportunities. Exposure to tropical cyclones was linked to an average 2.7 percentage point decline in primary school enrolment by 2010, a 14.2 per cent decrease, with girls more affected than boys (Jing et al. 2024). Over the past 20 years, approximately 410,000 children missed school because of tropical cyclones across low- and middle-income countries, resulting in a loss of over 4.1 million school years (Jing et al. 2024). UNICEF reported that in 2024 extreme climate events disrupted schooling for at least 242 million students in 85 countries (United Nations Children's Fund [UNICEF] 2023). Gender inequalities often increase women's vulnerability to disasters, especially in regions like Bangladesh where women tend to be less educated than men (Juran and Trivedi 2015). Additionally, since vulnerability to environmental crises varies depending on context and conditions (Muttarak and Lutz 2014), wealthier households can often afford online education and homeschooling if meteorological and hydrological hazards damage local schools. However, children from poor families have limited alternatives. Climate change-induced rising temperatures also hinder students' ability to learn at all ages: "Across countries, a 1°F [0.55°C] increase in average annual temperature is associated with 0.02 standard deviation lower math scores for 15-year-olds taking the 2012 Programme for International Student Assessment" (Park et al. 2020).

Pollution, including air and water contamination, also harms quality education by impairing students' ability to learn. Vulnerable populations, often living in polluted environments, are most affected. Landrigan et al. (2019) explain, "In children, early-life exposures to neurotoxic pollutants can permanently impair cognitive function thus contributing to school failure and reduced lifetime earnings." Balakrishnan and Tsaneva (2021) found that "air pollution is negatively correlated with academic performance" among children in rural India. Similarly, Mizen et al. (2020) described the academic effects as including "forgetfulness, inattentiveness and careless errors," which are critical for learning and exams. They also linked air pollution to increased school absences and found that children with lung diseases are more vulnerable. Additionally, Zhang et al. (2018) observed that the adverse effect of air pollution on cognitive performance worsens with age, limiting lifelong learning, especially in health and welfare decision-making. A study by Claudia Persico (2019) in Florida found that prenatal exposure to toxic wastes may have long-term consequences that could affect academic achievement in school, leading to grade repetition or even cognitive disabilities.

Biodiversity loss indirectly affects education by limiting opportunities to learn about various species. Access to such knowledge becomes difficult for future generations if biodiversity declines (Børresen et al. 2022). Additionally, biodiversity loss reduces access to Indigenous Knowledge and local solutions, leading to an increased dependence on solutions developed elsewhere.

Land degradation reduces ecological productivity and biodiversity (Ekka et al. 2023), which affects sustainable

education for future generations. Additional research is necessary to increase understanding of land degradation's effect on quality education.



7.2.5 SDG 5. Gender Equality

Research indicates that women and girls are disproportionately affected by environmental crises (Goh 2012; Sardar and Bhaduri 2022). These unequal effects hinder progress towards gender equality.

Climate change affects women's access to and control over essential resources like land and property and puts additional pressure on tasks traditionally carried out by women, such as cooking and collection of water and fuel. These effects significantly limit their ability to cope with adverse outcomes. Women and girls are especially vulnerable to extreme weather events, facing higher risks of death, illness, and livelihood loss. Examples include climate-induced weather events increasing gender-based violence, climate-related income reductions disrupting girls' education because families pull girls out of school first, droughts and floods leading to loss of livelihoods and a rise in child marriages, biodiversity decline harming women's health and eroding traditional knowledge, and under-representation in environmental decision-making marginalizing women's concerns in developing low-carbon economies (IUCN 2021; Anderson and Fisher 2022; OECD 2023; UNDP 2023). A 2019 United Nations Development Programme (UNDP) report states that over 60 per cent of deaths linked to extreme climate events in the past two decades involved women (Escovar and Balduzzi 2024). During disasters, women and children are 14 times more likely to die than men. For example, in the 2004 Indian Ocean Tsunami, out of 230,000 fatalities, 70 per cent were women (UNDRR 2023).

Figure 7.1 highlights the gender-specific effects of climate change across five key areas: land degradation and desertification; adverse health outcomes, including mortality and morbidity; marginalization in

Figure 7.1: Gender differential impact of climate change

climate change consultation and decision-making; increasing poverty and crises related to fuel and water collection; and loss of livelihoods. The figure also illustrates how these outcomes are interconnected.

The complexity of gender inequality in climate change and environmental sustainability has also influenced academic and policy discussions related to other environmental crises. Land degradation and desertification disproportionately affect women (UNFCCC 2022), and "women are the major actors in the global efforts to reverse and reduce land degradation" (Gurung et al. 2006).

Household and ambient air pollution was responsible for an estimated 6.7 million deaths worldwide in 2019 (WHO 2024). Women face a 50 per cent higher mortality rate from indoor air pollution compared to men (Rees and Choi 2019). In India, approximately 30 per cent of ambient air pollution originates from cooking with solid biomass, leading to 1.3 million deaths annually due to household air pollution.

Women around the world serve as farmers, herders, forest gatherers, water collectors, food processors, soil conservationists, and keepers of natural and built environments. However, their progress is often hindered by restricted rights to productive resources, limiting their ability to fulfil increasing roles in conserving biodiversity and preventing land degradation (Rocheleau 1995; Kelkar and Nathan 2024; UN Women 2024).

An OECD study highlights the interconnectedness of environmental crises and gender inequality, emphasizing that empowering women and girls (SDG 5) "not only helps reduce the disproportionate exposure but can help drive positive change and enhance the impact of these agendas" (OECD 2023).

7.2.6 SDG 6. Clean Water and Sanitation

The environmental crises, especially climate change and pollution, are threatening the achievement of SDG 6 and water security.

Increasing frequency, duration, and intensity of droughts, worsened by climate change, contribute to water scarcity (SDG 6.4) and threaten the supply of safe and affordable water (SDG 6.1) (Mishra et al. 2021; Visser-Quinn et al. 2021). Additionally, increased flooding caused by climate change endangers essential drinking water and wastewater infrastructure needed for SDGs 6.1 and 6.2 (Salameh 2023), while sea level rise is causing salinization of some coastal aquifers. Climate change is stressing the reliable supply of fresh water for all uses – such as food, energy, manufacturing, and drinking water – further contributing to water scarcity (SDG 6.4).

Water pollution is a major threat to safe drinking water (SDG 6.1) (WHO 2023). Key sources include untreated sewage (SDG 6.2), inadequate sanitation, and industrial wastewater (Schwarzenbach et al. 2010). The health implications of contaminated drinking water are well-documented (Wolf et al. 2023; Li et al. 2024). In 2019 alone, an estimated 1.4 million deaths and 74 million disability-adjusted life years could have been prevented through safe water, sanitation, and hygiene (Wolf et al. 2023). Poor water, sanitation, and hygiene are also linked to 69 per cent of diarrheal disease, 14 per cent of acute respiratory infections, and 10 per cent of undernutrition (Wolf et al. 2023).

Land degradation can worsen the effects of drought, leading to water scarcity, especially in arid regions, with negative consequences for food security and rural livelihoods (Hermans and McLeman 2021). It also speeds up soil erosion, which damages some surface water sources used for drinking (Bower et al. 2009). Additionally, soil compaction decreases infiltration and the recharge of certain groundwater sources (Bower et al. 2009). Sediment run-off, pesticides, and heavy metals are carried into water supplies through agricultural intensification, deforestation, and urban expansion (Mateo-Sagasta et al. 2017), thus polluting drinking water. As desertification advances, water supplies vital for agricultural production and community needs diminish, until the land can no longer support farming, natural vegetation, or daily life (Andreeva et al. 2022) . Urbanization increases impervious surfaces, which can slow the recharge of shallow aquifers and threaten the sustainability of some water sources (Wakode et al. 2018).

Biodiversity loss affects water supply and increases water stress in some regions due to systemic disruptions caused by invasive species. Worldwide, aquatic invasive species have caused US$345 billion of economic damage since 1971, with the largest cost linked to invasive mussels in North America that have damaged water and energy infrastructure (Cuthbert et al. 2021). Invasive species can also disturb the hydrology of freshwater systems by interfering with

natural infiltration and evapotranspiration processes. For instance, invasions of *Tamarix sp.* and *eucalyptus* have led to reduced stream flow in arid climates already experiencing water stress (Catford 2017; Le Maitre et al. 2023).

There are gender disparities in water collection: In 2022, 2.2 billion people lacked safely managed drinking water. In two-thirds of households, women are mainly responsible for collecting water, which has broader socioeconomic effects (WHO and UNICEF 2023). Also, in 2022, 152 countries had over 75 per cent of their populations with improved water access on premises. However, 41 countries had less than 50 per cent coverage, including 17 countries with less than 25 per cent coverage (WHO and UNICEF 2023). The lack of water on premises disproportionately affects women and girls.

7.2.7 SDG 7. Affordable and Clean Energy

Environmental crises are increasingly disrupting energy production and distribution, hindering SDG 7 and broader energy security, affecting both fossil fuel production and the transition to net-zero energy (**Table 7.3**). These crises are particularly worsening energy poverty and limiting energy access in low-income countries (Biswas et al. 2022, Khoday 2021).

Climate change negatively affects both fossil and renewable energy sources. Recent studies show that a 1°C increase above the optimal panel temperature of 25°C can cause about a 0.5 per cent decrease in photovoltaic or solar energy efficiency (Ebhota and Tabakov 2023; Saxena et al. 2024; Bamisile et al. 2025). Additionally, climate-induced droughts can disrupt electricity generation from hydroelectric, nuclear, and thermal power plants that depend heavily on water for steam production and cooling (In et al. 2022; Shuai et al. 2024). This leads to greater reliance on fossil fuels and portable generators, which in turn raises greenhouse gas emissions and air pollution. Gernaat et al. (2021) noted that under a high emissions scenario, global hydropower potential could decline by up to 10 per cent by 2100, with regional differences, and decrease further by 2050. The interconnected food-energy-water nexus worsens these challenges. For example, in countries like India and China, new coal-fired power plants compete with agriculture for water resources (Alkon et al. 2019; Singh and Tayal 2021). Simultaneous heat waves and droughts boost electricity demand for cooling, straining power grids, particularly in less developed regions (Leichenko and Silva 2014; Kapeller et al. 2024).

The economic costs from supply shocks and health impacts are about 2.5 times higher than the direct costs of energy production (Qiu et al. 2023). Consequently, electricity prices increase, disproportionately affecting marginalized and vulnerable groups by reducing access to affordable energy and elevating energy poverty risks (Byrne and Portanger 2016).

Biodiversity loss has mostly indirect effects on energy access by reducing plant species essential for biomass production. While this is a global issue, it is more pronounced in tropical regions (CBD 2020). Additionally, yields of energy crops are likely to decline as ecosystems degrade and natural flood defences weaken due to biodiversity loss. Under the worst climate change scenarios, crop yields – including those of energy crops – could decrease by up to 23 per cent (Izumi et al. 2020; Wing et al. 2021; Minoli et al. 2022). Biodiversity loss also indirectly affects pipeline stability through changes in vegetation that compromise land and soil integrity (US Department of Transportation 2022). This results in greater operational monitoring requirements for pipeline assets.

Pollution damages both grid and non-grid energy sources. For instance, acid rain contributes to solar panel corrosion, while airborne particulate matter reduces their productivity. In urban and industrial regions of the United States of America and Türkiye, PM_{10} has lowered the average annual solar transmittance – also known as "PM dimming" – by about 10 per cent, and up to 4 per cent in parts of East, Central, and South Asia, the Arabian peninsula, and Western Siberia (Özdemir 2019; Amini et al. 2024; Oh 2025), thus decreasing solar power output.

Pollution also indirectly damages wind farms. Acid rain corrodes turbine components, erodes metal surfaces and damages protective coatings, leading to reduced efficiency, higher maintenance costs, and shorter equipment lifespans. Consequently, air pollution reduces overall energy production efficiency. Achieving up to a 50 per cent reduction in yearly carbon emissions could boost power generation by

Table 7.3: The impacts of environmental crises on various energy sources

Energy source	Climate change	Air pollution	Biodiversity loss	Land degradation
Hydropower	Droughts reduce water availability (Shuai et al. 2024)		Vegetation loss reduces river flows, increasing soil erosion, impacting turbines (Obahoundje and Diedhiou 2022)	Erosion, water scarcity, and landslides impact infrastructure (Wasti, et al. 2022)
Nuclear	Droughts reduce cooling water availability (Gernaat et al. (2021)	Particulates, acid rain risk ineffective air filtration, corrosion, poor cooling		
Wind farms	Sea level rise, heat waves, and cyclones cause unpredictable wind patterns, affecting offshore wind farm infrastructure and power generation (Rapella et al. 2024; Gonçalves et al. 2024)	Corrosion from acid rain affects wind turbine machinery		Land degradation reduces land availability for onshore wind farm sites (Dhar et al. 2020; Tercan 2021)
Biomass and biofuels	Droughts reduce water availability for energy crops	Poor soil health reduces energy crop yields (Izumi et al. 2020; Wing et al. 2021; Minoli et al. 2022)	Deforestation disrupts ecosystems (CBD 2020)	
Solar	Extreme weather, hurricanes, hailstorms damage panels	Reduced solar intensity due to smog particulates (Özdemir 2019; Amini 2024; Oh 2025)		Reduced suitable land for solar farms (Dhar et al. 2020; Tercan 2021)
Oil pipelines	Structural damage from melting permafrost (Li et al. 2021; Wang et al. 2023; Zhang et al. 2024)	Acid rain corrodes machinery and components, and increases risks to worker health	Degradation of land and soil supporting pipelines (US Department of Transportation 2022)	Erosion and landslides damage pipelines
Power grids	Heat waves cause power spikes which stress power grids (Leichenko and Silva 2014; Kapeller et al. 2024)			Land degradation affects land availability for power grid infrastructure (Dhar et al. 2020; Tercan 2021)
Refineries	Sea level rise, storms and extreme weather disrupts operations and risks infrastructure damage, especially in coastal areas	Acid rain corrodes machinery, components and poses worker health risks	Soil erosion and habitat destruction increases landslides and flooding risks	Erosion and landslides damage infrastructure

approximately 10.3 terawatt hours/year in China and 2.5 terawatt hours/year in India, valued at roughly US$880 million and US$200 million annually.

Land degradation diminishes the supply and quality of biomass energy sources like firewood, which are commonly used in low-income countries, thereby worsening energy poverty. It also decreases the amount of suitable land available for solar and wind farms (Dhar et al. 2020; Tercan 2021). Land degradation severely disrupts the soil's structural integrity and water retention capacity, both of which are essential for supporting the infrastructure of renewable energy installations.

Environmental crises are increasingly disrupting energy production, distribution, and security, affecting both fossil fuels and renewables. These issues worsen

energy poverty and access, especially in low-income countries. Rising temperatures reduce solar panel efficiency, while water shortages impair hydroelectric, thermal, and nuclear plants. Droughts and heatwaves increase electricity demand, overloading power grids and prompting a shift back to fossil fuels, which exacerbates greenhouse gas emissions and air pollution. Melting Arctic permafrost and ice threaten oil and gas pipelines, increasing spill risks. Biodiversity loss reduces the yields of energy crops. Air pollution decreases the efficiency and lifespan of solar panels and wind turbines. Urgent actions are needed to mitigate these impacts and ensure equitable, clean, and affordable energy worldwide.

7.2.8 SDG 8. Decent Work and Economic Growth

Environmental crises are undermining economic development and employment (UNEP 2021b). While growth-focused economic systems significantly contribute to these crises, they are now also being weakened by them (UNEP 2019).

Climate change is causing significant economic harm, which is expected to grow, reducing "average global incomes by approximately 23 per cent by 2100" (Burke et al. 2015). Countries most affected will be those least responsible and with the fewest resources for adaptation.

Climate change impacts on jobs and work productivity are already being felt and are forecasted to worsen (ILO 2018a). Heat stress is expected to cut total working hours worldwide by 2.2 per cent and reduce global GDP by US$ 2.4 trillion by 2030 (ILO 2019), with low- and middle-income countries suffering the most (ILO 2019). Heat stress is especially challenging for outdoor workers such as in construction, "1 billion agricultural workers and 66 million textile workers, many working inside factories and workshops without air conditioning", and workers engaged in "refuse collection, emergency repair work, transport, tourism, and sport" (ILO 2019). Heat stress is more common in countries facing "decent work deficits", and excessive heat levels will worsen inequalities among nations and social groups (ILO 2019). Each year, on average, natural disasters caused or worsened by humans lead to the loss of 23 million working-life years, or about 0.8 per cent of a year's work (ILO 2018b).

Over the past 20 years, climate-related extreme weather has caused annual costs of US$143 billion (Newman and Noy 2023). The benefits of early action exceed the costs of inaction (Stern 2007; Heal 2009). Prevention costs are much lower than cleanup costs, as assets become stranded, leading to irreversible damage that adversely affects human health, economies, and productivity.

Climate change also damages critical infrastructure. The costs of the infrastructure damage along with required maintenance and repair costs exceed current levels by multiple times (IPCC 2022). These consequences disrupt lives, livelihoods, and well-being for a growing number of people, significantly undermining economic growth and development (IPCC 2022).

Pollution's economic costs are very high, far exceeding the costs of pollution reduction measures, in addition to harming health. Air pollution resulted in an estimated 6.4 million deaths and 93 billion days with illness in 2019 (World Bank 2021). The health-related costs reached approximately US$8.1 trillion in 2019, accounting for 6.1 per cent of global GDP (PPP adjusted) (World Bank Group 2022). For low- and middle-income countries, the cost was 8.9 per cent of GDP, while it was 3.0 per cent for high-income countries (World Bank Group 2022). The global cost of air pollution from fossil fuels is estimated at US$8 billion daily, or 3.3 per cent of global GDP (Farrow et al. 2020).

Land degradation also results in economic costs by decreasing land productivity, which affects food security, agricultural output, and overall economic development, particularly for vulnerable populations. The extent of land degradation has expanded, with at least 100 million hectares of healthy, productive land degraded annually between 2015 and 2019, directly affecting 1.3 billion people. This degradation has caused significant economic harm, and climate change is expected to further worsen these conditions (IPCC 2019).

Losses in biodiversity and ecosystems also lead to significant economic losses. Between 1997 and 2011, land-use changes caused an estimated decline of US$4.3 to 20.2 trillion annually in ecosystem services, depending on the valuation method (Costanza et al. 2014). Environmental degradation contributes to pollinator declines, putting global crop yields at risk

(UNEP 2021b), and causes a 3-5 per cent annual decline in the production of fruits, vegetables, and nuts (Smith et al. 2022). Climate-related extreme weather events further threaten ecosystem services (ILO 2018a). About 1.2 billion jobs – primarily in Africa, Asia, and the Pacific, where 80 per cent of the world's Indigenous Peoples as well as local communities live, depend directly on ecosystem services, representing roughly 40 per cent of global employment (ILO 2018b). However, all humans, in some way, rely on these services.

SDG 8.4 aims to decouple economic growth from environmental degradation, but progress remains limited. Research suggests that the prospect of achieving necessary absolute or relative decoupling is unlikely without significant reductions in material and energy consumption by high-consumption countries and social groups (Ward et al. 2016; Hickel and Kallis 2020; et al.Vaden et al. 2020; Parrique et al. 2019), while still maintaining human well-being (Jackson 2016; Lorek and Fuchs 2013). Without this action, there is a high risk that the economic growth will increasingly undermine its own foundation.

Alternative approaches to organizing economies are possible which can promote prosperity without relying on continuous economic growth while reducing environmental impacts (Raworth 2012; Jackson 2016; Hickel et al. 2022). Many Indigenous Peoples consider themselves prosperous without depending on economic growth (Kelly and Woods 2021). They effectively care for their living territories (Prosper et al. 2011; UNEP 2019; Hill et al. 2022) and resist resource extraction (Etchart 2017). Numerous Indigenous and decolonization movements critique the concept of perpetual economic growth, considering their challenges to be rooted in global economic systems (IPBES 2022), colonial modernities (Quijano 2000; Kimerling 2012; Arora and Stirling 2021), and green colonialism in conservation. Indigenous Peoples can develop new transformational pathways that transcend the framework of sustainable development centred on economic growth (Burke et al. 2023). Their ontologies and values can inspire global action (Bryer 2023), fostering well-being in harmony with nature (UNEP 2024). Current economic models are based on individualism and consumerism. However, there are alternative, sustainable economic models that emphasize the ethics of care as a way to build economies based on social justice, environmental sustainability, and collective well-being (IPBES 2022). The IPBES Transformative Change Assessment Report highlights systemic reforms in global economies, transforming governance, and shifting values to emphasize nature-connectedness as a crucial strategy (IPBES 2024).

7.2.9 SDG 9. Infrastructure, Industry and Innovation

Environmental crises are impacting industry and infrastructure and disrupting supply chains (World Economic Forum 2020). These sectors are vital for economic growth, employment, and poverty alleviation, as they rely heavily on natural resources and ecosystem services. In 2020, approximately half of global GDP – around US$44 trillion – was moderately or highly dependent on nature, and the top sectors were construction at US$4 trillion, agriculture at US$2.5 trillion, and food and beverages at US$1.4 trillion.

7.2.9.1 Impact on infrastructure

Extreme weather events linked to climate change, such as floods and droughts, are damaging infrastructure and production facilities, resulting in an estimated US$700 billion in related losses in 2022 (Coalition for Disaster Resilient Infrastructure and UNDP 2023). In low- and middle-income countries, these events result in approximately US$18 billion in annual direct damage to power generation and transportation infrastructure (Hallegatte 2019). For instance, a sea level rise of just 0.5 metres could interrupt electricity production at around 6,700 coastal thermoelectric power plants (C40 Cities 2018). **Figures 7.2** and **7.3** illustrate the effects of climate change on various infrastructure sectors.

Increased air pollution damages infrastructure, including the erosion of building materials and the deterioration of existing structures. Acid rain, a consequence of higher air pollution levels, is especially damaging to older infrastructure (Environment and Climate Change Canada 2018).

Biodiversity loss can lead to shortages and price fluctuations of raw materials needed for construction, infrastructure maintenance, and other industries. Biodiversity losses and changes can also disrupt supply chains (Principals for Responsible Investment

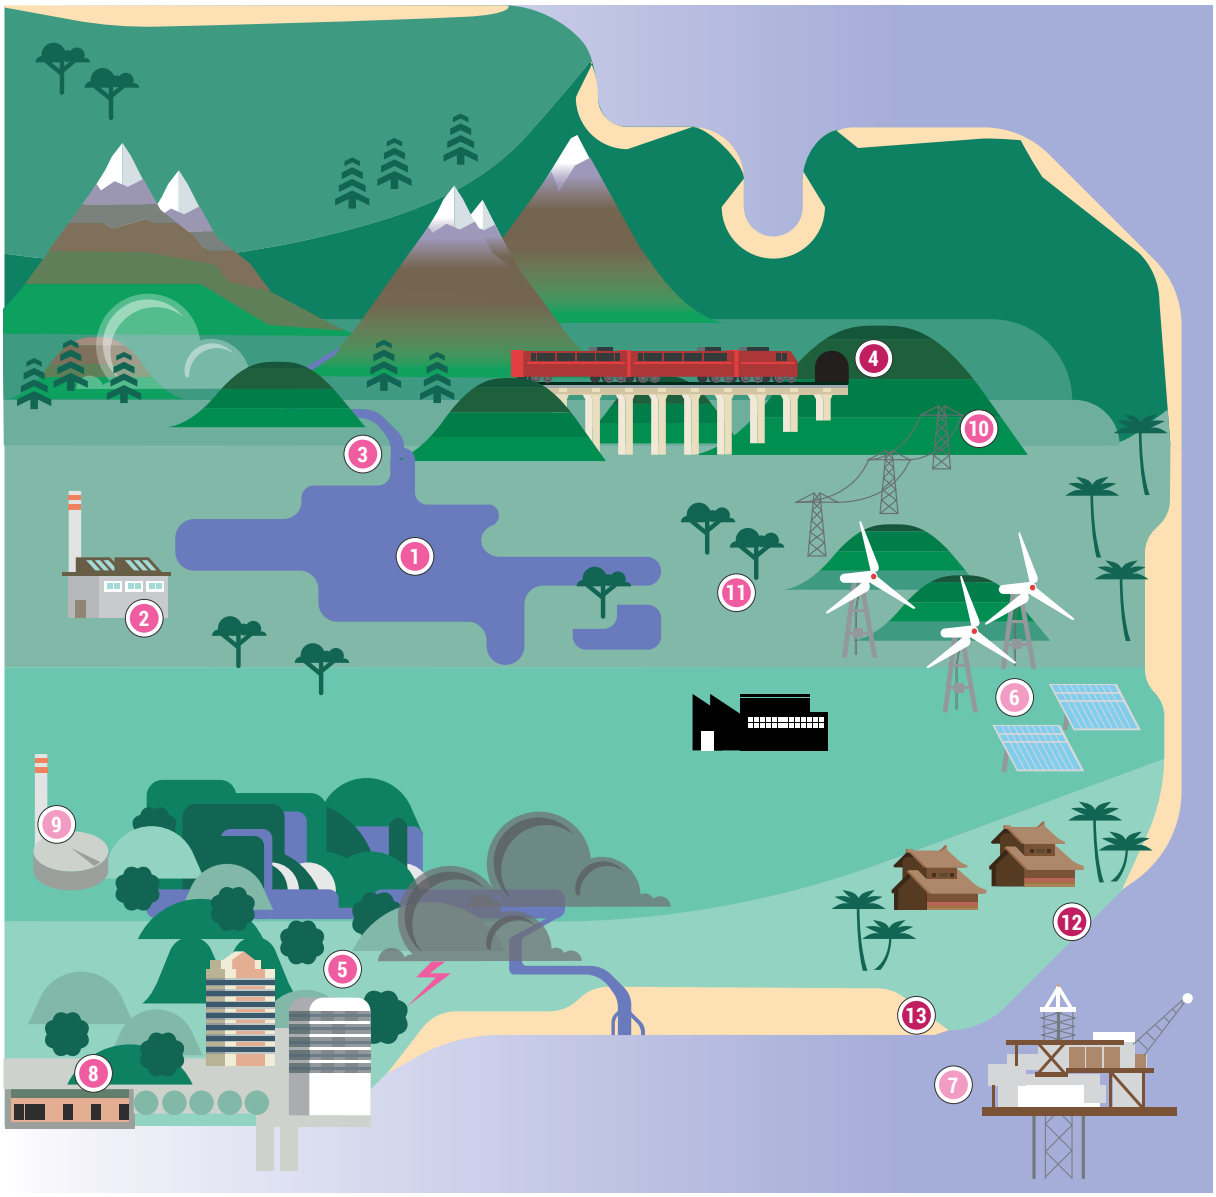
2023). Land degradation and soil erosion can change land topography, degrading roads, utility networks, and other infrastructure.

7.2.9.2 Impact on industries

Extreme weather events disrupt supply chains by reducing the availability of resources, raw materials, and labour, leading to significant production disruptions and potential relocations due to the amplification of existing socioeconomic inequalities among vulnerable worker communities, especially in natural resource-intensive industries such as fisheries and agriculture (Tchonkouang, Onyeaka and Nkoutchou 2024).

Water pollution poses a major threat to industrial production. Many industries, ranging from the tannery and fashion sectors to semiconductors, require large amounts of clean water for their operations. The food industry is one of the highest water-consuming sectors, using about two quadrillion gallons annually (Balsam 2020), followed by the textile industry, which requires approximately 79 trillion litres of clean water as of 2020 (Milton 2023). Excessive pesticide use also contaminates water supplies, disrupting industrial processes.



Tropospheric ozone results in annual losses of about 110 million tons of major staple crops, representing roughly 4 per cent of global crop production (CCAC, 2024).

7.2.9.3 Impact on small-scale enterprises

Many small-scale enterprises are particularly vulnerable to the impacts of climate change because

Figure 7.3: Examples of climate change impacts on infrastructure

High confidence Medium confidence Low confidence

1. Disruption of public water supply due to lower summer rainfall
2. Increased wind damage to above ground infrastructure
3. Increased frequency of river and surface water flooding
4. Increased delays and safety risks due to rail track damage during heatwaves
5. Increased ICT faults due to lightning strikes
6. Changes in yield from renewable 11 energy sources (onshore and offshore)
7. Disruption to offshore operations including energy extraction/ generation
8. Increased subsidence disrupting subterranean infrastructure
9. Reduced efficiency of waste treatment processes
10. Reduced power line capacity
11. Changes to vegetation and to performance of natural or 'green infrastructure'
12. Increased frequency of coastal flooding due to rising sea levels
13. Loss of beaches that provide natural protection to low-lying coastal areas

Source: UNEP (2021a)

of limited production capacity and narrow profit margins. They have very limited financial resources to relocate or rebuild after climate-induced disasters. About 30 per cent of small businesses are already affected by climate-related disasters, suffering from facility damage, loss of industrial symbiosis, disrupted supply chains, and workflow interruptions (Deloitte 2021, WTO 2022). Small-scale impacts of climate change on SMEs can have devastating consequences due to their limited production capacity. For instance, many smallholder farms are only marginally productive so even minor climate-related crop damage can lead to immediate and severe production and income losses (Lario 2022).

7.2.9.4 Impact on the industry retrofitting

Environmental crises impede sustainable industrial retrofitting (SDG 9.3) in ways similar to broader industry and infrastructure impacts. These include structural damage, supply chain disruptions, shortages of resources and labour, heightened occupational hazards for workers, and the need for relocation. Overall, such crises adversely affect many industries and their infrastructure (**Table 7.4**), as well as supply chains. The resulting economic costs decrease GDP, lead to job losses, and hinder economic development, ultimately undermining human well-being.

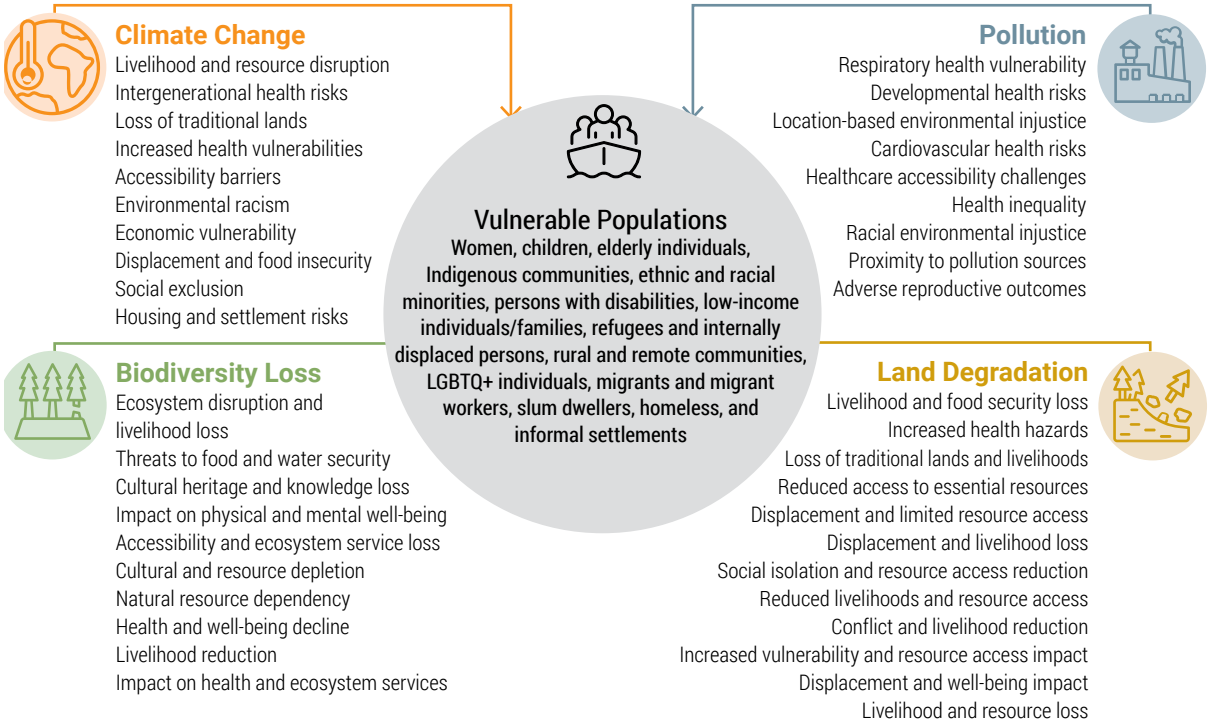
7.2.10 SDG 10. Reduced Inequalities

Interconnected global environmental crises disproportionately impact marginalized groups, obstructing progress towards SDG 10 (**Figure 7.4**) (Field and Barros 2014; WHO 2016; UNDP 2018; UNEP 2019; CBD 2020; Tessum et al. 2021; UNCCD 2022; Wagner et al. 2023).

Climate change disproportionately impacts marginalized groups, especially those residing in low-income areas, small island developing states, arable farmers, pastoralists, and Indigenous Peoples (IPCC 2022). These groups endure the harshest effects of extreme weather events, rising sea levels, and resource shortages, particularly those with limited adaptive capacities who live in informal urban settlements. Climate-related events, such as droughts, floods, and storms, worsen existing inequalities, and historical injustices amplify these vulnerabilities (IPCC 2018; CBD 2020; Marí Dell'Olmo et al. 2022).

Pollution disproportionately affects low-income and marginalized communities that do not generate it, especially those near hazardous sites like industrial zones, where dumpsites and landfills are often located close to their homes. These communities face higher rates of respiratory and other health issues, such as heart disease, due to greater exposure to air pollution. Other forms of pollution such as water pollution, soil contamination, and chemical exposure also worsen health risks. For example, contaminated water and hazardous waste contribute to long-term health problems and deepen socioeconomic disparities, widening inequality (WHO 2016; Mianabadi et al. 2022, 2023). Indoor air pollution from energy use also disproportionately affects marginalized groups (WHO 2016). Tackling these pollution-related inequalities is crucial for SDG 10 to promote health equity and ensure marginalized communities have equal access to clean air, water, and a healthy environment.

Biodiversity loss greatly affects vulnerable populations, including marginalized groups and Indigenous Peoples, who depend on natural resources for their livelihoods, cultural traditions, and overall well-being (Nkuba et al. 2020; Hoffmann 2022; Pirali Zefrehei et al. 2022a, 2022b). Biodiversity loss worsens food insecurity, erodes traditional knowledge, and can lead to displacement of these groups (IPBES 2019; Amini et al. 2023). Additionally, insufficient recognition of land rights makes Indigenous communities especially susceptible to dispossession, threatening their livelihoods, cultural identity, and increasing gender inequalities (Quiroga Eróstegui 2022; Bohman 2024). The effects of biodiversity loss are disproportionately felt by those who depend heavily on ecosystem services, such as low-income rural communities, making them particularly vulnerable to these changes (Davies et al. 2018).



Land degradation disproportionately affects vulnerable populations, worsening inequality by disrupting their livelihoods. The reduction of arable land and limited resource access increase food insecurity and economic hardship for marginalized and low-income groups that depend heavily on natural resources (UNCCD 2022).

Environmental racism intensifies existing inequalities by exposing disadvantaged groups, particularly people of colour and low-income groups, to higher ecological risks. This worsens

Figure 7.4: Impact of global environmental crises on vulnerable populations (SDG 10)

Sample Data:
- Double victimization
- Suffering more than 80% of illnesses, injuries, and deaths attributable to climate change
- 80% of the world's remaining biodiversity resides in Indigenous homelands
- A 1°C temperature increase can impact elderly health and mortality
- Disability increases disaster mortality 4 times
- 56% and 63% excess $PM_{2.5}$ exposure in Black and Hispanic minorities
- 80% of urban greenhouse gas emissions linked to high climate exposure in the poor
- 15.4 million refugees and 43.7 million displaced people in search of solutions amid environmental crises
- 15% higher suicide risk in rural Australian males during drought
- LGBTQ+ individuals exhibit stronger environmental preferences
- 10-30 million people annually
- Massive transformations: environmental impact on Majuli Island, India - A reduction from 1,255 sq km to 421 sq km

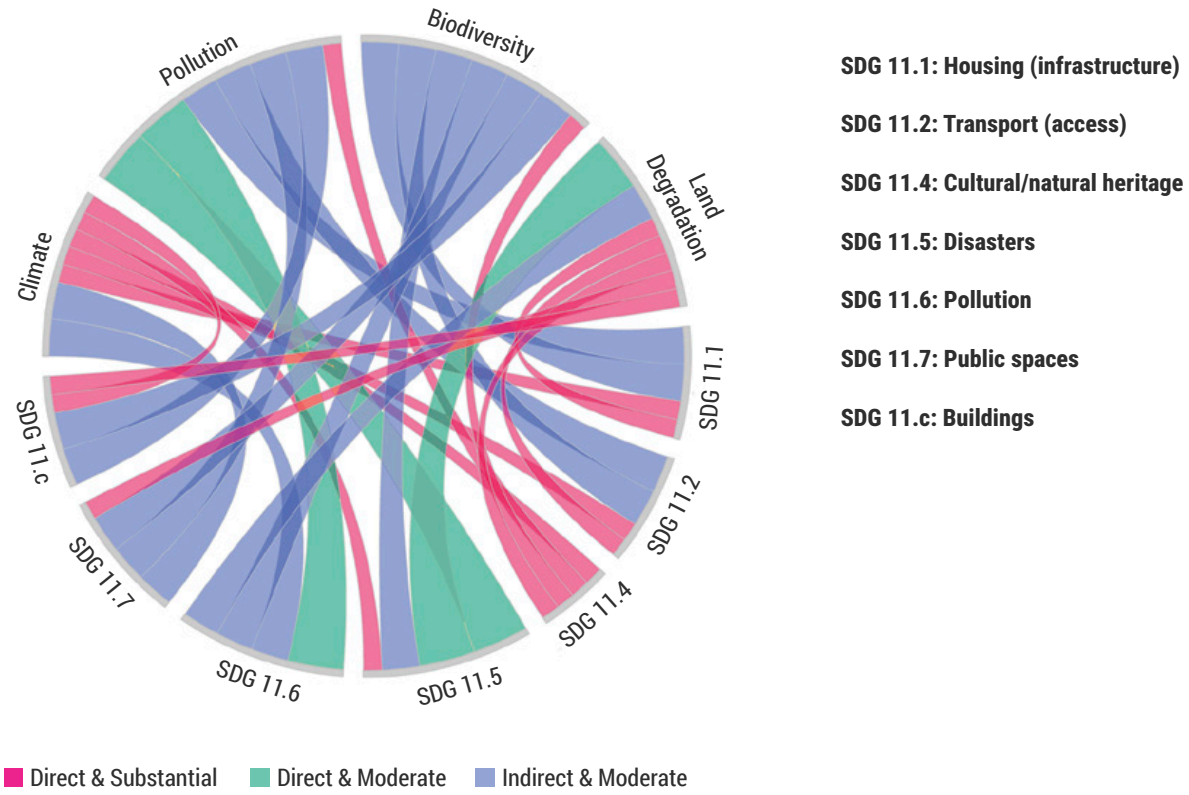
disparities in health, employment, and overall well-being (Mohai and Saha 2015; Gutterman 2022; Khine and Langkulsen 2023).



Addressing global environmental crises is crucial for reducing inequality and advancing justice. Immediate, comprehensive measures are needed to ensure that marginalized communities do not bear a disproportionate burden of environmental damage (UNEP 2019).

7.2.11 SDG 11. Sustainable Cities and Communities

Overall, environmental crises threaten both current and future progress towards SDG 11 (**Figure 7.5**). As these crises worsen, the existing progress on SDG 11 could potentially be reversed.

Climate change will hinder SDG targets related to housing, transport, heritage, and buildings due to increased flooding, drought, urban heat island effects, and sea level rise (Elmqvist and Andersson et al. 2019; Lin and Cao et al. 2021; Ozturk and Bozzolan et al. 2022; Lin and Melbourne-Thomas et al. 2023; Zhang and Cao et al. 2023). Additionally, heritage sites and buildings will suffer damage from extreme weather and air pollutants, such as sulfur dioxide and ozone (Xiao and Ning et al. 2022). Biodiversity loss will harm the ecosystem services of heritage and reduce their appeal to humans (Cave 2022). The proportion of the world's urban population breathing polluted air increased from 90 per cent in 2016 to 99 per cent in 2021, based on WHO air quality guidelines (UN 2019; UN 2022). Land degradation will seriously damage sociocultural values, slow economic development, threaten food and

Figure 7.5: Overview of environmental crises' impact on SDG 11 targets

water security, increase communities' vulnerability to natural hazards, and could potentially compromise geopolitical stability and security (Salehi et al. 2017). Some impacts, such as the effect of climate change on the urban environmental microbiome and its influence on SDG 11, require additional assessment (Zhu and Penuelas 2020).

The environmental crises impact SDG 11 differently across and within countries, with cities in developing countries and vulnerable urban populations bearing the heaviest burden. Coastal and island cities are particularly vulnerable to climate change (Xiao and Ning et al. 2022; Lin and Melbourne-Thomas et al. 2023). Approximately 1 billion people live in urban slums, mainly in low-income developing countries, which are some of the most environmentally sensitive and at-risk areas (UN 2022). Significant global disparities in greenspace exposure and inequality exist; for example, Asian cities have the lowest human exposure to greenspace at 13.49 per cent, which is much less than North American cities' 53.45 per cent, European cities' 39.25 per cent, and Australian and Oceanian cities' 42.51 per cent (Chen and Wu et al. 2022). Additionally, access to urban facilities varies widely among different groups, often disadvantaging large, vulnerable populations (Dadashpoor and Rostami et al. 2016).

Biodiversity provides essential ecosystem services for urban living environments, particularly for microorganisms. However, the diversity and abundance of microorganisms in affluent urban areas have noticeably declined (Alenius and Pakarinen et al. 2009). Global biodiversity loss may contribute to the development of allergic and autoimmune diseases because pollution reduces urban microbial diversity, which, according to the hygiene hypothesis, helps protect human immune systems (Zhu and Penuelas 2020; von Hertzen et al. 2011).

Regional natural ecosystems are vital for maintaining cities' resilience against environmental crises (Wendling and Garcia et al. 2021). For instance, nutrient cycling of food between urban areas and their surroundings directly influences urban sustainability (Lin and Gibson et al. 2014). The loss of natural landscapes within cities and the increase of surfaces, such as roads and rooftops, which absorb and emit heat more than natural surfaces, lead to heat islands and cause economic and health issues. Urban forests and trees are very important in reducing heat islands,

enhancing air and water quality, and supporting biodiversity (Grote and Samson et al. 2016; Manoli and Fatichi et al. 2019; Bux and Anderson et al. 2021; Cuthbert and Rau et al. 2022). Nature-based solutions should be emphasized in response strategies to the environmental crises.

7.2.12 SDG 12 Responsible Consumption and Production

Environmental crises hinder efforts to promote sustainable consumption and production, undermining the sustainable management and efficient use of natural resources.

Climate change threatens progress on the targets for sustainable waste management (12.4, 12.5), reduction of food waste and loss (12.3), resource efficiency (12.2), and sustainable practices (12.1, 12.6, 12.8, 12.a, 12.b, 12.c). It speeds up the release, redistribution, and remobilization of legacy pollutants and industrial contaminants, weakens current control measures, and challenges the enforcement of multilateral environmental agreements. Additionally, the climate crisis influences the longevity and spatial spread of volatile persistent organic pollutants (POPs), halogenated organic chemicals, and heavy metals (Nadal et al. 2015; Wagner et al. 2019 Zhang et al. 2021; Chai et al. 2022; Bolan et al. 2023; Langer et al. 2023). Melting ice – from ice caps, glaciers, sea ice – and thawing permafrost release legacy contaminants, such as industrial chemicals and heavy metals (Potapowicz et al. 2019; Kibria et al. 2021; Miner et al. 2021; Borgå et al. 2022; De Wit et al. 2022; Hung et al. 2022; Christensen 2024). Higher temperatures accelerate the release of POPs from ice, soil, and other environments, raising their levels in the atmosphere and helping them travel long distances. This includes higher amounts of polybrominated diphenyl ethers (Rigét et al. 2019; Zhang et al. 2021; Gong & Wang 2022). Increased climate-related wildfires and land degradation generate new POPs and polycyclic aromatic hydrocarbons (PAHs) from burning organic material. Intense fires remobilize pollutants like DDT and hexachlorocyclohexanes trapped in foliage, litter, and surface soil, causing them to volatilize back into the atmosphere. Deforestation, reforestation, and disruptions of contaminated sites release stored POPs and produce new POPs and PAHs (Gong et al. 2021; Li et al. 2024; Zhu et al. 2024). Rising temperatures also speed up pesticide breakdown and decrease their effectiveness, leading to more frequent applications and increased environmental contamination. Shifts in climate patterns can boost pesticide use in farming and introduce new chemicals and waste streams, resulting in more pollution (Pérez-Lucas et al. 2024).

Climate-related extreme weather events, along with mitigation and adaptation efforts, increase material demand by requiring climate-resilient infrastructure, population relocation, and pollution-control facilities. This leads to a larger material footprint, more raw material extraction, and higher per capita and GDP-linked consumption (Wang et al. 2020), thereby undermining target (12.2) on the efficient use of natural resources.

Climate-induced disruptions compromise waste-disposal infrastructure and the management of municipal, industrial, and hazardous waste by weakening sustainable waste practices, recycling systems, and secondary resource markets, thus hindering progress towards targets 12.4 and 12.5 (Amato et al. 2020; Brand and Spencer 2020; Kumar and Reddy 2020; Summers et al. 2021; Lincoln et al. 2023; Lebu et al. 2024; MacAfee and Löhr 2024).

Climate impacts and extreme weather events disrupt global supply chains (Tchonkouang et al. 2024), leading to material shortages that hinder sustainable consumption and production practices, making it more difficult to achieve targets related to material footprint and domestic material consumption (Gonzalez et al. 2019). They heighten the vulnerability of cross-border agrifood supply chains by disrupting transportation systems through delays, rerouting, and infrastructure stress, while also damaging postharvest storage and transport facilities; rising temperatures and heat stress accelerate food spoilage, reducing market value, and increasing waste (du Plessis, Goedhals-Gerber, and van Eeden 2024). Extreme weather events hinder green innovation by slowing economic growth, restricting financial development, widening income inequality, eroding human capital, and escalating political risks (Wen et al. 2023).

The biodiversity loss crisis, especially changes in species distribution and abundance – such as the decline of pollinators or the spread of invasive species and pests – disrupts food supply chains (Sabbahi et al. 2022). This situation leads to increased dependence on chemical inputs, which in turn increases resource use and hinders the effective management of chemicals.

Land degradation leads to an increased use of fertilizers, pesticides, and water to sustain agricultural productivity. It also changes soil properties – including pH, organic matter content, and moisture retention – affecting the soil's capacity to absorb, mobilize, and break down POPs (Tao et al. 2019; Gong et al. 2021et al.). Furthermore, activities such as deforestation, afforestation, and disturbance of contaminated sites release stored pollutants, creating new POPs and PAHs (Gong et al. 2021;et al. Li et al. 2024; Zhu et al. 2024).

The pollution and waste crisis contaminates crops, livestock, and aquatic resources with harmful substances such as POPs, heavy metals, and pesticides. This contamination forces the disposal of agrifood products, leading to increased food waste and hindering resource use reduction efforts (Tigchelaar et al. 2021; Cao 2023; Fred-Ahmadu et al. 2024). Additionally, pollution and higher temperatures accelerate the spoilage of fruits and vegetables (Wafula, Ouna, and Kamiri 2024). Pollution also poses challenges to sustainable manufacturing in the agrifood sector, obstructing progress toward target 12.3 on food waste (Fróna et al. 2021; Kumar et al. 2022; Onyeaka et al. 2023).

7.2.13 SDG 14 Life Below Water

Environmental crises weaken progress towards the sustainable use of oceans, seas, and marine resources for all, including Indigenous Peoples as well as local communities (SDG 14). Target 14.7 emphasizes the economic benefits for small island developing states (SIDS) of the sustainable use of marine resources, while 14.b focuses on providing small-scale artisanal fishers access to marine resources and markets. The 58 SIDS (UNEP 2019; Glass et al. 2022), along with small-scale and artisanal fishers (FAO 2016; FAO 2022), supply around 60 per cent of protein in some developing countries, including SIDS themselves (United Nations 2016). Their livelihoods largely depend on healthy marine ecosystems (Techera and Appadoo 2020). Nonetheless, SIDS' vulnerability is increased by factors such as low elevation of their islands, their geographic remoteness, and their small population and land size (Vousdoukas et al. 2023).

Climate change and coral reef loss harm food security, coastal protection, and the tourism industry (Bindoff et al. 2019; Eddy et al. 2021). The loss of coral reefs, especially in SIDS, significantly disrupts fish habitats, reducing fishing grounds (Thomas 2020). The forced migration of fish and ocean species from warming waters to more suitable habitats may cause severe economic losses for fishing communities. These include tuna, with a projected 17 per cent reduction in annual government revenue, and migratory oceanic pelagic fish near the Caribbean islands (Oxenford and Monnereau 2017). SIDS lost approximately US$153 billion from 1970 to 2020 due to extreme weather events, water hazards, and climate change – equivalent to about 11 times the average GDP of SIDS (WMO 2020). It is also projected that SIDS will face US$56 billion in losses from climate-related disasters such as floods and storms by 2050 under a 2°C warming scenario (Panwar et al. 2023).

Climate change has contributed to declines in the reproduction and size of several species, such as crustaceans and molluscs. This has affected 12 million artisanal fishers and their livelihoods in coastal African communities, pushing fishing communities to diversify their sources of income and adapt their fishing practices (Coalition for Fair Fisheries Arrangements 2021). The growth, reproduction, and survival of marine species are at risk due to lower oxygen levels, a problem worsened by climate change and nutrient pollution (Rose et al. 2019; Appadoo et al. 2022), which in turn reduces harvest yields.

Plastic debris, including fishing gear, food packaging, and single-use plastics, is a primary cause of marine pollution. Plastics damage the health of marine species and humans. For example, entanglement reduces the efficiency and productivity of commercial fisheries and aquaculture (Yang 2021; Marcharla et al. 2024), while consuming contaminated seafood poses health risks to people (Beaumont et al. 2019). Artisanal fishers in both SIDS and least developed countries (LDCs) are particularly vulnerable (Barrowclough and Eugui 2021). SIDS are often located near ocean gyres, resulting in debris accumulating on their shores (Lachmann et al. 2017), such as in Caribbean islands (Monsanto et al. 2023). Marine pollution also causes long-term damage to coral reef ecosystems, as seen on the Republic of the Marshall Islands.

Depletion of shallow water ecosystems, including habitats such as mangroves, seagrass beds, and estuaries, caused by offshore oil platforms and coastal refineries (Andrews et al 2021), harms the livelihoods and incomes of small-scale and artisanal fishers and coastal communities.

Pollution and climate change decrease fish stocks, lowering potential global food supplies and forcing small-scale and artisanal fishers to compete with larger fishers and tourism industries. Additionally, these fishers face economic losses from fish contaminated by land-based pollution (Nair and Nayak 2023).

Biodiversity loss and marine habitat degradation, driven by human activities such as overfishing and the use of harmful fishing gear, significantly reduce fish biomass and negatively affect food security and the livelihoods of coastal communities (Sumaila and Tai 2020). Reef fish and coastal species are also increasingly depleted due to rising global fishing pressures. SIDS rely heavily on fisheries, aquaculture, and tourism, earning about US$55 billion in 2019 from tourism alone (Mead 2021; UNESCO 2022). Maintaining high-quality marine and coastal ecosystems is crucial for sustaining these industries. The degradation of marine ecosystems can expose SIDS to natural disasters and diminish their ability to fully realize economic benefits (Martyr-Koller et al. 2021). Biodiversity loss also economically disadvantages women and small-scale fishers who supply fish to local markets.

Land and coastal degradation are driven by human activities like dam building, deforestation, and farming, which contribute to coastal erosion and change shoreline features (Mentaschi et al. 2018). Nearly half of the world's coastal wetlands have disappeared over the past century, making communities more vulnerable to flooding (Jungwiwattanaporn et al. 2023). Rising sea levels worsen the effects of coastal erosion and flooding from tropical storms and cyclones. This endangers large coastal megacities and also threatens small fisheries and local livelihoods. Climate change-driven land degradation speeds up the decline of vital coastal habitats such as corals, seagrasses, and mangroves, which support fisheries, aquaculture, tourism, and the marine food web in SIDS, mainly due to excessive sedimentation. Sea walls built to counter coastal erosion have often worsened coastal degradation by causing beach erosion, coastal squeeze, and loss of coastal biodiversity, affecting countries like Tuvalu, Kiribati, and the Bahamas (Martyr-Koller et al. 2021).

7.2.14 SDG 15. Life on Land

Although SDG 15 is considered as an "environmental" goal, its targets emphasize human needs, particularly 15.4, sustainable use of mountain ecosystems, and 15.6, access to genetic resources. The benefits of the environment for human well-being are reflected in ecosystem services, which include "provisioning services like food and water; regulating services such as flood and disease control; cultural benefits including spiritual, recreational, and cultural values; and supporting services like nutrient cycling that sustain life on Earth" (Millennium Assessment 2005). All these services rely on Earth's biodiversity (Millennium Assessment 2005; Diaz and Moore 2017).

The global environmental crises affect land and the communities reliant on land systems, including humans and all other living beings. These crises lead to a decline in biodiversity across genetic, species, and ecosystem levels (Sections 4.3.4, 4.3.5), which in turn degrades ecosystem services. The growing demand for these services accelerates these negative trends (Marques et al. 2019).

Mountain ecosystems (SDG 15.4) are key to terrestrial vertebrate diversity (Rahbek et al. 2019). Although they cover only 25 per cent of Earth's land (excluding Antarctica), they host 87 per cent of amphibian, bird, and mammal species (Rahbek et al. 2019).

Climate-linked shifts in temperature and precipitation (Habibullah et al. 2022) – intensified by economic development, habitat fragmentation, and intensive agriculture – lead to a decline in insect species' abundance and diversity in disturbed sites (Outhwaite et al. 2022), outbreaks of agricultural pests, such as locusts in Eastern Africa (Salih et al. 2020), forest pests (Jactel et al. 2019), and disruptions in pollination and seed dispersal (Teixido et al. 2022). These effects weaken the ability of land ecosystems to provide essential services to local communities (Mooney et al. 2009).

Pollution poses a significant global challenge to biodiversity, with approximately 10 million potentially contaminated sites identified worldwide. The full impact on biodiversity remains largely unknown (Chapter 4.3.1). Toxic chemicals accumulate in the environment and enter the food chain, exposing organisms to substances like heavy metals, pesticides, and radioactive elements (WHO 2022). In agriculture, pollutants decrease crop yields (Naidu et al. 2021) and cause "nutritional stress" due to excess chemicals (Zhu et al. 2020). Soil pollution is worsened by air pollution, further diminishing food production (Burney and Ramanathan 2014; Liu and Desai 2021).

Land degradation has already affected 25 per cent of the Earth's land, including 40 per cent of agricultural land (Pacheco 2018). Soil erosion decreased soil fertility, and habitat fragmentation result in biodiversity loss and the decline of ecosystem services such as food and water production, water purification, tourism, and spiritual benefits.

Biodiversity loss directly affects SDG 15.6, which focuses on sharing benefits derived from genetic resources. It also offers additional benefits for human well-being (Houlden et al. 2021). Floral biodiversity has been linked to better well-being and subjective health, such as reduced depression (Cox et al. 2017), lower blood pressure (Lindemann-Matthies and Matthies 2018), perceived restoration (Hoyle et al. 2019; Hussain et al. 2019), and overall well-being (Mavoa et al. 2019). These benefits tend to be more significant for disadvantaged socioeconomic groups and many Indigenous Peoples as well as local communities, whose health and well-being are deeply rooted in their relationship with land and nature (Rigolon et al. 2021). Furthermore, disparities exist in greenspace access among different social groups, influenced by socioeconomic status, race, ethnicity, or religion (et al.Sikorska et al. 2020; Laan and Piersma 2021; Liu et al. 2021; Sun et al. 2022).

The environmental crises interact and reinforce each other, creating a vicious cycle of degradation. For instance, climate change accelerates land degradation, while pollution contributes to biodiversity loss, both of which weaken the resilience of land systems. The decline in biodiversity and land health has significant economic and social impacts, particularly for Indigenous Peoples as well as local communities, who rely on land and its ecosystems for their well-being (Chapter 4.4).

7.2.15 SDG 16. Peace, Justice and Strong Institutions

The path to achieving SDG 16 on peace, justice, and strong institutions faces global challenges, including ongoing conflict, tension, sociopolitical uprisings, invasions, ethnic cleansing, injustice, riots, and violence within and between countries. These issues are undermining humanity's overall development and well-being (UNDP 2023; UN 2024). These conflicts and acts of violence have multiple causes. However, environmental crises often intensify the root causes of conflict and violence both domestically and internationally. Conflicts often emanate from competition over land and natural resources. Exploitation of natural resources has been associated with the origin of 40 per cent of intrastate conflicts since the mid-twentieth century (UNEP 2021b). Moreover, unsustainable and disproportionate consumption of natural resources results in pollution and environmental degradation, which ultimately hampers social cohesion and fosters injustice.

Environmental degradation resulting from unsustainable consumption and the failure to manage scarce resources fairly and effectively contributes to violence and injustice across national, regional, and international levels. Water resources often span borders, and in areas experiencing water stress, conflicts and violence are more likely to occur when governance and institutional capacity are weak (UNFCCC 2022). For example, in the Nile River basin, conflict has increased in recent years over shared water management to address water insecurity for food production, driven by rapid population growth and climate change (Fernández 2022).

Land degradation can threaten global peace and stability because it undermines food and water security. The gradual degradation of land can lead to the complete loss of people's food sources and livelihoods. This may increase forced migration within and between countries and increase risks to geopolitical stability and security (Gilbert 2017; Salehi et al. 2017).

Climate change indirectly worsens conflict, both within communities and across borders (UNFCCC 2022). The increase in climate-related cases at the United Nations and in arbitration tribunals underscores this trend, with the number of cases globally doubling from 2017 to 2022 (UNEP 2023). Additionally, the UNHCR reported that between 2008 and 2016, over 21.5 million people were displaced annually by sudden weather events – a majority of whom were Indigenous Peoples as well as local communities. The Institute for Economics and Peace forecasts that climate-induced disasters could displace up to 1.2 billion people by 2050 (Kumari et al. 2018; IEP 2020; Han et al. 2024). These displaced individuals often face exclusion, marginalization, inequality, and injustice in host communities. The proportion of refugees and asylum seekers from highly climate-vulnerable countries increased from 61 per cent in 2010 to 84 per cent in 2022, with only 1 per cent able to return home in 2020 due to worsening conditions and limited opportunities in their countries

of origin (UNHCR 2022). Moreover, it is estimated that 143 million people from the three primary climate hotspots – Sub-Saharan Africa, South Asia, and Latin America – may be internally displaced by 2050 (Kumari et al. 2018).

Biodiversity underpins the ecosystem services vital for all. Biodiversity loss and the decline of ecosystem functions can threaten livelihoods and destabilize the environment, potentially causing conflicts, violence, and maladaptive migration (Terton et al. 2022; Rist et al. 2023). Indigenous Peoples as well as local communities living close to nature are especially vulnerable to these risks. Moreover, the severe consequences of climate change, combined with the overexploitation of natural resources, threaten the equitable development of these marginalized groups (ICCA Consortium 2021; IPCC 2022; Reyes-García et al. 2024). The rapid extraction of resources often infringes on Indigenous Peoples' rights over their ancestral lands (Gilbert 2017).

Environmental crises can also destabilize governments by making it harder to meet basic human needs and undermining human well-being (UNDP 2024). A lack of support for inclusivity, equity, social cohesion, and accountability in governance can lead to economic instability, social unrest, geopolitical tensions, and growing scepticism (Lindvall 2021).

7.2.16 SDG 17. Partnerships For the Goals

The environmental crises undermine SDG 17 – the goal focused on the means of implementation – especially its targets on finance, technology, capacity-building, and trade.

A key obstacle to achieving the SDGs is insufficient financing, which reflects the lack of understanding among people and policymakers of the fundamental interdependence between humans and nature. The environmental crises exacerbate this problem by both increasing the overall cost of achieving the goals and reducing available funds to implement the goals because the resources are diverted to address the damages from the environmental crises.

Table 7.5 illustrates estimated SDG funding gaps of US$5 to 7 trillion annually, which is small compared to military spending, the costs of inaction, and the economic losses from climate change. This gap accounts for only about 5 per cent of the global annual value of biodiversity and ecosystems, estimated to be US$125 trillion (Costanza et al. 2014). Therefore, investing in SDGs can be viewed as a strategic approach to environmental protection, safeguarding ecosystem services, and promoting social well-being through a relatively modest investment relative to the value of biodiversity and ecosystems . The value of addressing crises becomes even more apparent when considering the monetary value of ecosystems: insufficient investment in SDGs and environmental sustainability is a poor business choice. Even without additional resources, how existing resources are allocated can greatly affect outcomes. The case for greater investment in the SDGs is even stronger when considering the consequences of inaction. Continued shortfalls in SDG funding will intensify the environmental crises and push systems past tipping points, making solutions more costly or impossible and potentially leading to widespread social disruption – the cost of which is beyond measure.

Table 7.5: SDG funding gap compared to global military spending, economic losses from the climate crisis, and benefits to the global economy from ecosystems

SDGs funding gap (2024 est.)	World total military spending (2023)	Cost of inaction/economic loss (climae change)	Value of biodiversity and ecosystems to the global economy
US$5-7 trillion per year of additional finance needed to achieve SDGs worldwide by 2030	**US$2.4 trillion** in 2023 (highest ever recorded)	**US$178 trillion** in net present value lost (2021-2070) or **US$2.5 trillion** lost per year	Total value of global ecosystem services in 2011 is **US$125 trillion** per year
		Global cost of climate change damage to be between **US$1.7 trillion** and **US$3.1 trillion** per year	

Sources: Costanza et al. (2014); Deloitte (2022); Newman (2023); UNGC (2023); World Economic Forum (2023); Tian et al. (2024)

The increasing costs of climate change and environmental degradation will hinder the implementation of other SDG 17 targets by redirecting resources away from capacity development and innovation (SDG 17.8; SDG 17.9).

Climate change and pollution also affect trade ((SDG 17.10 to SDG 17.12) (Chen et al. 2022). For example, drought is disrupting maritime transportation through key chokepoints, such as the Panama Canal (Gratton et al. 2022; Key et al. 2024), leading to global supply chain delays (SIPRI 2022). Europe's 2022 heatwave softened airport runways, disrupting flights (Burbidge 2018). Pollution can sometimes also disrupt travel (Xu et al. 2021). For example, thick smog caused severe delays and cancellations at New Delhi airport in January 2024 (Saxena 2024). Increasingly, extreme weather events disrupt land connectivity, cutting off access roads for medical facilities and food supplies to Indigenous and rural communities (Sangha et al. 2021; Arslanalp et al. 2023).

Natural disasters adversely affect foreign direct investment, as was illustrated by Anuchitworawong and Thampanishvong (2015) on the example of Thailand. Environmental crises elevate investment risks in developing countries (Chen et al. 2022), which are more susceptible to disasters (Batten et al. 2016). Such outcomes harm the social and economic dimensions of SDGs and threaten progress in technology transfer and innovation that comes with foreign direct investments (SDG 17.6 to SDG 17.8).

Globally, environmental crises are worsening conflicts and resource shortages, shifting attention and funding away from SDG implementation (also SDG 16) (UNSC 2018; World Bank 2022). Climate change and environmental degradation are seen as threat multipliers. Military and security spending have reached record highs of US$ 2.4 trillion in 2023 (SPIRI 2024), along with other expenditures on disaster response and environment-related crises, diverting funds that could otherwise support SDGs. These trends also weaken macroeconomic stability, policy coherence, and multilateral cooperation (SDG 17.13).

7.3 Common Themes

In assessing the effects of environmental crises on the socioeconomic aspects of the SDGs, several common themes emerged regarding the risks and consequences for people, vital infrastructure, the economy, and future development.

1. Consequences for people and their access to basic needs. Environmental crises disrupt access to, availability of, utilization of, and stability and security of resources. Access to food, water, energy, housing, education, land, and even clean air is hindered. These issues contribute to rising poverty and declining human health. They also impact most of the SDGs' socioeconomic targets, especially SDGs 1-7 and 11.

Environmental crises heighten the risk of both gradual and sudden development challenges, such as poverty traps and food insecurity. Climate change, extreme weather events, pollution, biodiversity loss, and land degradation disrupt food production, leading to decreased agricultural yields and increased hunger. Climate change undermines global efforts to address hunger, poverty, ill-health, and improve access to clean water and energy, affecting many aspects of sustainable development (WMO et al. 2020). Nearly 670 million people could face hunger by 2030. (SDGs 2, 3, 6, 7, 11)

Access to clean air is obstructed by air pollution. Air pollution is a significant health threat, particularly in urban areas, and is linked to nearly seven million premature deaths annually. (SDGs 3, 11)

Access to clean water is disrupted by various forms of pollution that make water unsafe. The water supply is also limited by climate impacts such as droughts, infrastructure damage, and land degradation. Managing water resources is difficult due to climate-related issues like floods, droughts, and changing precipitation patterns, as well as pollution and land degradation. (SDG 6)

Access to energy faces challenges from extreme weather events and climate change. These increase energy demand while disrupting supply. This also makes the clean energy transition more difficult and costly. (SDG 7)

Cities, which host over half of the world's population, are vulnerable to rising sea levels, storm surges, heat waves, heavy rainfall, flooding, drought, water shortages, air pollution, and land degradation. (SDG 11)

Climate change and pollution pose threats to oceans, marine ecosystems, and communities depending on them for food and livelihoods. (SDG 14)

2. Differentiated burdens on the most vulnerable. The most vulnerable and the world's poorest people, especially women and Indigenous Peoples as well as local communities, are often hardest hit by environmental crises, trapping them in poverty, increasing inequalities, and hindering progress across several SDGs, particularly SDGs 1 to 6, 8, and 10. These impacts disproportionately affect marginalized groups, intensifying inequalities and undermining sustainable development across all regions (IPCC 2023). Importantly, these effects are profound, long-lasting, and multifaceted, threatening people's physical environment, cultural and social systems, local governance, and livelihoods.

In more vulnerable regions like LDCs and SIDS, extreme weather and climate events have an increasing negative effect on GDP due to their rising frequency, impeding overall development. The societal effects of environmental crises – such as deaths from air pollution and climate-related floods and storms – are significantly more severe in areas with larger populations in vulnerable conditions.

3. Impacts on vital infrastructure assets, access and services. Environmental crises, such as extreme weather and climate events, cause immediate physical damage and disrupt infrastructure across sectors. This damage particularly affects essential services and economic activities such as health systems' hospitals (SDG 3), education's schools (SDG 4), energy installations (SDG 7), water and sanitation (SDG 6), industry (SDG 9), transportation, and housing (SDG 11). The damage also disrupts trade (SDG 17). Infrastructure is critically important because it influences the achievement of all SDGs – over 90 per cent of targets, including water (SDG 6), energy (SDG 7), industry and innovation (SDG 9), and educational facilities (SDG 4). Addressing gender considerations (SDG 5) in infrastructure, such as ensuring accessible transportation and sanitation that promotes menstrual hygiene, is essential to enable equitable access to services like education for all. Overall, damage to infrastructure from environmental crises obstructs progress towards many SDG targets.

4. Economic losses from environmental crises are extensive and growing. According to a 2023 WMO report, between 1970 to 2021, nearly 12,000 weather, climate, and water-related disasters were recorded, resulting in over 2 million deaths and US$4.3 trillion in damages. More than 90 per cent of these deaths and 60 per cent of economic losses occurred in developing countries, undermining sustainable development (WMO et al. 2023). Between 2021 and 2070, climate-related damages are projected to rise to about US$ 2.5 trillion annually, totalling US$178 trillion in net present value (Deloitte 2022). Heat

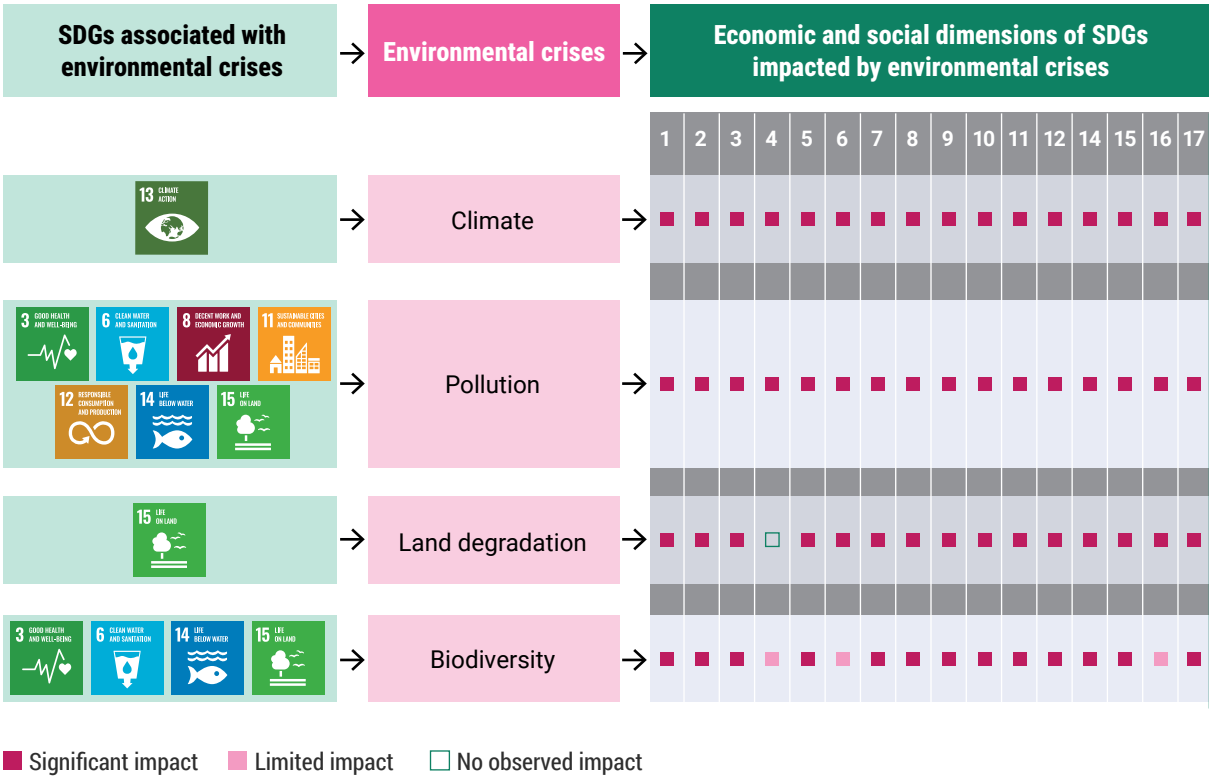
stress is expected to cut global working hours by 2.2 per cent and reduce global GDP by US$2.4 trillion in 2030 (ILO 2019). Air pollution-related health damages amounted to approximately US$8.1 trillion in 2019, or about 6.1 per cent of global GDP (PPP adjusted) (World Bank Group 2022).

The economic value of ecosystems and biodiversity was estimated at US$125 to 145 trillion per year in 2011, with an annual loss of US$4.2 to 20.2 trillion (Costanza et al. 2014), representing 5.7-27.3 per cent of that year's US$74 trillion global GDP. Extrapolated to 2022, the estimated economic value of ecosystems and biodiversity would have ranged from US$172 to 198 trillion, while annual losses would have ranged from US$ 5.7-27.3 trillion (Elder 2024). Approximately 1.2 billion jobs depend directly on ecosystem services, accounting for about 40 per cent of global employment (ILO 2018b). These jobs, along with indirectly related jobs, are at risk from ecosystem degradation.

Many industries experience economic damage from environmental crises, affecting sectors like agriculture, fishing, energy, manufacturing, transport, and buildings. These damages include infrastructure destruction from climate disasters and loss or deterioration of raw materials and inputs due to pollution and ecosystem degradation. They also include decreased worker availability and productivity caused by heat stress, health issues, and degraded educational outcomes, in addition to those resulting from disruptions in supply chains.

Environmental crises cause disproportionately high economic damage to developing nations, especially LDCs and SIDS. The 2022 Vulnerable Twenty Group Report highlights that the 55 most vulnerable countries lost US$525 billion from climate disasters between 2000 and 2019. Additionally, climate change reduced their annual GDP per capita growth by 25 per cent (Baarsch et al. 2022).

The UNEP adaptation gap report estimated that the average annual adaptation finance costs for LDCs and SIDS are around US$41 billion, ranging from US$16 to 83 billion, which is roughly 2 per cent of their GDP, with a range of 0.80 to 4 per cent (UNEP 2023).



5. Cascading and compounding adverse effects of environmental crises on the interconnected socioeconomic aspects of the SDGs reinforce and worsen each other. This is sometimes called a poly crisis (Lawrence et al. 2024). There are extensive interlinkages among SDGs which can magnify these adverse effects as well as potential synergies (Pradhan et al. 2017; Kroll et al. 2019; Independent Group of Scientists 2023). The food-energy-water nexus illustrates these connections among socioeconomic SDGs (FAO 2014; D'Odorico et al. 2018; Di Martino et al. 2023). For instance, disruptions in water production due to environmental crises have a compounding effect, negatively affecting food and energy production. Economic impacts also cascade – damage to infrastructure in one industry can disrupt supply chains across others, reducing economic growth and employment. These cascading effects increase vulnerabilities among Indigenous Peoples as well as local communities, severely affecting their ability to sustain their ways of life. Wars, conflicts, natural disasters, economic shocks, and pandemics further intensify the crises.

6. Overview of the impacts of environmental crises. This chapter concludes that the economic and social aspects of all SDGs were adversely affected by the environmental crises. The main findings are summarized in **Figure 7.6**. The climate and pollution crises impacted the socioeconomic aspects of every SDG, whereas land degradation primarily affected all but one (SDG 4). The biodiversity crisis had an adverse effect on all SDGs, although its impact on three specific SDGs (4, 6, 16) was limited. **Figure 7.6** also illustrates that many SDGs include targets reflecting environmental conditions and trends, many of which are in crisis, along with socioeconomic targets that suffer adverse effects from these environmental crises.

7.4 Conclusion

The environmental crises are undermining progress towards the economic and social dimensions of the SDGs, harming human well-being. These crises are imposing significant economic and social costs. They threaten energy, food, safe water, and housing. They damage human health and increase inequality and inequity. Environmental crises also exacerbate gender inequality and disproportionately affect women, girls, children in rural areas of developing countries,

Figure 7.6: SDGs Associated with Environmental Crises

Indigenous Peoples as well as local communities, and other people in vulnerable situations. As environmental crises worsen, their costs, damages, and inequities will continue to rise.

The socioeconomic effects of environmental crises will affect everyone, including the middle class, working people, and those in developed countries. While impacts will vary regionally and nationally, no group or area will be immune to the socioeconomic consequences of the environmental crises.

The implication is that significant effort is required to address the environmental crises, not only to accelerate progress in achieving SDGs by 2030 but also to prevent jeopardizing current levels of development. Therefore, the environment-related goals and targets of the SDGs need much higher prioritization to put the social and economic-related goals and targets on track. The scale and costs of damage from the environmental crises should be substantially reduced to minimize the resulting economic and social harm that undermines human well-being. A healthy environment forms the foundation for the economic and social aspects of the SDGs (UNEP 2019), so alleviating the environmental crises is essential for achieving the SDGs' economic and social objectives.

At the same time, environmental solutions should be designed and managed to directly support economic and social goals and targets, especially jobs, decent work, and poverty eradication (Matsushita et al. 2023; Elder 2024). As unsustainable industries are phased out, a clear pathway for displaced workers to find decent employment in sustainable industries is essential. Environmental solutions should support social and economic goals, such as poverty eradication, food security, and gender equality, while also providing decent work opportunities.

Crises such as wars and pandemics exacerbate the social and economic damage caused by environmental crises, making environmentally sustainable solutions even more urgent. Wars and pandemics are not reasons to delay action (Mori et al. 2021; Elder et al. 2022).

The primary implication for the post-2030 sustainable development agenda is that greater efforts are required to ensure environmental

Credit: Gorlovkv/Envato

sustainability – the foundation of economic prosperity and human well-being – and to tackle the root causes of environmental crises. It is widely recognized that traditional resource-intensive economic growth is a key driver of these crises (2.2.2, 2.2.5), and SDG 8.1, on economic growth, is considered one of the most significant trade-offs among the SDGs (Spaiser et al. 2017; Pradhan 2017; Kroll et al. 2019), as it conflicts with achieving other goals, particularly those related to the environment. Additionally, this chapter's discussion of SDGs 7, 8, 9, and 11 shows that the economic consequences of the environmental crises have become so severe that they are now hindering economic growth itself, through damage to infrastructure and economic assets and through reduced worker productivity and capacity to work. Governments committed to decouple economic growth from environmental harm in target 8.4, although it may not be fully achievable. To date, efforts to decouple have not significantly reduced the adverse impacts of traditional economic growth. This suggests that future discussions should focus on ways to directly meet socioeconomic needs – such as decent work, food security, housing, and transportation – rather than indirectly relying solely on economic growth, which has often left many behind.

Chapter summary

Credit: ImageSourceCur/Envato

Overall, the state of the environment in each of the five United Nations (UN) Regions is deteriorating (*well established*). Except for a few success stories, deteriorating environmental trends at the regional and subregional levels have persisted or intensified. The worsening trends are driven by the global environmental crises – climate change, biodiversity loss and land degradation, and pollution and waste – which often work in combination and have differentiated causes and effects, depending on scale and location {8.1}.

All global environmental crises are significant, but their impacts differ across the UN regions. As such, regional and subregional analysis is required to identify how to combat issues effectively (*well established*). This chapter has adopted a priority-based assessment where three of the most pressing environmental issues within each of the five UN regions were assessed, as selected by expert opinion and literature review. This approach is designed to streamline and strengthen environmental science-policy support at the subglobal levels and is expanded upon in Chapter 20 {8.1; Table 8.1}.

Although the specific issues faced by the UN regions are diverse, climate change is a common and compounding challenge across all regions, exacerbating local-level impacts of the environmental crises (*well established)*. These impacts are most pronounced in sensitive biomes and those that have been significantly degraded by human activities. For example, coral reefs in most regions are vulnerable to ocean acidification and bleaching, which affects economies, livelihoods and well-being. Warmer temperatures are driving the expansion of boreal forests and subarctic shrubs northward by up to 100 metres per year. Climate adaptation plays a key role in providing urgent, region-specific and multi-crisis solutions {8.2.3; 8.3.3; 8.5.2; 8.6.3}.

Socioeconomic impacts due to the global environmental crises are present across all UN regions (*well established*). The global environmental crises interact with each other and with regional environmental priority issues, resulting in socioeconomic issues such as climate-induced migration, poor health – for example, due to air pollution, food and water security, and increased inequalities. All communities are impacted, but vulnerable communities are disproportionately impacted {8.2; 8.3; 8.4; 8.5; 8.6; 8.7}.

Lands and territories managed by Indigenous Peoples are among the most bioculturally diverse due to their lengthy stewardship, but they are under increasing threat from the global environmental crises (*well established*). Climate change induces environmental and seasonal unpredictability, threatening human health, livelihoods and land-based spiritual relationships critical for ecosystem health. Land degradation, biodiversity loss and pollution also increase the vulnerability of Indigenous populations in all regions. Indigenous Knowledge systems are an important dimension in local adaptation strategies {8.2; 8.3; 8.4; 8.5; 8.6; IK & LK Chapeau Part B}.

Africa

Across Africa, resource exploitation – including the exploitation of land, forests and fisheries – is unsustainable (*established but incomplete*). This is impacting ecosystems and leading to food and water security. For example, countries such as Chad, Liberia and Sudan are water insecure, while South Africa is affected by high levels of freshwater pollution {8.2.3}.

Africa's terrestrial, marine and freshwater ecosystems are threatened by environmental degradation from the impacts of deforestation, soil erosion, and salinization of rivers (*established but incomplete*). Approximately 14 million km² of Africa's land is degraded, affecting people and costing US$9.3 billion annually. Africa loses 39,000 km² of forests per year. In 2018, East and West Africa were responsible for 13.9 per cent of global disaster-related displacements {8.2.1; 8.2.2; 8.2.4; 8.2.5}.

Climate change impacts Africa's subregions differently but significantly (*well established*), and it has undermined the region's ability to fulfil commitments under the African Union's Agenda 2063 and the SDGs. Floods are becoming more frequent in some parts of Africa. As many as 27.4 million people in East Africa were affected in 2022, while a further 4.5 million were affected in West Africa. Temperatures across the continent are rising faster than the global average, causing droughts in the Sahel, North Africa and Southern Africa. Hydropower generation is significantly reduced in Southern Africa, directly affecting Zambia, where 80 per cent of the electricity capacity is generated from hydropower {8.2.4; 8.2.5}.

Asia and the Pacific (AP)

Over 220 million people in the AP region were displaced between 2010 and 2021 due to climate-related events (*well established*). About 43 per cent of AP countries are among the most vulnerable to climate-related disasters globally. Climate change is threatening the Indigenous cultural heritage and land-use changes of AP countries faster than the global average {8.3.2}.

One-sixth of the AP's forested area was converted to agriculture and pastureland between 1990 and 2020 (*well established*). This land transformation has had a significant effect on ecosystems and biodiversity. Forty-five per cent of the region's vertebrate populations have been lost in the last 45 years. Between 1700 and 2020, over 40 per cent of global inland wetlands in China, India and Indonesia were lost. Conversely, recent land and species restoration projects in AP, such as the SAFE project in Bhutan, Cambodia, Lao People's Democratic Republic and Viet Nam, demonstrate the progress of the AP's ecosystem and biodiversity recovery {8.3.2; 8.3.4}.

Globally, six out of the top ten countries with the worst air pollution levels are from AP, leading to respiratory diseases, poor health and lower agricultural productivity (*well established*). Although PM_{10} particulate matter concentrations have decreased in several Northeast Asian countries over the past few decades, including China, Japan and the Republic of Korea, air pollution remains significant {8.3.4; 8.3.5}.

The average pollution-induced productivity loss is eight times higher in the region's developing countries than in its developed counterparts *(established but incomplete)*. Impacts are most pronounced in low-income and marginalized communities, including Indigenous Peoples and local communities {8.3.4; 8.3.5}.

Eastern Europe (EE)

Ecosystem services, especially on agricultural lands, are being degraded across the EE region *(well established)*. This is driven by two polarizing trends: intensive farming, leading to soil degradation, and abandonment of extensive farmland, through rural depopulation and biodiversity loss. Climate change is exacerbating these losses with EE now considered a global hotspot for increasing soil drought {8.4.3}.

EE relies heavily on fossil fuels and energy-inefficient technologies *(well established)*. Fossil fuels account for over 50 per cent of the total energy supply and consumption. Many EE countries are consequently facing significant challenges with air quality in cities and industrial regions. As many as 19 per cent of deaths in the Western Balkans are attributed to air pollution. The energy transition across EE remains slow, resulting in long-lasting environmental and socioeconomic impacts {8.4.4}.

EE has rich biodiversity and a strong network of protected areas, but climate change, land degradation and pollution remain a threat *(well established)*. Return or stabilization of some rare species indicates local successes of conservation. However, land-use change is driving biodiversity loss outside of protected areas. The planned construction of 3,000 small-scale hydroelectric dams in the Balkans to support the energy transition will significantly affect biodiverse riverine ecosystems. In the Arctic, climate change is leading to the thawing of permafrost, which in turn increases methane emissions {8.4.5}.

Armed conflicts are a crucial environmental threat in the EE region, often compounding other negative trends *(established but incomplete)*. Conflicts result in the depopulation of vast areas and the destruction of agricultural lands, hydropower dams, and irrigation systems. They also lead to landmine fields and military equipment debris in war zones and beyond {8.4.1; 8.4.5; Box 8.4}.

Latin America and the Caribbean (LAC)

Land degradation in LAC has both regional and global implications *(established but incomplete)*. An area roughly the size of Central America was deforested in LAC between 1992 and 2022, while between 2000 and 2019, agricultural land expanded by 49 per cent in South America, affecting forests and other tropical ecosystems. Deforestation has significantly impeded biodiversity, leading to a 95 per cent decline in the World Wildlife Fund's Living Planet Index – the worst regional score from 1970 to 2020. Economies, livelihoods and the health of populations, including those of Indigenous Peoples, have been affected. Continued loss of the Amazon forest could undermine global climate goals {8.5.3; 8.5.4}.

The region of LAC holds 30 per cent of global water resources, while 75 per cent of the region's population lacks safe access to water *(well established)*. Agriculture accounts for the largest demand for fresh water at 70 per cent. Pollution, ecosystem degradation and climate change are driving deteriorating conditions, with less than half the region's waterbodies considered to be of good quality. Increased flooding frequency and more intense droughts further threaten the region's water security. An 83 per cent retreat in the Andean glaciers contributes to the release of pollutants, global sea level rise, and impacts economic activities such as hydroelectric power generation, food production – that is, irrigation and transportation – notably through the Panama Canal {8.5.4; 8.5.5}.

Coastal and marine ecosystems are degrading in LAC, affecting the well-being of at least 27 per cent of its inhabitants *(well established)*. Widespread coral degradation occurs in Central America and northern South America. Ocean acidification contributed to a 37 per cent net erosion of the Mesoamerican Barrier Reef System. However, mangroves increased in extent by 12.9 per cent in the Caribbean and by 3.6 per cent in South America between 2010 and 2020. The region has experienced a rise in the frequency and intensity of extreme events that increase coastal degradation, erosion, flooding and disease. The sustainability of wild caught fisheries is low in the region, although some exclusive economic zones show an improving trend from 2012 to 2023 {8.5.5}.

Western Europe and Others Group (WEOG)

Ecological transformations – driven by alien organisms, habitat loss and land degradation – disrupt ecological processes, spread disease, and harm livelihoods and cultural heritage *(well established)*. Invasive species impose economic and ecological damage.

Protected areas are insufficient to prevent habitat loss. Species loss is especially acute in Australia and New Zealand. Arctic ecosystems are under stress from permafrost melting, threatening livelihoods and culturally significant species. Diseases spread by invertebrate vectors are expanding, exacerbated by existing health inequities {Figure 8.32; 8.6.2; 8.6.3}.

Extreme heatwaves, wildfires and storms are increasing in frequency, severity and impact *(well established)*. Heatwaves are extremely deadly, especially for vulnerable groups such as outdoor workers. Marine heatwaves damage coral reefs and promote toxic algal blooms. Expanding fire weather is driving forest and urban wildfires, destroying cultural resources and degrading air quality far from their source. Extreme storms cause coastal and river flooding, with loss of life, damage to infrastructure and cultural heritage, and long-lasting excess mortality. Europe suffered catastrophic flooding in 2021, 2023 and 2024. Climate adaptation and emission mitigation can alleviate the damages from extreme events {8.6.4}.

The WEOG region actively addresses waste and pollution issues, yet current lifestyles continue to produce excessive waste *(well established)*. The region continues to suffer from a long legacy of fossil fuel extraction and use. Material footprints are 1.5 to 3 times the global average, generating excessive waste. Inefficient nitrogen use in agriculture degrades aquatic systems and groundwater. Air pollution from fossil fuel combustion is decreasing. While $PM_{2.5}$ has fallen by 34 per cent since 2000 across WEOG, over 50 per cent of Europeans are still exposed to levels above 10 µg/m^3. Emerging contaminants, such as per- and polyfluoroalkyl substances, are ubiquitous {8.6.2; 8.6.5}.

Telecoupling

Telecoupling, that is, socioeconomic-environmental interactions over distances that are prompted by processes such as trade, investment, tourism, migration, species invasion, flows of ecosystem services, and armed conflict, can drive environmental deterioration *(established but incomplete)*. The environmental effects of telecoupling are varied but are often associated with greenhouse gas emissions and land use {8.7}.

Telecoupling adds a further layer of complexity as the authority to make decisions often lies outside the geographical areas with environmental impacts *(established but incomplete)*. Regions in the Global South are often harmed more than those in the Global North, though this is not always the case – as seen with the impact of wildfires {8.6; 8.7}.

8.1 Introduction

The global environmental crises – the crisis of climate change, the crisis of biodiversity loss, land degradation and desertification, and the crisis of pollution and waste – although established as common challenges at the international level, have different root causes and consequences depending on scale and location (Chapter 2; Global Environmental Crises Chapeau). For example, statistics on land degradation (**Figure 8.1**) illustrate the significant variation in regional and subregional trends, as well as their differences when compared to a global average. The 2024 Living Planet Index also emphasizes regional variations in biodiversity loss (World Wide Fund for Nature [WWF] 2024). This variability underscores the need for special attention to be paid to regional and subregional specificities in environmental decision-making, recognizing that one-size-fits-all policies and actions will not be effective in enabling the type of transformative change required to address the global environmental crises (Bennett, Peterson and Gordon 2021).

Since the publication of the sixth Global Environment Outlook (GEO-6) Regional Assessments in 2016, there has been a persistence, in many cases an acceleration, and proliferation of negative environmental trends in every region of the world associated with the global environmental crises, save a few pockets of noteworthy improvement (Food and Agriculture Organization 2020; United Nations Convention to Combat Desertification 2020; European Commission 2023; United Nations Economic and Social Commission for Asia and the Pacific et al. 2023; Fassinou et al. 2024; FiBL 2024; Vicente-Serrano et al. 2024). These deteriorating trends are clear signs that policy and action to address these challenges have been inadequate. As such, in positioning the GEO-7 report to respond to the increasing urgency associated with the mounting, complex and differentiated environmental challenges faced by regions and their subregions, this chapter has pivoted away from a traditional analysis of states and trends.

To more effectively inform solution pathways and policy options, as elaborated in Chapter 20, this

Figure 8.1: Proportion of degraded land in 2015 and 2019

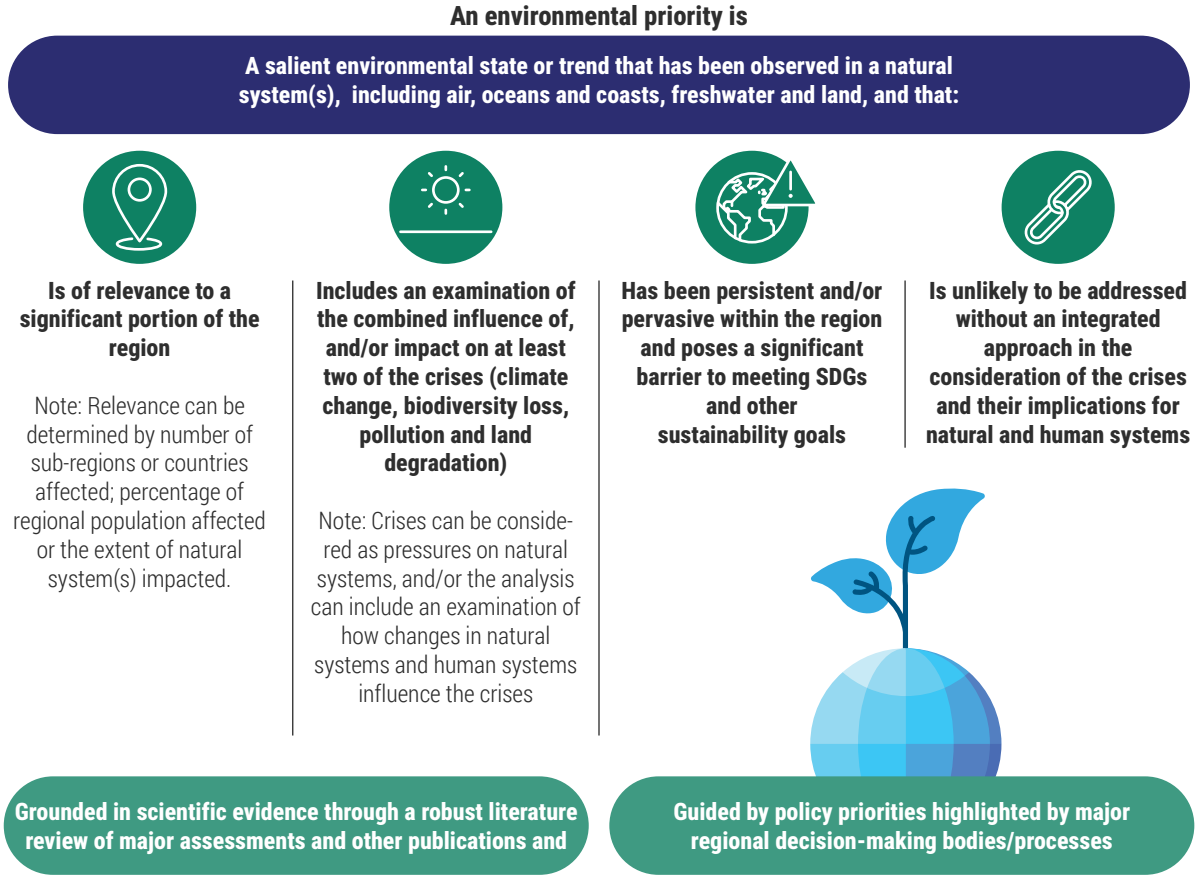
Note: The risk score is calculated as combined ratios of predicted environmental concentration and ecotoxicity of the 92 most used active ingredients in soil, surface water, groundwater and atmosphere.

Source: UNDESA (2023)

chapter highlights three environmental issues in each of the five United Nations regions, as grouped by the United Nations Department for General Assembly and Conference Management, that have been identified as high priorities in the context of the global environmental crises. These priorities (**Table 8.1**) were selected based on the criteria outlined in **Figure 8.2**. The regional experts involved in GEO-7 conducted both an in-depth analysis of the scientific literature and an examination of regional environmental issues highlighted or prioritized in the most recent policy documentation. As in other major global assessments, refinement of these issues occurred during the GEO-7 process through feedback from advisory bodies and stakeholders during formal reviews.

Within the context of each priority issue, the regional assessments examine trends in the environmental crises at the regional and subregional levels. They further analyse the implications of these trends for natural and human systems, noting in certain cases where there are adverse effects on populations, especially vulnerable populations, within the regions.

Where data is available, the relationships between and the combined effects of the global environmental crises are also analysed, for instance, where biodiversity loss exacerbates climate change and vice versa (Global Environmental Crises Chapeau). Through this lens, there is an opportunity to provide regional decision makers with a more focused analysis of areas for strategic environmental intervention that can potentially reduce the growing financial burden associated with global environmental crises at subglobal scales.



As part of this regional chapter, the implications of telecoupling arrangements are also considered. Telecoupling refers to socioeconomic and environmental interlinkages that span distances, driven largely by trade, tourism, migration, and investments (Liu 2020). These interconnections have environmental implications for all regions, but in differentiated ways. Additionally, the power to make decisions related to telecoupling arrangements often lies outside or goes beyond the country, subregion or region where environmental impacts are most felt. As such, it is important to understand the flows involved in telecoupling so that they can be effectively incorporated into policies and decisions at various scales (Chapter 20).

Finally, although the specific issues faced by the regions are diverse, climate change is a common and compounding challenge across all regions, exacerbating local-level impacts of the environmental crises. As such, there is a growing need to identify appropriate opportunities for adaptation (Chapter 20).

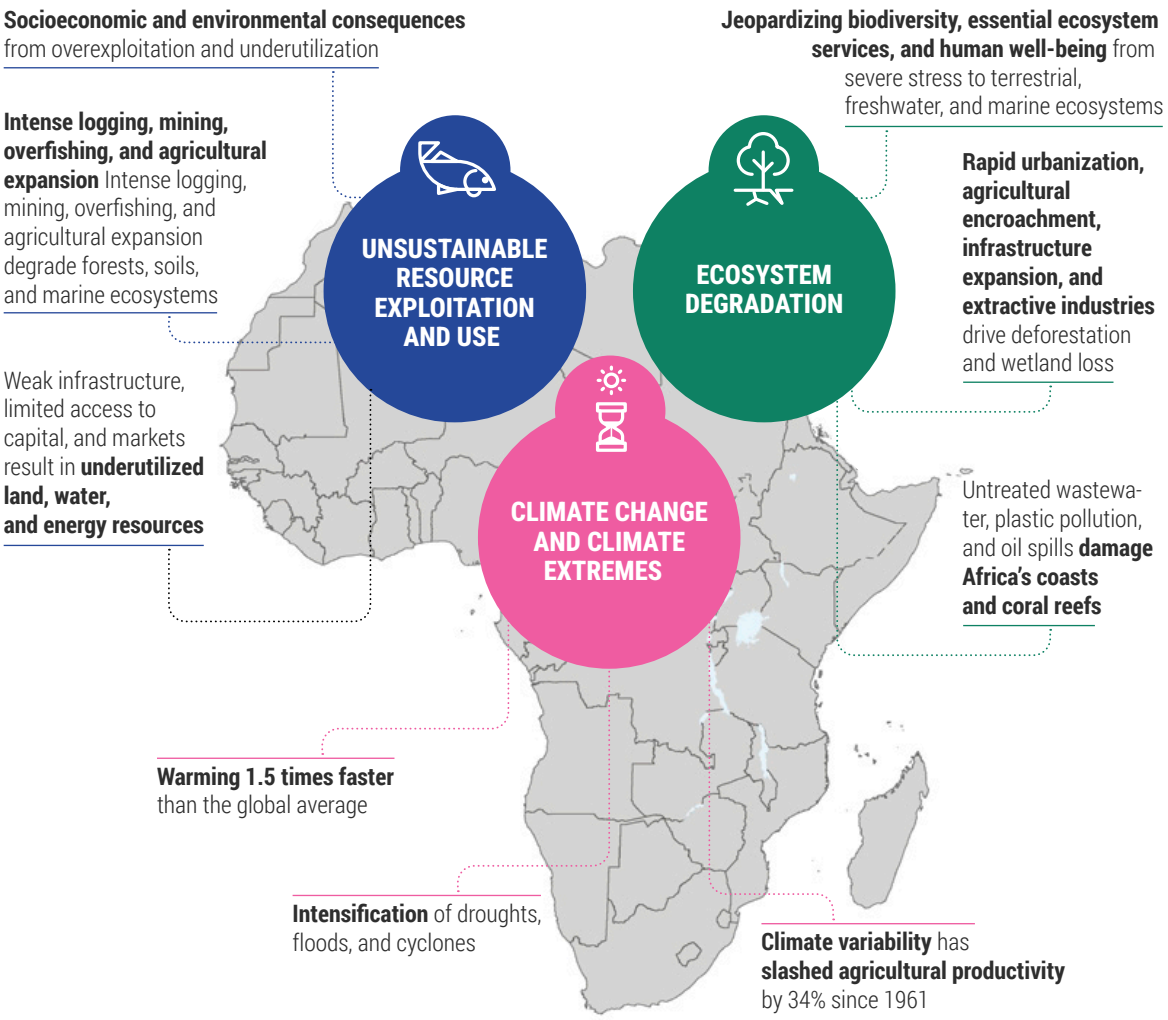
Table 8.1: The three environmental priorities identified for each region in GEO-7

Region	Priorities
Africa	Unsustainable resource exploitation and use Ecosystem degradation Climate change and climate extremes
Asia and the Pacific (AP)	Climate change impacts on development and cultural heritage Land-use change impacts on ecosystems Pollution and waste impacts on ecosystems and human health
Eastern Europe (EE)	Loss of ecosystem services due to unsustainable agriculture Unsustainable energy system effects on climate and health Biodiversity loss due to weak management frameworks
Latin America and Caribbean (LAC)	Changes in land-cover dynamics Changes in freshwater quality and availability Degradation of coastal and marine resources
Western Europe and Others Group (WEOG)	Biodiversity loss and ecosystem change Climate extreme events Pollution and waste

Figure 8.2: Criteria for selecting regional environmental priorities

8.2 Africa and subregions

8.2.1 Introduction



With a population of 1.5 billion (United Nations Department of Economic and Social Affairs [UNDESA] 2024) and a landmass of 30,143 million km^2 (United Nations Environment Programme [UNEP] 2016), Africa is a diverse region that includes deserts, rainforests and savannahs. The 54 countries on the African continent include 16 landlocked ones (United Nations Conference on Trade and Development [UNCTAD] 2023), which are divided into five subregions as shown in. As a sign of the extent to which Africa values its environment, the Great Green Wall initiative is on target to restore 1 million km^2 of land and to sequester 300 million tons of carbon by 2030, having already restored 200 thousand km^2 as of 2020 (United Nations Convention to Combat Desertification [UNCCD] 2020; Fassinou et al. 2024).

Despite these efforts, Africa has been deeply affected by the global environmental crises: the crisis of climate change, the crisis of biodiversity loss, land degradation and desertification, and the crisis of pollution and waste (**Figure 8.3**). The crises reinforce each other and interact with regional environmental priorities, resulting in environmental and socioeconomic impacts. In Africa and its subregions, climate change is a main driver of the impacts of the crises (Intergovernmental Panel on Climate Change [IPCC] 2019; Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services [IPBES] 2019; Nguyen et al. 2023).

As well as being adversely affected by the crises, Africa plays an increasing role in their exacerbation. For example, although Africa has relatively low emissions when compared with other regions, Africa's total CO_2 emissions more than doubled between 1990 and 2018, with an increase of 34 per cent from 1990–1999 and 2000–2009, and a further 31 per cent from 2010–2018 (Mostefaoui et al. 2024). This rise is compounded by an increasing carbon intensity of production, particularly as the region's top 20 emitters shift towards more carbon-intensive industrial systems (de Melo and Solleder 2023).

Climate change has reduced Africa's ability to achieve targets under the Sustainable Development Goals

Figure 8.3: The interplay of the global environmental crises and regional priority issues: effects on Africa's resource use, ecosystem degradation and climate extremes

Source: Africa Center for Strategic Studies [ACfSS] (2016); WMO (2023)

(SDGs) and the African Union's Agenda 2063, within the context of displaced people and worsening food insecurity. In Africa, more people are at risk of malaria due to warming temperatures (de Coning and Krampe 2020). Between 2019 and 2022, there were substantial increases in estimated case numbers in Nigeria with 5.3 million, Ethiopia with 2.4 million, Madagascar with 1.5 million, Uganda with 1.3 million, the United Republic of Tanzania with 1.3 million, Mali with 1.1 million and Mozambique with 1 million (World Health Organization [WHO] 2023a). Additionally, interacting with factors such as water scarcity and water pollution, climate change is exacerbating problems with the region's water availability, threatening food production and hydropower generation (Obahoundje and Diedhiou 2022). This has socioeconomic implications.

Africa's livelihood support systems – including food, energy and finance, already inadequate and stretched – are further compromised by the global environmental crises. The region, which is not on track to meet the food security and nutrition targets under SDGs 2 and 3, had 281.6 million undernourished people in 2020 (Food and Agriculture Organization of the United Nations [FAO], United Nations Economic Commission for Africa [ECA] and African Union Commission [AUC] 2021). With an electricity access rate of 49.2 per cent in sub-Saharan Africa in 2021, Africa's electricity deficit is the largest in the world (International Energy Agency [IEA] 2022).

The cost of borrowing from international markets is higher in Africa compared to other regions due to perceived high risk. In 2021, 40 per cent of African

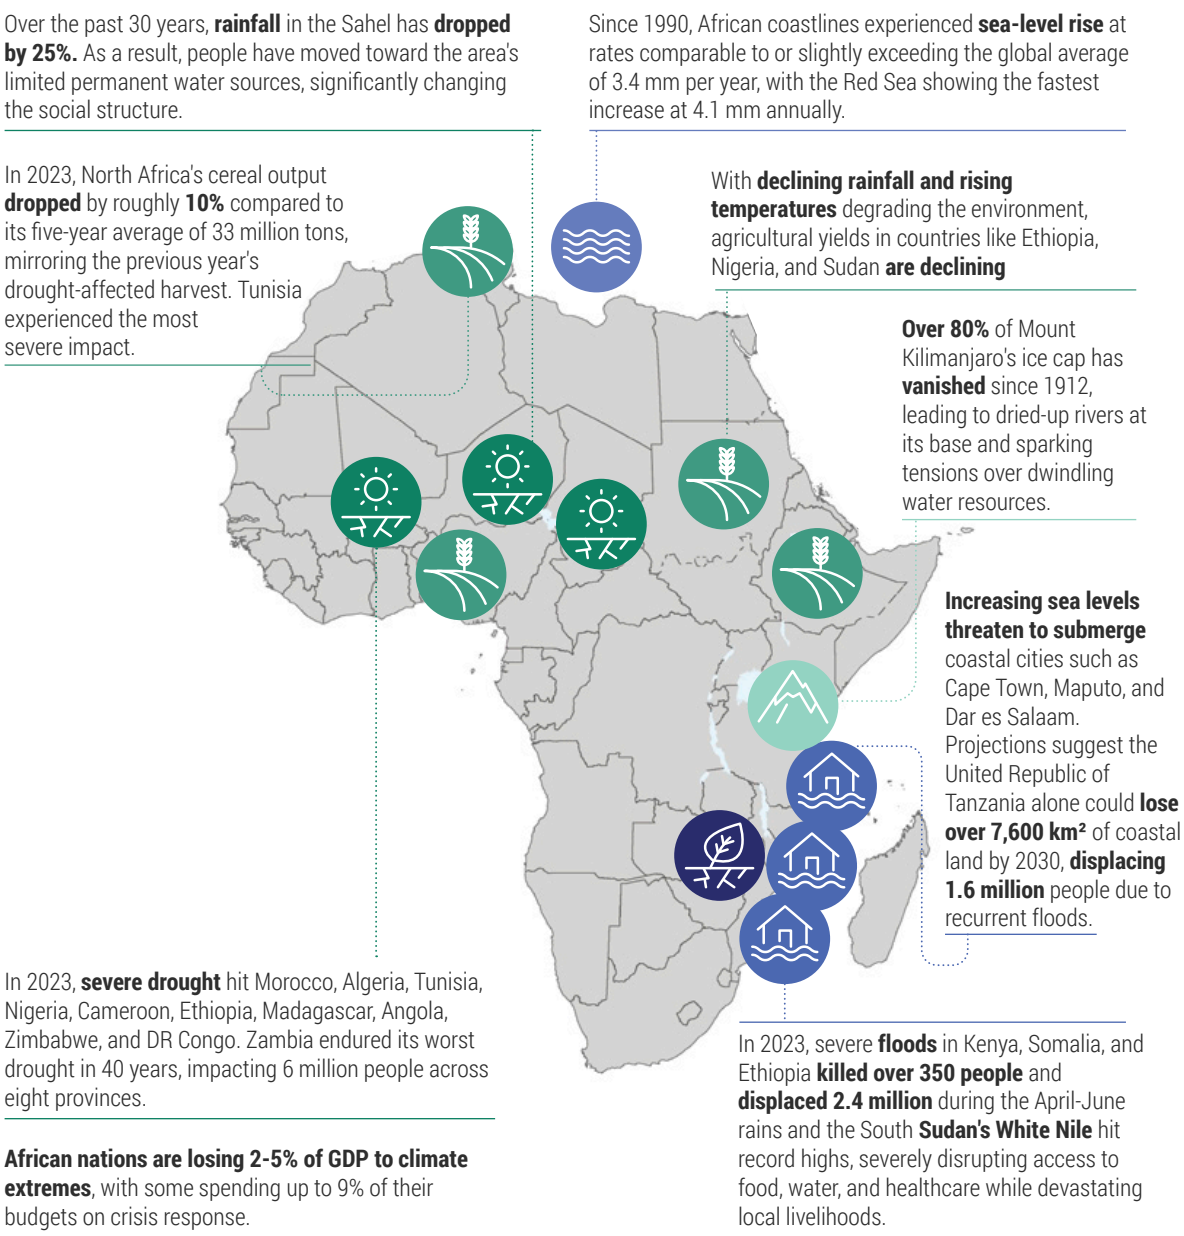
bonds yielded 8 per cent compared to around 1 per cent in advanced loans for developed economies (Gbohoui, Ouedraogo and Some 2023). As such, investments in infrastructure, including those for clean water supply and sanitation services, are lagging and resulting in the resurgence of diseases such as typhoid and cholera. Between 1 January 2022 and 16 July 2023, fourteen African countries reported 213,443 cholera cases resulting in 3,951 deaths (WHO Africa 2023b).

Building on the preceding chapters on states and trends of the physical environment, this chapter explores, in an integrated assessment approach, key issues affecting Africa and the extent to which these issues are affected by the global environmental crises (**Figure 8.3**). The assessment further explores the influence of the key issues on human issues, including energy, food, waste, health and economics. Through literature review and expert opinion (Section 8.1), the following issues emerged as priorities for Africa:

- unsustainable resource exploitation and use;
- ecosystem degradation; and
- climate change and climate extremes.

8.2.2 Interlinkages between the global environmental crises and regional priorities

Climate change is causing weather patterns across Africa to change, leading to increased climate variability and extreme events. Droughts have become more frequent in the Sahel and Southern Africa, with events occurring nearly every second year since 2000 (de Coning and Krampe 2020). The Sahel, East Africa and Southern Africa are particularly affected by droughts, while Central and West Africa are primarily threatened by floods. For example, in 2021, South Sudan experienced a third consecutive year of flooding, while heavy rainfall in Niger affected 100,000 people (Elagib et al. 2021; Zeufack et al. 2021; Centre for Research on the Epidemiology of Disasters [CRED] 2022). Cyclones are also becoming more frequent, with 9–12 occurring every year in the southern Indian Ocean, affecting countries such as Madagascar, Mozambique, and their neighbours (Kossin et al. 2020; Otto et al. 2022).



Sub-Saharan Africa experiences a heightened risk of extreme heat events. During the months of June through August, across the Sahel and the western Sahara Desert – approximately 15 per cent of West Africa – most of the population is at risk (Sylla et al. 2018). Exposure to heatwaves has increased in 88 per cent of urban settlements in Nigeria (Tuholske et al. 2021). Consequently, a significant proportion of the population in these subregions is susceptible to heat-related illnesses, including heat exhaustion, heat stroke, and heat cramps (Kunda, Gosling and Foody 2024). The high heat risk in the region is partly related to rapid urbanization, characterized by rapid population growth in high-density urban centres and informal settlements. In cities, large masses of people, industry and transportation are concentrated in compact areas, leading to pollution of the atmosphere, water bodies and soils, as well as the formation of large volumes of municipal and industrial waste.

Rising temperatures, sea levels, and ocean acidity are wreaking havoc on the continent's biodiversity. Consequences include coral bleaching, mollusc-shell decalcification, and a 20 per cent reduction in phytoplankton biomass in the western Indian Ocean since the 1960s (IPBES 2018; World Meteorological Organization [WMO] 2022). These changes devastate fisheries, aquaculture and marine life, with Africa potentially facing the loss of over half of its bird and mammal species, as well as a 20–30 per cent decrease in lake productivity (Chapman et al. 2022).

Climate change intensifies threats by altering weather patterns, leading to more frequent and severe droughts, heatwaves and floods (**Figure 8.4**). These conditions push species beyond their tolerance limits, disrupting ecosystems and food chains. For instance, droughts in the Sahel and extreme heat in Algeria threaten both flora and fauna, while erratic rainfall patterns further destabilize ecosystems (Pecl et al. 2017; Sintayehu 2018).

Africa's ecosystems are deeply affected by the global environmental crises. Unsustainable practices, such as logging, hunting and resource extraction, are major drivers of biodiversity loss (Leisher et al. 2022). This is felt in areas such as the Congo Basin, home to 10 per cent of the world's biodiversity, which is under severe threat from logging. This endangers species and the livelihoods of local communities (Tyukavina 2018; Rocha-Santos et al. 2019). Despite efforts in some countries, such as Nigeria, to curb deforestation, enforcement remains a challenge,

Figure 8.4: Selected effects of climate change on Africa

Source: Africa Center for Strategic Studies [ACfSS] 2016; WMO 2023

leading to further biodiversity loss. Vulnerable species, including amphibians and montane species, struggle to adapt, weakening ecosystems on which millions of Africans depend (Manes et al. 2021).

Africa has seen a dramatic decline in wildlife populations. Overexploitation is rife, with an inability to enforce protective regulations and entrenched unsustainable practices, such as trophy hunting. The region has experienced a decline of 76 per cent in the size of monitored vertebrate wildlife populations between 1970 and 2020, driven primarily by habitat loss, overexploitation, pollution, and the effects of climate change (WWF 2024).

Climate change exacerbates existing land degradation processes and introduces new challenges, such as increasingly severe floods and coastal erosion (Olsson et al. 2019). Coastal degradation is of particular concern. In 2020, it affected 1.4 million people in Benin, Côte d'Ivoire, Senegal and Togo, with 56 per cent of their coastlines eroding at an average rate of 1.8 m per year (Global Centre on Adaptation [GCA] 2022). Overall, 46 per cent, or 14 million km^2, of Africa's land area is degraded, affecting 485 million people and resulting

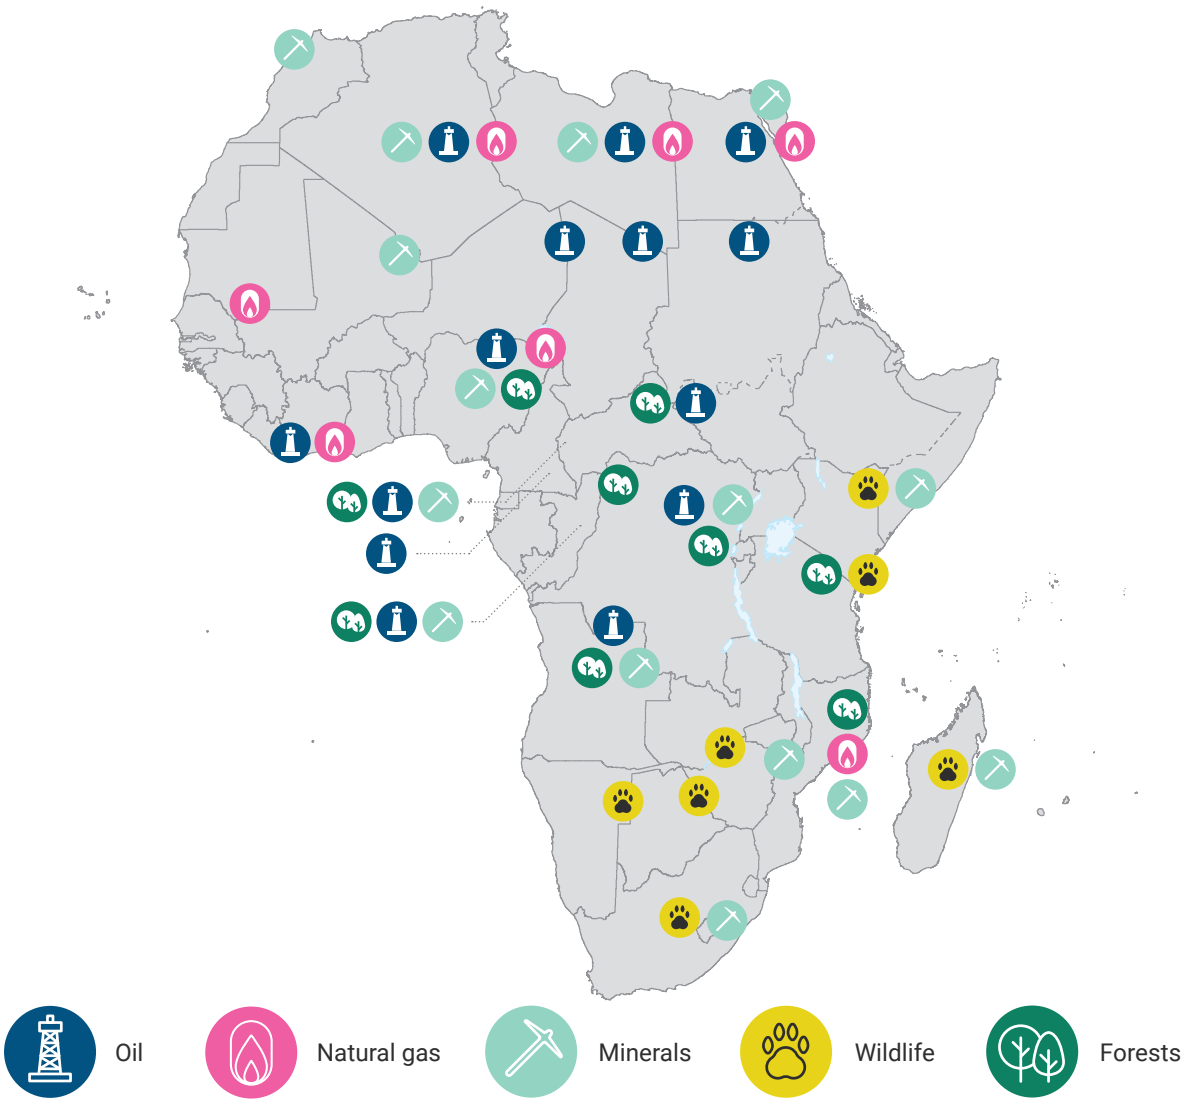
in an annual economic loss of US$9.3 billion (Olsson et al. 2019). Up to 80 per cent of Africa's cultivated land is degraded, losing 3,000–6,000 kg of nutrients per km^2 per year (Olsson et al. 2019).

Pollution, primarily driven by human activities, is another critical factor contributing to biodiversity loss in Africa. The continent is becoming a hotspot for water pollution, threatening aquatic life through rising water temperatures and sea surface temperature anomalies from 1991 to 2020, ranging from +0.3 to +1.5°C surrounding Africa, with 11 per cent of arable land affected by salinization, and contamination by organic and pathogen pollutants (Jones et al. 2023). In East Africa, rapid urbanization exacerbates the pollution crisis, with rivers contaminated by agricultural run-off, coffee processing waste, and inadequate sewage disposal (Chen et al. 2022). South Africa faces significant groundwater contamination issues, with chemicals and pathogens posing serious health risks (Masindi and Foteinis 2021). Soil pollution from pesticides, industrial solvents and heavy metals is also a significant concern, leading to health problems such as fertility issues, cognitive impairment, and diseases like cancer (Naidu et al. 2021). Improper incineration of pollutants contributes to air pollution, which is the second leading cause of death on the continent, resulting in approximately 1.1 million deaths in Africa in 2019 (Fisher et al. 2021).

Pollution alters the distribution of species and ecosystems. For instance, increasing CO_2 levels are driving bush encroachment because shrub and tree species are better adapted to higher CO_2 levels than grasses, threatening savannah habitats. This shift significantly affects ecosystem services, particularly cattle grazing, in areas such as Namibia's 260,000 km² savannahs (Archer et al. 2017; Belayneh and Tessema 2017; Scheiter et al. 2020).

Rapid urbanization across much of Africa significantly increases waste generation, with implications for water pollution and the spread of human diseases. Africa generates 180 million tons of waste, of which 70 per cent is openly dumped and 9 per cent is plastic waste (Ayeleru et al. 2020), which is reported mainly in the estuarine and marine environments (Akindele and Alimba 2021).

Africa's 121,545 km coastline (Liu et al. 2019) is particularly vulnerable to sea level rise, which has increased the frequency and severity of coastal flooding and erosion (Udinmade Ighedosa 2019). Rising ocean temperatures of +0.3 to +1.5°C around Africa over the last 30 years (Huang et al. 2020) have also led to a doubling in the number of cyclones making landfall since the 1970s (Africa Centre for Strategic Studies [ACSS] 2022). Category 5 cyclones in the southwestern Indian Ocean have not increased in frequency (Fitchett et al. 2016; Ranasinghe et al. 2021; Seneviratne et al. 2021), although tropical cyclones making landfall over central to northern Mozambique are increasing in frequency (Malherbe, Engelbrecht and Landman 2013; Muthige et al. 2018).



The deteriorating air quality in Africa threatens human health and has been linked to one in every five infant deaths and 16 per cent of all deaths in the region (Mlambo et al. 2023). Over the past five decades, air quality in Africa has deteriorated rapidly, making its cities among the most polluted globally, with particulate matter concentration levels between five and ten times the recommended levels (Mead et al. 2023). Air pollution in Nairobi, for instance, is five times higher than the limit recommended by the World Health Organization (Nakweya 2022). Comparatively, Kampala has poorer air quality, while Lagos, Nigeria, has the worst air quality in Africa (Kirenga et al. 2015; Abulude et al. 2020).

Food security, malnourishment and associated factors such as health, access to energy and access to or ownership of resources affect Africans inequitably based on their social class, gender, national rate of economic growth, and political stability (Wudil et al. 2022). The resulting crisis, fuelled by unsustainable rates of urbanization, has sparked insecurity crises in countries such as South Africa, where limited resources and the proliferation of informal settlements have exacerbated xenophobia (Mamabolo 2015; Hiropoulos 2020).

8.2.3 Priority issue: unsustainable resource exploitation and use

Africa's vast natural resources face a dual threat from both overexploitation and underutilization, resulting in environmental degradation and missed economic opportunities. Africa is rich in natural resources (**Figure 8.5**). The exploitation of these resources has significant environmental implications. This section explores how the continent's resources are currently

Figure 8.5: Africa's resources map

being used, focusing on the dual issues of overuse and underuse and the consequences for the environment and human systems.

Resource extraction drives economic growth but also causes significant environmental damage, threatening sustainable development. Southern Africa presents a contrasting scenario where Botswana and South Africa, rich in diamonds and gold, respectively, show how mineral wealth can contribute to economic growth but also lead to environmental challenges like water and soil acidification, such as pH ranges of 1.9–5.3 in soil (Mokwakwa 2021; Tibane and Mamba 2022; Laker 2023). Similarly, in West Africa, the oil sector contributes about 9 per cent to Nigeria's gross domestic product (GDP) but has led to significant environmental degradation in the Niger Delta (Ite et al. 2013; Sam and Zibima 2023; Sami and Taiwo 2023).

Economic activities, such as logging, further degrade the terrestrial environment in West African countries. In countries such as Burkina Faso, the growing population is driving agricultural expansion into forests, with the country experiencing a deforestation rate of approximately 1 per cent annually, translating to an estimated loss of 900 km^2 of forest per year over the past five years (FAO 2021). This expansion is driven mainly by subsistence agriculture and the increasing demand for arable land to support the growing population.

Illegal logging has become a major issue, particularly in protected areas where valuable timber species such as Pterocarpus erinaceus are targeted. The removal of these trees not only depletes forest resources but also disrupts local ecosystems, leading to soil erosion, loss of biodiversity, and reduced capacity

for carbon sequestration (Dimobe et al. 2015). This trend is replicated across Africa – notably in Zambia, Ghana and the United Republic of Tanzania – where medium-scale farms are established in, or expanded into, areas that were previously forested, exerting more pressure on finite forest resources to feed the growing population (Wineman, Jayne and Stevens 2022). Currently, an estimated 65 per cent of Africa's productive land is degraded, while 45 per cent of the continent's land area is affected by desertification (Mansourian and Berrahmouni 2021).

Africa faces rapid deforestation and soil degradation, which reduces land productivity and pressures forests for agricultural use. Africa is losing its forests and productive lands, with annual deforestation estimated at 390,000 km^2, particularly in countries such as Nigeria, the Democratic Republic of Congo, and Ethiopia (FAO 2021). The Democratic Republic of the Congo is driven by factors including damaged soil structure and quality from chemical pollution in agriculture, which has led to soil contamination and a subsequent reduction in soil fertility. The excessive use of agricultural chemicals, such as nitrogen-based fertilizers, also contributes to soil acidification and nutrient imbalances, further degrading soil quality (Vanlauwe et al. 2015; Acheampong and Opoku 2023). These issues reduce the productivity of agricultural land, necessitating further conversion of more forests into land for food production.

Overexploitation of aquatic resources threatens marine biodiversity and the economic viability of coastal communities. The unsustainable exploitation of aquatic resources through overfishing, sand harvesting, and dredging threatens coastal and marine ecosystems, eroding their ability to produce food or contribute to economic development. Illegal fishing and overfishing are particularly rampant along the West African coast, affecting vulnerable and endangered marine species, including dolphins, monk seals, sea turtles and some shark species, together with Palearctic seabirds that rely on the West African coast for breeding and shelter during winter (Lemrabott et al. 2024; Merceron et al. 2024).

Unsustainable water use and pollution are depleting and contaminating Africa's freshwater sources, exacerbating water scarcity. The most water insecure African countries are Chad (with a national water security score of 39 per cent), Comoros (40 per cent), Djibouti (32 per cent), Ethiopia (31 per cent), Eritrea (29 per cent), Liberia (36 per cent), Libya (37 per cent), Madagascar (37 per cent), Niger (38 per cent), Sierra Leone (38 per cent), South Sudan (37 per cent) and Sudan (30 per cent) (MacAlister et al. 2023).

The degradation of wetlands in Africa, driven by industrial pollution, oil spills, aquaculture expansion and unsustainable mangrove harvesting, has had devastating effects on biodiversity and ecological stability. In the Niger Delta region, for instance, wetlands have lost much of their capacity for carbon sequestration and water filtration, exacerbating freshwater scarcity and increasing vulnerability to flooding and coastal erosion. This degradation not only threatens local species but also jeopardizes the livelihoods of communities that depend on these ecosystems for sustenance (Zamboni et al. 2021; Sam et al. 2023; Wekesa et al. 2023; Turner and Ohimain 2024). In the African mainland, sources of fresh water are being depleted and polluted by agricultural activities and waste from industries and households. For example, DDT levels of 81.2 µg/L were found in South African fresh water (Makgoba et al. 2024). This pollution and unsustainable use of scarce water resources worsen the prevailing freshwater crisis on the continent while threatening human life and overall water security.

Climate change and land degradation are undermining Africa's ability to meet its growing food needs, thereby increasing the risks of malnutrition. The current output is already insufficient to feed the continent's population (Beltran-Pena and D'Odorico 2022), and Africa is facing a rising rate of malnutrition and declining food security (Adesete, Olanubi and Dauda 2023). Kenya's reliance on agriculture, which accounts for 33 per cent of its GDP, is threatened by recurrent droughts and land degradation (Kalele et al. 2021; Yilmaz and Njora 2021).

8.2.4 Priority issue: ecosystem degradation

Africa's ecosystems are facing severe degradation due to the global environmental crises (Olsson et al. 2019; Chomba et al. 2020; FAO 2020; Mansourian and Berrahmouni 2021). While Africa has food supply issues, the wider biodiversity loss is both a driver and a consequence of ecosystem degradation, creating a feedback loop that threatens ecological

integrity and the well-being of human health, water, food, nutrition, energy security and socioeconomic development across Africa. The continent hosts 17 per cent and 31 per cent of the world's forests and other wooded lands, respectively (IPBES 2018). Major drivers of degradation of Africa's ecosystems include increased consumption due to rapid population growth, land-use change due to the conversion of forests, rangelands and wetlands to agriculture, mining, unplanned urbanization, pollution and wastes, and other infrastructure development (Bradshaw and Di Minin 2019; IPCC 2022a).

Africa has lost an estimated 64 per cent of its wetlands since 1900, with a 20 per cent reduction between 1990 and 2020 (UNEP 2021). Wetlands are home to approximately 20 per cent of the continent's biodiversity, including numerous species of fish, birds, amphibians, and plants (Convention on Wetlands [Ramsar] 2022). Approximately 50 million people in Africa face water shortages due to wetland loss (Chelea et al. 2020), which jeopardizes food security and economic stability. However, an estimated 35 per cent of wetlands have been degraded due to land degradation, urbanization, and agricultural expansion (Ramsar 2022). In the Niger River Basin, 25 per cent of wetlands have been converted to farmland (UNEP 2020). Meanwhile, urbanization has led to over 50 per cent degradation of coastal wetlands in Lagos and Accra in West Africa (Ekumah et al. 2020; Adeleke 2022), while pollution from untreated sewage in the Nile Delta in North Africa has resulted in a 30 per cent decline in water quality (Morsy, Mishra and Galal 2020). Similarly, Southern Africa has lost 40 per cent of its wetlands due to land conversion for agriculture and urban development, particularly in the Limpopo Basin and the Okavango Delta (Gxokwe, Dube and Mazvimavi 2024). In East Africa, the area of wetlands around Lake Victoria has decreased by about 30 per cent due to urban and agricultural expansion (Cooperation for International Waters in Africa [CIWA] 2022).

Climate change exacerbates wetland loss, with average temperatures in Africa increasing at a rate 1.5 times faster than the global average (IPCC 2023). Droughts have led to a 30 per cent reduction in wetland areas around Lake Victoria and a 40 per cent reduction in water availability in the Sahel (UNEP 2022). Wetlands in the Lake Chad basin have shrunk by 90 per cent since the 1960s (Zhao, Cook and Vizy 2023), affecting biodiversity, food security and ecosystem services, with 28 per cent of wetland species at risk of extinction and about 40 per cent classified as threatened (IUCN 2023). Wetland degradation threatens livelihoods, with a 20 per cent decline in fish catches around Lake Victoria (Owonikoko and Momodu 2020) and decreased agricultural yields in the Niger Delta (Ramsar 2022).

Degradation of Africa's marine ecosystems and coastal areas is accelerating due to unsustainable human activities. Africa's coastal marine and coastal systems harbour 36 global biodiversity spots, 439 marine key biodiversity areas, and 148 marine and coastal Ramsar sites (World Bank 2022). The continent's marine and coastal ecosystems are experiencing a wide range of degradation, including overexploitation, habitat degradation and loss, unsustainable infrastructure development, pollution, coastal erosion, biodiversity loss, invasive species, and climate change (World Bank 2022). Pollution from untreated wastewater, oil spills and plastics poses a threat to marine ecosystems, tourism, shipping, fisheries, and human health (World Bank 2022). The effects manifest through the impairment of the oceans' carbon-storing function, which is damaged by the destruction of ecosystems such as mangroves, salt marshes and seagrasses. For example, pollution resulting from untreated domestic wastewater is estimated to cost US$31 million in Senegal and US$35 million in Côte d'Ivoire (World Bank 2022). Oil spills in the coastal delta of Nigeria were estimated to cost US$66 million, equivalent to 0.5 per cent of its GDP in 2018 (World Bank 2022) and plastic pollution led to a minimum lifecycle cost of about US$61 million in South Africa in 2019 (Sadan and De Kock 2021).

Climate change threatens biodiversity through a reduction in primary production and fish abundance. Increases in water acidification cause coral reef bleaching, leading to the destruction of fish and other marine life habitats (IPCC 2022b; IPCC 2022c; World Bank 2022). By 2016, in the western Indian Ocean, coral cover had decreased by 30–40 per cent of its 1998 levels (Moustahfid, Marsac, and Gangopadhyay 2018), due to mass coral bleaching that occurred during this time. These effects have negative consequences for the economies and livelihoods of coastal communities (World Bank 2022). For example, in Togo, coastal erosion led to a decrease in fish catch due to rocky shorelines that prevent the local population from landing their boats.

Mountainous regions are experiencing increased degradation due to human activities and climate change, with approximately 70 per cent of these key ecosystems affected (Adler et al. 2023). African mountains, which cover approximately 22 per cent of the continent, are vital ecosystems that support biodiversity, regulate the climate and sustain human livelihoods. However, deforestation and unsustainable agricultural practices have led to significant soil erosion and diminished water quality, with the East African Highlands experiencing a 20 per cent decline in vegetation cover (IPCC 2022d). Pollution from urban run-off exacerbates biodiversity loss, placing 30 per cent of mountain species at risk of extinction (IUCN 2023). Burundi and Rwanda face severe degradation, with a significant percentage of their land affected (Tall et al. 2022). As mountains are essential for agriculture, water supply and traditional knowledge, their decline jeopardizes food security and increases vulnerability to climate shocks for millions across Africa.

Glaciers have lost over 80 per cent of their volume since the early 1900s in East Africa, threatening local communities' water supply (Mastrorillo et al. 2016; Hinzmann et al. 2024). A critical concern is the receding glaciers in regions such as the Rwenzori Mountains of Uganda and the Democratic Republic of the Congo and Mount Kilimanjaro of the United Republic of Tanzania, vital water sources for about 5 million inhabitants (Garelick et al. 2022; Jackson et al. 2020; Hinzmann et al. 2024).

Savannah ecosystems cover about 65 per cent of Africa's land area but are increasingly threatened by human activities such as large-scale mining and oil extraction, leading to the degradation of these ecosystems (Hahn and Leßmeister 2021). Anthropogenic activities, including agricultural expansion, plantation forestry, overgrazing, human settlements, large-scale mining operations and climate change are accelerating the degradation of savannah ecosystems, leading to pollution and loss of biodiversity and endangering the livelihoods of pastoral communities (Dudley et al. 2021; Williams et al. 2022; IPCC 2022a; IPCC 2022b). For example, in East and Southern Africa, extractive industries, including oil and gas drilling and mining of gold, copper and coal, are increasingly encroaching on savannah regions. Agricultural activities, including the clearance of vast tracts of land for crops such as sugarcane, maize and soybeans, in the United Republic of Tanzania and Mozambique, contribute to the loss of native vegetation and biodiversity (Ahmed, Bryant and Edwards 2021; Benton et al. 2022). Climate change exacerbates these challenges due to rising temperatures and changing rainfall patterns, which increase the frequency of droughts and wildfires and reduce rangeland productivity. In Namibia, uncontrolled bushfires threaten Etosha and Namib Naukluft national parks (UNEP 2020). Droughts driven by climate change have led to significant livestock losses, particularly affecting pastoralist communities that depend on livestock grazing, with up to 30 per cent livestock losses in some regions due to recurrent droughts (IPCC 2022b).

Africa's inhabited dryland regions are under increasing threat from the global environmental crisis, reducing ecosystems' resilience, food security, and people's livelihoods (FAO 2019; Mbow et al. 2019; Samuel and Sylvia 2019). These ecosystems account for 11 per cent of the Earth's surface, 27 per cent of the world's total drylands, and 40 per cent of Africa's land area (Wei et al. 2021), supporting nearly 85 per cent of the population (Kogo, Kumar and Koech 2021).

Over 170 species in sub-Saharan Africa are listed in IUCN's endangered categories, with ecosystem degradation as a key driver of this trend. The largest class of threatened taxa is African primates, constituting 96 of the 172 listed species (Duporge et al. 2020). Illegal poaching and trafficking of wildlife pose a significant threat to Africa's iconic species, such as rhinos and elephants. These activities not only decimate populations but also disrupt ecological balance, having far-reaching consequences for local communities (Duporge et al. 2020; Lunstrum and Givá 2020; World Bank 2021; Mozer and Prost 2023). The introduction of the Nile perch, a voracious predator in Lake Victoria, and the invasive water hyacinth led to the decline and near extinction of native haplochromine cichlid fish, changes in the habitat and trophic dynamics, loss of species diversity among cichlids, and water clarity (Aloo et al. 2017; Nyamweya et al. 2018).

Conversely, the degradation of ecosystems has profound socioeconomic consequences. Rural communities, particularly in arid and semi-arid regions, depend heavily on ecosystem services for subsistence agriculture, pastoralism, energy and medicine. Biodiversity loss and land degradation reduce food and water security, increase exposure to climate-related hazards, and heighten the risk of conflict

Credit: osbmxhouse/Envato

over shrinking resources (Barbier and Hochard 2018; IPCC 2022d). Moreover, marginalized populations – especially women and Indigenous Peoples – are disproportionately affected due to their reliance on natural resources and limited adaptive capacity.

8.2.5 Priority issue: climate change and climate extremes

Rising temperatures are causing floods and coastal erosion in some parts of Africa and reducing precipitation in others (WMO 2021). Extreme sea level events are occurring more frequently, particularly in tropical regions. Countries where large proportions of the population live on the coast – such as Senegal at 41 per cent, Benin at 35 per cent, and Liberia at 29 per cent – are particularly vulnerable to sea level rise (ACSS 2022). In addition, since the 1980s, climate change has led to the doubling of marine heatwaves in Africa, destroying marine ecosystems, leading to the extinction of many marine species, and causing migration of marine life from their original habitats (Trisos et al. 2022; Nhantumbo, Dada and Ghomsi 2023).

Climatic changes are straining water systems (WMO 2021; IPCC 2022b). Due to decreased precipitation and increased evaporation, several major African water systems, including Lakes Kariba, Kivu, Tanganyika, Victoria and Malawi, experience regular low water storage levels. Climate change is causing more frequent and intense fluctuations in El Niño and La Niña years, which in turn affect Lake Victoria, 80 per cent of which is dependent on precipitation (Ransom 2021).

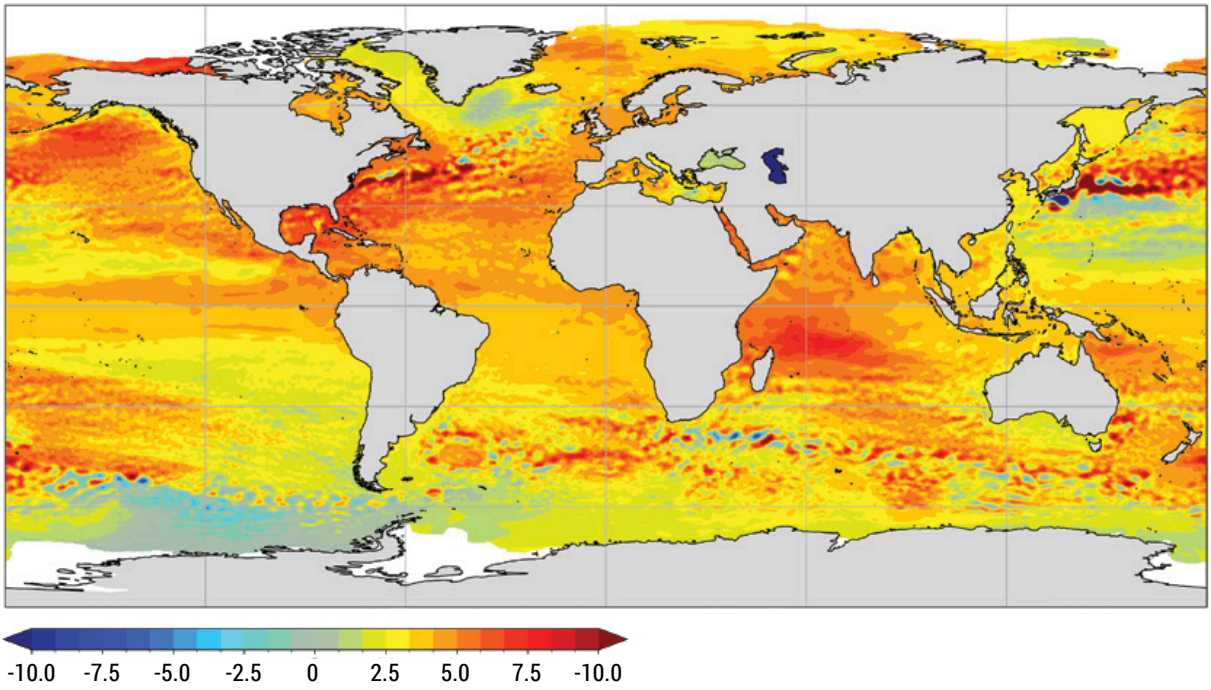
Rising temperatures, precipitation changes and the increased occurrence of disasters such as cyclones, severe storms and droughts contribute to the spread of diseases, food security problems, limited or no access to clean water and sanitation facilities, a high risk of waterborne disease, heat stroke, and mental health problems (integrated African Health Observatory [iAHO] 2024). Additionally, there has been an increasing number of waterborne disease outbreaks in Africa due to inadequate sanitation and unsafe water supplies. There is robust evidence in the region that the health impacts of climate change disproportionately affect the poorest individuals and children, and in some cases, can vary by gender and age (Nyahunda et al. 2020; Ragavan et al. 2020).

Persistent declines in food production are distressing Africa. Disruptions in agriculture led to increased hunger in Africa in 2020. Although the continent saw promising agricultural progress – with productivity rising by an average of 13 per cent annually from 2015 to 2020 and the agricultural trade deficit declining by 26 per cent – most African agriculture remains small-scale, rain-fed, and reliant on low

technology (African Development Bank [AfDB] 2021). These circumstances leave farmers particularly vulnerable to biological, economic and climate-related shocks, such as droughts, cyclones, floods and pest invasions like desert locusts, fall armyworm, and animal diseases like peste des petits ruminants. Consequently, disruptions from COVID-19 severely affected agricultural markets and farmer incomes. For instance, a survey conducted in mid-2020 in Malawi showed that 73 per cent of agricultural households reported reduced agricultural earnings due to the pandemic (Nolte, Sipangule and Wendt 2022).

Extreme weather conditions have resulted in a decline in agricultural production. While North Africa's cereal production in 2023 was 33 million tons, similar to the previous year's drought-stricken harvest, this is 10 per cent lower than the five-year average. Tunisia's cereal production decreased by over 80 per cent compared to the annual average, due to drought conditions (FAO 2023). Erratic rainfall and insecurity kept cereal production below average in northern parts of the Greater Horn of Africa. In Sudan, seasonal rains were below average and erratic, with long dry spells. Sorghum and millet production were expected to fall by about 25 per cent and 50 per cent, respectively, from 2022 levels (WMO 2023).

Renewable energy targets are at risk from the effects of climate change. Climate change will affect hydropower generation in Africa by reducing plant generation output (IEA 2020). For example, Zambia depends on hydropower for over 80 per cent of its electricity generation (IEA 2019). The output from major Zambezi hydropower plants could decrease by 10–20 per cent under drier climate conditions, leading to a rise in electricity costs by 20–30 per cent in the short term in the hydro-dependent countries of Mozambique and Zambia (Spalding-Fecher, Joyce and Winkler 2017). The reduction in the duration of the rainy season, coupled with frequent droughts, results in a decrease in water inflows into the Kariba reservoir (Ahmed et al. 2020; Arias et al. 2022;), which led to reduced output and the implementation of daily blackouts in August 2019 (Hill and Ndlovu 2019).



Climate hazards do not only impact the environment – they threaten socioeconomic development in Africa, which has been losing between 5 and 15 per cent of its GDP per capita growth due to climate change and its related impacts (AfDB 2022). Estimated losses in resource-rich countries, such as Botswana, Equatorial Guinea and Gabon, and services or manufacturing-based economies such as Mauritius and South Africa are lower than in other African countries that are heavily dependent on agriculture. Many of the countries most affected by climate change are already impoverished (AfDB 2022). Most of the effects are evident in the form of setbacks in agriculture, tourism, infrastructure and manufacturing.

Climate change is threatening Africa's infrastructure and settlements. This undermines SDGs such as SDG 11. Intense storm surges are worsening sea level rise, endangering coastal communities and infrastructure (Richardson et al. 2022). Coastal nations in West and Southern Africa, including Senegal, Nigeria and Angola, face erosion and sea level rise due to their low-lying lagoonal coasts. The situation is of concern because many of these countries have rapidly expanding coastal cities (**Figure 8.6**). The East Coast of Africa is also at risk, as sea level rise and climate variation may lead to coral and patch reef attenuation, which could increase the potential for erosion (Mafaranga 2020; Vousdoukas et al. 2022; Nhantumbo, Dada and Ghomsi 2023).

Climate change's slow-onset events, including droughts, desertification, deforestation, water scarcity, rising sea levels and coastal erosion, have led to increased migration in Africa over recent decades. This affects SDG progress related to SDG 6, 7, 13 and 15. In 2018 in sub-Saharan Africa, East and West Africa were hotspots for disaster-related displacements, with 1,437,7000 and 798,000 displaced people respectively, accounting for 13.9 per cent of the global total and one of the highest numbers on record (Internal Displacement Monitoring Centre [IDMC] 2019; IPCC 2022b; Trisos et al. 2022).

Climate change is straining health systems by increasing mortality and morbidity, threatening the realization of SDG 3. Climate change and land-management practices have led to an increase in dust storms, particularly in North Africa, which contributes to the spread of respiratory diseases such as asthma and bronchitis (D'Amato et al. 2016; Awadh 2023). Large numbers of people have been affected by climate-related hazards (**Figure 8.7**). In the Saharan regions and in addition to the respiratory and ophthalmic health risks linked to mobile sands and heatwaves, the population is also subject to cross-border diseases, such as malaria

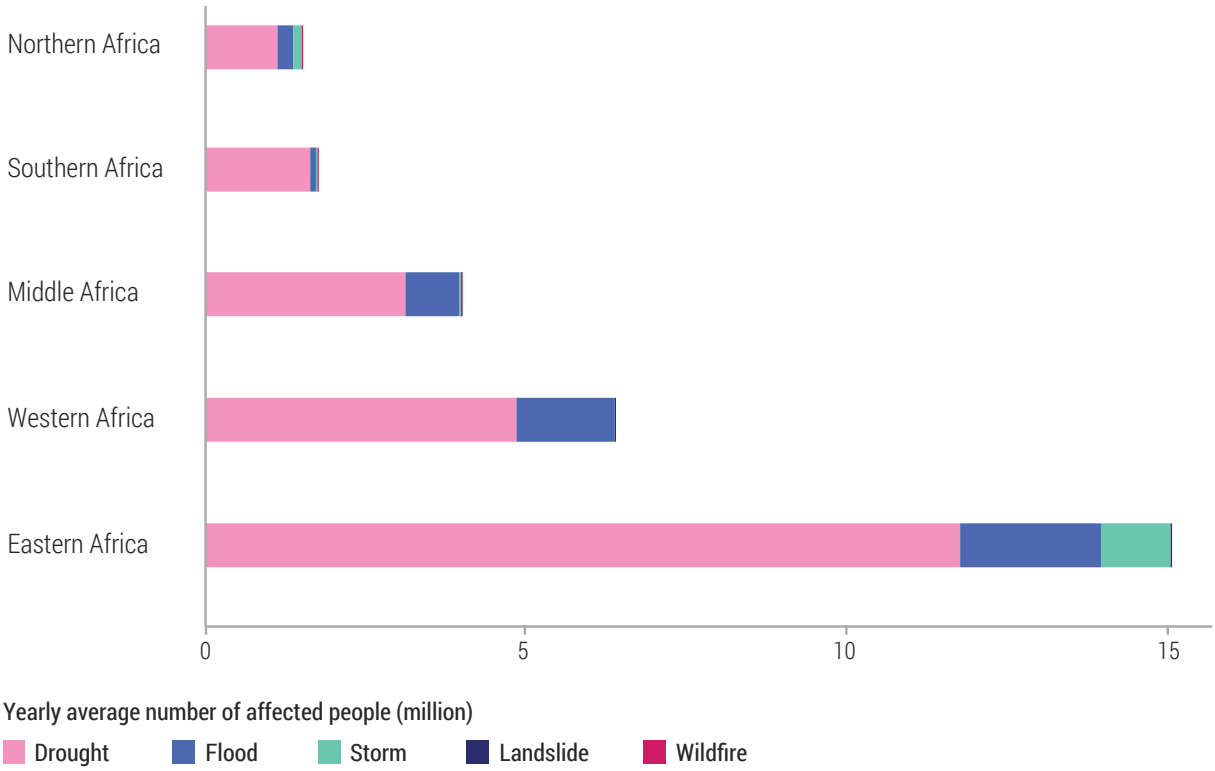


Figure 8.6: Sea level trends from 1999 to 2024

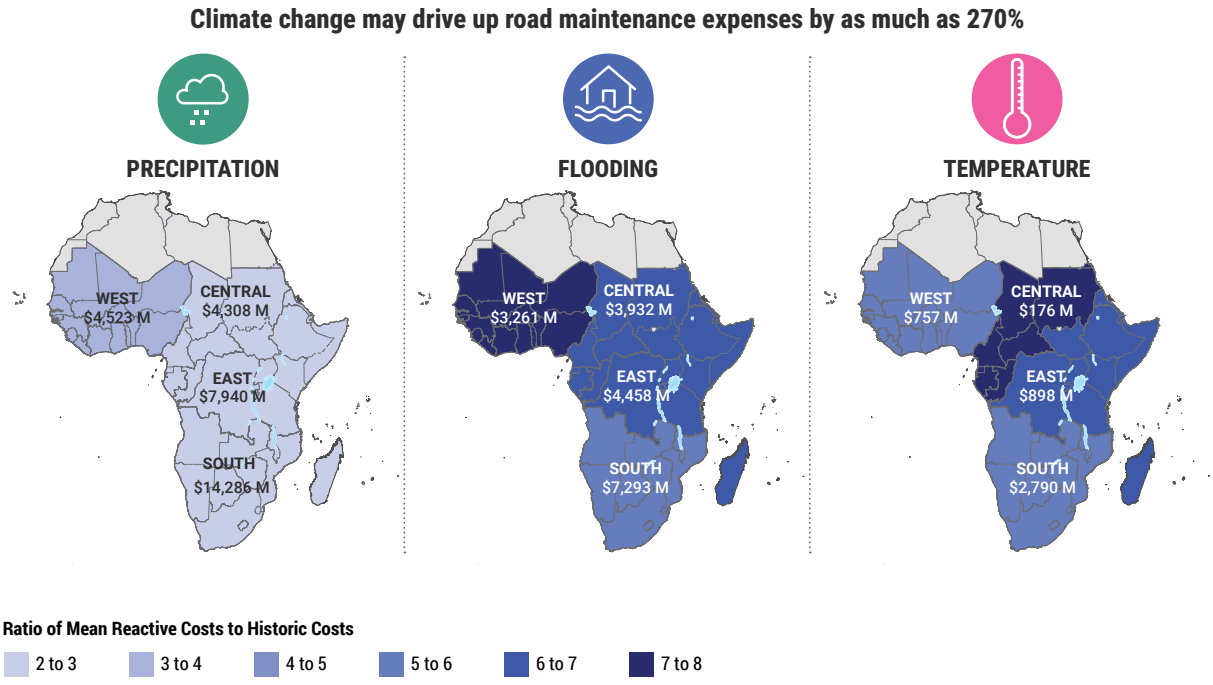
Figure 8.7: Climate-related hazards and number of affected people per sub-region of Africa

Note: Affected people refer to those requiring immediate assistance during a period of emergency or requiring basic survival needs, such as food, water, shelter, sanitation and medical attention. The figure presents the yearly average numbers from January 2011 to December 2024.

Source: EMDAT (2025)



and HIV, that risk spreading through the mobility of citizens or directly via exogenous migratory flows.

Extreme climate situations are directly related to the increased frequency and severity of emerging and re-emerging infectious diseases in Africa, including dengue, cholera and malaria, with more than 166 outbreaks registered in 2023. Malaria outbreaks have spread to areas that were previously unaffected and have become more common in East African highlands, where temperatures now support breeding of the vectors (Caminade et al. 2014; Caminade et al. 2019). A ninefold increase in dengue infections in Africa was reported in 2023, compared with 2019 (WHO 2023c).

Agriculture, which employs 55 to 62 per cent of Africans and accounts for almost a quarter of the continent's GDP, is almost entirely rain-fed (Bari and Dessus 2022). Lower agricultural productivity and sectoral growth due to weather extremes reduce revenue and worsen current account deficits, resulting in economic growth declining from 4 per cent to 3.6 per cent in 2022 and to 2.5 per cent in 2023.

Flood-induced damage in Africa was estimated at over US$4.4 billion between 2005 and 2020. Droughts and floods have reduced African GDP by 0.7 per cent and 0.4 per cent, respectively, since 1990 (Trisos et al. 2022). Climate damage to infrastructure puts massive African government investments at risk, mainly because most of these have been financed by public debt (International Monetary Fund [IMF] 2020). Eight of the 20 countries with the highest expected annual road and rail asset damage due to climate change, relative to their GDP, are in Africa (Trisos et al. 2022) (See also **Figure 8.8**). In addition, weather damage to transport infrastructure raises transport costs, affecting monetary policy. These costs are passed on to consumers, raising inflation. As climate change reduces domestic food production, the region imports more, which increases the current account deficit, erodes foreign reserves, reduces the foreign exchange available to service external debt, and influences exchange rates, thereby exposing African governments to weather-induced inflation (IMF 2020). **Table 8.2** shows anticipated climate change-induced GDP losses by 2030.

Figure 8.8: Estimated increase to road maintenance costs due to climate change

Note: The figures represent the overall impact of climate change on road maintenance expenses (in 2015 dollars, discounted at 6%) caused by precipitation, flooding, and temperature stress in Central, East, South, and West Africa. The color coding shows the proportion of reactive maintenance costs relative to past costs for each stressor in these regions. Flooding and temperature-related stresses are projected to lead to substantial rises in reactive costs compared to historical levels. The subregional grouping from this source differs from the UN regional groupings.

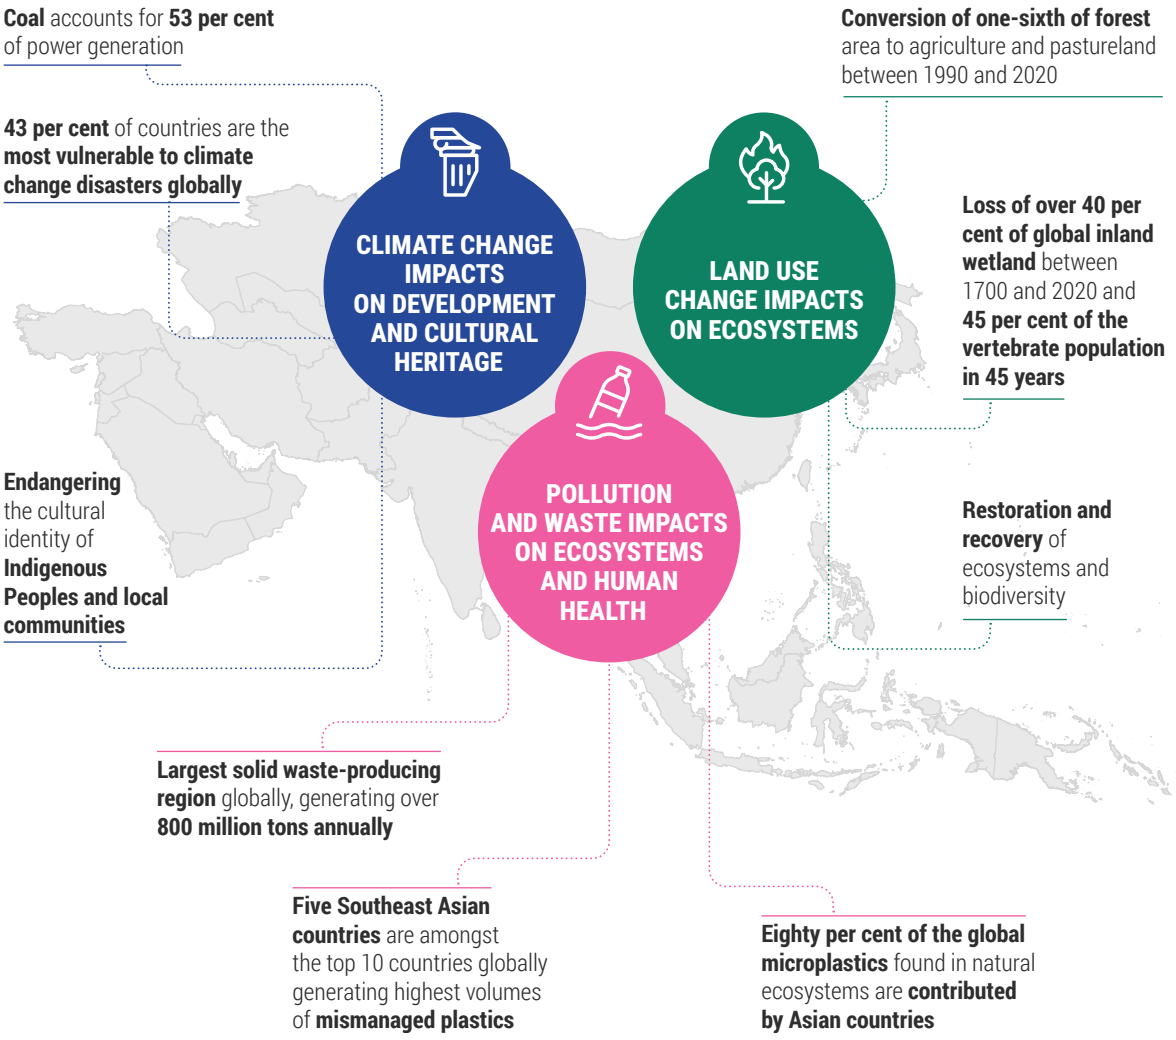
Climate change increasingly threatens Africa's tangible and intangible cultural heritage, particularly along coastlines. Currently, 56 heritage sites, or 20 per cent of total sites identified, face immediate risk from severe coastal events such as storm surges, high waves and erosion – events expected to grow more frequent and intense. North Africa has the highest exposure with 23 sites, followed by West Africa with 18, Southern Africa with 7, and East Africa and Small Island Developing States with 4 each. Tunisia, Morocco and Senegal have the most at-risk sites, with 7 sites each (Vousdoukas et al. 2022).

8.3 Asia and the Pacific and subregions



8.3.1 Introduction

The Asia and the Pacific region (AP) covers approximately 22 per cent of the total global land area with high social, cultural, biological and topographical diversity, which provides home to almost two-thirds of the world's population (Karki et al. 2018). The AP's human and other resource bases have enabled it to experience rapid economic growth (Ahmed, Ali and Kousar 2022). However, drivers and pressures (Chapter 2), especially economic development, have contributed to the global environmental crises and caused three related priority issues in AP. (**Figure 8.9**).

Climate change and associated disasters have caused significant economic and social damage in the AP, where approximately 40 per cent of countries are most vulnerable to climate change and related disasters. This vulnerability has resulted in about 2 million deaths from climate change-related disasters since 1970 (World Bank 2022; ESCAP 2023). The losses from such disasters – including floods, droughts, forest fires, sea level rise and marine acidification – are accelerated by poor adaptive capacities (UNEP 2022; World Bank 2022).

Land-use changes, as well as climate change and pollution and waste, have critically affected natural resources, leading to a decline in human well-being, particularly among poor and

Figure 8.9: The inter-play of the global environmental crises as they affect Eurasia's resource use, ecosystem degradation and climate extremes

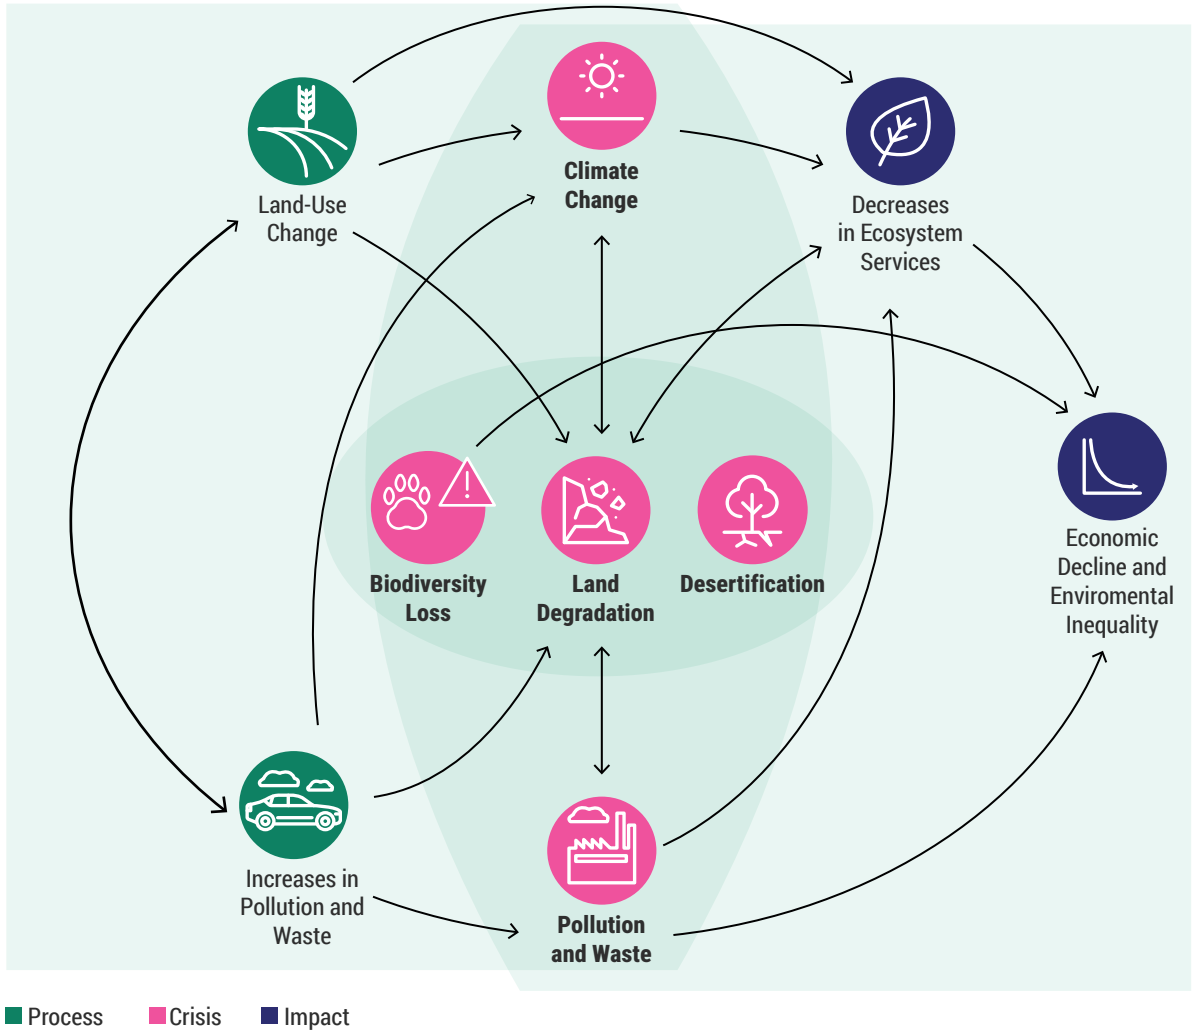
vulnerable communities in AP (Sibt et al. 2023). The increased demand for both ground and surface water for intensified agricultural output and industrial needs has put the quantity and quality of regional water resources under stress. This stress results in the degradation of wetlands and marine aquatic resources. Building dams accelerates damaging effects on natural floodplain regulation, fish-spawning habitats and rice production, putting the livelihoods of natural resources-dependent Indigenous communities at risk (Ullah et al. 2021).

Environmental pollutants and waste in AP have led to serious health issues and risks to economic growth. Anthropogenic sources, including industrial activities, mining, agriculture, livestock, and consumer lifestyles, significantly pollute the soil, damage agricultural crop yields and endanger human health (FAO and UNEP 2021). For example, very high levels of air pollution with fine particulate matter ($PM_{2.5}$) are responsible for staple crop losses of 5–20 per cent in maize, rice, soy, and wheat in the region (CCAC and UNEP 2019).

Pollutants are closely associated with environmental inequality and injustice in the AP (ESCAP 2018) due to unevenly distributed impacts and effects. Pollution has a greater impact on vulnerable groups, such as women, youth, low-income people, and Indigenous Peoples and local communities and their traditional ways of life. For example, more frequent heatwaves that exceed dangerous levels, especially in South Asia and the Arabian Peninsula, pose a serious threat to poor, vulnerable people working outdoors (IFRC and OCHA 2022). Low-income people living in compact urban settlements face a greater risk of health problems due to their

inability to manage resources to cope with heat (Berger et al. 2022).

8.3.2 Interlinkages between the global environmental crises and regional priorities



As described in the Global Environmental Crises Chapeau, the global environmental crises – the crisis of climate change, the crisis of biodiversity loss, land degradation and desertification, and the crisis of pollution and waste – are intrinsically linked.

In AP, intensive land-use changes and rising pollution and waste – from high in the Himalayas to the coasts – have created a complex web of drivers and pressures that exacerbate the global environmental crises. The result is a critical decline in ecosystem services in the region and, ultimately, economic decline, and environmental inequality and injustice (**Figure 8.10**).

The AP has undergone extensive land-use transformation to agriculture and pastureland since the 1960s. This land-use change has produced large quantities of air pollutants, pesticides, plastics and other solid wastes, leading to enhanced climate change, a rapid loss of biodiversity and ecosystems, and increased pollution (Alavaisha et al. 2021; Takeuchi et al. 2021; Kondo et al. 2022; Ng et al. 2023). These changes weaken greenhouse gases (GHG) mitigation efforts and adaptation capacity to climate change, increase pollution and waste, and accelerate land further degradation in AP (Ullah et al. 2021; Sibt et al. 2023).

Climate change exacerbates biodiversity loss through altered weather patterns, intensified extreme events, and accelerated habitat destruction (Ajilogba and Walker 2021). Pollution and waste have caused significant biodiversity loss through the excessive use of pesticides, and the pervasiveness and accumulation

Figure 8.10: Selected interlinkages assessed within the Asia and Pacific region

of plastic debris and microplastics in benthic sediments and marine biota (Curren and Leong 2019). Biodiversity loss amplifies vulnerabilities to climate impacts, exacerbating pollution challenges, adversely affecting ecosystem functionality and threatening species survival. The AP region lost 45 per cent of its vertebrate population in 45 years, with India losing 12 per cent of its wild mammals, 19 per cent of its amphibians and 3 per cent of its birds (WWF 2023).

These drivers and pressures heighten socioeconomic vulnerabilities, especially among marginalized groups. Individuals living in poverty are more inclined to downplay the risks associated with toxic exposure and future health concerns in favour of immediate economic gratification (Citaristi 2022). Poverty and economic disparities are closely linked to the generation of waste and other human-induced environmental hazards (Kaÿmierczak 2018; Mihai et al. 2021). However, there are significant gaps in the region's ability to address these challenges, particularly in terms of ensuring full and effective participation of Indigenous Peoples and local communities, as well as their knowledge systems. These circumstances stem from issues including inadequate policies, limited finances, technological disparities and varying levels of readiness and monitoring among nations.

8.3.3 Priority issue: climate change impacts on development and cultural heritage

Climate change is threatening both tangible and intangible cultural heritage in the AP region, contributing to the losses and damages that are increasing faster in this region than the global average. The degradation of heritage sites exacerbates inequality, endangers cultural identity and imposes economic pressures on Indigenous Peoples and local communities. For example, the cultural values and environmental knowledge of Kazakh herders in Mongolia are at risk due to climate change (Simpson et al. 2022), as are the Batad Rice Terraces in the Philippines (Ducusin et al. 2019), a globally significant agricultural heritage system. These impacts threaten not only biodiversity and sustainable productivity but also the preservation of traditions and cultural practices of Indigenous Peoples in Indigenous and traditional territories.

Thirteen Asian countries are among the most vulnerable to the consequences of climate change, with significant economic and financial implications (World Bank 2023). For example, Bangladesh incurs annual losses of US$1 billion from tropical cyclones (World Bank 2022). South Asia is particularly threatened by wildfires, floods and storms, which could affect 10–18 per cent of the region's GDP, higher than in North America or Europe (World Economic Forum 2022).

Climate change presents a multifaceted challenge in the AP due to its diverse landscapes and growing populations, resulting in escalating climate risks (Ajilogba and Walker 2021). Rising temperatures in Asia have increased the frequency of heatwaves, with a 10 per cent chance of one annually in West Asia (Japan International Research Center for Agricultural Sciences 2024). Thawed permafrost has increased subsidence rates by 2–5 fold in the Tibetan Northern Plateau between 2003 and 2019 (Daout et al. 2020).

Altered weather patterns have shifted the Asian monsoon, with the East Asian Summer Monsoon's rainfall intensity increasing, leading to more extreme weather events such as cyclones, floods, and droughts (ESCAP 2022). Climate change is exacerbating air pollution and the urban heat island effect, particularly in rapidly growing East Asian cities, where temperatures are on average 1.6–2.0 °C warmer than their immediate rural surroundings.

The region also faces significant land degradation, particularly in South Asia, where a conservative estimate suggests that economic losses amount to US$10 billion annually, thereby heightening vulnerability to natural disasters (Ahmed et al. 2022; UNCCD 2022; Lal 2023). Ocean acidification and coral bleaching are disrupting marine ecosystems, threatening the livelihoods of approximately 200 million people who depend on fisheries and endangering food security (World Bank 2019).

Additionally, rising sea levels pose a severe risk to coastal megacities and low-lying islands in the AP region (ESCAP 2022; UNDP 2024). Some cities at risk include Tokyo, Manila, Jakarta and Ho Chi Minh (Cao et al. 2021), while low-lying Small Island Developing States (SIDS) include the Maldives, Tuvalu, and Kiribati (Oppenheimer et al. 2019). Freshwater scarcity is worsening due to changing hydrological patterns, threatening agriculture in critical South Asian river basins and affecting 347 million children under 18 who suffer from high or extremely high

water scarcity (Ahmad et al. 2023; UNICEF 2023; Vakulchuk et al. 2023).

Between 1990 and 2020, the loss of 4.3 per cent of the region's mangrove forests resulted in a 70 per cent reduction in global carbon stock (Stankovic et al. 2023) (UNESCAP 2023). However, the region's vast mangrove forests, particularly in Southeast Asia, offer significant potential for nature-based solutions for both mitigation and adaptation.

Environmental inequalities and climate change contribute to migration and exacerbate existing inequalities. Climate change is intensifying inequality and injustice across AP. In 2022, Asia experienced 81 climate-induced disasters, with over 83 per cent being floods and storms (United Nations 2023).

In 2022, the whole region experienced 140 disasters, resulting in 7,500 deaths and affecting over 64 million people. Climate change significantly influences migration patterns in the region, particularly in the Indian subcontinent, where heatwaves and droughts have driven people from rural areas to cities as a coping strategy (WMO 2023).

Between 2010 and 2021, over 220 million people in AP were displaced due to climate-related events, accounting for more than three-quarters of the global total (Internal Displacement Monitoring Centre 2022). East and Southeast Asia saw the highest displacement numbers, while the Pacific SIDS faced the greatest risks. In 2022, floods accounted for 90 per cent of displacements in South Asia, while in East Asia and the Pacific, 2.7 million people were displaced by floods (International Displacement Monitoring Centre 2022).

Climate action in the AP is ongoing, but more is needed. AP is responsible for about half of global GHG emissions (Ahmed et al. 2022). Between 2019 and 2021, three of the 14 Pacific SIDS nations, five of the 11 G20 countries, three of the 14 least developed countries, and seven of the 10 emerging and developing economies in the AP successfully reduced their GHG emissions (UNESCAP 2023). Although some countries in the AP, such as the Philippines, the Republic of Korea, Indonesia, Nepal and Thailand, have begun implementing policy frameworks for net-zero transitions, overall progress is uneven due to factors such as insufficient technical and financial support.

8.3.4 Priority issue: land-use change impacts on ecosystems

The AP region has undergone extensive land-use transformation to agriculture and pastureland since the 1960s, leading to severe land degradation and a rapid loss of biodiversity and natural ecosystems (Alavaisha et al. 2021; Takeuchi et al. 2021; Kondo et al. 2022). About 40 per cent of the world's agricultural land is in the AP region, of which almost 31 per cent is arable, 4 per cent is used for permanent crops, and 65 per cent consists of permanent meadows and pastures (UNEP 2019). Large areas of islands, inland wetlands, coral reefs, and various forest types in AP have been converted to agriculture and pastureland, and the development has caused a rapid biodiversity loss (Takeuchi et al. 2021). The Southeast Asian countries lost about one-sixth of their forest area between 1990 and 2020 due to global demand for palm oil, timber and rubber (Organisation for Economic Cooperation and Development [OECD] and FAO 2017; Chopra et al. 2022). Agriculture is the major driver for the loss of primary vegetation, followed by urban, infrastructural and industrial developments (Scheyvens et al. 2019). Pastoral and Indigenous agricultural and agroforestry systems are the traditional occupations of Indigenous Peoples, and cultural identities play a vital role in biodiversity conservation and land degradation recovery.

Southeast Asia experiences an annual forest loss of 1.2 per cent – the highest rate of deforestation among major tropical regions (Nanyang Technological University 2023). Agriculture and illegal logging are the leading causes of deforestation and forest degradation. South and Southeast Asia have experienced the largest partial canopy cover loss globally, comprising timber logging at 80 per cent, fuelwood collection at 12 per cent, and uncontrolled fires at 5 per cent. Land degradation, affecting about 8.5 million km^2 or 28 per cent of the AP's land area, poses a significant threat to biodiversity (ESCAP 2022).

Deforestation and forest degradation destroy key ocean and coastal habitats of ecologically important species, weakening biodiversity resilience to climate change due to decreased space for species to shift (Díaz 2019). Deforestation of 32,200 km^2 per year from 2001 to 2019 in Southeast Asia, along with forest degradation, led to increases in GHG emissions, disruption of water cycles, soil erosion, and disrupted

livelihoods (Feng et al. 2021; WWF 2023). Converting mangroves to aquaculture and other land-use types reduces the buffer between sea and land, which increases vulnerability to natural disasters (Scheyvens et al. 2019). The decline of natural wetlands has resulted in a substantial decrease in waterbirds (Xu et al. 2019; Mao et al. 2022), which threatens bird migration across East Asia (Xu et al. 2019). Growing anthropogenic and climate-related factors, including coastal erosion, storm surges, tropical cyclones and rising sea levels, threaten the most productive and biologically diverse coastal habitats, such as mangroves (Kadaverugu et al. 2022).

Asia accounts for three-quarters of the net global tidal wetland decrease between 1999 and 2019 due to climate change, wetland transformation to agricultural and aquacultural lands, and infrastructure developments, of which almost 70 per cent occurred in Indonesia, China and Myanmar (The Nature Conservancy 2022). Coastal and marine ecosystems, including coral reefs, seagrass and mangroves, are important to island nations in AP, but destructive fishing methods and environmental change threaten them (Ross et al. 2019). More than 10,000 km^2 of coastal areas in China have been affected by seawater intrusion due to overexploitation of groundwater for domestic, agricultural and industrial uses (King et al. 2022).

Inland wetlands are disappearing three times faster than forests in Asia (Convention on Wetlands 2021). Between 1700 and 2020, approximately 3.4 million km^2 of inland wetlands worldwide were lost, primarily for conversion to croplands (Fluet-Chouinard et al. 2023). China, India, and Indonesia are among the top five countries that account for more than 40 per cent of global wetland losses (Fluet-Chouinard et al. 2023).

One initiative addressing this is the Sustaining an Abundance of Forest Ecosystems (SAFE) Project: a collaborative initiative between the Korea Forest Service and the United Nations Environment Programme (UNEP) (AFoCo 2023). Since 2023, the initiative has launched multiple projects aimed at conserving and restoring vulnerable forest ecosystems across selected Asian countries, including Bhutan, Cambodia, Lao PDR, and Viet Nam, by prioritizing areas of high biodiversity value (AFoCo n.d.). These ongoing projects aim to address climate change and biodiversity loss by empowering local communities, developing community-based forest management plans, restoring degraded forests, conserving habitats of endangered species, and advancing sustainable forest management practices.

Conversions to agricultural lands mainly cause soil pollution, leading to land degradation. In China, 22.1 per cent of farmland soil had a mixture of contaminants. Chemical industries, agriculture and afforestation-deforestation are significant activities in ASEAN countries affecting soil quality. High levels of lead, copper, zinc, iron and mercury have been detected in the sediments of Pacific SIDS such as Fiji's Suva Harbour. Papua New Guinea, the Solomon Islands and Vanuatu also continue to experience high levels of these trace elements in harbour sediments (FAO 2023). In the Bengal Delta, extracting groundwater for rice irrigation moves arsenic from groundwater to surface soils (Ivy 2023). Approximately 45 per cent of net sown agricultural land was severely degraded, and urbanization increases trace elements, including cadmium, chromium, lead and mercury in urbanized soils of South Asia (Pereira et al. 2023). In Pacific SIDS, land degradation is a major concern. Currently, population pressure, large-scale agriculture using poor agricultural practices, deforestation through commercial logging, mining, dredging, land tenure issues and changing climate have been identified as major factors behind increasing rates of land degradation across the islands in the region (Wairiu 2017; Duncan et al. 2020).

Conversions to agricultural lands led to a loss of natural freshwater resources. AP's rapid economic growth has led to the depletion of natural resources, primarily due to the overuse of groundwater for irrigation (Ahmed et al. 2022). Groundwater loss, commonly greater than 0.5 m per year this century, has rapidly depleted aquifers in major food-producing regions in Asia (Dangar et al. 2021; Wu et al. 2022; Jasechko et al. 2024). As the world's largest consumer of groundwater, India's groundwater has provided 60 per cent of the nation's irrigation supply since 2010. Groundwater loss in northwest India is higher than 20 m and declines at a rate beyond 1 m per year, which is exacerbated by climate change (Dangar et al. 2021; Bhattarai et al. 2023). If current depletion trends continue, there may be a 20 per cent decrease in cropping intensity nationwide and a 68 per cent decrease in groundwater-depleted regions (Jain et al. 2021). The groundwater-depletion rate of China

Credit: © UNEP

was 20.4 km^3 per year on average from 1965–2016, especially in the arid and semi-arid areas of northern China (Huang et al. 2023), where overexploiting groundwater for domestic, agricultural and industrial uses, aggravated by climate change, has caused land subsidence of about 920,000 km^2 (Zheng and Guo 2022). Some parts of northern Jakarta have sunk by four metres over the past two decades, primarily due to illegal groundwater extraction (UNFCCC 2022).

8.3.5 Priority issue: pollution and waste impacts on ecosystems and human health

Cities in AP have experienced combinations of harmful effects from industrial and transportation emissions and the burning of agricultural waste. Globally, six out of the ten countries with the worst air pollution levels are from AP (Rahmayani et al. 2023). South Asia, with the highest population, has the lowest GHG emissions per capita, while East Asia, the second highest population, has very high emissions per capita (IPCC 2022). Although PM_{10} concentrations have decreased in several Northeast Asian countries over the past few decades, including China, Japan and the Republic of Korea, air pollution remains significant (Lee, Song and Choi 2024).

Plastic production in AP countries contributes to emissions and damages human health. Many regions in Asia are hotspots for plastic pollution, with microplastics contributing 80 per cent of global totals, from various sources, that end up in ecosystems (Phuong et al. 2022; Aung et al. 2021). Carbon dioxide emissions from plastic production in China's transportation sector, India's construction sector and Indonesia's electronic sector have increased over fiftyfold since 1995 (Cabernard et al. 2022). Five Southeast Asian countries – Viet Nam, the Philippines, Thailand, Indonesia and Malaysia – are among the world's 10 countries generating the highest volumes of mismanaged plastics, at 1.5 million metric tons per year for these Asian countries (Ng et al. 2023). Plastic pollution harms Indigenous Peoples in coastal and marine ecosystems, wetlands, rivers and forests by contaminating food sources, such as fish and shellfish. It further threatens traditional Indigenous Knowledge and Local Knowledge, innovations, practices, food, health, biocultural systems and traditional ways of life throughout the AP region.

Excessive use of pesticides on agricultural lands is causing water pollution. Countries from South and Southeast Asia are the largest consumers of pesticides (Kumar et al. 2023). Unregulated and excessive use of chemical fertilizers has led to low nitrogen use efficiency, more environmental pollution and enhanced GHG emissions (Kishore, Alvi and Krupnik 2021; Fan et al. 2023). India and China consume more than 42 per

cent of global nitrogen fertilizer (Sapkota and Takele 2023). Agricultural activities have taken a heavy toll on environmental quality in Central Asia (Cheema et al. 2024). Major rivers in Asia, including the Ganges, Irrawaddy, Mekong, Pearl, Yangtze, Yellow, Liao and Amur, are among the largest conduits of pesticides to the world's oceans (Maggi, Tang and Tubiello 2023). Rivers in Central Asia, including Amu Darya, Syr Darya and Chu Talas, are also polluted by industrial waste and agricultural run-off (Liu 2021).

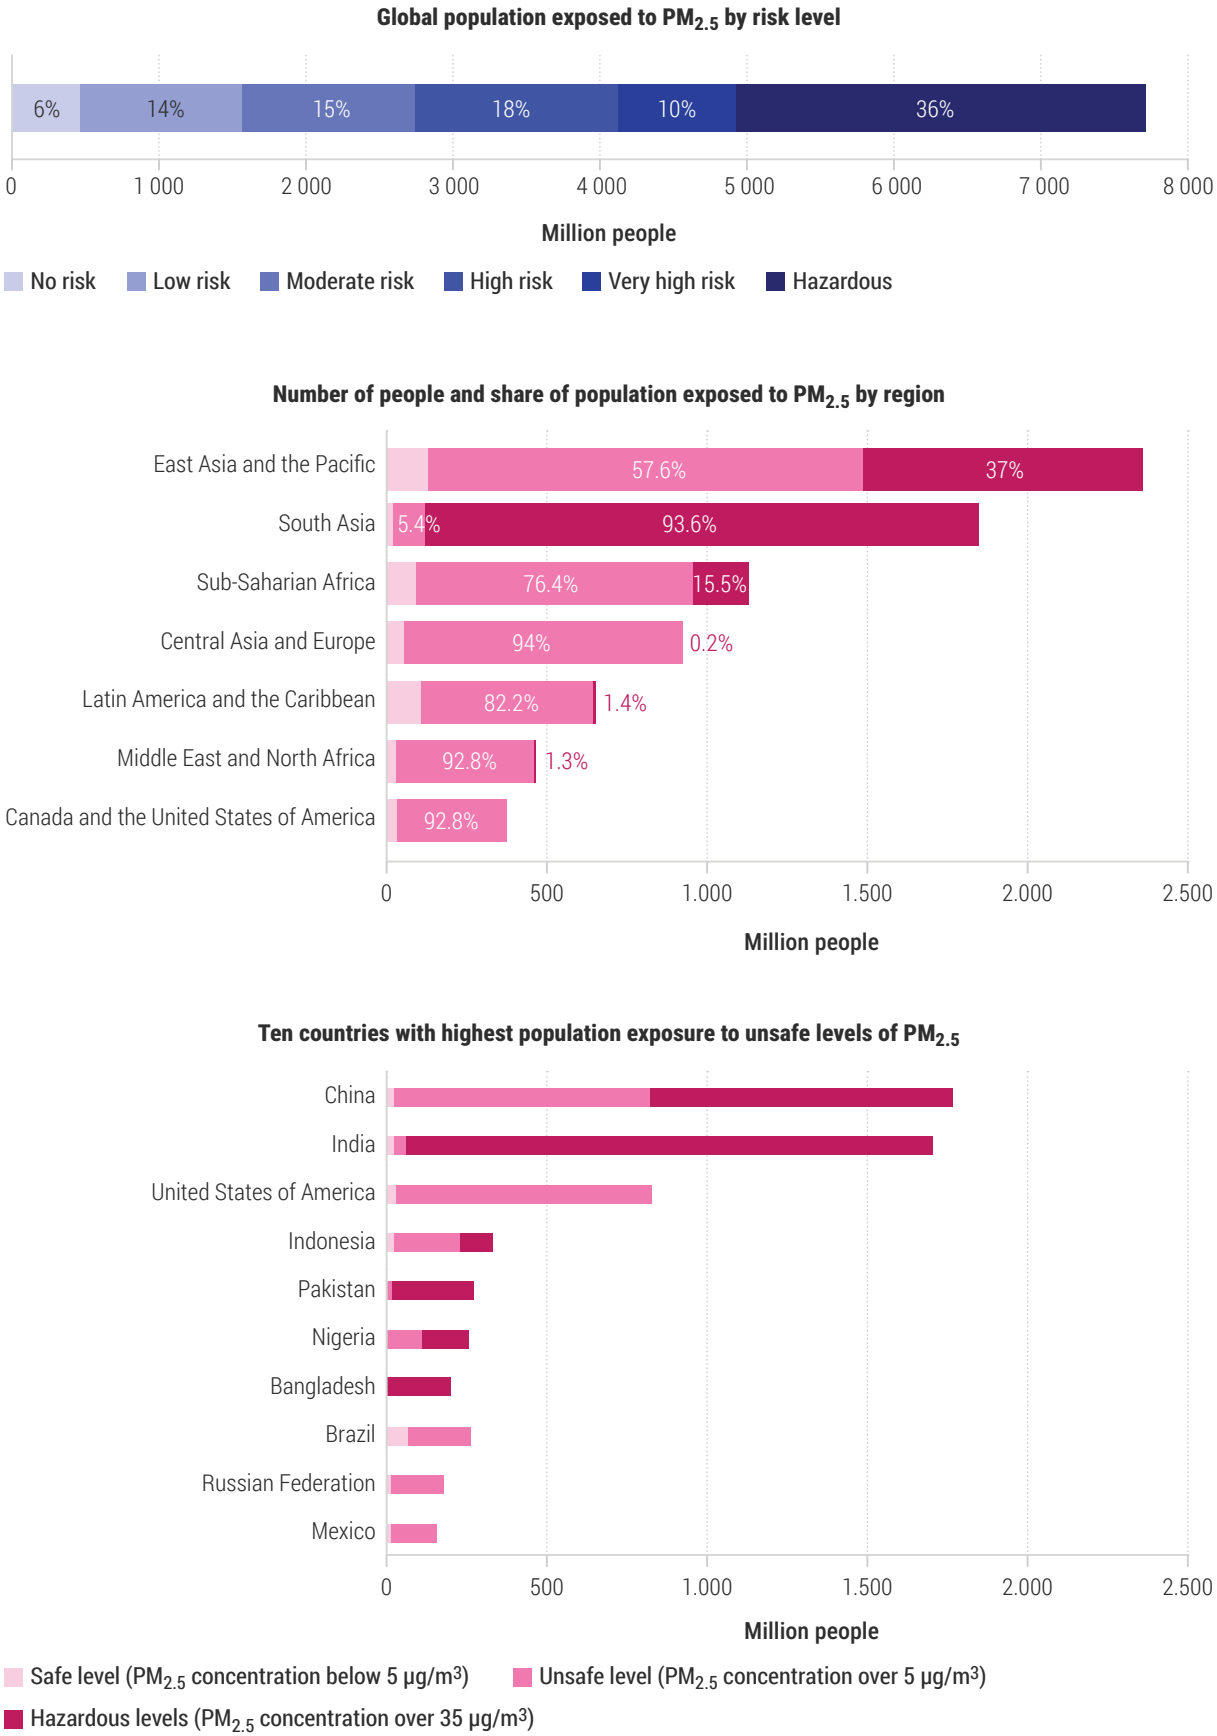
High concentrations of antibiotics from aquaculture expansion were identified in water bodies in many Asian countries, resulting in ecosystem degradation (Tang et al. 2021). There are high levels of aquaculture-related antibiotics in the surface waters of some South Asian countries (Hannah et al. 2023). Aquaculture expansion has resulted in drug resistance in freshwater ecosystems in many Northeast and South Asian countries (Sahar et al. 2021).

Unsustainable industrial practices have threatened the marine and freshwater ecosystems in the AP region. Pollution and environmental degradation threaten nearly 37 per cent of species in freshwater ecosystems in AP (IPBES 2022). Some South Asian countries are among the world's top wastewater-producing countries with the lowest reuse rates, at less than 5 per cent (UNEP 2023). Due to ecosystem degradation, there has been a 50–70 per cent decline in dolphin habitat in Asia (WWF 2019).

Landfill sites in many Asian countries are significant sources of pollution, particularly in terms of water and air. Asia is the largest solid-waste-producing region globally, generating over 800 million tons per year (Agamuthu and Babel 2023). More than half the waste ends up in dumps (Kaza et al. 2018). Open dumping and unsanitary landfill sites in Southeast and South Asian countries are causing unprecedented water and air pollution. Methane emissions from landfills across South Asia and Central Asia are widely reported (UNEP 2021).

Exposure to air pollution in the AP is a significant contributor to premature deaths and economic losses. Air pollution exposure reduces the overall average life expectancy by 1.6 years in Southeast Asia (Greenstone and Hasenkopf 2023). Three-quarters of air pollution's adverse effects on global life expectancy occur in just six Asian countries: Bangladesh experiences an 8.3-year reduction in life expectancy, India a 5.3-year reduction, Nepal a 4.6-year reduction, Pakistan a 3.9-year reduction, China a 3.1-year reduction, and Indonesia a 1.2-year reduction (Greenstone 2023). Together, these six countries account for 75 per cent of the years of life lost due to air pollution.

Of the total population of AP, 99 per cent of those in the South and 95 per cent of those in the East are exposed to unsafe $PM_{2.5}$ conditions (**Figure 8.11**). $PM_{2.5}$ in the air of populous cities is mostly anthropogenic in South and East Asia (IPCC 2022).



Air pollution causes a 9.3 per cent loss of GDP in regions of East Asia and the Pacific, and a 10.3 per cent loss in South Asia (The World Bank 2022). The average loss of productivity among workers due to pollution is eight times higher in developing countries than in developed countries within the AP (World Economic Forum 2022).

In 25 Asian countries, the total economic loss due to premature deaths attributed to $PM_{2.5}$ exposure amounts to US$45 billion, of which 65 per cent of the affected were male. In China alone, pollution caused 879,000 premature deaths in 2017 (Nansai et al. 2020). In some Northeast Asian countries, household fuel consumption for cooking and heating contributed to more than 1.4 million premature deaths in 2019, particularly in rural low-income families (Zhao et al. 2019). Mortality rates increased by 0.36 per cent in China for every 10 μg/m^3 rise in PM_{10} concentration (Xie and Gao 2024). Losses of welfare in South and Southeast Asia due to air pollution are estimated at 7.5 per cent of regional GDP (Jabbar et al. 2022).

The pollution burden in many Asian countries disproportionately falls on the rural population (Shupler et al. 2020). For instance, while urban governance to mitigate pollution in China is getting more stringent, polluters set up factories in rural industrial parks where they enjoy greater freedom to dump toxins into the environment (Zhang 2023). Since 2000, the increase in the number of "cancer villages" – small communities in China located near pollution sources where cancer rates are substantially higher than the national average, currently 462 villages – especially near river basins, indicates how inequality and injustice stemming from pollution create burdens in rural areas (Cui 2020).

The increased cost of healthcare associated with pollution is rising in many countries in Asia, accounting

Figure 8.11: Exposure to air pollution

Source: Rentschler and Leonova (2023)

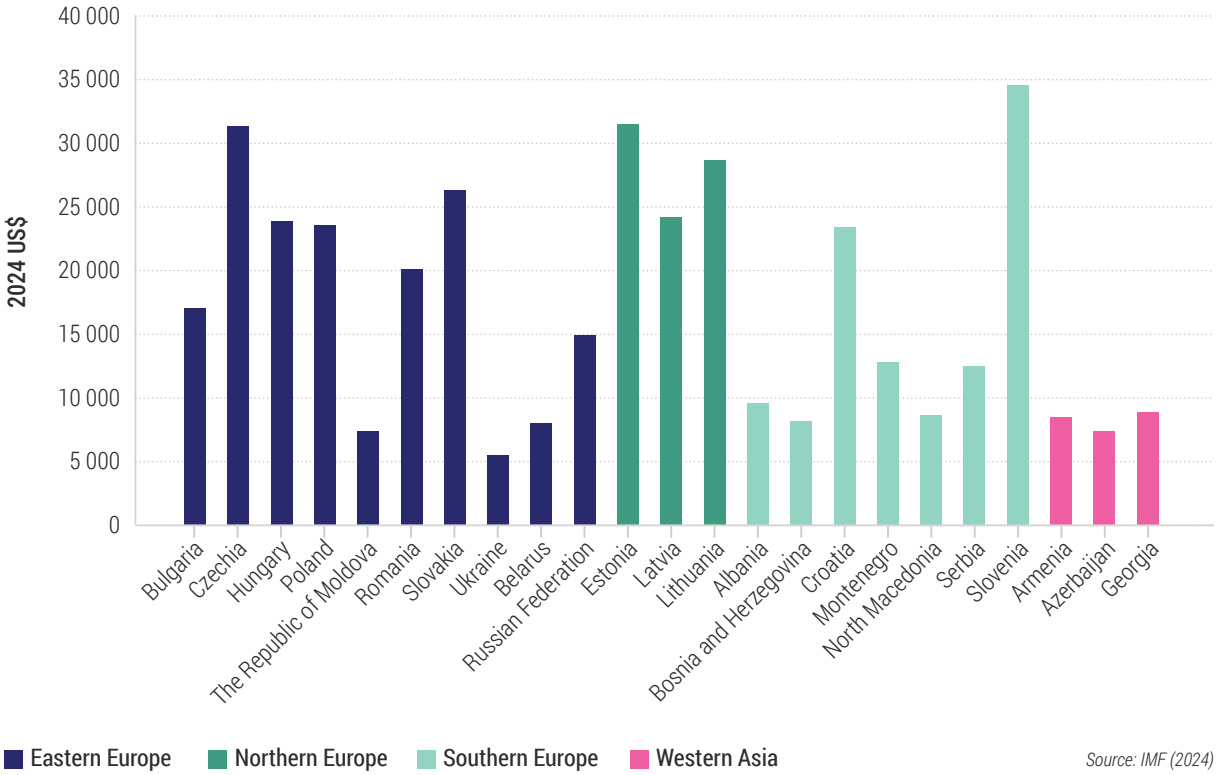
for 92 per cent of the lives lost worldwide due to air pollution. However, only 6.5 per cent of governments in Asia provide accessible data on air quality (IIASA 2023). At 3.3 per cent of global GDP in 2019, older people and low-income groups in South and Southeast Asia incur disproportionately higher healthcare costs related to air pollution (Ma et al. 2023). Twelve million babies in South Asia and 4.3 million in East Asia live in areas where outdoor air quality surpasses six times the WHO thresholds (Jabbar et al. 2022). In addition, economic damages from IQ loss due to lead poisoning accounted for a 2 per cent loss in Asia's GDP (UNICEF 2020).

Health impacts of pollution are unevenly distributed among various sociodemographic groups. South Asia is the hotspot for stillbirths related to $PM_{2.5}$ (Xue et al. 2022). The highest number of annual stillbirths attributable to $PM_{2.5}$ exposure was recorded in India at 217,000, China at 64,000, Bangladesh at 49,000, and Pakistan at 110,000. Incidents of paediatric asthma attributable to nitrous oxide in the air are rising in South Asia and the Middle East (Paciência et al. 2022). Exposure to air pollution contributes to a significantly higher rate of stunting among South Asians, by 38 per cent, compared to the global average (Saif and Anwar 2023). South Asians have a 2–3 times higher risk of cardiovascular diseases and diabetes due to early and lifelong exposure to pollution (Wilder et al. 2024). In addition, women in some Asian countries are at far greater risk of cancer compared to men, being 45 per cent more likely due to indoor air pollution (Chu, Wang and Su 2023).

Five South Asian countries account for approximately 188 million people who are exposed to arsenic-contaminated groundwater (Aryan et al. 2024). Infants and children are more exposed to arsenic-contaminated water due to their smaller body mass. Prolonged exposure can cause impaired cognitive development and DNA damage. Girls are at high risk of cancer due to arsenic exposure (Rana et al. 2022). Dangerous exposures are not limited to arsenic. Research in the Ganges River basin area in India has revealed that the presence of faecal coliforms exceeds safety standards. Exposure to such conditions adversely affects the reading and writing scores of children (Islam and Ghorai 2024).

Hazardous waste in the AP poses a threat to public health and safety. Industry owners gain four times more benefits from ships at the end-of-life cycle than workers and local communities, due to weak regulations and the absence of mechanisms to internalize environmental costs (Mathew 2021). The result is that areas near shipbreaking sites in South Asia are contaminated with carcinogens such as asbestos and polychlorinated biphenyls (PCBs) (Dewan and Sibilia 2024). For instance, 35 per cent of workers from shipbreaking yards in Bangladesh have been diagnosed with asbestosis caused by exposure to asbestos dust due to the lack of workplace safety standards (NGO Shipbreaking Platform 2023). In addition, accidents like explosions, fire and suffocation cause deaths of shipbreaking workers (430 deaths since 2009) in South Asian countries (Wan 2021).

8.4 Eastern Europe and subregions



8.4.1 Introduction

The Eastern Europe (EE) region consists of 23 countries that cover a vast and diverse area, spanning from the Baltic Sea in the west to the Pacific Ocean in the east. It encompasses a wide range of ecosystems, from polar deserts and tundra in the Arctic to subtropical regions in the South Caucasus, and broadleaf forests in the west through boreal forests and steppes to temperate rainforests in the Russian Far East. Most of the countries either belong to the European Union (EU) or are EU accession countries, while a smaller proportion cooperate with the Eurasian Economic Union.

The EE's diverse politics and economics (**Figure 8.12**) have produced different socioeconomic development models across the region. As a result, there are different procedures of environmental policy and planning. Many past and present conflicts, along with their implications, further complicate this complex picture. This can undermine avenues for coherent regional policies and cross-boundary solutions.

Large arable monocultures, which prevail in many EE landscapes, are highly vulnerable to climate change. Climate change is projected to cause a significant increase in water erosion, soil degradation and loss of soil organic matter, undermining water retention and increasing irrigation demands that can lead to salinization. The risk of spring droughts is of particular concern. The abandonment of semi-subsistence farming and extensive management practices, loss

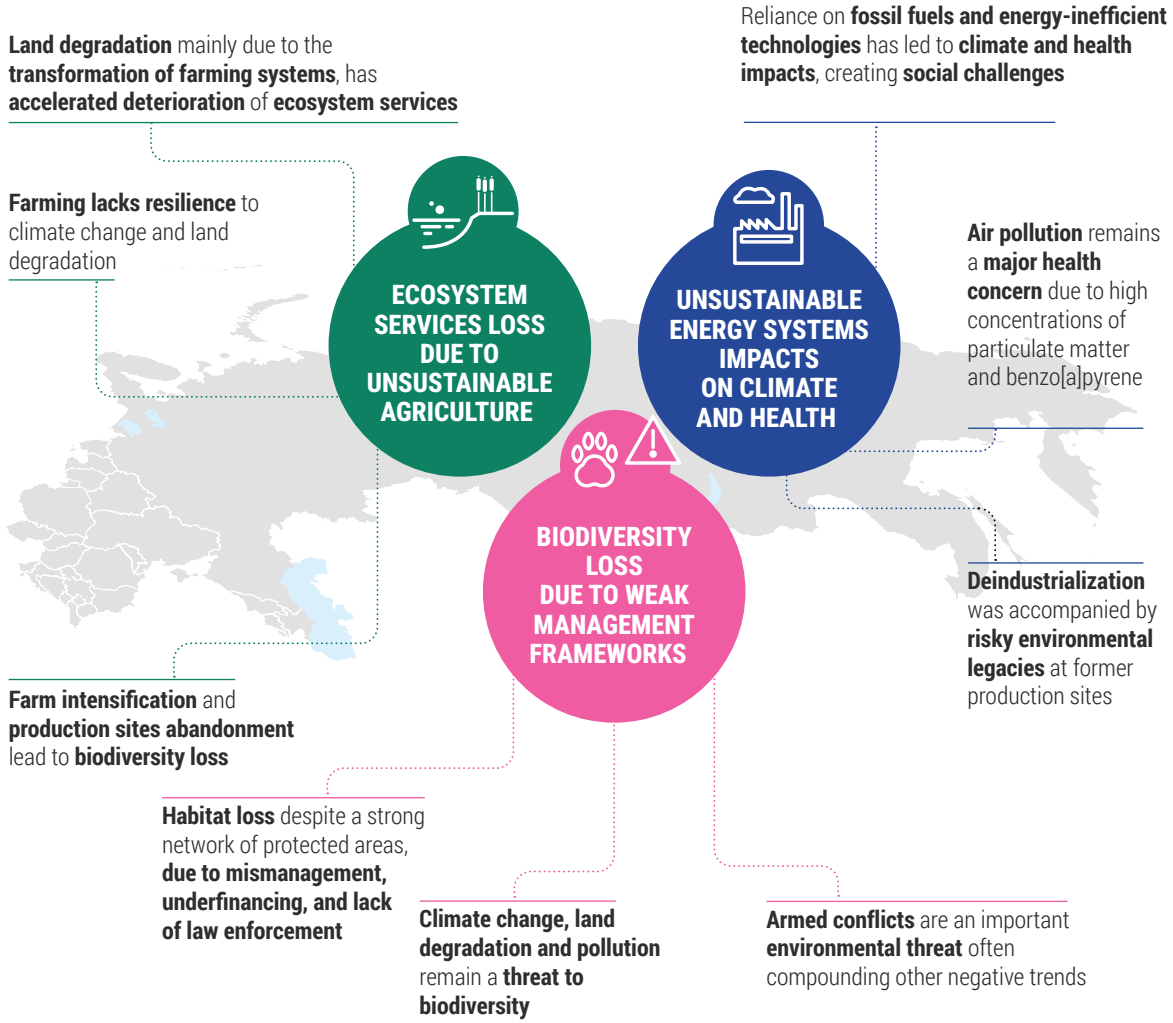
Figure 8.12: GDP per capita of Eastern European sub-regions

Source: IMF (2024)

of local knowledge and high-nature-value farmland are leading to the demise of important resilient agricultural landscapes.

Although EE is rich in a variety of resources that could be used for renewable energy, countries still depend heavily on different types of fossil fuels. Over time, many countries have developed their own fossil-fuel-based energy sources, including coal, brown coal and lignite, among others. Additionally, military conflict in the region has driven a need to find additional diverse sources of natural gas.

Historically, countries in the region established numerous protected areas. Some of these areas are among the largest in the world, such as those protected in the Russian Federation. Proper management of this system, the development of ecological networks, and the preservation of biodiversity remain important priorities that will require more robust management strategies.



Considering the specific nature of EE, the global environmental crises – the crises of climate change, biodiversity loss, land degradation and desertification, and pollution and waste – manifest in three main circumstances (**Figure 8.13**). Land degradation, primarily due to the transformation of farming systems, has accelerated the deterioration of ecosystem services. As well, a heavy reliance on fossil fuels and energy-inefficient technologies has led to significant climate and health consequences, creating social challenges. At the same time and despite a strong network of protected areas, the threat of habitat loss across the region remains high, mainly due to mismanagement, underfunding and inadequate law enforcement.

8.4.2 Interlinkages between the global environmental crises and regional priorities

As in other regions, EE's environmental challenges cannot be understood in isolation. The global environmental crises – the crisis of climate change, the crisis of biodiversity loss, land degradation and desertification, and the crisis of pollution and waste – are intertwined and mutually reinforcing (Global Environmental Crises Chapeau).

In EE, climate change intensifies land degradation through more frequent droughts, flooding and shifting precipitation patterns, all of which impact agricultural productivity. In parts of EE, large-scale monocultures erode soil health and biodiversity, creating a cycle of

Figure 8.13: The interplay of the global environmental crises and regional priority issues: effects on Eastern Europe's ecosystem services, health and energy, and biodiversity

ecological decline. These impacts are compounded by unsustainable land-use practices (Section 8.4.5) (European Environment Agency [EEA] 2019; EEA 2024).

The EE region's reliance on fossil fuels and energy-intensive heavy industries drives climate change and air pollution. High levels of emissions contribute to climate change and degrade air quality, impacting human health. This is especially true in urban areas where pollution from fossil fuels, especially coal, leads to respiratory illnesses and environmental degradation (EEA 2023a).

Pollution and biodiversity loss are also linked. Eutrophicating pollutants originating from point sources such as cities and industrial activities, and non-point sources such as agriculture, affect freshwater quality and inland seas such as the Baltic and Black Seas (EEA 2015; Breitburg et al. 2018; Modabberi et al. 2020). The loss of biodiversity reduces ecosystem resilience, making landscapes more vulnerable (IPBES 2019; United Nations Economic Commission for Europe 2023).

These global crises interact with regional priorities and issues such as ecosystem loss, unsustainable agriculture, energy transformations, the impact of air pollution on human health, and land degradation. Further understanding of the regional priority issues can help to identify how to address and mitigate the global environmental crises in EE (Chapter 20).

8.4.3 Priority issue: ecosystem loss due to unsustainable agriculture

Land degradation, driven by transformation of farming systems, has accelerated the deterioration of ecosystem services across the region.

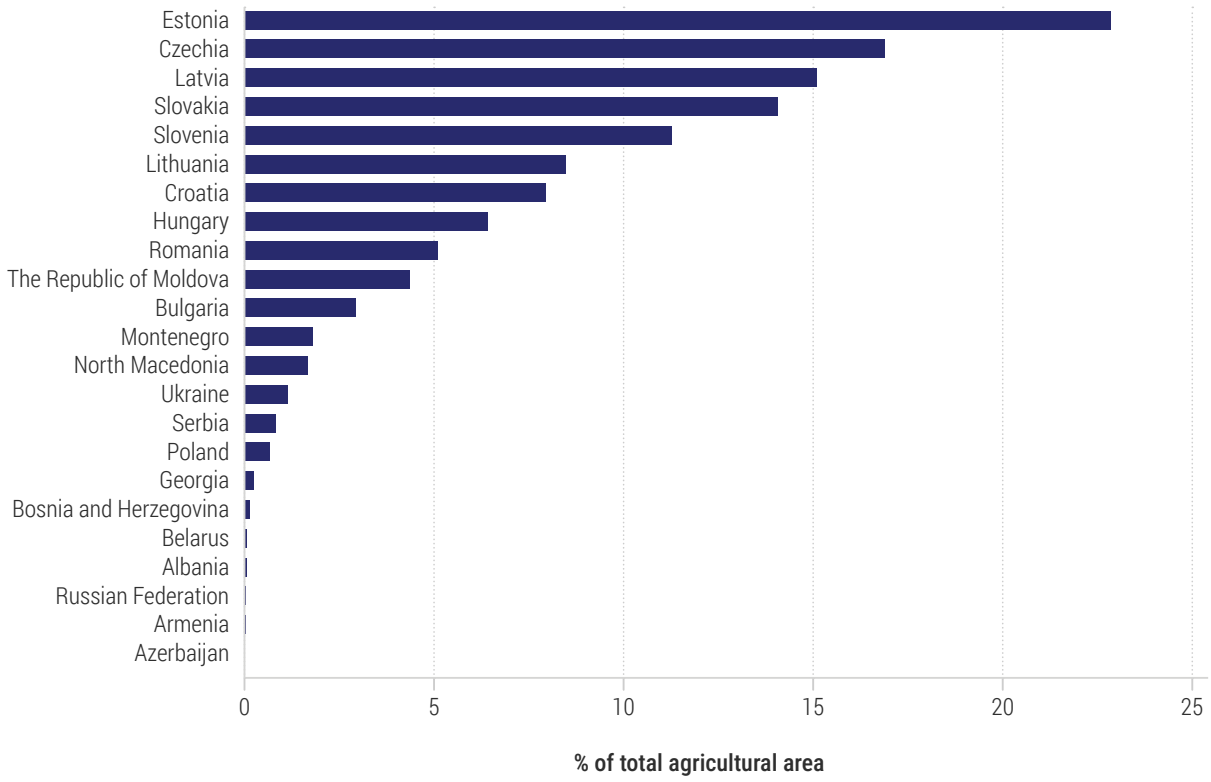
Food systems arguably resist sustainability transition more than other economic sectors in EE, largely due to the increasing polarization of agriculture. Two dominant and contrasting contemporary trends contribute to large-scale degradation of ecosystem services: intensive farming, which leads to soil degradation (EEA 2019; Rigal et al. 2023; EEA 2024); and abandonment of extensive farmland, often associated with rural depopulation and biodiversity loss (IPBES 2018; Dengler et al. 2020). Despite variation in these patterns within the region, the overall trends hold across EE. To date, neither governments nor the farming sector have been able to develop and implement sustainable solutions to address either of these two trends. While large-scale farms remain environmentally unsustainable, an economically viable solution is lacking for extensive management.

Large-scale agribusinesses, often spanning several dozen square kilometres, are often owned and operated by former collective farm managers or newly emerged elites (see also **Box 8.1**). Investment companies – notably in the Russian Federation, Ukraine and Romania – invest heavily in agriculture, focusing on export-oriented grain production (Petrescu-Mag et al. 2020; Uzun et al. 2019; Visser et al. 2019; Tleubayev et al. 2021; Graubner et al. 2021; Khodakivska 2023; Liao and Agrawal 2024). This segment has become an integral part of the global food economy. A substantial part of this grain is used as a source of animal feed (FAO 2024).

The smallholder farming model of some countries in the Balkans and Caucasus, as well as in parts of Poland and Romania, struggles to remain viable. Along with economic pressures, rural depopulation and the ageing of smallholder farmers lead to the cessation of centuries-old practices (Živanović et al. 2022). In some rural areas of Bosnia and Herzegovina, for example, the population decreased by 75 per cent between 1991 and 2023 (Agency for Statistics of Bosnia and Herzegovina [BHAS] 1991; Institute for Statistics of the Federation of Bosnia and Herzegovina [FBiH] 2024). Additionally, the decline of mixed farming due to agricultural specializations has led to the abandonment of extensive grassland plots in arable landscapes previously used to graze livestock and produce hay (Dengler et al. 2020). As a result, EE has been a hotspot of farmland abandonment (IPBES 2018).

Notably, organic farming and, more recently, regenerative practices are emerging as major trends in some countries. The total area of organic farms in EE increased by 18 per cent between 2018 and 2021 alone (FiBL 2025) (**Figure 8.14**). Although these practices are only present in a small minority of farms, the importance of these trends is twofold: local improvement in soil health and the restoration of biodiversity in the short term, which increases climate adaptation capacity; and a path to overcome polarized farming methods in the longer term. If scaled, they may offer a new model for EE food systems that will be both environmentally and economically sustainable.

Farming in EE lacks resilience to climate change and land degradation.



Fields tend to be generally large, reaching dozens of hectares, particularly in the Russian Federation and Ukraine (Lesiv et al. 2019). The region is home to eight of the ten EU countries with the highest average area of arable monocultures (Gális 2020). While the average field size in the EU is 0.04 km^2, the average field size in Slovakia, for example, is 0.12 km^2, and 46 per cent of the fields are larger than 0.3 km^2 (Gális 2020).

Accounting for only 7 per cent of the world's agricultural land but producing 22 per cent of the world's wheat, the EE region is important for global food security. But

Box 8.1: Where has the agriculture in Eastern Europe come from?

The concentration of farms, typical of temperate biomes in the second half of the 20th century, was even more rapid in much of EE than elsewhere due to forced collectivization. However, after the collapse of collective agriculture in the 1990s, paths diverged. While some farms changed hands but retained the pre-1990 highly concentrated structure, land has been returned to smallholders elsewhere (Hartvigsen 2014; Gorgan and Hartvigsen 2022).

Figure 8.14: Share of total agricultural area used for organic farming in the Eastern Europe countries in 2023

Source: FIBL (2025)

large arable monocultures, which prevail in many EE landscapes, are highly vulnerable to climate change. Climate change is projected to cause significant increases in water erosion (Panagos et al. 2021). Soil degradation and loss of organic matter undermine water retention; increased demands on irrigation can lead to salinization; and crop specialization (due to intensive farming models) restrains farmers' choices (EEA 2019; EEA 2024). EE is one of the global hotspots of increasing soil drought (Řehoř et al. 2024). The risk of spring droughts is of particular concern because newly established crops often lack sufficient moisture to support their growth. This lack typically results in reduced yields. Meanwhile, the abandonment of semi-subsistence farming and local knowledge, extensive management practices and high nature-value farmland leads to the demise of important, resilient agricultural landscapes.

Soil monitoring systems have been extensively developed in the EE region, providing large amounts of detailed spatial data (Jones et al. 2005). Despite these resources, intensive farming has led to soil degradation (Ivanov et al. 2020; Golosov et al. 2021; Pozniak et al. 2021; MNRERF 2022; EEA 2023c; Li et al. 2025). Water erosion affects 35–43 per cent of farmland in Caucasus countries, about one-third in the Republic of Moldova and Ukraine, and 26 per cent in the Russian Federation (FAO and ITPS 2015; Bejan et al. 2022). Large-scale farm businesses in the flat landscapes of the Russian Federation, Ukraine and parts of Romania are also prone to wind erosion. In Ukraine alone, the area affected by erosion has increased by 800 to 900 km^2 every year (FAO 2020).

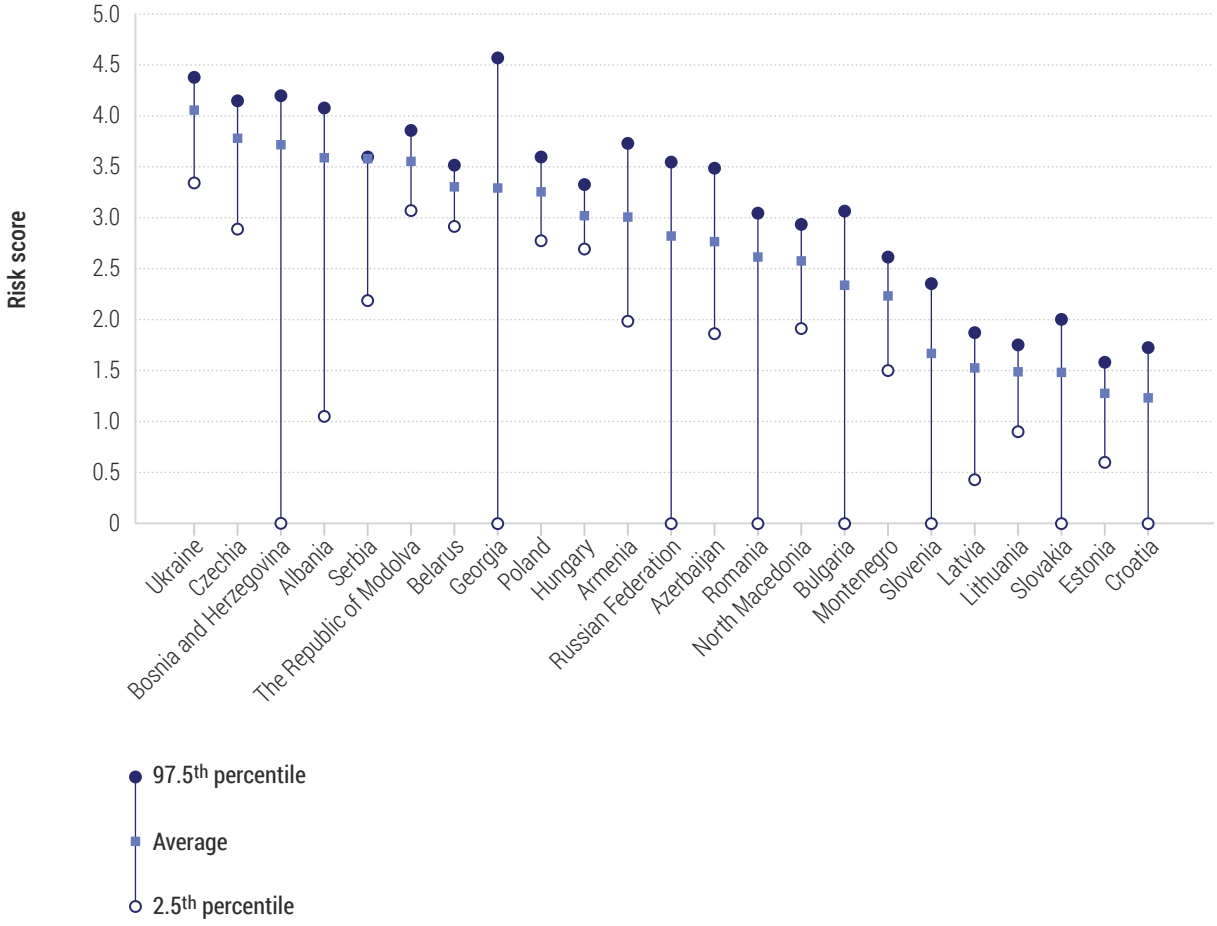
In some countries, most of the land is owned by smallholders but farmed by tenant agribusinesses. In many cases, renting land leads to unsustainable soil use because tenants lack incentives to ensure long-term productivity (Sklenicka et al. 2015). However, soil awareness, a significant movement particularly among the younger generation of farmers, small landowners and the public, is slowly shifting attitudes towards soil as an integral part of the environment, rather than simply a means of production.

Both farm intensification and abandonment lead to biodiversity loss.

The polarized structure of regional agriculture affects biodiversity in two contrasting ways. Large agribusinesses often emphasize intensive farming, a major driver of the rapid decline in biodiversity, as seen in the decrease in common bird species, for instance (Hanzelka et al. 2019; Reif and Hanzelka 2020; Rigal et al. 2023). Globally, EE is the region where very large fields are concentrated more than anywhere else (Lesiv et al. 2019). Landscape homogenization leads to a decline of ecosystem services such as pollination and pest control. In some countries, high inputs of mineral fertilizers and pesticides contribute to biodiversity loss, including the decline of soil biota. Conversion to arable land and intensive management of grasslands – excessive fertilization, re-seeding, overgrazing and high frequency of cutting – decrease species richness in meadows and pastures (Dengler et al. 2020; Török et al. 2020; Karapinar 2021; Pe'er et al. 2022). In EU Member states, Common Agricultural Policy subsidies facilitate increasing agricultural intensity along with stability (Pe'er et al. 2020).

Under certain circumstances, farming abandonment has often had a positive impact on biodiversity. In the steppe region of the Russian Federation alone, the closure in the 1990s of 260,000 km^2 of intensive farms with low productivity led to the restoration of grassland habitats and the prevention of further soil erosion and salinization (Hölzel et al. 2002; Smelansky and Tishkov 2012; Tsymbarovich et al. 2020), while creating a substantial carbon sink (Kudeyarov 2019). The legacy of the Virgin Lands Campaign, a politically driven effort to convert the steppe to arable land in the 1950s and 1960s, has been largely reversed. However, this phase is mostly over.

The current abandonment primarily affects extensive grasslands on dry plains, wetlands, and in mountainous areas. Vacated species-rich farmland that cultivated grasslands, woodland pastures and orchards gradually becomes overgrown with scrub and trees, and landscapes lose their heterogeneity (Török et al. 2018; Dengler et al. 2020; Török et al. 2020; Karapinar 2021). However, traditional farmlands often provide important species-rich habitats (European Commission, Directorate-General for Environment et al. 2016; Török et al. 2020). Ancient, flower-rich hay meadows in the Carpathian Mountains hold global records for small-scale plant diversity, surpassing those of tropical rainforests (Roleček et al. 2025). The ongoing demise of extensive semi-subsistence agriculture and agroforestry is currently the most important cause of biodiversity loss in EE farming landscapes, with devastating consequences for a range of threatened bird, insect and plant species (Tryjanowski et al. 2011; Sutcliffe et al. 2015; European Commission, Directorate-General for Environment et al. 2016; IPBES 2018; Török et al. 2018; Dengler et al. 2020; Török et al. 2020; Prangel et al. 2024).



Many EU countries have implemented agri-environmental payments to prevent land abandonment and intensification, both of which lead to biodiversity loss (Batáry et al. 2015; ECA 2020). These payments influence the economic choices of commercial farmers, often enabling the survival of ancient grasslands (Dengler et al. 2020; Török et al. 2020). However, as these measures are designed to operate on commercial farms under the EU's Common Agricultural Policy, they are less effective in preserving the small-scale mosaic of traditionally managed ecosystems. Furthermore, agri-environmental payments focus on specific farming practices and are poorly suited to reshaping the food systems or addressing wider demographic and cultural changes.

Intensive farming is the key source of nutrient pollution.

The intensive production model of large farm businesses often involves high inputs of agrochemicals. Aggregate pesticide risk is also high in some countries, such as Ukraine, due to the use of relatively small amounts of more hazardous pesticides (Tang et al. 2021) (**Figure 8.15**). There has been a substantial effort to reduce soil contamination by obsolete pesticides since around 2000. However, this issue remains significant in several EE countries (FAO and UNEP 2021).

Heavy application of mineral fertilizers and manure contributes to nitrogen and phosphorus pollution. Average nitrogen and phosphate fertilizer use has increased steadily in recent years, following a decline in the 1990s, ranging from relatively low levels of 20 kg per hectare of cropland in the Russian Federation to 179 kg in Armenia between 2018 and 2021 (FAO 2023). Nitrogen surplus is relatively high in EU countries such as Czechia and Hungary, even if it does not reach the extreme levels of some Western European countries (EEA 2020b). Vast areas of the northern and eastern Russian Federation, as well as some

Figure 8.15: Pesticide risk scores of the Eastern European region

Note: The risk score is calculated as combined ratios of predicted environmental concentration and ecotoxicity of the 92 most used active ingredients in soil, surface water, groundwater and atmosphere.

Source: Tang et al. (2021)

mountain ranges, remain largely unaffected by this threat because the currently harsh climate precludes significant agricultural activity.

Nutrient overload leads to toxic algal blooms in the most stressed rivers and lakes, affecting drinking water quality, the recreation industry and fisheries. The region's main farming lands drain into its three semi-enclosed seas and the world's largest lake, each of which is naturally highly sensitive to water eutrophication (EEA 2015; Breitburg et al. 2018; Modabberi et al. 2020). Agriculture is the key cause of nutrient overload in the Baltic, Black, Azov and Caspian Seas, with some areas affected by widespread hypoxia – a lack of oxygen. Almost half of the total waterborne nutrient inputs in the Baltic Sea originate from agriculture (HELCOM 2023). The Volga River basin, which accounts for approximately 45 per cent of the Russian Federation's agriculture, drains into the Caspian Sea (Mozafari et al. 2023).

8.4.4 Priority issue: unsustainable energy system effects on climate and health

Heavy reliance on fossil fuels and energy-inefficient technologies has led to climate, health and social impacts.

While substantially below the global average, air pollution remains a significant health concern in many EE countries. This is mainly due to high concentrations of particulate matter and benzopyrenes, mostly caused by burning coal for heating individual houses and buildings. Millions of households in EE cities and rural areas still use coal and, to a lesser extent, fuelwood, to heat their homes (UNEP 2021; Zgłobicki et al. 2024; Andersen et al. 2025). The Western Balkans and Poland, in particular, are air pollution hotspots (Health Effects Institute [HEI] 2020; EEA 2023a). Air pollution is responsible for 15 to 19 per cent of deaths in Western Balkan cities (UNEP 2019). The economic

costs of health damage caused by coal power plants are estimated to be in the range of EUR6.1 billion to EUR11.5 billion (equivalent to US$6.8 billion to US$12.9 billion in 2019) (Puljic et al. 2019). Caucasus countries have reached similar levels of air pollution (HEI 2020).

Provisioning systems – a set of elements that interact to transform resources to satisfy human needs – require the use of raw materials, particularly for heating (UNEP 2024) (See also **Box 8.2**). Energy systems in EE countries still depend heavily on fossil fuels, often due to obsolete energy-inefficient technologies that require high energy usage. The transition from non-renewable raw materials to clean energy poses a significant energy poverty challenge. In 2024, millions of people in EE struggled to adequately heat their homes (European Commission n.d.). Nearly 7 per cent of the EU population were behind on utility bills, and around 1 per cent lived in homes with issues including leaks, dampness, or rot as of 2020; 11 of the 23 EE countries are in the EU (Eurostat 2025). These problems remain particularly severe in countries where a substantial portion of the population still relies on solid heating fuels, exacerbating fuel poverty (EEA 2023a). This trend has been reinforced by the rise in energy prices over the past two years since the onset of war in Ukraine (Guan et al. 2023), alongside the reorientation of oil and gas export flows from the Russian Federation to Asia due to the embargo. Meanwhile, domestic extraction of raw materials in EE, the Caucasus and Central Asia remains the world's second highest, amounting to 19 tons per person in 2020 (UNEP 2024).

Coal remains the dominant energy source in the Balkans, driving high emissions and energy inefficiency. In 2022, coal accounted for over 60 per cent of gross electricity generation, with 54 per cent of this coal in the form of lignite (Berlin Process Summit 2022). Outdated infrastructure – much of it over 30 years old – contributes to inefficiencies, while site reclamation activities are often delayed or neglected (Energy Community Secretariat 2021). District heating is also fossil-fuel-based: 97 per cent is based on fossil fuels, with only three per cent from renewable energy (Ali et al. 2022). The energy sector is the largest contributor to GHG emissions in the Balkans region at 53–87 per cent, and coal-based energy production accounts for two-thirds of the region's CO_2 emissions (Berishaj 2021). The carbon intensity of electricity production in the Balkans exceeded that of the EU-27 by more than three times in 2020. In 2019, Balkan power plants emitted 10 times more CO_2 per unit of GDP than those in the EU-27, and this ratio unfortunately worsened in 2020 (Energy Community Secretariat 2021). Similarly, regarding pollution, the Norilsk industrial complex in the Russian Federation, the world's most polluted Arctic region, releases 1.86 million tons of sulfur dioxide (SO_2) annually (Raputa et al. 2019; Kirdyanov et al. 2020).

Recent regulatory efforts in parts of EE showcase a tangible improvement in air quality. In 2019, local

Box 8.2: Forest fuel exports in Eastern Europe

Bioenergy is an essential resource in rural communities. While enhancing the resilience of local economies, fuelwood use can provide an economic lifeline to ancient species-rich management such as coppice woodlands (Camia et al. 2021).

The EE region is a major supplier of biomass for heat and electricity in Western Europe and East Asia (Thurner et al. 2022; EEA 2023d). However, the increasing demand for wood chips and wood pellets used for export accelerates industrial-scale logging of native forests in the Baltic countries (Kuresoo, S., Kuresoo, L. and Lilleväli 2020). The Carpathian Mountains are similarly affected. Consequently, the Land Use, Land-Use Change and Forestry (LULUCF) sector has become a net source of emissions in some EE countries (EEA 2023b). The extraction of dead trees and snags for bioenergy further deprives forest ecosystems of an important resource for species, including birds, beetles and fungi (Thorn et al. 2020; Camia et al. 2021). Unfortunately, many of the region's remaining primary forests are still unprotected (Sabatini et al. 2020). The broader adoption of sustainable forest management practices would help reduce pressure on forest ecosystems.

authorities introduced a ban on household use of coal in the historical city of Kraków, Poland, to reduce urban air pollution. Approximately 65,000 solid fuel furnaces were removed, and particulate matter (PM) concentrations decreased to, or below, statutory levels (European Commission 2023). Similarly, in 2023, Slovenia banned the installation of heating boilers for fuel oil and coal, signalling a shift away from household fossil fuel use.

Transformation towards sustainable landscapes

The use of renewable energy as an energy source varies across EE. According to the IEA (2022), Latvia, Albania, Montenegro and Estonia reached the highest share with around 40 per cent, whereas Armenia at 9 per cent, the Russian Federation at 4 per cent and Azerbaijan at 1 per cent have the lowest. The average share of modern renewables across the whole of Europe, for comparison, was 19 per cent (IEA 2022; Vafeas et al. 2024). Many countries in the EE region support the funding of projects focused on transforming energy systems for positive environmental impacts (Dembicka-Niemiec, Szafranek-Stefaniuk and Kalinichenko 2023) (**Box 8.3**).

The energy transformation and clean technologies will rely on raw materials such as critical minerals, including lithium, cobalt, nickel, titanium and tungsten, among others. The dependence on these raw materials may lead to both environmental and economic risks. For example, disruptions to global markets caused by conflict have exposed vulnerabilities in the secure supply of raw materials essential for industrial production and for the green transition (Koyamparambath et al. 2025).

Across EE, heavy industries began to shrink from the early 1990s, following the fall of the Eastern Bloc. The transformation processes of industrial closures were accompanied by the discovery of high-risk environmental legacies at former production sites (Robb 1994; Bridge 2004). Mining industries often leave heavily altered landscapes. In EE, these pollution legacies have often not been remediated because of funding problems or unclear ownership issues (Harfst and Wirth 2011; Wirth et al. 2018) and improper implementation of legislation. Overall, the post-mining futures of these sites are often perceived as entailing decay, disinvestment, and polluted industrial wastelands (Marot and Harfst 2021).

Box 8.3: Geothermal energy in Eastern Europe

The first geothermal station in the Russian Federation was built in 1966, namely Pauzetskaya on the Kamchatka peninsula. Currently, there are four geothermal stations in the Russian Federation – three on Kamchatka and one on Kunashir Island in the Pacific – with a total capacity of about 88 MWt (National Association of Oil and Gas Service [NANGS] 2022).

Geotermia Podhalańska S.A. was the first installation in Poland, which was established in 1993 to utilize geothermal resources, contributing directly to a reduction in SO_2 concentration by approximately 68 per cent over the period 2004–2018, lowering suspended PM_{10} concentrations and reducing CO_2 emissions (Geotermia Podhalańska S.A. n.d), as well as developing energy clusters to increase the use of geothermal resources with a joint initiative in the region (Czaplicka-Kotas, Kulczycka and Iwaszczuk 2020).

Slovakia has significant potential to use geothermal energy and contribute to a decrease in GHG emissions. In 2023, the EU's Just Transition Fund allocated more than EUR 56 million, equivalent to US$60 million in 2023, to support geothermal energy and heat distribution in the Košice region. Ďurkov, with its geothermal wells, has been designated as a national project. It is also one of the largest geothermal projects in the region (Geotermálna Energia 2024).

A significant opportunity lies in utilizing geothermal energy for both heating and spas in the Carpathian Region (Lis and Savchenko 2022).

Credit: MaplesImages/Envato

However, there are now good examples for the proper management of these areas, including both reclamation of coal mines, as demonstrated by good management of the post-mining area in the Upper Silesia region, and metal recovery from waste, as conducted by ZGH Bolesław SA in Poland, as well as reclamation towards tourism facilities. Such success often depends on particularly unique or salient examples of the mining heritage – not least United Nations Educational, Scientific and Cultural Organization (UNESCO) World Heritage sites, such as the Wieliczka Mine in Poland (Pactwa et al. 2021).

Nowadays, extractive industries continue to generate significant volumes of waste across most EE countries, even though the total share of these activities occupies a relatively small share of countries' land use. Locally, however, they can have severe impacts. As extractive waste constitutes a large proportion of total waste in this region, its management is critical as part of the transformation to a circular economy. Monitoring systems should consider the exploration, extraction, and physical and chemical processing of ores and other minerals, in line with the waste management hierarchy (Kulczycka and Dziobek 2021).

Across the region, many sites still store waste from historical mining activities. However, these legacy sites are increasingly viewed as strategic assets. The EU Green Deal and the New Industrial Strategy for Europe recognize access to raw materials and the security of supply from both primary and secondary sources as essential for the EU's transition to sustainability (Nowaczek et al. 2021). Recovering raw materials from post-mining heaps and dumps, as well as from urban mining, could play a role in this transition. Additionally, in 2025, the European Commission, as part of the Clean Industrial Deal, proposed creating an EU Critical Raw Material Centre to purchase raw materials jointly.

Mining has left a diverse range of environmental concerns across EE. The most severe environmental concerns included the loss of landscapes, aesthetic degradation, surface water and groundwater pollution or depletion, air pollution and loss of biodiversity. Although some of these concerns have already been realized, others pose ongoing potential risks (Kivinen et al. 2020).

8.4.5 Priority issue: biodiversity loss due to weak management frameworks

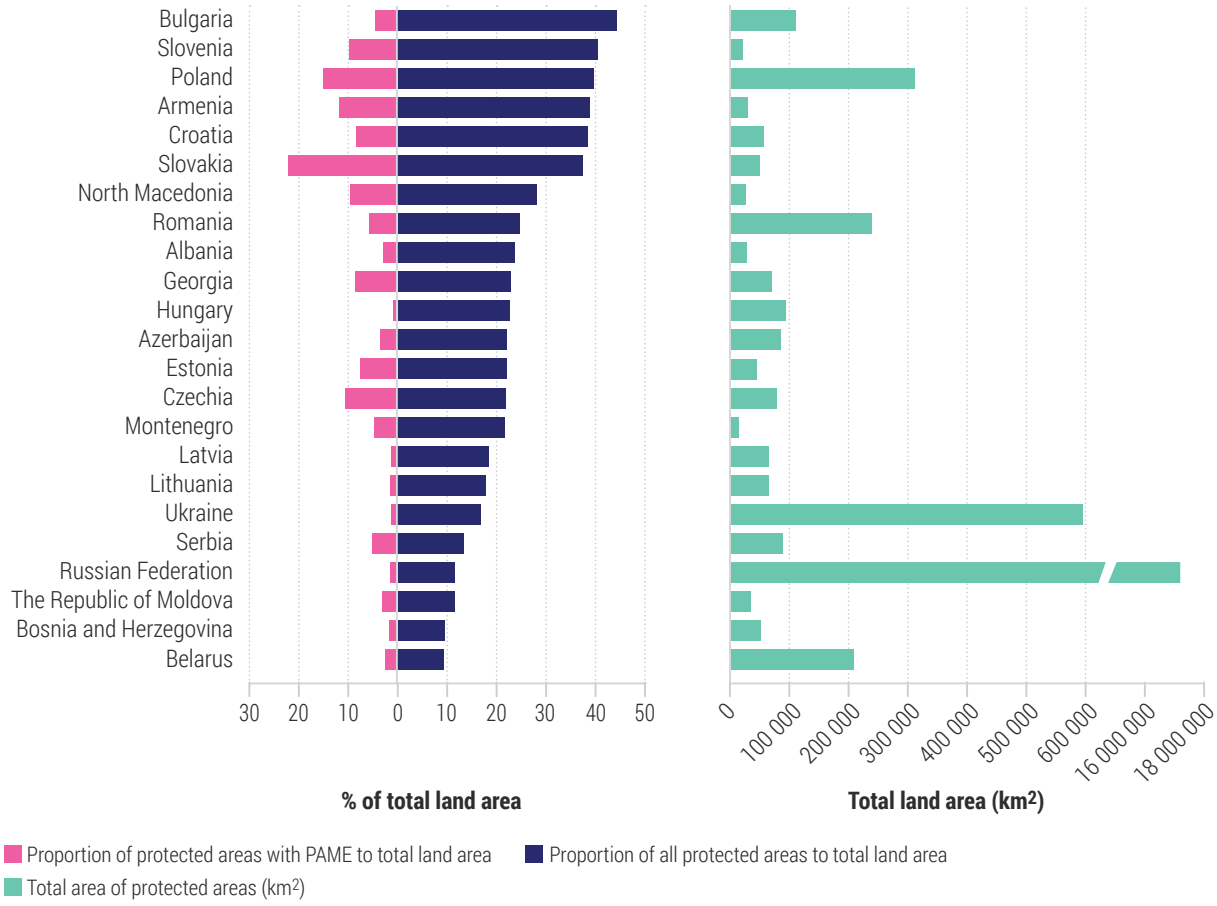
Despite a strong network of protected areas, the threat of habitat loss across the region remains high, mainly due to mismanagement, underfunding and inadequate law enforcement.

In many EE countries, a system of protected areas started to develop in the 19th century. During the 20th century, it grew significantly, with iconic sites including the Danube and Volga River deltas, Białowieża/Byelavyezhskaya Pushcha, the Tatra Mountains, Kazbegi, Wrangel Island, Baikal, Sikhote-Alin and many others. The EE region gave rise to many early conservation efforts by establishing strict nature protection areas. The idea of ecological networks also originated in EE. The green networks developed within Natura 2000 and Emerald are of critical importance (IPBES 2018).

Protected areas already cover more than 30 per cent of the land area in six countries – Armenia, Slovakia, Slovenia, Bulgaria, Poland and Croatia - achieving the target of the Kunming-Montreal Global Biodiversity Framework (**Figure 8.16**). The Russian Federation has the most protected areas, numbering 11,900, and the greatest expanse at 2,421,000 km^2 in 2021 (MNRERF 2022). Over the last two decades, protected area coverage in EE increased by approximately 150 per cent in the Republic of Moldova, 100 per cent in Azerbaijan, 75 per cent in Ukraine, 37 per cent in Georgia, 29 per cent in the Russian Federation, 26 per cent in Armenia and 17 per cent in Belarus (EEA 2020a). Meanwhile, protected area policies evolved towards sustainability principles that aim to provide economic and social benefits along with biodiversity objectives (Yakusheva 2019).

If properly maintained and developed, the protected area system can partly offset the biodiversity loss that is occurring due to adverse trends in land-use change. The ability of EE states to maintain and expand this network, however, is uncertain in the current economic and political context. Key conservation institutions are often understaffed, underfunded, and lack the systems and resources to ensure efficient management of their countries' vast natural heritage (Novikau 2021). Species protection lacks comprehensive data and is often limited to a few flagship species. Illegal logging, hunting, fishing, overgrazing and unsustainable infrastructure development within protected areas remain as chronic threats (Brochet et al. 2019; Zazanashvilli et al. 2020; Cazzolla Gatti et al. 2021; MNRERF 2022; Shytov and Shytov 2022; Shytov 2023; Ghoddousi et al. 2024). A typical example is the Hutovo Blato Nature Park in Bosnia and Herzegovina, a wetland of international importance, especially for migratory birds and endemic fish species, and recognized by the Ramsar Convention. The park suffers from degradation due to logging, the development of tourist facilities and weekend houses, the exploitation of mineral resources, and agricultural development (Hrelja 2019).

Biodiversity of the region is affected by negative trends outside of protected areas.



Climate change is mostly affecting biodiversity in the Arctic and mountain regions due to the melting of glaciers and permafrost soils (Álvarez Fernández 2021; Shivanna 2022). There is a threat of growing methane release from melting permafrost in the tundra during summer. Methane concentrations at the Tiksi and Teriberka monitoring stations in the Russian Federation Arctic have grown from 1,900 ppb in 2012 to up to 2,000 ppb in 2021 (MNRERF 2022).

Climate change is partly responsible for the increase in forest fires and pest outbreaks in Siberia and in the Balkans, along with other human-made factors, including forest monocultures and inadequate forest management (Alfthan et al. 2015; Alikadić et al. 2016; Ratknic et al. 2018; Natole et al. 2021; Kharuk et al. 2021; Kharuk et al. 2022; Ponomarev et al. 2023; Luo et al. 2024; Mataković et al. 2024). In turn, forest fires and diebacks also contribute to the release of greenhouse gases (GHGs).

Land-use change is the major direct driver of change in both biodiversity and ecosystem services degradation in EE (IPBES 2018; FAO 2021). Biodiversity is threatened by intensive agriculture and unsustainable forestry (Pe'er et al. 2022; Kjučukov et al. 2022; Rigal et al. 2023). In the past, local knowledge pertaining to soil management and land sustainability was replaced by uniform types of cultivation that do not necessarily respect the local environment, as discussed in Section 8.4.3. Hydropower dams produce renewable electricity but have a significant influence on rivers and impede native freshwater fauna. In the Balkans, a region with exceptionally high levels of fish species richness and endemism, around 3,000 small-scale hydropower dams are planned, although they are often in conflict with the EU Biodiversity Strategy. Some 90 per cent of the projected hydropower dams are small and will contribute little to the total installed capacity but will have a significant impact on river fragmentation (Carolli et al. 2023).

Soil degradation threatens soil biodiversity by compromising or destroying the habitat of the soil biota (Section 8.4.3). Agricultural lands had the highest

Figure 8.16: Proportion of protected area, including terrestrial and inland waters areas, with and without Protected Area Management Effectiveness (PAME) assessment in Eastern Europe

Source: UNEP-WCMC and IUCN (2025)

levels of threats to soil biodiversity. The EE countries have up to 10 per cent of their soils ranked at a high level of threat, while the boreal region has the lowest threat because of the small share of agricultural lands (CEEweb for Biodiversity 2021). Soil biodiversity tends to regenerate in abandoned and fallow arable land as monocultures disappear, and fertilizers and pesticide applications cease (Pulleman et al. 2022).

Microplastic pollution has considerable consequences for biota, the environment and public health (Savuca et al. 2022). Agricultural crop quality, the growth and photosynthesis of plants, and biodiversity are threatened by the presence of microplastics (Dong et al. 2021; Yang et al. 2021). In addition, microplastics can adsorb and transport contaminants, such as heavy metals and other pollutants, in soil and river environments (Castan et al. 2021). Moreover, the health of soil organisms and the enzymatic activities of these organisms are disturbed by microplastic contamination (Boughattas et al. 2022).

More than 80 per cent of marine pollution, with a high proportion of plastic material, comes from land-based activities (Dobrzycka-Krahel and Bogalecka 2022). Pressure at the coast from mismanaged plastic packaging and small non-packaging plastic items is particularly intense in the Mediterranean Sea and the Black Sea. The total amount of mismanaged plastic packaging waste at the coast even increased in these two regions from 2012 to 2018, while in the Baltic Sea, it slightly decreased (Veiga et al. 2022). Plastic waste represents 95 to 100 per cent of marine floating waste and 50 per cent of litter on seabeds in the Mediterranean Sea (UNEP/MAP and Plan Bleu 2020). Plastics make up 83 per cent of the marine litter found in the Black Sea. Plastics are the most common litter category in the Baltic Sea (Veiga et al. 2022). Rivers constitute critical pathways of the transport of litter from land into the sea. An average of 7.5 g of plastic litter per 1,000 m^3 s^{-1} with respect to the mean flow (4.2 tons per day or 1,533 tons per year) is transported via the Danube to the Black Sea (Lechner et al. 2014). Marine plastic

pollution has increased tenfold since 1980 (Veiga et al. 2022; Savuca et al. 2022), while air and soil pollution are also on the rise (FAO and UNEP 2021; HEI 2022; Chen et al. 2024).

The EU Nature Restoration Regulation is the first continent-wide, comprehensive law of its kind, and a key element of the EU Biodiversity Strategy (Hering et al. 2023). Relatively well-preserved habitats and healthy populations of many species in EE countries provide policy opportunities not available in the western parts of the continent. Restoring nature in forests, wetlands and grasslands in EE is often easier and less costly than in northwestern Europe. Rather than restoring ecosystems from scratch, national implementation of the Nature Restoration Regulation in Balkan, Baltic and Central European countries will often entail improved management to realize the biodiversity potential of existing land cover. For example, the region's nearly 2.3 million km^2 of peatlands are a globally significant ecosystem (Karapinar 2021). Many of them are degraded, offering prime opportunities for restoration.

Indigenous Knowledge and Local Knowledge (IK & LK) are widespread within EE, and provide unique insights into environmental challenges in the region.

The Russian Federation Arctic, encompassing vast areas of taiga and tundra, is home to approximately 30 groups of Indigenous Peoples, with a total population of around 180,000 (Russian Association of Indigenous Peoples of the North 2021). Many still work in traditional occupations, such as reindeer herding, as well as hunting and fishing. The continued expansion of extractive industries and infrastructure projects on Indigenous Peoples' lands leads to toxic pollution and environmental damage. Under current legislation, they have rights to their land in principle. However, none of the "territories of traditional nature use" have been implemented at the federal level so far (Sharapova et al. 2022). In 2020, the Russian Federation adopted the Arctic Development Strategy, which envisions the implementation of investment projects, social and economic development, improving the quality of life for the local population, and creating a stable financial basis for traditional lands in the form of a special fund (Novoselov et al. 2021). Often, incoming companies provide local people with compensation in the form of modern technology, such as snowmobiles and radio sets, which enable them to conduct their traditional husbandry more effectively and partly offset the gradual decline in the herder population. On the other hand, there are concerns that the Russian Federation has withdrawn from the Framework Convention for the Protection of National Minorities and is one of the few countries in the world not to have endorsed the UN Declaration on the Rights of Indigenous Peoples. Additionally, due to ongoing geopolitical confrontations, the long-term cooperation in the Arctic region between the Russian Federation and the EU has been suspended.

Traditional knowledge of extensive farming is an important dimension of biodiversity in many EE rural regions (Section 8.4.3). Conservation of agrobiodiversity is closely linked to socioeconomic issues, so globalization and EU rules could affect the use and existence of old, traditional and native genetic material. In today's post-communist countries, traditional knowledge concerning land tenure and cultivation was disrupted by the collectivization of land, which led to the ploughing of biodiversity-rich boundaries between fields and the cultivation of monocultures in large fields. These practices destroyed significant components of ecosystems and their biological diversity. The local knowledge was replaced by unified planning. Currently, it is possible to observe the emergence of farms that practise regenerative agriculture and utilize the local knowledge of the older generation.

Biocultural heritage use, such as wild food and medicinal plants gathered in natural and seminatural habitats, remains common practice in many rural parts of the region (Varga et al. 2019; Łuczaj et al. 2019; Vári et al. 2020; Babai et al. 2020; Pruse et al. 2021; Aziz et al. 2022; Nowak-Olejnik and Mocior 2022). Informal food markets that locally sell home-made products contribute to the sustainability and diversity of food systems (Soukand et al. 2022). Interestingly, these traditions are increasingly popular in modern city markets and create food tourism in some EE countries, providing a new and economically viable value for local knowledge (Soukand et al. 2022; Luković et al. 2024). The increased use of quality labels to highlight traditional regional products, promoted by EU policies, is an example of local knowledge preservation and realization.

Similarly, food production in family allotments and gardens is a local tradition widely practised, with surprisingly large environmental and social benefits. The Russian Federation's dacha gardens produce a significant share of the country's food output, especially

Box 8.4: The influence of conflicts in the EE region on the environment

The war in Ukraine, which escalated on 24 February 2022, has already resulted in environmental repercussions unprecedented since World War II. Some critical natural areas in the war zones are currently being damaged or destroyed (Pereira et al. 2022).

Besides the direct destruction of natural and human-managed ecosystems and the loss of associated ecosystem services, the long-lasting environmental effects of war include widespread contamination of soils, water resources and biota by persistent pollutants, comparable to the consequences of large-scale industrial disasters (Solokha et al. 2023). There is significant destruction of infrastructure in the war zone, of towns and villages, oil refineries, bridges and dams. The destruction of the Kakhovka dam resulted in massive flooding of the downstream area and a change in the hydrological regime of the lower Dnipro River. Nuclear power stations in Zaporizhzhia on the Ukrainian side and in Kursk on the Russian Federation side are located close to the war zone, with all associated risks. The problem of landmines left by war is both profound and long-term. Unprecedented rehabilitation action will be required as soon as the war has ended (UNEP 2023). The war in Ukraine also spurred a massive migration of hundreds of thousands of people out of the conflict areas (United Nations High Commissioner for Refugees 2025).

Environmental damage is also evident in the Russian Federation, as well as in the Black Sea. The damages in the Black Sea and its littoral zone may result in a spillover of environmental consequences to other countries (Pereira et al. 2022).

A peculiar aspect of post-conflict situations is the significant change from pre-war ecosystems. Bosnia-Herzegovina experienced a military conflict three decades ago, and diverse consequences have become evident. The human pressure on ecosystems decreased due to depopulation.The original agricultural landscapes are either non-existent or have undergone considerable transformation. An example of such a change in Bosnia-Herzegovina is the plant succession in the Sarajevo Canton area, as well as the spread of *Pinus mugo* due to reduced grazing by sheep (Ljusa and Custovic 2025). The depopulation of mountain areas has encouraged the spread of species such as *Pinus heldreichii* (Bosnian pine), an endemic and relict Balkan-Apennine pine species (Meštrović 2007). Depopulation has also led to fewer people harvesting medicinal plants, sometimes to the point of overexploitation, which has contributed to the revival of many species.

in fruits and vegetables. Half of Poles and one-third of Hungarians grow food at home, and 18 per cent of the Czech consumption of fruit, vegetables and potatoes comes from garden plots (Jehlička 2021). Research shows that families do not grow their own food out of necessity, to cope with shortages and economic crisis. They view it as a cultural tradition and part of local identity, a hobby and a source of healthy, fresh food, inadvertently creating what researchers call a "quiet sustainability" model (Jehlička 2021; Daněk et al. 2022). Indeed, the practice is common in affluent countries of Central Europe and occurs almost evenly across society, irrespective of education, employment status or income (Jehlička 2021; Daněk et al. 2022).

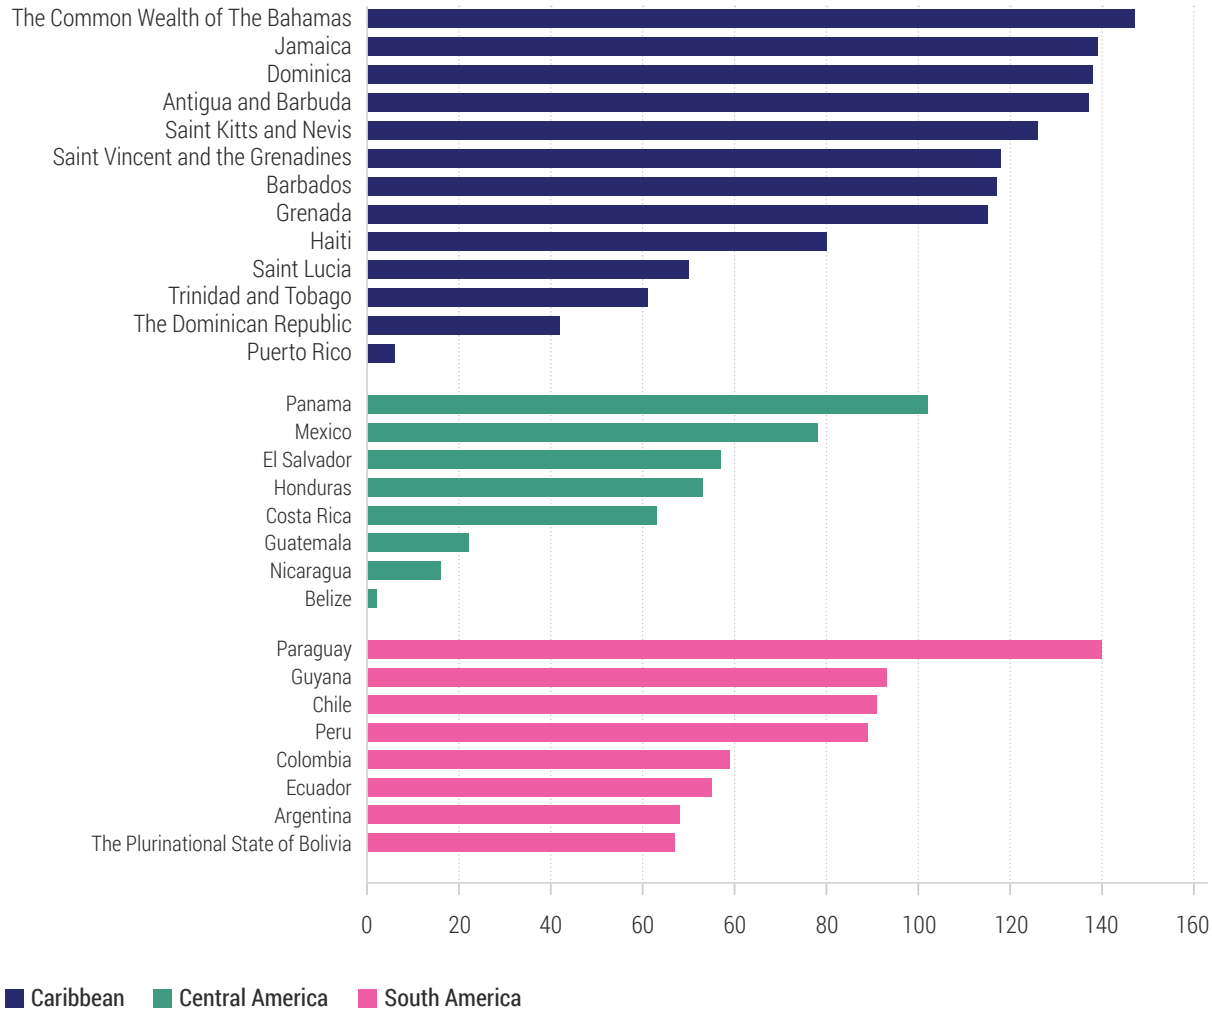
8.5 Latin America and the Caribbean and subregions

8.5.1 Introduction

Latin America and the Caribbean (LAC) is home to more than 664 million people, of whom 81.86 per cent live in an urban setting (World Bank 2023). The region encompasses 33 countries in three subregions – the Caribbean with 13, Central America with 8 and South America with 12 countries – and covers more than 19 million km^2 of land and 16 million km^2 of maritime territory with over 70,000 km of coastline. LAC constitutes a significant global freshwater

Credit: wirestock/Envato

reservoir, accounting for approximately 30 per cent of the world's water resources. However, the region faces substantial disparities in the distribution of this essential resource, with nearly 25 per cent of the region's population residing in water-scarce areas (Lentini 2022; Rodríguez et al. 2022). Agricultural and livestock activities account for 70 per cent of freshwater demand, while household and industrial use represent 11–15 per cent and 15–19 per cent, respectively (Lentini 2022).



The LAC region is home to a vast array of ecosystems and species. The region includes six megadiverse countries – Brazil, Colombia, Mexico, Peru, Ecuador and Venezuela – providing opportunities for global conservation (UNEP-WCMC 2020). The region's extensive marine territory encompasses 19 Small Island Developing States (SIDS), the Mesoamerican Barrier Reef and other vital marine environments (UNEP 2020), and 47 global marine ecoregions (Tambutti et al. 2020).

The region is also characterized by a diversity of cultures, peoples, languages, traditions and histories. This diversity contributes to vibrant national identities, but it also poses challenges related to social cohesion and equitable development (UNESCO 2020). While there are prosperous countries in the region, at both national and subnational levels, the region also faces significant socioeconomic challenges, including inequality, poverty, and unequal access to and control over basic services such as water and energy (Economic Commission for Latin America and the Caribbean [ECLAC] 2021).

The global environmental crises – climate change, biodiversity loss and land degradation, and pollution and waste – interact and generate effects differently in various parts of the region, necessitating nuanced and localized approaches to address specific challenges (UNDP 2019) (**Figure 8.17** and **Figure 8.18**).

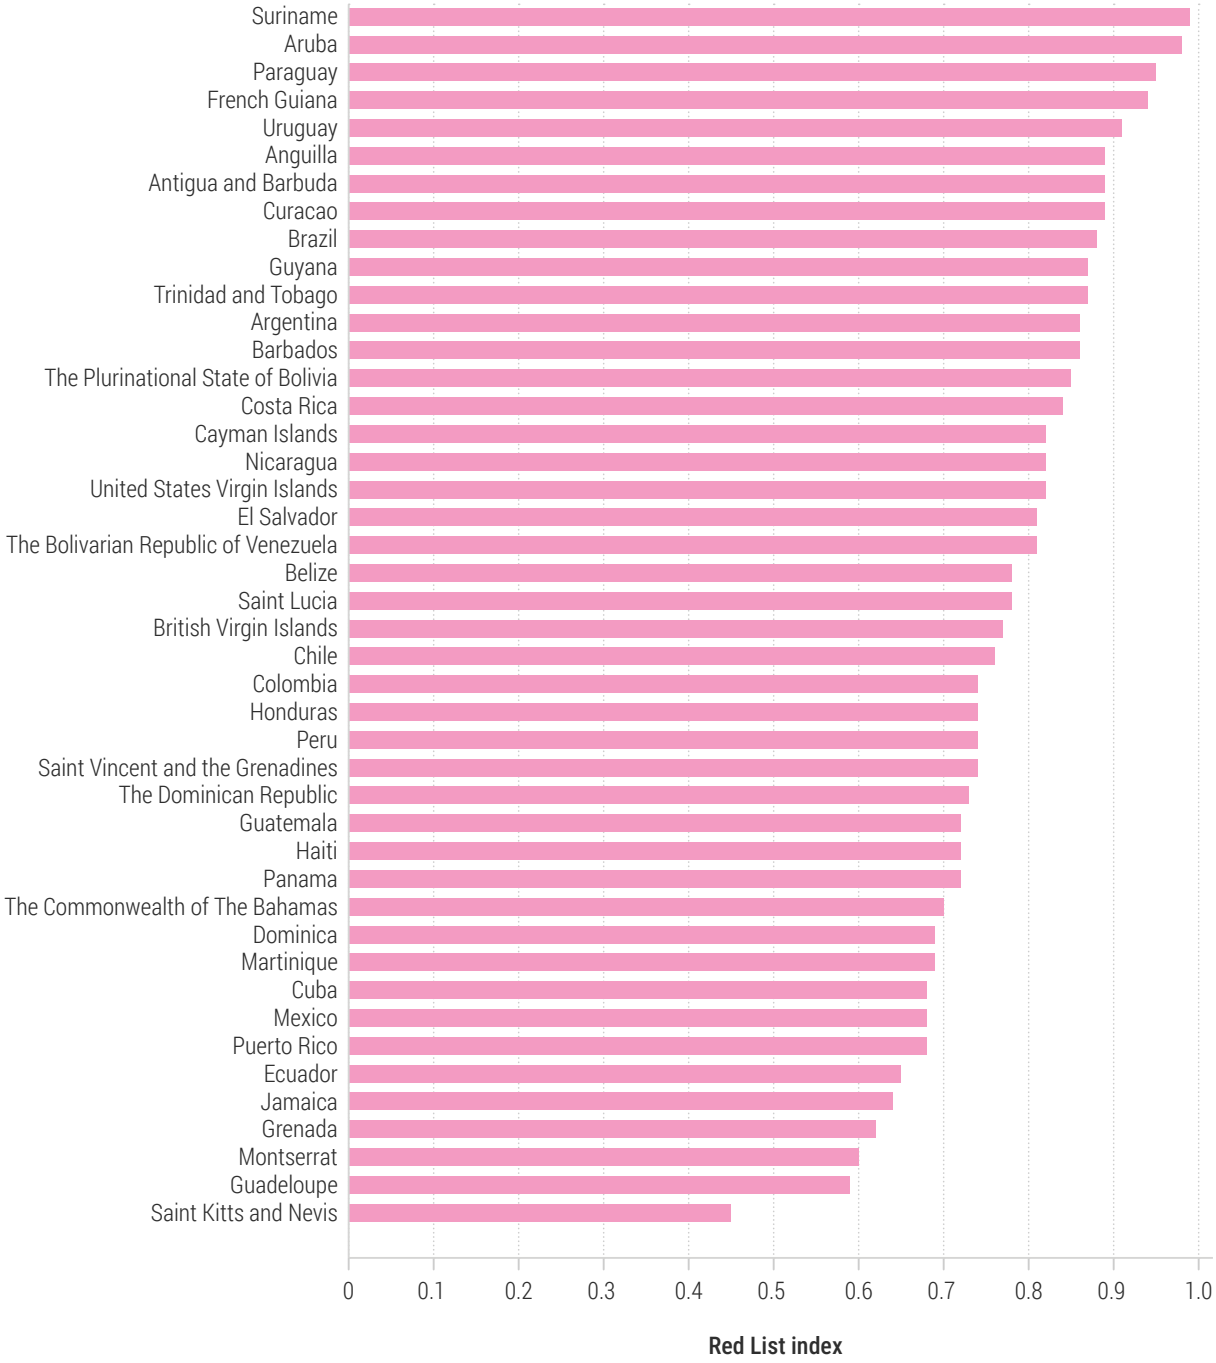
The global environmental crises – encompassing climate change, biodiversity loss, land degradation and desertification, and pollution and waste – threaten the delicate balance of the region's ecosystems, especially with regard to deforestation and soil erosion, leading to consequences for biodiversity and human well-being (IPBES 2019). In this context, most

Figure 8.17: Latin America and the Caribbean Climate Risk Index (CRI) 2022

Note: The CRI indicates how extreme weather events affect countries. It is a backward-looking index (previous 2 years) that ranks countries by their health and human effects (fatalities and affected, injured, and homeless people). Higher numbers mean countries that have been more affected in the past two years by extreme weather events.
*The countries not included in this figure do not have data available

Source: Germanwatch (2025)

countries face significant vulnerabilities and social gaps, including hunger and food insecurity. Many of these issues affect Indigenous and other minority groups in a disproportionate way (UNEP-WCMC 2020).



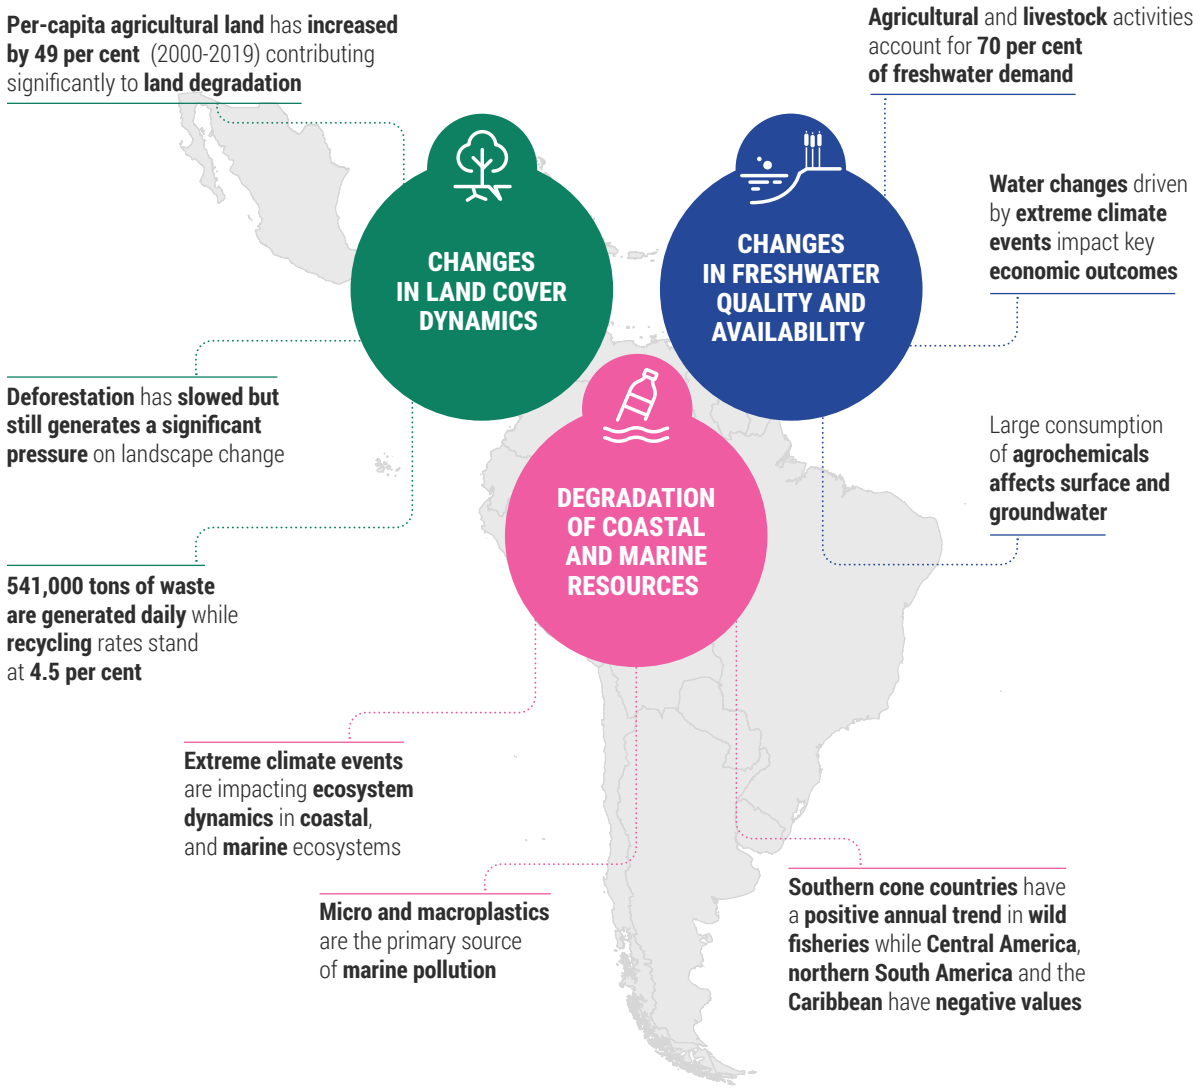
8.5.2 Interlinkages between the global environmental crises and regional priorities

The global environmental crises act in synergistic ways as driving forces of environmental change (Global Environmental Crises Chapeau). For LAC, this report has identified three key priorities (**Figure 8.17**) where the interlinkages among the crises lead to significant consequences for people and ecosystems:

- changes in land-cover dynamics
- changes in freshwater quality and availability
- degradation of coastal and marine resources

Land-cover dynamics refer to how biophysical processes on land interact with each other, and how human activities might affect them. Climate change aggravates desertification (IPCC 2019; Hagen et al. 2022), increases wildfire risks (Hagen et al. 2022; Jones

Figure 8.18: Red List Index 2023 for countries in Latin America and the Caribbean



Note: The IUCN Red List Index determines the overall extinction risk of animal, fungus and plant species. A Red List Index value of 0 equates to all species having gone extinct and a value of 1 indicates that there is no current extinction risk to species.

Source: IUCN and BirdLife International, processed by Our World in Data (2024)

et al. 2022), and affects the range of endemic species (Silva et al. 2019; Tovar et al. 2022). Biodiversity loss, primarily due to land-use changes such as urbanization and agricultural expansion, reduces ecosystem services, resulting in a less resilient environment (IPBES 2018). Land degradation, exacerbated by unsustainable farming and deforestation, decreases soil fertility and increases migration (UNCCD 2019; UNCCD 2022). Pollution from land sources contributes to biodiversity loss (Laterra et al. 2019) and climate change.

Changes in freshwater quality and availability have significant effects in the LAC region. Climate change

Figure 8.19: The interplay of the global environmental crises and regional priority issues: effects on Latin America and the Caribbean's land cover dynamics, freshwater quality and availability, and coastal and marine resources

alters hydrometeorological patterns, affecting the intensity and frequency of rainfall (Carvalho et al. 2020), and leading to ecosystem stress (Sheldon 2019) and land degradation (Hermans et al. 2021). Pollution from agrochemicals, microorganisms, industrial compounds and plastics, as well as soil erosion and other forms of land degradation, threaten water quality (Warren-Vega et al. 2023). Biodiversity loss and land degradation significantly impact freshwater regulation ecosystem services (IPBES 2018).

In the LAC region, coastal and marine resources are degrading at an accelerated rate due to anthropogenic activities (Tambutti et al. 2020). Greenhouse gas emission overload causes ocean acidification (Findlay and Turley 2021). Together with climate change's extreme events, such as ocean heating, this leads to coral bleaching (Cortes et al. 2020). Rising sea levels drive onshore land degradation through erosion and the salinization of coastal soils and aquifers (Hagen et al. 2022). Marine pollution results mainly from land-based sources. Microplastics and hypoxic zones are becoming increasingly prevalent in marine and coastal areas (Tambutti et al. 2020). Overall, the loss of coastal ecosystems exacerbates the impacts of other crises.

8.5.3 Priority issue: changes in land-cover dynamics

How we change the land alters, and in most instances degrades, global environmental processes. LAC is home to a diverse range of ecosystems, from tropical rainforests to some of the driest deserts on Earth, which provide the region with a higher-

than-average availability of natural resources per person (IPBES 2018). The regional emphasis on extractive industries and agricultural activities can constrain the capacity of ecosystems to maintain this supply of natural goods and services. Land-use changes – including deforestation, habitat conversion and agricultural expansion – also affect water regulation ecosystem services and can lead to land degradation. Many of these initiatives have generated socioecological conflicts: by 2018, more than 60 per cent of the environmental defenders killed in the world were from Latin America (Picq 2020). Indigenous Peoples and local communities are disproportionately affected by such conflicts (Billon and Lujala 2020).

The interacting global environmental crises affect land-cover dynamics in the region.

Climate change contributes to desertification, particularly in areas adjacent to existing deserts and drylands (IPCC 2019). Some areas of northeastern Brazil are undergoing desertification, due to decreasing rainfall and increasing deforestation (Burrell et al. 2020). Wetlands, too, are drastically transforming as drying trends persist in some areas of Mexico and Central America, which threatens migrating bird species (Xi et al. 2020).

Climate shifts affect species distribution, resulting in disruptions to ecosystem composition and function. Climate change consequences are more substantial on endemic species, as their habitat conditions and ranges are more restricted. The most prominent adverse effects are on terrestrial endemic species in South America, with about 30 per cent of assessed species threatened with extinction (Manes et al. 2021). Climate change in mountainous areas causes whole ecosystems to migrate and fragment as they move upward. Andean grasslands will dry out and be invaded by trees, while the cloud forest will shrink due to the reduction in cloud immersion and frost in the Tropical Andes (Helmer et al. 2019).

Climate change also increases wildfire risks in LAC (IPCC 2023). Record heat and low humidity in 2022 led to more than a 200 per cent increase in hotspots in Brazil, Paraguay and Argentina (WMO 2023). In the case of the Amazon, the lengthening of the dry season may be catastrophic for its rainforest, increasing vulnerability to forest fires (Hagen et al. 2022).

The interaction between climate change and land degradation in the Amazon highlights the interlinkages of global environmental crises. Deforestation in the Amazon generates substantial warming over distances as far as 100 km from the forest-loss location (Butt et al. 2023). Deforestation and forest degradation also generate GHGs, but at the same time contribute to the savannization of the Amazon rainforest, a form of land degradation with profound livelihood impacts both to Indigenous and local rainforest dwellers, and people in the Tropical Andes (Quintanilla et al. 2022).

Deforestation has slowed in the region, but it still generates significant pressure on landscape change (FAO 2020). Between 1992 and 2022, the area deforested in the LAC region reached approximately the size of Guatemala, Belize, Honduras, Nicaragua, Costa Rica and Panama combined (FAO 2025). While forest cover has decreased in South and Central America, it is increasing in the Caribbean. Forest fires are the predominant pressure in the tropics, primarily used for clearing forests to establish cattle ranches or for agriculture (FAO 2022). Although mangroves are regrowing in South America and the Caribbean, their numbers continue to decline in Central America (**Figure 8.28**) (FAO 2020). According to the Living Planet Index, from 1970 to 2020 in LAC, trends in the viability of wild populations of monitored terrestrial, marine and aquatic vertebrates declined by 95 per cent (World Wide Fund for Nature [WWF] 2024).

LAC is the only region where per capita agricultural land has increased, emphasizing its role as a global food producer. Habitat transformation continues throughout South America – particularly in Brazil, Paraguay and the Plurinational State of Bolivia, among others – where tropical ecosystems are being converted into agricultural fields and pastures (UNCCD 2019). Between 2000 and 2019, agricultural land in South America expanded by 49 per cent, with 61 per cent of that expansion occurring on land usually left fallow for long periods or pastures (Potapov et al. 2021). In the Caribbean, agricultural land area remains nearly constant, while it has decreased slightly in Central America (FAO 2023a). The loss of habitats is expected to continue, particularly in South and Central America (Powers and Jetz 2019).

Current management practices in South and Central America have contributed to soil degradation (Prăvălie et al. 2023). As soil productivity declines, more

land needs to be cleared to maintain production. Furthermore, the more land cleared, the more agricultural expansion significantly contributes to land degradation in the Amazon Basin, the fragile Andean grasslands (UNCCD 2019) and the Southern Cone pampas (Song et al. 2021; Foucher et al. 2023). In Uruguay, grasslands were converted into forest plantations in the mid-1990s and, after 2000, into soybean fields, resulting in increased erosion rates.

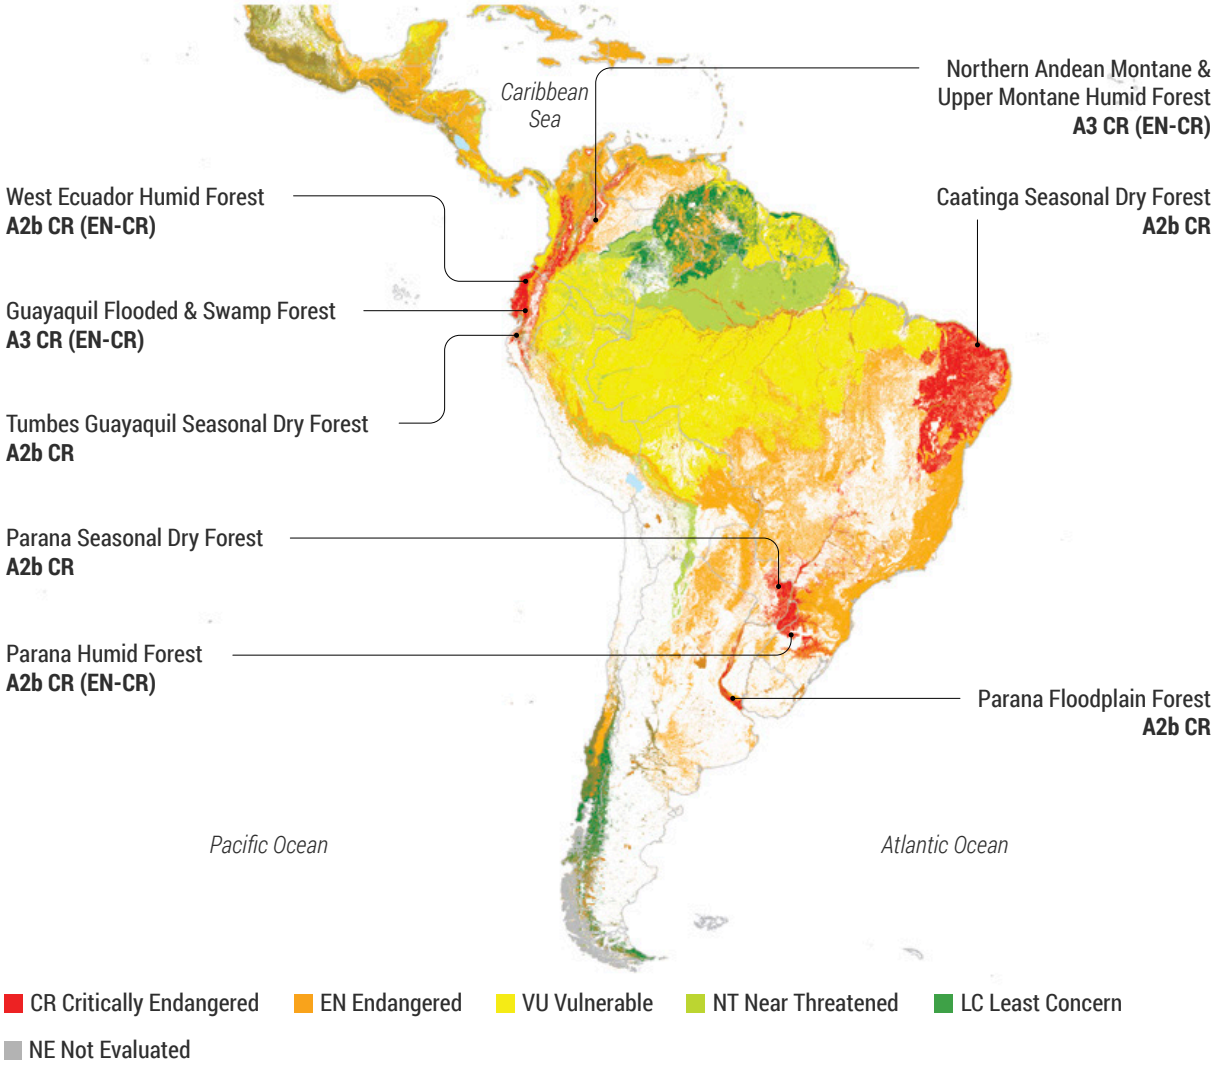
Land-use competition also contributes to the transformation of ecosystems. In the Caribbean, a land-limited subregion with an abundance of natural assets, particularly beaches, the lack of regulation or enforcement and the marginalization of local communities contribute to unsustainable land-use changes. Tourism has a direct effect on coastal ecosystem loss through urbanization and infrastructure development at the expense of natural vegetation and rural land use. An example from coastal Belize indicates that natural vegetation declined nearly 11 per cent, while urban areas increased by 39 per cent between 2000 and 2017 (Sweetman et al. 2019). The development of tourism infrastructure in the Mexican Riviera Maya, for instance, has intensified resource depletion and disrupted traditional and Indigenous livelihoods, undermining land-management practices in ancestral territories (Fernandez et al. 2020).

Moreover, land degradation contributes to rural–urban migration because land no longer guarantees the subsistence of smallholder families. In Central America, severe soil degradation is associated with drought. Areas in Mexico (Nuevo León, Oaxaca) exemplify how soil degradation has forced the displacement of rural communities (Méndez et al. 2010).

Urban air pollution is recognized as one of the most pressing environmental issues in LAC, especially in the form of particulate matter (PM) (Gómez Peláez et al. 2020). Although data are limited (Gómez Peláez et al. 2020), $PM_{2.5}$ and PM_{10} exceeded the WHO guidelines between 2010 and 2017 in the assessed cities (Gouveia et al. 2021). Furthermore, the region does not show a strong trend in reducing PM pollution.

In LAC, 541,000 tons of waste are generated daily, and this is expected to increase to at least 640,000 tons by 2050 (UNEP 2018). Higher-income countries, such as Chile and Trinidad and Tobago, tend to generate more waste than lower-income nations, such as Haiti and Nicaragua (Margallo et al. 2019). Six SIDS are in the region's top 10 countries in terms of waste generation (Margallo et al. 2019). Although waste management has improved, about 27 per cent of waste is disposed of in open dumpsites (UNEP 2018). Primarily an urban phenomenon, there is limited information on the status of rural areas, where the use of agrochemicals affects both land and freshwater systems.

Urbanization may generate pollution hotspots that degrade local and regional air, land and water conditions. For example, climate change exacerbates urban heat islands in the region (Palme and Carrasco 2022), where more than 80 per cent of the population resides in urban settlements (ECLAC 2023a). The use of biomass as fuel for cooking and heating, mostly in rural households but also present in urban settings, is a critical source of indoor air pollution (Jorquera et al. 2019; Manzano et al. 2022).



Changes in land-cover dynamics have impacts on natural and human systems.

Current land management in LAC continues to degrade terrestrial ecosystems (IPBES 2018; UNEP 2019). Since the beginning of the 20th century, forest cover in the region has declined from 70 per cent to 50 per cent (UNCCD 2019). Most of the region's remaining forests (**Figure 8.20**) face some level of threat (Ferrer-Paris et al. 2019).

Forest deforestation and regrowth influence water regulation ecosystem services in the Andean subregion (Bonnesoeur et al. 2019), while to the east, in the Chaco, poor land management contributes to a decrease in soil organic carbon, which in turn affects water regulation ecosystem services (Baldassini and Paruelo 2020). Agrofuel production in the region relies heavily on fresh water, particularly when based on sugarcane and palm oil plantations (Zhong et al. 2021).

Land-cover dynamics affect the ability of soils to provide ecosystem services. The capacity of vegetation to protect soils declined between 2001 and 2013 in large areas of Argentina and Brazil (Guerra et al. 2020). Results also suggest that between 2006 and 2013, erosion risk increased in South and Central America. Approximately one-third of this risk is attributed to vegetation dynamics, while the remaining two-thirds is a result of climate change. The erosion rates in South

Figure 8.20: Latin America and the Caribbean forests risk assessment

Source: Ferrer-Paris et al. (2019)

America are expected to increase by 37 per cent under current scenarios of climate change by the end of the 21st century (Riquetti et al. 2023).

Changes in wildlands and poor agricultural management contribute to erosion, leading to sedimentation on floodplains and coastal areas (Fagundes et al. 2021). Sea levels in LAC have increased at a greater rate than those in the South Atlantic and the subtropical North Atlantic (WMO 2023). Sea level rise poses a significant threat to the livelihoods of growing coastal populations (Tambutti et al. 2020).

In the LAC region, fire plays a crucial role in the transformation of forests into agricultural land (Armenteras et al. 2021) and in the management of agricultural land (Mendez-Espinosa et al. 2019). Fires in the Amazon and northern South America have significantly deteriorated air quality across vast portions of the basin, including places far away from the fires (Butt et al. 2020; Ballesteros-González et al. 2020). Research shows that from 2018 to 2021, people's exposure to extreme high fire danger increased in 9 out of 12 South American countries compared to the baseline period of 2001–2004 (Hartinger et al. 2023).

Fuelwood remains a dominant cooking fuel for rural LAC households (Schilmann et al. 2021). Wood collection occurs in forests and agricultural landscapes. Estimates of the number of fuelwood users range from 70 to 160 million as of 2021 (Schilmann et al. 2021). Large-scale deforestation in the remaining forested landscapes may lead to a scarcity of fuelwood for rural populations.

Agricultural production is very heterogeneous in LAC. Agroindustrial operations coexist with small, subsistence farms. The region is a leading exporter

of agricultural products, including soybeans, livestock, maize and coffee, among others. Brazil is the largest agricultural producer and exporter in the region, followed by Argentina, Mexico and Chile (FAO 2023a). Despite LAC being a food basket, malnutrition is persistent, with greater impact on people with lower income, women, Indigenous and Afrodescendant Peoples (PAHO 2023). For example, Indigenous communities in the Amazon depend on nearby resources produced in home gardens or collected in the forest or rivers. The expansion of agro-industry and mining contributes to habitat destruction and biodiversity degradation, compromising Indigenous nutrition and food security (Penafiel et al. 2019; Bergazo-Curie and Vranken 2025). As a result, landscape transformation has affected local and Indigenous communities, disrupting their traditional land management and cultural practices (Aoki et al. 2016). This loss of knowledge is also evident in LAC's Afrodescendant communities. Traditional knowledge, brought from Africa to Latin America, is being eroded by industrial agriculture and natural resource extraction, affecting communities in Colombia, Peru, Ecuador, Brazil and Venezuela. These activities caused the displacement of many Afrodescendant communities (Mosquera-Vallejo 2020).

Agriculture has led to the intensive use of agrochemicals, with consequences for rural populations (Timmerman 2019). However, the effects are not limited to rural areas, as these compounds can also reach urban dwellers through air currents and contaminated food (Hendges et al. 2019).

Sea level rise reduces suitable lands for agriculture in SIDS and other coastal areas, and it leads to increases in food-borne, waterborne, and vector-borne diseases, such as malaria and dengue, as well as to increases in premature deaths.

Recycling rates in LAC are approximately 4.5 per cent (Kaza et al. 2018), with the majority being informal (Ziglio and Ambrizzi 2024). Some of the solid waste associated with agricultural practices in the region requires the intensive use of plastics, making recycling difficult (Cadena et al. 2021). In LAC, estimates indicate that food waste accounts for between 8 and 10 per cent of the food weight entering households (Chen et al. 2020). These amounts of waste can be considered as an additional pressure to transform wildlands into agricultural fields.

8.5.4 Priority issue: changes in freshwater quality and availability

Increasing water scarcity and decreasing quality form a dual threat to nature and people.

Although LAC holds 30 per cent of the world's freshwater resources, 25 per cent of its population lacks access to safe drinking water, and 66 per cent still do not have adequate sanitation services (ECLAC 2023a). Climate change, land degradation, and pollution are exacerbating the freshwater crisis in LAC (IPCC 2022a), with changes being experienced in both water quality and availability.

The interacting crises affect the region.

Climate change affects LAC's freshwater resources by altering the intensity and frequency of rainfall, reducing soil humidity and infiltration capacities, and changing river run-off (Lentini 2022). These changes are exacerbated by alterations in vegetation cover. For example, in the Amazon, deforestation has decreased moisture in the lower atmosphere, leading to increased drought and fire in self-reinforcing feedback loops (IPCC 2022a).

Drought conditions in 2022 across the La Plata Basin in South America were the worst since 1944 (WMO 2023). Parts of Argentina, Paraguay, Uruguay, Chile and southern Brazil recorded below-normal to much-below-normal river discharge in 2022. The effects of drought have been severe in drylands, where a third of the region's population is concentrated. Effects are most pronounced in places like Peru, where 80 per cent of the people live in arid or semi-arid environments. In addition, between 1997 and 2017, the region experienced an 80 per cent increase in the frequency of floods, compared with the previous 20 years.

Glacier melt in South America contributes to sea level rise, increases sediment load and releases trapped contaminants (Santofimia et al. 2017; Magnússon et al. 2020; Vergara et al. 2024). Between 2000 and 2015, the largest contributions came from the Patagonian icefields, where 83 per cent of mass loss occurred, primarily from dynamic adjustments of large glaciers. These changes contribute to global sea level rise (Braun et al. 2019). Colombia's glaciers, such as those in the Sierra Nevada del Cocuy and the Sierra Nevada de Santa Marta, have experienced dramatic reductions

in size, losing over 90 per cent of their total mass in the last century. This loss not only threatens local water supplies but also contributes to downstream water scarcity and reduced river flows (IDEAM 2023). Rising sea levels, intensified by extreme weather, such as hurricanes and storm surges, pose a serious threat to water quality in coastal regions.

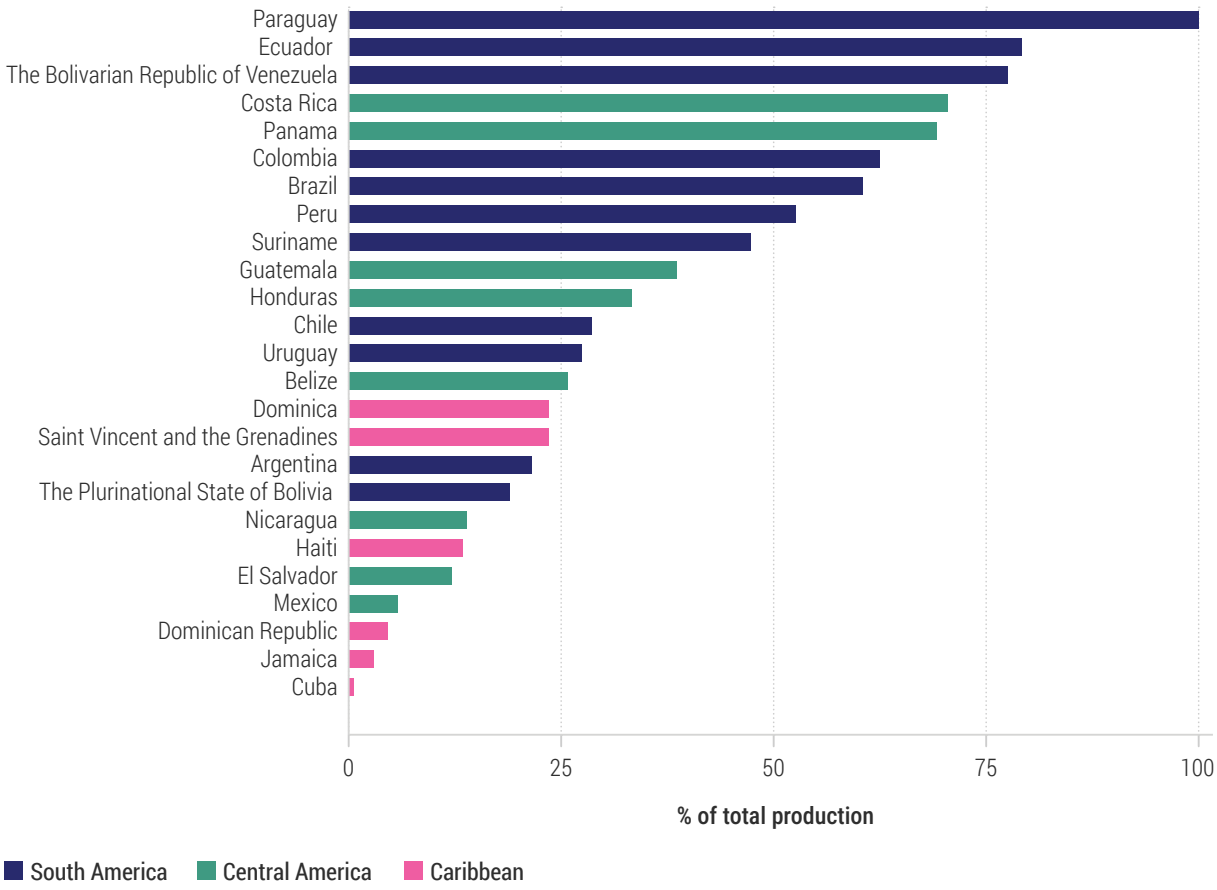
The LAC region is one of the world's largest consumers of agrochemicals, deteriorating the quality of surface and groundwater (Sharma et al. 2019). Land degradation results in increased run-off into freshwater and coastal marine systems and promotes pollution by agrochemicals and other contaminants. Intensive livestock production adds to the problem by releasing manure that contaminates both aquatic ecosystems and groundwater.

Watershed degradation from the discharge of untreated effluent in peri-urban and rural areas is significantly damaging the quality of both surface water and groundwater (World Bank 2023). In several countries, inadequate solid waste management results in the prevalence of plastic debris and emerging contaminants, leading to leaching that pollutes both surface and groundwater (Olivatto et al. 2019; Dagwar and Dutta 2024). These solid wastes also constitute an important source of coastal and marine pollution through various pathways, including run-off, wastewater discharge and atmospheric transport.

Changes in freshwater quality and availability impact natural and human systems.

Water changes driven by extreme climate events are adversely affecting the region's key economic sectors (WMO 2022). For example, drought conditions between 2020 and 2022 in the Río de La Plata Basin severely impacted agriculture, inland navigation, energy production and water supply (Rivera 2024), increasing the possibility of conflict between countries (Barbosa and Ribeiro 2024). In 2023, the Panama Canal faced operational challenges due to warm ENSO conditions, resulting in an estimated earnings loss of US$200 million (WMO 2022; Dhal 2024).

Drought-induced water scarcity is a significant concern, particularly in regions heavily dependent on hydroelectric power generation, such as Paraguay, Ecuador and Venezuela (World Bank 2023) (**Figure 8.21**). For example, Ecuador's Coca Codo Sinclair hydroelectric plant has faced interruptions due to reduced river flows from the Coca River, attributed to both climate variability and increased blockages caused by landslides (IDB 2022).



Water scarcity and quality directly threaten food security in the region. Agricultural irrigation accounts for 35–86 per cent of the total available water (Salazar et al. 2022). Droughts in the Southern Cone disrupt agricultural production, particularly for small farmers who depend on rain-fed agriculture (Loukos and Arathoon 2021). The region's SIDS also face threats to food production (World Bank 2022), highlighting the urgent need to improve water-use efficiency in agriculture, where limited water availability is already a major constraint (IPCC 2022a). Effective water management is a key concern because the use of the region's freshwater ecosystems for damming is having an impact on freshwater biodiversity and fisheries. For example, Andean-Amazon tributaries, which play a vital role in sustaining local fisheries, are losing biodiversity due to these hydrological alterations (Caldas et al. 2022; de Oliveira Lima et al. 2024).

According to the UN-Water report (United Nations 2022), indicators on water quality and management in LAC highlight that 48 per cent of monitored water bodies in the region have good ambient water quality (SDG indicator 6.3.2, 2021). Moreover, the degree of implementation of integrated water resources management reaches 37 per cent in LAC (SDG indicator 6.5.1, 2020). Regarding ecosystems, 24 per cent of the water basins in the region are experiencing rapid changes in the area covered by surface waters (SDG 6 indicator 6.6.1, 2020) (United Nations 2022).

Coastal regions in many LAC countries are experiencing land retreat due to a combination of sea level rise, human-induced tidal surges, and subsidence from human activities. These encroachments lead to increased salinity in coastal areas, affecting both ecosystems and freshwater resources, particularly in the Caribbean SIDS (IPCC 2022a; CARICOM 2020). Mangroves are particularly vulnerable due to their limited capacity to migrate inland as sea levels rise (IPBES 2019).

Freshwater pollution, caused by pesticides, emerging contaminants, microplastics and eutrophication, impairs aquatic ecosystems and soil quality. Combined with increasing competition for water resources, this

Figure 8.21: Share of electricity production from hydropower in Latin America and the Caribbean

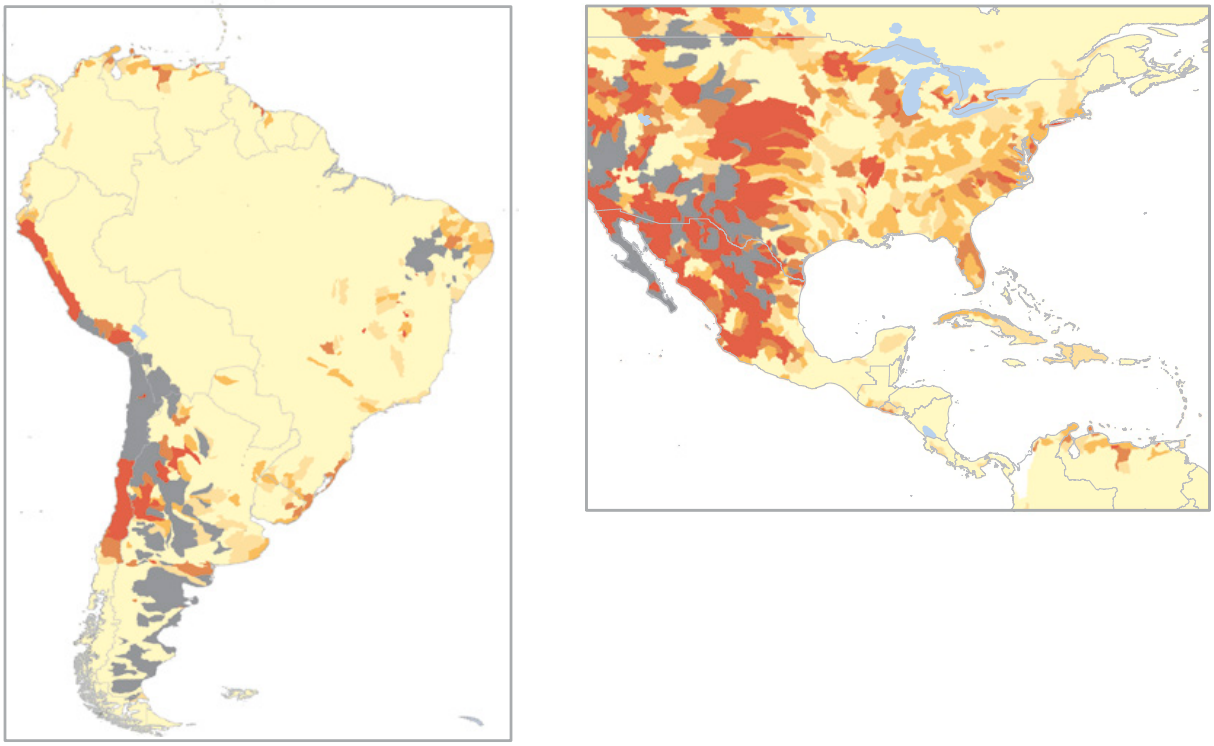
Source: Energy Institute (2023)

pollution has generated tensions and conflicts among stakeholders, compounding existing inequalities in water access (CARICOM 2020). Vulnerable populations, including rural communities, women and Indigenous groups, are disproportionately affected (Oswald-Spring 2022). In high-altitude Andean grassland areas, these damages are particularly severe, disrupting the ritual and creation-acknowledgement practices of peasant and Indigenous communities, who regard water as a vital part of their worldview. The disruptions heighten social risks and strain rural–urban relations and territorial disputes (Parra 2023).

The increasing exploration for oil, gas and lithium, which often involves specialized techniques, is further compromising water quality and contributing to environmental and social pressures, particularly in subregions where biodiversity and traditional economic activities are already at risk (ECLAC 2023b). The elevated use of pharmaceutical products in aquaculture is also contributing to increased food contamination levels in the region. It is worth noting that water pollution is linked to atmospheric pollution and exacerbates health risks for human populations (Münzel et al. 2023).

Increasing urbanization and population growth are driving demand for water services, requiring greater investments in climate-resilient sanitation infrastructure (UN-Habitat 2023). Nevertheless, around 161 million and 431 million people in LAC cannot access safe drinking water and safe sanitation, respectively, leading to a higher incidence of waterborne diseases and malnutrition, and vector-borne diseases such as dengue and Zika. These are becoming more prevalent due to climate change (Lentini 2022). In 2019, more than 2.7 million cases of dengue were reported in LAC, of which 22,127 were severe, with 1,206 deaths reported (IPCC 2022a; Santos et al. 2023; WHO 2023).

Key indicators on water and health in LAC include access to drinking water, sanitation, and wastewater treatment. In this sense, 75 per cent of the regional population has access to safely managed drinking



water services (SDG indicator 6.1.1), while 49 per cent use safely managed sanitation services (SDG indicator 6.2.1a). Additionally, 46 per cent of domestic wastewater in the region is safely treated (SDG indicator 6.3.1) (United Nations 2022).

Water is often produced and extracted from lands traditionally inhabited by Indigenous Peoples and local communities (Mena and Hofstede 2006; Mosquera et al. 2023). Indigenous communities are often not consulted on development models affecting natural resources on their lands, disrupting both their traditional socioenvironmental organization and the ecosystem processes those traditions reflect. It is essential to recognize the need to safeguard their territories and to ensure prior consultation under international agreements, as it is both just and crucial to achieving sustainable water governance (CNA 2020; UNDESA 2022).

LAC has many areas with high water stress (**Figure 8.22**) and an average loss rate of 40 per cent before it reaches the end user. Estimates suggest that by 2040, Peru, Chile, Mexico, the Dominican Republic and Argentina will be most at risk from water stress (World Bank 2022). Over-extraction of water from aquifers, obsolete distribution infrastructure and leaks in supply networks exacerbate the problems throughout the region.

Transboundary water cooperation, which includes shared rivers, lakes and aquifers, is critical for ensuring sustainable management of water resources and achieving SDG 6: "Ensure availability and sustainable management of water and sanitation for all". Of the 33 countries that make up the LAC region, 22 share transboundary rivers, lakes and aquifers. Most countries have low coverage of operational arrangements in relation to transboundary water cooperation. It also influences the levels of coverage for transboundary aquifers. Only four countries – Argentina, Brazil, Ecuador and Paraguay – have 90 per cent or more of their transboundary river and lake basin area covered. In Central America, transboundary basins occupy more than 42 per cent of its territory, totalling 221,000 km^2, with approximately 21 million inhabitants (UNESCO 2021).

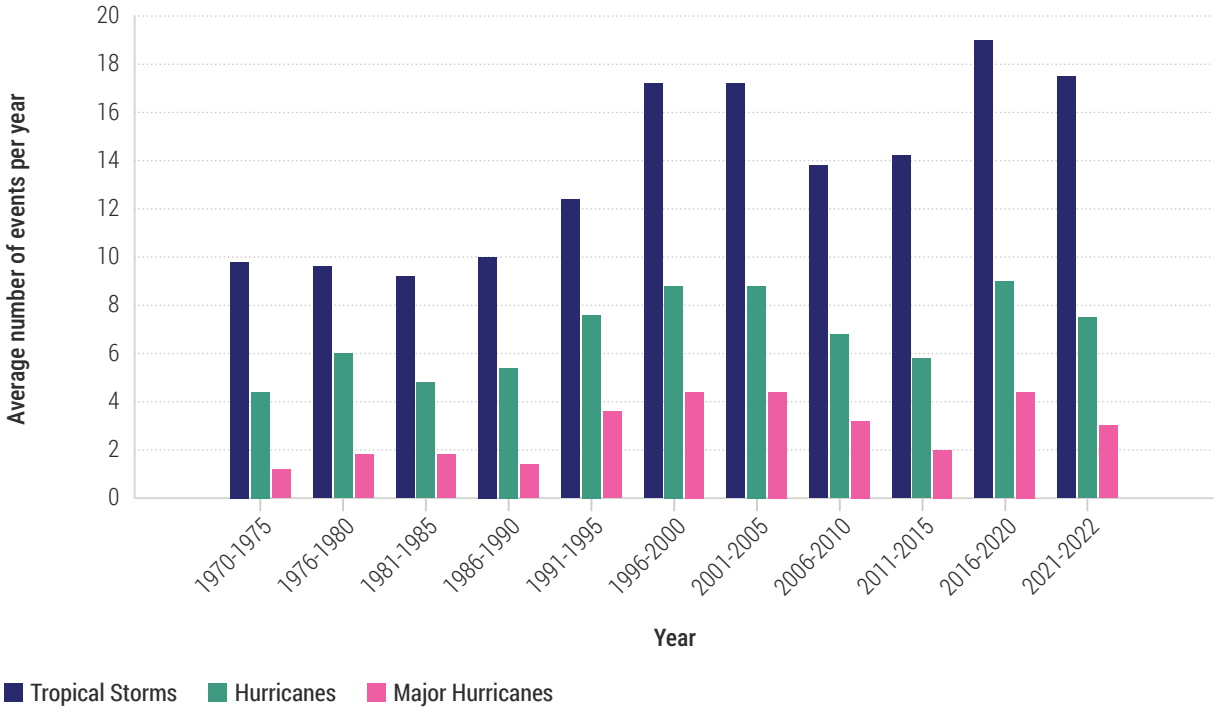
8.5.5 Priority issue: degradation of coastal and marine resources

Coastal and marine resources are degrading at unprecedented rates: our common future is very uncertain without them.

The LAC region covers 16 million km^2 of marine territory and includes 47 of the 258 global marine ecoregions (Tambutti et al. 2020). Twenty-three out of the 33 countries in LAC have more marine than terrestrial territory, and 27 per cent of the region's population lives in coastal areas (Tambutti et al. 2020).

The consequences of hurricanes, droughts, torrential rains and other extreme events are altering ecosystem dynamics in coastal and marine ecosystems across LAC (WMO 2023). Critical areas for human well-being, affected by these events, include energy, food, health and finance (WMO 2023).



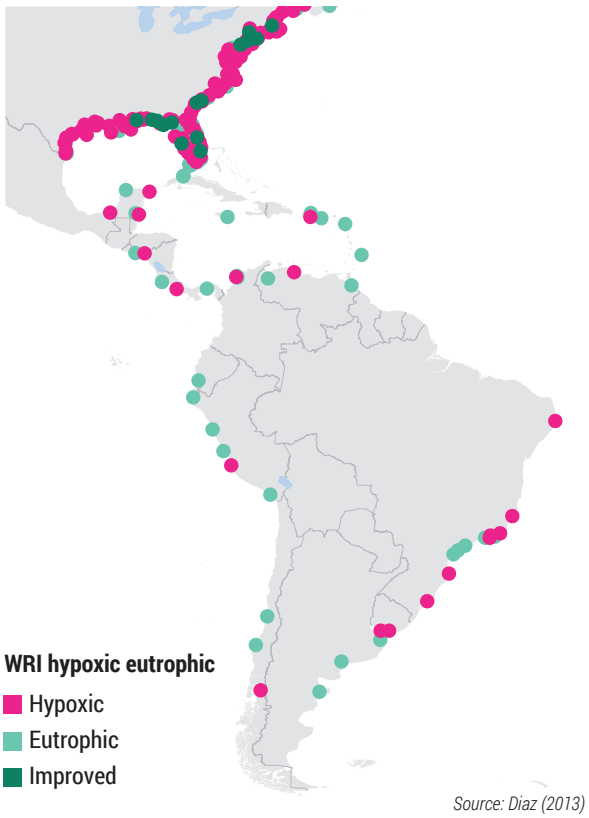
Interacting crises intensify pressures and accelerate the decline of coastal and marine ecosystems.

Climate change drives the degradation of coastal and marine ecosystems (Castellanos et al. 2022). Impacts include the reduction of coral cover in Central America and northern South America, as well as an increasing number of coral-bleaching events. Other marine ecosystems affected in the region include estuaries, salt marshes and mangroves (Castellanos et al. 2022). LAC has experienced an increase in the frequency and intensity of extreme events (**Figure 8.23**), leading to increased coastal inundation and a higher risk of waterborne and other diseases. Warm ENSO events also contribute by causing extreme rainfall, flooding and landslides in the Ecuadorian (Thielen et al. 2023) and Peruvian coastal plains (Son et al. 2020).

Ecosystem changes and degradation are increasing as extreme events become more frequent (Levin et al. 2020). Consequently, the ability of these ecosystems to cope with extreme events has decreased (França et al. 2020; Vincent et al. 2021).

Global estimates indicate that nearly 50 per cent of the region's beaches could be fully underwater by the end of the century (Vousdoukas et al. 2020). In Central and South America, sea level rise is the prevalent process leading to beach loss, while in the Caribbean, geological, anthropogenic and other physical factors are dominant (Vousdoukas et al. 2020).

Figure 8.23: Average number of yearly tropical storms, hurricanes, and major hurricanes in the Atlantic



Source: Tropical Cyclone Climatology, NOAA (2022)

Increasing CO_2 concentrations contribute to the acidification of the ocean, which causes coral reef degradation (Tambutti et al. 2020). Some of the more acidic waters are found on the Pacific coast, from Mexico to Ecuador (Ocean Health Index [OHI] 2023). Higher water temperatures result in more frequent coral-bleaching events. This threat is higher in the Sea of Cortés but is also present along the Pacific Coast of Central America and in the Caribbean (Tambutti et al. 2020).

The region has a uniquely productive marine area, representing a significant portion of global marine biodiversity. It includes the second-largest barrier reef in the world and the Caribbean, which is one of the world's primary centres of endemic biodiversity (Tambutti et al. 2020). Marine pollution originates primarily from land-based sources. Hypoxia affects the Large Marine Ecosystems across LAC jurisdictional boundaries and cannot be effectively addressed without multinational collaboration (**Figure 8.24**) (Diaz 2013; Tambutti et al. 2020).

Pharmaceutical and personal-care-product residues in aquatic ecosystems are an emerging concern.

Figure 8.24: Eutrophication and hypoxic zones in Latin America and the Caribbean and parts of the United States of America

Source: Diaz (2013)

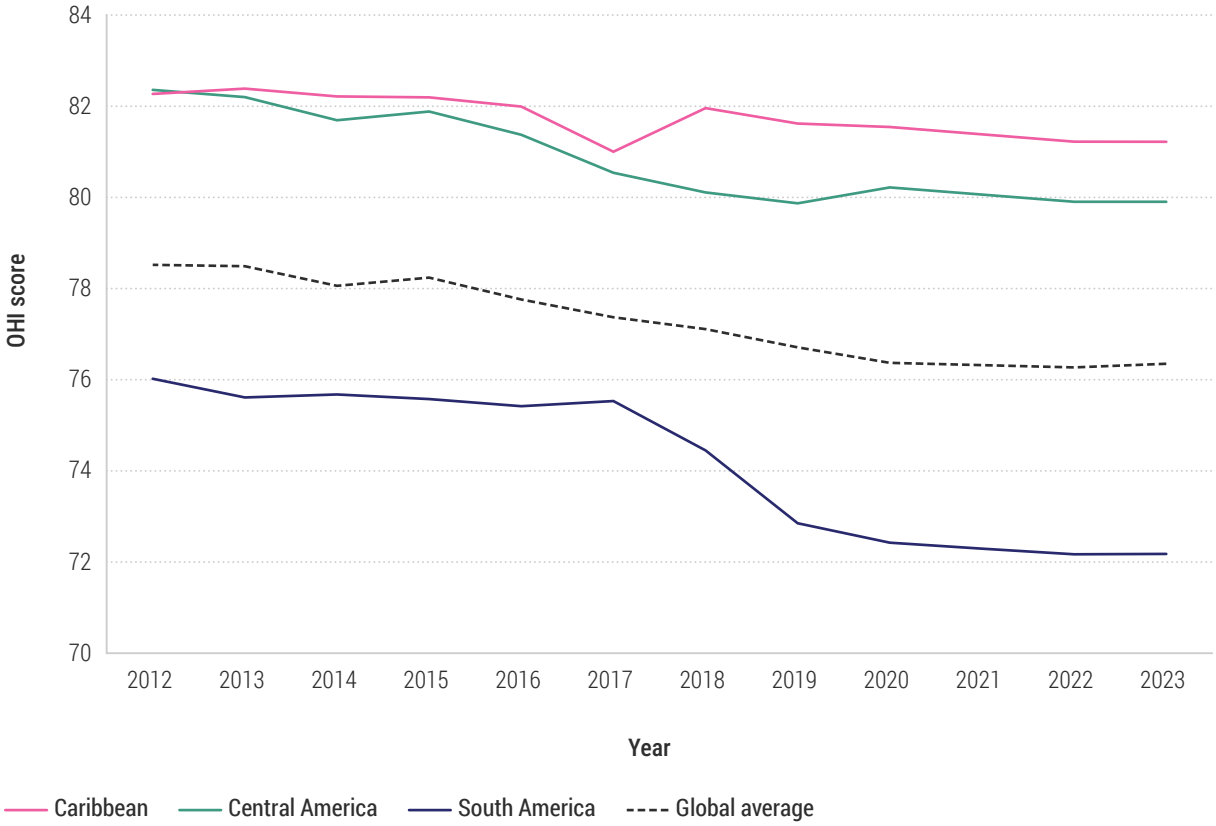
There is no comprehensive assessment for the region (Pemberthy et al. 2020), but examples from Colombia (Pemberthy et al. 2020) and Brazil (Mello et al. 2022) indicate that pharmaceuticals such as ibuprofen can be found in low concentrations in coastal waters. While these chemicals were not detected in the marine organisms sampled in Colombia, they were found to bioaccumulate in certain seafood species in Brazil.

Micro- and macroplastics are the primary sources of marine pollution in LAC, with their amounts increasing (Tambutti et al. 2020). In the Atlantic area, the abundance of floating plastic is 100 times higher than in any other LAC Large Marine Ecosystem (Tambutti et al. 2020). In the Caribbean, pollution is further exacerbated by the cruise ship industry. A single medium-sized ship can produce 140,808 m^3 of waste annually, with the majority comprising greywater and treated sewage that can be legally dumped at sea (Kotrikla et al. 2021). In 2023, around 150 cruise ships sailed in the Caribbean, making it the top destination for cruise travellers (CLIA 2024).

Land degradation results from coastal development, offshore pollution, erosion and salinization of coastal soils, as well as landslides and the retreat and erosion of estuary deltas (Zhou et al. 2022). Chile, Mexico and Argentina, among others, are highly exposed to coastal erosion that imperils their beaches. Climate-related storms contribute to beach erosion and flooding that exacerbate inland degradation (Vallarino et al. 2023).

Degradation of coastal and marine resources affects natural and human systems.

The Ocean Health Index (OHI) measures the capacity of oceans to deliver benefits to people, both in the present and in the future (Halpern et al. 2012). It incorporates the capacity of oceans to provide benefits such as food, a sense of place, livelihoods and economies, clean water, coastal protection, carbon storage, tourism and recreation. Its value ranges from 0 to 100, and lower values mean less sustainable use. The OHI global value for 2023 was 73. In LAC, OHI values for the same year range from 61 to 82, with the lowest values reported in the Caribbean (**Figure 8.25**).



In 2023, the OHI for the LAC region was around 72.5 per cent, slightly lower than the global average of 73 per cent. Scores are higher in South (75.35) and Central America (73.8) and lower in the Caribbean (71.29) (OHI 2023). The region's 2023 scores generally fall below

global averages in food provision, natural products, and tourism and recreation. However, some OHI components are improving in specific subregions, indicating positive developments in certain areas (2012–2023) (OHI 2023); for example, OHI food provisioning increases in South America and decreases slightly in Central America and the Caribbean, while the OHI natural products component and the tourism and recreation component increase in all regions.

Coastal regions heavily reliant on groundwater for irrigation and human consumption are experiencing increased saline intrusion, particularly in the drier areas of South America and the Caribbean (Dupar 2019; Taleisnik and Lavado 2020). In areas such as the Yaqui Valley in Mexico, groundwater withdrawals exceeding recharge rates lead to aquifer contamination by saline water, a problem also observed in arid and semi-arid coastal regions of Chile, Colombia and Argentina (Vigglizo and Ricard 2020). The situation is expected to worsen in many areas as climate change continues to reduce rainfall (Dupar 2019). Coastal soils are increasingly susceptible to salinity changes due to climate-change-induced shifting rainfall and discharge patterns, for example, saline intrusion in the northeastern coast of Brazil, and significant changes to coastal ecosystems (Soares et al. 2021). Additional contributors to coastal degradation in LAC include port and marina development, driven by the intensification of tourism and trade at global, regional and local levels (Anbleyth-Evans 2023; OECD 2023). Sand extraction has been identified as a factor that reduces beach integrity and defence against extreme events (Vallarino et al. 2023). Land-use changes also affect freshwater availability in coastal regions. For instance, the impounding and management of the São Francisco River for hydroelectric power in Brazil has increased the salinity of its estuarine environment, affecting both land and coastal ecosystems (Paiva et al. 2024).

Coastal areas face significant erosion due to various processes (Villate Daza 2020; Mesquita et al. 2022; Zhou et al. 2022; Anbleyth-Evans 2023; Botero 2023;

Figure 8.25: Ocean Health Index trends (biodiversity component) for Latin America and the Caribbean from 2012 to 2023

Note: For clear comparison across the sub-regions, the values of the vertical axis start at 70

Source: OHI (2023)

Vallarino et al. 2023), including beach tourism, port and tourism infrastructure development, and nearshore and offshore oil and gas exploration. For example, in Belize, the use of fill material from sea floor dredging to support tourism infrastructure development affects both coastal and marine environments (Sweetman et al. 2019).

Coastal and marine biodiversity is threatened by extreme environmental events, through habitat loss and the increased vulnerability of valuable ecosystems (CARICOM 2020). The OHI biodiversity component (Halpern et al. 2012) indicates the status of habitats and species. For LAC, there is a declining trend with a more significant reduction in South America (**Figure 8.25**). However, there are countries – Peru, Chile and the Bahamas – with a rising trend in this indicator, suggesting the outcome from improved management.

Mangroves provide many ecosystem services, including protection against climate change and extreme events (Del Valle et al. 2019; Rastogi et al. 2021; Ferreira et al. 2022). In LAC, mangrove extents have increased due to restoration projects, but also because of better data collection (FAO 2020; FAO 2023). Between 2010 and 2020, there was a net gain in mangrove areas in South America and the Caribbean, with a slight decrease in Central America (FAO 2020; FAO 2023b) (**Figure 8.26**).

The Caribbean has been significantly damaged by the invasion of Sargassum, smothering beaches, coastlines and the marine environment (Kanhai et al. 2022).

Despite some positive trends in specific subregions, ecosystem services such as coastal protection and livelihoods are degraded, alongside declines in macrofauna, seagrasses and brown algae, and increases in cyanobacteria (Climate Studies Group Mona 2020; França et al. 2020; Malone and Newton 2020; Carroll et al. 2023). Algal blooms and hypoxia are becoming more frequent, as observed in Venezuela's estuary-like Lake Maracaibo (Maberly et al. 2020).

Ocean acidification is evident in coral reefs, with the Mesoamerican Barrier Reef experiencing a net erosion of 37 per cent. Other marine changes include ecosystem reshaping, disruption of natural food webs due to the introduction of exotic invasive species, and coral diseases (Tambutti et al. 2020).

The discovery of offshore oil deposits in the Guyana basin contributes to the expansion of fossil fuel production (Wong et al. 2020). The operation of

Figure 8.26: Subregional trends in mangrove forests in Latin America and the Caribbean from 1990 to 2020

Source: FAO (2020)

offshore platforms generates pollution and causes disturbances that can have long-term implications for marine and coastal ecosystems (Zhou et al. 2022).

Oceans and coastal areas are key ecosystems for livelihoods and food security in the LAC region. The importance of fisheries in nutrition is particularly relevant for coastal communities in the Caribbean, where 16.5 per cent of the total animal protein consumption comes from coastal fishing. This proportion is lower in Central America at 9.44 per cent and South America at 5.96 per cent (Tambutti et al. 2020). For the period 2012–2024, Southern Cone countries, including Colombia, Panama and Venezuela, have exhibited a positive annual trend in wild fisheries. In contrast, Central America and the Caribbean, except for the Bahamas and some of the Lesser Antilles, have shown negative values, indicating overharvesting (OHI 2025).

Climate change negatively impacts fisheries in key fishing areas, for example, the Gulf of California and Humboldt Current upwelling zones (Tambutti et al. 2020). In the Caribbean, the adverse effects of climate change are expected to intensify by 2050 (Carroll et al. 2023), exacerbating losses in livelihoods that depend on fisheries and marine resources. Increasing coastal flooding and erosion could make the Caribbean one of the fastest-displaced communities globally, with severe implications for economic activities (Global Americas 2019).

In LAC, SIDS rely heavily on their marine and coastal assets for economic growth and livelihoods, through fisheries and tourism (Tambutti et al. 2020). The Caribbean Sea, covering less than 1 per cent of the world's ocean area, contributes an estimated 27 per cent to the global ocean economy. Tourism accounts for over 15 per cent of GDP and 13 per cent of employment in the region (UNDP Latin America and the Caribbean 2023).

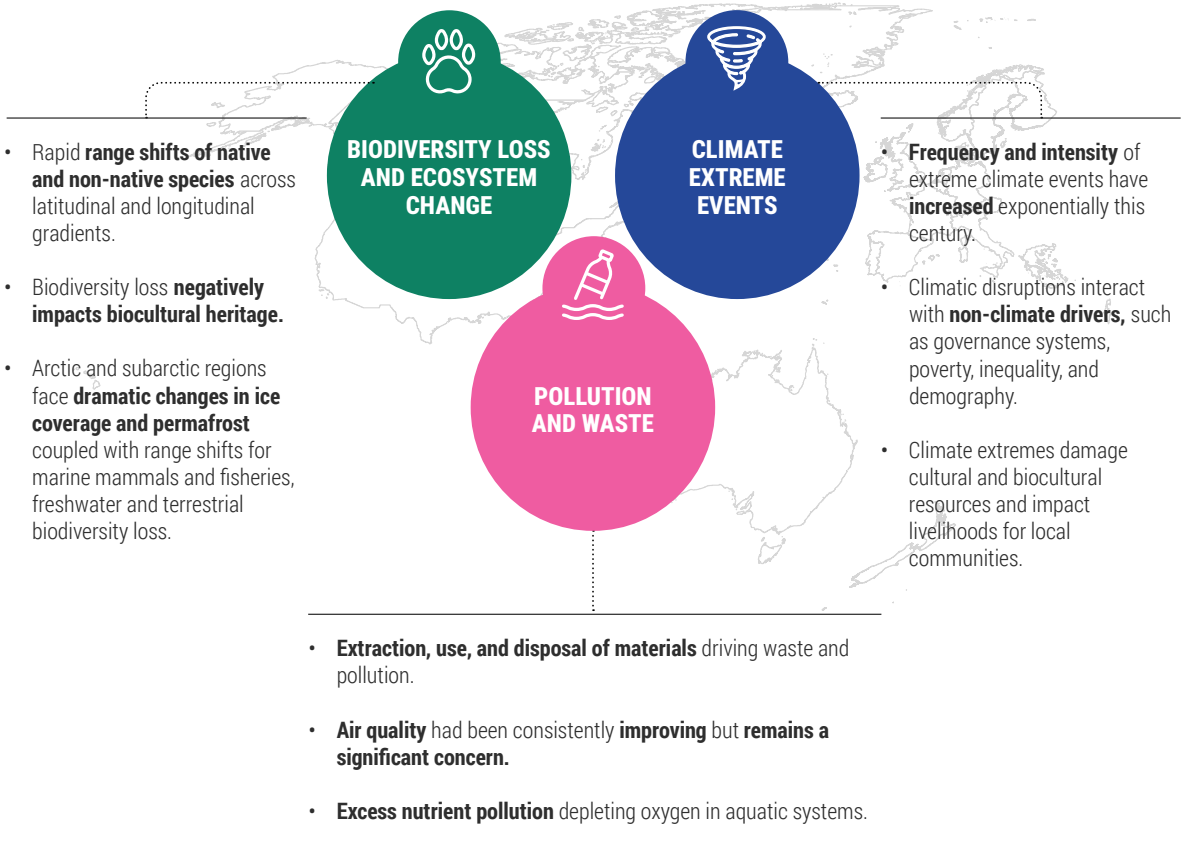
The global environmental crises affect fisheries through ocean warming, acidification, coral bleaching (Mendehall et al. 2020; Lam et al. 2020), coastal habitat transformation, and pollution (Cortes et al. 2020), among other factors. Small-scale fisheries represent over 90 per cent of the catches in the Caribbean, over 40 per cent in Central America, and more than 20 per cent in South America. In terms of value, small-scale fisheries account for about 80 per cent of commercial value in the Caribbean, while more than 60 per cent and about 50 per cent in Central America and South America, respectively (Tambutti et al. 2020). Despite its socioeconomic relevance, small-scale fisheries do not have guaranteed access to adequate resources and face significant inequality (Tambutti et al. 2020). The LAC region loses approximately US$5.8 billion annually compared to its optimal economic yield, accounting for around 7 per cent of global losses (Tambutti et al. 2020). The Southeast Pacific is the only LAC marine region where over 50 per cent of fishery stocks are harvested unsustainably (FAO 2022). Although the LAC region has declared 20 per cent of its marine surface as marine protected areas, exceeding the SDG 14.5 target, the distribution is uneven and over 20 countries have yet to achieve this goal. The effectiveness of these protected areas depends on adequate financial resources to support management plans (Tambutti et al. 2020).

8.6 Western Europe and Others Group and subregions

8.6.1 Introduction

The Western Europe and Others Group (WEOG) includes 28 middle- and high-income member states and their territories. This diverse region encompasses a broad range of ecosystems, including temperate forests, tundra, high mountains, grasslands, drylands and deserts, as well as coastal and freshwater environments. Numerous cultural communities maintain deep connections to their local landscapes and seascapes, and these ties are threatened by the global environmental crises of climate change, biodiversity loss and land degradation, and pollution and waste. Words from Canada resonate across WEOG: "First Nations, Métis, and Inuit recognize the existential threat that climate change poses to their cultural survival" (UNEP-WCMC and IUCN 2021; Lulham et al. 2023; Li et al. 2024), stating that "…climate change constitutes a state of emergency for our lands, waters, animals, and people" (Assembly of First Nations 2019).

Despite economic and technological advantages, the environmental outlook for WEOG remains deeply concerning due to the long-term impacts of industrialization and high consumption. Three priority issues, which can have differing local manifestations, dominate the region's



environmental trajectory: biodiversity loss and ecosystem change, extreme climatic events, and pollution and waste. These are closely interlinked, reflecting broader environmental crises (**Figure 8.27**).

Biodiversity loss and ecosystem change

Biodiversity loss and ecosystem change pose risks to food security, and human health and well-being. These changes are accelerating throughout the region, driven by climate change, land-use transformation, and shifting species distributions across latitudinal and longitudinal gradients. For example, different organisms, particularly invertebrate pollinators, are experiencing sharp declines and significant range shifts (Otto et al. 2025; Richards et al. 2025). Ecosystems are being transformed through the interactions of multiple factors such as invasive alien species, changes in fire and flood regimes, and melting permafrost. For example, invasive alien grasses have fuelled extreme fires in Hawaii, and melting permafrost promotes the expansion of new species in the Arctic. Diseases carried by ticks and other vectors are extending beyond their historical regions. These profound ecological changes are deeply disruptive to biocultural heritage and human livelihoods.

WEOG countries have taken steps to address these threats to biodiversity, including expanding the number of protected areas across land, coastal and marine environments since 2010. Indigenous communities across the WEOG continue to demonstrate effective environmental stewardship grounded in local communities and cultural knowledge. For example, in Australia, Langaliki Robin, Indigenous leader of Walalkara – the country's oldest Indigenous Protected Area – highlights the importance of Tjukurpa (Dreaming Law) as the foundation of conservation efforts (Robin et al. 2022). In Canada, First Nations, Métis, and Inuit peoples have developed effective, culturally informed community-based monitoring and protection programmes, including successful caribou monitoring and breeding initiatives ((Lamb et al. 2022; Priadka 2025) and monitoring for contaminants in traditional foods (Goldzadeh et al. 2021; Baker 2021).

Figure 8.27: The interplay of the global environmental crises and regional priority issues: effects on Western Europe and Others Group's biodiversity and ecosystems, climate extreme events, and pollution and waste

Credit: bortescristian/Envato

Extreme events

The frequency and severity of extreme climatic events – especially heatwaves, floods and wildfires – have increased dramatically in recent decades, causing loss of life, disruption of communities and destruction of infrastructure. In Europe, heat-related mortality has surged, with 61,000 deaths recorded in 2022 alone (van Daalen et al. 2022; Ballester et al. 2023; European Commission 2023). Across the United States of America, extended heat events have shattered records, particularly summer night-time temperatures (NOAA 2024). The intensification of wildfires, floods and extreme storms has been well documented and affects both urban and rural residents (Qian et al. 2022; Donatti 2024). Extreme events amplify existing inequities, disproportionately impacting already vulnerable populations. Communities with fewer resources face greater mortality risks and slower recovery processes following disasters (U.S. Government Accountability Office 2021).

Pollution and waste

Despite ongoing interventions, WEOG countries continue to experience excessive waste and persistent pollution driven by high resource consumption, rapid turnover of consumer goods, and industrialized agriculture. Synthetic substances, such as per- and polyfluoroalkyl substances and microplastics, are pervasive in WEOG, and many have unknown health effects (EEA 2022b; UNEP and Secretariat of the Basel, Rotterdam and Stockholm Conventions 2023). Despite ongoing efforts in WEOG to promote sustainable agriculture, nutrient pollution and pesticides continue to threaten both ecological and human health (Baron et al. 2014; Mosley et al. 2023; Zhou et al. 2023). Trends in air quality across WEOG are encouraging, yet 90 per cent of Europeans living in cities are still breathing unhealthy levels of fine particles (EEA 2023a). Overconsumption and waste, largely associated with lifestyles of high-income countries, are underlying drivers of the global environmental crises of climate change, biodiversity loss and land degradation, and pollution and waste. The convergence of biodiversity loss, intensifying extreme events and persistent pollution presents a deeply challenging environmental outlook for WEOG.

8.6.2 Interlinkages between the global environmental crises and regional priorities

The global environmental crises have disrupted ecosystem services and functions, particularly in the northern and southern temperate latitudes of the biomes within WEOG. Extreme heat events, catastrophic wildfires, land degradation, and invasive alien species are all interlinked and result in measurable impacts on both human and ecosystem health (Hantson et al. 2022; Chowdhury et al. 2024). Legacy industrial activities pose a threat to human and ecosystem health through the persistence of chemicals and metals (Adewumi and Ogundele 2024) in the environment, which contributes to long-term pollution and health

Credit: bortescristian/Envato

issues. Without intervention, many organisms face an extinction risk (Goulson 2019; Ceballos et al. 2020).

WEOG countries also have a long legacy of mineral and fossil fuel extraction, consuming over 30 per cent of global energy. Material consumption footprints are well above the global average, associated with elevated standards of living, excessive consumption and waste production (Oswald et al. 2020). Food production using intensive, industrial-scale agriculture impedes ecosystem services, such as pollination, which underpins 30 per cent of the global food supply (IPBES 2019; Vujić et al. 2022). Excess fertilizers impair freshwater systems, contaminate groundwater and contribute to the loss of biodiversity and soil organisms (Tibbett, Fraser and Duddigan 2020; Bolster et al. 2023). In addition, excessive and continued use of pesticides such as neonicotinoids is known to have adverse effects on bees and other pollinators (Camp and Lehmann 2021; Zhang et al. 2023; Mamy et al. 2024). They are banned for outdoor use in the European Union (European Commission 2024), but they continue to be used elsewhere. Similarly, organophosphates and carbamate pesticides can have severe ecological consequences, such as in vulture populations (Ives et al. 2022; Santangeli et al. 2022) but continue to be in widespread use. The status and trends of many invertebrate and non-vascular plants, such as mosses and lichens, which comprise a large proportion of the world's biodiversity (Secretariat of the Convention on Biological Diversity 2020), and the impacts of legacy chemicals on these groups, are largely unknown. Such data uncertainty compounds the urgency of addressing biodiversity loss (IUCN 2024).

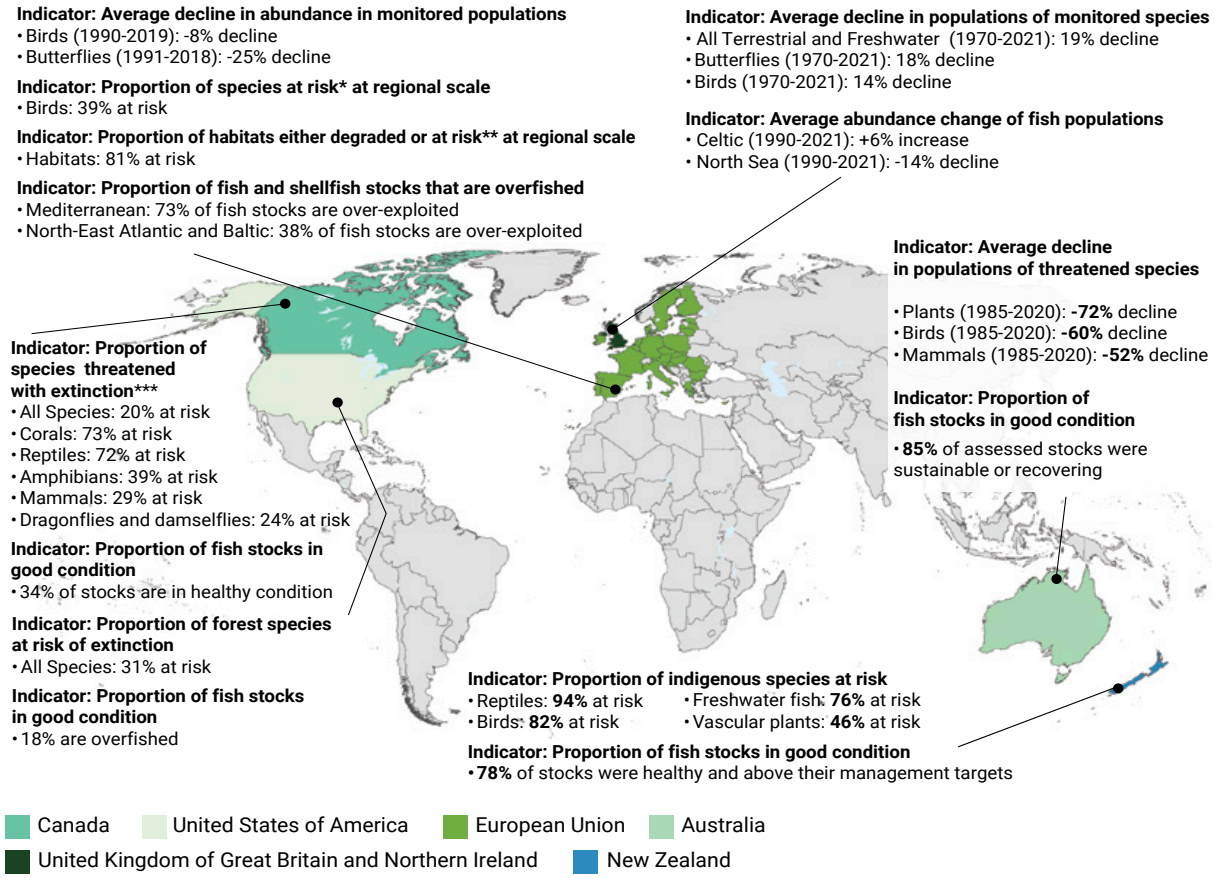
In summary, the global environmental crises affecting WEOG countries are complex; however, interventions in three priority areas have shown some progress. For example, emerging technologies, such as non-expert digital data sets, aid in identifying areas of biodiversity loss and species changes and can help determine the response of different taxa to changing environmental conditions. Policy interventions can reduce the presence of chemical pollutants and fertilizers (Zacharias and Kaplan 2023; de Vries et al. 2024). New strategies for adaptation and early warning systems are identifying potential climate extremes, such as severe weather and storm forecasting, supporting adaptation for infrastructure (EEA 2024a). Additionally, increasing the extent of protected areas – to 30 per cent by 2030 (UN-CBD 2022; Kunming-Montreal Global Biodiversity Framework 2022) – and of heritage sites creates priority strategies to address

habitat and land degradation, as well as biodiversity loss (Day et al. 2020; Hilty et al. 2020).

8.6.3 Priority issue: biodiversity loss and ecosystem change

Biodiversity continues to decline while ecosystems are being transformed by habitat loss, invasive alien species and range shifts of native and naturalized species.

WEOG countries are ecologically and environmentally diverse, with well-documented areas of high endemism (Costello et al. 2017; Harrison and Noss 2017; Sabatini et al. 2022; UNEP-WCMC 2022). However, there are over 37,000 known and established invasive alien species worldwide, with a disproportionate number found in the boreal and temperate forests and agricultural areas that dominate WEOG (IPBES 2023). New invasions are reported regularly, despite substantial efforts by many countries to control the movement of invasive species across their borders. Ecosystems are continually being transformed by human activity, land degradation and pollutants that collectively contribute to biodiversity loss, impeding terrestrial and coastal ecosystems and local livelihoods (IPBES 2019; Secretariat of the Convention on Biological Diversity 2020; WWF 2024). Additionally, hypoxia caused by nutrient pollution is a widespread problem throughout WEOG, with notable examples including anoxic "black water" events in Australia (Mosley et al. 2023; Waddington et al. 2023) and expanding hypoxia in the Gulf of Mexico (Rabalais and Turner 2019). Changes in sea currents and range shifts for associated species are common throughout WEOG, particularly in its Arctic and sub-Arctic regions (Chan et al. 2019; Talloni-Álvarez et al. 2019; Krause-Jensen et al. 2020; Ingvaldsen et al. 2021).



Changes to ecosystem composition and diversity are occurring at unprecedented rates, leading to ecosystem transformations. Rapid range shifts of native and non-native species are occurring across latitudinal gradients and various habitat types (McElwee et al. 2023). Invasive alien species can transform ecosystems by altering the fuel basis for wildland fires or displacing native species, as exemplified by changes in pollinator species composition driven by the introduction of domesticated honeybees (Page and Williams 2023). The economic costs of invasive alien species can be significant, estimated at US$20 billion annually in the United States of America alone (Fantle-Lepczyk et al. 2022). The economic and ecological damage from invasive alien species is well-recognized, and several ambitious national and international strategies have been adopted to reduce and prevent the spread of invasive species (New Zealand Department of Conservation 2020; European Union 2014; U.S. Department of the Interior 2021; European Union 2022; IPBES 2023; Environment and Climate Change Canada 2024).

Species compositions are shifting throughout temperate biomes as many species migrate poleward due to rising temperatures, such as tropical wetland mangroves in a northward shift along the coastal regions of the southern United States of America (Osland et al. 2021). Similar trends occur across elevation gradients, where organisms in the European Alps have shifted upward in elevation by an average of 18–25 metres per decade since 1970 (Vitasse et al. 2021). Despite the long history of research within WEOG, information on species loss and range shifts is limited for many smaller taxa, such as invertebrates and non-vascular plants, due to a lack of data on these organisms to determine population trends (**Figure 8.28**) (IPBES 2019). The cascading repercussions of climate change, invasive alien species, depletion of natural resources, and land-based pollution contribute to the loss of species that are important for ecosystem functions and of biocultural importance (Mattalia et al. 2024).

Arctic and sub-Arctic habitats – including boreal regions, permafrost and tundra – are degrading, and coastal zones are experiencing shifts in currents and ocean warming events. The loss of permafrost and Arctic habitats has severe implications for local communities (IPCC 2022; Pörtner et al. 2023). There are 1,162 permafrost settlements with 5 million inhabitants in the Arctic circumpolar region, of which 1 million live along a coast, with 45 per cent of these settlements at risk of thawing permafrost (Ramage et al. 2021). More than 60 per cent of Alaska Native communities are estimated to be at risk of losing culturally important organisms (McElwee et al. 2023; Mucioki 2024). Permafrost loss in Alaska, for example, has increased by 60 per cent since 1950, associated with climate change and wildfires (Chen et al. 2021).

Warmer temperatures are driving the expansion of boreal forests and subarctic shrubs northward by up to 100 metres per year in Western Europe (Rees et al. 2020; Nill et al. 2022). These transformations in Arctic tundra may simultaneously increase above-

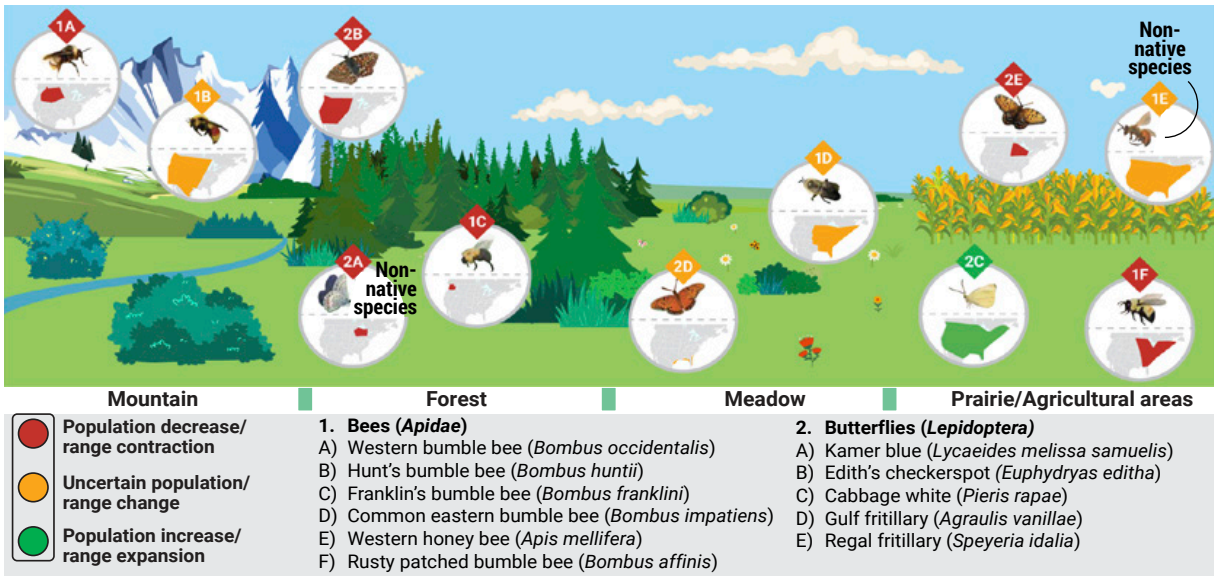
(2023b); McGinley et al.(2023); EEA (2024d); Environment and Climate Change Canada (2024);Ministry for Primary Industries (2024); National Marine Fisheries Service (2024); Roelofs (2024)

ground carbon stocks while depleting soil carbon due to changes in soil microbial communities (Parker et al. 2021). Ocean current shifts around Greenland have cascading effects on ice-flow patterns (McPherson et al. 2024), and consequently, on the movement patterns of marine species (van Weelden, Towers and Bosker 2021; Heide-Jørgensen et al. 2023). Similarly, rapid transformations are occurring in Arctic marine ecosystems as warmer waters are carried further north, leading to an increase in warm-water species, including crustaceans such as lobsters (McElwee et al. 2023). For example, the biomass of cold-water kelp beds off Nova Scotia, Canada, has declined by 85–99 per cent since 1950 and has been replaced by non-native algae that are more tolerant of warmer waters (Venegas et al. 2023).

One-third of the protected areas in Europe and the United States of America lost more than 10 per cent of their protected habitats between 2003 and 2019 (Li et al. 2024). Integrated systems of protected areas show promise for vertebrate species. However, additional interventions are needed to slow biodiversity loss for other taxonomic groups, as there is a significant risk that protected areas will provide only limited benefits to biodiversity (IPBES 2019; IUCN – World Commission on Protected Areas 2024). Western Europe's terrestrial protected areas covered 26 per cent of the land in 2021, for example. However, within these areas, 63 per cent of species have a poor conservation status, 27 per cent have a good conservation status, and only 6 per cent have an improving conservation status (EEA 2023a). Within the United States of America, birds are declining across all habitats except wetlands (North American Bird Conservation Initiative 2022), while pollinators and other invertebrates are too data-deficient to be assessed adequately (IPBES 2019; McElwee et al. 2023; Richards et al. 2025). In Mediterranean countries, protected areas associated with biologically diverse hotspots are one strategy to prevent species losses,



but those areas are fragmented (Assis et al. 2021; Donnelly and Rodríguez-Rodríguez 2022), and rare but exceptionally diverse landscapes, such as karst ground-water-dependent ecosystems, are increasingly under pressure from human disturbance, climate change and water extraction (Siegel et al. 2023). The protection of marine and coastal areas has also increased as part of the global commitment to protect 30 per cent of land and territorial waters by 2030 (Wolff et al. 2018; NOAA 2020; Convention on Biological Diversity 2022; Gignoux-Wolfsohn et al. 2024). Within the United States of America, 12 per cent of the land is in some form of protected status. However, some groups, such as birds, continue to decline within these protected areas, apart from wetlands (North American Bird Conservation Initiative 2022).

The rapid changes and losses of species undermine ecosystem services. Changing seasonal patterns contribute to range shifts of some species and declining populations of others. These declines occur particularly at higher elevations and latitudes in boreal systems where glacial retreat and loss of snow cover transform downslope processes across the Arctic and in cold-water marine ecosystems, such as cold-water fisheries in Canada (Boldt et al. 2021). Similarly, warming ocean currents shift marine species' movements and impair coral reef resilience in Australia (Cresswell et al. 2021; Mekonnen et al. 2021).

Range shifts and population declines are also occurring for terrestrial systems among invertebrates, particularly wild pollinators (**Figure 8.29**) and soil organisms across Western Europe and North America (Goulson 2019; Sánchez-Bayo and Wyckhuys 2019; van der Sluijs 2020; Dicks et al. 2021; Phillips et al. 2024). Such declines contribute to reduced yields in fruit and nut production, affecting 5–8 per cent of commercial crops with a US$577 billion market value (IPBES 2019; Jansson and Hofmockel 2020; Riggi et al. 2023). In New Zealand, declines of domesticated pollinators such as the western honeybee Apis mellifera impede honey exports and local economies (World Integrated Trade Solution – UNSD Comtrade 2024), in contrast with global honey production increases (Hall et al. 2021; Stahlmann-Brown, Manaaki Whenua and Robertson 2024).

Biodiversity loss affects Indigenous Peoples. Changes in the abundance and distribution of cultural keystone species, such as salmon, pose a threat to food security, particularly in the Arctic (Anderson et al. 2023; Mattalia 2024). Changes in species distribution in the Arctic, and especially the presence of invasive species in the Barents Sea, have impaired the livelihoods and cultural basis of local and Saami populations along the Norwegian coast. Climate change in Sápmi has increased the risk of hazards, injuries, food insecurity, and disease for the Saami (The Saami Council 2023), leading to fewer opportunities for cultural practices

Figure 8.29: Pollinator shifts in response to changing climate conditions

Note: Insect pollinators, even those within the same group, show a wide range of reactions to environmental pressures. Recent climate changes over the past few decades have driven complex shifts in where species are found. The bumble bee species have responded differently over the last decade, including moving within their current habitats, contracting their ranges, or facing extinction risks. Similar patterns have been observed in butterflies, with some species declining or shifting within their ranges, while others are expanding across the country.

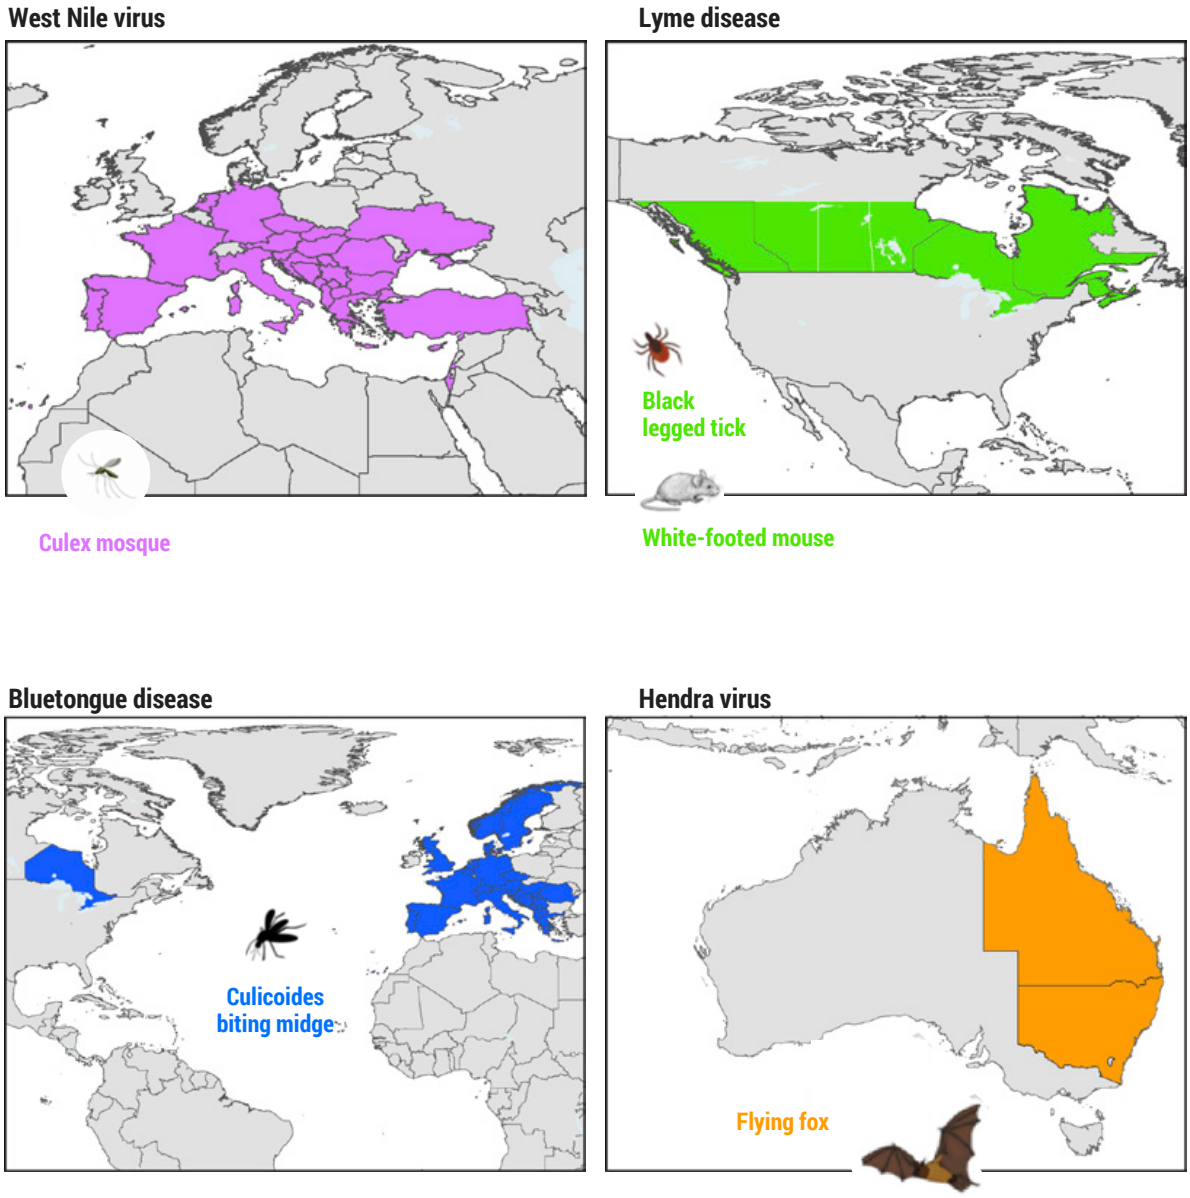
and knowledge transmission, as well as ecological grief (Markkula et al. 2024). Additionally, warming temperatures leading to the loss of sea ice and reduced snow cover produce range shifts in cold-water species, threatening the economic security of many Indigenous Peoples (Arctic Monitoring and Assessment Programme 2018; Galappaththi et al. 2019; Zhang et al. 2019; Reed et al. 2024).

Climate change particularly disrupts the livelihoods and well-being of communities dependent on natural resources (Bolster et al. 2023; Domke et al. 2023; Jay et al. 2023; May et al. 2023; EEA 2024a). Agricultural employment throughout WEOG is affected by cascading and compounding consequences from invasive species, extreme weather events and shifting water resources that threaten local community livelihoods (Bolster et al. 2023; Jay et al. 2023). Heat, changing rainfall patterns and loss of pollinators are all interlinked and potentially disrupt local community livelihoods throughout the WEOG.

Invertebrate, such as mosquitoes and ticks, and vertebrate, such as rodents, disease vectors have been increasing. The spread and range shifts of invasive alien and native disease vectors have direct consequences for human health and well-being (Caminade et al. 2019; Baker et al. 2022). Outbreaks of disease have increased in range and intensity, associated with expanding populations of disease vectors that occur throughout WEOG, including West Nile fever, Tick-borne encephalitis, Lyme disease, bluetongue, leishmaniasis, and malaria (Brugueras et al. 2020; Rocklöv and Dubrow 2020; Hauser et al. 2021; Semenza and Paz 2021; van Daalen et al. 2022; McElwee et al. 2023). Population trends of disease vectors are often associated with warmer temperatures that increase the reproductive rate and range of vectors and pathogens alike (**Figure 8.30**) (Caminade et al. 2019; Semenza and Paz 2021; Baker et al. 2022). Disease risk is exacerbated by the interconnectivity of global transport systems, urbanization, and human movements (Rocklöv and Dubrow 2020; Baker et al. 2022). In addition, increased disease risk can be linked to ageing infrastructure and poor sanitation that promote disease vectors, such as mosquitoes thriving in stagnant stormwater drainage, and exacerbate existing health inequities (Ebi and Hess 2020; Baker et al. 2022; Berberian et al. 2022; Lansbury Hall and Crosby 2022). Biosecurity is a rising issue within Australia and the United States of America, where the spread of vectors and pests has major human and economic repercussions for agriculture and endemic biota.



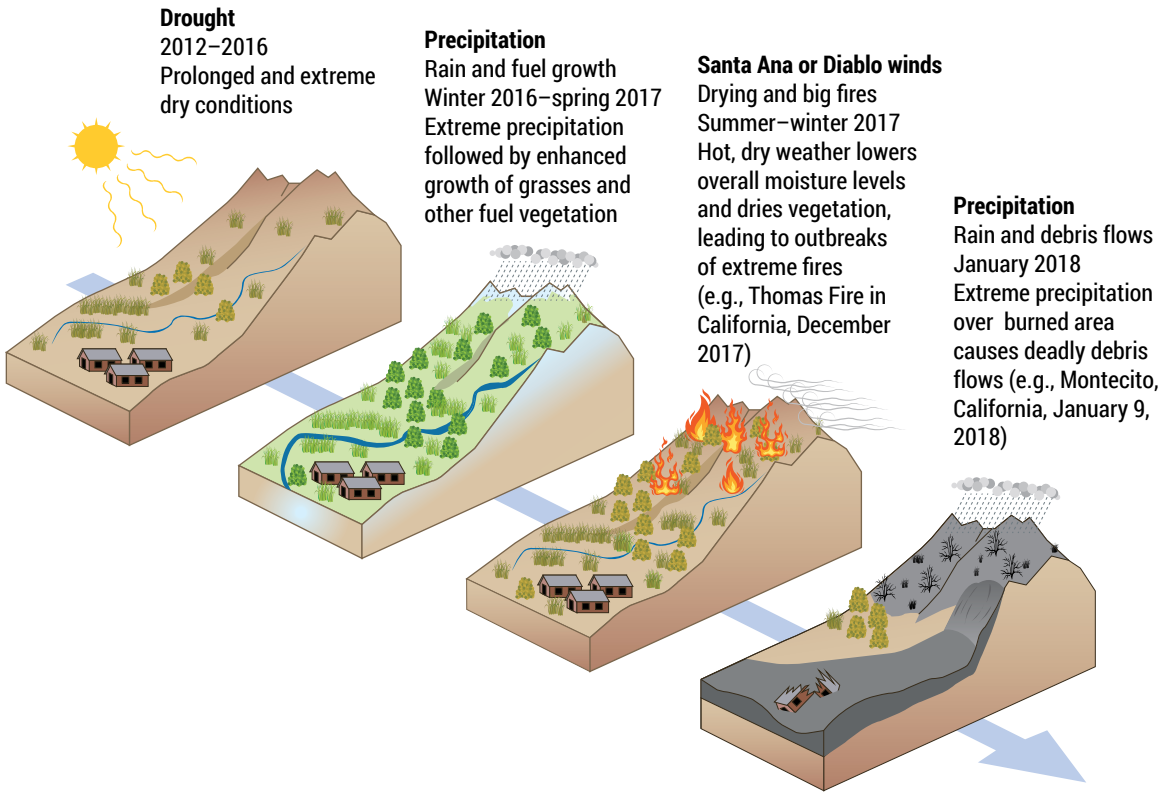
Biodiversity loss adversely affects biocultural heritage. Conservation and protection of eco-cultural resources is challenging (Rotherham 2022) because of the concomitant loss of cultural knowledge, critical information, and traditional management practices that are required for sustainable land management (Lindholm and Ekblom 2019). For example, medieval hedgerow networks in central Spain have been degraded, leading to a decline in many hedge species (Arnaiz-Schmitz et al. 2018).

8.6.4 Priority issue: climate extreme events

Climate disruptions interact with non-climate drivers, such as governance systems, poverty, inequality and demography, amplifying the impacts of extreme events, such as heatwaves, wildfires, floods and severe storms across WEOG (Chancel et al. 2023; Parks et al. 2023; Bouchama et al. 2024; United States of America, Department of Labor and Occupational Safety and Health Administration 2024; La 2024; Galvez-Hernandez et al. 2025). Heatwaves are among the deadliest climate events, with heat index records regularly broken across WEOG (Ebi et al. 2021; Romanello et al. 2023; Zachariah et al. 2023). In the United States of America, heatwaves have increased in frequency,

duration and intensity every decade since the 1960s, with the number of annual heatwaves tripling (United States Environmental Protection Agency [EPA] 2024), along with increasing average temperature and precipitation. Over 800 excess deaths were attributed to a 2021 heat dome along the Pacific coast of North America (White et al. 2023). A year later, heat-related mortality exceeded 60,000 in Europe (Ballester et al. 2023; La 2024). Notably, despite even higher temperatures in 2023, European heat-related mortality was slightly lower, likely due to better preparation (Gallo et al. 2024). Agricultural, construction, and other outdoor workers experience heightened risk of heat exposure, stress and health effects, as well as decreased productivity (European Academies' Science Advisory Council 2019; International Labour Office 2019). The adverse effects of heat are amplified in urban areas, particularly in those lacking shade trees, parks or green spaces (Kabisch et al. 2023).

Figure 8.30: Selected case studies of diseases, disease vectors and significant changes in range or prevalence in response to climate change



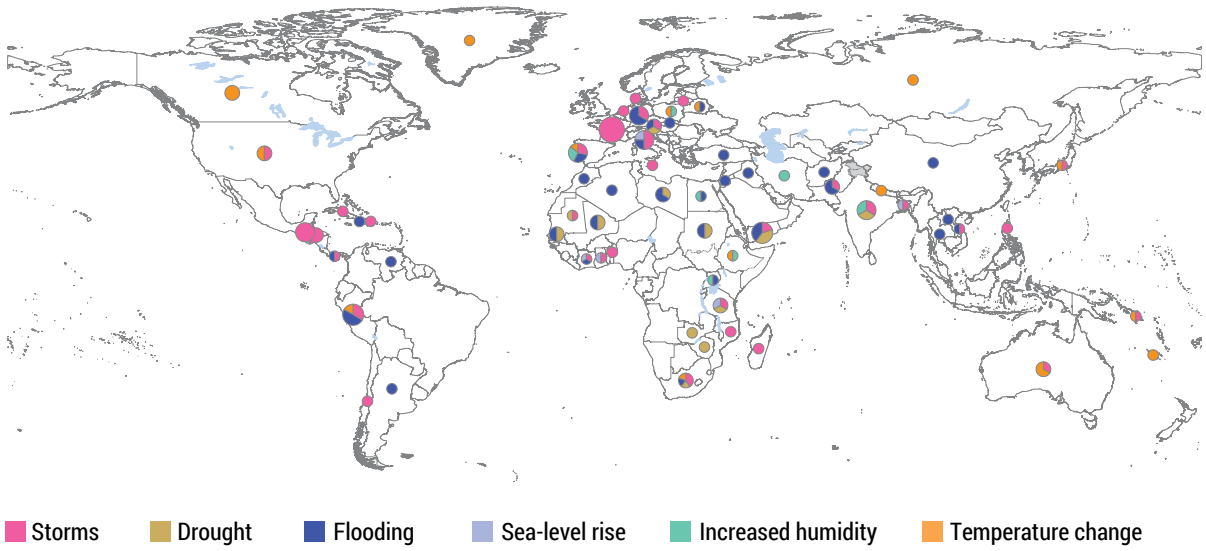
Data sources: Caminade et al. (2019); Semenza and Paz (2021); Baker et al. (2022); ECDC (2025); Government of Canada (2025); WOAH (2025)

Extreme heat contributes to biodiversity loss for both terrestrial and marine organisms. Critical marine environments, such as coral reefs and kelp forests, are vulnerable to marine heatwaves (Wolff et al. 2018; Leggat et al. 2019; Smith et al. 2023; NOAA 2024). The Great Barrier Reef in Australia has suffered mass bleaching events tied to high temperatures in 2020, 2022 and 2024 (Henley et al. 2024). Documented impacts of extreme marine heat on the Pacific coast of North America include decreased phytoplankton production, toxic algal blooms and disrupted food webs, leading to mortality of fish, pinnipeds, baleen whales and seabirds (Jones et al. 2018; Piatt et al. 2020; Arimitsu et al. 2021; Gomes et al. 2024). Heat is a contributing factor to toxic algal blooms in marine and freshwater systems in Australia, North America and Europe (Facey et al. 2022; Perry et al. 2023).

Extreme wildfires have detrimental impacts on land and soil systems, as well as human health. The frequency and intensity of wildfires have increased exponentially in the 21st century in western American conifer forests, northern boreal forests, and the southeastern Australian bush (Abram et al. 2021; Cunningham et al. 2024). These trends are overwhelming the resilience of even historically fire-adapted ecosystems (McLauchlan et al. 2020). Massive wildfires have also occurred in Greece in 2023, Türkiye in 2021, Canada in 2023 and the southern and western United States of America in 2023 and 2025, respectively. The Canadian fires were driven by high temperatures, early snowmelt and a multiannual drought. They burned 150,000 km^2 and released about 65 million tons of carbon (Byrne et al. 2024; Jain et al. 2024). Since 1980, the length of the "fire weather" season – conditions conducive to the ignition and spread of fires – has expanded dramatically in the Mediterranean region, southeastern Australia, and western North America (Jones et al. 2022; Parks Canada 2024). Evidence suggests that climate change is driving the striking expansion of fire weather in recent decades and exacerbating its ensuing repercussions (**Figure 8.31**) (Jones et al. 2022; Cunningham et al. 2024; Hetzer et al. 2024).

Figure 8.31: Drivers and impacts of wildfires, which are accentuated by climate change, based on an example from Southern California in 2012–2018

Note: This example illustrates the phenomenon of a cascading hazard, a form of compound climate hazard in which interactions among consecutive climate extreme events result in the amplification of their impacts



Source: AghaKouchak et al. (2020)

Wildfires damage cultural and biocultural resources and disrupt the livelihoods of local communities. Recent wildfires in the United States of America have destroyed cultural heritage sites in Lahaina, Hawaii, including the Na ʻAikane o Maui Cultural and Research Centre, which contained Native Hawaiian genealogical records and maps (Arango 2023). In summer 2024, fires destroyed 90 per cent of the ancient Turkish port city of Assos, which was founded in the 8th century B.C.E. and was a popular tourist site (Bassler 2024). In addition, wildfires destroyed 50 km^2 of the unique Laurisilva of Madeira Forest in Portugal in 2024, part of the EU Natura 2000 protected areas (European Commission: Joint Research Centre et al. 2023; BirdLife International 2024; European Parliament 2024).

Extreme precipitation, hurricanes and other storm events across WEOG are increasing in intensity and frequency (Seneviratne et al. 2021; Clarke et al. 2022). Although in the past the primary hazard from hurricanes was coastal storm surges, between 2013 and 2024, freshwater flooding caused 57 per cent of direct fatalities from hurricanes in the United States of America, with lasting damage to local communities (Brennan et al. 2023). Excess mortality persists for 15 years after a major tropical cyclone (Young and Hsiang 2024). In Germany and Belgium, extreme rainfall and flooding in 2021, enhanced by climate change, caused extensive damage to infrastructure, including railway lines, houses and roads, with 200 fatalities (Szymczak et al. 2022; Tradowsky et al. 2023). In September 2023, Storm Daniel produced extreme rainfall over Greece and parts of Türkiye, causing floods in both countries, and flooding 30 per cent of the cotton crop in the Thessalian plain (He et al. 2024; WMO 2024). The highest recorded rainfall event in Spain's history, which occurred in October 2024, resulted in catastrophic flooding, leading to 232 deaths in Valencia (Galvez-Hernandez et al. 2025). Storms are also the principal cause of damage to UNESCO World Heritage Sites in Europe (Clarke et al. 2025) (**Figure 8.32**). In 2023, one-third of European rivers exceeded the flood threshold (Copernicus Climate Change Service 2024). Such events are likely to increase in frequency. Record-breaking rainfall and flooding in Eastern Australia in 2022 have been attributed to prolonged La Niña conditions (Gillett et al. 2023; Huang et al. 2024; Malan et al. 2024). New Zealand's North Island suffered extreme rainfall and flooding in January and February 2023 from ex-tropical cyclones Hale and Gabrielle, resulting in 15 deaths (WMO 2024). Climate change is driving the rapid intensification and increased rainfall of Gulf of Mexico hurricanes, as seen in Hurricane Milton in 2024 (Clarke et al. 2024; World Weather Attribution 2024).

In coastal regions, extreme events have intensified consequences for ecosystems and infrastructure due

Figure 8.32: Global distribution of climatic hazards documented by UNESCO to have climate change impacts on World Heritage Sites by country

Note: The size of the circle represents the number of sites affected per country, while the pie slices represent the number and type

Source: Modified from UNESCO (2025)

to the compounding effects of sea level rise, storm surges, heavy precipitation and river floods. Coastal storms and storm surges, exacerbated by sea level rise, and associated saltwater intrusions, are converting forested wetlands in the southeastern United States of America to marshes, shrublands or "ghost forests" with loss of stored carbon (Smart et al. 2020; Ury et al. 2021; Powell et al. 2022; White et al. 2022; Sacatelli et al. 2023). Saltwater intrusions are affecting nutrient cycling and degrading the productivity of coastal farmland in the eastern United States of America (Weissman and Tully 2020; O'Donnell et al. 2024). For example, a survey of 15 coastal counties in the mid-Atlantic United States of America found that the percentage of farmland within 100 metres of a salt patch nearly doubled from 350 km^2 in 2012 to 680 km^2 in 2017 (Mondal et al. 2023). Storms have further compounding effects in the Arctic, where the landfast ice that has typically protected coastlines is melting in the warming climate (Hošeková et al. 2021; Henke et al. 2024). As a result, some coastlines in northern and western Alaska are eroding by over 20 metres per year (Huntington et al. 2023). In the Arctic, saltwater intrusion accelerates the loss of coastal permafrost, which in turn degrades infrastructure such as roads and runways (Guimond et al. 2021; Huntington et al. 2023). Some Northern European coastlines are suffering from erosion. For example, the North Norfolk towns of Happisburgh, Eccles and Hemsby in the United Kingdom of Great Britain and Northern Ireland have lost buildings and infrastructure to the sea, with an indicative property loss of 90 residential and commercial spaces (Coastwise 2023).

Ageing and inadequate infrastructure compounds the risk of extreme events in WEOG. Occurring with increased frequency and intensity, extreme weather events damage transportation, energy production and water treatment systems, and other infrastructure. (Zamuda et al. 2023, Zachariah et al. 2023) (Figure 8.33). One third of Canada's infrastructure is in need of updating or replacement to withstand new climate conditions (Lulham et al. 2023). In the United States of America coastal areas, ageing infrastructure combined with human modification of coastal ecosystems has increased the likelihood of coastal flooding (May et al. 2023). Protecting cultural heritage sites from climate extremes is especially challenging (Sesana et al. 2021; Blavier et al. 2023). In European Union countries, the introduction of housing renovation targets (European Commission 2020) offers a key opportunity to enhance climate resilience.

The increasing incidence of floods, droughts, wildfires, heatwaves and other events has adverse economic impacts, including supply chain disruptions, decreased economic output and changes in the geographic distribution of economic opportunities (Hsiang et al. 2023; Jay et al. 2023; EEA 2024a). Food production is already critically threatened by heat and drought in southern and central Europe. Impacts are unevenly distributed across economic sectors and socioeconomic groups (Hsiang et al. 2023). For example, in Canada, climate change is contributing to the unpredictability of supply chains, especially in Indigenous fly-in communities in the Arctic, which are compromised by ageing infrastructure, hazardous sea ice, thawing permafrost and loss of winter roads using frozen waterways (Reed et al. 2022; Lulham et al. 2023). Indigenous Peoples in Australia were more than four times more likely to report flooding and displacement than non-Indigenous Australians (Matthews et al. 2019; Cresswell et al. 2021).

Distinct local communities, such as the Gullah Geechee, who inhabit coastal lowlands of the southeastern United States of America, are threatened by multiple climate change hazards, including sea level rise, more frequent storms and increased coastal erosion (Ghahramani et al. 2020). Arctic Indigenous communities face a series of interrelated challenges to food security and are among those most affected by the consequences of climate change, which increase vulnerability in food systems (Kovacs et al. 2021; Jørgensen 2024). The loss of sea ice is undermining traditional Inuit lifeways by limiting the ability to hunt seals and whales (Inuit Tapiriit Kanatami 2019; Hauser et al. 2021; Adger et al. 2022).

8.6.5 Priority issue: pollution and waste

WEOG countries have progressed in addressing waste and pollution issues. However, high-consumption lifestyles continue to produce excessive waste.

The material footprint of WEOG countries greatly exceeds the global average of 13.0 metric tons per capita. In 2021, Canada produced 40.0 tons, New Zealand produced 33.3 tons, the United States of America produced 31.6 tons, Australia produced 31.9 tons, and the European Union averaged 15.0 tons per capita (2022) (Vienna University of Economics and Business – Institute for Ecological Economics n.d.). Particle emissions from combustion, especially

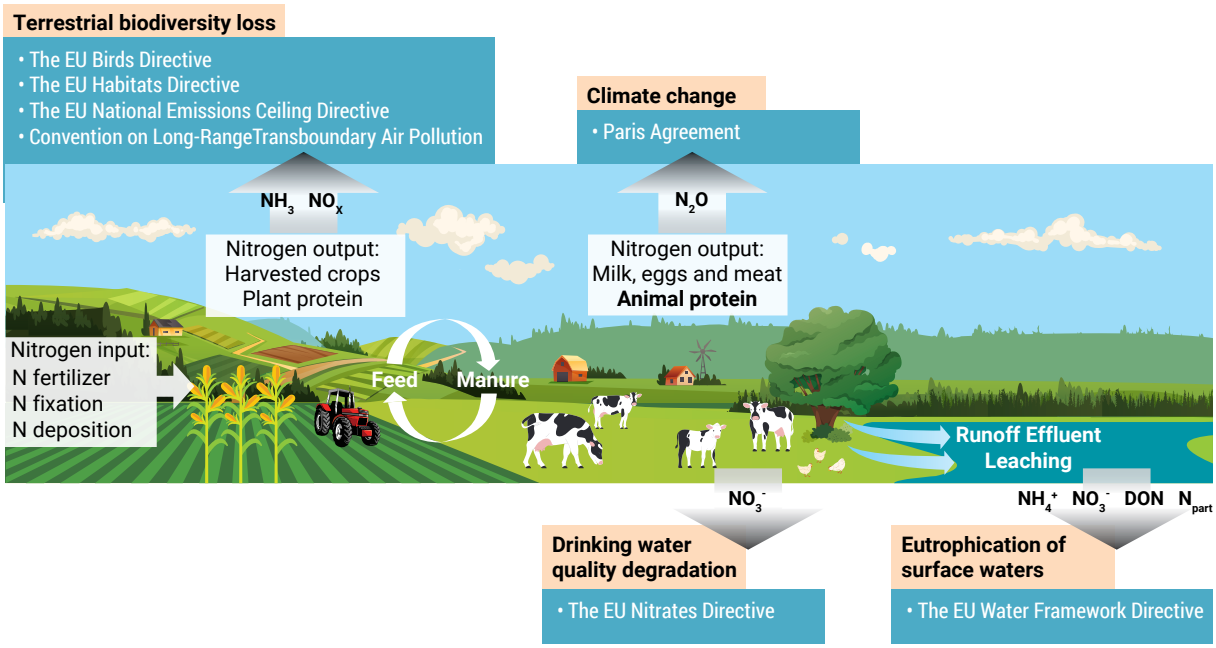
$PM_{2.5}$, remain the most significant environmental health threat in Europe, with over 50 per cent of the population exposed to levels above 10 µg/m^3 (Yang et al. 2022; EEA 2023d). While management of hazardous materials in WEOG countries is improving, unanticipated risks continue to emerge. For example, perfluoroalkyl and polyfluoroalkyl substances include about 5,000 compounds that are ubiquitous in industry and consumer goods, while risk analyses of these chemicals are relatively recent (DeWitt et al. 2024).

The effects of air, water and soil pollution are not equitable across WEOG. Low-income, homeless and historically marginalized people are at heightened risk (Goodling 2019; Hausman and Stolper 2021; Liu et al. 2021). Historical restrictive zoning based on racial and ethnic factors in the United States of America continues to manifest as increased risk from floods (Bidadian et al. 2024; Salazar-Miranda et al. 2024), air pollution (Lane et al. 2022), heatwaves (Li et al. 2024), pollution from proximity to oil and gas wells (Cushing et al. 2023; Gonzalez et al. 2023), and exposure to pesticides (Donley et al. 2022). Similar trends are observed in Europe, where minority ethnic groups in London are exposed to concentrations of nitrogen dioxide that are up to 27 per cent higher than those of the general population (EEA 2018; Cushing et al. 2023; van den Brekel et al. 2024). Half of London's

hospital admissions for asthma are children from these groups (London Assembly 2022). Throughout the WEOG region, migrants are increasingly vulnerable due to discrimination, precarious housing, hazardous work environments, and limited access to essential services (Méndez et al. 2020; Fong and Bell 2021; Rana et al. 2022; United States of America, Centers for Disease Control and Prevention 2024).



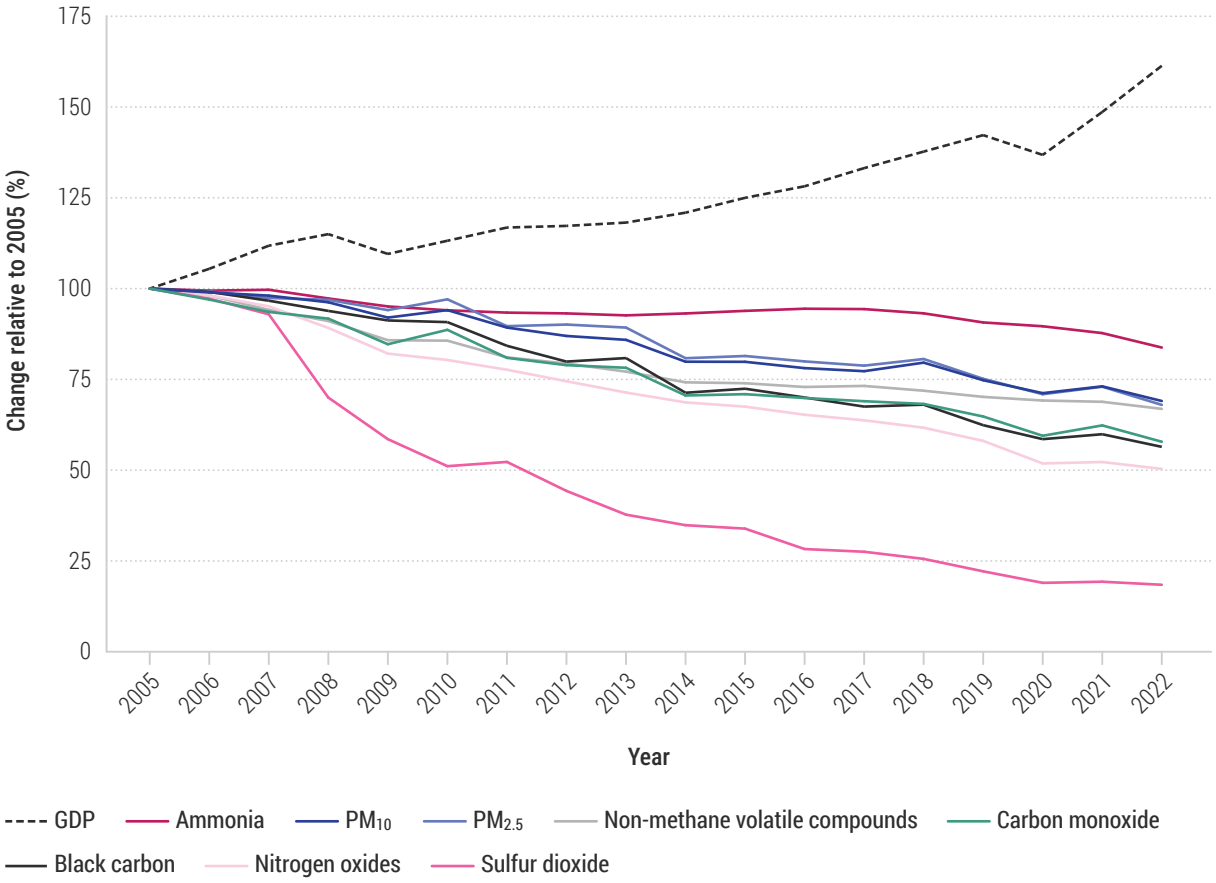
Impacts of pollution on Indigenous Peoples within WEOG are multifaceted. Indigenous lands have been exploited, often without prior and informed consent, for fossil fuel and mineral extraction, causing lingering polluted lands, air and waters (Fernández-Llamazares et al. 2020). For example, people of the Yellowknives Dene First Nation in Canada were subject to arsenic contamination from gold mining long after the nearby Giant Mine closed (Sandlos and Keeling 2017). The Arctic has been disproportionately affected by persistent organic pollutants, which bioaccumulate in marine mammals, fish and birds – species that are crucial for the sustenance and culture of Indigenous communities (Fernández-Llamazares et al. 2020). For example, East Greenland Inuit hunters have the highest blood-serum concentrations of polyfluoroalkyl compounds recorded outside industrially polluted sites (Sonne et al. 2023).

Cultural heritage is at particular risk from air pollution and associated acid deposition (Spezzano 2021). Air pollution is degrading the world's oldest and most prominent example of petroglyphs, the Dampier Rock Art Complex in northwestern Australia. Comprising approximately one million carvings across 400 km^2, the site is tens of thousands of years old and depicts extinct species, including the Tasmanian Tiger (Neumann et al. 2022; Smith et al. 2022).

Human disruption of the nitrogen cycle has been severe in WEOG, primarily driven by unsustainable agricultural practices. Applications of synthetic fertilizer increased rapidly from the mid-20th century, peaking around the 1990s, and leaving excess nitrogen in soils and groundwater (**Figure 8.34**) (Tian et al. 2020; Tian et al. 2022). Although deposition of reactive nitrogen from the atmosphere began to decrease in Europe in the 1980s and the United States of America in the 1990s with environmental regulations and incentives, levels still exceed thresholds that threaten forests and plant biodiversity (UNEP 2019; FAO and UNEP 2021; Schulte-Uebbing et al. 2022; Chen, Xiao and Chen 2023; de Vries et al. 2024).

Significant efforts in the United States of America have focused on reducing nutrients released to waterways as agricultural run-off from current and historical over-fertilized croplands, as well as from livestock manure accumulations (Van Meter, Byrnes and Basu 2023). This excess nutrient pollution, including both nitrogen and phosphorus, depletes oxygen, creating hypoxia in

Figure 8.34: Nitrogen cycle and impacts of excess nitrogen on human and natural systems, as well as European Union directives and international agreements aiming to reducethese impacts



aquatic systems that damages freshwater and coastal environments and results in harmful algal blooms, decreased fish biodiversity, and loss of estuarine species (Baron et al. 2014; Mosley et al. 2023; Zhou et al. 2023). Extensive hypoxic zones have been documented in the Gulf of Mexico, Baltic Sea, and the Coorong estuary of Australia (Rabalais and Turner 2019; Mosley et al. 2023; EEA 2024b). Excess nitrogen also manifests as elevated nitrate levels in groundwater, degrading drinking water sources (Ortmeyer, Hansen and Banning 2023; Van Meter, Schultz and Chang 2023) and contributing to socioeconomic inequities, for example, by contaminating many traditional aquifers of Aboriginal Australians (Balasooriga et al. 2023). Despite legislation addressing nutrient pollution, the average nitrate concentration in European Union groundwater did not change significantly from 2000 to 2021, and 14 per cent of groundwater stations exceeded the maximum allowable concentration in 2019 (EEA 2023b). Finally, excess nitrogen in the soil induces the release of nitrous oxide, a potent greenhouse gas (Canadell et al. 2021; Cheng et al. 2022; Wang, Faloona and Houlton 2023). Due to nitrogen's multifaceted roles as a necessary nutrient, an air pollutant, a greenhouse gas component and a disruptor of plant biodiversity, its influences reach inextricably to the global food system, ecosystem health, and human well-being (Schulte-Uebbing et al. 2022).

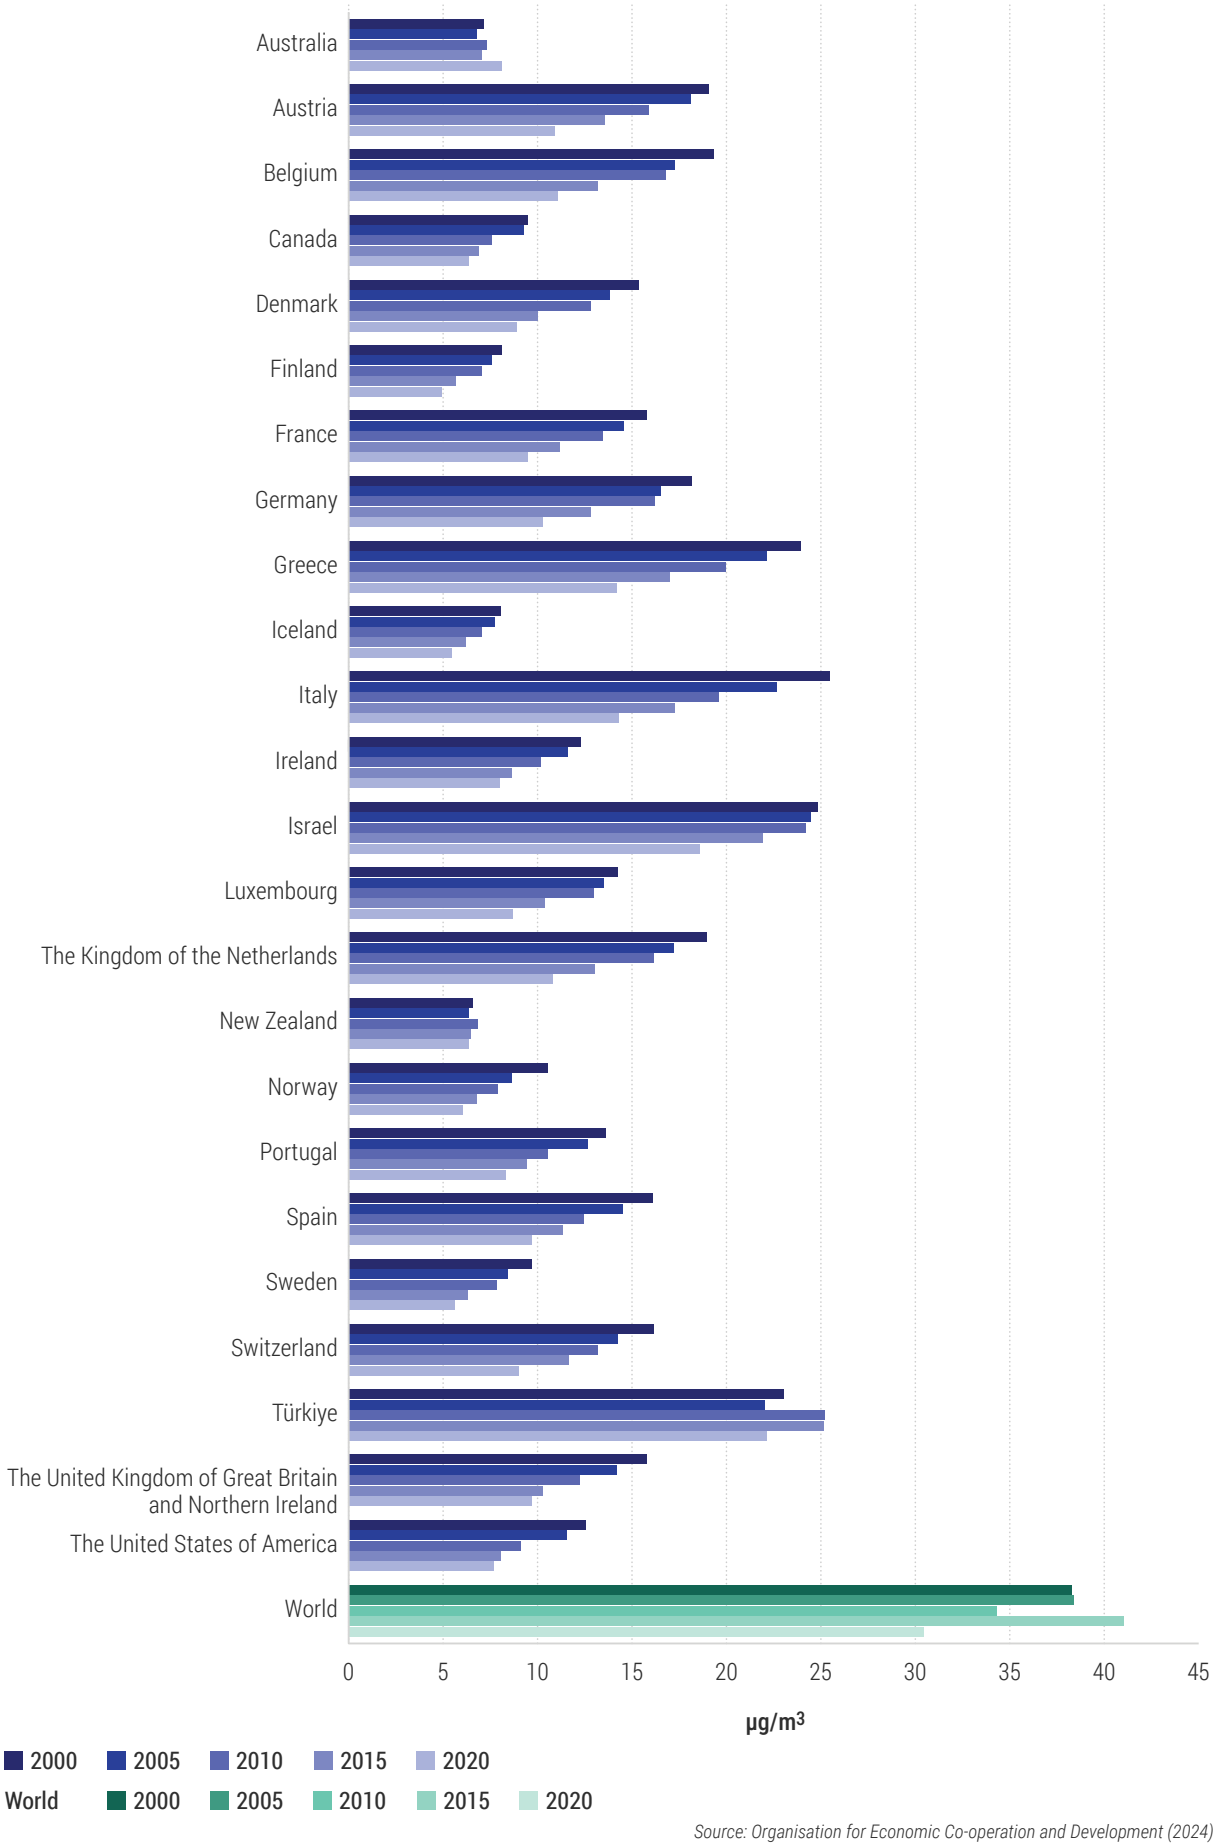
A strong association has been documented between pesticide exposure and declines in populations of beneficial species (Mamy et al. 2022; EEA 2023c). In 2020, nearly a quarter of all freshwater monitoring sites across Europe found one or more pesticides above the thresholds of concern, while 83 per cent of agricultural soils contained pesticide residues (EEA 2023c). A 33 per cent decrease in pesticide use and a 2021 shift towards targeted products in Western Europe from a 2015–2017 baseline (EEA 2023c) may not immediately correlate with reduced toxicity for pollinators and other non-target organisms. In the United States of America, while the total mass of applied insecticides has decreased by 40 per cent since the 1990s, and harm to birds and mammals has decreased, both broad-spectrum and newer selective pesticides are highly toxic to non-targeted beneficial species such as native bees, beetles, dragonflies and wasps (Dicks et al. 2021; Schulz et al. 2021; Mata et al. 2024).

Exposure to synthetic chemicals and plastics is pervasive; many are persistent, and health impacts are still emerging (EEA 2022b; UNEP and Secretariat of the Basel, Rotterdam and Stockholm Conventions 2023). More than 3,000 chemicals of concern are found in plastic consumer goods (UNEP and Secretariat of the Basel, Rotterdam and Stockholm Conventions 2023). In New Zealand, polyfluorinated alkyl substances are found in soil, water and human serum (Coakley et al. 2018; Lenka et al. 2022), despite efforts to phase out the most toxic of them (UNEP and Secretariat of the Basel, Rotterdam and Stockholm Conventions 2023). Wastewater biosolids from treatment plants have been applied to agricultural soils for many decades, and the recent discovery in the United States of America of accumulated polyfluorinated alkyl substances from this practice has become an emerging health crisis (Buttle et al. 2023; Pozzebon and Seifert 2023; Gewurtz et al. 2024; Saliu and Sauvé 2024; Zhou et al. 2024). Current evidence links exposure to polyfluoroalkyl compounds with decreased antibody responses and reduced infant and fetal growth (United States of America, National Academies of Sciences, Engineering, and Medicine et al. 2022). Microplastics have been implicated as drivers of colorectal cancer (Li et al. 2023; Bruno et al. 2024). Although acute poisoning by pesticides in WEOG is below global rates, these substances are widely distributed throughout the population (Tudi et al. 2022). Vulnerable individuals, notably farmworkers and their families, experience heightened exposure. Pesticides, polyfluorinated alkyl substances, and other persistent organic pollutants have been detected in over 90 per cent of people sampled in Europe (Ottenbros et al. 2023), the United States of America (Kurwadkar et al. 2022) and Canada (Gibson 2020). A large-scale human biomonitoring study conducted between 2014 and 2021 across five European countries found that at least two pesticides were detected in the bodies of 84 per cent of survey participants, with higher pesticide levels in children (EEA 2023c). Strong or suspected links have been established between pesticide exposure and an increased risk of several chronic diseases (Leemans et al. 2019; Rayasam et al. 2022; EEA 2023c).

Air quality has been consistently improving in WEOG countries, but it remains a significant concern. In Western Europe, airborne emissions of pollutants have decreased significantly over the past two decades, though trends for ammonia are weaker (**Figure 8.35**) (Tang et al. 2021; Van Damme et al. 2022; Burns et al. 2023; Wang et al. 2023a; EEA 2024c; Liu et al. 2024). Yet, more than 90 per cent of urban Europeans

Figure 8.35: Trends in emissions of major air pollutants from 2005 to 2022 for the European Union

Source: EEA (2024d)



still breathe harmful levels of fine particulate matter, causing more than 200,000 premature deaths per year (EEA 2023d). Air pollution remains a critical health hazard, particularly for children, older people, marginalized communities, urban residents, and agricultural and industrial workers (EEA 2018; Lane et al. 2022; Zalzal and Hatzopoulou 2022; EEA 2023d; Romanello et al. 2023; de Souza et al. 2024).

Between 2000 and 2020, the exposure to $PM_{2.5}$ decreased by 34 per cent on average across the WEOG region, with all countries except Australia showing decreases (**Figure 8.36**) (OECD 2024a). Wildfire smoke can reverse that trend intermittently. For example, in 2023, smoke from wildfires crossed international borders between Canada and the United States of America, substantially decreasing air quality and resulting in a 30 per cent increase in asthma emergencies in New York City, United States of America, alone (Chen et al. 2023; Thurston, Yu and Luglio 2023).

Extraction, use and disposal of materials drive waste and pollution in the high-consumption societies of WEOG. Countries within the WEOG region are characterized by very high per capita levels of domestic material consumption and material footprint (UNEP and International Resource Panel 2024). Despite a 17 per cent reduction observed since 2000, North America's material footprint totalled 30 tons per capita in 2020, almost three times the global average. Western Europe showed 10 per cent reductions in material footprint between 2000 and 2020, moving from 19 to 17 tons per capita (UNEP and International Resource Panel 2024). Per capita volumes of municipal solid waste generated within WEOG are also among the highest in the world, at 1.0–1.5 kg/day in Western Europe and Australia/New Zealand and 2.25 kg/day in North America (UNEP 2024). Over 35 per cent of municipal waste is recycled in WEOG countries. In Western Europe, much of the balance is burned for energy, while the rest of WEOG relies on landfills (UNEP 2024).

Between 2010 and 2020, countries within the European Union reduced total waste generation by four per cent, partially attributed to the effect of the COVID-19

Figure 8.36: Mean population-weighted exposure to PM2.5 from 2000 to 2020

Source: Organisation for Economic Co-operation and Development (2024)

Credit: nd3000/Envato

pandemic and lower production of mineral wastes (EEA 2023e). Recent spikes in waste production have occurred across several WEOG countries – Austria, Belgium, Finland, Norway, Luxembourg – while the United States of America has consistently high volumes, and some keep increasing over time, as demonstrated by the United States of America, Denmark, New Zealand and Switzerland (EEA 2022c; OECD 2024b). However, data gaps and heterogeneity in reporting standards affect the quality of these data sets, limiting direct comparability.

The high material consumption of most WEOG residents drives a rapid turnover of consumer goods, which contributes to waste generation at every stage of the supply chain. For example, the fast-fashion industry expanded dramatically in the late 1990s, primarily based on polyester plastic fibres (Niinimäki et al. 2020). Textiles cause environmental damage during fibre production using pesticides and emissions from polyester fabrication, manufacture and dying of materials, and distribution along the supply chain (Niinimäki et al. 2020). Clothing purchases have increased, while their usage timespan has decreased, resulting in a commensurate increase in waste generation. Each United States of America citizen typically purchases a new item of clothing every 5.5 days. In 2018, each discarded an average of about 47 kg of textiles, excluding clothing donated to charities, marking an 80 per cent increase since 2000 (Schumacher and Forster 2022). Approximately 85 per cent of discarded clothing in WEOG countries ended up in landfills or were incinerated (EEA 2022d; Schumacher and Forster 2022). Several countries across the WEOG region have been increasingly active in promoting and fostering the uptake of circular-economy principles, regulations and business models (Australia Department of Climate Change, Energy, the Environment and Water 2024; EEA 2024d; EPA 2024; Government of Canada 2025; Didiezic et al. 2025). Since 2015, a comprehensive set of policies has been introduced and implemented across EU countries, which are showing positive trends but limited long-term improvements (EEA 2024d). Between 2010 and 2022, the EU economy showed only a slight increase in the circularity rate, from 10.5 to 11.5 per cent, yet confirming Europe as the world region that consumes the highest proportion of its recycled materials (EEA 2024d).

8.7 Telecoupling

8.7.1 Introduction

Across regions and subregions, interlinkages are growing between human and natural systems,

driven by processes such as trade, investment, tourism, migration, species invasion, and flows of ecosystem services (Liu 2020), as well as armed conflict (UNEP 2024). These interconnections are referred to as telecoupling – an umbrella concept that encompasses socioeconomic and environmental interactions spanning distances (Liu et al. 2013). Telecoupling offers a valuable opportunity to examine how decisions or activities in one country or region can have environmental and socioeconomic implications in other places. Through the application of the telecoupling framework (Liu et al. 2013) with five major components – systems such as countries or regions, flows, agents, causes such as drivers, and effects including feedback – it is possible to characterize and better understand these complex relationships.

Within the scope of this section, it is not possible to cover the full range of telecoupling. Special focus is placed on four types of telecoupling to highlight notable regional interconnections: trade, foreign direct investment, migration, and tourism (**Figure 8.37**).

Trade flows across regions between 2017 and 2021 totalled more than US$7 trillion (**Table 8.3**). AP is the largest sending system and the second-largest receiving system, while WEOG was the largest receiving system and the second-largest sending system. Africa was both the smallest sending and receiving system. EE ranked third, and LAC was fourth in both imports and exports. The top three trade relationships were between AP and WEOG, EE and WEOG, and WEOG and LAC.

According to the total investments sent and received (**Table 8.4**), WEOG ranked the highest, followed by AP, LAC, EE and Africa, respectively. In terms of paired relationships, AP and WEOG had the largest investment flows, followed by WEOG and LAC, and then by WEOG and EE.

In terms of migration (**Table 8.5**), WEOG was the smallest sending system and the largest receiving system. EE was the largest sending system and the fourth largest receiving system. AP, Africa, and LAC ranked 2nd, 3rd and 4th in sending, and 2nd, 5th and 3rd in receiving, respectively. In terms of paired relationships, AP and WEOG had the strongest relationship, followed by EE and WEOG, and Africa and WEOG.

Regarding international tourism (**Table 8.6**), WEOG was both the largest sending and receiving system, and Africa was the smallest sending and receiving system. In terms of paired relationships, EE and WEOG

	Africa	Asia	Eastern Europe	Western Europe	Latin America
Africa	17.9	4.4	0.2	4.8	0.1
Asia	3.3	148.1	10.3	48.6	1.2
Eastern Europe	2.8	10.6	46.8	55.0	0.9
Western Europe	12.8	36.7	40.4	345.2	53.8
Latin America	0.3	1.0	0.4	28.1	22.6

had the strongest flow, followed by WEOG and LAC, and then AP and WEOG.

8.7.2 Effects of telecoupling

Activities and decisions in one place influence environmental and socioeconomic conditions in distant places. These effects of telecoupling on human and natural systems are complex and can be negative or positive. They vary across sending, receiving and spillover systems. Sending and receiving systems are places that send and receive flows of goods, products, people, information, species and financial capital. Spillover systems refer to other systems that are affected by the interactions between sending and receiving systems (Liu et al. 2018). For example, soybean production in Brazil and trade with China and some European countries generate a substantial amount of GHGs, which affect the climate worldwide, including countries that do not trade soybeans with Brazil (da Silva et al. 2021). To date, studies on the effects of foreign direct investment, tourism and migration have primarily focused on receiving systems, with relatively less attention to sending and spillover systems (Duan et al. 2022; Liu 2023). In contrast, research on trade has focused mainly on sending systems, with less attention paid to receiving and spillover systems (Silva et al. 2023). Overall, spillover systems have received the least attention, so many of their effects are unknown or underestimated (Liu et al. 2018; Sachs et al. 2024).

Trade

Trade has been extensively studied. Recent research shows that, in the context of the SDGs, developed countries received more environmental benefits from international trade while developing countries benefited less or even suffered (Xu et al. 2020; Xiao et al. 2024). Additionally, trade between distant countries has had higher positive effects than trade between neighbouring countries (Xu et al. 2020; Xiao et al. 2024). Trade can have both positive and negative socioeconomic and environmental effects in various ways. For example, oil palm expansion for trade has benefited both producing and non-producing countries' economies by providing employment opportunities and promoting the export of crude palm oil, leading to poverty reduction and enhanced food security in producer countries. Negative effects in producing countries, such as those in Southeast Asia, include conflicts between local communities and oil palm companies, increased domestic economic inequality and environmental harm, including the emission of GHGs and biodiversity loss. Environmental benefits or positive effects in receiving countries come from saving resources and avoiding pollution by importing products from producing countries.

Foreign direct investment

Studies on foreign direct investment (FDI) have primarily focused on receiving systems and indicate that FDI increases financial capital stock, promotes

Credit: Bluesandisland/Envato

technological innovations, provides employment opportunities and increases per capita income (Destek and Okumus 2019). On natural systems, FDI has a non-linear effect on the environmental quality of EE countries (Christoforidis and Katrakilidis 2022), increases CO_2 emissions and total GHGs in African countries (Opoku and Boachie 2020), and increases the chemical oxygen demand but reduces the emissions of SO_2 and smoke dust in China through technological innovation (Hao et al. 2019). Between 1990 and 2018, FDI significantly increased CO_2 emissions in AP and Africa, but had insignificant effects in the LAC and European regions (Azam and Raza 2022).

Migration

Migration has mixed effects on the sending and receiving systems. It can reduce pressures on the environment and natural resources in sending systems, the origins of migrants, by reducing population sizes (Adger et al. 2024). In contrast, migration can increase environmental pollution and resource competition in the receiving systems due to consumption (Dedeoğlu et al. 2021; Ahmed et al. 2024; Delazeri et al. 2022; Chen and Goutte 2025). Migration also has substantial socioeconomic impacts. For example, the departure of skilled individuals can lead to a loss of human capital in the sending countries and a gain for the receiving countries (Beine et al. 2001; Stark et al. 1997; Bharadwaj et al. 2023; Nabulsi 2025).

Tourism

Many telecoupling studies have estimated carbon emissions – a major indicator of tourism's environmental impacts – in receiving systems but have disregarded the emissions in tourists' sending systems or spillover systems. To address this knowledge gap, Duan et al. (2022) applied the telecoupling framework and found that for China's international tourism, sending systems had a significant reduction in emissions, while spillover systems had large increases in emissions.

Four well-documented examples of different types of telecoupling are highlighted in **Table 8.7.**

Finally, the effects of telecoupling may also vary over time or development stages. For example, To et al. (2019) found that in 25 emerging markets in Asia between 1980 and 2016, FDI increased CO_2 emissions during the early stage. However, levels subsequently decreased during the late stage, consistent with the Environmental Kuznets Curve hypothesis. Additional research on telecoupling will bolster current understanding of the complexity of these types of relationships and their implications for policy and action.

Table 8.7: Implications of four selected telecoupling types on natural and human systems

Telecoupling type	Trade	Foreign direct investment (FDI)	Migration	Tourism
Example	International tomato trade	Belt and Road Initiative	Transnational labour migration	International tourism
Sending systems	Spain, The Netherlands	China	Myanmar	Canada, China, Denmark, Finland, France, Germany, Norway, Poland, Sweden, United Kingdom of Great Britain and Northern Ireland, United States of America
Receiving systems	Germany	More than 150 countries receive investment from the Initiative	China	Iceland

Table 8.7: Implications of four selected telecoupling types on natural and human systems (cont.)

Telecoupling type	Trade	Foreign direct investment (FDI)	Migration	Tourism
Spillover systems	West Africa, Poland	Other countries affected by the Initiative (e.g. United States of America)	Countries and regions that receive cash crops produced in China by labour migrants from Myanmar	• Countries with layover flights (transit) for tourists to Iceland • Countries where tourism cruise ships go through such as Argentina • Other countries affected by CO_2 emissions from tourism
Effects	**Sending systems:** • Water use and pollution • CO_2 emissions • Land-use change • Varying effects on biodiversity • Negative effects on landscape aesthetics • Farmers' income from tomato production • Contribution to national economy (GDP) **Receiving systems:** • Increased per capita tomato consumption by nearly fivefold • Nutritional benefits • Saving water and other resources **Spillover systems:** • Higher wages for and remittances from migrant workers	**Sending system:** • Political and economic gains (e.g. internationalization of China's currency, promotion of exports) **Receiving systems:** • Substantial loss of natural land • Environmental pollution from construction • Increase in built-up land • Financial support for infrastructure projects • Improved economic development • Largely positive public sentiment towards the projects • Debt stress in some countries **Spillover systems** • Environmental and geopolitical concerns by the United States of America and many other wealthy countries	**Sending systems:** • Increasing remittances **Receiving systems:** • Agricultural expansion and intensification of upland for cash crops **Spillover systems:** • Received cash crops produced by migrants from Myanmar	**Sending systems:** • Financial loss by tourists' spending in receiving and spillover systems **Receiving systems:** • Elevated CO_2 emissions from international flights and ships, and travel in Iceland via rental cars • Over 10% of Iceland's GDP from tourism industry • Need for safety infrastructure **Spillover systems:** • Financial gain from tourists who make layovers • Negative effects from CO_2 emissions from tourism
